PREFACE

This seventh edition of *March's Advanced Organic Chemistry* has been thoroughly updated to include new advances in areas of Organic chemistry published between 2005 and 2010. Every topic retained from the sixth edition has been brought up to date if there was activity in that area during that five year period. Changes also include a significant rewrite of most of the book. More than 5500 new references have been added for work published since 2005. As with the sixth edition, many older references were deleted to make room for new ones, and in cases where a series of papers by the same principal author were cited, all but the most recent were deleted. The older citations are usually found by referring to the more recent publication(s). Many of the figures relating to molecular orbitals dated to the 1960s. In all cases possible, they have been replaced by molecular orbitals drawings using Spartan software from Wavefunction, Inc. The fundamental structure of the seventh edition is essentially the same as that of all previous ones.

The goal, as in previous editions is to give equal weight to the three fundamental aspects of the study of organic chemistry: reactions, mechanisms, and structure. A student who has completed a course based on this book should be able to approach the literature directly, with a sound knowledge of modern organic chemistry. Major special areas of organic chemistry: terpenes, carbohydrates, proteins, many organometallic reagents, combinatorial chemistry, polymerization and electrochemical reactions, steroids, and so on, have been treated lightly or ignored completely. The use of this book in the first year of graduate study should help master the fundamentals. It is hoped that this book will lead a student to consult the many excellent books and review articles cited for various topics in order to understand the subject in more detail. Indeed, many of these topics are so vast, they cannot be explained completely in this book.

The organization is based on reaction types, and a relatively few principles suffice to explain nearly all of them despite the large number of organic reactions. Accordingly, the reactions-mechanisms section of this book (Part II) is divided into 10 chapters (10–19), each concerned with a different type of reaction. In the first part of each chapter, the appropriate basic mechanisms are discussed along with considerations of reactivity and orientation, while the second part consists of numbered sections devoted to individual reactions, where the scope and the mechanism of each reaction are discussed. Numbered sections are used for the reactions and are set in boldface. Since the methods for the preparation of individual classes of compounds (ketones, nitriles, etc.) are not treated all in one place, an updated and revised index has been provided (Appendix B) by use of which the synthesis of a given type of compound will be found. It is important to note that the numbers for each reaction in the 7th edition are *different* from editions 1–5 in many cases, but are the same as found in the 6th edition. For this reason, a correlation table is included at the end of this Preface that directly correlates the sections found in the 5th edition with the new ones in both the 6th and 7th editions.

The structure of organic compounds is discussed in Chapters 1–5 (Part I). This section provides a necessary background for understanding mechanisms and is also important in its own right. The discussion begins with chemical bonding (Chapt. 1) and ends with a chapter on stereochemistry (Chapt. 4). Two chapters follow (Chapt 6–7) on reaction mechanisms in general, one for ordinary reactions and the other for photochemical reactions. Part 1 concludes with two more chapters (Chapt 8 and 9) that give further background to the study of mechanisms.

The IUPAC names for many organic transformations are included, first introduced in the 3rd edition. Since then the rules have been broadened to cover additional cases; hence more such names are given in this edition. Furthermore, International Union of Pure and Applied Chemistry (IUPAC) has now published a system for designating reaction mechanisms, and some of the simpler designations are included.

Appendix A is devoted to the literature of organic chemistry.

In treating subjects as broad as structure, reactions, and mechanisms of organic chemistry, it is impossible to cover each topic in great depth, and this would not be desirable even if possible. This book is intended to point the reader to the primary literature of the areas it covers. To this end, there are >20,000 references to original papers. Secondary literature sources including reviews, books, and monographs have been included as well. Appendix A provides a brief introduction to using computer-based search engines (e.g., *Reaxys*[®] and *SciFinder*[®]).

Although basically designed as a reference text for a one-year course on the graduate level, this book can also be used in advanced undergraduate courses, but only after completion of a one-year course in organic chemistry. A one year course in both inorganic and physical chemistry would be most helpful. It has been my experience that students who have completed the first-year courses often have a hazy recollection of the material and greatly profit from a representation of the material if it is easily accessible. The material in the first nine chapters, particularly Chapters 1, 2, 4, 6, and 8 may be helpful for reviewing such material when this book is used in connection with a course.

This book is probably most valuable as a reasonably up-to-date reference work. Students preparing for qualifying examinations and practicing organic chemists will find that Part II contains a survey of what is known about the mechanism and scope of a large number of reactions, arranged in an orderly manner based on reaction type and on which bonds are broken and formed.

For units of energy, IUPAC mandates joules, and many journals do use this unit exclusively. However, organic chemists who publish in United States journals commonly use calories. Virtually all energy values are presented in both calories and joules. Although IUPAC does not recommend angstrom units for bond distances, but rather picometers (pm), a vast number of bond distances published in the literature are in angstrom units, and this book therefore uses angstrom units.

I would like to acknowledge the contributions of those chemists cited and thanked by Professor March in the first-four editions, and those I thanked in the 5th and 6th editions. This book would not be possible without their contributions. For the 7th edition, I thank Lou Allinger for pointing out the deficiencies in the hyperconjugation section, and graciously helping me write the new section appearing in this new edition. I thank Warren Hehre for his invaluable help in calculating and presenting the molecular orbital drawings using Spartan. I also thank Adrian Shell (Elsevier) for facilitating the transfer of material relating to the program *Reaxys*, discussed in Appendix A. I thank the many people who have contributed comments or have pointed out errors in the 6th edition that were

invaluable to putting together the 7th edition. I thank Warren Hehre and Sean Ohlinger of Wavefunction, Inc., Irvine, CA (www.wavefun.com) for providing Spartan 10 Macintosh (v. 1.0.1), allowing the incorporation of Spartan models for selected molecules and intermediates. All structures and line drawings in this book were done using ChemDraw[®] Ultra 11.0.1 (350440), graciously provided by CambridgeSoft Corporation, Cambridge, MA (www.cambridgesoft.com).

Special thanks are due to the Interscience division of John Wiley & Sons and to Jonathan Rose. Special thanks are also given to Kristen Parrish and Amanda Amanullah, at Wiley for their fine work as editors in turning the manuscript into the finished book as well as Sanchari Sil of Thomson Digital. I also thank Jeanette Stiefel for an excellent job of copy editing the manuscript.

With gratitude, I acknowledge the work of Jerry March, upon whose work this new edition is built, and who is responsible for the concept of this book and for carrying it through four very successful editions. I used Jerry's book as a student and it is an honor to continue this tradition.

I encourage those who read and use the 7th edition to contact me directly with comments, errors, and with publications that might be appropriate for future editions. I hope that this new edition will due justice to the tradition that Professor March began with the first edition.

Finally, I want to thank my wife Sarah for her patience and understanding during the preparation of this manuscript. I also thank my son Steven for his support. Without their support, this work would not have been possible.

MICHAEL B. SMITH
May, 2012

BIOGRAPHICAL STATEMENT

Professor Michael B. Smith was born in Detroit, Michigan in 1946. In 1957, he and his family moved to Madison Heights, Virginia. After graduation from Amherst County high school, he entered Ferrum Jr. College and graduated with an A.A. Professor Smith transferred to Virginia Polytechnic Institute (Virginia Tech), where he did undergraduate research with Professor Harold Bell, and graduated with a B.S in chemistry in 1969. After working as an analytical chemist at the Newport News Shipbuilding and Dry Dock Co. (Tenneco) in Newport News, Virginia for three years, he began graduate studies at Purdue University under the mentorship of Professor Joseph Wolinsky. Professor Smith graduated with a Ph.D. in Organic chemistry in 1977. He spent one year as a faculty research associate at the Arizona State University in the Cancer Research Institute, directed by Professor George R. Pettit, and a second year doing postdoctoral work at the Massachusetts Institute of Technology under the mentorship of Professor Sidney Hecht. In 1979 he began his independent academic career, where he now holds the rank of full professor.

Professor Smith is the author of approximately 90 independent research articles, and 20 published books. The books include the 5th and 6th edition of *March's Advanced Organic Chemistry* (Wiley), volumes 6–12 of the *Compendium of Organic Synthetic Methods* (Wiley), *Organic Chemistry a Two Semester Course* (HarperCollins) into its 2nd edition, and *Organic Synthesis* (Elsevier) in its 3rd edition. A new undergraduate organic chemistry book, *Organic Chemistry: An Acid-Base Approach*, was published in 2011 by the CRC Press.

Professor Smith's current research involves the synthesis and structural verification of lipids obtained from the dental pathogen *Porphyromonas gingivalis*, which show inflammatory activity, induce bone degeneration and are involved in triggering multiple sclerosis. A main area of research is the synthesis of fluorescent dye-heterocyclic conjugates that target hypoxic cancerous tumors, allowing non-invasive fluorescence imaging in the near IR. The synthesis of anti-cancer alkaloids is also ongoing.

INTRODUCTION

This book contains 19 chapters. Chapters 1–9 may be thought of as an introduction to Part II. The first-five chapters deal with the structure of organic compounds. These chapters discuss the kinds of bonding important in organic chemistry, the fundamental principles of conformation and stereochemistry of organic molecules, and reactive intermediates in organic chemistry. Chapters 6–9 are concerned with general principles of mechanism in organic chemistry, including acids and bases, photochemistry, sonochemistry and microwave irradiation, and finally the relationship between structure and reactivity.

Chapters 10–19, which make up Part II, are directly concerned with the nature and the scope of organic reactions and their mechanisms.

Localized Chemical Bonding

Localized chemical bonding may be defined as bonding in which the electrons are shared by two and only two nuclei. Such bonding is the essential feature associated with the structure of organic molecules.¹ Chapter 2 will discuss *delocalized bonding*, in which electrons are shared by more than two nuclei.

1.A. COVALENT BONDING²

Wave mechanics is based on the fundamental principle that electrons behave as waves (e.g., they can be diffracted). Consequently, a wave equation can be written for electrons, in the same sense that light waves, sound waves, and so on, can be described by wave equations. The equation that serves as a mathematical model for electrons is known as the *Schrödinger equation*, which for a one-electron system is

$$\frac{\delta^2\psi}{\delta x^2} + \frac{\delta^2\psi}{\delta y^2} + \frac{\delta^2\psi}{\delta z^2} + \frac{8\pi^2m}{h^2}(E - V)\psi = 0$$

where m is the mass of the electron, E is its total energy, V is its potential energy, and h is Planck's constant. In physical terms, the function (Ψ) expresses the square root of the probability of finding the electron at any position defined by the coordinates x , y , and z , where the origin is at the nucleus. For systems containing more than one electron, the equation is similar, but more complicated.

The Schrödinger equation is a differential equation, so solutions to it are themselves equations, but the solutions are not differential equations. They are just simple equations for which graphs can be drawn. Such graphs are essentially three-dimensional (3D)

² This treatment of orbitals is simplified by necessity. For more detailed treatments of orbital theory, as applied to organic chemistry, see Matthews, P.S.C. *Quantum Chemistry of Atoms and Molecules*, Cambridge University Press, Cambridge, **1986**; Clark, T. *A Handbook of Computational Chemistry*, Wiley, NY, **1985**; Albright, T.A.; Burdett, J.K.; Whangbo, M. *Orbital Interactions in Chemistry*, Wiley, NY, **1985**; MacWeeny, R.M. *Coulson's Valence*, Oxford University Press, Oxford, **1980**; Murrell, J.N.; Kettle, S.F.A.; Tedder, J.M. *The Chemical Bond*, Wiley, NY, **1978**; Dewar, M.J.S.; Dougherty, R.C. *The PMO Theory of Organic Chemistry*, Plenum, NY, **1975**; Zimmerman, H.E. *Quantum Mechanics for Organic Chemists*, Academic Press, NY, **1975**; Borden, W.T. *Modern Molecular Orbital Theory for Organic Chemists*, Prentice-Hall, Englewood Cliffs, NJ, **1975**.

FIG. 1.1. (a) The 1s orbital. (b) The three 2p orbitals.

pictures that show the electron density, and these pictures are called *orbitals* or electron clouds. Most students are familiar with the shapes of the *s* and *p* atomic orbitals (Fig. 1.1). Note that each *p* orbital has a *node*: A region in space where the probability of finding the electron is extremely small.³ Also note that in Fig. 1.1 some lobes of the orbitals are labeled + and others -. These signs do not refer to positive or negative *charges*, since both lobes of an electron cloud must be negatively charged. They are the signs of the wave function Ψ . When a node separates two parts of an orbital, a point of zero electron density, Ψ always has opposite signs on the two sides of the node. According to the *Pauli exclusion principle*, no more than two electrons can be present in any orbital, and they must have opposite spins.

Unfortunately, the Schrödinger equation can be solved exactly only for one-electron systems (e.g., the hydrogen atom). If it could be solved exactly for molecules containing two or more electrons,⁴ a precise picture of the shape of the orbitals available to each electron (especially for the important ground state) would become available, as well as the energy for each orbital. Since exact solutions are not available, drastic approximations must be made. There are two chief general methods of approximation: the molecular orbital (MO) method and the valence bond method.

In the MO method, bonding is considered to arise from the overlap of atomic orbitals. When any number of atomic orbitals overlap, they combine to form an equal number of new orbitals, called *molecular orbitals*. Molecular orbitals differ from atomic orbitals in that an electron cloud effectively surrounds the nuclei of two or more atoms, rather than just one atom. In other words, the electrons are shared by two atoms rather than being localized on one atom. In localized bonding for a single covalent bond, the number of atomic orbitals that overlap is two (each containing one electron), so that two molecular orbitals are generated. One of these, called a *bonding orbital*, has a lower energy than the original atomic orbitals (otherwise a bond would not form), and the other, called an *antibonding orbital*, has a higher

³ When wave mechanical calculations are made according to the Schrödinger equation, the probability of finding the electron in a node is zero, but this treatment ignores relativistic considerations. When such considerations are applied, Dirac has shown that nodes do have a very small electron density: Powell, R.E. *J. Chem. Educ.* **1968**, 45, 558. See also, Ellison, F.O.; Hollingsworth, C.A. *J. Chem. Educ.* **1976**, 53, 767; McKelvey, D.R. *J. Chem. Educ.* **1983**, 60, 112; Nelson, P.G. *J. Chem. Educ.* **1990**, 67, 643. FIG. 1.2. Overlap of two 1s orbitals gives rise to a σ and a σ^* orbital.

energy. Orbitals of lower energy fill first. Since the two original atomic orbitals each held one electron, both of these electrons will reside in the new molecular *bonding* orbital, which is lower in energy. Remember that any orbital can hold two electrons. The higher energy antibonding orbital remains empty in the ground state.

The strength of a bond is determined by the amount of electron density that resides between the two nuclei. The greater the overlap of the orbitals, the stronger the bond, but total overlap is prevented by repulsion between the nuclei. Figure 1.2 shows the bonding and antibonding orbitals that arise by the overlap of two 1s electrons. Note that since the antibonding orbital has a node between the nuclei, there is practically no electron density in that area, so that this orbital cannot be expected to bond very well. When the centers of electron density are on the axis common to the two nuclei, the molecular orbitals formed by the overlap of two atomic orbitals are called σ (*sigma*) orbitals, and the bonds are called σ bonds. The corresponding antibonding orbitals are designated σ^* . Sigma orbitals may be formed by the overlap of any of the atomic orbital (*s*, *p*, *d*, or *f*) whether the same or different, not only by the overlap of two *s* orbitals. However, the two lobes that overlap must have the same sign: A positive *s* orbital can form a bond only by overlapping with another positive *s* orbital or with a positive lobe of a *p*, *d*, or *f* orbital. Any σ molecular orbital may be represented as approximately ellipsoidal in shape.

Orbitals are frequently designated by their symmetry properties. The σ orbital of hydrogen is often written ψ_g . The *g* stands for *gerade*. A *gerade* orbital is one in which the sign on the orbital does not change when it is inverted through its center of symmetry. The σ^* orbital is *ungerade* (designated ψ_u). An *ungerade* orbital changes sign when inverted through its center of symmetry.

In MO calculations, the *linear combination of atomic orbitals* (known as LCAO) generates a wave function from a linear combination of overlapped atomic orbitals. Addition of the atomic orbitals gives the bonding MO:

$$\psi = c_A\psi_A + c_B\psi_B \quad (1-1)$$

The functions ψ_A and ψ_B are the functions for the atomic orbitals of atoms A and B, respectively, and c_A and c_B represent weighting factors. Subtraction is also a linear combination:

$$\psi = c_A\psi_A - c_B\psi_B \quad (1-2)$$

This gives rise to the antibonding molecular orbital.

In the valence bond method, a wave equation is written for each of various possible electronic structures that a molecule may have (each of these is called a *canonical form*), and the total ψ is obtained by summation of as many of these as seem plausible, each with its weighting factor:

$$\psi = c_1\psi_1 + c_2\psi_2 + \cdots \quad (1-3)$$

This resembles Eq. (1-1), but here each ψ represents a wave equation for an imaginary canonical form and each c is the amount contributed to the total picture by that form. For example, a wave function can be written for each of the following canonical forms of the hydrogen molecule⁵:

Values for c in each method are obtained by solving the equation for various values of each c , and choosing the solution of lowest energy. In practice, both methods give similar solutions for molecules that contain only localized electrons, and these are in agreement with the Lewis structures long familiar to the organic chemist. Delocalized systems are considered in Chapter 2. Note that orbital functions can indeed be reconstructed from measured data using several different approaches. Often, however, the results are still less accurate than those achieved with purely theoretical methods.⁶

1.B. MULTIPLE VALENCE

A univalent atom has only one orbital available for bonding. But atoms with a valence of 2 or more must form bonds by using at least two orbitals. An oxygen atom has two half-filled orbitals, giving it a valence of 2. It forms single bonds by the overlap of these with the orbitals of two other atoms. According to the principle of maximum overlap, the other two nuclei should form an angle of 90° with the oxygen nucleus, since the two available orbitals on oxygen are p orbitals, which are perpendicular. If this is correct, nitrogen, which has three mutually perpendicular p orbitals, would have bond angles of 90° when it forms three single bonds. However, these are not the observed bond angles. The bond angles in water are,⁷ $104^\circ 27'$, and in ammonia, $106^\circ 46'$. For alcohols and ethers, the angles are even larger (see Sec. 1.K). A discussion of this will be deferred to Section 1.K, but it is important to note that covalent compounds do have definite bond angles. Although the atoms are continuously vibrating, the mean position is the same for each molecule of a given compound.

⁵ In this book, a pair of electrons in a bond is represented by two dots.

1.C. HYBRIDIZATION

Consider the case of mercury. Its electronic structure is

Although it has no half-filled orbitals, it has a valence of 2 and forms two covalent bonds. This result can be explained by imagining that one of the $6s$ electrons is promoted to a vacant $6p$ orbital to give the excited configuration

In this state, the atom has two half-filled orbitals, but they are not equivalent. If bonding were to occur by the overlap of these orbitals with the orbitals of external atoms, the two bonds would not be equivalent. The bond formed from the $6p$ orbital would be more stable than the one formed from the $6s$ orbital, since a larger amount of overlap is possible with the former. A more stable situation is achieved when, in the course of bond formation, the $6s$ and $6p$ orbitals combine to form two new orbitals that *are* equivalent; these are shown in Fig. 1.3.

The new molecular orbitals are a mixture of the two original orbitals, so they are called *hybrid orbitals*. Each orbital is a merger of an s and p orbital and is called an sp orbital. The sp orbitals, each of which consists of a large lobe and a very small one, arise only in the bonding process and do not represent a possible structure for the free atom. A mercury atom forms its two bonds by overlapping each of the large lobes shown in Fig. 1.3 with an orbital from an external atom. The orbital of this external atom may be any of the atomic orbitals previously considered (s , p , d , or f), or it may be another hybrid orbital. Note that only lobes of the same sign can overlap. In any of these cases, the molecular orbital that arises is called a σ orbital since it fits the previous definition of a σ orbital.

In general, equivalent orbitals lie as far away from each other as possible because of mutual repulsion, so two sp orbitals form an angle of 180° . In other words, an atom that forms only two σ bonds uses two sp orbitals so HgCl_2 , for example, should be a linear molecule, and it is. This kind of hybridization is called *digonal hybridization*. An sp hybrid orbital forms a stronger covalent bond than either an s or a p orbital because it extends out in space in the direction of the other atom's orbital farther than the s or the p and permits

FIG. 1.3. The two sp orbitals formed by mercury.

greater overlap. Compare HgCl_2 with water (OH_2). It is known that the shape of HgCl_2 is linear, but water is angular. This fact suggests that the hybrid orbitals utilized by oxygen in water is different from those used by mercury in HgCl_2 .

Many other kinds of hybridization are possible. Consider boron, which has the electronic configuration $1s^2 2s^2 2p^1$ yet has a valence of 3. To begin, boron has only three valence electrons available to form bonds, hence the valence of three. Any hybridization model must take this into account. As before, imagine promotion of an electron and hybridization:

In this case, there are three equivalent hybrid orbitals, each called sp^2 (*trigonal hybridization*). This method of designating hybrid orbitals is perhaps unfortunate since nonhybrid orbitals are designated by single letters, but keep in mind that *each* of the three orbitals is called sp^2 . The key is to understand that the atom forms two σ bonds for sp hybridization and three σ bonds for sp^2 hybridization. The sp^2 hybrid orbitals just noted are shown in Fig. 1.4. The three axes are all in one plane and point to the corners of an equilateral triangle. This accords with the known structure of BF_3 , a planar molecule with angles of 120° .

Another type of hybrid orbital is possible, formed by atoms that can form four σ bonds. Carbon is an important atom that can form four single bonds (four σ bonds). Imagine promotion of an electron and hybridization that leads to

There are four equivalent molecular orbitals, each called sp^3 , and electron repulsion leads to a shape in which the orbitals point to the corners of a regular tetrahedron (Fig. 1.4). A typical molecule is methane (CH_4) and assuming that carbon forms four bonds with sp^3 hybrid orbitals, the bond angles of methane would thus be expected to be $109^\circ 28'$, which is the angle for a regular tetrahedron. In reality, electrons are not “promoted” in atomic orbitals, but atomic orbitals are different from molecular orbitals (e.g., those found in methane). The model of promoting an electron is a mathematical device to describe molecular orbitals using the atomic orbitals.

The hybrid orbitals discussed in this section stem from only one possible approximate solution of the Schrödinger equation. The s and the three p atomic orbitals used to form sp^3 orbitals, for example, can be combined in other equally valid ways. As will be seen in Section 1.E, the four C—H bonds of methane do not always behave as if they are

FIG. 1.4. The three sp^2 and the four sp^3 orbitals.

equivalent. Bickelhaupt⁶ has proposed an alternative approach to the bonding in carbon suggesting that the maximum coordination number of carbon cannot exceed four because it is too small to allow more than four substituents approach and form the appropriate bonds.

1.D. MULTIPLE BONDS

If ethylene ($\text{H}_2\text{C}=\text{CH}_2$) is examined in terms of the MO concepts discussed so far, each carbon has three σ bonds, one to each of the three atoms. Therefore, sp^2 orbitals are used to form those three bonds. These sp^2 orbitals arise from hybridization of the $2s^1$, $2p_x^1$, and $2p_y^1$ electrons after promotion of electrons (Sec. 1.C). In general, any carbon atom that is bonded to only three different atoms uses sp^2 orbitals for this bonding. The three σ bonds of ethylene are one to each of two hydrogen atoms and one to the other carbon. Each carbon therefore has another electron in the $2p_z$ orbital that is perpendicular to the plane of the sp^2 orbitals. The two parallel $2p_z$ orbitals, one on each of the two adjacent carbon atoms, can overlap sideways to generate a bonding and an antibonding orbital (Fig. 1.5). In the ground state, both electrons go into the bonding orbital and the antibonding orbital remains vacant. In other words, a new bond is formed, but it is formed by sideways overlap of adjacent p orbitals rather than direct overlap of σ orbitals. Molecular orbitals formed by the overlap of atomic

FIG. 1.5. (a) Overlapping p orbitals form a π and a π^* orbital. The σ orbitals are shown in (a). The π orbitals are shown in (b) as the highest occupied molecular orbital (HOMO) (on the left) and the LUMO. In (c), the electron potential map of ethylene shows the concentration of electron density above and below the plane of the atoms, consistent with a π bond.

FIG. 1.6. The σ orbitals of acetylene.

orbitals whose axes are parallel are called π orbitals if they are bonding and π^* if they are antibonding.

In this picture of ethylene, there are two bonds connecting the adjacent carbon atoms, but the two orbitals that make up the double bond are not equivalent.⁸ This means that the two bonds are different one from the other. The σ orbital is ellipsoidal and symmetrical about the C—C axis, and this is the familiar σ bond. The π orbital is in the shape of two ellipsoids, one above the plane and one below, and forms the second bond, a π bond. The plane itself represents a node for the π orbital. In order for the p orbitals to maintain maximum overlap, they must be parallel. Since both a σ bond and the π bond connect the two carbon atoms, free rotation is not possible about the double bond. In other words, the two p orbitals would have to reduce their overlap to allow one H—C—H plane to rotate with respect to the other (i.e., the π bond would have to disappear). With two sp^2 hybrid carbon atoms in ethylene, the six atoms associated with the double bond ($H_2C=CH_2$) are in a plane with angles that should be $\sim 120^\circ$. Double bonds are shorter than the corresponding single bonds because maximum stability is obtained when the p orbitals overlap as much as possible (see Sec. 1.J). Double bonds between carbon and oxygen (C=O) or nitrogen (C=N) similarly consist of one σ and one π orbital.

When carbon is connected to another carbon atom by a triple bond, as in acetylene ($HC\equiv CH$), each carbon is connected to only two other atoms by a σ bond, and hence uses sp hybridization. This fact requires that the four atoms of acetylene (2H and 2C) are in a straight line (Fig. 1.6).⁹ Each carbon has two p orbitals remaining, with one electron in each. These orbitals are perpendicular to each other and also to the C—C axis. They overlap in the manner shown in Fig. 1.7 to form two π orbitals. A triple bond is thus composed of one σ and two π orbitals. Triple bonds between carbon and nitrogen can be represented in a similar manner, $C\equiv N$.

For most organic molecules, double and triple bonds typically involve the first-row elements carbon, nitrogen, and oxygen.¹⁰ Second-row elements tend to form weaker π bonds than do the first-row elements,¹¹ so multiple bonds are less common and compounds containing them are generally less stable.¹² Compounds with C=S bonds are known, for example, and C=S compounds are generally much less stable than the corresponding C=O compounds (however, see $p\pi-d\pi$ bonding in Sec. 2.H). Stable compounds with

(b) Electron potential map of acetylene showing the concentration of electron density between the carbon atoms, consistent with two orthogonal π bonds.

$\text{Si}=\text{C}$ and $\text{Si}=\text{Si}$ bonds are rare, but examples have been reported,¹³ including a pair of *cis* and *trans* $\text{Si}=\text{Si}$ isomers.¹⁴

There is at least one report of a so-called two-electron, four-center C—C bond for the dimer of tetracyanoethylene.¹⁵ While such multi-center bonding is not formally an example of the multiple bonding described in this section, it constitutes a different type of bonding when compared to the simple C—C bonds described earlier.

1.E. PHOTOELECTRON SPECTROSCOPY

Based on the hybridization model, methane is expected to have four equivalent σ bonds. Indeed, the four bonds of methane are equivalent according to most physical and chemical methods of detection. The *nuclear magnetic resonance* (NMR) and the *infrared* (IR) spectrum of methane show *no* peaks that can be attributed to different kinds of C—H bonds. However, there is one physical technique showing that the eight valence electrons of methane can be differentiated. In this technique, called *photoelectron spectroscopy* (PES),¹⁶ a molecule or free atom is bombarded with vacuum *ultraviolet* (UV) radiation, causing an electron to be ejected. The energy of the ejected electron can be measured, and the difference between the energy of the radiation used and that of the ejected electron is

¹³ For $\text{Si}=\text{C}$ bonds, see Fink, M.J.; DeYoung, D.J.; West, R.; Michl, J. *J. Am. Chem. FIG. 1.8. Photoelectron spectrum of N₂.¹⁸ [Reprinted with permission from Brundle, C.R.; Robin, M.B. in Nachod, F.C.; Zuckerman, J.J. *Determination of Organic Structures by Physical Methods*, Vol. 1, Academic Press, NY, **1971**, p. 18. Copyright © 1971, with permission from Elsevier Science. With permission of C. Richard Brundle, 2012.]

the *ionization potential* of that electron. A molecule that contains several electrons of differing energies can lose any one of them as long as its ionization potential is less than the energy of the radiation used. A single molecule loses only one electron; the loss of two electrons by any individual molecule almost never occurs. Since electrons reside in orbitals, a photoelectron spectrum consists of a series of bands, each corresponding to an orbital of a different energy. The spectrum gives a direct experimental picture of all orbitals that are present, and they are ejected in ascending order of their energies, provided that radiation of sufficiently high energy is used.¹⁷ Broad bands usually correspond to strongly bonding electrons and narrow bands to weakly bonding or nonbonding electrons.

Using PES, it is possible to probe the validity of the hybridization model for bonding. Dinitrogen (N₂) is a typical diatomic molecule and is shown in Fig. 1.8.¹⁸ The N₂ molecule has the electronic structure shown in Fig. 1.9: The two 2s orbitals of the nitrogen atoms combine to give the two orbitals marked 1 (bonding) and 2 (antibonding), while the six 2p orbitals combine to give six orbitals, three of which (marked 3, 4, and 5) are bonding. The three antibonding orbitals (not indicated in Fig. 1.9) are unoccupied. Electrons ejected from orbital 1 are not found in Fig. 1.8 because the ionization potential of these electrons is greater than the energy of the light used (they can be seen when higher energy light is used). The broad band in Fig. 1.8 corresponds to the four electrons in the degenerate orbitals 3 and 4. The individual peaks within this band are caused by different vibrational levels (see Chap. 7). The triple bond of N₂ is therefore composed of these two orbitals and orbital 1. The bands corresponding to orbitals 2 and 5 are narrow; hence these orbitals contribute little to the bonding and may be regarded as the two unshared pairs of $\tilde{N} \equiv \tilde{N}$. Note that this result is contrary to that expected from a naive consideration of orbital overlaps, where it

¹⁷ The correlation is not perfect, but the limitations do not seriously detract from the usefulness of the method. The technique is not limited to vacuum UV radiation. Higher energy radiation can also be used.

¹⁸ From Brundle, C.R.; Robin, M.B., in Nachod, F.C.; Zuckerman, J.J. *Determination of Organic Structures by Physical Methods*, Vol. 3, Academic Press, NY, **1971**, p. 18.

FIG. 1.9. Electronic structure of N_2 (inner-shell electrons omitted).

would be expected that the two unshared pairs would be those of orbitals 1 and 2, resulting from the overlap of the filled $2s$ orbitals. In addition, the triple bond would be composed of orbitals 3, 4, and 5, resulting from overlap of the p orbitals. This example is one illustration of the value of PES.

The photoelectron spectrum of methane¹⁹ in Fig. 1.10 shows two bands,²⁰ at ~ 23 and 14 eV, and not the single band expected from the equivalency of the four C—H bonds. Indeed, Fig. 1.10 suggests that carbon uses the available orbitals to form four bonds and the electrons in the bonds are distributed between carbon and the four atoms involved in the bonds. Remember that the hybridization model predicts four identical σ bonds made by overlap of four identical hybrid orbitals. The band at 23 eV comes from two electrons in a low-energy

FIG. 1.10. Photoelectron spectroscopy scan of methane. [Reprinted with permission from Brundle, C.R.; Robin, M.B. *J. Chem. Phys.* **1970**, 53, 2196. Copyright © 1970, American Institute of Physics.]

²⁰ A third band, at 290 eV, caused by the $1s$ electrons of carbon, can also be found if radiation of sufficiently high energy is used.

level (called the a_1 level), which can be regarded as arising from a combination of the $2s$ orbital of carbon with an appropriate combination of hydrogen $1s$ orbitals. The band at 14 eV comes from six electrons in a triply degenerate level (the t_2 level), arising from a combination of the three $2p$ orbitals of carbon with other combinations of $1s$ hydrogen orbitals. As mentioned above, most physical and chemical processes cannot distinguish these levels, but PES can. The photoelectron spectra of many other organic molecules are known as well,²¹ including monocyclic alkenes, in which bands < 10 eV are due to π -orbital ionization and those > 10 eV originate from ionization of σ orbitals only.²² Note that ordinary sp^3 hybridization is not adequate to explain phenomena involving ionized molecules (e.g., the $\text{CH}_4^{\bullet+}$ radical ion, which is left behind when an electron is ejected from methane). For these phenomena, it is necessary to use other combinations of atomic orbitals (see Sec. 1.C).

1.F. ELECTRONIC STRUCTURES OF MOLECULES

For each molecule, ion, or free radical that has only localized electrons, it is possible to draw an electronic formula, called a *Lewis structure*, which shows the location of these electrons. Only the valence electrons are shown. Valence electrons may be found in covalent bonds connecting two atoms or they may be unshared.²³ Drawing these structures correctly is essential, since the position of electrons changes in the course of a reaction, and it is necessary to know where the electrons are initially before one can follow where they are going. To this end, the following rules operate:

1. The total number of valence electrons in the molecule (or ion or free radical) must be the sum of all outer-shell electrons “contributed” to the molecule by each atom plus the negative charge or minus the positive charge, for the case of ions. Thus, for H_2SO_4 , there are 2 (one for each hydrogen) + 6 (for the sulfur) + 24 (6 for each oxygen) = 32; while for SO_4^{2-} , the number is also 32, since each atom “contributes” 6 plus 2 for the negative charge.
2. Once the number of valence electrons has been ascertained, it is necessary to determine which of them are found in covalent bonds and which are unshared. Unshared electrons (either a single electron or a pair) form part of the outer shell of just one atom, but electrons in a covalent bond are part of the outer shell of both atoms of the bond. *First-row atoms* (B, C, N, O, F) *can have a maximum of eight valence electrons*, and usually have this number, although some cases are known where a first-row atom has only six or seven. Where there is a choice between a structure that has six or seven electrons around a first-row atom and one in which all such atoms have an octet, the structure based on the octet is generally lower in energy than the one that is observed. For example, ethylene is

²¹ See Robinson, J.W., *Practical Handbook of Spectroscopy*, CRC Press, Boca Raton, FL, **1991**, p. 178.

²² Novak, I.; Potts, A.W. *Tetrahedron* **1997**, 53, 14713.

²³ It has been argued that although the Lewis picture of two electrons making up a covalent bond may work well for organic compounds, it cannot be successfully applied to the majority of inorganic compounds: Jørgensen, C.K. *Top. Curr. Chem.* **1984**, 124, 1.

There are a few exceptions. For the molecule O_2 , the structure $\dot{O}-\dot{O}$ has a lower energy than $\ddot{O}=\ddot{O}$. Although first-row atoms are limited to 8 valence electrons, this is not so for second-row atoms, which can accommodate 10 or even 12 because empty d orbitals may be utilized.²⁴ For example, PCl_5 and SF_6 are stable compounds, and the hybridization model can be used to explain this fact. In SF_6 , one s and one p electron from the ground state $3s^2 3p^4$ of the sulfur are promoted to empty d orbitals, and the six orbitals hybridize to give six $sp^3 d^2$ orbitals, which point to the corners of a regular octahedron.

3. It is customary to show the formal charge on each atom. For this purpose, an atom is considered to “own” all unshared electrons, but only *one-half of the electrons in covalent bonds*. The sum of electrons that thus “belong” to an atom is compared with the number “contributed” by the atom. An excess belonging to the atom results in a negative charge, and a deficiency results in a positive charge. The total of the formal charges on all atoms equals the charge on the whole molecule or ion. Note that the counting procedure is not the same for determining formal charge as for determining the number of valence electrons. For both purposes, an atom “owns” all unshared electrons, but for outer-shell purposes it “owns” both the electrons of the covalent bond, while for formal-charge purposes it “owns” only one-half of these electrons.

Examples of electronic structures are

A coordinate-covalent bond (sometimes called a dative bond), represented by an arrow, is one in which both electrons come from the same atom; that is, the bond can be regarded as being formed by the overlap of an orbital containing two electrons with an empty one. Thus trimethylamine *N*-oxide would be represented:

For a coordinate-covalent bond, the rule concerning formal charge is amended so that both electrons count for the donor and neither for the recipient. Thus the nitrogen and oxygen atoms of trimethylamine oxide bear no formal charges. However, it is apparent that the electronic picture is exactly the same as the picture of trimethylamine *N*-oxide given just above, and there is a choice of drawing an arrowhead or a charge separation. Some compounds (e.g., amine *N*-oxides) must be drawn one way or the other. It is usually simpler to use charge separation.

1.G. ELECTRONEGATIVITY

The electron cloud that bonds two atoms is not symmetrical (with respect to the plane that is the perpendicular bisector of the bond) except when the two atoms are the same and have the same substituents. A symmetrical electron cloud typically occurs when there is a bond

²⁴ For a review concerning sulfur compounds with a valence shell larger than eight, see Salmond, W.G. *Q. Rev. Chem. Soc.* **1968**, 22, 235.

between two identical atoms, and an unsymmetrical electron cloud occurs when there are two different atoms. When there are two different atoms, and one is more electronegative than the other, the electron cloud is necessarily distorted toward one side of the bond or the other, depending on which atom (nucleus plus electrons) maintains the greater attraction for the cloud. This attraction is called *electronegativity*;²⁵ and it is greatest for atoms in the upper-right corner of the periodic table and lowest for atoms in the lower-left corner. Thus a bond between fluorine and carbon (C—F) shows distortion of the electron cloud associated with the bond, so that there is a higher probability of finding the electrons near the fluorine than near the carbon. Such a bond is said to be *polarized*, and the C—F bond is an example of a polarized covalent bond. The polarization gives the fluorine a partial negative charge (δ^-) and the carbon a partial positive charge (δ^+).

A number of attempts have been made to set up quantitative tables of electronegativity that will indicate the direction and extent of electron-cloud distortion for a bond between any pair of atoms. The most popular of these scales, devised by Pauling, is based on bond energies (see Sec. 1.L) of diatomic molecules. It is rationalized that if the electron distribution were symmetrical in a molecule A—B, the bond energy would be the mean of the energies of A—A and B—B, since in these cases the cloud must be undistorted. If the actual bond energy of A—B is higher than this (and it usually is), it is the result of the partial charges (the charges attract each other and make a stronger bond, which requires more energy to break). It is necessary to assign a value to one element arbitrarily ($F = 4.0$). Then the electronegativity of another is obtained from the difference between the actual energy of A—B and the mean of A—A and B—B (this difference is called Δ) by the formula

$$x_A - x_B = \sqrt{\frac{\Delta}{23.06}}$$

where x_A and x_B are the electronegativities of the known and unknown atoms and 23.06 is an arbitrary constant. Part of the scale derived from this treatment is shown in Table 1.1.^{26,27}

Other treatments²⁸ have led to scales that are based on different principles, for example, the average of the ionization potential and the electron affinity,²⁹ the average one-electron energy of valence-shell electrons in ground-state free atoms,³⁰ or the “compactness” of an atom’s electron cloud.²⁴ In some of these treatments, electronegativities can be calculated for different valence states, for different hybridizations (e.g., *sp* carbon atoms are more electronegative than *sp*², which are still more electronegative than *sp*³),³¹ and even

differently for primary, secondary, and tertiary carbon atoms. Also, electronegativity values can be calculated for groups rather than atoms (Table 1.2).³²

Electronegativity information can be obtained from NMR spectra. In the absence of a magnetically anisotropic group³³ the chemical shift of a ¹H or a ¹³C nucleus is approximately proportional to the electron density around it, and hence to the electronegativity of the atom or group to which it is attached. The greater the electronegativity of the atom or group, the lower the electron density around the proton, and the further downfield the chemical shift [relative to tetramethylsilane (TMS) as zero ppm]. An example of the use of this correlation is found in the variation of chemical shift of the *ring* protons in the series toluene, ethylbenzene, isopropylbenzene, and *tert*-butylbenzene (there is a magnetically anisotropic group here, but its effect should be constant throughout the series). The electron density surrounding the ring protons decreases³⁴ in the order given.³⁵ However, this type of correlation is by no means perfect, since all the measurements are made in a powerful field, which itself may affect the electron density distribution.

³² Inamoto, N.; Masuda, S. *Chem. Lett.* **1982**, 1003. See also, Bratsch, S.G. *J. Chem. Educ.* **1988**, *65*, 223; Mulla, J. *J. Am. Chem. Soc.* **1985**, *107*, 7271; Zefirov, N.S.; Kirpichenok, M.A.; Izmailov, F.F.; Trofimov, M.I. *Dokl. Chem.* **1987**, *296*, 440; Boyd, R.J.; Edgecombe, K.E. *J. Am. Chem. Soc.* **1988**, *110*, 4182.

³³ A magnetically anisotropic group is one that is not equally magnetized along all three axes. The most common such groups are benzene rings (see Sec. 2.I) and triple bonds.

³⁴ This order is opposite to that expected from the field effect (Sec. 1.I). It is an example of the *Baker–Nathan order* (Sec. 2.M).

³⁵ Moodie, R.B.; Connor, T.M.; Stewart, R. *Can. J. Chem.* **1960**, *38*, 626.

Coupling constants between the two protons of a system $-\text{CH}-\text{CH}-\text{X}$ have also been found to depend on the electronegativity of X.³⁶

When the difference in electronegativities is great, the electron density in an orbital may be effectively localized on only one nucleus. This is an *ionic bond*, which is seen to arise naturally out of the previous discussion. It is possible to view polarized covalent bonds as intermediates between ionic and covalent bonds. With this view, the extent of electron-cloud distortion is expressed as the percent ionic character of a bond. In this model, there is a continuous gradation from ionic to covalent bonds.

1.H. DIPOLE MOMENT

The *dipole moment* is a property of a molecule that results from charge separations like those discussed above. However, it is not possible to measure the dipole moment of an individual bond within a molecule. Only the total moment of the molecule may be measured, and it is the vectorial sum of the individual bond moments.³⁷ These individual moments are roughly the same from molecule to molecule,³⁸ but this constancy is by no means universal. Thus, from the dipole moments of toluene and nitrobenzene (Fig. 1.11)³⁹ the moment of *p*-nitrotoluene is predicted to be ~ 4.36 D. The actual value 4.39 D is reasonable. However, the moment of

FIG. 1.11. Some dipole moments, in Debye units, measured in benzene. In the 3D model, the arrow indicates the direction of the dipole moment for the molecule, pointing to the negative part of the molecule.³⁹

³⁶ Williamson, K.L. *J. Am. Chem. Soc.* **1963**, 85, 516; Laszlo, P.; Schleyer, P.v.R. *J. Am. Chem. Soc.* **1963**, 85, 2709; Niwa, J. *Bull. Chem. Soc. Jpn.* **1967**, 40, 2192.

³⁷ See Exner, O. *Dipole Moments in Organic Chemistry*, Georg Thieme Publishers, Stuttgart, **1975**; McClellan, A. L. *Tables of Experimental Dipole Moments*, Vol. 1, W.H. Freeman, San Francisco, **1963**; Vol. 2, Rahara Enterprises, El Cerrito, CA, **1974**.

³⁸ For example, see Koudelka, J.; Exner, O. *Collect. Czech. Chem. Commun.* **1985**, 50, 188, 200.

³⁹ The values for toluene, nitrobenzene, and *p*-nitrotoluene are from McClellan, A.L., *Tables of Experimental Dipole Moments*, Vol. 1, W.H. Freeman: San Francisco, **1963**; Vol. 2, Rahara Enterprises, El Cerrito, CA, **1974**. The values for phenol and *p*-cresol were determined by Goode, E.V.; Ibbitson, D.A. *J. Chem. Soc.* **1960**, 4265.

p-cresol (1.57 D) is quite far from the predicted value of 1.11 D. In some cases, molecules may have substantial individual bond moments, but no total moments at all because the individual moments are canceled out by the overall symmetry of the molecule. Some examples are CCl₄, *trans*-1,2-dibromoethene, and *p*-dinitrobenzene.

Because of the small difference between the electronegativities of carbon and hydrogen, alkanes have very small dipole moments, so small that they are difficult to measure. For example, the dipole moment of isobutane is 0.132 D⁴⁰ and that of propane is 0.085 D.⁴¹ Of course, methane and ethane, because of their symmetry, have no dipole moments.⁴² Few organic molecules have dipole moments > 7 D.

1.1. INDUCTIVE AND FIELD EFFECTS

The C—C bond in ethane has no polarity because it connects two equivalent atoms, with identical electronegativities. The presence of a more electronegative atom attached to one of the carbon atoms will lead to bond polarization, however, in what is known as an induced dipole. The C—C bond in chloroethane, for example, is polarized by the presence of the electronegative chlorine atom. This polarization is actually the sum

of two effects. In the first of these, the C-1 atom is deprived of some of its electron density by the greater electronegativity of Cl, and this effect is partially compensated by drawing the C—C electrons closer to itself. The result is a polarization of this bond and a slightly positive charge on the C-2 atom: an induced dipole. This polarization of one bond caused by the polarization of an adjacent bond is known as an *inductive effect*. The effect is greatest for adjacent bonds but may also be felt farther away; thus the polarization of the C—C bond causes a (slight) polarization of the three methyl C—H bonds. As a practical matter, the effect is negligible if the polarizing group is more than three bonds away.

The other effect operates not through bonds, but directly through space or solvent molecules, and is called a *field effect*.⁴³ It is often very difficult to separate the two kinds of effect, but a number of cases have been reported. This is generally accomplished by taking advantage of the fact that the field effect depends on the geometry of the molecule, but the inductive effect depends only on the nature of the bonds. For example, in isomers, **1** and **2**⁴⁴ the inductive effect of the chlorine atoms on the position of the electrons in the COOH group (and hence on the

⁴⁰ Lide Jr., D.R.; Mann, D.E. *J. Chem. Phys.* **1958**, 29, 914.

⁴¹ Muentner, J.S.; Laurie, V.W. *J. Chem. Phys.* **1966**, 45, 855.

⁴² Actually, symmetrical tetrahedral molecules like methane do have extremely small dipole moments, caused by centrifugal distortion effects; these moments are so small that they can be ignored for all practical purposes. For CH₄, μ is $\sim 5.4 \times 10^{-6}$ D: Ozier, I. *Phys. Rev. Lett.* **1971**, 27, 1329; Rosenberg, A.; Ozier, I.; Kudian, A.K. *J. Chem. Phys.* **1972**, 57, 568.

⁴³ Roberts, J.D.; Moreland, Jr., W.T. *J. Am. Chem. Soc.* **1953**, 75, 2167.

⁴⁴ This example is from Grubbs, E.J.; Fitzgerald, R.; Phillips, R.E.; Petty, R. *Tetrahedron* **1971**, 27, 935.

acidity, see Chap. 8) should be the same since the same bonds intervene. The field effect is different, however, because the chlorine atoms are closer in space to the COOH in **1** than they are in **2**. Thus, a comparison of the acidity of **1** and **2** should reveal whether a field effect is truly operating. The evidence obtained from such experiments is overwhelming that field effects are much more important than inductive effects.⁴⁵ In most cases, the two types of effect are considered together; in this book, they will not be separated but will use the name *field effect* to refer to their combined action.⁴⁶ Note that the field effect for **1** may be viewed as internal hydrogen bonding (see Sec. 3.A).

Functional groups can be classified as electron withdrawing ($-I$) or electron donating ($+I$) groups relative to hydrogen. This means, for example, that NO₂, a $-I$ group, will draw electrons to itself more than a hydrogen atom would if it occupied the same position in the molecule.

Thus, in α -nitrotoluene, the electrons in the N—C bond are farther away from the carbon atom than the electrons in the H—C bond of toluene. Similarly, the electrons of the C—Ph bond are farther away from the ring in α -nitrotoluene than they are in toluene. Field effects are always comparison effects. For example, compare the $-I$ or $+I$ effect of one group with another (usually hydrogen). Therefore, it may be said that, compared with hydrogen, the NO₂ group is electron withdrawing and the O[−] group is electron donating or electron releasing. However, there is no actual donation or withdrawal of electrons, but rather electron distortion or electron redistribution. While withdrawing and releasing terms are convenient to use, the terms merely represent a difference in the position of electrons due to the difference in electronegativity between H and NO₂ or between H and O[−].

Table 1.3 lists a number of the most common $-I$ and $+I$ groups.⁴⁷ It can be seen that compared with hydrogen, most groups are electron withdrawing. The only electron-donating groups are those with a formal negative charge (but not even all these), atoms of low electronegativity (Si,⁴⁸ Mg, etc., and perhaps alkyl groups). Alkyl groups⁴⁹ were formerly regarded as electron donating, but many examples of behavior have been found that can be interpreted only by the conclusion that alkyl groups are electron withdrawing compared with hydrogen.⁵⁰ In accord with this is the value of 2.472 for the group electronegativity of CH₃ (Table 1.2) compared with 2.176 for H. When an alkyl group is attached to an unsaturated or trivalent carbon (or other atom), its behavior is best explained by assuming it is $+I$ (see, e.g., Sec. 5.A.ii, 5.B.i, 8.E, 11.B.i), but when it is

⁴⁵ See Schneider, H.; Becker, N. *J. Phys. Org. Chem.* **1989**, 2, 214; Bowden, K.; Ghadir, K.D.F. *J. Chem. Soc. Perkin Trans. 2* **1990**, 1333. Also see Exner, O.; Fiedler, P. *Collect. Czech. Chem. Commun.* **1980**, 45, 1251; Li, Y.; Schuster, G.B. *J. Org. Chem.* **1987**, 52, 3975.

⁴⁶ There has been some question as to whether it is even meaningful to maintain the distinction between the two types of effect: see Grob, C.A. *Helv. Chim. Acta* **1985**, 68, 882; Lenoir, D.; Frank, R.M. *Chem. Ber.* **1985**, 118, 753; Sacher, E. *Tetrahedron Lett.* **1986**, 27, 4683.

CH ₃	CN	OAr	C≡CR
D	SO ₂ Ar	COOR	Ar
			C≡CR ₂

^aThe groups are listed approximately in order of decreasing strength for both -I and +I groups. [Reprinted with permission from Ceppi, E.; Eckhardt, W.; Grob, C.A. *Tetrahedron Lett.* **1973**, 3627. Copyright © 1973, with permission from Elsevier Science.]

connected to a saturated atom, the results are not as clear, and alkyl groups seem to be +I in some cases and -I in others⁵¹ (see also, Sec. 8.F). When connected to a positive carbon, alkyl groups are clearly electron releasing.

It is clear that the field-effect order of alkyl groups attached to unsaturated systems is tertiary > secondary > primary > CH₃, but this order is not always maintained when the groups are attached to saturated systems. Deuterium is electron donating with respect to hydrogen.⁵² Other things being equal, atoms with *sp* bonding generally have a greater electron-withdrawing power than those with *sp*² bonding, which in turn have more electron-withdrawing power than those with *sp*³ bonding.⁵³ This accounts for the fact that aryl, vinylic, and alkynyl groups are -I. Field effects always decrease with increasing distance, and in most cases (except when a very powerful +I or -I group is involved), cause very little difference in a bond four bonds away or more. There is evidence that field effects can be affected by the solvent.⁵⁴

For discussions of field effects on acid and base strength and on reactivity, see Chapters 8 and 9, respectively.

1.J. BOND DISTANCES⁵⁵

The distances between atoms in a molecule are characteristic properties of the molecule and can give information if compared with the same bond in different molecules. The chief methods of determining bond distances and angles are X-ray diffraction (only for solids),

TABLE 1.4 Bond Lengths between sp^3 Carbons in Some Compounds

C—C Bond in	Reference	Bond Length (Å)
Diamond	58	1.544
C ₂ H ₆	59	1.5324 ± 0.0011
C ₂ H ₅ Cl	60	1.5495 ± 0.0005
C ₃ H ₈	61	1.532 ± 0.003
Cyclohexane	62	1.540 ± 0.015
<i>tert</i> -Butyl chloride	63	1.532
<i>n</i> -Butane to <i>n</i> -heptane	64	1.531–1.534
Isobutane	65	1.535 ± 0.001

electron diffraction (only for gases), and spectroscopic methods, especially microwave spectroscopy. The distance between the atoms of a bond is not constant, since the molecule is always vibrating; the measurements obtained are therefore average values, so that different methods give different results.⁵⁶ However, this must be taken into account only when fine distinctions are made.

Measurements vary in accuracy, but indications are that similar bonds have fairly constant lengths from one molecule to the next. While exceptions are known,⁵⁷ the variation is generally < 1%. Table 1.4 shows distances for single bonds between two sp^3 carbons.^{58–65} However, an analysis of C—OR bond distances in >2000 ethers and carboxylic esters (all with sp^3 carbon) shows that this distance increases with increasing electron withdrawal in the R group and as the C changes from primary to secondary to tertiary.⁶⁶ For these compounds, mean bond lengths of the various types ranged from 1.418 to 1.475 Å. Certain substituents can also influence bond length. The presence of a silyl substituent β^- to a C—O (ester) linkage can lengthen the C—O, thereby weakening it.⁶⁷ This finding is believed to result from $\sigma-\sigma^*$ interactions in which the C—Si σ bonding orbital acts as the donor and the C—O σ^* orbitals acts as the receptor.

Bond distances for some important bond types are given in Table 1.5.⁶⁸ Although a typical carbon–carbon single bond has a bond length of ~ 1.54 Å, certain molecules are known that have significantly longer bond lengths.⁶⁹ Calculations have been done for unstable molecules that showed them to have long bond lengths, and an analysis of the X-ray structure for a photoisomer (**4**) of [2.2]-tetrabenzoparacyclophane, **3A** (also see Sec. 2.G), showed a C—C bond length of 1.77 Å.^{69,70} Note that **3A** is shown as the molecular model **3B** for comparison with photoisomer **4**, which has the two four-membered ring moieties. Long bond lengths have been observed in stable molecules (e.g., benzocyclobutane derivatives).⁷¹ A bond length of 1.729 Å was reliably measured in 1,1-di-*tert*-butyl-2,2-diphenyl-3,8-dichlorocyclobutan[*b*]naphthalene, **5**.⁷² X-ray analysis of several of these derivations confirmed the presence of long C—C bonds, with **6** having a confirmed bond length of 1.734 Å.⁷³

A theoretical study has been reported, using computer simulation to apply encapsulation, strapping back, and stiffening to “squeeze” C—C bonds, leading to shorter bonds than would be observed if hybridization and conjugative effects operated alone.⁷⁴ The additional strain caused by threefold symmetric geometry constraints is believed responsible for this effect rather than changes in hybridization alone, as postulated by others.^{75–82}

⁶⁸ Except where noted, values are from Allen, F.H.; Kennard, O.; Watson, D.G.; Brammer, L.; Orpen, A.G.; Taylor, R. *J. Chem. Soc. Perkin Trans. 2* **1987**, S1–S19 (follows p. 1914). In this source, values are given to three significant figures.

^aThe values given are average lengths and do not necessarily apply exactly to the compounds mentioned.⁸⁰
 [Reproduced from Allen F.H.; Kennard, O.; Watson, D.G.; Brammer, L.; Orpen, A.G.; Taylor R. *J. Chem. Soc. Perkin Trans. 2* **1987**, S1–S19 with permission from the Royal Society of Chemistry.]

There are indications that a C—D bond is slightly shorter than a corresponding C—H bond. Thus, electron-diffraction measurements of C₂H₆ and C₂D₆ showed a C—H bond distance of 1.1122 ± 0.0012 Å and a C—D distance of 1.1071 ± 0.0012 Å.⁵⁹

As seen in Table 1.5, carbon bonds are shortened by increasing *s* character. This is most often explained by the fact that, as the percentage of *s* character in a hybrid orbital

increases, the orbital becomes more like an s orbital and hence is held more tightly by the nucleus than an orbital with less s character. However, other explanations have also been offered (see Sec. 2.C), and the matter is not completely settled. In general, molecules with one π bond ($X=X$) have shorter bond distances when compared to single bonds, $X-X$, and molecules with two π bonds ($X\equiv X$) have even shorter bond lengths. Indeed, the bond length clearly decreases in the molecules H_3C-CH_3 , $H_2C=CH_2$, and $HC\equiv CH$: C—C bond lengths of 1.538, 1.338, and 1.203 Å.⁸³ There is work that suggests the absence of σ bonds may play a role in producing short bond distances in molecules that contain only π bonds.⁸⁴ This suggests that σ bonds prevent π bonds from adopting their optimal shorter distances. Such bonds occur in some organometallic compounds.

1.K. BOND ANGLES

The bond angles of sp^3 carbon should be the tetrahedral angle $109^\circ 28'$ when the four atoms or groups are relatively small and identical, as in methane, neopentane, or carbon tetrachloride. As atoms or groups become larger, bond angles are distorted to accommodate the larger size of the attached units. In most cases, the angles deviate a little from the pure tetrahedral value unless two or more units are very large. Molecular models 7–9 illustrate this phenomenon. The H—C—H bond angles in methane (7) are calculated for the model to be $109^\circ 47'$, whereas the Br—C—H bond angle in 8 is calculated to be 108.08° and the Br—C—Br bond angle in 9 is calculated to be 113.38° . Note that the C—Br bond length is longer than the C—H bond lengths. As the bond angles expand to accommodate the larger atoms, the H—C—H bond angles in 8 and 9 must compress to a smaller angle. In 2-bromopropane, the bromine atom also has a methyl group (compare with bromomethane 8 where Br competes with H) and, the C—C—Br angle in 2-bromopropane is 114.2° .⁸⁵

Variations are generally found from the ideal values of 120° and 180° for sp^2 and sp carbon, respectively. These deviations occur because of slightly different hybridizations; that is, a carbon bonded to four other atoms hybridizes one s and three p orbitals, but the four hybrid orbitals thus formed are generally not exactly equivalent, nor does each contain exactly 25% s and 75% p character. Because the four atoms have (in the most general case) different electronegativities, each makes its own demand for electrons from the carbon atom.⁸⁶ The carbon atom supplies more p character when it is bonded to more

TABLE 1.6 Oxygen, Sulfur, and Nitrogen Bond Angles in Some Compounds

Angle	Value	Compound	Reference
H—O—H	104°27'	Water	7
C—O—H	107–109°	Methanol	62
C—O—C	111°43'	Dimethyl ether	88
C—O—C	124° ± 5°	Diphenyl ether	89
H—S—H	92.1°	Hydrogen sulfide	82
C—S—H	99.4°	Methanethiol	82
C—S—C	99.1°	Dimethyl sulfide	90
H—N—H	106°46'	Ammonia	7
H—N—H	106°	Methylamine	91
C—N—H	112°	Methylamine	83
C—N—C	108.7°	Trimethylamine	92

electronegative atoms, so that in chloromethane, for example, the bond to chlorine has somewhat $> 75\%$ p character, which of course requires that the other three bonds have somewhat less, since there are only three p orbitals (and one s) to be divided among the four hybrid orbitals.⁸⁷ Of course, in strained molecules (e.g., **3–6**), the bond angles may be greatly distorted from the ideal values (also see Sec. 4.Q).

For molecules that contain oxygen and nitrogen, angles of 90° are predicted from p^2 bonding. However, as seen in Section 1.B, the angles of water and ammonia are much larger than this, as are the angles of other organic molecules that contain oxygen and nitrogen (Table 1.6).^{88–92} In fact, they are much closer to the tetrahedral angle of $109^\circ 28'$ than to 90° . These facts have led to the suggestion that in these compounds oxygen and nitrogen use sp^3 bonding. Using the hybridization model, these atoms are said to form bonds by the overlap of two (or three) p orbitals with $1s$ orbitals of the hydrogen atoms, which means that they hybridize their $2s$ and $2p$ orbitals to form four sp^3 orbitals and then use only two (or three) of these for bonding with hydrogen, the others remaining occupied by unshared pairs (also called *lone pairs*). If this description is valid, and it is generally accepted by most chemists today,⁹³ it becomes necessary to explain why the angles of these two compounds are in fact not $109^\circ 28'$ but a few degrees smaller. One explanation that has been offered is that the unshared electron pair actually has a greater steric requirement (see Sec. 4.Q) than the electrons in a bond, since there is no second nucleus to draw away some of the electron density and the bonds are thus crowded together. However, most evidence is that unshared pairs have smaller steric requirements than bonds⁹⁴ and the explanation most commonly

⁸⁷ This assumption has been challenged: see Pomerantz, M.; Liebman, J.F. *Tetrahedron Lett.* **1975**, 2385.

accepted is that the hybridization is not pure sp^3 . As seen above, an atom supplies more p character when it is bonded to more electronegative atoms. An unshared pair may be considered to be an “atom” of the lowest possible electronegativity, since there is no attracting power at all. Consequently, the unshared pairs have more s and the bonds more p character than pure sp^3 orbitals, making the bonds somewhat more like p^2 bonds and reducing the angle. However, these arguments ignore the steric effect of the atoms or groups attached to oxygen or nitrogen. As seen in Table 1.6, oxygen, nitrogen, and sulfur angles generally increase with decreasing electronegativity of the substituents. Note that the explanation given above cannot explain why some of these angles are *greater* than the tetrahedral angle.

1.L. BOND ENERGIES⁹⁵

There are two kinds of bond energy. The energy necessary to cleave a bond to give the constituent radicals is called the *dissociation energy* (D). For example, D for $\text{H}_2\text{O} \rightarrow \text{HO} + \text{H}$ is $118 \text{ kcal mol}^{-1}$ (494 kJ mol^{-1}). However, this is not taken as the energy of the O—H bond in water, since D for $\text{H—O} \rightarrow \text{H} + \text{O}$ is $100 \text{ kcal mol}^{-1}$ (418 kJ mol^{-1}). The average of these two values, $109 \text{ kcal mol}^{-1}$ (456 kJ mol^{-1}), is taken as the *bond energy* (E). In diatomic molecules, of course, $D = E$.

The D values may be easy or difficult to measure. They can be estimated by various techniques.⁹⁶ When properly applied, “Pauling’s original electronegativity equation accurately describes homolytic bond dissociation enthalpies of common covalent bonds, including highly polar ones, with an average deviation of ($1.5 \text{ kcal mol}^{-1}$ ($\sim 6.3 \text{ kJ mol}^{-1}$) from literature values)”.⁹⁷ Whether measured or calculated, there is no question as to what D values mean. With E values the matter is not so simple. For methane, the total energy of conversion from CH_4 to $\text{C} + 4\text{H}$ (at 0 K) is $393 \text{ kcal mol}^{-1}$ (1644 kJ mol^{-1}).⁹⁸ Consequently, E for the C—H bond in methane is 98 kcal mol^{-1} (411 kJ mol^{-1}) at 0 K. The more usual practice is not to measure the heat of atomization (i.e., the energy necessary to convert a compound to its atoms) directly, but to calculate it from the heat of combustion. Such a calculation is shown in Fig. 1.12.

Heats of combustion are very accurately known for hydrocarbons.⁹⁹ For methane, the value at 25°C is $212.8 \text{ kcal mol}^{-1}$ ($890.4 \text{ kJ mol}^{-1}$), which leads to a heat of atomization of $398.0 \text{ kcal mol}^{-1}$ (1665 kJ mol^{-1}) or a value of E for the C—H bond at 25°C of $99.5 \text{ kcal mol}^{-1}$ (416 kJ mol^{-1}). This method is fine for molecules like methane in which all the

FIG. 1.12. Calculation of the heat of atomization of ethane at 25 °C.

bonds are equivalent, but for more complicated molecules, assumptions must be made. Thus for ethane, the heat of atomization at 25 °C is 676.1 kcal mol⁻¹ or 2829 kJ mol⁻¹ (Fig. 1.12), and it must be decided how much of this energy is due to the C—C bond and how much to the six C—H bonds. Any assumption must be artificial, since there is no way of actually obtaining this information, and indeed the question has no real meaning. If the assumption is made that E for each of the C—H bonds is the same as E for the C—H bond in methane (99.5 kcal mol⁻¹ or 416 kJ mol⁻¹), then 6×99.5 (or 416) = 597.0 (or 2498), leaving 79.1 kcal mol⁻¹ (331 kJ mol⁻¹) for the C—C bond. However, a similar calculation for propane gives a value of 80.3 (or 336) for the C—C bond, and for isobutane, the value is 81.6 (or 341). A consideration of heats of atomization of isomers also illustrates the difficulty. The E values for the C—C bonds in pentane, isopentane, and neopentane, similarly calculated from heats of atomization, are (at 25 °C) 81.1, 81.8, and 82.4 kcal mol⁻¹ (339, 342, 345 kJ mol⁻¹), respectively, even though all of them have twelve C—H bonds and four C—C bonds.

These differences have been attributed to various factors caused by the introduction of new structural features. Thus isopentane has a tertiary carbon whose C—H bond does not have exactly the same amount of s character as the C—H bond in pentane, which for that matter contains secondary carbons not possessed by methane. It is known that D values, which *can* be measured, are not the same for primary, secondary, and tertiary C—H bonds (see Table 5.2). There is also the steric factor (see Sec. 4.Q). Hence it is certainly incorrect to use the value of 99.5 kcal mol⁻¹ (416 kJ mol⁻¹) from methane as the E value for all C—H bonds. Several empirical equations have been devised that account for these factors; the total energy can be computed¹⁰⁰ if the proper set of parameters (one for each structural feature) is inserted. Of course, these parameters are originally calculated from the known total energies of some molecules that contain the structural feature.

Table 1.7 gives E values for various bonds.^{101–104} The values given are averaged over a large series of compounds. The literature contains charts that take hybridization into account (thus an sp^3 C—H bond does not have the same energy as an sp^2 C—H bond).¹⁰⁵ Bond dissociation

energies, both calculated and experientially determined, are constantly being refined. Improved values are available for the O—O bond of peroxides,¹⁰⁶ the C—H bond in alkyl amines,¹⁰⁷ the N—H bond in aniline derivatives,¹⁰⁸ the N—H bond in protonated amines,¹⁰⁹ the O—H bond in phenols,¹¹⁰ the C—H bond in alkenes,¹¹¹ amides and ketones,¹¹² and in CH₂X₂ and CH₃X derivatives (X = COOR, C=O, SR, NO₂, etc.),¹¹³ the O—H and S—H bonds of alcohols and thiols,¹¹⁴ and the C—Si bond of aromatic silanes.¹¹⁵ Solvent plays a role in the *E* values. When phenols bearing electron-releasing groups are in aqueous media, calculations show that the bond dissociation energies decrease due to hydrogen-bonding interactions with water molecules, while electron-withdrawing substituents on the phenol increase the bond dissociation energies.¹¹⁶

Certain generalizations can be derived from the data in Table 1.7.

1. There is a correlation of bond strengths with bond distances. A comparison of Tables 1.5 and 1.7 shows that, in general, *shorter bonds are stronger bonds*. Since it is

- known that increasing s character shortens bonds (Sec. 1.J), it follows that bond strengths increase with increasing s character. Calculations show that ring strain has a significant effect on bond dissociation energy, particularly the C—H bond of hydrocarbons, because it forces the compound to adopt an undesirable hybridization.¹¹⁷
2. Bonds become weaker moving down the periodic table. Compare C—O and C—S, or the carbon–halogen bonds C—F, C—Cl, C—Br, C—I. This is a consequence of the first generalization, since bond distances must increase going down the periodic table because the number of inner electrons increases. However, note that “high-level *ab initio* molecular orbital calculations confirm that the effect of alkyl substituents on R—X bond dissociation energies varies according to the nature of X (the stabilizing influence of the ionic configurations to increase in the order Me < Et < *i*-Pr < *t*-Bu), accounting for the *increase* (rather than expected decrease) in the R—X bond dissociation energies with increasing alkylation in the R—OCH₃, R—OH, and R—F molecules. This effect of X has been explained in terms of the increasing contribution of the ionic R⁺X[−] configuration for electronegative X substituents.”¹¹⁸
 3. Double bonds are both shorter and stronger than the corresponding single bonds, but not twice as strong, because π overlap is < σ overlap. This means that a σ bond is stronger than a π bond. The difference in energy between a single bond, say C—C, and the corresponding double bond is the amount of energy necessary to cause rotation around the double bond.¹¹⁹

Calculations suggest that covalent bond strength and also equilibrium bond length are not determined by maximum overlap of the σ valence orbitals, as described in previous sections.¹²⁰ Rather, orbital interactions, Pauli repulsion, and quasiclassical electrostatic attraction determine both.

Solvents are thought to play a role in bond dissociation energy of molecules, as noted for phenol above, and also for intermediates (see Chap 5). It has been assumed that the solvation enthalpies were small and they have been largely ignored in calculations involving various reactions. Solvent effects on the bond dissociation energy of a molecule may arise from the difference in solvation enthalpies between the molecule and the key intermediate. For radical reactions that involve polar molecules, the radical–solvent interaction may be larger.¹²¹

Delocalized Chemical Bonding

Although the bonding of many compounds can be adequately described by a single Lewis structure (Sec. 1.F), this is insufficient for many other compounds. Such compounds contain one or more bonding orbitals that are not restricted to two atoms, but rather they are spread out over three or more atoms. Such bonding is said to be *delocalized*.¹ In other words, the bonding electrons are dispersed over several atoms rather than localized on one atom. This Chapter 2 will discuss those compounds that must be represented in this way.

The two chief general methods of approximately solving the wave equation, discussed in Chapter 1, are also used for compounds containing delocalized bonds.² In the valence bond method, several possible Lewis structures (called *canonical forms*) are drawn, and the molecule is taken to be a weighted average of them. Each Ψ in Eq. (1–3), represents one of these structures. Therefore,

$$\Psi = c_1\psi_1 + c_2\psi_2 + \cdots$$

is the representation of a real structure as a weighted average of two or more canonical forms, which is called *resonance*. For benzene the canonical forms are drawn as **1** and **2**. Double-headed arrows (\longleftrightarrow) are used to indicate resonance. When the wave equation is solved, it is found that the energy value obtained by equal participation of **1** and **2** is lower than that for **1** or **2** alone. If **3–5** (called *Dewar structures*) are also considered, the value is lower still. According to this method, **1** and **2** contribute 39% each to the actual molecule and the others 7.3% each.³ The carbon–carbon bond order is 1.463 (not 1.5, which would be the case if only **1** and **2** contributed).

In the valence bond method, the *bond order* of a particular bond is the sum of the weights of those canonical forms in which the bond is double plus 1 for the single bond that

FIG. 2.1. (a) Traditional drawing of the overlapping p orbitals that comprise the π -cloud in benzene. (b) The electrostatic potential map of benzene, indicating the high concentration of electron density above and below the plane of the atoms, but in the center of the six-membered ring, consistent with the aromatic cloud.

is present in all of them.⁴ Thus, according to this picture, each C—C bond is not halfway between a single and a double bond but is somewhat less. The energy of the actual molecule is obviously less than that of any one Lewis structure, since otherwise it would have one of those structures. The difference in energy between the actual molecule and the Lewis structure of lowest energy is called the *resonance energy*. Of course, the Lewis structures are not real, and their energies can only be estimated. Resonance in benzene is possible by overlap of the p orbitals, orthogonal to the plane of carbon and hydrogen atoms. This resonance is associated with the aromatic π -cloud. Figure 2.1 shows the planar σ -bond framework of benzene, with the overlapping p -orbitals forming the aromatic π -cloud. Figure 2.1 also shows the electron potential map of benzene. Note the darker area above the middle of the ring that corresponds to high electron density, consistent with the high electron density of the aromatic π -cloud.

2.A. MOLECULAR ORBITALS

While the resonance picture is often used to describe the structure of molecules, as structures become more complicated (e.g., naphthalene and pyridine), quantitative valence bond calculations become much more difficult. Therefore, the MO method is used much more often for the solution of wave equations.⁵ Examination of benzene by this method (qualitatively) shows that each carbon atom, being connected to three other atoms, uses sp^2

FIG. 2.2. The molecular orbitals of benzene, showing the three bonding orbitals, as generated by Spartan.10, v.1.0.1.

orbitals to form σ bonds, so that all 12 atoms are in one plane. This method shows that each carbon has a remaining p orbital that contains one electron, and each orbital can overlap equally with the two adjacent p orbitals. This overlap of six orbitals (see Fig. 2.2) produces six new orbitals, and the three lower energy orbitals are bonding. These three (called π orbitals) all occupy approximately the same space.⁶ One of the three is of lower energy than the other two, which are degenerate. They each have the plane of the ring as a node and so are in two parts, one above and one below the plane. The two orbitals of higher energy also have another node. The six electrons that occupy this torus-shaped cloud are called the *aromatic sextet*. A torus-shaped object is essentially a doughnut-shaped object. According to this explanation, the symmetrical hexagonal structure of benzene is caused by both the σ bonds and the (orbitals). Based on MO calculations, this symmetry is probably caused by the σ framework alone, and that the (π system would favor three localized double

bonds.⁶ The carbon–carbon bond order for benzene, calculated by the MO method, is 1.667.⁷

For planar unsaturated molecules that are aromatic, many *MO calculations* have been made by treating the σ and π electrons separately. It is assumed that the σ orbitals can be treated as localized bonds and the calculations involve only the π electrons. The first such calculations were made by Hückel, and such calculations are often called *Hückel molecular orbital (HMO) calculations*.⁸ Because electron–electron repulsions are either neglected or averaged out in the HMO method, another approach, the *self-consistent field (SCF)*, or *Hartree–Fock*, method, was devised.⁹ Although these methods give many useful results for planar unsaturated and aromatic molecules, they are often unsuccessful for other molecules. It would obviously be better if all electrons, both σ and π , could be included in the calculations. The development of modern computers has now made this possible.¹⁰ Many such calculations have been made¹¹ using a number of methods, among them an extension of the Hückel method¹² and the application of the SCF method to all valence electrons.¹³

One type of MO calculation that includes all electrons is called *ab initio*.¹⁴ Despite the name (which means “from first principles”) this type does involve some assumptions. Treatments that use certain simplifying assumptions (but still include all electrons) are called *semiempirical* methods.¹⁵ One of the first of these was called CNDO (Complete Neglect of Differential Overlap),¹⁶ but as computers have become more powerful, this has been superseded by more modern methods, including MINDO/3 (Modified Intermediate Neglect of Differential Overlap),¹⁷ MNDO (Modified Neglect of Diatomic Overlap),¹⁷ and AM1 (Austin Model 1), all of which were introduced by M.J. Dewar et al.¹⁸ There is also the PM3, or Parameterized Model number 3, which has the same formalism and equations as the AM1 method, but AM1 takes some of the parameter values from spectroscopic

measurements, whereas PM3 treats them as optimizable values.¹⁹ Semiempirical calculations are generally regarded as less accurate than *ab initio* methods,²⁰ but are much faster and cheaper.²¹ Note that modern computers are capable of completing >3 billion calculations per second, which makes MO calculations practical in modern organic chemistry.

Molecular orbital calculations, whether by *ab initio* or semiempirical methods, can be used to obtain structures (bond distances and angles), energies (e.g., heats of formation), dipole moments, ionization energies, and other properties of molecules, ions, and radicals: not only of stable ones, but also of those so unstable that these properties cannot be obtained from experimental measurements.²² Many of these calculations have been performed on transition states (Sec. 6.D). This is the only way to get this information, since transition states are not directly observable. Of course, it is not possible to check data obtained for unstable molecules and transition states against any experimental values, so that the reliability of the various MO methods for these cases is always a question. However, confidence in them increases when (1) different MO methods give similar results, and (2) a particular MO method works well for cases that can be checked against experimental methods.²³

Both the valence bond and MO methods show that there is delocalization in benzene. For example, each predicts that the six carbon–carbon bonds should have equal lengths, which is true. Since each method is useful for certain purposes, one or the other will be used as appropriate. Recent *ab initio*, SCF calculations confirm that the delocalization effect acts to strongly stabilize symmetric benzene, consistent with the concepts of classical resonance theory.²⁴ It is known that substituents influence the extent of resonance.²⁵

2.B. BOND ENERGIES AND DISTANCES IN COMPOUNDS CONTAINING DELOCALIZED BONDS

If the energies of all the bonds in benzene are added, taking the values from a source like Table 1.7, the value for the heat of atomization is less than the experimentally determined value (Fig. 2.3) of 1323 kcal mol⁻¹ (5535 kJ mol⁻¹). If *E* values for a C=C double bond obtained from cyclohexene (148.8 kcal mol⁻¹; 622.6 kJ mol⁻¹) are used, a C—C single bond from cyclohexane (81.8 kcal mol⁻¹, 342 kJ mol⁻¹), and C—H bonds from methane (99.5 kcal mol⁻¹, 416 kJ mol⁻¹), a value of 1289 kcal mol⁻¹ (5390 kJ mol⁻¹) is obtained for structure **1** or **2**. By this calculation, the resonance energy is 34 kcal mol⁻¹ (145 kJ mol⁻¹). Of course, this is an arbitrary calculation since, in addition to the fact that a heat of atomization is calculated for a nonexistent structure (**1**), *E* values must be used that do not have a firm basis in reality. The actual C—H bond energy for benzene has been measured to be 113.5 ± 0.5 kcal mol⁻¹ at 300 K and estimated to be 112.0 ± 0.6 kcal mol⁻¹ (469 kJ mol⁻¹) at 0 K.²⁶ The heat of atomization of a real molecule can be measured, but resonance

FIG. 2.3. Resonance energy in benzene.

energy can never be measured, only estimated, because only an intelligent guess can be made at that of the Lewis structure of lowest energy.

Another method frequently used for estimation of resonance energy involves measurements of heats of hydrogenation.²⁷ The heat of hydrogenation of cyclohexene is $28.6 \text{ kcal mol}^{-1}$ (120 kJ mol^{-1}), so a hypothetical **1** or **2** with three double bonds is expected to have a heat of hydrogenation of $\sim 85.8 \text{ kcal mol}^{-1}$ (360 kJ mol^{-1}). Benzene has a measured heat of hydrogenation of $49.8 \text{ kcal mol}^{-1}$ (208 kJ mol^{-1}), and the difference between the measured and expected value is the *resonance energy*, 36 kcal mol^{-1} (152 kJ mol^{-1}). By any calculation, the real molecule is more stable than a hypothetical **1** or **2**.

The energies of the six benzene orbitals can be calculated from HMO theory in terms of two quantities that are labeled α and β . Here α is the amount of energy possessed by an isolated $2p$ orbital before overlap, while β (called the *resonance integral*) is an energy unit expressing the degree of stabilization resulting from π -orbital overlap. A negative value of β corresponds to stabilization, and the energies of the six orbitals are (lowest to highest): $\alpha + 2\beta$, $\alpha + \beta$, $\alpha + \beta$, $\alpha - \beta$, $\alpha - \beta$, and $\alpha - 2\beta$.²⁸ The total energy of the three occupied orbitals is $6\alpha + 8\beta$, since there are two electrons in each orbital. The energy of an ordinary double bond is $\alpha + \beta$, so that structure **1** or **2** has an energy of $6\alpha + 6\beta$ and the resonance energy of benzene is 2β . Unfortunately, there is no convenient way to calculate the value of β from MO theory. Benzene is often given a value of β of $\sim 18 \text{ kcal mol}^{-1}$ (76 kJ mol^{-1}); this number is one-half of the resonance energy calculated from heats of combustion or hydrogenation. Using *ab initio* calculations, bond resonance energies for many aromatic hydrocarbons other than benzene have been reported.²⁹

Isodesmic and homodesmotic reactions are frequently used for the study of aromaticity from the energetic point of view.³⁰ However, the energy of the reactions used experimentally, or in calculations, may reflect only the relative aromaticity of benzene and not its absolute

²⁷ See Jensen, J.L. *Prog. Phys. Org. Chem.* **1976**, 12, 189.

aromaticity. New homodesmotic reactions based on radical systems predict an absolute aromaticity of $29.13 \text{ kcal mol}^{-1}$ ($121.9 \text{ kJ mol}^{-1}$) for benzene and an absolute antiaromaticity (Sec. 2.K.ii) of $40.28 \text{ kcal mol}^{-1}$ ($168.5 \text{ kJ mol}^{-1}$) for cyclobutadiene at the MP4 (SDQ)/6-31G-(d,p) level.³¹

Compounds that exhibit delocalization are expected to have bond distances that lie between the values given in Table 1.5. This is certainly the case for benzene, since the carbon–carbon bond distance is 1.40 \AA ,³² which is between the 1.48 \AA for an sp^2 – sp^2 C–C single bond and the 1.32 \AA of the sp^2 – sp^2 C=C double bond.³³

2.C. MOLECULES THAT HAVE DELOCALIZED BONDS

There are four main types of structure that exhibit delocalization:

1. *Double (or Triple) Bonds in Conjugation.*³⁴ The double bonds in benzene are conjugated, of course, but the conjugation exists in acyclic molecules (e.g., butadiene, **6**). In the MO picture (Fig. 2.4), the overlap of four orbitals gives

FIG. 2.4. The four π orbitals of butadiene, formed by overlap of four p orbitals.

³¹ Suresh, C.H.; Koga, N. *J. Org. Chem.* **2002**, 67, 1965. The heat of hydrogenation of phenylcyclobutadiene is reported to be $57.4 \pm 4.9 \text{ kcal mol}^{-1}$ ($240.3 \text{ kJ mol}^{-1}$): Fattahi, A.; Lis, L.; Kass, S.R. *J. Am. Chem. Soc.* **2005**, 127, 3065.

³² Tamagawa, K.; Iijima, T.; Kimura, M. *J. Mol. Struct.* **1976**, 30, 243.

³³ The average C–C bond distance in aromatic rings is 1.38 \AA : Allen, F.H.; Kennard, O.; Watson, D.G.; Brammer, L.; Orpen, A.G.; Taylor, R. *J. Chem. Soc. Perkin Trans. 2* **1987**, p. S8.

³⁴ See Simmons, H.E. *Prog. Phys. Org. Chem.* 1970, 7, 1; Popov, E.M.; Kogan, G.A. *Russ. Chem. Rev.* 1968, 37, 119.

two bonding orbitals that contain four electrons and two vacant antibonding orbitals. It can be seen that each orbital has one more node than the one of next lower energy. The energies of the four orbitals are (lowest to highest): $\alpha + 1.618\beta$, $\alpha + 0.618\beta$, $\alpha - 0.618\beta$, and $\alpha - 1.618\beta$; hence the total energy of the two occupied orbitals is $4\alpha + 4.472\beta$. Since the energy of two isolated double bonds is $4\alpha + 4\beta$, the resonance energy by this calculation is 0.472β .

In the resonance picture, structures **7** and **8** are considered to contribute.

Despite the invocation of structures **7** and **8** in the resonance picture, butadiene and similar conjugated systems are *not* considered to be resonance stabilized in the ground state. The bond order of the central bond should be > 1 and that of the other carbon-carbon bonds < 2 , although neither predicts that the three bonds have equal electron density. Molecular orbital bond orders of 1.894 and 1.447 have been calculated.³⁵

The existence of delocalization in butadiene and similar molecules has been questioned. The bond lengths in butadiene are 1.34 Å for the double bonds and 1.48 Å for the single bond.³⁶ Since the typical single-bond distance of a bond that is not adjacent to an unsaturated group is 1.53 Å (Sec. 1.K), it has been argued that the shorter single bond in butadiene provides evidence for resonance. However, this shortening can also be explained by hybridization changes (See Sec. 1.K); and other explanations have also been offered.³⁷ Resonance energies for butadienes, calculated from heats of combustion or hydrogenation, are only $\sim 4 \text{ kcal mol}^{-1}$ (17 kJ mol^{-1}), and these values may not be entirely attributable to resonance.³⁸ Thus, a calculation from heat of atomization data gives a resonance energy of $4.6 \text{ kcal mol}^{-1}$ (19 kJ mol^{-1}) for *cis*-1,3-pentadiene, and $-0.2 \text{ kcal mol}^{-1}$ (-0.8 kJ mol^{-1}), for 1,4-pentadiene. These two compounds, each of which possesses two double bonds, two C—C single bonds, and eight C—H bonds, would seem to offer a direct comparison of a conjugated with a nonconjugated compound, but they are nevertheless not strictly comparable. The former has three sp^3 C—H and five sp^2 C—H bonds, while the latter has two and six, respectively. Also, the two single C—C bonds of the 1,4-diene are both sp^2 – sp^3 bonds, while in the 1,3-diene, one is sp^2 – sp^3 and the other is sp^2 – sp^2 . Therefore, it may be that some of the already small value of 4 kcal mol^{-1} (17 kJ mol^{-1}) is not resonance energy, but arises from differing energies of bonds of different hybridization.³⁹ As noted above, butadiene and related molecules are generally considered not to be resonance stabilized in the ground state.

³⁶ Marais, D.J.; Sheppard, N.; Stoicheff, B.P. *Tetrahedron* **1962**, 17, 163.

³⁷ Politzer, P.; Harris, D.O. *Tetrahedron* **1971**, 27, 1567.

³⁸ For a discussion of so-called Y-aromaticity, and the relative stability of the butadienyl dication in relation to other dications, see Dworkin, A.; Naumann, R.; Seigfred, C.; Karty, J.M.; Mo, Y. *J. Org. Chem.* **2005**, 70, 7605.

³⁹ For negative views on delocalization in butadiene and similar molecules, see Dewar, M.J.S.; Gleicher, G.J. *J. Am. Chem. Soc.* **1965**, 87, 692; Mikhailov, B.M. *J. Gen. Chem. USSR* **1966**, 36, 379. For positive views, see Miyazaki, T.; Shigetani, T.; Shinoda, H. *Bull. Chem. Soc. Jpn.* **1971**, 44, 1491; Altmann, J.A.; Reynolds, W.F. *J. Mol. Struct.* **1977**, 36, 149. In general, the negative argument is that resonance involving excited structures, (e.g., **7** and **8**) is unimportant. (see rule 6 in Sec.2.E). See Popov, E.M.; Kogan, G.A. *Russ. Chem. Rev.* **1968**, 37, 119, pp. 119–124.

FIG. 2.5. Three orbitals of an allylic carbon, formed by overlap of three p orbitals.

Although bond distances fail to show it and the resonance energy is low, butadiene is planar.⁴⁰ This has been taken as an indication that there is some delocalization. Similar effects are found in other conjugated systems (e.g., $\text{C}=\text{C}-\text{C}=\text{O}$ ⁴¹ and $\text{C}=\text{C}-\text{C}=\text{N}$), in longer systems with three or more multiple bonds in conjugation, and where double or triple bonds are conjugated with aromatic rings. Diynes (e.g., 1,3-butadiyne, **9**) are also conjugated molecules. Based on calculations, Rogers et al.⁴² reported that the conjugation stabilization of 1,3-butadiyne is zero. Later calculations concluded that consideration of hyperconjugative interactions (Sec. 2.M) provides a more refined measure of conjugative stabilization.⁴³ When this measure is used, the conjugation energies of the isomerization and hydrogenation reactions considered agree with a conjugative stabilization of 9.3 (0.5 kcal mol⁻¹ for diynes and 8.2 0.1 kcal mol⁻¹ for dienes).

2. *Double (or Triple) Bonds in Conjugation with a p Orbital on an Adjacent Atom.*

When a p orbital is on an atom adjacent to a double bond, there are three parallel p orbitals that overlap. As previously noted, it is a general rule that the overlap of n atomic orbitals creates n molecular orbitals, so overlap of a p orbital with an adjacent double bond gives rise to three new orbitals, as shown in Fig. 2.5. The middle orbital is a *nonbonding orbital* of zero-bonding energy. The central carbon atom does not participate in the nonbonding orbital.

⁴⁰ Wiberg, K.B.; Rosenberg, R.E.; Rablen, P.R. *J. Am. Chem. Soc.* **1991**, 113, 2890.

⁴¹ See Patai, S.; Rappoport, Z. *The Chemistry of Enones*, two parts; Wiley, NY, **1989**.

⁴² Rogers, D.W.; Matsunaga, N.; McLafferty, F.J.; Zavitsas, A.A.; Liebman, J.F. *J. Org. Chem.* **2004**, 69, 7143.

⁴³ Jarowski, P.D.; Wodrich, M.D.; Wannere, C.S.; Schleyer, P.v.R.; Houk, K.N. *J. Am. Chem. Soc.* **2004**, 126, 15036.

There are three cases: the original p orbital may have contained two, one, or no electrons. Since the original double bond contributes two electrons, the total number of electrons accommodated by the new orbitals is four, three, or two, respectively. A typical example of the first situation is vinyl chloride, ($\text{CH}_2=\text{CH}-\text{Cl}$). Although the p orbital of the chlorine atom is filled, it still overlaps with the double bond (See **10**). The four electrons occupy the two molecular orbitals of lowest energies, which is an example of resonance involving overlap between unfilled orbitals and a *filled* orbital. Canonical forms for vinyl chloride are shown in **11** (see Sec. 2.M).

Any system that contains an atom that has an unshared pair and is directly attached to a multiple-bond atom can show this type of delocalization. Resonance delocalization is more important with charged species (e.g., the carbonate ion) and true resonance contributors can be drawn:

The resonance delocalization in allylic carbanions, (e.g., $\text{CH}_2=\text{CH}-\text{CH}_2^-$), is another example.

The other two cases have a p orbital that contains only one electron (radicals) or no electrons (cations). Allylic free radicals have one electron in the nonbonding orbital. In allylic cations, this orbital is vacant and only the bonding orbital is occupied. The orbital structures of the allylic carbanion, free radical, and cation differ from each other, only in that the nonbonding orbital is filled, half-filled, or empty. Since this is an orbital of zero bonding energy, it follows that the bonding π energies of the three species relative to electrons in the $2p$ orbitals of free atoms are the same. The electrons in the nonbonding orbital do not contribute to the bonding energy, positively or negatively.⁴⁴

The resonance picture best describes three species that are charged or contain an unshared electron with double bonds in conjugation with, respectively, an unshared pair, an unpaired electron, and an empty orbital as in the allyl cation **12** (also see Chap 5).

⁴⁴ It has been argued that the geometry is forced upon allylic systems by the σ framework, and not the π system: Shaik, S.S.; Hiberty, P.C.; Ohanessian, G.; Lefour, J. *Nouv. J. Chim.*, **1985**, 9, 385. *ab initio* calculations suggest that the allyl cation has significant resonance stabilization, but the allyl anion has little stabilization: Wiberg, K.B.; Breneman, C.M.; LePage, T.J. *J. Am. Chem. Soc.* **1990**, 112, 61.

3. *π -Allyl and Other η -Complexes.* In the presence of transition metals, delocalized electrons in allylic cations may be donated to the metal, resulting in stabilization.⁴⁵ In a carbon–metal bond (e.g., $\text{H}_3\text{C}-\text{Fe}$), the carbon donates (shares) one electron with the metal, and is considered to be a one-electron donor. With a π bond (e.g., that found in ethylene), both electrons can be donated to the metal to form a complex (e.g., **14**) by reaction of Wilkinson's catalyst (**13**) with an alkene and hydrogen gas,⁴⁶ in addition, π bond is considered to be a two-electron donor. In these two cases, the electron donating ability of the group coordinated to the metal (the ligand) is indicated by terminology η^1 , η^2 , η^3 , and so on, for a one-, two-, and three-electron donor, respectively.

Ligands are categorized as η -ligands according to the ability to donate electrons to the metal. A hydrogen atom (as in **14**) or a halogen ligand (as in **13**) are η^1 ligands. An amine (NR_3), a phosphine (PR_3 , as in **13**, **14**, and **18**), CO (as in **16** or **17**), an ether (OR_2) or a thioether (SR_2) are η^2 ligands. Hydrocarbon ligands include alkyl (as the methyl in **15**) or aryl with a carbon–metal bond (η^1), alkenes or carbenes (η^2 , see Sec. 3.C.i), π -allyl (η^3), conjugated dienes (e.g., 1,3-butadiene) (η^4), cyclopentadienyl (η^5 , as in **15** and see Sec. 2.I.ii), and arenes or benzene (η^6).⁴⁷ Note that in the formation of **14** from **13**, the two-electron donor alkene displaces a two-electron donor phosphine. Other typical complexes include chromium hexacarbonyl ($\text{Cr}(\text{CO})_6$, **16**), with six η^2 CO ligands; $\eta^6\text{-C}_6\text{H}_6\text{Cr}(\text{CO})_3$ (**18**), and *tetrakis*-triphenylphosphinopalladium (0), (**17**), with four η^2 phosphine ligands.

In the context of this section, the electron-delocalized ligand π -allyl (**12**) is an η^3 donor and it is well known that allylic halides react with PdCl_2 to form a bis- η^3 -complex **19** (see **20**).⁴⁸ Complexes (e.g., **19**) react with nucleophiles to give the corresponding coupling product (**10–60**).⁴⁹ The reaction of allylic acetates or carbons and a catalytic amount of $\text{Pd}(0)$ compounds also lead to an η^3 -complex that can react with nucleophiles.⁵⁰

4. *Hyperconjugation*. The type of delocalization called *hyperconjugation* is discussed in Section 2.M.

Note that there are examples of delocalization that cannot be strictly classified as any of these types.

2.D. CROSS-CONJUGATION⁵¹

In a cross-conjugated compound, three groups are present, two of which are not conjugated with each other, although each is conjugated with the third. Some examples are benzophenone (**21**), triene (**22**),⁵² and divinyl ether (**23**). The MO method shows that the overlap of six *p* orbitals in **22** (a member of a family of compounds known as dendralenes)⁵² gives six molecular orbitals, and the three bonding orbitals are shown in Fig. 2.6, along with their energies. Note that two of the carbon atoms do not participate in the $\alpha + \beta$ orbital.

The total energy of the three occupied orbitals is $6\alpha + 6.900\beta$, so the resonance energy is 0.900β . Molecular orbital bond orders are 1.930 for the C-1–C-2 bond, 1.859 for the C-3–C-6 bond, and 1.363 for the C-2–C-3 bond.⁵¹ Comparing these values with those for butadiene (Sec. 2.C), the C-1–C-2 bond contains more and the C-3–C-6 bond less double-bond character than the double bonds in butadiene. The resonance picture supports

FIG. 2.6. The three bonding orbitals of the dendralene, 3-methylene-1,4-pentadiene (**22**).

⁵¹ See Phelan, N.F.; Orchin, M. *J. Chem. Educ.* **1968**, 45, 633.

⁵² For a review of such compounds, see Hopf, H. *Angew. Chem. Int. Ed.* **1984**, 23, 948.

this conclusion, since each C-1–C-2 bond is double in three of the five canonical forms, while the C-3–C-6 bond is double in only one. In most cases, it is easier to treat cross-conjugated molecules by the MO method than by the valence bond method.

One consequence of this phenomenon is that the bond length of a cross-conjugated C=C unit is slightly longer than that of a non-cross-conjugated bond. In **24**, for example, the cross-conjugated bond is $\sim 0.01 \text{ \AA}$ longer.⁵³ The conjugative effect of a C=C or C \equiv C unit can be measured for a conjugated enone: $4.2 \text{ kcal mol}^{-1}$ (17.6 kJ mol^{-1}) for an ethenyl substituent, but $\sim 2.3 \text{ kcal mol}^{-1}$ (9.6 kJ mol^{-1}) for an ethynyl substituent, which is more variable.⁵⁴

The phenomenon of homoconjugation is related to cross-conjugation in that there are C=C units in close proximity, but not conjugated one to the other. Homoconjugation arises when the termini of two orthogonal π -systems are held in close proximity, as in compounds with a spiro-tetrahedral carbon atom.⁵⁵ Spiro[4.4]nonatetraene (**25**)⁵⁶ is an example and it is known that the HOMO (see Sec. 15.60) of **25** is raised relative to cyclopentadiene, whereas the LUMO is unaffected.⁵⁷ Another example is **26**, where there are bond length distortions caused by electronic interactions between the unsaturated bicyclic moiety and the cyclopropyl moiety.⁵⁸ It is assumed that cyclopropyl homoconjugation is responsible for this effect.

2.E. THE RULES OF RESONANCE

One way to express the actual structure of a molecule containing delocalized bonds is to draw several possible structures and to assume that the actual molecule is a hybrid of them. These structures are called canonical forms, but they are not real structures. In other words, the molecule does *not* rapidly shift between them and a given compound has a single actual structure. That structure is always the same all the time and is taken to be a weighted average of all the canonical forms. Drawing canonical forms and deriving the true structures from them is guided by certain rules, including the following:

1. All the canonical forms must be *bona fide* Lewis structures (Sec. 1.F). For example, none of them may have a carbon with five bonds.
2. The positions of the nuclei must be the same in all the structures. This means that when drawing the various canonical forms, the *electrons* are simply arranged in different ways. For this reason, shorthand ways of representing resonance are easy

to devise:

Invoking hyperconjugation (Sec. 2.M), resonance interaction of chlorine with the benzene ring can be represented as shown in **27** or **28** and both representations have been used in the literature to save space. However, the curved-arrow method of **27** will not be used since arrows in this book are used to express the actual movement of electrons in reactions. Representations like **28** will be used occasionally, but more often one or more of the canonical forms will be used. The convention used in dashed-line formulas like **28** is that bonds that are present in all canonical forms are drawn as solid lines, while bonds that are not present in all forms are drawn as dashed lines. A downside of this model is that electron transfer in reactions associated with benzene rings is difficult to track. For this reason, one of the canonical forms is most often used, as mentioned. In most resonance, σ bonds are not involved, and only the π or unshared electrons are utilized. This finding means that writing one canonical form for a molecule, allowed the others to be written by merely moving π and unshared electrons.

3. All atoms taking part in the resonance, (i.e., covered by delocalized electrons), must lie in a plane or nearly so (see Sec. 2.G). This, of course, does not apply to atoms that have the same bonding in all the canonical forms. Maximum overlap of the p orbitals leads to the planarity.
4. All canonical forms must have the same number of unpaired electrons. Thus the diradical structure $\bullet\text{CH}_2\text{CH}=\text{CH}-\text{CH}_2\bullet$ is not a valid canonical form for butadiene.
5. The energy of the actual molecule is lower than that of any form, so delocalization is a stabilizing phenomenon.⁵⁹
6. All canonical forms do not contribute equally to the true molecule. Each form contributes in proportion to its stability, the most stable form contributing most. Thus, for ethylene, the form $^+\text{CH}_2-\text{CH}_2^-$ has such a high energy compared to $\text{CH}_2=\text{CH}_2$ that it essentially does not contribute at all. This argument was applied to butadiene.³⁹ Equivalent canonical forms, (e.g., **1** and **2**) contribute equally. The greater the number of significant structures that can be written and the more nearly equal they are, the greater the resonance energy, other things being equal.

It is not always easy to decide relative stabilities of imaginary structures; the chemist is often guided by intuition.⁶⁰ However, the following rules may be helpful:

- (a) Structures with more covalent bonds are ordinarily more stable than those with fewer (cf. **6** and **7**).
- (b) Stability is decreased by an increase in charge separation. Structures with formal charges are less stable than uncharged structures. Structures with more than two

⁵⁹ It has been argued that resonance is not a stabilizing phenomenon in all systems, especially in acyclic ions: Wiberg, K.B. *Chemtracts. Org. Chem.* **1989**, 2, 85. See also, Siggel, M.R.; Streitwieser, Jr., A.; Thomas, T.D. *J. Am. Chem. Soc.* **1988**, 110, 8022; Thomas, T.D.; Carroll, T.X.; Siggel, M.R. *J. Org. Chem.* **1988**, 53, 1812.

⁶⁰ A quantitative method for weighting canonical forms was proposed by Gasteiger, J.; Saller, H. *Angew. Chem. Int. Ed.* **1985**, 24, 687.

formal charges usually contribute very little. An especially unfavorable type of structure is one with two like charges on adjacent atoms.

- (c) Structures that carry a negative charge on a more electronegative atom are more stable than those in which the charge is on a less electronegative atom. Thus, enolate anion **30** is more stable than canonical form **29**. Similarly, positive charges are best carried on atoms of low electronegativity.

- (d) Structures with distorted bond angles or lengths are unstable, (e.g., contributor **31** for ethane).

2.F. THE RESONANCE EFFECT

Resonance always results in a different distribution of electron density than would be the case if there were no resonance (i.e., the electrons are dispersed over several atoms rather than concentrated on one atom). For example, if **32** were the actual structure of aniline, the two unshared electrons of the nitrogen would reside entirely on that atom. The structure of **32** can be represented as a hybrid that includes contributions from the canonical forms shown, indicating that the electron density of the unshared pair does not reside entirely on the nitrogen, but is spread over the ring. However, as shown by the accompanying electron potential map for aniline, the charge distribution is such that most of the electron density resides on nitrogen. The decrease in electron density at one position (and corresponding increase elsewhere) means that the NH₂ contributes or donates electrons to the ring by a resonance effect (“electron releasing,” although no actual contribution takes place), and is called the *resonance* or *mesomeric effect*. To emphasize this point, the canonical forms associated with **32** indicate electron release from the nitrogen to the benzene ring (the mesomeric effect), and do not necessarily indicate that there are four canonical forms. In ammonia, where resonance is absent, the unshared pair *is* located on the nitrogen atom. As with the field effect (Sec. 1.I), a certain molecule (in this case ammonia) maybe thought of as a substrate and effects of substitution on the electron density may be studied. When one of the hydrogen atoms of the ammonia molecule is replaced by a benzene ring (to make aniline, **32**), the electrons are “withdrawn” from the ring by the resonance effect, just as when a methyl group replaces a hydrogen atom of benzene, electrons are “donated” by the field effect of the methyl. Note the increased electron density on the nitrogen in the model, as indicated by the darker area that is above the middle of the model as well and on the nitrogen (on the right side of the model) when compared to benzene in Fig. 2.1*b*. The idea of donation or withdrawal merely arises from the comparison of a compound with a closely related one or a real compound with a canonical form.

2.G. STERIC INHIBITION OF RESONANCE AND THE INFLUENCES OF STRAIN

Rule 3 above states that all the atoms covered by delocalized electrons must lie in a plane or nearly so. Many examples are known where resonance is diminished or prevented because the atoms are sterically forced out of planarity. It is known that if para substituents are able to interact via the through-resonance mechanism, π -electron delocalization due to the substituent effects leads to an increase of stability.⁶¹ If the substituents are both electron donating, there is a significant decrease in stability.

Bond lengths for the *o*- and *p*-nitro groups in picryl iodide (**33**) are quite different.⁶² Distance *a* in **33** is 1.45 Å, whereas *b* is 1.35 Å. This phenomenon can be explained if the oxygen atoms of the *p*-nitro group are in the plane of the ring and thus in resonance with it, so that *b* has partial double-bond character, while the oxygen atoms of the *o*-nitro groups are forced out of the plane by the large iodine atom. As discussed in Section 2.M, the difference in bond length is associated with hyperconjugative effects, represented by the canonical form.

Compound **34** is recognized as a Dewar-form of anthracene.⁶³ Dewar benzene forms (e.g., benzvalene) (**3**) are recognized as possible valence isomers of benzene.⁶⁴ Since **35** is the actual structure of anthracene, it is reasonable to ask if **34** is a canonical structure? The answer is no, because the 9,10 substituents prevent the system from being planar, so **34** is the actual structure of the molecule and it is not in resonance with forms like **35**. This finding is a consequence of rule 2 (Sec. 2.E). In order for a **35**-like structure to contribute to resonance in **34**, the nuclei would have to be in the same positions in both forms. In anthracene itself (**35**), Dewar structures are thought to contribute to the structure, however.

Even the benzene ring can be forced out of planarity.⁶⁵ In [5]-paracyclophane⁶⁶ (**36**) the presence of a short bridge (this is the shortest para bridge known for a benzene ring) forces

the benzene ring to become boat shaped. The distortion in the benzene ring is apparent in the molecular model of **36** that is provided. The parent **36** has so far not proven stable enough for isolation, but a UV spectrum was obtained and showed that the benzene ring was aromatic, despite the distortion.⁶⁷ The 8,11-dichloro analogue of **36** is a stable solid, and X-ray diffraction showed that benzene ring to be boat-shaped, with one end of the boat bending $\sim 27^\circ$ out of the plane, and the other $\sim 12^\circ$.⁶⁸ This compound too is aromatic, as shown by UV and NMR spectra. [6]-Paracyclophanes are also bent,⁶⁹ but in [7]-paracyclophanes the bridge is long enough so that the ring is only moderately distorted. Similarly, [*n,m*]paracyclophanes (**37**), where *n* and *m* are both 3 or less (the smallest yet prepared is [2.2]-paracyclophane),⁷⁰ have bent (boat-shaped) benzene rings. All these compounds have properties that depart significantly from those of ordinary benzene compounds. Strained paracyclophanes exhibit both π - and σ -strain, and the effect of the two types of strain on the geometry is approximately additive.⁷¹ In “belt” cyclophane (**38**),⁷² the molecule has a pyramidal structure with C_3 symmetry rather than the planar structure found in [18]annulene. 1,8-Dioxo[8](2,70-pyrenophane (**39**))⁷³ is another severely distorted aromatic hydrocarbon (see **39A**), in which the bridge undergoes rapid pseudorotation (Sec. 4.O.iv). A recent study showed that despite substantial changes in the hybridization of carbon atoms involving changes in the σ -electron structure of pyrenophane (e.g., **39**), the aromaticity of the system decreases slightly and regularly upon increasing the bend angle θ from 0° to 109.2° .⁷⁴ Heterocyclic paracyclophane analogues have been prepared, (e.g., the [2.*n*](2,5)pyridinophanes).⁷⁵

There are many examples of molecules in which benzene rings are forced out of planarity, including 7-circulene (**40**),⁷⁶ 9,8-diphenyltetrabenz[*a,c,h,j*]anthracene (**41**),⁷⁷ and **42**⁷⁸ (see also, Sec. 4.Q.iv). These have been called tormented aromatic systems.⁷⁹ The “record” for twisting an aromatic π -electron system appears to be 9,10,11,12,13,14,15,16-octaphenyldibenzo[*a,c*]naphthacene (**43**),⁸⁰ which has an end-to-end twist of 105°. This was 1.5 times greater than that observed in any previous polyaromatic hydrocarbon. Perchlorotriphenylene has been reported in the literature and said to show severe molecular twisting, however, recent work suggests this molecule was not actually isolated, with perchlorofluorene-9-spirocyclohexa-2',5'-diene being formed instead.⁸¹ The X-ray structure of the linear [3]phenylene (benzo[3,4]cyclobuta[1,2-*b*]biphenylene, **44**) has been obtained, and it shows a relatively large degree of bond alternation while the center distorts to a cyclic bis-(allyl) frame.⁸²

It is also possible to fuse strained rings on benzene, which induces great strain on the benzene ring. In **45**, the benzene ring is compressed by the saturated environment of the tetrahydropyran units and the strain leads to distortion of the benzene ring into a *boat* conformation.⁸³

The term strain-induced bond localization was introduced in 1930 by Mills and Nixon⁸⁴ and is commonly referred to as the *Mills–Nixon effect* (see Sec. 11.B.v). Ortho-fused aromatic compounds, (e.g., benzocyclopropene, **46**), are known as cycloproparenes⁸⁵ and are highly strained. Cyclopropabenzene (**46**) is a stable molecule with a strain energy of 68 kcal mol^{−1} (284.5 kJ mol^{−1}),⁸⁶ and the annellated bond is always the shortest, although

in benzocyclobutene (**47**) the adjacent bond is the shortest.⁸⁷ The bonds of annellation and those adjacent are strained. In cycloproparenes, there is the expectation of partial aromatic bond localization, with bond length alternation in the aromatic ring.⁸⁸ When the bridging units are saturated, the benzene ring current is essentially unchanged, but annellation with one or more cyclobutadieno units disrupts the benzene ring current.⁸⁹ The chemistry of the cycloproparenes is dominated by the influence of the high strain energy. When fused to a benzene ring, the bicyclo[1.1.0]butane unit also leads to strain-induced localization of aromatic π bonds.⁹⁰

2.H. $p\pi-d\pi$ BONDING. YLIDS

In Section 1.D, it was stated that, in general, atoms of the second row of the periodic table do not form stable double bonds of the type discussed in Chapter 1 (π bonds formed by overlap of parallel p orbitals). However, there is another type of double bond that is particularly common for the second-row atoms sulfur and phosphorus. Such a double bond is found in sulfurous acid, (H_2SO_3). While the $\text{S}=\text{O}$ double bond contains one s orbital, the second orbital is not a π orbital formed by overlap of half-filled p orbitals. Instead it is formed by overlap of a filled p orbital from the oxygen with an empty d orbital from the sulfur. It is called a $p\pi-d\pi$ orbital.⁹¹ Note that this molecule may be represented by two canonical forms, but the bond is nevertheless localized, despite the resonance that is inherent to this structure. Some other examples of $p\pi-d\pi$ bonding are the phosphine oxides, sulfones, hypophosphorus acid, and sulfoxides. Nitrogen analogues are known, but they are less stable than the phosphorus compounds because the resonance is lacking. For example, amine oxides, analogues of phosphine oxides, can only be written $\text{R}_3\text{N}^+-\text{O}^-$. The $p\pi-d\pi$ canonical form is impossible since nitrogen is limited to eight outer-shell electrons.

In all the examples given above, an oxygen atom donates the electron pair and, indeed, oxygen is the most common such atom. In another important class of compounds, called

ylids, this atom is carbon.⁹² There are three common types of ylids: P,⁹³ S,⁹⁴ and N ylids,⁹⁵ although As,⁹⁶ Se, and so on, ylids are also known. Ylids may be defined as compounds in which a positively charged atom from group 15 or 16 of the periodic table is connected to a carbon atom carrying an unshared pair of electrons (+ and – charges on adjacent atoms). Because of $p\pi-d\pi$ bonding, two canonical forms can be written for P and S, but there is only one for N ylids. Phosphorus ylids are much more stable than N ylids (see also **12–22**) which is one reason why N ylids tend to react more like carbanions (see **13–31** and **18–21**). While S ylids are generally less stable than P ylids, they are rather common.

In almost all compounds that have $p\pi-d\pi$ bonds, the central atom is connected to four or three atoms and an unshared pair, and the bonding is approximately tetrahedral. The $p\pi-d\pi$ bond, therefore, does not greatly change the geometry of the molecule in contrast to the normal π bond, which changes an atom from tetrahedral to trigonal. Calculations show that nonstabilized phosphonium ylids have nonplanar ylid carbon geometries whereas stabilized ylids have planar ylid carbons.⁹⁷

2.I. AROMATICITY⁹⁸

In the 19th century, it was recognized that aromatic compounds⁹⁹ differ greatly from unsaturated aliphatic compounds,¹⁰⁰ but for many years chemists were hard pressed to

⁹² See Johnson, A.W. *Ylid Chemistry*, Academic Press, NY, **1966**; Morris, D.G., *Surv. Prog. Chem.* **1983**, *10*, 189; Lowe, P.A. *Chem. Ind. (London)* **1970**, 1070. See Padwa, A.; Hornbuckle, S.F. *Chem. Rev.* **1991**, *91*, 263.

⁹³ Although the phosphorus ylid shown has three R groups on the phosphorus atom, other phosphorus ylids are known where other atoms, (e.g. oxygen), replace one or more of these R groups. When the three groups are all alkyl or aryl, the phosphorus ylid is also called a phosphorane.

arrive at a mutually satisfactory definition of aromatic character.¹⁰¹ Qualitatively, there has never been real disagreement. Definitions include statements that aromatic compounds are characterized by a special stability and that they undergo substitution reactions more easily than addition reactions. These definitions are vague, however, and not easily applied to borderline cases. Definitions of aromaticity¹⁰² must encompass molecules ranging from polycyclic conjugated hydrocarbons,¹⁰³ to heterocyclic compounds¹⁰⁴ of various ring sizes, to reactive intermediates. In 1925, Armit and Robinson¹⁰⁵ recognized that the aromatic properties of the benzene ring are related to the presence of a closed loop of electrons, the aromatic sextet (aromatic compounds are thus the archetypal examples of delocalized bonding), but determining whether rings other than the benzene ring possessed such a loop remained difficult. With the advent of magnetic techniques, most notably NMR, it is possible to determine experimentally whether or not a compound has a closed ring of electrons. Aromaticity can now be defined as the ability to sustain an induced ring current. A compound with this ability is called *diatropic*. Although this definition also has its flaws,¹⁰⁶ it is the one most commonly accepted today. There are several methods of determining whether a compound can sustain a ring current, but the most important one is based on NMR chemical shifts.¹⁰⁷ Water-soluble calix[4]resorcarenes (see Sec. 3.C.ii) have been developed as an enantioselective NMR shift reagents for aromatic compounds.¹⁰⁸ In order to understand this, it is necessary to remember that, as a general rule, the value of the chemical shift of a proton in an NMR spectrum depends on the electron density of its bond; the greater the density of the electron cloud surrounding or partially surrounding a proton, the more upfield is its chemical shift (a lower value of δ). However, this rule has several exceptions; one is for protons in the vicinity of an aromatic ring. When an external magnetic field is imposed upon an aromatic ring (as in an NMR instrument), the closed loop of aromatic electrons circulates in a diamagnetic ring current, which generates a field of its own (ring current; known as magnetic anisotropy). As seen in Fig. 2.7, this induced field curves around and in the area of the proton is parallel to the external field, so the field “seen” by the aromatic protons is greater than it would have been in the absence of the diamagnetic ring current. The protons are moved downfield (to higher δ) compared to where they would be if electron density were the only factor. Thus ordinary alkene hydrogen atoms are found at $\sim 5\text{--}6\delta$, while the hydrogen atoms of benzene rings are located at $7\text{--}8\delta$. However, if there were protons located above or within the ring, they would be subjected to a *decreased* field and should appear at lower δ values than normal CH_2 groups (normal δ for CH_2 is $\sim 1\text{--}2$). The NMR spectrum of [10]paracyclophane (**48A**)

FIG. 2.7. Ring current in benzene.

showed that this was indeed the case,¹⁰⁹ and the CH₂ peaks were shifted to lower δ the closer they were to the middle of the chain. This fact that a portion of the methylene chain is positioned directly over the benzene ring is easier to see in the molecular model **48B**, and those protons are subject to the anisotropy shift.

It follows from this analysis that aromaticity can be determined from an NMR spectrum. If the protons attached to the ring are shifted downfield from the normal alkene region, it can be concluded that the molecule is diatropic and hence aromatic. In addition, if the compound has protons above or within the ring (see an example of the latter in Sec. 2.K.vi), then these will be shifted upfield if the compound is diatropic. However, local framework effects are important to aromaticity, and it has been argued that downfield chemical shifts of arene hydrogen atoms are not reliable indicators of aromaticity.¹¹⁰ One drawback to this method is that it cannot be applied to compounds that have no protons in either category (e.g, the dianion of squaric acid see Sec. 2.L). Unfortunately, ¹³C NMR is of no help here, since these spectra do not show ring currents.¹¹¹

Bickelhaupt has argued that “double-bond delocalization” actually refers to bond-length equalization. The major effect is argued to be optimal sigma overlap, where the π electrons force the bonds to a somewhat shorter distance. For antiaromatic systems, the π electrons are said to have a stronger localizing drive.¹¹¹

It has been shown that when the nucleus independent chemical shifts for a set of aromatic and antiaromatic hydrocarbons are summed, there is a linear relationship with the magnetic susceptibility exaltation (the difference between the measured magnetic susceptibility of a compound and a calculated value based on group additivity tables) for neutral, cationic, and monoanionic species.¹¹² Aromatic and antiaromatic dianions show a similar relationship, but with a different slope.¹¹²

It appears that there are both energetic and magnetic criteria for aromaticity. The so-called *circuit resonance energy*¹¹³ is an important quantity that connects energetic and magnetic criteria of aromaticity. It is defined as a contribution of each cyclic path in a polycyclic π -system to the aromatic stabilization energy. The individual circuit contributions to aromaticity from the magnetic response of a polycyclic system have been determined, and named circuit resonance energies, with the same sign and essentially the same magnitude as the corresponding cyclic conjugation energy defined by Bosanac and by Gutman.¹¹⁴ Ring-current diamagnetism was taken as the tendency of a cyclic π system to retain aromatic stabilization energy of the individual circuits.

Antiaromatic systems exhibit a *paramagnetic* ring current,¹¹⁵ which causes protons on the outside of the ring to be shifted *upfield* while any inner protons are shifted *downfield*, in sharp contrast to a diamagnetic ring current, which causes shifts in the opposite directions (see above). Compounds that sustain a paramagnetic ring current are called *paratropic* and are prevalent in four and eight-electron systems. As with aromaticity, antiaromaticity should be at a maximum when the molecule is planar and when bond distances are equal. The diamagnetic and paramagnetic effects of the ring currents associated with aromatic and antiaromatic compounds (i.e., shielding and deshielding of nuclei) can be measured by a simple and efficient criterion known as nucleus independent chemical shift (NICS).¹¹⁶ The aromatic–antiaromatic ring currents reflect the extra π -effects that the molecules experience. The unique near zero value of NICS at the cyclobutadiene ring center is due to cancellation by large and opposite anisotropic components.¹¹⁷

Apart from the experimental NMR techniques, there are at least four theoretical models for aromaticity that have been compared and evaluated for predictive ability.¹¹⁸ The *Hess–Schaad model*¹¹⁹ is good for predicting aromatic stability of benzenoid hydrocarbons, but does not predict reactivity. The *Herndon model*¹²⁰ is also good for predicting aromatic stability, but is unreliable for benzenoidicity and does not predict reactivity. The *conjugated-circuit model*¹²¹

is very good for predicting aromatic stability but not reactivity, and the *hardness model*¹²² is best for predicting kinetic stability. Delocalization energy of π electrons has been used as an index for aromaticity in polycyclic aromatic hydrocarbons.¹²³ The claims for linear relationships between aromaticity and energetics, geometries, and magnetic criteria were said to be *invalid* for any representative set of heteroaromatics in which the number of heteroatoms varies.¹²⁴

It should be emphasized that the old and new definitions of aromaticity are not necessarily parallel. If a compound is diatropic, and therefore aromatic under the new definition, it is more stable than the canonical form of lowest energy, but this does not mean that it will be stable to air, light, or common reagents, since *this* stability is determined not by the resonance energy, but by the difference in free energy between the molecule and the transition states for the reactions involved. These differences may be quite small, even if the resonance energy is large. A unified theory has been developed that relates ring currents, resonance energies, and aromatic character.¹²⁵ Note that aromaticity varies in magnitude relatively and sometimes absolutely with the molecular environment, which includes the polarity of the medium.¹²⁶

The vast majority of aromatic compounds have a closed loop of six electrons in a ring (the aromatic sextet), and those compounds will be considered first.¹²⁷ Note that a “formula periodic table” for the benzenoid polyaromatic hydrocarbons has been developed.¹²⁸

2.1.i. Six-Membered Rings

Not only is the benzene ring aromatic, but so are many heterocyclic analogues in which one or more heteroatoms replace carbon in the ring.¹²⁹ When nitrogen is the heteroatom, there is a sextet and there is an unshared pair on the nitrogen that does not participate in the aromaticity. Therefore, derivatives (e.g., *N*-oxides or pyridinium ions) are still aromatic. There are more significant canonical forms (e.g., **49**) for nitrogen heterocycles than for benzene. Where oxygen or sulfur is the heteroatom, it must be present in its ionic form (**50**) in order to possess the valence of 3 demanded for participation in such a system. Thus, pyran (**51**) is not aromatic, but the pyrylium ion (**50**) is.¹³⁰

In systems of fused six-membered aromatic rings,¹³¹ the principal canonical forms are usually not all equivalent. Naphthalene, (**52**) has a central double bond and is thus different from the other two canonical forms, which are equivalent to each other.¹³² For naphthalene, these are the only forms that can be drawn

without consideration of Dewar forms or those with charge separation.¹³³ If it is assumed that the three forms contribute equally, the 1,2-bond has more double-bond character than the 2,3-bond. Molecular orbital calculations show bond orders of 1.724 and 1.603, respectively (cf. benzene, 1.667). In agreement with these predictions, the 1,2 and 2,3 bond distances are 1.36 and 1.415 Å, respectively,¹³⁴ and ozone (**19–09** and **15–58**) preferentially attacks the 1,2-bond.¹³⁵ This nonequivalency of bonds, called *partial bond fixation*,¹³⁶ is found in nearly all fused aromatic systems. Note that a strained naphthalene derivative has been prepared in which one benzene ring is fused to two bicyclic systems. In this new naphthalene derivative, one six-membered ring has equalized bond lengths, but the other ring has alternating bond lengths.¹³⁷ The aromaticity of cation, anion, and ion-radical derivatives of naphthalene and other arenes has also been calculated.¹³⁸ A six-membered ring with a circle is often used to indicate an aromatic system, but Kekulé structures having the C=C units rather than a circle are used most often in this book. This statement is made here because one circle can be used for benzene, but it would be misleading to use two circles for naphthalene, for example, because that would imply 12 aromatic electrons, when naphthalene has only 10.¹³⁹

In phenanthrene, where the 9,10-bond is a single bond in only one of five canonical forms (**53**), bond fixation is significant and this bond is readily attacked by many reagents:¹⁴⁰ It has been observed that increased steric crowding leads to an increase in Dewar-benzene-type structures.¹⁴¹ In general, there is a good correlation between bond distances in fused aromatic compounds and bond orders. Another experimental quantity that correlates well with the bond order of a given bond in an aromatic system is the NMR

coupling constant for coupling between the hydrogen atoms on the two carbons of the bond.¹⁴²

The resonance energies of fused systems increase as the number of principal canonical forms increases, as predicted by rule 6 (Sec. 2.E).¹⁴³ Thus, for benzene, naphthalene, anthracene, and phenanthrene, for which can be drawn, respectively, two, three, four, and five principal canonical forms, the resonance energies are, respectively, 36, 61, 84, and 92 kcal mol⁻¹ (152, 255, 351, and 385 kJ mol⁻¹), calculated from heat of combustion data.¹⁴⁴ Note that when phenanthrene, which has a total resonance energy of 92 kcal mol⁻¹ (385 kJ mol⁻¹), loses the 9,10-bond by attack of a reagent (e.g., ozone or bromine), two complete benzene rings remain, each with 36 kcal mol⁻¹ (152 kJ mol⁻¹) that would be lost if those rings were similarly attacked. The fact that anthracene undergoes many reactions across the 9,10-positions can be explained in a similar manner. Resonance energies for fused systems can be estimated by counting canonical forms.¹⁴⁵ Calculations offer complementary evidence for the repulsive character of the H-H interactions in phenanthrene's bay region.¹⁴⁶

Not all fused systems can be fully aromatic. Thus for phenalene (**54**) there is no way to distribute double bonds so that each carbon has one single and one double bond.¹⁴⁷ However, phenalene is acidic and reacts with potassium methoxide to give the corresponding anion (**55**), which is completely aromatic. So are the corresponding radical and cation, in which the resonance energies are the same (see Sec. 2.I.iii).¹⁴⁸

Molecules that contain fused rings (e.g., phenanthrene or anthracene) are generally referred to as linear or angular polyacenes. **Acenes** are a class of organic compounds and polycyclic aromatic hydrocarbons made up of linearly fused benzene rings. In a fused system, with a focus on each individual ring, there are not six electrons for each ring.¹⁴⁹ In naphthalene, for example, if one ring is to have six, the other must have only four. The greater reactivity of the ring system of naphthalene compared with benzene has been explained by regarding one of the naphthalene rings as aromatic and the other as a butadiene system.¹⁵⁰ This effect can become extreme, as in the case of triphenylene.¹⁵¹ For this compound, there are eight canonical forms like **56**, in which none of the three bonds marked *a* is a double bond and only one form (**57**) in which at least one of them is double. Thus the molecule behaves as if the 18 electrons were distributed so as to give each of the outer rings a sextet, while the middle ring is “empty”. Since none of the outer rings need share any electrons with an adjacent ring, they are as stable as benzene. Triphenylene, unlike most fused aromatic hydrocarbons, does not dissolve in concentrated sulfuric acid and has a low reactivity.¹⁵² This phenomenon, whereby some rings in fused systems give up part of their aromaticity to adjacent rings, is called *annellation* and can be demonstrated by UV spectra,¹³¹ as well as chemical reactivity. In general, an increase of size of both linear and angular polyacenes is associated with a substantial decrease in their aromaticity, with a greater decrease for the linear polyacenes.¹⁵³ Note that molecular loops and belts can be made that involve acenes.¹⁵⁴

2.1.ii. Five, Seven, and Eight-Membered Rings

Aromatic sextets can also be present in five- and seven-membered rings. If a five-membered ring has two double bonds, and the fifth atom possesses an unshared pair of electrons, as in pyrrole, the ring has five *p* orbitals that can overlap to create five new orbitals: three bonding and two antibonding. There are six electrons for these orbitals: the four *p* orbitals of the double bonds each contribute one and the filled orbital contributes

the other two. The six electrons occupy the bonding orbitals and constitute an aromatic sextet, illustrated in Fig. 2.8. The electron potential map of pyrrole in Fig. 2.8 shows the aromatic cloud (dark area near the top of the model), indicative of significant electron

density. The heterocyclic compounds pyrrole, thiophene, and furan are the most important examples of this kind of aromaticity, although furan has a lower degree of aromaticity when compared to the other two.¹⁵⁵ Resonance energies for these three compounds are, respectively, 21, 29, and 16 kcal mol⁻¹ (88, 121, and 67 kJ mol⁻¹).¹⁵⁶ The aromaticity can also be shown by canonical forms, (e.g., for pyrrole):

In contrast to pyridine, the unshared pair in canonical structure **A** in pyrrole is needed for the aromatic sextet. Since the electron pair is not available for donation, pyrrole is a much weaker base than pyridine.

The fifth atom may be carbon rather than a heteroatom, if carbon has an unshared pair (as in an anion). Cyclopentadiene is known to react with a suitable base, and loss of a proton to give a carbanion that is aromatic and therefore quite stable, although it is reactive to alkylating agents and electrophilic reagents. Due to formation of the stable cyclopentadienyl anion, cyclopentadiene ($pK_a \sim 16$) is approximately as strong an acid as water. The cyclopentadienide ion is sometimes represented as in **58**, although more commonly one of the canonical forms is used. Resonance in this ion is greater than in pyrrole, thiophene, and furan, since all five

forms are equivalent, and the resonance energy for **58** has been estimated to be 24–27 kcal mol⁻¹ (100–113 kJ mol⁻¹).¹⁵⁷ All five carbons are equivalent, as demonstrated by labeling the starting compound with ¹⁴C and finding all positions equally labeled when

¹⁵⁵ The order of aromaticity of these compounds is benzene > thiophene > pyrrole > furan, as calculated by an aromaticity index based on bond distance measurements. This index has been calculated for five- and six-membered monocyclic and bicyclic heterocycles: Bird, C.W. *Tetrahedron* **1985**, 41, 1409; **1986**, 42, 89; **1987**, 43, 4725.

cyclopentadiene was regenerated.¹⁵⁸ As expected for an aromatic system, **58** is diatropic¹⁵⁹ and aromatic substitutions (see Chapters 11 and 13) on it have been successfully carried out.¹⁶⁰ Average bond order has been proposed as a parameter to evaluate the aromaticity of such rings, but there is poor correlation with nonaromatic and antiaromatic systems.¹⁶¹ A model that relies on calculating relative aromaticity from appropriate molecular fragments has also been developed.¹⁶² Bird¹⁶³ devised the aromatic index (I_A , or aromaticity index), which is a statistical evaluation of the extent of ring bond order, and has been used as a criterion of aromaticity. Another bond-order index was proposed by Pozharskii,¹⁶⁴ which builds on the work of Fringuelli et al.¹⁶⁵ Absolute hardness (see Sec. 8.E), calculated from molecular refractions for a range of aromatic and heteroaromatic compounds, shows good linear correlation with aromaticity.¹⁶⁶ Indene and fluorene are also acidic ($pK_a \sim 20$ and 23, respectively), but less so than cyclopentadiene, since annellation causes the electrons to be less available to the five-membered ring. On the other hand, the acidity of 1,2,3,4,5-pentakis(trifluoromethyl)cyclopentadiene (**59**) is greater than that of nitric acid,¹⁶⁷ because of the electron-withdrawing effects of the trifluoromethyl groups (see Sec. 8.F). Modifications of the Bird¹⁶³ and Pozharskii¹⁶⁴ systems have been introduced that are particularly useful for five-membered ring heterocycles.¹⁶⁸ Recent work introduced a new local aromaticity measure, defined as the mean of Bader's electron delocalization index (DI)¹⁶⁹ of para-related carbon atoms in six-membered rings.¹⁷⁰ Bond resonance energy has been used as an indicator of local aromaticity.¹⁷¹ The relative merits of several aromaticity indices has been discussed.¹⁷²

As seen above, relative acidity can be used to study the aromatic character of the resulting conjugate base of a given compound. In sharp contrast to cyclopentadiene (see Sec. 2.I.ii) is cycloheptatriene (**60**), which has no unusual acidity. This would be hard to explain without the aromatic sextet theory, since, on the basis of resonance forms or a simple consideration of orbital overlaps, **61** should be as stable as the cyclopentadienyl anion (**58**). This eight electron system is antiaromatic, however. While **61** has been

prepared in solution,¹⁷³ it is less stable than **58** and far less stable than **62**, in which **60** has lost not a proton but the equivalent of a hydride ion. The six double-bond electrons of **62** overlap with the empty orbital on the seventh carbon and there is a sextet of electrons covering seven carbon atoms. The cycloheptatrienyl cation (known as the *tropylium ion*, **62**) is quite stable,¹⁷⁴ but are generally formed from the corresponding halide rather than by loss of a hydride. Tropylium bromide (**63**), which could be completely covalent if the electrons of the bromine were sufficiently attracted to the ring, is actually better viewed as an ionic compound.¹⁷⁵ Many substituted tropylium ions have been prepared to probe the aromaticity, structure, and reactivity of such systems.¹⁷⁶ As with **58**, the equivalence of the carbon atoms in **62** has been demonstrated by isotopic labeling.¹⁷⁷ The aromatic cycloheptatrienyl cations $C_7Me_7^+$ and $C_7Ph_7^+$ are known,¹⁷⁸ although their coordination complexes with transition metals have been problematic, possibly because they assume a boat-like rather than a planar conformation¹⁷⁹

Tropone (**64**) is another seven-membered ring that shows some aromatic character. This molecule would have an aromatic sextet if the two C=O electrons stayed away from the ring and resided near the electronegative oxygen atom. In fact, tropones are stable compounds, and tropolones (**65**) are found in nature.¹⁸⁰ However, analyses of dipole moments, NMR spectra, and X-ray diffraction measurements show that tropones and tropolones display appreciable bond alternations.¹⁸¹ These molecules must be regarded as essentially non-aromatic, although some have aromatic character. Tropolones readily undergo aromatic substitution, emphasizing that the old and the new definitions of aromaticity are not always parallel. It is known that **65** is acidic ($pK_a \sim 6.7$),¹⁸² in large part because the resulting anion has aromatic character. Indeed, **65** is considered to be a vinylogous carboxylic acid. In sharp contrast to **64**, cyclopentadienone (**66**) has been isolated only in an Ar matrix < 38 K.¹⁸³ Above this temperature it dimerizes. Many earlier

attempts to prepare it were unsuccessful.¹⁸⁴ As in **64**, the electronegative oxygen atom draws electron density to itself, but in this case it leaves only four electrons and the molecule is unstable. Some derivatives of **66** have been prepared.¹⁴⁵

The *metallocenes* (also called *sandwich compounds*) constitute another type of five-membered aromatic compound in which two cyclopentadienide rings form a sandwich around a metal. The best known of these is ferrocene, where the η^5 -coordination of the two cyclopentadienyl rings to iron is apparent in the 3D model **67**. Other metallocenes have been prepared with Co, Ni, Cr, Ti, V, and many other metals.¹⁸⁵ As a reminder (see Sec. 2.C), the η terminology refers to π -donation of electrons to the metal (η^3 for π -allyl systems, η^6 for coordination to a benzene ring, etc.), and η^5 refers to donation of five π -electrons to the iron. Ferrocene is quite stable, subliming $>100^\circ\text{C}$ and unchanged at 400°C . The two rings rotate freely.¹⁸⁶ Many aromatic substitutions (Chapter 11) have been carried out on metallocenes.¹⁸⁷ Metallocenes containing two metal atoms and three cyclopentadienyl rings have also been prepared and are known as *triple-decker sandwiches*.¹⁸⁸ Even tetradecker, pentadecker, and hexadecker sandwiches have been reported.¹⁸⁹

The bonding in ferrocene may be looked upon in simplified MO terms as follows.¹⁹⁰ Each of the cyclopentadienide rings has five molecular orbitals: three filled bonding and two empty antibonding orbitals (Sec. 2.I.ii). The outer shell of the Fe atom possesses nine atomic orbitals, that is, one $4s$, three $4p$, and five $3d$ orbitals. The six filled orbitals of the two cyclopentadienide rings overlap with the s , three p , and two of the d orbitals of the Fe to form 12 new orbitals, six of which are bonding. These six orbitals make up two ring-metal triple bonds. In addition, further bonding results from the overlap of the empty antibonding orbitals of the rings with additional filled d orbitals of the iron. All told, there are 18 electrons (10 of which may be considered to come from the rings and 8 from iron in the

zero oxidation state) in nine orbitals; six of these are strongly bonding and three weakly bonding or nonbonding.

The tropylium ion has an aromatic sextet spread over seven carbon atoms. An analogous ion, with the sextet spread over eight carbon atoms, is the 1,3,5,7-tetramethylcyclooctatetraene dication (**68**). This ion, which is stable in solution at -50°C , is diatropic and approximately planar. The dication **68** is not stable above about -30°C .¹⁹¹

2.1.iii. Other Systems Containing Aromatic Sextets

Simple resonance theory predicts that pentalene (**69**), azulene (**70**), and heptalene (**71**) should be aromatic, although no nonionic canonical form can have a double bond at the ring junction. Molecular orbital calculations show that azulene should be stable but not the other two. This finding is borne out by experiment. Heptalene has been prepared,¹⁹² but reacts readily with oxygen, acids, and bromine, is easily hydrogenated, and polymerizes on standing. Analysis of its NMR spectrum shows that it is not planar.¹⁹³ The 3,8-dibromo and 3,8-dicarbomethoxy derivatives of **71** are stable in air at room temperature, but are not diatropic.¹⁹⁴ A number of methylated heptalenes and dimethyl 1,2-heptalenedicarboxylates have also been prepared and are stable non-aromatic compounds.¹⁹⁵ Pentalene has not been prepared,¹⁹⁶ but the hexaphenyl¹⁹⁷ and 1,3,5-tri-*tert*-butyl derivatives¹⁹⁸ are known. The former is air sensitive in solution. The latter is stable, but X-ray diffraction and photoelectron spectral data show bond alternation.¹⁹⁹ Pentalene and its methyl and dimethyl derivatives have been formed in solution, but they dimerize before they can be isolated.²⁰⁰ Many other attempts to prepare these two systems have failed.

In sharp contrast to **69** and **71**, azulene (**70**) is a blue solid, is quite stable, and many of its derivatives are known.²⁰¹ Azulene readily undergoes aromatic substitution. Azulene may be regarded as a combination of **58** and **62** and, indeed, possesses a dipole moment of $0.8 D$ (see **72**).²⁰² Interestingly, if two electrons are added to pentalene, a stable dianion (**73**) results.²⁰³ It can be concluded that an aromatic system of electrons will be spread over two rings only if 10 electrons (not 8 or 12) are available for aromaticity. $[n,m]$ -Fulvalenes ($n \neq m$, where fulvalene is **74**), as well as azulene are known to shift their π -electrons due to the influence of dipolar aromatic resonance structures.²⁰⁴ However, calculations showed that dipolar resonance structures contribute only 5% to the electronic structure of heptafulvalene (**75**), although 22–31% to calicene (**76**).²⁰⁵ Based on Baird's theory,²⁰⁶ these molecules are influenced by aromaticity in both the ground and excited states, therefore acting as aromatic "chameleons." This premise was confirmed in work by Ottosson and co-workers.²⁰⁴ Aromaticity indexes for various substituted fulvalene compounds has been reported.²⁰⁷

2.J. ALTERNANT AND NONALTERNANT HYDROCARBONS²⁰⁸

Aromatic hydrocarbons can be divided into alternant and nonalternant hydrocarbons. In alternant hydrocarbons, the conjugated carbon atoms can be divided into two sets such that no two atoms of the same set are directly linked. For convenience, one set may be starred. Naphthalene is an alternant and azulene a nonalternant hydrocarbon:

In alternant hydrocarbons, the bonding and antibonding orbitals occur in pairs; that is, for every bonding orbital with an energy $-E$ there is an antibonding one with energy $+E$

FIG. 2.9. Energy levels in odd- and even-alternant hydrocarbons.²⁰⁹ The arrows represent electrons. The orbitals are shown as having different energies, but some may be degenerate.

(Fig. 2.9²⁰⁹). Even-alternant hydrocarbons are those with an even number of conjugated atoms, that is, an equal number of starred and unstarred atoms. For these hydrocarbons all the bonding orbitals are filled and the π electrons are uniformly spread over the unsaturated atoms.

As with the allylic system, odd-alternant hydrocarbons (which must be carbocations, carbanions, or radicals) in addition to equal and opposite bonding and antibonding orbitals also have a nonbonding orbital of zero energy. When an odd number of orbitals overlap, an odd number is created. Since orbitals of alternant hydrocarbons occur in $-E$ and $+E$ pairs, one orbital can have no partner and must therefore have zero-bonding energy. For example, in the benzylic system the cation has an unoccupied nonbonding orbital, the free radical has one electron there and the carbanion has two (Fig. 2.10). As with the allylic system, all three species have the same bonding energy. The charge distribution (or unpaired-electron

FIG. 2.10. Energy levels for the benzyl cation, free radical, and carbanion. Since α is the energy of a p orbital (Sec. 2.B), the nonbonding orbital has no bonding energy.

²⁰⁹ Taken from Dewar, M.J.S *Prog. Org. Chem.* **1953**, 2, 1, p. 8.

distribution) over the entire molecule is also the same for the three species and can be calculated by a relatively simple process.²⁰⁸

For nonalternant hydrocarbons, the energies of the bonding and antibonding orbitals are not equal and opposite and charge distributions are not the same in cations, anions, and radicals. Calculations are much more difficult, but have been carried out.²¹⁰ Theoretical approaches to calculate topological polarization and reactivity of these hydrocarbons have been reported.²¹¹

2.K. AROMATIC SYSTEMS WITH ELECTRON NUMBERS OTHER THAN SIX

The special stability of benzene is well recognized, and this stability is also associated with rings that are similar, but of different sizes, (e.g., cyclobutadiene (**77**), cyclooctatetraene (**78**), cyclodecapentaene (**79**))²¹²,

and so on. The general name *annulene* is given to these compounds,²¹³ benzene being [6]annulene, and **77–79** being called, respectively, [4], [8], and [10]annulene.²¹⁴ By a naïve consideration of resonance forms, these annulenes and higher ones should be as aromatic as benzene. Yet they proved remarkably elusive. The ubiquitous benzene ring is found in thousands of natural products, in coal and petroleum, and is formed by strong treatment of many noncyclic compounds. None of the other annulene ring systems has ever been found in nature and, except for cyclooctatetraene, their synthesis is not simple. Obviously, there is something special about the number six in a cyclic system of electrons.

Hückel's rule, based on MO calculations,²¹⁵ predicts that electron rings will constitute an aromatic system only if the number of electrons in the ring is of the form $4n + 2$, where n is zero or any position integer. Systems that contain $4n$ electrons are predicted to be nonaromatic.

²¹⁵ See Nakajima, T. *Pure Appl. Chem.* **1971**, *28*, 219; *Fortschr. Chem. Forsch.* **1972**, *32*, 1.

The rule predicts that rings of 2, 6, 10, 14, and so on, electrons will be aromatic, while rings of 4, 8, 12, and so on, will not be. This is actually a consequence of *Hund's rule*. The first pair of electrons in an annulene goes into the π orbital of lowest energy. After that the bonding orbitals are degenerate and occur in pairs of equal energy. When there is a total of four electrons, Hund's rule predicts that two will be in the lowest orbital, but the other two will be unpaired, so that the system will exist as a diradical rather than as two pairs. The degeneracy can be removed if the molecule is distorted from maximum molecular symmetry to a structure of lesser symmetry. For example, if **77** assumes a rectangular rather than a square shape, one of the previously degenerate orbitals has a lower energy than the other and will be occupied by two electrons. In this case, of course, the double bonds are essentially separate and the molecule is still not aromatic. Distortions of symmetry can also occur when one or more carbons are replaced by heteroatoms or in other ways.²¹⁶ The enthalpy of formation of cyclobutadiene was reported by Kass and co-workers.²¹⁷ There is a brief discussion of the importance of cyclobutadiene with respect to antiaromaticity.²¹⁸ A word of caution is in order for MO calculations in these systems. It is known that *ab initio* computations on benzene at electron-correlated MP2, MP3, CISD, and CCSD levels using a number of popular basis sets²¹⁹ give anomalous, nonplanar equilibrium structures.²²⁰ The origin of these anomalies has been addressed.²²⁰

In the following sections, systems with various numbers of electrons are discussed. Any probe of aromaticity must include (1) the presence of a diamagnetic ring current; (2) equal or approximately equal bond distances, except when the symmetry of the system is disturbed by a heteroatom or in some other way; (3) planarity; (4) chemical stability; (5) the ability to undergo aromatic substitution.

2.K.i Systems of Two Electrons²²¹

Obviously, there can be no ring of two carbon atoms (a double bond may be regarded as a degenerate case). However, by analogy to the tropylium ion, a three-membered ring with a double bond and a positive charge on the third atom (the *cyclopropenyl cation*) is a $4n + 2$ system and expected to show aromaticity. Unsubstituted **80** has been prepared,²²² as well as several derivatives, (e.g., the trichloro, diphenyl, and dipropyl derivatives), and they are stable despite bond angles of only 60°. Tripropylcyclopropenyl,²²³ tricyclopropylcyclopropenyl,²²⁴ chlorodipropylcyclopropenyl,²²⁵ and chloro-bis-dialkylaminocyclopropenyl²²⁶ cations are among the most stable carbocations known, being stable even in

water solution. The tri-*tert*-butylcyclopropenyl cation is also very stable.²²⁷ In addition, cyclopropenone and several of its derivatives are stable compounds,²²⁸ in accord with the corresponding stability of the tropones.²²⁹ The ring system **80** is nonalternant and the corresponding radical and anion, which do not have an aromatic duet, have electrons in antibonding orbitals, so that their energies are much higher. As with **58** and **62**, the equivalence of the three carbon atoms in the triphenylcyclopropenyl cation has been demonstrated by ¹⁴C labeling experiments.²³⁰ The interesting dications **81** (R = Me or Ph) have been prepared,²³¹ and they too should represent aromatic systems of two electrons.²³²

2.K.ii. Systems of Four Electrons: Antiaromaticity

The most obvious compound in which to look for a closed loop of four electrons is cyclobutadiene (**77**).²³³ *Hückel's rule* predicts no aromatic character since 4 is not a number generated from $4n + 2$. There is a long history of attempts to prepare this compound and its simple derivatives, and those experiments fully bear out *Hückel's* prediction. Cyclobutadienes display none of the characteristics that would lead us to call them aromatic, and there is evidence that a closed loop of four electrons is actually *antiaromatic*.²³⁴ If such compounds simply lacked aromaticity, we would expect them to be about as stable as similar nonaromatic compounds, but both theory and experiment show that they are *much less stable*.²³⁵ An antiaromatic compound may be defined as a compound that is destabilized by a closed loop of electrons.

Cyclobutadiene was first prepared by Pettit and co-workers.²³⁶ It is now clear that **77** and its simple derivatives are extremely unstable compounds with very short lifetimes (they dimerize by a *Diels–Alder reaction*; see **15–60**) unless they are stabilized in some fashion,

either at ordinary temperatures embedded in the cavity of a hemicarcerand²³⁷ (see the structure of a carcerand in Sec. 3.C.iii), or in matrices at very low temperatures (generally < 35 K). In either of these cases, the cyclobutadiene molecules are forced to remain apart from each other, and other molecules cannot get in. The structures of **77** and some of its derivatives have been studied a number of times using the low-temperature matrix technique.²³⁸ The ground-state structure of **77** is a rectangular diene (not a diradical), as shown by the (Ir) spectra of **77** and deuterated **77** trapped in matrices,²³⁹ as well as by a photoelectron spectrum.²⁴⁰ Molecular orbital calculations agree.²⁴¹ The same conclusion was also reached in an elegant experiment in which 1,2-dideuterocyclobutadiene was generated. If **77** is a rectangular diene, the dideutero compound should exist as two isomers, as shown.

The compound was generated (as an intermediate that was not isolated) and two isomers were indeed found.²⁴² The cyclobutadiene molecule is not static, even in the matrices. There are two forms (**77a** and **77b**) that rapidly interconvert.²⁴³ Note that there is experimental evidence that the aromatic and antiaromatic characters of neutral and dianionic systems are measurably increased via deuteration.²⁴⁴

There are some simple cyclobutadienes that are stable at room temperature for varying periods of time. These either have bulky substituents or carry certain other stabilizing substituents, such as seen in tri-*tert*-butylcyclobutadiene (**83**).²⁴⁵ Such compounds are relatively stable because dimerization is sterically hindered. Examination of the NMR spectrum of **82** showed that the ring proton ($\delta = 5.38$) was shifted *upfield*, compared with the position expected for a nonaromatic proton, (e.g., cyclopentadiene). As will be seen in Section. 2.K.vi, this indicates that the compound is antiaromatic.

The other type of stable cyclobutadiene has two electron-donating and two electron-withdrawing groups,²⁴⁶ and is stable in the absence of water.²⁴⁷ An example is **83**. The stability of these compounds is generally attributed to the resonance shown, a type of resonance stabilization called the *push–pull or captodative effect*,²⁴⁸ although it has been concluded from a PES that second-order bond fixation is more important.²⁴⁹ An X-ray crystallographic study of **83** has shown²⁵⁰ the ring to be a distorted square with bond lengths of 1.46 Å and angles of 87° and 93°.

It is clear that simple cyclobutadienes, which could easily adopt a square planar shape if that would result in aromatic stabilization, do not in fact do so and are not aromatic. The high reactivity of these compounds is not caused merely by steric strain, since the strain should be no greater than that of simple cyclopropenes, which are known compounds. It is probably caused by antiaromaticity.²⁵¹

The cyclobutadiene system can be stabilized as a η^4 -complex with metals,²⁵² as with the iron complex **84** (see Chap 3), but in these cases electron density is withdrawn from the ring by the metal and there is no aromatic quartet. In fact, these cyclobutadiene–metal complexes can be looked upon as systems containing an aromatic duet. The ring is square planar,²⁵³ the compounds undergo aromatic substitution,²⁵⁴ and NMR spectra of mono-substituted derivatives show that the C-2 and C-4 protons are equivalent.²²⁹

Other systems that have been studied as possible aromatic or antiaromatic four-electron systems include the cyclopropenyl anion (**86**) and the cyclopentadienyl cation (**87**).²⁵⁵ With respect to **86**, HMO theory predicts that an unconjugated **85** (i.e., a single canonical

form) is more stable than a conjugated **86**,²⁵⁶ so that **85** would actually lose stability by forming a closed loop of four electrons. The HMO theory is supported by experiment. Among other evidence, it has been shown that **88** ($R = \text{COPh}$) loses its proton in hydrogen-exchange reactions ~ 6000 times more slowly than **89** ($R = \text{COPh}$).²⁵⁷ Where $R = \text{CN}$, the ratio is $\sim 10,000$.²⁵⁸ This indicates that **88** are much more reluctant to form carbanions (which would have to be cyclopropenyl carbanions) than **89**, which form ordinary carbanions. Thus the carbanions of **88** are less stable than corresponding ordinary carbanions. Although derivatives of cyclopropenyl anion have been prepared as fleeting intermediates (as in the exchange reactions mentioned above), all attempts to prepare the ion or any of its derivatives as relatively stable species have so far met with failure.²⁵⁹

In the case of **87**, the ion has been prepared and shown to be a diradical in the ground state,²⁶⁰ as predicted by the discussion in Section 2.K.ii.²⁶¹ Evidence that **87** is not only nonaromatic, but is antiaromatic comes from studies on **90** and **92**.²⁶² When **90** is treated with silver perchlorate in propionic acid, the molecule is rapidly solvolyzed (a reaction in which the intermediate **91** is formed; see Chapters 5 and 10). Under the same conditions, **92** undergoes no solvolysis at all; that is, **87** does not form. If **87** were merely nonaromatic, it should be about as stable as **91** (which of course has no resonance stabilization at all). The fact that it is so much more reluctant to form indicates that **87** is much less stable than **91**. Note that under certain conditions, **91** can be generated solvolytically.²⁶³

The fact that **86** and **87** are not aromatic while the cyclopropenyl cation (**80**) and the cyclopentadienyl anion (**58**) is strong evidence for *Hückel's rule* since simple resonance theory predicts no difference between **86** and **80** or **87** and **58** (the same number of equivalent canonical forms can be drawn for **86** as for **80** and for **87** as for **58**).

2.K.iii. Systems of Eight Electrons

Cyclooctatetraene²⁶⁴ ([8]annulene, **78a**) is not planar, but tub shaped,²⁶⁵ so it is neither aromatic nor antiaromatic, since both these conditions require overlap of parallel *p* orbitals. The reason for the lack of planarity is that a regular octagon has angles of 135°, while sp² angles are most stable at 120°. To avoid the strain, the molecule assumes a nonplanar shape, in which orbital overlap is greatly diminished.²⁶⁶ Single- and double-bond distances in **78** are, respectively, 1.46 and 1.33 Å, which is expected for a compound made up of four individual double bonds.²⁶⁵ The *Jahn–Teller effect* has been invoked to explain the instability of such antiaromatic compounds.²⁶⁷ The Jahn–Teller effect arises from molecular distortions due to an electronically degenerate ground state.²⁶⁸

The reactivity is also what would be expected for a linear polyene. Reactive intermediates can be formed in solution. Dehydrohalogenation of bromocyclooctatetraene at –100 °C has been reported, for example, and trapping by immediate electron transfer gave a stable solution of the [8]annulyne anion radical.²⁶⁹

The cyclooctadiendiynes **93** and **94** are planar conjugated eight-electron systems (the four extra triple-bond electrons do not participate), which NMR evidence show to be antiaromatic.²⁷⁰ There is evidence that part of the reason for the lack of planarity in **78** itself is that a planar molecule would have to be antiaromatic.²⁷¹ The cycloheptatrienyl anion (**61**) also has eight electrons, but does not behave like an aromatic system.¹⁶⁷ The bond lengths for a series of molecules containing the cycloheptatrienide anion have recently been published.²⁷² The NMR spectrum of the benzocycloheptatrienyl anion (**95**) shows that, like **82**, **93**, and **94**, this compound is antiaromatic.²⁷³ A new antiaromatic compound 1,4-biphenylene quinone (**96**) was prepared, but it rapidly dimerizes due to instability.²⁷⁴

2.K.iv. Systems of Ten Electrons²⁷⁵

There are three possible geometrical isomers of [10]annulene: the all-*cis* (**97**), the mono-*trans* (**98**), and the *cis-trans-cis-cis-trans* (**79**). If Hückel's rule applies, they should be planar. But it is far from obvious that the

molecules would adopt a planar shape, since they must overcome considerable strain to do so. For a regular decagon (**97**) the angles would have to be 144° , considerably larger than the 120° required for sp^2 angles. Some of this strain would also be present in **98**, but this kind of strain is eliminated in **79** since all the angles are 120° . However, it was pointed out by Mislow²⁷⁶ that the hydrogen atoms in the 1 and 6 positions should interfere with each other and force the molecule out of planarity. Such configurational changes are not necessarily without cost energetically. It has been determined that configurational changes in [14]annulene, for example, requires Möbius antiaromatic bond shifting.²⁷⁷

Compounds **97** and **98** have been prepared²⁷⁸ as crystalline solids at -80°C . The NMR spectra show that all the hydrogen atoms lie in the alkene region, and it was concluded that neither compound is aromatic. Calculations on **98** suggest that it may indeed be aromatic, although the other isomers are not.²⁷⁹ It is known that the Hartree-Fock (HF) method incorrectly favors bond-length-alternating structures for [10]annulene, and aromatic structures are incorrectly favored by density functional theory. Improved calculations predict that the twist conformation is lowest in energy, and the naphthalene-like and heart-shaped conformations lie higher than the twist by 1.40 and 4.24 kcal mol⁻¹ (5.86 and 17.75 kJ mol⁻¹), respectively.²⁸⁰ Analysis of ¹³C and ¹H NMR spectra suggest that neither is planar. However, the preparation of several compounds that have large angles, but that are definitely planar 10-electron aromatic systems, clearly demonstrate that the angle strain is not insurmountable. Among these are the dianion **99**, the anions **100** and **101**, and the

azonine **102**.²⁸¹ Compound **99**²⁸² has angles of $\sim -135^\circ$, while **100**²⁸³ and **101**²⁸⁴ have angles of $\sim 140^\circ$, which are not very far from 144° . The inner proton in **101**²⁸⁵ which is the mono-trans isomer of the all-*cis* **100** is found far upfield in the NMR (-3.5δ). For **97** and **98**, the cost in strain energy to achieve planarity apparently outweighs the extra stability that would come from an aromatic ring. Further emphasizing the delicate balance between these factors, it is known that the oxygen analogue of **102** ($X=O$, oxonin) and the *N*-carbethoxy derivative of **102** ($X=CH$) are nonaromatic and nonplanar, while **102** ($X=N$) is aromatic and planar.²⁸⁶ Other azaannulenes are known, including Vogel's 2,7-methanoazaannulene,²⁸⁷ as well as 3,8-methanoaza[10]annulene,²⁸⁸ and the alkoxy derivative of both.²⁸⁹ Calculations for aza[10]annulene concluded that the best olefinic twist isomer is 2.1 kcal mol^{-1} (8.8 kJ mol^{-1}) more stable than the aromatic form,²⁹⁰ and is probably the more stable form.

So far, **79** from above has not been prepared despite many attempts. However, there are various ways of avoiding the interference between the two inner protons. The approach that has been most successful involves bridging the 1 and 6 positions.²⁹¹ Thus, 1,6-methano[10]annulene (**103**)²⁹² and its oxygen and nitrogen analogues **104**²⁹³ and **105**²⁹⁴ have been prepared, and they are stable compounds, are diatropic, and undergo aromatic substitution.²⁹⁵ For example, the perimeter protons of **103** are found at $6.9\text{--}7.3\delta$, while the bridge protons are at -0.5δ . The crystal structure of **103** shows that the perimeter is nonplanar,

but the bond distances are in the range 1.37–1.42 Å.²⁹⁶ It has therefore been amply demonstrated that a closed loop of 10 electrons is an aromatic system, although some molecules that could conceivably have such a system are too distorted from planarity to be aromatic. A small distortion from planarity (as in **103**) does not prevent aromaticity, at least in part because the σ orbitals so distort themselves as to maximize the favorable (parallel) overlap of p orbitals to form the aromatic 10-electron loop.²⁹⁷

In **106**, where **103** is fused to two benzene rings in such a way that no canonical form can be written in which both benzene rings have six electrons, the aromaticity is diminished by annellation, as shown by the fact that the molecule rapidly converts to the more stable **107**, in which both benzene rings can be fully aromatic²⁹⁸ (this is similar to the cycloheptatriene–norcaradiene conversions discussed in **18–32**).

Molecules can sustain significant distortion from planarity and retain their aromatic character. 1,3-Bis(trichloroacetyl)homoazulene (**108**) qualifies as aromatic using the geometric criterion that there is only a small average deviation from the C—C bond length in the [10]annulene perimeter.²⁹⁹ The X-ray crystal structure shows that the 1,5-bridge distorts the [10]annulene π -system away from planarity (see the 3D model) with torsion angles as large as 42.2° at the bridgehead position, but **108** does not lose its aromaticity.

2.K.v. Systems of More Than Ten Electrons: $4n + 2$ Electrons³⁰⁰

Extrapolating from the discussion of [10]annulene, larger $4n + 2$ systems are expected to be aromatic if they are planar. Mislow²⁷⁶ predicted that [14]annulene (**109**) would possess

the same type of interference as **79**, although to a lesser degree. This is borne out by experiment. Compound **109** is aromatic (it is diatropic; inner protons at 0.00 δ , outer protons at 7.6 δ),³⁰¹ but is highly reactive and is completely destroyed by light and air in 1 day. X-ray analysis shows that although there are no alternating single and double bonds (the molecule is not planar).³⁰² A number of stable bridged [14]annulenes have been prepared³⁰³ [e.g., *trans*-15,16-dimethyldihydropyrene (**110**),³⁰⁴ *syn*-1,6:8,13-diimino[14]annulene (**111**),³⁰⁵ and *syn*- and *anti*-1,6:8,13-bismethano[14]annulene (**112** and **113**)].³⁰⁶ The dihydropyrene (**110**, and its diethyl and dipropyl homologues) is undoubtedly aromatic: The π perimeter is approximately planar,³⁰⁷ the bond distances are all 1.39–1.40 Å, and the molecule undergoes aromatic substitution³⁰⁴ as well as being diatropic.³⁰⁸ The outer protons are found at 8.14–8.67 δ , while the CH₃ protons are at –4.25 δ . Other nonplanar aromatic dihydropyrenes are known.³⁰⁹ Annulenes **111** and **112** are also diatropic,³¹⁰ although X-ray crystallography indicates that the π periphery in **111** is not quite planar.³¹¹ In **113**, the geometry of the molecule greatly reduces the overlap of the *p* orbitals at the bridgehead positions with adjacent *p* orbitals, and it is definitely not aromatic,³¹² as shown by NMR spectra³⁰⁶ and X-ray crystallography, from which bond distances of 1.33–1.36 Å for the double bonds and 1.44–1.49 Å for the single bonds have been obtained.³¹³ In contrast, all the bond distances in **111** are \sim 1.38–1.40 Å.³¹¹

Another way of eliminating the hydrogen interferences of [14]annulene is to introduce one or more triple bonds into the system, as in dehydro[14]annulene

(**114**).³¹⁴ All five known dehydro[14]annulenes are diatropic, and **87** can be nitrated or sulfonated.³¹⁵ The extra electrons of the triple bond do not form part of the

aromatic system, but it simply exists as a localized bond. There has been a debate concerning the extent of delocalization in dehydrobenzoannulenes,³¹⁶ but there is evidence for a weak, but discernible ring current.³¹⁷ 3,4,7,8,9,10,13,14-Octahydro[14]annulene (**116**) has been prepared, for example, and the evidence supported its aromaticity.³¹⁸ This study suggested that increasing benzoannulation of the parent **116** led to a step-down in aromaticity, a result of competing ring currents in the annulenic system. Note that [12]annulyne has been prepared.³¹⁹

[18]Annulene (**115**) is diatropic:³²⁰ the 12 outer protons are found at $\sim \delta = 9$ and the 6 inner protons at $\sim \delta = -3$. X-ray crystallography³²¹ shows that it is nearly planar, so that interference of the inner hydrogen atoms is not important in annulenes this large. Compound **115** is reasonably stable, being distillable at reduced pressures, and undergoes aromatic substitutions³²² (Chapter 11). The C—C bond distances are not equal, but they do not alternate. There are 12 inner bonds of $\sim 1.38 \text{ \AA}$ and 6 outer bonds of $\sim 1.42 \text{ \AA}$.³²¹ Compound **115** has been estimated to have a resonance energy of $\sim 37 \text{ kcal mol}^{-1}$ (155 kJ mol^{-1}), similar to that of benzene.³²³

The known bridged [18]annulenes are also diatropic,³²⁴ as are most of the known dehydro[18]annulenes.³²⁵ The dianions of open and bridged [16]annulenes³²⁶ are also 18-electron aromatic systems,³²⁷ and there are dibenzo[18]annulenes.³²⁸

[22]Annulene³²⁹ and dehydro[22]annulene³³⁰ are also diatropic. A dehydrobenzo[22]annulene has been prepared that has eight $\text{C}\equiv\text{C}$ units, is planar, and possesses a weak induced ring current.³³¹ In the latter compound, there are 13 outer protons at 6.25–8.45 δ and 7 inner protons at 0.70–3.45 δ . Some aromatic bridged [22]annulenes are known.³³² [26]Annulene has not yet been prepared, but several dehydro[26]annulenes are aromatic.³³³ Furthermore, the dianion of 1,3,7,9,13,15,19,21-octadehydro[24]annulene is another 26-electron system that is aromatic.³³⁴ Ojima and et al.³³⁵ prepared bridged dehydro derivatives of [26], [30], and [34]annulenes. All are diatropic. The same workers prepared a bridged tetrahydro[38]annulene,³³⁵ which showed no ring current. On the other hand, the dianion of the cyclophane, (**117**) also has 38 perimeter electrons, and this species is diatropic.³³⁶

There is now no doubt that $4n + 2$ systems are aromatic if they can be planar, although **97** and **113** among others, demonstrate that not all such systems are in fact planar enough for aromaticity. Both **109** and **111** prove that absolute planarity is not required for aromaticity, but that aromaticity decreases with decreasing planarity.

The ^1H NMR spectrum of **118** (called kekulene) showed that in a case where electrons can form either aromatic sextets or larger systems, the sextets are preferred.³³⁷ There was initial speculation that kekulene might be *superaromatic*, that is, it would show enhanced aromatic stabilization. Calculations suggest that there is no enhanced stabilization.³³⁸ The 48 π electrons of **118** might, in theory, prefer structure **118a**, where each ring is a fused benzene ring, or **118b**, which has a [30]annulene on the outside and an [18]annulene on the inside. The ^1H NMR spectrum of this compound shows three peaks at $\delta = 7.94$, 8.37, and 10.45 in a ratio of 2:1:1. Examination of the structure shows that **118** contains three groups of protons. The peak at 7.94 δ is attributed to the 12 ortho protons and the peak at 8.37 δ to the six external para protons. The remaining peak comes from the six inner protons. If the molecule preferred **118b**, this peak should be upfield, probably with a negative δ , as in the case of **115**. The fact that this peak is far downfield indicates that the electrons prefer to be in benzenoid rings. Note that in the case of the dianion of **117**, the opposite situation prevails. In this ion, the 38-electron system is preferred even though 24 of these must come from the six benzene rings, which therefore cannot have aromatic sextets.

Phenacenes are a family of “graphite ribbons,” where benzene rings are fused together in an alternating pattern. Phenanthrene is the simplest member of this family and other members include the 22 electron system picene (**119**), the 26 electron system fulminene (**120**) and the larger member of this family, the 30 electron [7]phenacene, with seven rings (**121**).³³⁹ In the series benzene to heptacene, reactivity increases although acene resonance energies per π electron are nearly constant. The inner rings of the “acenes” are more reactive, and calculations showed that those rings are more aromatic than the outer rings, and are even more aromatic than benzene itself.³⁴⁰ *N*-Heteroacenes are also known.³⁴¹

A super-ring molecule is formed by rolling a polyacene molecule into one ring with one edge benzene ring folding into the other. These are called cyclopolyacenes or cyclacenes.³⁴² Although the *zigzag* cyclohexacenes (**122**) are highly aromatic (this example is a 22 electron system), the linear cyclohexacenes (e.g., the 24 electron **123**) are much less aromatic.³⁴³ It is possible to deform an acene by attaching bulky substituents to its periphery by single covalent bonds. The presence of these substituents, which often leads to twisting of torsion angles, is usually easier than distortion of bond angles or C-C bond lengths. Such compounds are called twisted acenes.³⁴⁴

2.K.vi. Systems of More Than 10 Electrons: $4n$ Electrons²⁴⁹

As seen in Section 2.K.ii, these systems are expected to be not only nonaromatic, but also antiaromatic. The [12]annulene (**124**) has been prepared.³⁴⁵ In solution, **124** exhibits rapid conformational mobility (as do many other annulenes),³⁴⁶ and above -150°C in this particular case, all protons are magnetically equivalent. However, at -170°C the mobility is greatly slowed and the three inner protons are found at $\sim 8\delta$ while the nine

outer protons are at $\sim 6\delta$. Interaction of the ‘internal’ hydrogen atoms in annulene (**124**) leads to nonplanarity. Above -50°C , **124** is unstable and rearranges to **125**. Several bridged and dehydro[12]annulenes are known, for example, 5-bromo-1,9-didehydro[12]annulene (**126**),³⁴⁷ cycl[3.3.3]azine (**127**),³⁴⁸ *s*-indacene (**128**),³⁴⁹ and 1,7-methano[12]annulene (**129**).³⁵⁰ *s*-Indacene is a planar, conjugated system perturbed by two cross links, and studies showed that the low-energy structure has *localized* double bonds. In these compounds, both hydrogen interference and conformational mobility are prevented. In **127–129**, the bridge prevents conformational changes, while in **126** the bromine atom is too large to be found inside the ring. The NMR spectra show that all four compounds are paratropic, the inner proton of **126** being found at 16.4δ . The dication of **112**³⁵¹ and the dianion of **103**³⁵² are also 12-electron paratropic species. An interesting 12-electron [13]annulenone has recently been reported, 5,10-dimethyl[13]annulenone (**130**). This annulenone is the first monocyclic annulene larger than tropene,³⁵³ and a linearly-fused benzodehydro[12]annulene system has been reported.³⁵⁴

The results for [16]annulene are similar. The compound was synthesized in two different ways,³⁵⁵ both of which gave **131**, which in solution is in equilibrium with **132**. Above -50°C there is conformational mobility, resulting in the magnetic equivalence of all protons, but at -130°C the compound is clearly paratropic: There are 4 protons at 10.56 δ and 12 at 5.35 δ . In the solid state, where the compound exists entirely as **131**, X-ray crystallography³⁵⁶ shows that the molecules are nonplanar with almost complete bond alternation: The single bonds are 1.44–1.47 Å and the double bonds are 1.31–1.35 Å. A number of dehydro and bridged [16]annulenes are also paratropic,³⁵⁷ as are [20]annulene,³⁵⁸ and [24]annulene.³⁵⁹ However, a bridged tetradehydro[32]annulene was atropic.³³³

Both pyracylene (**133**),³⁶⁰ which because of strain is stable only in solution, and dipoleadiene (**134**)³⁶¹ are paratropic, as shown by NMR spectra. These molecules might have been expected to behave like naphthalenes with outer bridges, but the outer π frameworks (12 and 16 electrons, respectively) constitute antiaromatic systems with an extra central double bond. With respect to **133**, the $4n+2$ rule predicts pyracylene to be “aromatic” if it is regarded as a 10- π -electron naphthalene unit connected to two 2- π -electron etheno systems, but “antiaromatic” if it is viewed as a 12- π -electron cyclo-dodecahexaene periphery perturbed by an internal cross-linked etheno unit.³⁶² Recent studies have concluded on energetic grounds that **133** is a “borderline” case, in terms of aromaticity–antiaromaticity character.³⁶⁰ Dipoleadiene appears to be antiaromatic.³⁶¹

The fact that many $4n$ systems are paratropic even though they may be nonplanar and have unequal bond distances indicates that if planarity were enforced, the ring currents

might be even greater. The NMR spectrum of the dianion of **110**³⁶³ (and its diethyl and dipropyl homologues)³⁶⁴ effectively illustrate this point. Recall that in **110**, the outer protons were found at 8.14–8.67 δ with the methyl protons at -4.25 δ . For the dianion, however, which is forced to have approximately the same planar geometry, but now has 16 electrons, the outer protons are shifted to about -3 δ while the methyl protons are found at ~ 21 δ , a shift of ~ 25 δ ! A converse shift was made when [16]annulenes that were antiaromatic were converted to 18-electron dianions that were aromatic.²⁸² In these cases, the changes in NMR chemical shifts were almost as dramatic. Heat-of-combustion measures also show that [16]annulene is much less stable than its dianion.³⁶⁵ It has also been reported that the fluorenyl cation shows substantial destabilization, suggesting that it is an antiaromatic species.³⁶⁶

It seems clear that $4n$ systems will be at a maximum where a molecule is constrained to be planar (as in **86** or the dianion of **110**) but, where possible, the molecule will distort itself from planarity and avoid equal bond distances in order to reduce. In some cases (e.g., cyclo-octatetraene), the distortion and bond alternation are great enough to be completely avoided. In other cases, (e.g., **124** or **131**), it is apparently not possible for the molecules to avoid at least some p orbital overlap. Such molecules show evidence of paramagnetic ring currents, although the degree of is not as great as in molecules (e.g., **86** or the dianion of **110**).

The concept of “Möbius aromaticity” was conceived by Helbronner in 1964,³⁶⁷ when he suggested that large cyclic $[4n]$ annulenes might be stabilized if the π orbitals were twisted gradually around a Möbius strip. This concept is illustrated by the diagrams labeled Hückel, which is a destabilized $[4n]$ system, in contrast to the Möbius model, which is a stabilized $[4n]$ system.³⁶⁸ Zimmerman generalized this idea and applied the “Hückel–Möbius concept” to the analysis of ground-state systems [e.g., barrelene (**135**)].³⁶⁹ In 1998, a computational reinterpretation of existing experimental evidence for $(\text{CH})_9^+$ as a Möbius aromatic cyclic annulene with $4n$ π -electrons was reported.³⁷⁰ This reversal of

[4*n*]annulene antiaromaticity has been demonstrated by stacking rings into a superphane.³⁷¹ A superphane is a sixfold bridged cyclophane with all arene positions in the corresponding dimer taken up by ethylene spacers.³⁷² A recent computational study predicted several Möbius local minima for [12], [16], and [20]annulenes.³⁷³ A twisted [16]annulene has been prepared and calculations suggested it should show Möbius aromaticity.³⁷⁴ High-performance liquid chromatography (HPLC) separation of isomers gave **136**, and the authors concluded it is Möbius aromatic. The synthesis and study of molecules that demonstrate Möbius aromaticity continues to be an area of interest.³⁷⁵

2.L. OTHER AROMATIC COMPOUNDS

Three additional types of aromatic compounds must be noted.

1. *Mesoionic Compounds*:³⁷⁶ These compounds cannot be satisfactorily represented by Lewis structures not involving charge separation. Most of them contain five-membered rings. The most common are the *sydnones*, stable aromatic compounds that undergo aromatic substitution when R' is hydrogen.

2. *The Dianion of Squaric Acid*.³⁷⁷ The stability of this system is illustrated by the fact that the pK_1 of squaric acid³⁷⁸ is ~ 1.5 and the pK_2 is ~ 3.5 ,³⁷⁹ which means that even the second proton is given up much more readily than the proton of acetic acid.³⁸⁰ The analogous three-,³⁸¹ five-, and six-membered ring compounds are also known.³⁸²

Ed.* **1966**, *5*, 888.

3. *Homoaromatic Compounds*. When cyclooctatetraene is dissolved in concentrated H_2SO_4 , a proton adds to one of the double bonds to form the homotropylium ion (**137**).³⁸³ In this species, an aromatic sextet is spread over seven carbons, as in the tropylium ion. The eighth carbon is an sp^3 carbon and so cannot take part in the aromaticity. The NMR spectra show the presence of a diatropic ring current: H_b is found at $\delta = -0.3$; H_a at 5.1 δ ; H_1 and H_7 at 6.4 δ ; H_2 – H_6 at 8.5 δ . This ion is an example of a *homoaromatic* compound, generally defined as a compound that contains one or more³⁸⁴ sp^3 -hybridized carbon atoms in an otherwise conjugated cycle.³⁸⁵

In order for the orbitals to overlap most effectively so as to close a loop, the sp^3 atoms are forced to lie almost vertically above the plane of the aromatic atoms.³⁸⁶ In **137**, H_b is directly above the aromatic sextet, and so is shifted far upfield in the NMR. Virtually all homoaromatic compounds so far discovered are ions, and the existence of homoaromatic character in uncharged systems³⁸⁷ has been questioned.³⁸⁸ However, neutral homoaromaticity in some heterocyclic compounds has been observed by replacing CH_2 at C-2 in bicyclo[3.2.1]octa-3,6-diene with $\text{X} = \text{BH}$, AlH , Be , Mg , O , S , PH , NH (antihomoaromatic for $\text{X} = \text{BH}$, AlH , and Be ; nonhomoaromatic for $\text{X} = \text{O}$, S , NH , PH); replacement of CH at C-3 in bicyclo[3.2.1]octa-3,6-dien-2-yl anion with PH , S , NH , O (homoaromatic for $\text{X} = \text{S}$, PH , NH , O); and replacement at C-2 and C-3 with N and O (homoaromatic).³⁸⁹ Homoaromatic ions of 2 and 10 electrons are also known.

³⁸³ Haddon, R.C. *J. Am. Chem. Soc.* **1988**, *110*, 1108. See also, Childs, R.F.; Mulholland, D.L.; Varadarajan, A.; Yeroushalmi, S. *J. Org. Chem.* **1983**, *48*, 1431. See also, Alkorta, I.; Elguero, J.; Eckert-Maksić, M.; Maksić, Z.B. *Tetrahedron* **2004**, *60*, 2259.

³⁸⁴ If a compound contains two such atoms it is bishomoaromatic; if three, trishomoaromatic, and so on. For examples see Paquette, L.A. *Angew. Chem. Int. Ed.* **1978**, *17*, 106.

³⁸⁵ See Childs, R.F. *Acc. Chem. Res.* **1984**, *17*, 347; Paquette, L.A. *Angew. Chem. Int. Ed.* **1978**, *17*, 106; Garratt, P.J. *Aromaticity*, Wiley, NY, **1986**, pp. 5–45; and in Olah, G.A.; Schleyer, P.v.R. *Carbonium Ions*, Wiley, NY, Vol. 3, **1972**, the reviews by Story, P.R.; Clark Jr., B.C. 1007–1098, pp. 1073–1093.

³⁸⁶ Calculations show that only $\sim 60\%$ of the chemical shift difference between H_a and H_b is the result of the aromatic ring current, and that even H_a is shielded; it would appear at $\delta \sim 5.5$ without the ring current: Childs, R.F.; McGlinchey, M.J.; Varadarajan, A. *J. Am. Chem. Soc.* **1984**, *106*, 5974.

³⁸⁷ Examples of uncharged homoantiaromatic compounds have been claimed: See Scott, L.T.; Cooney, M.J.; Rogers, D.W.; Dejoongruang, K. *J. Am. Chem. Soc.* **1988**, *110*, 7244.

³⁸⁸ Houk, K.N.; Gandour, R.W.; Strozier, R.W.; Rondan, N.G.; Paquette, L.A. *J. Am. Chem. Soc.* **1979**, *101*, 6797; Paquette, L.A.; Snow, R.A.; Muthard, J.L.; Cynkowski, T. *J. Am. Chem. ³⁸⁹ Freeman, P.K. *J. Org. Chem.* **2005**, *70*, 1998. See the discussion for methano[10]annulenes, Caramori, G.F.; de Oliveira, K.T.; Galembeck, S.E.; Bultinck, P.; Constantino, M.G. *J. Org. Chem.* **2007**, *72*, 76.

New conceptual applications to 3D homoaromatic systems with cubane, dodecahedrane, and adamantane frameworks have been presented.³⁹⁰ This concept includes families of spherical homoaromatics with both two and eight mobile electrons. Each set has complete *spherical homoaromaticity*, that is, all the sp^2 carbon atoms in a highly symmetrical framework are separated by one or two sp^3 -hybridized atoms.

4. *Fullerenes*. Fullerenes are a family of aromatic hydrocarbons³⁹¹ based on the parent buckminsterfullerene (**138**; C_{60})³⁹² that have a variety of very interesting properties.³⁹³ Derivatives of **138** are sometimes called buckyballs. Molecular orbital calculations show that “fullerene aromaticity lies within 2 kcal mol^{-1} (8.4 kJ mol^{-1}) per carbon of a hypothetical ball of rolled up graphite.”³⁹⁴ Fullerenes may exhibit what is known as spherical aromaticity (3D aromaticity),³⁹⁵ and the *Hückel rule* cannot be used for spherical systems (e.g., fullerenes). The $2(n + 1)^2$ rule was proposed by Hirsch et al.,³⁹⁶ as the 3D analogue of the $4n + 2$ rule for planar systems proposed by Hückel.³⁹⁷ Heterofullerenes are also known.³⁹⁸

Buckybowls constitute another class of polynuclear aromatic hydrocarbons, and they are essentially fragments of **138**. Corannulene (**139**)³⁹⁹ (also called 5-circulene), for example, is the simplest curved-surface hydrocarbon possessing a carbon framework that be identified with the buckminsterfullerene surface. It has been synthesized by Scott, et al.³⁹⁹ and several other groups.⁴⁰⁰ Corannulene is a flexible molecule, with a bowl–bowl inversion barrier of $\sim 10\text{--}11 \text{ kcal mol}^{-1}$

(41.8–46.0 kJ mol⁻¹).⁴⁰¹ Benzocorannulenes are known,⁴⁰² and other bowl-shaped hydrocarbons include acenaphtho[3,2,1,8-*ijklm*]diindeno[4,3,2,1-*cdef*-1',2',3',4'*pqra*]triphenylene.⁴⁰³ The inversion barrier to buckybowl inversion has been lowered by such benzannulation of the rim.⁴⁰⁴ Other semibuckminsterfullerenes include C_{2v}-C₃₀H₁₂ and C₃-C₃₀H₁₂.³⁹⁹ Larger fullerenes include C₆₀, C₈₀, C₈₄, and fullerenes are known that contain an endohedral metal (e.g., scandium or even Sc₃N).⁴⁰⁵ Synthetic methods often generate mixtures of fullerenes that must be separated, as in the report of new methods for separating C₈₄-fullerenes.⁴⁰⁶ A homofullerene has been prepared,⁴⁰⁷ and the azaaceptanidenide anion, which is a bowl-shaped heterocycle, has been prepared.⁴⁰⁸

2.M. HYPERCONJUGATION

Conjugation in molecules (e.g., 1,3-butadiene and benzene) was well known to organic chemists in the 19th century. For example, it became understood that one could view 1,3-butadiene as two ethylene units. The overlap of the end *p* orbitals of the two ethylenes that are to be attached leads to conjugation, which in turn leads to a lowering of the energy of the system, a change in geometry in several respects, and most obviously, to changes in chemical and physical properties of the molecule. In this case, two *p* orbitals overlap. Mulliken suggested that if one has a sigma orbital overlapping with a *p* orbital, then one has “hyperconjugation.” Qualitatively hyperconjugation is similar to conjugation, but smaller. When a methyl group is attached to ethylene, for example, there is a shift of the UV absorption spectrum to longer wavelength, an increase in the reactivity of the molecule, and a lowering of energy, similar to the changes that occur in the ethylene to butadiene case, but to a lesser extent. Hyperconjugation shows the same effects, but to a lesser amount, because the sigma orbital lies at a lower energy than the π orbital. Hence the electrons delocalize out of the sigma orbital in hyperconjugation to a lesser extent than from a π orbital in conjugation. The term hyperconjugation therefore arises from the hyperconjugative forms that make small but definite contributions to the ground state of a molecule.⁴⁰⁹

Another delocalization phenomenon has been discussed that involves σ electrons.⁴¹⁰ Baker and Nathan⁴¹¹ observed that the rates of reaction of p-substituted benzyl bromides with pyridine (see Reaction **10-31**) were opposite from the results expected from electron release. That is, the methyl-substituted compound reacted fastest and the tert-butyl substituted compound reacted slowest. This appeared to be an anomalous electron-release pattern for alkyl groups because the field effect predicted the order of electron release for simple alkyl groups connected to an unsaturated system should be tert-butyl > isopropyl > ethyl > methyl. At least one hydrogen atom should be attached to the α -carbon that is connected to the sp^2 carbon for the Baker–Nathan effect. The Baker–Nathan effect has clouded the issue because some interpreted that it indicates hyperconjugation occurs with hydrogen and a double bond, but either did not occur or occurred to a very small amount with carbon. In the 1930s, Baker and Nathan did not have the tools to experimentally or theoretically understand hyperconjugation to any great extent. Those chemists looked for lowering of energy that could be detected, but these experiments do not necessarily help to explain hyperconjugation. Indeed, it is now known that the Baker–Nathan effect is a result of changes in solvation energy⁴¹² and has very little to do with hyperconjugation. It was recently reported that hyperconjugation is an important factor determining alkane C—H bond dissociation energies.⁴¹³ In certain instances where the Baker–Nathan effect was found to apply in solution, the order was completely reversed in the gas phase.⁴¹⁴ Since the molecular structures are unchanged in going from the gas phase into solution, it appears that each alkyl group is solvated to a different extent.⁴¹⁵ However, this only demonstrates that the Baker–Nathan effect is not the same as hyperconjugation. The structural changes that occur upon hyperconjugation can be determined from quantum mechanics and from experiment. Such changes can be qualitatively predicted by looking at the resonance structures involved.

Hyperconjugation is probably important for carbocations, as well as for free radicals⁴¹⁶ and for excited states of molecules.⁴¹⁷ In free radicals and carbocations, the canonical forms display no more charge separation than the main form. Muller and Mulliken call this *isovalent hyperconjugation*.

Apart from contributions to aromaticity, hyperconjugation has been used to explain the stability of intermediates (e.g., carbocations, see Chapter 5 for an introduction to carbocations). It was stated that C—C hyperconjugation is most important in stabilizing carbocations when the C—C bond(s) involved have more than 75% *p* character.⁴¹⁸ This effect can be illustrated by a typical case (e.g., carbocation **140**), where hyperconjugation is invoked to explain the relative stability of the ion as attached groups are varied. If the

orbitals of an adjacent C—H bond align with the empty orbital of the positive center; a canonical form can be

drawn by electron donation to C^+ to form a canonical form that is formally an alkene and H^+ . Note that the H in **140** could be any atom and C could be any sp^2 -hybridized atom and hyperconjugation would still occur. The key part is that a σ -bond overlaps a π -bond. For **140**, an alkene and a closely bound proton constitute a canonical form that helps stabilize the carbocation. Each of the three methyl hydrogen atoms in **140** can contribute to the hyperconjugative stabilization. In other words, resonance contributors involving the C—H bonds represent the bond elongation due to hyperconjugation, and provide stabilization of a carbocation.⁴¹⁹ To determine whether hyperconjugation is important in a given situation using molecular modeling, one must ask if the localized model is adequate for that situation at the particular level of precision, or whether the model must be corrected by including some delocalization.⁴²⁰ To a first approximation, delocalization can be neglected, but it is needed for better approximations. The effect of the alkene canonical form on **140** is that the electrons in the C—H bond are closer to the carbon than if hyperconjugation did not contribute at all.

In neutral molecules, the structural elements noted above should be present for hyperconjugation. There is usually at least one sp^2 -hybridized atom, usually carbon, but for hyperconjugation in general, all that is needed is a σ -bond. Resonating structures due to hyperconjugation may be written involving “no bonds” between the alpha carbon and hydrogen atoms, as shown below for propene.

Contributions of this type are seen by a comparison of the X-ray data for **141** and **142** with the calculated data (MM40). The bond length for bond *a* in **141** is 1.571 Å by analysis of the X-ray data, but analysis by MM40 calculations gave a value of 1.565 Å.⁴²¹ Similar analysis of bond *a* in **142** gave an experimental value of 1.627 Å, but MM40 calculations gave a value of 1.589 Å. The calculated values are shorter than the actual values. When hyperconjugation was included in the MM4 calculations, the calculated values were 1.574 Å for **141** and 1.623 Å for **142**.⁴²¹ The hyperconjugative stretching effect was calculated to be 0.009 Å for **141** and 0.034 Å for **142**. This work suggests that hyperconjugation is actually a bond stretching effect,⁴²¹ and it has been represented as resonance contributors several times in this

chapter. If the bond elongation found in propene, due to hyperconjugation, is represented as the canonical forms shown for **143**, the charge separation illustrates bond elongation. In a different example using toluene, there is evidence that the main interaction between methyl groups and the ring system in the positive ions of aromatic hydrocarbons is due to hyperconjugation rather than an inductive effect.⁴²²

There is evidence that bond length effects were the result of the *s* character of the saturated carbon rather than of neutral hyperconjugation.⁴²³ These experimental results seem to follow from hyperconjugation in the ground states of neutral molecules, and there is evidence in favor of hyperconjugation.⁴²⁴ Indeed, hyperconjugation appears to operate for both carbon and hydrogen in various systems (supported by quantum mechanics).⁴²⁵ These works tie together experimental and computational results into a unified picture that supports hyperconjugation.^{424,425} A study of the one-bond coupling constants for the aromatic system **144**

appears to provide structural evidence for hyperconjugation in a neutral ground state.⁴²⁶ Hyperconjugation in the ground state of neutral molecules has been called *sacrificial hyperconjugation* by Muller and Mulliken.⁴²⁷

Another way to view this phenomenon is to say that electron release is permitted by a mechanism that is essentially a type of tautomeric effect (Sec. 2.N). Dewar suggested that the delocalization of electrons of single bonds (hyperconjugation) and of p or π electrons (conjugation) should be included as part of the electronic description only if the localized bond picture fails.⁴²⁸ This result is a good first approximation, but modern molecular mechanics allows a much better analysis.

Hyperconjugation has been invoked to explain various aspects of aromaticity, as utilized early in this chapter. It is known that 5,5-disubstituted cyclopentadienes, where the substituents are electropositive groups, show enhanced cyclic conjugation in comparison with cyclopentadiene itself.⁴²⁹ 5,5-Distannylcyclopentadiene, for example, was found to be nearly as aromatic as furan. This is explained by hyperconjugative electron donation by the substituents, resulting in a partially anionic ring.⁴²⁴ Another effect is the so-called C*-aromaticity, which is a

hyperconjugative effect found in small disubstituted rings that leads to lowering of ring-strain energies for the unsaturated rings, particularly when electronegative substituents are attached.⁴³⁰

2.N. TAUTOMERISM⁴³¹

There is another topic that is important for an understanding of chemical bonding in organic compounds. For most compounds, all the molecules are represented by a single structure. But for many compounds, there is a mixture of two or more structurally distinct compounds that are in rapid equilibrium. When this phenomenon, called *tautomerism*,⁴³² exists, there is a rapid shift back and forth among the molecules. In most cases, it is a proton that shifts from one atom of a molecule to another. Mass spectrometry was used to study tautomerism,⁴³³ which takes several forms.

2.N.i Keto–Enol Tautomerism^{434–444}

A very common form of tautomerism is that between a carbonyl compound containing an α hydrogen and its enol form.⁴⁴⁵ Such equilibria are pH dependent, as in the case of 2-acetylcyclohexanone.⁴⁴⁶ In simple cases ($\text{R}^2 = \text{H}$, alkyl, OR, etc.), the equilibrium lies well to the left (Table 2.1). Examining the bond energies in Table 1.7 leads to an explanation for this fact. The keto form differs from the enol form by the presence of a C—H, a C—C, and a

TABLE 2.1 The Enol Content of Some Carbonyl Compounds

Compound	Enol Content (%)	Reference
Acetone	6×10^{-7}	435
PhCOCH ₃	1.1×10^{-6}	436
Cyclopentanone	1×10^{-6}	437
CH ₃ CHO	6×10^{-5}	438
Cyclohexanone	4×10^{-5}	437
Butanal	5.5×10^{-4}	439
(CH ₃) ₂ CHCHO	1.4×10^{-2}	439,440
Ph ₂ CHCHO	9.1	441
CH ₃ COOEt	No enol found ^a	437
CH ₃ COCH ₂ COOEt	8.4	442
CH ₃ COCH ₂ COCH ₃	80	353
PhCOCH ₂ COCH ₃	89.2	437
EtOOCCH ₂ COOEt	7.7×10^{-3}	437
N≡CCH ₂ COOEt	2.5×10^{-1}	437
Indane-1-one	3.3×10^{-8}	443
Malonamide	No enol found	444

^aLess than 1 part in 10 million.

C=O bond, whereas the enol has a C=C, a C—O, and an O—H bond. The approximate sum of the first three is 359 kcal mol⁻¹ (1500 kJ mol⁻¹) and of the second three is 347 kcal mol⁻¹ (1452 kJ mol⁻¹). The keto form is thermodynamically more stable by ~12 kcal mol⁻¹ (48 kJ mol⁻¹), and in most cases the enol forms cannot normally be isolated.⁴⁴⁷ In certain cases, however, a larger amount of the enol form is present, and it can even be the predominant form.⁴⁴⁸ There are three main types of the more stable enols:⁴⁴⁹

1. Molecules in which the enolic double bond is in conjugation with another double bond. Some of these are shown in Table 2.1. Carboxylic esters have a much smaller enol content than ketones, for example. In molecules like acetoacetic ester (**145**), the enol is also stabilized by internal hydrogen bonding, which is unavailable to the keto form:

Analysis of acetoacetamide by gas electron diffraction shows that it exists as a mixture of 63% enol tautomer and 37% diketo form at 74°C.⁴⁵⁰ There is a discussion of electron delocalization with respect to amides.⁴⁵¹

⁴⁴⁷ For reviews on the generation of unstable enols, see Kresge, A.J. *Pure Appl. Chem.* **1991**, 63, 213; Capon, B. in Rappoport, Z. *The Chemistry of Enols*, Wiley, NY, **1990**, pp. 307–322.

⁴⁴⁸ For reviews of stable enols, see Kresge, A.J. *Acc. Chem. Res.* **1990**, 23, 43; Hart, H.; Rappoport, Z.; Biali, S.E. in Rappoport, Z. *The Chemistry of Enols*, Wiley, NY, **1990**, pp. 481–589; Hart, H. *Chem. Rev.* **1979**, 79, 515; Hart, H.; Sasaoka, M. *J. Chem. Educ.* **1980**, 57, 685.

⁴⁴⁹ For some examples of other types, see Pratt, D.V.; Hopkins, P.B. *J. Am. Chem. Soc.* **1987**, 109, 5553; Nadler, E. B.; Rappoport, Z.; Arad, D.; Apeloig, Y. *J. Am. Chem. Soc.* **1987**, 109, 7873.

⁴⁵⁰ Belova, N.V.; Girichev, G.V.; Shlykov, S.A.; Oberhammer, H. *J. Org. Chem.* **2006**, 71, 5298.

⁴⁵¹ Mujika, J.I.; Matxain, J.M.; Eriksson, L.A.; Lopez, X. *Chem. Eur. J.* **2006**, 12, 7215; Kemnitz, C.R.; Loewen, M.J. *J. Am. Chem. Soc.* **2007**, 129, 2521.

2. Molecules that contain two or three bulky aryl groups.⁴⁵² An example is 2,2-dimesitylethenol (**146**), where the keto content at equilibrium is only 5%.⁴⁵³ In cases such as this, steric hindrance (Sec. 4.Q.iv) destabilizes the keto form. In **146**, the two aryl groups are $\sim 120^\circ$ apart, but in **147** they must move closer together ($\sim 109.5^\circ$). Such compounds are often called *Fuson-type enols*.⁴⁵⁴ There is one example of an amide with a bulky aryl group [*N*-methyl bis(2,4,6-triisopropylphenyl)acetamide] that has a measurable enol content, in sharp contrast to most amides.⁴⁵⁵

3. Highly fluorinated enols (e.g., **148**).⁴⁵⁶

In this case, the enol form is not more stable than the keto form (**149**). The enol form is less stable, and converts to the keto form upon prolonged heating. It can, however, be kept at room temperature for long periods of time because the tautomerization Reaction (12-3) is very slow, owing to the electron-withdrawing power of the fluorines.

Frequently, when the enol content is high, both forms can be isolated. The pure keto form of acetoacetic ester melts at -39°C , while the enol is a liquid even at -78°C . Each can be kept at room temperature for days if catalysts, (e.g., acids or bases) are rigorously excluded.⁴⁵⁷ Even the simplest enol, vinyl alcohol ($\text{CH}_2=\text{CHOH}$), has been prepared in the gas phase at room temperature, where it has a half-life of ~ 30 min.⁴⁵⁸ The enol $\text{Me}_2\text{C}=\text{CCHOH}$ is indefinitely stable in the solid state at -78°C and has a half-life of ~ 24 h in the liquid state at 25°C .⁴⁵⁹ When both forms cannot be isolated, the extent of enolization is often measured by NMR.⁴⁶⁰

⁴⁶⁰ Cravero, R.M.; González-Sierra, M.; Olivieri, A.C. *J. Chem. Soc. Perkin Trans. 2* **1993**, 1067.

The extent of enolization⁴⁶¹ is greatly affected by solvent,⁴⁶² concentration, and temperature. Lactone enols, for example, have been shown to be stable in the gas phase, but unstable in solution.⁴⁶³ Another example is acetoacetic ester, which has an enol content of 0.4% in water and 19.8% in toluene.⁴⁶⁴ In this case, water reduces the enol concentration by hydrogen bonding with the carbonyl, making this group less available for internal hydrogen bonding. The effect of temperature is clear from the enol content of pentan-2,4-dione ($\text{CH}_3\text{COCH}_2\text{COCH}_3$), which was found to be 95, 68, and 44%, respectively, at 22, 180, and 275 °C.⁴⁶⁵ When a strong base is present, both the enol and the keto form can lose a proton. The resulting anion (the *enolate ion*) is the same in both cases. Since **150** and **151** differ only in placement of electrons, *they are not tautomers, but canonical forms*. The true structure of the enolate ion is a hybrid of **150** and **151** although **151** contributes more, since in this form the negative charge is on the more electronegative atom.

2.N.ii Other Proton-Shift Tautomerism

The valence tautomerism is discussed of a proton from either tautomer is the same because of resonance. Some examples follows:⁴⁶⁶

1. Phenol–Keto Tautomerism.⁴⁶⁷

For most simple phenols, this equilibrium lies well to the side of the phenol, which is aromatic. For phenol itself, there is no evidence for the existence of the keto form.⁴⁶⁸ However, the keto form becomes important and may predominate: (1) where certain groups, (e.g., a second OH group or an N=O group), are present;⁴⁶⁹ (2) in systems of fused aromatic rings⁴⁷⁰; (3) in heterocyclic systems. In many heterocyclic compounds in the liquid phase or in solution, the keto form is more stable,⁴⁷¹ although in the vapor phase the positions of many of these equilibria are reversed.⁴⁷² For example, **152** is the only form detectable in ethanolic solution in the equilibrium between 4-pyridone (**152**) and 4-hydroxypyridine (**153**), while **153** predominates in the vapor phase.⁴⁷² In other heterocycles, the hydroxy-form predominates. 2-Hydroxypyridone (**154**) and pyridone-2-thiol (**156**)⁴⁷³ are in equilibrium with their tautomers, 2-pyridone (**155**) and pyridine-2-thione (**157**), respectively. In both cases, the most stable form is the hydroxy or thiol tautomer, **154** and **156**.⁴⁷⁴

2. Nitroso–Oxime Tautomerism.

The equilibrium shown for formaldehyde oxime and nitrosomethane illustrates this process.⁴⁷⁵ In molecules where the products are stable, the equilibrium lies far to the right, and as a rule nitroso compounds are stable only when there is not a hydrogen.

3. Aliphatic Nitro Compounds Are in Equilibrium with Aci Forms.

The nitro form is much more stable than the aci form, in sharp contrast to the parallel case of nitroso-oxime tautomerism, undoubtedly because the nitro form has resonance not found in the nitroso case. Aci forms of nitro compounds are also called nitronic acids and azinic acids.

4. Imine–Enamine Tautomerism.⁴⁷⁶

Enamines are normally stable only when no hydrogen is attached to the nitrogen ($\text{R}_2\text{C}=\text{CR}-\text{NR}_2$). Otherwise, the imine form predominates.⁴⁷⁷ The energy of various imine–enamine tautomers has been calculated.⁴⁷⁸ In the case of 6-amino-fulvene-1-aldimines, tautomerism was observed in the solid state, as well as in solution.⁴⁷⁹ Porphyrins and porphycenes also undergo this type of tautomerism, and the two tautomers may be imaged using single-molecule spectroscopy.⁴⁸⁰

5. Ring–Chain Tautomerism. Ring–chain tautomerism⁴⁸¹ occurs in sugars (aldehyde vs the pyranose or furanose structures), and in γ -oxocarboxylic acids.⁴⁸² In benzamide carbaldehyde, (**159**), whose ring-chain tautomer is **158**, the equilibrium favors the cyclic form (**159**).⁴⁸³ Similarly, benzoic acid 2-carbaldehyde (**160**) exists largely as the cyclic form (**161**).⁴⁸⁴ In these latter cases, and in many others, this tautomerism influences chemical reactivity. Conversion of **160** to an ester, for example, is difficult since most standard methods lead to the OR derivative of **161** rather than the ester of **160**. Ring–chain tautomerism also occurs in spirooxathianes,⁴⁸⁵ in decahydroquinazolines (e.g. **162** and **163**),⁴⁸⁶ in other 1,3-heterocycles,⁴⁸⁷ and in 2-ferrocenyl-2,4-dihydro-1H-3,1-benzoxazine derivatives.⁴⁸⁸

Bonding Weaker Than Covalent

The discussions in Chapters 1 and 2 focused on the structure of molecules as an aggregate of atoms in a distinct 3D arrangement, held together by bonds with energies on the order of 50–100 kcal mol⁻¹ (200–400 kJ mol⁻¹). There are also very weak attractive forces *between* molecules, on the order of a few tenths of a kilocalorie per mole. These forces, called *van der Waals forces*,¹ are caused by electrostatic attractions, such as those between dipole and dipole, or induced dipole and induced dipole, and are responsible for liquefaction of gases at sufficiently low temperatures. The bonding discussed in this chapter has energies on the order of 2–10 kcal mol⁻¹ (9–40 kJ/mol⁻¹), which is intermediate between the bond orders given above, and produces clusters of molecules. Compounds will also be discussed in which portions of molecules are held together without any attractive forces at all.

3.A. HYDROGEN BONDING²

A *hydrogen bond* is less than a covalent bond, but it is an attractive force between a functional group A—H and an atom or group of atoms B in the same or a different molecule.³ With exceptions to be noted later, hydrogen bonds are *assumed to form only when A is oxygen, nitrogen, or fluorine and when B is oxygen, nitrogen, or fluorine*.⁴ The ability of functional groups to act as hydrogen-bond acids and bases can be obtained from either equilibrium constants for 1:1 hydrogen bonding or overall hydrogen-bond constants.⁴ There are so-called unconventional hydrogen bonds, particularly with organometallic complexes

and transition metal or main group hydrides.⁵ This chapter will largely ignore such compounds. In normal hydrogen bonds, to oxygen or nitrogen, oxygen may be singly or doubly bonded and the nitrogen singly, doubly, or triply bonded. In structures, hydrogen bonds are usually represented by dotted or dashed lines, as shown in the following examples:

Hydrogen bonds can exist in solid⁶ and liquid phases, and in solution.⁷ The efficacy of many organic reactions that will be discussed in later chapters is due to the use of an aqueous media,⁸ which is due in part, to the hydrogen-bonding nature of such media.⁹ Even in the gas phase, compounds that form particularly strong hydrogen bonds may remain associated.¹⁰ Acetic acid, for example, exists in the gas phase as a dimer, except at very low pressures.¹¹ In the liquid phase and in solution, hydrogen bonds rapidly form and break. The mean lifetime of the $\text{NH}_3 \cdots \text{H}_2\text{O}$ bond is 2×10^{-12} s, for example.¹² Except for a few very strong hydrogen bonds¹³ (e.g., the $\text{FH} \cdots \text{F}^-$ bond) which has an energy of $\sim 50 \text{ kcal mol}^{-1}$ or 210 kJ mol^{-1} , the strongest hydrogen bonds are those connecting one carboxylic acid with another. The energies of these bonds are in the range of $6\text{--}8 \text{ kcal mol}^{-1}$ or $25\text{--}30 \text{ kJ mol}^{-1}$ (for carboxylic acids, this refers to the energy of each bond). In general, short contact hydrogen bonds between fluorine and HO or NH are rare.¹⁴ Other $\text{OH} \cdots \text{O}$ and $\text{NH} \cdots \text{N}$ bonds¹⁵ have energies of $3\text{--}6 \text{ kcal mol}^{-1}$ ($12\text{--}25 \text{ kJ mol}^{-1}$). The intramolecular $\text{O}=\text{H} \cdots \text{N}$ hydrogen bond in hydroxy-amines is also rather strong.¹⁶

To a first approximation, the strength of a hydrogen bond will increase with increasing acidity of $A-H$ ¹⁷ and basicity of B , but the parallel is far from exact.¹⁸ A quantitative measure of the strengths of hydrogen bonds has been established, involving the use of an α scale to represent hydrogen-bond donor acidities and a β scale for hydrogen-bond acceptor basicities.¹⁹ The use of the β scale, along with another parameter (ξ), allows hydrogen-bond basicities to be related to proton-transfer basicities (pK values).²⁰ A database has been developed to locate all possible occurrences of bimolecular cyclic hydrogen-bond motifs in the Cambridge Structural Database,²¹ and donor–acceptor, as well as polarity parameters, have been calculated for hydrogen-bonding solvents.²² Bickelhaupt and co-workers²² has stated that hydrogen bonds ($X-H \cdots Y$) have significant covalent interactions that stem from donor–acceptor orbital interactions between the lone-pair electrons of Y and the empty σ^* acceptor orbital of $X-H$, so they are not predominantly electrostatic phenomena.

When two compounds whose molecules form hydrogen bonds with each other are both dissolved in water, the hydrogen bond between the two molecules is usually greatly weakened or completely removed.²³ This finding means that the molecules generally form hydrogen bonds with the water molecules (intermolecular) rather than with each other (intramolecular), presumably because the water molecules are present in such great numbers. In amides, the oxygen atom is the preferred site of protonation or complexation with water.²⁴ In the case of dicarboxylic acids, arguments have been presented that there is little or no evidence for strong hydrogen bonding in aqueous solution,²⁵ although other studies concluded that strong, intramolecular hydrogen bonding can exist in aqueous acetone solutions (0.31 mole-fraction water) of hydrogen maleate and hydrogen *cis*-cyclohexane-1,2-dicarboxylate.²⁶

Many studies have been made of the geometry of hydrogen bonds,²⁷ and in most (though not all) cases the evidence shows that the hydrogen is on or near the straight line

formed by A and B.²⁸ This is true both in the solid state (where X-ray crystallography and neutron diffraction have been used to determine structures),²⁹ and in solution.³⁰ It is significant that the vast majority of intramolecular hydrogen bonding occurs where *six-membered rings* (counting the hydrogen as one of the six) can be formed, in which linearity of the hydrogen bond is geometrically favorable. Intramolecular hydrogen bonding is much rarer in five-membered rings, where linearity is usually not favored (although it is known). A novel nine-membered intramolecular hydrogen bond has been reported.³¹

In certain cases X-ray crystallography has shown that a single H—A can form simultaneous hydrogen bonds with two B atoms (*bifurcated* or *three-center hydrogen bonds*). An example is an adduct (**1**) formed from pentane-2,4-dione in its enol form (Sec. 2.N.i) and diethylamine. In **1**, the O—H hydrogen simultaneously bonds³² to an O and an N, where the N—H hydrogen forms a hydrogen bond with the O of another pentane-2,4-dione molecule.³³ On the other hand, the B atom (in this case oxygen) forms simultaneous hydrogen bonds with two A···H hydrogens in the adduct (**2**) formed from 1,8-biphenylenediol and hexamethylphosphoramide (HMPA),³⁴ Another such case is found in methyl hydrazine carboxylate (**3**).³⁵ Except for the special case of FH···F[−] bonds (see above), the hydrogen is not equidistant between A and B. For example, the O—H distance in ice is 0.97 Å, while the H···O distance is 1.79 Å.³⁶ A theoretical study of the vinyl alcohol–vinyl alcoholate system (i.e., an enol–enolate anion system) concluded the hydrogen bonding is strong but asymmetric.³⁷ The hydrogen bond in the enol of malonaldehyde, in organic solvents, is asymmetric with the hydrogen atom closer to the basic oxygen atom.³⁸ There is evidence, however, that symmetrical hydrogen bonds to carboxylates should be regarded as two-center rather than three-center hydrogen bonds since the criteria traditionally used to infer three-center hydrogen bonding are inadequate for carboxylates.³⁹ There is also an example of cooperative hydrogen bonding [O—H···C≡C—H···Ph] in crystalline 2-ethynyl-6,8-diphenyl-7*H*-benzocyclohepten-7-ol (**4**).⁴⁰ Related to this discussion is the work that showed the hydrogen bond radii for OH, NH, and acidic CH groups to be 0.60 ± 0.15 , 0.76 ± 0.15 , and 1.10 ± 0.20 Å, respectively.⁴¹

Hydrogen bonding has been detected in many ways, including measurements of dipole moments, solubility behavior, freezing-point lowering, and heats of mixing, but one important way is by the effect of the hydrogen bond on IR spectroscopy.⁴² The IR frequencies of functional groups (e.g., O—H or C=O) are shifted when the group is hydrogen bonded. Hydrogen bonding always moves the peak toward lower frequencies, for both the A—H and the B groups, though the shift is greater for the former. For example, a free OH group of an alcohol or phenol absorbs at $\sim 3590\text{--}3650\text{ cm}^{-1}$, and a hydrogen-bonded OH group is found $\sim 50\text{--}100\text{ cm}^{-1}$ lower.⁴³ In many cases, in dilute solution, there is partial hydrogen bonding, that is, some OH groups are free and some are hydrogen bonded. In such cases, two peaks appear.

Infrared spectroscopy can also distinguish between inter- and intramolecular hydrogen bonding, since intermolecular peaks are intensified by an increase in concentration while intramolecular peaks are unaffected. Other types of spectra that have been used for the detection of hydrogen bonding include Raman, electronic,⁴⁴ and NMR.⁴⁵ Since hydrogen bonding involves a rapid movement of protons from one atom to another, NMR records an average value that is often broadened. Hydrogen bonding can be detected because it usually produces a chemical shift to a lower field. For example, carboxylic acid–carboxylate systems arising from either mono- or diacids generally exhibit a downfield resonance (16–22 ppm), which indicates “strong” hydrogen bonding in anhydrous, aprotic solvents.⁴⁶ Hydrogen bonding changes with temperature and concentration, and comparison of spectra taken under different conditions also serves to detect and measure it. As with IR spectra, intramolecular hydrogen bonding in the NMR can be distinguished from intermolecular by its constancy when the concentration is varied. The spin–spin coupling constant across a hydrogen bond, obtained by NMR studies, has been shown to provide a “fingerprint” for hydrogen-bond type.⁴⁷ Indeed, the determination of $^1J_{\text{CH}}$ correlates with the strength of the hydrogen bonds formed by an alcohol.⁴⁸

Hydrogen bonds are important because of the effects they have on the properties of compounds, among them:

1. Intermolecular hydrogen bonding raises boiling points and frequently melting points.
2. If hydrogen bonding is possible between solute and solvent, this greatly increases solubility and often results in large or even infinite solubility where none would otherwise be expected.
3. Hydrogen bonding causes lack of ideality in gas and solution laws.
4. As previously mentioned, hydrogen bonding changes spectral absorption positions.
5. Hydrogen bonding, especially the intramolecular variety, changes many chemical properties. For example, it is responsible for the large amount of enol present in certain tautomeric equilibria (see Sec. 2.N). Also, by influencing the conformation of molecules (see Chapter 4), it often plays a significant role in determining reaction rates.⁴⁹ Hydrogen bonding is also important in maintaining the 3D structures of protein and nucleic acid molecules.

Besides oxygen, nitrogen, and fluorine, there is evidence that weaker hydrogen bonding exists in other systems.⁵⁰ Although many searches have been made for hydrogen bonding where A is carbon,⁵¹ only three types of C—H bonds have been found that are acidic enough to form weak hydrogen bonds.⁵² These are found in terminal alkynes ($\text{RC}\equiv\text{CH}$),⁵³ chloroform and some other halogenated alkanes, and HCN. Sterically unhindered C—H groups (CHCl_3 , CH_2Cl_2 , $\text{RC}\equiv\text{CH}$) form short contact hydrogen bonds with carbonyl acceptors, where there is a significant preference for coordination with the conventional carbonyl lone-pair direction.⁵⁴ Weak hydrogen bonds are formed by compounds containing S—H bonds.⁵⁵ There has been much speculation regarding other possibilities for B. There is evidence that Cl can form weak hydrogen bonds,⁵⁶ but Br and I form very weak bonds if at all.⁵⁷ However, the *ions* Cl^- , Br^- , and I^- form hydrogen bonds that are much stronger than those of the covalently bonded atoms.⁵⁸ As noted above, the $\text{FH}\cdots\text{F}^-$ bond is especially strong. In this case, the

hydrogen is equidistant from the fluorine atoms.⁵⁹ Similarly, a sulfur atom⁵⁵ can be the B component ($A \cdots B$) in weak hydrogen bonds,⁶⁰ but the ^-SH ion forms much stronger bonds.⁶¹ There are theoretical studies of weak hydrogen bonding.⁶² Hydrogen bonding has been directly observed (by NMR and IR) between a negatively charged carbon (see carbanions in Chapter 5) and an OH group in the same molecule.⁶³ Isocyanides ($R-N \equiv C^-$) constitute another type of molecule in which carbon is the B component that forms a rather strong hydrogen bond.⁶⁴ There is evidence that double and triple bonds, aromatic rings,⁶⁵ and even cyclopropane rings⁶⁶ may be the B component of hydrogen bonds, but these bonds are very weak. An interesting case is that of the *in*-bicyclo[4.4.4]-1-tetradecyl cation **5** (see out-in isomerism, Sec. 4.L The NMR and IR spectra show that the actual structure of this ion is **6**, in which both the A and the B component of the hydrogen bond is a carbon.⁶⁷ These are sometimes called 3-center-2-electron $C-H-C$ bonds.⁶⁸ A technique called generalized population analysis has been developed to study this type of multicenter bonding.⁶⁹

A weak ($\sim 1.5 \text{ kcal mol}^{-1}$, 6.3 kJ mol^{-1}) and rare $C-H \cdots O=C$ hydrogen bond has been reported in a class of compounds known as a [6]semirubin (a dipyrinone).⁷⁰ There is also evidence for a $C-H \cdots N/CH \cdots OH$ bond in the crystal structures of α,β -unsaturated ketones carrying a terminal pyridine subunit,⁷¹ and for $R_3N^+-C-H \cdots O=C$ hydrogen bonding.⁷²

Deuterium also forms hydrogen bonds; in some systems these seem to be stronger than the corresponding hydrogen bonds; in others, weaker.⁷³ Weak hydrogen bonds can be formed between a π bond (from both alkenes and aromatic compounds) and an appropriate hydrogen. For example, IR data in dilute dichloromethane suggests that the predominant

⁵⁹ In a few cases, the presence of an unsymmetrical cation causes the hydrogen to be closer to one fluorine than to the other: Williams, J.M.; Schneemeyer, L.F. *J. Am. Chem. Soc.* **1973**, 95, 5780.

The π electrons of aromatic rings can interact with charged species, yielding strong cation– π interactions that are dominated by electrostatic and polarization effects.⁸¹ An interaction with CH units is also possible. For CH– π interactions in both alkyl- and aryl-based model systems, dispersion effects dominate the interaction, but the electrostatics term is also relevant for aryl CH– π interactions.⁸²

Detection of π – π interactions has largely relied on NMR based techniques (e.g., chemical shifts variations),⁸³ and Nuclear Overhauser Effect Spectroscopy (NOESY) or Rotating-Frame NOE Spectroscopy (ROESY).⁸⁴ Diffusion-ordered NMR spectroscopy (DOSY) has also been used to detect π – π stacked complexes.⁸⁵

3.C. ADDITION COMPOUNDS

When the reaction of two compounds results in a product that contains all the mass of the two compounds, the product is called an *addition compound*. There are several kinds. The remainder of this chapter will discuss addition compounds in which the molecules of the starting materials remain more or less intact and weak bonds hold two or more molecules together. There are four broad classes: electron donor–acceptor complexes, complexes formed by crown ethers and similar compounds, inclusion compounds, and catenanes.

3.C.i. Electron Donor–Acceptor Complexes⁸⁶

In *electron donor–acceptor (EDA) complexes*,⁸⁷ there is always a donor and an acceptor molecule. The donor may donate an unshared pair (an n donor) or a pair of electrons in a π orbital of a double bond or aromatic system (a π donor). The electronic spectrum constitutes a good test for the presence of an EDA complex. These complexes generally exhibit a spectrum (called a *charge-transfer spectrum*) that is not the same as the sum of the spectra of the two individual molecules.⁸⁸ Because the first excited state of the

⁸⁷ These have often been called *charge-transfer complexes*, but this term implies that the bonding involves charge transfer, which is not always the case, so that the more neutral name EDA complex is preferable. See Mulliken, R.S.; Person, W.B. *J. Am. Chem. Soc.* **1969**, *91*, 3409.

⁸⁸ Also see Bentley, M.D.; Dewar, M.J.S. *Tetrahedron Lett.* **1967**, 5043.

complex is relatively close in energy to the ground state, there is usually a peak in the visible or near-UV region, and EDA complexes are often colored. Many EDA complexes are unstable and exist only in solutions in equilibrium with their components, but others are stable solids. In most EDA complexes, the donor and acceptor molecules are present in an integral ratio, most often 1:1, but complexes with nonintegral ratios are also known. There are several types of acceptor molecules; complexes formed by two of them will be discussed.

1. *Complexes in which the Acceptor is a Metal Ion and the Donor is an Alkene or an Aromatic Ring.*

The n donors do not give EDA complexes with metal ions, but form covalent bonds instead).⁸⁹ Many metal ions form complexes with alkenes, dienes (usually conjugated, but not always), alkynes, and aromatic rings that are often stable solids. The donor (or ligand) molecules in these complexes are classified by the prefix *hapto*⁹⁰ and/or the descriptor η^n (the Greek letter *eta*), where n indicates how many atoms the ligand uses to bond with the metal.⁹¹

The generally accepted picture of the bonding in these complexes,⁹² first proposed by Dewar,⁹³ can be illustrated by the ethylene complex with silver (**9**), in which the alkene unit forms an η^2 -complex with the silver ion (the alkene functions as a 2-electron donating ligand to the metal). There is evidence of π -complexation of Na^+ by $\text{C}=\text{C}$.⁹⁴ In the case of the silver complex, the bond is not from one atom of the $\text{C}=\text{C}$ unit to the silver ion, but from the π center (two electrons are transferred from the alkene to the metal ion). Ethene has two π -electrons and is a dihapto or η^2 ligand, as are other simple alkenes. Similarly, benzene has six π electrons and is a hexahapto or η^6 ligand. Ferrocene (**10**) is an

⁸⁹ See Collman, J.P.; Hegedus, L.S.; Norton, J.R.; Finke, R.G. *Principles and Applications of Organotransition Metal Chemistry*, 2nd ed, University Science Books, Mill Valley, CA, **1987**; Alper, H. *Transition Metal Organometallics in Organic Synthesis*, 2 Vols., Academic Press, NY, **1976**, **1978**. For general reviews, see Churchill, M.R.; Mason, R. *Adv. Organomet. Chem.* **1967**, 5, 93; Cais, M. in Patai, S. *The Chemistry of Alkenes*, Vol. 1, Wiley, NY, **1964**, pp. 335–385; Nakamura, A. *J. Organomet. Chem.* **1990**, 400, 35; Bennett, M.A.; Schwemlein, H.P. *Angew. Chem. Int. Ed.* **1989**, 28, 1296; metals-pentadienyl ions, Powell, P. *Adv. Organomet. Chem.* **1986**, 26, 125; complexes of main group metals. For a list of review articles on this subject, see Bruce, M.I. *Adv. Organomet. Chem.* **1972**, 10, 273, pp. 317–321.

⁹⁰ For a discussion of how this system originated, see Cotton, F.A. *J. Organomet. Chem.* **1975**, 100, 29.

⁹¹ Another prefix used for complexes is μ (mu), which indicates that the ligand bridges two metal atoms.

⁹² See Pearson, A.J. *Metallo-organic Chemistry* Wiley, NY, **1985**; Ittel, S.D.; Ibers, J.A. *Adv. Organomet. Chem.* **1976**, 14, 33; Hartley, F.R. *Chem. Rev.* **1973**, 73, 163; *Angew. Chem. Int. Ed.* **1972**, 11, 596.

⁹⁴ Hu, J.; Gokel, G.W.; Barbour, L.J. *Chem. Commun.* **2001**, 1858.

example of a *metallocene*, with two cyclopentadienyl ligands (each is a five-electron donor or an η^5 ligand), and ferrocene is properly called bis(η^5 -cyclopentadienyl)iron(II). This system can be extended to compounds in which only a single σ bond connects the organic group to the metal, (e.g., $\text{C}_6\text{H}_5\text{—Li}$ a monohapto or η^1 ligand), and to complexes in which the organic group is an ion, (π -allyl complexes, e.g., **11**), in which the allyl ligand is trihapto or η^3 . Note that in a compound such as allyllithium, where a σ bond connects the carbon to the metal, the allyl group is referred to as monohapto or η^1 .

As mentioned, benzene is an η^6 ligand that forms complexes with silver and other metals.⁹⁵ When the metal involved has a coordination number > 1 , more than one donor molecule (ligand) participates. The CO group is a common ligand (a two-electron donating or η^2 ligand), and in metal complexes the CO group is classified as a metal carbonyl. Benzenechromium tricarbonyl (**12**) is a stable compound⁹⁶ that illustrates both benzene and carbonyl ligands. Three arrows are shown to represent the six-electron donation (an η^6 ligand), but the accompanying model gives a clearer picture of the bonding. Cyclooctatetraene is an eight-electron donating or η^8 ligand that also forms complexes with metals. Metallocenes (e.g., **10**) may be considered a special case of this type of complex, although the bonding in metallocenes is much stronger.

⁹⁵ See Zeiss, H.; Wheatley, P.J.; Winkler, H.J.S. *Benzenoid Metal Complexes*, Ronald Press, NY, **1966**.

⁹⁶ Nicholls, B.; Whiting, M.C. *J. Chem. Soc.* **1959**, 551. For reviews of arene-transition metal complexes, see Uemura, M. *Adv. Met.-Org. Chem.* **1991**, 2, 195; Silverthorn, W.E. *Adv. Organomet. Chem.* **1975**, 13, 47.

In a number of cases, alkenes that are too unstable to be isolated as discrete molecules have been isolated in the form of their metal complexes. An example is norbornadienone, which was isolated as its iron–tricarbonyl complex (**13**),⁹⁷ where the norbornadiene unit is an η^4 ligand, and each of the carbonyl units are η^2 ligands. The free dienone spontaneously decomposes to carbon monoxide and benzene (see Reaction 17–28).

2. Complexes in Which the Acceptor Is an Organic Molecule.

Picric acid (2,4,6-trinitrophenol) and similar polynitro compounds are the most important of these.⁹⁸ Picric acid forms addition compounds with many aromatic hydrocarbons, aromatic amines, aliphatic amines, alkenes, and other compounds. These addition compounds are usually solids that have definite melting points and have been used as derivatives of the compounds in question. They are called picrates, and are addition compounds and not salts of picric acids. Unfortunately, the actual salts of picric acid are also called picrates. Similar complexes are formed between phenols and quinones (quinhydrone).⁹⁹ Alkenes that contain electron-withdrawing substituents also act as acceptor molecules, as do carbon tetrahalides¹⁰⁰ and certain anhydrides.¹⁰¹ A particularly strong alkene acceptor is tetracyanoethylene.¹⁰²

The bonding in these cases is more difficult to explain than in the previous case, and indeed no truly satisfactory explanation is available.¹⁰³ The difficulty is that the donor has a pair of electrons to contribute (both n donors and π donors are found here), but the acceptor does not have a vacant orbital. Simple attraction of the dipole–induced-dipole type accounts for some of the bonding,¹⁰⁴ but is too weak to explain the bonding in all cases.¹⁰⁵ Nitromethane, with about the same dipole moment as nitrobenzene, is an example of a molecule that forms much weaker complexes. Some other type of bonding clearly must also be present in many EDA complexes. The exact nature of this bonding, called *charge-transfer bonding*, is not well understood, but it presumably involves some kind of donor–acceptor interaction.

3.C.ii Crown Ether Complexes and Cryptates¹⁰⁶

Crown ethers are large-ring compounds that contain several oxygen atoms, usually in a regular pattern. Examples are 12-crown-4 (**14**; where 12 is the size of the ring and 4 represents the number of coordinating atoms, here oxygen),¹⁰⁷ dicyclohexano-18-crown-6 (**15**), and 15-crown-5 (**16**). These compounds have the property¹⁰⁸ of forming complexes with positive ions, generally metallic ions (though not usually ions of transition metals) or ammonium and substituted ammonium ions.¹⁰⁹ The crown ether is called the *host* and the ion is the *guest*. In most cases, the ions are held tightly in the center of the cavity.¹¹⁰ Each crown ether binds different ions, depending on the size of the cavity. For example, **14** binds Li^{+111} , but not K^{+} ,¹¹² while **15** binds K^{+} but not Li^{+} .¹¹³ Similarly, **15** binds Hg^{2+} , but not Cd^{2+} or Zn^{2+} , and Sr^{2+} but not Ca^{2+} .¹¹⁴ 18-Crown-5 binds alkali and ammonium cations >1000 times weaker than 18-crown-6, presumably because the larger 18-crown-6 cavity involves more hydrogen bonds.¹¹⁵ The complexes can frequently be prepared as well-defined sharp-melting solids.

Apart from their obvious utility in separating mixtures of cations,¹¹⁶ crown ethers are widely used in organic synthesis (see the discussion on Sec. 10.G.v). Chiral crown ethers have been used for the resolution of racemic mixtures (Sec. 4.A). Although crown ethers are most frequently used to complex cations, amines, phenols, and other neutral molecules have also been complexed¹¹⁷ (see Sec. 4.L for the complexing of anions).¹¹⁸ Macrocycles containing nitrogen (azacrown ethers) or sulfur atoms (thiacrown ethers)¹¹⁹ (e.g., **17** and **18**),¹²⁰ have complexing properties similar to other crown ethers, as do mixed-heteroatom crown ethers (e.g., **19**,¹²¹ **20**,¹²² or **21**¹²³).

Bicyclic molecules (e.g., **20**) can surround the enclosed ion in 3D, binding it even more tightly than the monocyclic crown ethers. Bicyclics and cycles of higher order¹²⁴ are called *cryptands* and the complexes formed are called *cryptates* (monocyclic compounds are sometimes called cryptands). When the molecule contains a cavity that can accommodate a guest molecule, usually through hydrogen-bonding interactions,

¹¹⁶ Crown ethers have been used to separate isotopes of cations, (e.g., ⁴⁴Ca from ⁴⁰Ca). For a review, see Heumann, K.G. *Top. Curr. Chem.* **1985**, 127, 77.

it is sometimes called a *cavitand*.¹²⁵ The tricyclic cryptand **21** has 10 binding sites and a spherical cavity.⁹⁸ Another molecule with a spherical cavity (though not a cryptand) is **22**, which complexes Li^+ and Na^+ (preferentially Na^+), but not K^+ , Mg^{2+} , or Ca^{2+} .¹²⁶ Molecules such as these, whose cavities can be occupied only by spherical entities, have been called *spherands*.⁸³ Other types are *calixarenes*¹²⁷ (e.g., **23**).¹²⁸ Spherand-type calixarenes are known.¹²⁹ There is significant hydrogen bonding involving the phenolic OH units in [4]calixarenes, but this diminishes as the size of the cavity increases in larger ring calixarenes.¹³⁰ There are also calix[6]arenes¹³¹ that have been shown to have conformational isomers (Sec. 4.O) in equilibrium (cone vs alternate) that can sometimes be isolated:¹³² calix[8]arenes,¹³³ azacalixarenes,¹³⁴ homooxacalixarenes,¹³⁵ and calix[9–20]arenes.¹³⁶ Note that substitution of the unoccupied “meta” positions immobilizes calix[4]arenes and the conformational mobility (Sec. 4.O.iv) in calix[8]arenes is substantially diminished.¹³⁷ Amide-bridged calix[4]arenes¹³⁸ calix[4]azulene,¹³⁹ and quinone-bridged calix[6]arenes.¹⁴⁰ are known, and diammoniumcalix[4]arene has been prepared.¹⁴¹ Enantiopure calix[4]resorcinarene derivatives are known,¹⁴² and water-soluble calix[4]arenes have been prepared.¹⁴³ There are also a variety of calix [*n*]crown ethers,¹⁴⁴ some of which are cryptands¹⁴⁵ and there is evidence for formation of a calix[4]arene-proton complex.¹⁴⁶

The bonding in these complexes is the result of ion-dipole attractions between the heteroatoms and the positive ions. The parameters of the host-guest interactions can sometimes be measured by NMR.¹⁵⁵

It has been implied that the ability of these host molecules to bind guests is often very specific, often linked to the hydrogen-bonding ability of the host,¹⁵⁶ enabling the host to pull just one molecule or ion out of a mixture. This is called *molecular recognition*.¹⁵⁷ In general, cryptands, with their well-defined 3D cavities, are better for this than monocyclic crown ethers or ether derivatives. An example is the host (**30**), which selectively binds the dication **31** ($n = 5$) rather than **31** ($n = 4$), and **31** ($n = 6$) rather than **31** ($n = 7$).¹⁵⁸ The host **32**, which is water-soluble, forms 1:1 complexes with neutral aromatic hydrocarbons (e.g., pyrene and fluoranthene), and even (though more weakly) with biphenyl and naphthalene, I is also capable of transporting them through an aqueous phase.¹⁵⁹

Of course, it has long been known that molecular recognition is very important in biochemistry. The action of enzymes and various other biological molecules is extremely specific because these molecules also have host cavities that are able to recognize only one or a few particular types of guest molecules. Now, organic chemists can synthesize non-natural hosts that can also perform crude (compared to biological molecules) molecular recognition. The macrocycle **33** has been used as a catalyst, for the hydrolysis of acetyl phosphate and the synthesis of pyrophosphate.¹⁶⁰

No matter what type of host, the strongest attractions occur when combination with the guest causes the smallest amount of distortion of the host.¹⁶¹ That is, a fully preorganized

host will bind better than a host whose molecular shape must change in order to accommodate the guest.

3.C.iii Inclusion Compounds

This type of addition compound is different from either the EDA complexes or the crown ether type of complexes previously discussed. Here, the host forms a crystal lattice that has spaces large enough for the guest to fit into. *van der Waals forces* constitute the only bonding between the host and the guest. There are two main types, depending on the shape of the space.¹⁶² The spaces in *inclusion compounds*, are in the shape of long tunnels or channels, while the other type, often called *clathrate*,¹⁶³ or *cage compounds*, have spaces that are completely enclosed. In both types, the guest molecule must fit into the space and potential guests that are too large or too small will not go into the lattice, so that the addition compound will not form. Such structures need not be restricted to large molecules. Indeed, the structure and stability of the hydrogen clathrate hydrate with cyclohexanone is known.¹⁶⁴

Several important host molecules are known, and inclusion compounds include small molecules (e.g., urea).¹⁶⁵ Hydrogen sulfide forms hexagonal clathrate hydrate cages, and a guest molecule (e.g., pinacolone), may be present, as shown in Fig. 3.1.¹⁶⁶ Commonly, *van der Waals forces* between the host and the guest, while small, are essential to the stability of the structure. Which molecules can be a guest is usually dependent on their shapes and sizes and not necessarily on any electronic or chemical effects. For example, octane and 1-bromooctane are suitable guests for urea, but 2-bromooctane, 2-methylheptane, and 2-methyloctane are not. Also, both dibutyl maleate and dibutyl fumarate are guests; neither diethyl maleate nor diethyl fumarate is a guest, but dipropyl fumarate is a guest and dipropyl maleate is not.¹⁶⁷ In these complexes, there is usually no integral molar ratio (though by chance there may be). For example, the octane/urea ratio is 1:6.73.¹⁶⁸ A deuterium quadrupole echo spectroscopy study of a urea complex showed that the urea molecules do not remain rigid, but undergo 180° flips about the C=O axis at the rate of $>10^6 \text{ s}^{-1}$ at 30 °C.¹⁶⁹

FIG. 3.1. X-ray structure of pinacolone in a H_2S hexagonal clathrate hydrate cage molecule at 100 K.¹⁶⁶ [Reprinted with permission from Alavi, S.; Udachin, K.; Ripmeester, J.A. *Chem. Eur. J.* **2010**, *16*, 1017, Wiley–VCH Verlag GmbH & Co. KGaA, Weinheim. Copyright © 2010 by Wiley–VCH Verlag.]

The complexes are solids, but are not useful as derivatives, since they melt, with decomposition of the complex at the melting point of urea. They are useful, however, in separating isomers that would be quite difficult to separate otherwise. Thiourea also forms inclusion compounds though with channels of larger diameter, so that *n*-alkanes cannot be guests but, (e.g., 2-bromooctane, cyclohexane, and chloroform readily fit).

Hydroquinone is a useful host for clathrates.¹⁷⁰ Three molecules, held together by hydrogen bonding, make a cage in which fits one molecule of guest. Typical guests are methanol (but not ethanol), sulfur dioxide, carbon dioxide, and argon (but not neon). One important use is the isolation of anhydrous hydrazine as complex.¹⁷¹ Anhydrous hydrazine is highly explosive, so preparation by distillation of aq hydrazine solutions is both difficult and dangerous. The inclusion complex can be readily isolated and reactions done in the solid state (e.g., the reaction with esters to give hydrazides, Reaction 16–75).¹⁷² In contrast to the inclusion compounds, the crystal lattices here can exist partially empty. Another host is water. Usually six molecules of water form the cage and many guest molecules, among them Cl_2 , propane, and methyl iodide, can fit. The water clathrates (see Fig. 3.1), which are solids, can normally be kept only at low temperatures; at room temperature, they decompose.¹⁷¹ Methane hydrate, which is a promising energy source that exists in vast quantities at the seabed of various oceans,¹⁷³ is an example of this type of

clathrate. Another inorganic host is sodium chloride (and some other alkali halides), which can encapsulate organic molecules (e.g., benzene, naphthalene, and diphenylmethane).¹⁷⁴

Among other hosts¹⁷⁵ for inclusion and/or clathrate compounds are deoxycholic acid,¹⁷⁶ cholic acid,¹⁷⁷ anthracene compounds, (e.g., **34**),¹⁷⁸ dibenzo-24-crown-8,¹⁷⁹ and the compound **35**, which has been called a *carcerand*.¹⁸⁰ When carcerand-type molecules trap ions or other molecules (called guests), the resulting complex is called a carciplex.¹⁸¹ It has been shown that in some cases, the motion of the guest within the carciplex is restricted.¹⁸²

FIG. 3.2. β -Cyclodextrin.

3.C.iv Cyclodextrins

There is one type of host that can form both channel and cage complexes. This type is called *cyclodextrins* or *cycloamyloses*.¹⁸³ The host molecules are made up of six, seven, or eight glucose units connected in a large ring, called, respectively, α -, β -, or γ -cyclodextrin (Fig. 3.2 shows the β or seven-membered ring compound). The three molecules are in the shape of hollow truncated cones (Fig. 3.3) with primary OH groups projecting from the narrow side of the cones and secondary OH group from the wide side. As expected for carbohydrate molecules, all of them are soluble in water and the cavities normally fill with water molecules held in place by hydrogen bonds (6, 12, and 17 H_2O molecules for the α , β , and γ forms, respectively), but the insides of the cones are less polar than the outsides, so that nonpolar organic molecules readily displace the water. The polarity of such cavities has been probed by a chemical reaction: the solvolysis of benzoyl halides Reaction (16–57).¹⁸⁴ Thus the cyclodextrins form 1:1 cage complexes with many guests, ranging in size from the noble gases to large organic molecules. A guest molecule must not be too large or it will not fit, though many stable complexes are known in which one end of the guest molecule protrudes from the cavity (Fig. 3.4). On the other hand, if the guest is too small, it may go through the bottom hole (though some small polar molecules, e.g., methanol, do form complexes in which the cavity also contains some water molecules). Since the cavities of the three cyclodextrins are of different sizes (Fig. 3.3), a large variety of guests can be accommodated. Since

cyclodextrins are nontoxic (they are actually small starch molecules), they are now used industrially to encapsulate foods and drugs.¹⁸⁷

The cyclodextrins also form channel-type complexes, in which the host molecules are stacked on top of each other, like coins in a row.¹⁸⁸ For example, α -cyclodextrin (cyclohexaamylose) forms cage complexes with acetic, propionic, and butyric acids, but channel complexes with valeric and higher acids. Capped cyclodextrins are known.¹⁸⁹

3.D. CATENANES AND ROTAXANES¹⁹⁰

These compounds contain two or more independent portions that are not bonded to each other by any valence forces, but nevertheless must remain linked. [*n*]-*Catenanes* (where *n* corresponds to the number of

linked rings) are made up of two or more rings held together as links in a chain, while in *rotaxanes* a linear portion is threaded through a ring and cannot get away because of bulky end groups. Among several types of bulky molecular units, porphyrin units have been used to cap rotaxanes¹⁹¹ as have C₆₀ fullerenes.¹⁹² [2]Rotaxanes and [2]catenanes are quite common, and [3]catenanes are known having rather robust amide linkages.¹⁹³ More intricate variants [e.g., oligocatenanes,¹⁹⁴ molecular necklaces (a cyclic oligorotaxane in which a number of small rings are threaded onto a large ring),¹⁹⁵ and cyclic daisy chains (an interwoven chain in which each monomer unit acts as a donor and an acceptor for a threading interaction)]¹⁹⁶ are known. Ring-in-ring complexes have also been reported.¹⁹⁷ Molecular thread, ribbon, and belt assemblies have been synthesized.¹⁹⁸ Rotaxanes have been used as the basis for molecular switches,¹⁹⁹ and a rotaxane eciplex has been generated that may have applications to molecular-scale photonic devices.²⁰⁰

Transitional isomers are possible in [2]rotaxanes.²⁰¹ Catenanes and rotaxanes can be prepared by statistical methods or directed syntheses.²⁰² Catenanes can contain heteroatoms and heterocyclic units. In some cases, the catenane exists in equilibrium with the cyclic-non-catenane structures and in some cases this exchange is thought to proceed by

ligand exchange and a Möbius strip mechanism.²⁰³ An example of a statistical synthesis of a rotaxane is a reaction where a compound **A** is bonded at two positions to another compound **B** in the presence of a large ring **C**. It is hoped that some **A** molecules would by chance be threaded through **C** before combining with the two **B** molecules, so that some rotaxane (**D**) would be formed along with the normal product **E**.²⁰⁴ In a directed synthesis,²⁰⁵ the separate parts of the molecule are held together by other bonds that are later cleaved.

Rotation of one unit through the other catenanes is complex, often driven by making and breaking key hydrogen bonds or π - π interactions. In the case of the isophthaloyl [2]catenane (**36**), the rate-determining steps do not necessarily correspond to the passage of the bulkiest groups.²⁰⁶

Singly and doubly interlocked [2]catenanes²⁰⁷ can exist as *topological stereoisomers*²⁰⁸ (see Sec. 4.G for a discussion of diastereomers). Catenanes **37** and **38** are such stereoisomers, and would be expected to have identical mass spectra. Analysis showed that

37 is more constrained and cannot readily accommodate an excess of energy during the mass spectrometry ionization process and, hence, breaks more easily.

Catenanes, molecular knots, and other molecules in these structural categories can exist as enantiomers. In other words, stereoisomers can be generated in some cases. This phenomenon was first predicted by Frisch and Wassermann,²⁰⁹ and the first stereoisomeric catenanes and molecular knots were synthesized by Sauvage and Dietrich-Buchecker.²¹⁰ Enantiomeric resolution has been achieved.²¹¹ A chiral [3]rotaxane containing two achiral wheels, mechanically bonded has been reported,²¹² generating a cyclodiastereomeric compound, and the enantiomers were separated using chiral HPLC. The terms cyclo-enantiomerism and cyclodiastereomerism were introduced by Prelog et. al.²¹³ This type of stereoisomerism occurs in cyclic arrangements of several centrally chiral elements in combination with an orientation of the macrocycle.²¹²

A rotaxane can also be an inclusion compound.²¹⁴ The molecule contains bulky end groups (or “stoppers,” e.g., triisopropylsilyl groups, $i\text{Pr}_3\text{Si}-$) and a chain that consists of a series of $-\text{O}-\text{CH}_2\text{CH}_2-\text{O}-$ groups, but also contains two benzene rings. Cyclodextrins have been threaded onto axle molecules.²¹⁵ The ring (or bead) around the chain is a macrocycle containing two benzene rings and four pyridine rings. It is preferentially attracted to one of the benzene rings in the chain. The benzene moiety serves as a “station” for the “bead.” However, symmetry of the chain can make the two “stations” equivalent, so that the “bead” is equally attracted to them, and the “bead” actually moves back and forth rapidly between the two “stations,” as shown by the temperature dependence of the NMR spectrum.²¹⁶ This molecule has been called a *molecular shuttle*. A copper(I) complexed rotaxane has been prepared with two fullerene (see Sec. 2.L) stoppers.²¹⁷

Another variation of these molecules is called molecular knots (e.g., **39**), where the \bigcirc represents a metal [in this case, Cu(I)].²¹⁸ This is particularly interesting since knotted forms of deoxyribonucleic acid (DNA) have been reported.²¹⁹ There are mechanically interlocked molecules, and one example is known as suit[2]ane.²²⁰

3.E. CUCURBIT[M]URIL-BASED GYROSCANE

A new molecule known as gyroscane has been prepared, and proposed as a new supramolecular form.²²¹ The class of compounds known as cucurbit[*n*]urils, abbreviated Q_n (**40**),²²² are condensation products of glycoluril and formaldehyde. These macrocycles can act as molecular hosts. The new “supramolecular form is one in which a smaller macrocycle (Q5) is located inside a larger macrocycle (Q10), with facile rotation of one relative to the other in solution (see **41**).²²¹ The image of a ring rotating independently inside another ring, which resembles a gyroscope, suggests the name gyroscane for this new class of supramolecular system.”²²²

Stereochemistry and Conformation

The discussions in Chapters 1–3 focused on electron distribution in organic molecules. In this chapter, the focus will be on the 3D structure of organic compounds.¹ The structure may be such that *stereoisomerism*² is possible. Stereoisomers are compounds made up of the same atoms bonded by the same sequence of bonds, but having different 3D structures that are not interchangeable. These structures are called *configurations*.

4.A. OPTICAL ACTIVITY AND CHIRALITY³

Any material that rotates the plane of polarized light is said to be *optically active*. If a pure compound is optically active, the molecule is nonsuperimposable on its mirror image. If a molecule is superimposable on its mirror image, the two structures constitute the same compound and the compound does not rotate the plane of polarized light; it is *optically inactive*. The property of nonsuperimposability of an object on its mirror image is called *chirality*. If a molecule is not superimposable on its mirror image, it is *chiral*. If it is superimposable on its mirror image, it is *achiral*. The relationship between optical activity and chirality is absolute. No exceptions are known, and many thousands of cases have been found in accord with it (however, see Sec. 4.C). The ultimate criterion, then, for optical activity is chirality (nonsuperimposability on the mirror image). This finding is both a necessary and a sufficient condition.⁴ This fact has been used as evidence for the structure determination of many compounds, and historically the tetrahedral nature of carbon was deduced from the hypothesis that the relationship might be true. Note that parity violation

FIG. 4.1. Enantiomers of 2-butanol.

represents an essential property of particle and atomic handedness, and has been related to chirality.⁵

If a molecule is nonsuperimposable on its mirror image, the mirror image must be a different molecule, since superimposability is the same as identity. In each case of optical activity of a pure compound there are two and only two isomers, called *enantiomers* (sometimes *enantiomorphs*), which differ in structure only in the left- and right-handedness of their orientations (see the enantiomers for 2-butanol in Fig. 4.1). Enantiomers have identical⁶ physical and chemical properties except in two important respects:

1. They rotate the plane of polarized light in opposite directions, although in equal amounts. The isomer that rotates the plane to the left (counterclockwise) is called the *levo isomer* and is designated (–), while the one that rotates the plane to the right (clockwise) is called the *dextro isomer* and is designated (+). Because they differ in this property they are often called *optical antipodes*.
2. They may react at different rates with other chiral compounds. These rates may be so close together that the distinction is practically useless, or they may be so far apart that one enantiomer undergoes the reaction at a convenient rate while the other does not react at all. This finding is the reason that many compounds are biologically active while their enantiomers are not. Enantiomers react at the same rate with achiral compounds.⁷

In general, it may be said that enantiomers have identical properties in a symmetrical environment, but their properties may differ in an unsymmetrical environment.⁸ Besides the important differences previously noted, enantiomers may react at different rates with achiral molecules if an optically active *catalyst* is present; they may have different

⁵ Avalos, M.; Babiano, R.; Cintas, P.; Jiménez, J.L.; Palacios, J.C. *Tetrahedron Asymm.* **2000**, *11*, 2845.

⁶ Interactions among electrons, nucleons, and certain components of nucleons (e.g., bosons), called *weak interactions*, violate parity; that is, mirror image interactions do not have the same energy. It has been contended that interactions of this sort cause one of a pair of enantiomers to be (slightly) more stable than the other. See Tranter, G.E. *J. Chem. Soc. Chem. Commun.* **1986**, 60, and references cited therein. See also, Barron, L.D. *Chem. Soc. Rev.* **1986**, *15*, 189.

solubilities in an optically active *solvent*; they may have different indexes of refraction or absorption spectra *when examined with circularly polarized light*, and so on. In most cases, these differences are too small to be useful and are often too small to be measured.

Although pure compounds are always optically active if they are composed of chiral molecules, mixtures of equal amounts of enantiomers are optically inactive since the equal and opposite rotations cancel. Such mixtures are called *racemic mixtures*⁹ or *racemates*.¹⁰ Their properties are not always the same as those of the individual enantiomers. The properties in the gaseous or liquid state or in solution usually are the same, since such a mixture is nearly ideal, but properties involving the solid state¹¹ (e.g., melting points, solubilities, and heats of fusion), are often different. Thus racemic tartaric acid has a melting point of 204–206 °C and a solubility in water at 20 °C of 206 g L⁻¹ while for the (+) or the (–) enantiomer, the corresponding figures are 170 °C and 1390 g L⁻¹. The separation of a racemic mixture into its two optically active components is called *resolution*. The presence of optical activity always proves that a given compound is chiral, but its absence does not prove that the compound is achiral. A compound that is optically inactive may be achiral, or it may be a racemic mixture (see also, Sec. 4.C).

4.A.i. Dependence of Rotation on Conditions of Measurement

The *amount* of rotation α is not a constant for a given enantiomer; it depends on the length of the sample vessel, the temperature, the solvent¹² and concentration (for solutions), the pressure (for gases), and the wavelength of light.¹³ Of course, rotations determined for the same compound under the same conditions are identical. The length of the vessel and the concentration or pressure determine the number of molecules in the path of the beam, and α is linear with this. To make it possible for one value of α for a pure compound to be compared with another α for that compound taken under different circumstances, a physical property is defined, called the *specific rotation* $[\alpha]$, which is

$$[\alpha] = \frac{\alpha}{lc} \text{ for solutions} \quad [\alpha] = \frac{\alpha}{ld} \text{ for pure compounds}$$

where α is the observed rotation, l is the cell length in decimeters, c is the concentration in grams per milliliter, and d is the density in the same units. The specific rotation is usually given along with the temperature and wavelength of light used for the measurement, in this manner: $[\alpha]_{546}^{25}$. These conditions must be duplicated for comparison of rotations, since there is no way to put them into a simple formula. The expression $[\alpha]_D$ means that the rotation was measured with sodium D light; that is, $\lambda = 589 \text{ nm}$. The *molar rotation* $[M]_{\lambda}^t$ is the specific rotation times the molecular weight divided by 100.

It must be emphasized that the value of α changes with conditions, but the molecular structure is unchanged. This finding is true even when the changes in conditions are

⁹ Strictly speaking, the term *racemic mixture* applies only when the mixture of molecules is present as separate solid phases, but in this book this expression refers to any equimolar mixture of enantiomeric molecules, liquid, solid, gaseous, or in solution.

¹¹ See Wynberg, H.; Lorand, J.P. *J. Org. Chem.* **1981**, *46*, 2538 and references cited therein.

¹² A good example is found in Kumata, Y.; Furukawa, J.; Fueno, T. *Bull. Chem. Soc. Jpn.* **1970**, *43*, 3920.

¹³ For a review of polarimetry see Lyle, G.G.; Lyle, R.E. in Morrison, J.D. *Asymmetric Synthesis*, Vol. 1, Academic Press, NY, **1983**, pp. 13–27.

sufficient to change not only the amount of rotation, but even the direction. Thus one of the enantiomers of aspartic acid, when dissolved in water, has $[\alpha]_D$ equal to $+4.36^\circ$ at 20°C and -1.86° at 90°C , although the molecular structure is unchanged. A consequence of such cases is that there is a temperature at which there is *no* rotation (in this case 75°C). Of course, the other enantiomer exhibits opposite behavior.

Other cases are known in which the direction of rotation is reversed by changes in wavelength, solvent, and even concentration.¹⁴ In theory, there should be no change in $[\alpha]$ with concentration, since this is taken into account in the formula, but associations, dissociations, and solute–solvent interactions often cause nonlinear behavior. For example, $[\alpha]_D^{24}$ for (–)-2-ethyl-2-methylsuccinic acid in CHCl_3 is -5.0° at $c = 16.5 \text{ g } 100 \text{ mL}^{-1}$ (0.165 g mL^{-1}), -0.7° at $c = 10.6$, $+1.7^\circ$ at $c = 8.5$, and $+18.9^\circ$ at $c = 2.2$.¹⁵ Note that the concentration is sometimes reported in $\text{g } 100 \text{ mL}^{-1}$ (as shown) or as g dL^{-1} (decaliters) rather than the standard g mL^{-1} . One should always check the concentration term to be certain. Note that calculation of the optical rotation of (*R*)-(–)-3-chloro-1-butene found a remarkably large dependence on the $\text{C}=\text{C}-\text{C}-\text{C}$ torsional angle.¹⁶ However, the observed rotations are a factor of 2.6 smaller than the calculated values, independent of both conformation and wavelength from 589 to 365 nm.

4.B. WHAT KINDS OF MOLECULES DISPLAY OPTICAL ACTIVITY?

Although the ultimate criterion is, of course, nonsuperimposability on the mirror image (chirality), other tests may be used that are simpler to apply, but not always accurate. One such test is the presence of a *plane of symmetry*.¹⁷ A plane of symmetry¹⁸ (also called a *mirror plane*) is a plane passing through an object such that the part on one side of the plane is the exact reflection of the part on the other side (the plane acting as a mirror). *Compounds possessing such a plane are always optically inactive*, but there are a few cases known in which compounds lack a plane of symmetry and are nevertheless inactive. Such compounds possess a *center of symmetry* (e.g., in α -truxillic acid), or an *alternating axis of symmetry* as in **1**.¹⁹ A center of symmetry¹⁸ is a point within an object such that a straight line drawn from any part or element of the object to the center and extended an equal distance on the other side encounters an equal part or element. An alternating axis of symmetry¹⁸ of order n is an axis such that when an object containing such an axis is rotated by $360^\circ/n$ about the axis and then reflection is effected across a plane at right angles to the axis, a new object is obtained that is indistinguishable from the original one. Compounds that lack an alternating axis of symmetry are always chiral.

¹⁴ For examples, see Shriner, R.L.; Adams, R.; Marvel, C.S. in Gilman, H. *Advanced Organic Chemistry*, Vol. 1, 2nd ed. Wiley, NY, **1943**, pp. 291–301.

A molecule that contains just one *stereogenic carbon atom* (defined as a carbon atom connected to four different groups; also called a *chiral atom* or an *asymmetric carbon atom*) is always chiral, and hence optically active.²⁰ As seen in Fig. 4.1, such a molecule *cannot* have a plane of symmetry, whatever the identity of the four atoms or groups, as long as they are all different. However, optical activity may be present in molecules with no stereogenic atom.²¹ Some molecules with two or more stereogenic carbon atoms, however, are superimposable on their mirror images (called *meso* compounds), and hence inactive principally because there is symmetry. Examples of such compounds will be discussed subsequently.

Optically active compounds may be classified into several categories.

1. *Compounds with a Stereogenic Carbon Atom.* If there is only one such atom, the molecule must be optically active, no matter how slight the differences are among the four groups. An example is 1,12-dibromo-6-methyldodecane, which has one stereogenic carbon and will be optically active. Optical activity has been detected even in cases²² (e.g., 1-butanol-1-*d*), where one group is hydrogen and another deuterium:²³ The stereogenic carbon is connected to OH, H, D, and a propyl group.

Although enantiomers will exhibit specific rotation of equal magnitude but opposite sign, the difference may be too small to be measured accurately. In optically active compounds, the amount of rotation is greatly dependent on the nature of the four groups, in general increasing with increasing differences in polarizabilities among the groups. Alkyl groups have very similar polarizabilities²⁴ and the optical activity of 5-ethyl-5-propylundecane is too low to be measurable at any wavelength between 280 and 580 nm.²⁵

2. *Compounds with Other Quadrivalent Stereogenic Atoms.*²⁶ Any molecule with an atom that has four bonds pointing to the corners of a tetrahedron will be optically

²⁰ For discussions of the relationship between a chiral carbon and chirality, see Mislow, K.; Siegel, J. *J. Am. Chem. Soc.* **1984**, 106, 3319; Brand, D.J.; Fisher, J. *J. Chem. Educ.* **1987**, 64, 1035.

²⁶ For compounds with asymmetric atoms other than carbon, see Aylett, B.J. *Prog. Stereochem.* **1969**, 4, 213; Belloli, R. *J. Chem. Educ.* **1969**, 46, 640; Sokolov, V.I.; Reutov, O.A. *Russ. Chem. Rev.* **1965**, 34, 1.

active if the four groups are different. Among atoms in this category are Si,²⁷ Ge, Sn,²⁸ and N (in quaternary salts or *N*-oxides).²⁹ In sulfones, the sulfur bonds have a tetrahedral array, but since two of the groups are always oxygen, no chirality results. However, the preparation³⁰ of an optically active sulfone (**2**) in which one oxygen is ¹⁶O and the other is ¹⁸O illustrates the point that slight differences in groups are all that is necessary. This point has been taken even further with the preparation of ester **3**, both enantiomers of which have been prepared.³¹ Optically active chiral phosphates (**4**) have similarly been made.³²

3. *Compounds with Tervalent Stereogenic Atoms.* Atoms with pyramidal bonding³³ might be expected to give rise to optical activity if the atom is connected to three different groups, since the unshared pair of electrons is analogous to a fourth group, necessarily different from the others. For example, a secondary or tertiary amine

where X, Y, and Z are different and the fourth group is the electron pair would be expected to be chiral and thus resolvable. Many attempts have been made to resolve such compounds, but until 1968 all of them failed because of *pyramidal inversion* (also called *fluxional inversion*), which is a rapid oscillation of the unshared pair from one side of the XYZ plane to the other, thus converting the molecule into its enantiomer.³⁴ For ammonia, there are 2×10^{11} inversions every second. The inversion is less rapid in substituted ammonia derivatives³⁵ (amines, amides, etc.). The interconversion barrier for endo versus exo methyl in *N*-methyl-2-azabicyclo[2.2.1]heptane, for example, is $0.3 \text{ kcal mol}^{-1}$ (1.26 kJ mol^{-1}).³⁶ In this case, torsional strain plays a significant role, along with angle strain, in determining inversion barriers. Two types of nitrogen atom

invert particularly slowly, namely, a nitrogen atom in a three-membered ring and a nitrogen atom connected to another atom bearing an

N-Methyl-2-azabicyclo[2.2.1]heptane

unshared pair. Even in such compounds, however, pyramidal inversion proved too rapid to permit isolation of separate isomers for many years. This goal was accomplished²⁹ only when compounds were synthesized in which both features are combined: a nitrogen atom in a three-membered ring connected to an atom containing an unshared pair. For example, the two isomers of 1-chloro-2-methylaziridine (**5** and **6**) were separated and do not interconvert at room temperature.³⁷ In suitable cases, this barrier to inversion can result in compounds that are optically active solely because of a chiral tervalent nitrogen atom. For example, **7** has been resolved into its separate enantiomers.³⁸ Note that in this case too, the nitrogen is connected to an atom with an unshared pair. Conformational stability has also been demonstrated for oxaziridines,³⁹ diaziridines (e.g., **8**),⁴⁰ triaziridines (e.g., **9**),⁴¹ and 1,2-oxazolidines (e.g., **10**),⁴² even though in this case the ring is five membered. However, note that the nitrogen atom in **10** is connected to two oxygen atoms.

Compound **11** is another example in which nitrogen is connected to two oxygen atoms. In this case there is no ring at all, but it has been resolved into (+) and (−) enantiomers ($[\alpha]_{\text{D}}^{20} \approx \pm 3^\circ$).⁴³ This compound and several similar ones reported in the same paper are the first examples of compounds whose optical activity is solely due to an acyclic tervalent chiral nitrogen atom. However, **11** is not optically stable and racemizes at 20°C with a half-life of 1.22 h. A similar compound (**11**, with OCH_2Ph replaced by OEt) has a longer half-life, 37.5 h at 20°C.

In molecules in which the nitrogen atom is at a bridgehead, pyramidal inversion is of course prevented. Such molecules, if chiral, can be resolved even without the presence of the two structural features noted above. For example, optically active **12** (*Tröger's base*) has been prepared.⁴⁴ Phosphorus inverts more slowly and arsenic still more slowly.⁴⁵ Nonbridgehead phosphorus,⁴⁶ arsenic, and antimony compounds have also been resolved (e.g., **13**).⁴⁷ Sulfur exhibits pyramidal bonding in sulfoxides, sulfinic esters, sulfonium salts, and sulfites. Examples of each of these have been resolved.⁴⁸ An interesting example is (+)- $\text{Ph}^{12}\text{CH}_2\text{SO}^{13}\text{CH}_2\text{Ph}$, a sulfoxide in which the two alkyl groups differ only in ^{12}C versus ^{13}C , but which has $[\alpha]_{280} = +0.71^\circ$.⁴⁹ A computational study indicates that base-catalyzed inversion at sulfur in sulfoxides is possible via a tetrahedral intermediate.⁵⁰

4. *Suitably Substituted Adamantanes.* Adamantanes bearing four different substituents at the bridgehead positions are chiral and optically active and **14**, for example, has been resolved.⁵¹ This type of molecule is a kind of expanded tetrahedron and has the same symmetry properties as any other tetrahedron.

FIG. 4.2. Perpendicular dissymmetric planes and a chiral molecule with no stereogenic center.

5. *Restricted Rotation Giving Rise to Perpendicular Dissymmetric Planes.* Certain compounds that do not contain asymmetric atoms are nevertheless chiral, as illustrated in Fig. 4.2. For such compounds, there are two perpendicular planes (see I), neither of which can be bisected by a plane of symmetry (as illustrated by II). If either plane could be so bisected, the molecule would be superimposable on its mirror image, since such a plane would be a plane of symmetry. These points will be illustrated by examples.

Biphenyls that contain four large groups in the ortho positions cannot freely rotate about the central bond because of steric hindrance.⁵² For example, the activation energy (rotational barrier) for the enantiomerization process of the chiral 2-carboxy-2'-methoxy-6-nitrobiphenyl was determined, $\Delta G^\ddagger = 21.8 \pm 0.1 \text{ kcal mol}^{-1}$ (91.3 kJ mol^{-1}).⁵³ In such compounds, the two rings are in perpendicular planes. If either ring is symmetrically substituted, the molecule has a plane of symmetry. For example, consider the biaryls:

Ring B is symmetrically substituted. A plane drawn perpendicular to ring B contains all the atoms and groups in ring A; hence, it is a plane of symmetry and the compound is achiral. On the other hand, consider

⁵² When the two rings of a biphenyl are connected by a bridge, rotation is of course impossible. For a review of such compounds, see Hall, D.M. *Prog. Stereochem.* **1969**, 4, 1.

⁵³ Ceccacci, F.; Mancini, G.; Mencarelli, P.; Villani, C. *Tetrahedron Asym.* **2003**, 14, 3117.

In this molecule, there is no plane of symmetry and the molecule is chiral; many such compounds have been resolved. Note that groups in the para position cannot cause lack of symmetry. Isomers that can be separated only because rotation about single bonds is prevented or greatly slowed are called *atropisomers*.⁵⁴ 9,9'-Bianthryls also show hindered rotation and exhibit atropisomers.⁵⁵ Low-temperature NMR is sometimes used to detect atropisomers in certain systems [1,2,4,5-tetra(*o*-tolyl)benzene, e.g.].⁵⁶ Configurationally stable atropisomers are known.⁵⁷

It is not always necessary for four large ortho groups to be present in order for rotation to be prevented. Compounds with three and even two groups, if large enough, can have hindered rotation and, if suitably substituted, can be resolved. An example is biphenyl-2,2'-bis-sulfonic acid.⁵⁸ In some cases, the groups may be large enough to slow rotation greatly, but not to prevent it completely. In such cases, optically active compounds can be prepared that slowly racemize on standing. Thus, **15** loses its optical activity with a half-life of 9.4 min in ethanol at 25°C.⁵⁹ Compounds with greater rotational stability can often be racemized if higher temperatures are used to supply the energy necessary to force the groups past each other.⁶⁰

Atropisomerism occurs in other systems as well, including monopyrroles.⁶¹ Sulfoxide (**16**), for example, forms atropisomers with an interconversion barrier with its atropisomer of 18–19 kcal mol⁻¹ (75.4–79.5 kJ mol⁻¹).⁶² The atropisomers of hindered naphthyl alcohols (e.g., **17**) exist as the *sp*-atropisomer (**17a**) and the *ap*-atropisomer (**17b**).⁶³ Atropisomers can also be formed in organometallic

compounds, [e.g., the bis(phosphinoplatinum) complex (see **18**)] generated by reaction with (R)-BINAP [(2*R*₁ 3*S*)-2,2'-bis(diphenylphosphino)-1,1'-binaphyl, see Reaction **19-36**].⁶⁴

It is possible to isolate isomers in some cases, often due to restricted rotation. In 9,10-bis(trifluorovinyl)phenanthrene (**19**) torsional diastereomers (see Sec. 4.G) are formed. The value of *K* for interconversion of **19a** and **19b** is 0.48, with $\Delta G^0 = 15.1 \text{ kcal mol}^{-1}$.⁶⁵ The ability to isolate atropisomers can depend on interactions with solvent, as in the isolation of atropisomeric colchicinoid alkaloids, which have been isolated, characterized, and their dichroic behavior described.⁶⁶

In allenes, the central carbon is *sp* hybridized. The remaining two *p* orbitals are perpendicular to each other and each overlaps with the *p* orbital of one adjacent carbon atom, forcing the two remaining bonds of each carbon into perpendicular planes. Thus allenes fall into the category represented by Fig. 4.2. Like biphenyls, allenes are chiral *only* if both sides are unsymmetrically substituted.⁶⁷ These cases are completely different from the cis–trans isomerism of compounds with one double bond (Sec. 4.K). In the latter cases, the four groups are all in one plane, the isomers are not enantiomers, and neither is chiral, while in allenes the groups are in two perpendicular planes and the isomers are a pair of optically active enantiomers.

When a molecule has three, five, or any *odd* number of cumulative double bonds, orbital overlap causes the four groups to occupy one plane and cis–trans isomerism is observed. When four, six, or any *even* number of cumulative double bonds exist, the situation is analogous to that in the allenes and optical activity is possible. Compound **20** has been resolved.⁶⁸

Other types of compounds that contain the system illustrated in Fig. 4.2 and that are similarly chiral if both sides are dissymmetric include spiranes (e.g., **21**), and compounds with exocyclic double bonds (e.g., **22**). Atropisomerism exists in (1,5)-bridgedcalix[8]arenes (see Sec. 3.C.ii).⁶⁹

6. *Chirality due to a Helical Shape.*⁷⁰ Several compounds have been prepared that are chiral because they have a shape that is actually helical and can therefore be left- or right handed in orientation. The entire molecule is usually less than one full turn of the helix, but this does not alter the possibility of left- and right handedness. An example is hexahelicene,⁷¹ in which one side of the molecule must lie above the other because of crowding.⁷² The rotational barrier for helicene is $\sim 22.9 \text{ kcal mol}^{-1}$ (95.9 kJ mol^{-1}), and significantly higher when substituents are present.⁷³ It has been shown that the dianion of helicene retains its chirality.⁷⁴ Chiral discrimination of helicenes is possible.⁷⁵ 1,16-Diazo[6]helicene has also been prepared and, interestingly, does not act as a proton sponge (see Sec. 8.F) because the helical structure leaves the basic nitrogen atoms too far apart. Heptalene is another compound that is not planar (Sec. 2.I.iii). Its twisted structure makes it chiral, but the enantiomers rapidly interconvert.⁷⁶

trans-Cyclooctene (see also, Sec. 4.K.i) also exhibits helical chirality because the carbon chain must lie above the double bond on one side and below it on the other.⁷⁷ Similar helical chirality also appears in fulgide **23**⁷⁸ and dispiro-1,3-dioxane (**24**), shows two enantiomers (**24a** and **24b**).⁷⁹

7. *Optical Activity Caused by Restricted Rotation of Other Types.* Substituted paracyclophanes may be optically active⁸⁰ and **25**, for example, has been resolved.⁸¹ In this case, chirality results because the benzene ring cannot rotate in such a way that the carboxyl group goes through the alicyclic ring. Many chiral layered cyclophanes (e.g., **26**), have been prepared.⁸² Another cyclophane⁸³ with a different type of chirality is [12][12]paracyclophane (**27**), where the chirality arises from the relative orientation of the two rings attached to the central benzene ring.⁸⁴ An acetylenic cyclophane was shown to have helical chirality.⁸⁵ Metallocenes (Sec. 2.I.ii) substituted with at least two different groups on one ring are also chiral.⁸⁶ Several hundred such compounds have been resolved, one being **28**. Chirality is also found in other metallic complexes of suitable geometry.⁸⁷ Fumaric acid–iron tetracarbonyl (**29**) has been resolved,⁸⁸ and 1,2,3,4-tetramethylcyclooctatetraene (**30**) is also chiral.⁸⁹ This molecule, which exists in the tub form (Sec. 2.K), has

neither a plane nor an alternating axis of symmetry. Another compound that is chiral solely because of hindered rotation is the propeller-shaped perchlorotriphenylamine, which has been resolved.⁹⁰ The 2,5-dideuterio derivative (**31**) of barrelene is chiral, though the parent hydrocarbon and the monodeuterio derivative are not. Compound **25** has been prepared in optically active form⁹¹ and is another case where chirality is due to isotopic substitution.

The main molecular chain in compound **32** has the form of a Möbius strip (see Fig. 15.7 and 3D model **33**).⁹² This molecule has no stereogenic carbons, nor does it have a rigid shape, a plane, nor an alternating axis of symmetry. However, **32** has been synthesized and shown to be chiral.⁹³ Rings containing 50 or more members should be able to exist as knots (**34**, and see **39** on Sec. 3.D). Such a knot would be nonsuperimposable on its mirror image. Calixarenes,⁹⁴ crown ethers,⁹⁵ catenanes, and rotaxanes (see Sec. 3.D) can also be chiral if suitably substituted.⁹⁶ For example, **40** and **41** are nonsuperimposable mirror images.

A stereogenic center may be created from an achiral molecule via a chemical reaction. One example is the α -bromination of a carboxylic acid (Hell–Volhardt–Zelenskii reaction, **12-05**) to form the α -bromo acid.

In this case, the α -carbon in the product is the stereogenic carbon. If there are no asymmetric components in the reaction, the product must be racemic. This means that no optically active material can be created if all starting materials and conditions are optically inactive.⁹⁷ This statement also holds when one begins with a racemic mixture, unless there is kinetic resolution (Sec. 4.I). Thus racemic 2-butanol, treated with HBr, must give racemic 2-bromobutane.

4.C. THE FISCHER PROJECTION

For a thorough understanding of stereochemistry, it is useful to examine molecular models (like those depicted in Fig. 4.1). However, this is not feasible when writing on paper. In 1891, Emil Fischer displayed amino acids and some carbohydrates in a particular way known as a *Fischer projection*. This is simply a method of representing and “edge-viewed” tetrahedral on paper. By this convention, the model is held so that the two bonds in front of the paper are horizontal and those behind the paper are vertical, as shown for 2-aminopropanoic acid (alanine). With modern computers, molecular models are readily available, but the ability to write structures in two dimensions to represent a 3D form remains important.

In order to obtain proper results with these formulas, remember that they are projections and must be treated differently from the models in testing for superimposability. Every

⁹⁷ There is one exception to this statement. In a very few cases, racemic mixtures may crystalize from solution in such a way that all the (+) molecules go into one crystal and the (–) molecules into another. If one of the crystals crystallizes before the other, a rapid filtration results in optically active material. For a discussion, see Pincock, R.E.; Wilson, K.R. *J. Chem. Educ.* **1973**, *50*, 455.

plane is superimposable on its mirror image; hence with these formulas there must be added the restriction that they may not be taken out of the plane of the blackboard or paper. Also, they may not be rotated 90° , although 180° rotation is permissible:

It is also permissible to keep any one group fixed and to rotate the other three clockwise or counterclockwise (because this can be done with models):

However, the *interchange* of any two groups results in the conversion of an enantiomer into its mirror image (this applies to models, as well as to the Fischer projections).

With these restrictions Fischer projections may be used instead of models to test whether a molecule containing a stereogenic carbon is superimposable on its mirror image. However, there are no such conventions for molecules whose chirality arises from anything other than chiral atoms (category 5 in Sec. 4.C).

4.D. ABSOLUTE CONFIGURATION

Suppose there are two test tubes, one containing (–)-lactic acid and the other the (+) enantiomer. One test tube contains **37** and the other **38**. How can they be distinguished?

To generate a model to answer this question, Rosanoff proposed that one compound be chosen as a standard and a configuration arbitrarily assigned to it. The compound chosen was glyceraldehyde because of its relationship to the sugars. The (+) isomer was assigned the configuration shown in **39** and given the label D. The (–) isomer, designated to be **39**, was given the label L. With a standard, other compounds could then be related to it. For example, (+)-glyceraldehyde, oxidized with mercuric oxide, gives (–)-glyceric acid:

Since it is highly improbable that the configuration at the central carbon changed, it can be concluded that (–)-glyceric acid has the same configuration as (+)-glyceraldehyde and therefore (–)-glyceric acid is also called D. This example emphasizes that molecules with

the same configuration need not rotate the plane of polarized light in the same direction. This fact should not surprise us when we remember that the same compound can rotate the plane in opposite directions under different conditions.

Once the configuration of the glyceric acids was known (in relation to the glycer-aldehydes), it was then possible to relate other compounds to either of these, and each time a new compound was related, others could be related to *it*. In this way, many thousands of compounds were related, indirectly, to D- or L-glyceraldehyde. It was determined that **37**, which has the D configuration, is the isomer that rotates the plane of polarized light to the left. Even compounds without asymmetric atoms (e.g., biphenyls and allenes), have been placed in the D or L series.⁹⁸ When a compound has been placed in the D or L series, its *absolute configuration* is said to be known.⁹⁹

In 1951, it became possible to determine that Rosanoff's guess was right. Ordinary X-ray crystallography cannot distinguish between a D and a L isomer, but by use of a special technique, Bijvoet et al.¹⁰⁰ was able to examine sodium rubidium tartrate, compared it with glyceraldehyde, and found that Rosanoff had made the correct choice. It was perhaps historically fitting that the first true absolute configuration should have been determined on a salt of tartaric acid, since Pasteur made his great discoveries on another salt of this acid.

In spite of the former widespread use of D and L to denote absolute configuration, the method is not without faults. This method does not apply to all compounds that have a stereogenic center, but only those that can be structurally related to glyceraldehyde. The DL system is rarely used, therefore, except for certain groups of compounds (e.g., carbohydrates and amino acids). A more general model is required to distinguish the stereogenic centers of enantiomers.

4.D.i. The CAHN-INGOLD-PRELOG System

The system that is used universally is the *Cahn-Ingold-Prelog* system (or the CIP system), in which the four groups on a stereogenic carbon are ranked (prioritized) according to a set of sequence rules.¹⁰¹ For the most part, only a few of these rules are sufficient to deal with the vast majority of chiral compounds.

1. Prioritize substituents in order of decreasing atomic number of the atom directly joined to the carbon.

⁹⁸ The use of small *d* and *l* is now discouraged, since some authors used it for rotation, and some for configuration. However, a racemic mixture is still a *dl* mixture, since there is no ambiguity here.

⁹⁹ For lists of absolute configurations of thousands of compounds, with references, mostly expressed as (*R*) or (*S*) rather than D or L, see Klyne, W.; Buckingham, J. *Atlas of Stereochemistry*, 2nd ed., 2 Vols., Oxford University Press, Oxford, **1978**; Jacques, J.; Gros, C.; Bourcier, S.; Brienne, M.J.; Toullec, J. *Absolute Configurations* (Vol. 4 of Kagan, H. *Stereochemistry*), Georg Thieme Publishers, Stuttgart, **1977**.

2. A tritium atom takes precedence over deuterium, which in turn takes precedence over ordinary hydrogen. Similarly, any higher isotope (e.g., ^{14}C) takes precedence over any lower one.
3. Where two or more of the atoms connected to the stereogenic carbon are the same, the atomic number of the second atom determines the order. For example, in the molecule $\text{Me}_2\text{CH}-\text{CHBr}-\text{CH}_2\text{OH}$, the CH_2OH group takes precedence over the Me_2CH group because oxygen has a higher atomic number than carbon. Note that this is so even though there are two carbons in Me_2CH , and only one oxygen in CH_2OH . If two or more atoms connected to the second atom are the same, the third atom determines the precedence, and so on.
4. All atoms except hydrogen are formally given a valence of 4. Where the actual valence is less (as in nitrogen, oxygen, or a carbanion), phantom atoms (designated by a subscript 0) are used to bring the valence up to 4. These phantom atoms are assigned an atomic number of zero and necessarily rank lowest. Thus the ligand $-\text{NHMe}_2$ ranks higher than $-\text{NMe}_2$.
5. Double and triple bonds are counted as if they were split into two or three single bonds, respectively, as in the examples in Table 4.1 (note the treatment of the phenyl group). Note that in a $\text{C}=\text{C}$ double bond, the two carbon atoms are *each* regarded as being connected to two carbon atoms and that one of the latter is counted as having three phantom substituents.

Using the four groups in Table 4.1 (aldehyde, vinyl, alkynyl, phenyl), the first atoms are connected, respectively, to (H, O, O), (H, C, C), (C, C, C), and (C, C, C). That is enough to establish that $-\text{CHO}$ ranks first and $-\text{CH}=\text{CH}_2$ last, since even one oxygen outranks three carbons and three carbons outrank two carbons and a hydrogen. To classify the remaining two groups, proceed further along the chains. Note that $-\text{C}_6\text{H}_5$ has two of its (C, C, C) carbons connected to (C, C, H), while the third is ($_{000}$) and is thus preferred to $-\text{C}\equiv\text{CH}$, which has only one (C, C, H) and two ($_{000}$)s.

TABLE 4.1 How Four Common Groups Are Treated in the Cahn-Ingold-Prelog System

Group	Treated as if it Were	Group	Treated as if it Were
$\begin{array}{c} \text{H} \\ \diagdown \\ \text{C}=\text{O} \\ \diagup \end{array}$	$\begin{array}{c} \text{H} \\ \\ -\text{C}-\text{O}^{\text{OO}}-\text{O}^{\text{OOO}} \\ \\ \text{C}^{\text{OOO}} \end{array}$	$\begin{array}{c} \diagdown \\ \text{C}=\text{CH}_2 \\ \\ \text{H} \end{array}$	$\begin{array}{c} \text{H} \quad \text{H} \\ \quad \\ -\text{C}-\text{C}-\text{C}^{\text{OOO}} \\ \quad \\ \text{C}^{\text{OOO}} \quad \text{H} \end{array}$
$-\text{C}\equiv\text{C}-\text{H}$	$\begin{array}{c} \text{C}^{\text{OOO}} \quad \text{H} \\ \quad \\ -\text{C}-\text{C}-\text{C}^{\text{OOO}} \\ \quad \\ \text{C}^{\text{OOO}} \end{array}$	$-\text{C}_6\text{H}_5$	$\begin{array}{c} \text{C}^{\text{OOO}} \quad \diagdown \\ \quad \\ \text{H}-\text{C}-\text{C}-\text{C}^{\text{OOO}} \\ \quad \quad \\ \text{H}-\text{C}-\text{C}-\text{C}^{\text{OOO}} \\ \quad \\ \text{C}^{\text{OOO}} \end{array}$

By application of the above rules, some groups in descending order of precedence are COOH, CPh, COMe, CHO, CH(OH)₂, *o*-tolyl, *m*-tolyl, *p*-tolyl, phenyl, C≡CH, *tert*-butyl, cyclohexyl, vinyl, isopropyl, benzyl, neopentyl, allyl, *n*-pentyl, ethyl, methyl, deuterium, and hydrogen. Using the CIP rules, the four groups of glyceraldehyde are arranged in the sequence: OH, CHO, CH₂OH, H.

Once the order is determined, a model is required to determine the absolute configuration (i.e., which structure correlates to which enantiomer). The model used is known as the *steering wheel model*, where the molecule is held so that the lowest group in the sequence is pointed away from the viewer. Once the lowest priority group is held in that position, if the other groups, in the order listed, are oriented clockwise, the molecule is designated (*R*), and if counterclockwise (*S*). For glyceraldehyde, the (+) enantiomer is shown here and the CIP rules and the steering wheel model was used to assign an absolute configuration of (*R*).

The CIP rules and steering wheel model are used to assign an absolute configuration to the following molecules. In **A**, the isopropyl carbon is higher in priority than the bromine-containing chain, and the methyl group is the lowest priority. Turning the molecule to place the methyl group to the rear makes this an (*R*) configuration. In **B**, there are two stereogenic centers, where the (*S*) center has the chain containing the (*R*) center as the lowest priority, and the (*R*) center has the methyl group as the low priority. In **C**, there are two (*S*) centers, but the hydroxyl-bearing carbon in the middle of the molecule is *not* a stereogenic carbon. Close inspection of **C** shows that this carbon has two identical groups [CH(OH)CH₂OH].

The CIP system is unambiguous and easily applicable in most cases. The CIP system also has been extended to chiral compounds that do not contain stereogenic centers, but rather have a chiral axis.¹⁰² Compounds having a chiral axis include unsymmetrical allenes, biaryls that exhibit atropisomerism (see Sec. 4.C, category 5), and alkyldiene cyclohexane derivatives, molecular propellers and gears, helicenes, cyclophanes, annulenes, *trans*-cycloalkenes, and metallocenes. A series of rules have been proposed to address these cases based on what is called an “extended tetrahedron mode”, but the rules can be ambiguous in the case of cyclophanes and a few other systems.¹⁰³

4.D.ii. Methods of Determining Configuration¹⁰⁴

In all the methods,¹⁰⁵ it is necessary to relate the compound of unknown configuration to another whose configuration is known. The most important methods of doing this follow:

1. *Conversion of the Unknown to, or Formation of the Unknown from, a Compound of Known Configuration Without Disturbing the Stereogenic Center.* The glyceraldehyde–glyceric acid example above is

one example. The stereogenic center was not disturbed, and the configuration of the product (glyceric acid) is the same as the starting material (glyceraldehyde). Retention of the same absolute configuration such as with glyceraldehyde-to-glyceric acid is not always the case. If the reaction sequence does not disturb (change) the stereogenic center, the absolute configuration depends on the nature of the groups. For example, when (*R*)-1-bromo-2-butanol is reduced to 2-butanol without disturbing the stereogenic center, the product is the (*S*) enantiomer because CH_3CH_2 ranks lower than BrCH_2 , but higher than CH_3 .

2. *Conversion at the Stereogenic Center if the Mechanism is Known.* An $\text{S}_{\text{N}}2$ mechanism proceeds with inversion of configuration at a stereogenic carbon (Sec. 10.A.i). Indeed, a series of such transformations allowed the stereogenic center in lactic acid to be correlated to that in alanine.

3. *Biochemical Methods.* In a series of similar compounds (e.g., amino acids or certain types of steroids), a given enzyme will usually attack only molecules with one kind of configuration. If the enzyme attacks only the L form of eight amino acids, say, then attack on the unknown ninth amino acid will demonstrate that it is also the L form.

¹⁰⁵ Except the X-ray method of Bijvoet.

4. *Optical Comparison.* It is sometimes possible to use the sign and extent of rotation to determine which isomer has which configuration. In a homologous series, the rotation usually changes gradually and in one direction. If the configurations of enough members of the series are known, the configurations of the missing ones can be determined by extrapolation. Also, certain groups contribute more or less fixed amounts to the rotation of the parent molecule, especially when the parent is a rigid system (e.g., a steroid).
5. *The Special X-Ray Method of Bijvoet.* This method gives direct answers and has been used in a number of cases.⁸⁶
6. *Derivatize the Alcohol with a Chiral Nonracemic Reagent and Examine the Ratio of Resulting Diastereomers by Gas Chromatography.*¹⁰⁶ This method is one of the most useful for determining enantiomeric composition. Many derivatizing agents are available, but one class widely used are derivatives of α -methoxy- α -trifluoromethylphenyl acetic acid (MTPA, Mosher's acid, **41**).¹⁰⁷ Reaction with a chiral nonracemic alcohol (R^*OH) generates a Mosher's ester (**42**) that can be analyzed for diastereomeric composition by 1H or ^{19}F NMR, as well as by chromatographic techniques.¹⁰⁸ Complexation with lanthanide shift reagents allow the signals of the MTPA ester to be resolved and used to determine enantiomeric composition.¹⁰⁹ This NMR method, as well as other related methods,¹¹⁰ are effective for determining the absolute configuration of an alcohol of interest (R^*OH , where R^* is a group containing a stereogenic center).¹¹¹ Two, of many other reagents that have been developed to determine the enantiopurity of alcohols and amines, include **43** and **44**. Chloromethyl lactam (**43**) reacts with R^*OH or R^*NHR (R^*NH_2),¹¹² forming derivatives that allow analysis by 1H NMR and **44** reacts with alkoxides (R^*O^-)¹¹³ to form a derivative that can be analyzed by ^{31}P NMR. For a more detailed discussion of methods to determine optical purity, see Section 4.J.

¹¹³ Alexakis, A.; Mutti, S.; Mangeney, P. *J. Org. Chem.* **1992**, 57, 1224.

7. *Other Methods.* Other methods have also been used for determining absolute configuration in a variety of molecules, including optical rotatory dispersion,¹¹⁴ circular dichroism (CD),¹¹⁵ and asymmetric synthesis (Sec. 4.H). Optical rotatory dispersion (ORD) is a measurement of specific rotation $[\alpha]$ as a function of wavelength.¹¹⁶ The change of specific rotation $[\alpha]$ or molar rotation $[\Phi]$ with wavelength is measured, and a plot of either versus wavelength is often related to the sense of chirality or the substance under consideration. In general, the absolute value of the rotation increases as the wavelength decreases. The plot of CD is the differential absorption of left and right circularly polarized radiation by a nonracemic sample, taking place only in spectral regions in which absorption bands are found in the isotropic UV or visible (vis) electronic spectrum.¹¹⁷ The primary application of both ORD and CD is for the assignment of configuration or conformation.¹¹⁸ Configurational and conformational analyses have been carried out using IR and vibrational circular dichroism (VCD) spectroscopies.¹¹⁹

One example, and one of the more effective methods for derivatizing 1,2-diols, is the method employing dimolybdenum tetraacetate $[\text{Mo}_2(\text{AcO})_4]$ developed by Snatzke and Frelek.¹²⁰ Exposure of the resulting complex to air leads, in most cases, to a significant induced CD spectrum (known as ICD). The method can be used for a variety of 1,2-diols.¹²¹

8. *NMR Databases.* Kishi and co-worker's¹²² developed an NMR database¹²³ of various molecules in chiral solvents, for the assignment of relative and absolute stereochemistry without derivatization or degradation. Kishi referred to this database as a "universal NMR database."¹²⁴ The diagram provided for diols **45** illustrates the method (see Fig. 4.3). The graph presents the difference in

FIG. 4.3. Proton NMR analysis for assignment of stereochemistry.

carbon chemical shifts between the average and the values for **45** (100 MHz) in DMBA (*N*, α -dimethylbenzylamine). Spectra were recorded in both enantiomers of the solvent, where the solid bar was recorded in (*R*)-DMBA and the shaded bar in (*S*)-DMBA. The *x*- and *y*-axes represent the carbon number and $\Delta\delta$ ($\delta_{45a-h} - \delta_{ave}$ in ppm), respectively. The graphs are taken from “the ^{13}C NMR database in (*R*)- and (*S*)-DMBA as a deviation in chemical shift for each carbon of a given diastereomer from the average chemical shift of the carbon in question. Each diastereomer exhibits an almost identical NMR profile for (*R*)- and (*S*)-DMBA, but shows an NMR profile distinct and differing from the other diastereomers, demonstrating that the database in (*R*)- and/or (*S*)-DMBA can be used for prediction of the relative stereochemistry of structural motifs in an intact form.”¹²⁵

A ^1H NMR analysis method has been developed that leads to the assignment of the stereochemistry of β -hydroxy ketones, by visual inspection of the ABX patterns for the (*R*)-methylene unit of the β -hydroxyketones.¹²⁶ Since β -hydroxy ketones are derived from the aldol reaction (**16-34**), this method is particularly useful in organic synthesis. A method has also been developed that uses ^{13}C NMR to determine the relative stereochemistry of 2,3-dialkylpentenoic acids.¹²⁷

4.E. THE CAUSE OF OPTICAL ACTIVITY

The question may be asked: Just why does a chiral molecule rotate the plane of polarized light? Theoretically, the answer to this question is known, and in a greatly simplified form may be explained as follows.¹²⁸

Whenever any light hits any molecule in a transparent material, the light is slowed because of interactions with the molecule. This phenomenon on a gross scale is responsible for the refraction of light, and the decrease in velocity is proportional to the refractive index of the material. The extent of interaction depends on the polarizability of the molecule. Plane-polarized light may be regarded as being made up of two kinds of circularly polarized light. Circularly polarized light has the appearance (or would have, if one could see the wave) of a helix propagating around the axis of light motion, and one kind is a left and the other is a right-handed helix. As long as the plane-polarized light is passing through a symmetrical region, the two circularly polarized components travel at the same speed. However, a chiral molecule has a different polarizability depending on whether it is approached from the left or the right. One circularly polarized component approaches the molecule, so to speak, from the left and sees a different polarizability (hence on a gross scale, a different refractive index) than the other and is slowed to a different extent. This would seem to mean that the left- and right-handed circularly polarized components travel at different velocities, since each has been slowed to a different extent. However, it is not possible for two components of the same light to be traveling at different velocities. What actually takes place, therefore, is that the faster component “pulls” the other toward it, resulting in rotation of the plane. Empirical methods for the prediction of the sign and amount of rotation based on bond refractions and polarizabilities of groups in a molecule have been devised,¹²⁹ and have given fairly good results in many cases.

In liquids and gases, the molecules are randomly oriented. A molecule that is optically inactive because it has a plane of symmetry will very seldom be oriented so that the plane of the polarized light coincides with the plane of symmetry. When it is so oriented, that particular molecule does not rotate the plane, but all others not oriented in that manner do rotate the plane, even though the molecules are achiral. There is no net rotation because even though the molecules are present in large numbers and randomly oriented, there will always be another molecule later on in the path of the light that is oriented exactly opposite and will rotate the plane back again. Even if nearly all molecules rotate the plane individually, the total rotation is zero. For chiral molecules, however (if there is no racemic mixture), no opposite orientation is present and there is a net rotation.

An interesting phenomenon was observed when the CD of chiral molecules was measured in achiral solvents. The chiral solvent contributed as much as 10–20% to the

¹²⁸ See Eliel, E.L.; Wilen, S.H.; Mander, L.N. *Stereochemistry of Organic Compounds*, Wiley-Interscience, NY, **1994**, pp. 93–94, 992–999; Wheland, G.W. *Advanced Organic Chemistry*, 3rd ed., Wiley, NY, **1960**, pp. 204–211; Caldwell, D.J.; Eyring, H. *The Theory of Optical Activity* Wiley, NY, **1971**; Buckingham, A.D.; Stiles, P.J. *Acc. CD intensity in some cases. Apparently, the chiral compound can induce a solvation structure that is chiral, even when the solvent molecules themselves are achiral.¹³⁰

4.F. MOLECULES WITH MORE THAN ONE STEREOGENIC CENTER

When a molecule has two stereogenic centers, each has its own configuration and can be classified (*R*) or (*S*) by the CIP method. There are a total of four isomers, since the first center may be (*R*) or (*S*) and so may the second. Each is drawn as both the Fischer projection and in the extended conformation. Since a molecule can have only one mirror image, only one of the other three can be the enantiomer of **A**. This enantiomer is **B** [the mirror image of an (*R*) center is *always* an (*S*) center]. Both **C** and **D** are a second pair of enantiomers and the relationship of **C** and **D** to **A** and **B** is designated by the term *diastereomer*. Diastereomers may be defined as *stereoisomers that are not enantiomers (they are stereoisomers that are not mirror images, and not superimposable)*. Since **C** and **D** are enantiomers, they must have identical properties, except as noted in Section 4.A, and the same is true for **A** and **B**. However, the properties of **A** and **B** are not identical with those of **C** and **D**. They are different compounds, which means that they have different melting points, boiling points, solubilities, reactivity, and all other physical, chemical, and spectral properties. The properties are usually *similar*, but not *identical*. In particular, diastereomers have different specific rotations; indeed one diastereomer may be chiral and rotate the plane of polarized light while another may be achiral and not rotate at all (an example is presented below).

It is now possible to see why, as mentioned in Section 4.A, enantiomers react at different rates with other chiral molecules, but at the same rate with achiral molecules. In the latter case, the activated complex formed from the (*R*) enantiomer and the other molecule is the mirror image of the activated complex formed from the (*S*) enantiomer and the other molecule. Since the two activated complexes are enantiomeric, their energies are the same and the rates of the reactions in which they are formed must be the same (see Chapter 6). However, when an (*R*) enantiomer reacts with a chiral molecule that has, say, the (*R*) configuration, the activated complex has two chiral centers with configurations (*R*) and (*R*), while the activated complex formed from the (*S*) enantiomer has the configurations (*S*) and (*R*). The two activated complexes are diastereomeric, do not have the same energies, and consequently are formed at different rates.

¹³⁰ Fidler, J.; Rodger, P.M.; Rodger, A. *J. Chem. Soc. Perkin Trans. 2* **1993**, 235.

The three stereoisomers of tartaric acid

Although four is the maximum possible number of isomers when the compound has two stereogenic centers (chiral compounds without a stereogenic carbon, or with one stereogenic carbon and another type of stereogenic center, also follow the rules described here), some compounds have fewer. When the three groups on one stereogenic atom are the same as those on the other, one of the isomers (called a *meso* form) has a plane of symmetry, and hence is optically inactive, even though it has two stereogenic carbons. Tartaric acid is a typical case. As shown, there are only three isomers of tartaric acid: a pair of enantiomers and an inactive *meso* form. For compounds that have two stereogenic atoms, *meso* forms are found only where the four groups on one of the chiral atoms are the same as those on the other chiral atom.

In compounds with two or more stereogenic centers, the maximum number of isomers can be calculated from the formula 2^n , where n is the number of stereogenic centers. The actual number may be less than this, owing to *meso* forms,¹³¹ but never more. An interesting case is that of 2,3,4-pentanetriol (or any similar molecule). The middle carbon is not asymmetric when the 2- and 4-carbons are both (*R*) [or both (*S*)]; labeled the *dl* pair. The compound when one of them is (*R*) and the other (*S*) is asymmetric (labeled *meso*). The middle carbon in such compounds is called a *pseudoasymmetric* carbon. In such cases, there are four isomers: two *meso* forms and one *dl* pair. Remember that the *meso* forms are superimposable on their mirror images, and that there are no other stereoisomers. Two diastereomers that have a different configuration at only one chiral center are called *epimers*.

The small letters used for the pseudoasymmetric center are assigned using established rules. An atom that is tetrahedrally substituted and bonded to four different entities, two and only two of which have opposite configurations, is stereogenic. The descriptors “*r*” and “*s*” are used to denote such centers; they are assigned in accordance with Sequence Rule 5, taking into consideration that “(*R*)” has precedence over “(*S*)” in the order of priority.¹³² Step 1: configuration “(*R*)” or “(*S*)” is assigned to stereogenic centers C-2 and C-4; Using 1,2,3-trichloropentane as an example, Step 2: Configuration at C-3 is assigned by applying sequence rule, “(*R*)” precedes “(*S*)”, and if (*R*) precedes (*S*), then Cl is the highest priority, followed by (*R*) and then (*S*): C-3 is *r*. The exchange of the

¹³¹ For a method of generating all stereoisomers consistent with a given empirical formula, suitable for computer use, see Nourse, J.G.; Carhart, R.E.; Smith, D.H.; Djerassi, C. *J. Am. Chem. Soc.* **1979**, 101, 1216; **1980**, 102, 6289.

¹³² Available at http://old.iupac.org/reports/provisional/abstract04/favre_310305.html, Preferred IUPAC Names, Chapter 9, September, 2004, p. 6.

Cl and H atoms at C-3 of the compound on the left generates the compound on the right, and “3*r*” becomes “3*s*”

In compounds with two or more stereogenic centers, the absolute configuration must be separately determined for each center. The usual procedure is to determine the configuration at one center by the methods discussed in Section 4.E.ii, and then to relate the configuration at that center to the others in the molecule. One method is X-ray crystallography, which, as previously noted, cannot be used to determine the absolute configuration at any stereogenic center. This method does give *relative configurations* of all the stereogenic centers in a molecule, and if the absolute configuration of one stereogenic center is independently determined, the absolute configurations of all are then known. Other physical and chemical methods have also been used for this purpose.

How to name the different stereoisomers of a compound when there are more than two is potentially a problem.² Enantiomers have the same IUPAC name, being distinguished by (*R*) and (*S*) or D and L or (+) or (–). In the early days of organic chemistry, it was customary to give each pair of enantiomers a different name or at least a different prefix (e.g., *epi*-, *peri*-, etc.). Thus the aldohexoses are called glucose, mannose, idose, and so on, although they are all 2,3,4,5,6-pentahydroxyhexanal (in their open-chain forms). This practice was partially due to lack of knowledge about which isomers had which configurations.¹³³ Today it is customary to describe *each chiral position* separately as either (*R*) or (*S*) or, in special fields, to use other symbols. Thus, in the case of steroids, groups above the “plane” of the ring system are designated β, and those below it α. Solid lines are typically used to depict β groups and dashed lines for α groups. An example is 1α-chloro-5-cholesten-3β-ol, showing the OH group on the top side of the molecule (up) and the chlorine atom on the bottom side (down).

1α-Chloro-5-cholesten-3β-ol

For many open-chain compounds, prefixes are used that are derived from the names of the corresponding sugars and that describe the whole system rather than each chiral center separately. Two such common prefixes are *erythro*- and *threo*-, which are applied to systems containing two stereogenic carbons when two of the

¹³³ A method has been developed for the determination of stereochemistry in six-membered chair-like rings using residual dipolar couplings. See Yan, J.; Kline, A. D.; Mo, H.; Shapiro, M. J.; Zartler, E. R. *J. Org. Chem.* **2003**, 68, 1786.

groups are the same and the third is different.¹³⁴ The erythro pair has the identical groups on the same side when drawn in the Fischer convention, and if Y were changed to Z, it would be meso. The threo pair has them on opposite sides, and if Y were changed to Z, it would still be a *dl* pair. Another system¹³⁵ for designating stereoisomers¹³⁶ uses the terms *syn* and *anti*. The “main chain” of the molecule is drawn in the common zigzag manner. Then if two non-hydrogen substituents are on the same side of the plane defined by the main chain, the designation is *syn*; otherwise it is *anti*.

4.G. ASYMMETRIC SYNTHESIS

Organic chemists often wish to synthesize a chiral compound in the form of a single enantiomer or diastereomer, rather than as a mixture of stereoisomers. There are two basic ways in which this can be done.¹³⁷ The first way, which is more common, is to begin with a single stereoisomer, and to use a synthesis that does not affect the stereogenic center (or centers). The optically active starting compound can be obtained by a previous synthesis, or by resolution of a racemic mixture (Sec. 4.I). If possible, the starting material is obtained from Nature, since many compounds (e.g., amino acids, sugars, and steroids), are present in Nature in the form of a single enantiomer or diastereomer. These compounds have been referred to as a *chiral pool*; that is, readily available compounds that can be used as starting materials.¹³⁸ This term is not used much now.

The other basic method is called *asymmetric synthesis*,¹³⁹ or *stereoselective synthesis*. As mentioned earlier, optically active materials cannot be created from inactive starting materials and conditions, except in the manner previously noted.⁹⁷ However, when a new stereogenic center is created, the two possible enantiomers need not be formed in equal amounts if anything is present that is not symmetric. Asymmetric synthesis may be categorized into four headings:

1. *Active Substrate*. If a new stereogenic center is created in a molecule that is already optically active, the product will generate diastereomers and the two diastereomers may not (except fortuitously) be formed in equal amounts. The reason is that the direction of attack by the reagent is determined by the groups already there. For certain additions to the carbon–oxygen double bond of ketones containing an asymmetric α carbon, *Cram's rule* predicts which of two diastereomers will predominate (diastereoselectivity).^{140,141} The reaction of **46**, which has a stereogenic center at the α -carbon, and HCN can generate two possible diastereomers (**47** and **48**).

If **46** is observed along its axis, it may be represented as in **49** (Sec. 4.O.i), where S, M, and L stand for small, medium, and large, respectively. The oxygen of the carbonyl orients itself between the small- and the medium-sized groups. The rule requires that the incoming group preferentially attacks on the side of the plane containing the small group. By this rule, it can be predicted that **48** will be formed in larger amounts than **47**.

Another model uses transition state models **50** and **51** to predict diastereoselectivity in what is known as the *Felkin–Anh model*.¹⁴² This model assumes the favored transition state will be that with the greatest separation between the incoming group and any electronegative substituent at the α -carbon. The so-called *Cornforth model* has also been presented as a model for carbonyl addition to halogenated compounds,¹⁴³ and it assumes that the electron pairs on the carbonyl oxygen and on the halogen repel and assume an anti-conformation.

Many reactions of this type are known, and in some the extent of favoritism approaches 100% (e.g., see Reaction **12-12**).¹⁴⁴ The farther away the reaction site is from the chiral center, the less influence the latter has and the more equal the amounts of diastereomers formed. There are many examples of asymmetric induction via nucleophilic acyl addition to carbonyl compounds (Reactions **16-24** and **16-25**). Enolborane addition to α -heteroatom substituted aldehydes has been evaluated using the Cornforth and the Felkin–Anh models.¹⁴⁵

In a special case of this type of asymmetric synthesis, a compound (**52**) with achiral molecules, but whose crystals are chiral, was converted by UV light to a single enantiomer of a chiral product (**53**).¹⁴⁶

It is often possible to convert an achiral compound to a chiral compound by (1) addition of a chiral group; (2) running an asymmetric synthesis, and (3) cleavage of the original chiral group. The original chiral group is called a *chiral auxiliary*.

¹⁴⁶ Evans, S.V.; Garcia-Garibay, M.; Omkaram, N.; Scheffer, J.R.; Trotter, J.; Wireko, F. *J. Am. Chem. Soc.* **1986**, 108, 5648; Garcia-Garibay, M.; Scheffer, J.R.; Trotter, J.; Wireko, F. *Tetrahedron Lett.* **1987**, 28, 4789. For an earlier example, see Penzien, K.; Schmidt, G.M.J. *Angew. Chem. Int. Ed.* **1969**, 8, 608.

An example is conversion of the achiral 2-pentanone to the chiral 4-methyl-3-heptanone, (**55**).¹⁴⁷ In this case, >99% of the product was the (*S*) enantiomer. As noted, compound **54** is called a *chiral auxiliary* because it is used to induce asymmetry and is then removed.

2. *Active Reagent*. A pair of enantiomers can be separated by an active reagent that reacts faster with one of them than it does with the other (this is also a method of resolution). If the absolute configuration of the reagent is known, the configuration of the enantiomers can often be determined by a knowledge of the mechanism and

by determining which diastereomer is preferentially formed.¹⁴⁸ Creation of a new stereogenic center in an inactive molecule can also be accomplished with an optically active reagent, although it is rare for 100% selectivity to be observed. An example^{149,150} is the reduction of methyl benzoylformate with optically active *N*-benzyl-3-(hydroxymethyl)-4-methyl-1,4-dihydropyridine (**56**) to produce mandelic acid (after hydrolysis) that contained ~97.5% of the (*S*)-(+)-isomer and 2.5% of the (*R*)-(–)-isomer (for another example, see Reaction 15-16). Note that the other product, (**57**), is not chiral. Reactions like this, in which one reagent (in this case **56**) gives up its chirality to another, are called *self-immolative*.

In another example:

chirality is transferred from one atom to another in the same molecule.¹⁵¹

A reaction in which an inactive substrate is converted selectively to one of two enantiomers is called an *enantioselective* reaction, and the process is called *asymmetric induction*. These terms apply to reactions in this category and in categories 3 and 4.

When an optically active substrate reacts with an optically active reagent to form two new stereogenic centers, it is possible for both centers to be created in the desired sense. This type of process is called *double asymmetric synthesis*¹⁵² (for an example, see Reaction 16-34).

3. *Optically Active Catalyst or Solvent.*¹⁵³ Many such examples are found in the literature, among them reduction of ketones and substituted alkenes to optically active (though not optically pure) secondary alcohols and substituted alkanes by treatment with hydrogen and a chiral homogeneous hydrogenation catalyst (reactions 16-23 and 15-11),¹⁵⁴ the treatment of aldehydes or ketones with organometallic compounds in the presence of a chiral catalyst (see Reaction 16-24), and the conversion of alkenes to optically active epoxides by treatment with a hydroperoxide and a chiral catalyst (see Reaction 15-50). In some instances, the ratio of enantiomers prepared in this way is 99:1 or more.¹⁵⁵ Other examples of the use of a chiral catalyst or solvent are the conversion of chlorofumaric acid (in the form of its diion) to the (–)-*threo* isomer of the diion of chloromalic acid by treatment with H₂O and the enzyme fumarase,¹⁵⁶ as well as the preparation of

optically active aldols (aldol condensation, see Reaction **16-35**) by the condensation of enolate anions with optically active substrates.¹⁵⁷

4. *Reactions in the Presence of Circularly Polarized Light.*¹⁵⁸ If the light used to initiate a photochemical reaction (see Chap. 7) of achiral reagents is circularly polarized, then, in theory, a chiral product richer in one enantiomer might be obtained. However, such experiments have not proved fruitful. In certain instances, the use of left- and right-circularly polarized light *has* given products with opposite rotations¹⁵⁹ (showing that the principle is valid), but up to now the extent of favoritism has always been <1%.

4.H. METHODS OF RESOLUTION¹⁶⁰

A pair of enantiomers can be separated in several ways, but conversion to diastereomers and separation of these by fractional crystallization or chromatographic methods are used most often. In this method and in some of the others, both isomers can be recovered, but in some methods it is necessary to destroy one.

1. *Conversion to Diastereomers.* If the racemic mixture to be resolved contains a carboxyl group (and no strongly basic group), it is possible to form a salt with an optically active base. Since the base used is, say, the (S) form, there will be a mixture of two salts produced having the configurations (SS) and (RS). Although the acids are enantiomers, the salts are diastereomers and have different properties. The property most often used for separation is differential solubility. The mixture of diastereomeric salts is allowed to crystallize from a suitable solvent.

Since the solubilities are different, the initial crystals formed will be richer in one diastereomer. Filtration at this point will already have achieved a partial resolution. Unfortunately, the difference in solubility is rarely if ever great enough to effect total separation with one crystallization. When fractional crystallizations must be used, the process is long and tedious. Fortunately, naturally occurring optically active bases (mostly alkaloids) are readily available. Among the most commonly used are brucine, ephedrine, strychnine, and morphine. Once the two diastereomers have been separated, it is easy to convert the salts back to the free acids and the recovered base can be used again.

Most resolution of this type is done on carboxylic acids and often, when a molecule does not contain a carboxyl group, it is converted to a carboxylic acid before resolution is attempted. Racemic compounds (e.g., 2-aminocyclohexanol derivatives) react with carboxylic acids (e.g., optically active mandelic acid), to give diastereomers that are separated and then converted to enantiopure compounds.¹⁶¹ Racemic bases can be converted to diastereomeric salts with active acids. The principle of conversion to diastereomers is not confined to carboxylic acids, and other functional groups¹⁶² may be coupled to an optically active reagent.¹⁶³ Alcohols¹⁶⁴ can be converted to diastereomeric esters, aldehydes to diastereomeric hydrazones, and so on. Amino alcohols have been resolved using boric acid and chiral binaphthols.¹⁶⁵ Phosphine oxides¹⁶⁶ and chiral calix[4]arenes¹⁶⁷ have been resolved. Chiral crown ethers have been used to separate mixtures of enantiomeric alkylammonium and arylammonium ions, by the formation of diastereomeric complexes¹⁶⁸ (see also, category 3, below). Even hydrocarbons can be converted to diastereomeric inclusion compounds,¹⁶⁹ with urea. Urea is not chiral, but the cage structure is.¹⁷⁰ Racemic unsaturated hydrocarbons have been resolved as inclusion complex crystals with a chiral host compound derived from tartaric acid.¹⁷¹ *trans*-Cyclooctene (Sec. 4.C, category 6) was resolved by conversion to a Pt complex containing an optically active amine.¹⁷²

Fractional crystallization has always been the most common method for the separation of diastereomers. When it can be used, binary phase diagrams for the diastereomeric salts have been used to calculate the efficiency of optical resolution.¹⁷³ However, it is tedious and the fact that it is limited to solids prompted a search for other methods. Fractional distillation has given only limited separation, but gas chromatography (GC)¹⁷⁴ and preparative liquid chromatography using chiral columns¹⁷⁵ have proved to be more useful. In many cases, they have supplanted fractional crystallization, especially where the quantities to be resolved are small.¹⁷⁶

2. *Differential Absorption.* When a racemic mixture is placed on a chromatographic column, if the column consists of chiral substances, then in principle the enantiomers should move along the column at different rates and should be separable without having to be converted to diastereomers.¹⁷⁶ This has been successfully accomplished with paper, column, thin-layer,¹⁷⁷ and gas and liquid chromatography.¹⁷⁸ For example, racemic mandelic acid has been almost completely resolved by column chromatography on starch.¹⁷⁹ Many workers have achieved separations with gas and liquid chromatography by the use of columns packed with chiral absorbents.¹⁸⁰ Columns packed with chiral materials are now commercially available and are capable of separating the enantiomers of certain types of compounds.¹⁸¹
3. *Chiral Recognition.* The use of chiral hosts to form diastereomeric inclusion compounds was mentioned above. But in some cases it is possible for a host to form an inclusion compound with one enantiomer of a racemic guest, but not the other. This is called *chiral recognition*. One enantiomer fits into the chiral host cavity, the other does not. More often, both diastereomers are formed, but one forms more rapidly than the other, so that if the guest is removed it is already partially resolved (this is a form of kinetic resolution, see category 6). An example is use of the chiral crown ether (**58**) partially to resolve the racemic amine salt (**59**).¹⁸² When an

aqueous solution of **59** was mixed with a solution of optically active **58** in chloroform, and the layers separated, the chloroform layer contained about twice as much of the complex between **58** and (*R*)-**59** as of the diastereomeric complex. Many other chiral crown ethers and cryptands have been used, as have been cyclodextrins,¹⁸³ cholic acid,¹⁸⁴ and other kinds of hosts.¹⁶⁹ Of course, enzymes are generally very good at chiral recognition, and much of the work in this area has been an attempt to mimic the action of enzymes.

4. *Biochemical Processes.*¹⁸⁵ Reactions catalyzed by enzymes can be utilized for this kind of resolution.¹⁸⁶ Biological molecules may react at different rates with the two enantiomers. For example, a certain bacterium may digest one enantiomer, but not the other. Pig liver esterase has been used for the selective cleavage of one enantiomeric ester.¹⁸⁷ This method is limited, since it is necessary to find the proper organism and since one of the enantiomers is destroyed in the process. However, when the proper organism is found, the method leads to a high extent of resolution since biological processes are usually very stereoselective. This process has been called chemoenzymatic dynamic kinetic resolution.¹⁸⁸
5. *Mechanical Separation.*¹⁸⁹ This is the method by which Pasteur proved that racemic tartaric acid was actually a mixture of (+)- and (–)-tartaric acids.¹⁹⁰ In the case of racemic sodium ammonium tartrate, the enantiomers crystallize separately: all the (+) molecules going into one crystal and all the (–) into another. Since the crystals too are nonsuperimposable, their appearance is not identical and a trained crystallographer can separate them with tweezers.¹⁹¹ However, this is seldom a practical method, since few compounds crystallize in this manner. Even sodium ammonium tartrate does so only when it is crystallized

¹⁹⁰ Besides discovering this method of resolution, Pasteur also discovered the method of conversion to diastereomers and separation by fractional crystallization and the method of biochemical separation (and, by extension, kinetic resolution).

¹⁹¹ This is a case of optically active materials arising from inactive materials. However, it may be argued that an optically active investigator is required to use the tweezers. Perhaps a hypothetical human being constructed entirely of inactive molecules would be unable to tell the difference between left- and right-handed crystals.

$<27^{\circ}\text{C}$. A more useful variation of the method, although still not very common, is the seeding of a racemic solution with something that will cause only one enantiomer to crystallize.¹⁹² An interesting example of the mechanical separation technique was reported in the isolation of heptahelicene (Sec. 4.C. Category 7). One enantiomer of this

compound, which incidentally has the extremely high rotation of $[\alpha]_{\text{D}}^{20} = +6200^{\circ}$ spontaneously crystallizes from benzene.¹⁹³ In the case of 1,1'-binaphthyl, optically active crystals can be formed simply by heating polycrystalline racemic samples of the compound at $76\text{--}150^{\circ}\text{C}$. A phase change from one crystal form to another takes place.¹⁹⁴ Note that 1,1'-binaphthyl is one of the few compounds that can be resolved by the Pasteur tweezer method. In some cases, resolution can be achieved by enantioselective crystallization in the presence of a chiral additive.¹⁹⁵ Spontaneous resolution has also been achieved by sublimation. In the case of the norborneol derivative **60**, when the racemic solid is subjected to sublimation, the (+) molecules condense into one crystal and the (−) molecules into another.¹⁹⁶ In this case, the crystals are superimposable, unlike the situation with sodium ammonium tartrate, but the investigators were able to remove a single crystal, which proved optically active.

6. *Kinetic Resolution.*¹⁹⁷ Since enantiomers react with chiral compounds at different rates, it is sometimes possible to effect a partial separation by stopping the reaction before completion. This method is very similar to the asymmetric syntheses discussed in Section 4.C, category 5. A method has been developed to evaluate the enantiomeric ratio of kinetic resolution using only the extent of substrate conversion.¹⁹⁸ An important application of this method is the resolution of racemic alkenes by treatment with optically active diisopinocampheylborane,¹⁹⁹ since alkenes do not easily lend themselves to conversion to diastereomers if no

other functional groups are present. Another example is the resolution of allylic alcohols (e.g., **61**) with one enantiomer of a chiral epoxidation agent (see Reaction **15-50**).²⁰⁰ In the case of **61**, the discrimination was extreme. One enantiomer was converted to the epoxide and the other was not, the rate ratio (hence the selectivity factor) being >100 . Of course, in this method only one of the enantiomers of the original racemic mixture is obtained, but there are at least two possible ways of getting the other: (1) use of the other enantiomer of the chiral reagent and (2) conversion of the product to the starting compound by a reaction that preserves the stereochemistry.

Kinetic resolution of racemic allylic acetates²⁰¹ has been accomplished via asymmetric dihydroxylation (Reaction **15-48**), and 2-oxoimidazolidine-4-carboxylates have been developed as new chiral auxiliaries for the kinetic resolution of amines.²⁰² A planar chiral cyclic ether was found to be stable at ambient temperatures, but resolved by kinetic resolution.²⁰³

7. *Deracemization*. In this type of process, one enantiomer is converted to the other, so that a racemic mixture is converted to a pure enantiomer, or to a mixture enriched in one enantiomer (*enantioenriched*). This finding is not quite the same as the methods of resolution previously mentioned, although an outside optically active substance is required. To effect the deracemization, two conditions are necessary: (1) the enantiomers must complex differently with the optically active substance and (2) they must interconvert under the conditions of the experiment. When racemic thioesters were placed in solution with a specific optically active amide for 28 days, the solution contained 89% of one enantiomer and 11% of the other.²⁰⁴ In this case, the presence of a base (Et_3N) was necessary for the interconversion to take place. Biocatalytic deracemization processes induce deracemization of chiral secondary alcohols.²⁰⁵ In a specific example, *Sphingomonas paucimobilis* NCIMB 8195 catalyzes the efficient deracemization of many secondary alcohols in up to 90% yield of the (*R*)-alcohol.²⁰⁶

4.I. OPTICAL PURITY²⁰⁷

An attempt to resolve a racemic mixture by one of the methods described in Section 4.I has given either a pure compound or a new mixture. How can the purity of the two enantiomers obtained be determined? If the (+) isomer is contaminated by, say, 20% of the (–) isomer, how can this be determined? If the value of $[\alpha]$ for the pure material ($[\alpha]_{\max}$) is known, the purity of a sample is easily determined by measuring its rotation. For example, if $[\alpha]_{\max}$ is $+80^\circ$ and the resolved (+) enantiomer contains 20% of the (–) isomer, $[\alpha]$ for the sample will be $+48^\circ$.²⁰⁸ Optical purity is defined as

$$\text{Percent optical purity} = \frac{[\alpha]_{\text{obs}}}{[\alpha]_{\max}} \times 100$$

Assuming a linear relationship between $[\alpha]$ and concentration, which is true for most cases, the optical purity is equal to the percent excess of one enantiomer over the other:

$$\text{Optical purity} = \text{percent enantiomeric excess (\%ee)}^{209} = \frac{[R] - [S]}{[R] + [S]} \times 100 = (\%R) - (\%S)$$

How is the value of $[\alpha]_{\max}$ determined? It is plain that we have two related problems here; namely, what are the optical purities of our two samples and what is the value of $[\alpha]_{\max}$. Finding the properties of one also gives the other. Several methods for solving these problems are known.

One of these methods involves the use of NMR²¹⁰ (see Sec. 4.E.ii, category 7). If there is a nonracemic mixture of two enantiomers and the proportions constitute an unknown, convert the mixture into a mixture of diastereomers with an optically pure reagent and look at the NMR spectrum of the resulting mixture, for example,

²⁰⁷ For a review, see Raban, M.; Mislow, K. *Top. Stereochem.* **1967**, 2, 199.

²⁰⁸ If a sample contains 80% (+) and 20% (–) isomer, the (–) isomer cancels an equal amount of (+) isomer and the mixture behaves as if 60% of it were (+) and the other 40% inactive. Therefore the rotation is 60% of 80° or 48° . This type of calculation, however, is not valid for cases in which $[\alpha]$ is dependent on concentration (Sec. 4.B); see Horeau, A. *Tetrahedron Lett.* **1969**, 3121.

²⁰⁹ For a method to measure %ee using electrooptics, see Walba, D.M.; Eshdat, L.; Korblova, E.; Shao, R.; Clark, N.A. *Angew. Chem. Int. Ed.* **2007**, 46, 1473.

Educ.* **1969**, 46, 351; Tokles, M.; Snyder, J.K. *Tetrahedron Lett.* **1988**, 29, 6063. For a review, see Yamaguchi, S. in Morrison, J. D. *Asymmetric Synthesis*, Vol. 1, Academic Press, NY, **1983**, pp. 125–152. See also, Raban, M.; Mislow, K. *Top. Stereochem.* **1967**, 2, 199.

If the NMR spectrum of the starting mixture is examined, only one peak would be found (split into a doublet by the C—H) for the Me protons, since enantiomers give identical NMR spectra.²¹¹ But the two amides are not enantiomers and each Me gives its own doublet. From the intensity of the two peaks, the relative proportions of the two diastereomers (and hence of the original enantiomers) can be determined. Alternatively, the “unsplit” OMe peaks could have been used. This method was satisfactorily used to determine the optical purity of a sample of 1-phenylethylamine (the case shown above),²¹² as well as other cases, but it is obvious that sometimes corresponding groups in diastereomeric molecules will give NMR signals that are too close together for resolution. In such cases, one may resort to the use of a different optically pure reagent. The ¹³C NMR can be used in a similar manner.²¹³ It is also possible to use these spectra to determine the absolute configuration of the original enantiomers by comparing the spectra of the diastereomers with those of the original enantiomers.²¹⁴ From a series of experiments with related compounds of known configurations it can be determined in which direction one or more of the ¹H or ¹³C NMR peaks are shifted by formation of the diastereomer. It is then assumed that the peaks of the enantiomers of unknown configuration will be shifted the same way.

A closely related method does not require conversion of enantiomers to diastereomers, but relies on the fact that (in principle, at least) enantiomers have different NMR spectra *in a chiral solvent*, or when mixed with a chiral molecule (in which case transient diastereomeric species may form, see Sec. 4.E.ii). In such cases, the peaks may be separated enough to permit the proportions of enantiomers to be determined from their intensities.²¹⁵ Another variation, which gives better results in many cases, is to use an achiral solvent, but with the addition of a *chiral lanthanide shift reagent* [e.g., *tris*[3-trifluoroacetyl-*d*-camphorato]europium(III)].²¹⁶ Lanthanide shift reagents have the property of spreading NMR peaks of compounds with which they can form coordination compounds (e.g., alcohols, carbonyl compounds, and amines). Chiral lanthanide shift reagents shift the peaks of the two enantiomers of many such compounds to different extents.

Another method, involving GC,²¹⁷ is similar in principle to the NMR chiral complex method. A mixture of enantiomers whose purity is to be determined is converted by means of an optically pure reagent into a mixture of two diastereomers. These diastereomers are then separated by GC and the ratios are determined from the peak areas. Once again, the

²¹¹ Though enantiomers give identical NMR spectra, the spectrum of a single enantiomer may be different from that of the racemic mixture, even in solution. See Williams, T.; Pitcher, R.G.; Bommer, P.; Gutzwiller, J.; Uskoković, M. *J. Am. Chem. Soc.* **1969**, *91*, 1871.

ratio of diastereomers is the same as that of the original enantiomers. High-pressure liquid chromatography has been used in a similar manner and has wider applicability.²¹⁸ The direct separation of enantiomers by gas or liquid chromatography on a chiral column has also been used to determine optical purity.²¹⁹

Other methods²²⁰ involve isotopic dilution,²²¹ kinetic resolution,²²² ¹³C NMR relaxation rates of diastereomeric complexes,²²³ and circular polarization of luminescence.²²⁴

4.J. *cis-trans* ISOMERISM

Compounds in which rotation is restricted may exhibit *cis-trans* isomerism.²²⁵ These compounds do not rotate the plane of polarized light (unless they also happen to be chiral), and the properties of the isomers are not identical. The two most important types are isomerism resulting from double bonds and that resulting from rings.

4.J.i. *cis-trans* Isomerism Resulting from Double Bonds

It has been mentioned (Sec. 1.D) that the two carbon atoms of a C=C double bond and the four atoms directly attached to them are all in the same plane and that the presence of the π -bond prevents rotation around the double bond. This means that in the case of a molecule WXC=CYZ, stereoisomerism exists when $W \neq X$ and $Y \neq Z$. There are two and only two isomers (**62** and **63**), each superimposable on its mirror image unless one of the groups happens to carry a stereogenic center. Note that **62** and **63** are diastereomers, by the definition given in Section 4.E.i. There are two ways to name such isomers. In the older and less versatile method, one isomer is called *cis* and the other *trans*. When each carbon of the C=C unit has an *identical group* (W in **62** and **63**), but fits the substitution pattern of **62** and **63**, the *cis-trans* nomenclature system may be applied. When the two identical groups are on the same side (W and W in **62**), it is labeled *cis*. *cis*-3-Hexene is shown as an example. When the two identical groups are on opposite side (W and W in **63**) it is labeled *trans*. *trans*-3-Hexene is shown as an example. Unfortunately, there is no obvious way to apply this method when the four groups are different.

²²⁴ Schippers, P.H.; Dekkers, H.P.J.M. *Tetrahedron* **1982**, *38*, 2089.

²²⁵ *cis-trans* isomerism was formerly called *geometrical isomerism*.

The newer and more widely applicable method can be applied to all cases, and is based on the CIP system (Sec. 4.E.i). The two groups at each carbon of the C=C unit are ranked by the sequence rules. The isomer with the two higher ranking groups on the same side of the double bond is called (*Z*) (for the German word *zusammen* meaning *together*). The isomer with the two higher ranking groups on opposite sides of the double bond is called (*E*) (for *entgegen* meaning *opposite*).²²⁶ A few examples are shown. Note that the (*Z*) isomer is not necessarily the one that would be called *cis* under the older system (e.g., **64** and **65**). Like *cis* and *trans*, (*E*) and (*Z*) are used as prefixes; for example, **65** is called (*E*)-1-bromo-1,2-dichloroethene.

This type of isomerism is also possible with other double bonds (e.g., C=N,²²⁷ N=N,²²⁸ or even C=S),²²⁹ although in these cases only two or three groups are connected to the double-bond atoms. In the case of imines, oximes, and other C=N compounds, if W = Y, **66** may be called *syn* and **67** *anti*, but (*E*) and (*Z*) are used here too.²³⁰ In azo compounds there is no ambiguity. Compound **68** is always *syn* or (*Z*) regardless of the nature of W and Y.

If there is more than one double bond²³¹ in a molecule and if $W \neq X$ and $Y \neq Z$ for each, the number of isomers in the most general case is 2^n , although this number may be decreased if some of the substituents are the same, as in the three 2,5-heptadienes shown.

When a molecule contains a double bond and a stereogenic carbon, there are four isomers, a *cis* pair of enantiomers and a *trans* pair, shown for 4-methylhex-2-ene.

²²⁶ For a complete description of the system, see *Pure Appl. Chem.* **1976**, 45, 13; *Nomenclature of Organic Chemistry*, Pergamon, Elmsford, NY, **1979** (the Blue Book).

²²⁹ King, J.F.; Durst, T. *Can. J. Chem.* **1966**, 44, 819.

²³⁰ A mechanism has been reported for the acid-catalyzed *Z/E* isomerization of imines. See Johnson, J.E.; Morales, N.M.; Gorczyca, A.M.; Dolliver, D.D.; McAllister, M.A. *J. Org. Chem.* **2001**, 66, 7979.

²³¹ This rule does not apply to allenes, which do not show *cis-trans* isomerism (see Sec. 4.C, category 5).

Double bonds in small rings are so constrained that they must be *cis*. From cyclopropene (a known system) to cycloheptene, double bonds in a stable ring *cannot* be *trans*. However, the cyclooctene ring is large enough to permit *trans* double bonds to exist (see Sec. 4.C, category 7), and for rings larger than 10- or 11-membered, *trans* isomers are more stable²³² (see also, Sec. 4.Q.ii).

In a few cases, single-bond rotation is so slowed that *cis* and *trans* isomers can be isolated even where no double bond exists²³³ (see also, Sec. 4.Q.iv). One example is *N*-methyl-*N*-benzylthiomesitylylide (**69** and **70**).²³⁴ The isomers are stable in the crystalline state, but interconvert with a half-life of ~ 25 h in CDCl_3 at 50°C .²³⁵ This type of isomerism is rare; it is found chiefly in certain amides and thioamides, because resonance gives the single-bond some double-bond character and slows rotation.⁵⁴ (For other examples of restricted rotation about single bonds, see Sec. 4.Q.iv.)

Conversely, there are compounds in which nearly free rotation is possible around what are formally $\text{C}=\text{C}$ double bonds. These compounds, called *push-pull* or *captodative* ethylenes, have two electron-withdrawing groups on one carbon and two electron-donating groups on the other (**71**).²³⁶ The contribution of diionic

TABLE 4.2 Some Properties of Maleic and Fumaric Acids

	Maleic Acid	Fumaric Acid
Property	Maleic Acid	Fumaric Acid
Melting point (°C)	130	286
Solubility in water at 25 °C (g L ⁻¹)	788	7
K_1 (at 25°C)	1.5×10^{-2}	1×10^{-3}
K_2 (at 25°C)	2.6×10^{-7}	3×10^{-5}

canonical forms, such as the one shown, decreases the double-bond character and allows easier rotation. For example, compound **72** has a barrier to rotation of 13 kcal mol⁻¹ (55 kJ mol⁻¹),²³⁷ compared to a typical value of ~62–65 kcal mol⁻¹ (260–270 kJ mol⁻¹) for simple alkenes.

Since they are diastereomers, *cis-trans* isomers always differ in properties; the differences may range from very slight to considerable. The properties of maleic acid are so different from those of fumaric acid (Table 4.2) that it is not surprising that they have different names. Since they generally have more symmetry than *cis* isomers, *trans* isomers in most cases have higher melting points and lower solubilities in inert solvents. The *cis* isomer usually has a higher heat of combustion, which indicates a lower thermochemical stability. Other noticeably different properties are densities, acid strengths, boiling points, and various types of spectra, but the differences are too involved to be discussed here.

It is also important to note that *trans*-alkenes are often more stable than *cis*-alkenes due to diminished steric hindrance (Sec. 4.Q.iv), but this is not always the case. It is known, for example, that *cis*-1,2-difluoroethene is thermodynamically more stable than *trans*-1,2-difluoroethene. This appears to be due to delocalization of halogen lone-pair electrons and an antiperiplanar effect between vicinal antiperiplanar bonds.²³⁸

4.J.ii *cis-trans* Isomerism of Monocyclic Compounds

Although rings of four carbons and larger are not generally planar (see Sec. 4.O), they will be treated as such in this section, since the correct number of isomers can be determined when this is done²³⁹ and the principles are easier to visualize (see Sec. 4.O).

²³⁷ Sandström, J.; Wennerbeck, I. *Acta Chem. Scand. Ser. B*, **1978**, 32, 421.

²³⁸ Yamamoto, T.; Tomoda, S. *Chem. Lett.* **1997**, 1069.

²³⁹ See Leonard, J.E.; Hammond, G.S.; Simmons, H.E. *J. Am. Chem. Soc.* **1975**, 97, 5052.

The presence of a ring, like that of a double bond, prevents rotation. *cis* and *trans* isomers are possible whenever there are two carbons on a ring, each of which is substituted by two different groups. The two carbons need not be adjacent. Examples follow:

In some cases, the two stereoisomers can interconvert. In *cis*- and *trans*-disubstituted cyclopropanones, for example, there is reversible interconversion that favors the more stable *trans* isomer. This fluxional isomerization occurs via ring opening to an unseen oxyallyl *valence bond* isomer.²⁴⁰

While *cis* and *trans* isomers are possible for rings, the restrictions are that W may equal Y and X may equal Z, but W may not equal X and Y may not equal Z. There is an important difference from the double-bond case: The substituted carbons may be stereogenic carbons. This means that there may be more than two isomers. In the most general case, where W, X, Y, and Z are all different, there are four isomers since neither the *cis* nor the *trans* isomer is superimposable on its mirror image. This is true regardless of ring size or which carbons are involved, except that in rings of even-numbered size when W, X, Y, and Z are at opposite corners. Cyclohexane derivative **73**, for example, has no stereogenic carbons because there is a plane of symmetry. Imagine a focus on the chlorine-bearing carbon, and view each “arm” of the ring as a group. There are two identical groups so the carbon will not be stereogenic. When W = Y and X = Z, the *cis* isomer is always superimposable on its mirror image. Hence, this isomer is a meso compound, while the *trans* isomer consists of a *dl* pair, except in the case noted above. Again, the *cis* isomer has a plane of symmetry while the *trans* does not.

Rings with more than two differently substituted carbons can be dealt with using similar principles. In some cases, it is not easy to tell the number of isomers by inspection.¹⁰⁷ The best method may be to count the number *n* of differently substituted carbons (these will usually be asymmetric, but not always, e.g., in **73**), and then to draw 2^n structures, crossing out those that can be superimposed on others (usually the easiest method is to look for a plane of symmetry). By this means, it can be determined that for 1,2,3-cyclohexanetriol there are two meso compounds and a *dl* pair; and for 1,2,3,4,5,6-hexachlorocyclohexane there are seven meso compounds and a *dl* pair. Similar principles apply to heterocyclic rings as long as there are carbons (or other ring atoms) containing two different groups.

²⁴⁰ Sorensen, T.S.; Sun, F. *J. Chem. Soc. Perkin Trans. 2* **1998**, 1053.

Cyclic stereoisomers containing only two differently substituted carbons are named either *cis* or *trans*, as previously indicated. The (*Z*, *E*) system is not used for cyclic compounds. However, *cis-trans* nomenclature will not suffice for compounds with more than two differently substituted atoms. For these compounds, a system is used in which the configuration of each group is given with respect to a reference group, which is chosen as the group attached to the lowest-numbered ring member bearing a substituent giving rise to *cis-trans* isomerism. The reference group is indicated by the symbol *r*. Three stereoisomers named according to this system are 3(*S*), 5(*R*)-dimethylcyclohexan-*s*-1-ol (**74**), 3(*S*), 5(*R*)-dimethylcyclohexan-*r*-1-ol (**75**), and 3(*S*), 5(*S*)-dimethylcyclohexan-*s*-1-ol (**76**). The last example demonstrates the rule that when there are two otherwise equivalent ways of going around the ring, one chooses the path that gives the *cis* designation to the first substituent after the reference. Another example is 2(*S*), 4(*S*)-dimethyl-6*s*-ethyl-1,3-dioxane (**77**).

4.J.iii. *cis-trans* Isomerism of Fused and Bridged Ring Systems

Fused bicyclic systems are those in which two rings share two and only two atoms. In such systems, there is no new principle. The fusion may be *cis* or *trans*, as illustrated by *cis*- and *trans*-decalin. However, when the rings are small enough, the *trans* configuration is impossible and the junction must be *cis*. The smallest *trans* junction that has been prepared when one ring is four membered is a four–five junction; *trans*-bicyclo[3.2.0]heptane (**78**) is known.²⁴¹ For the bicyclo[2.2.0] system (a four–four fusion), only *cis* compounds have been made. The smallest known *trans* junction when one ring is three membered is a six–three junction (a bicyclo[4.1.0] system). An example is **79**.²⁴² When one ring is three-membered and the other eight-membered (an eight–three junction), the *trans*-fused isomer is more stable than the corresponding *cis*-fused isomer.²⁴³

In *bridged* bicyclic ring systems, two rings share more than two atoms. In these cases, there may be fewer than 2^n isomers, because of the structure of the system. For example, there are only two isomers of camphor (a pair of enantiomers), although it has two stereogenic carbons. In both isomers, the methyl and hydrogen are *cis*. The *trans* pair of

²⁴³ Corbally, R.P.; Perkins, M.J.; Carson, A.S.; Laye, P.G.; Steele, W.V. *J. Chem. Soc. Chem. Commun.* **1978**, 778.

enantiomers is impossible in this case, since the bridge *must* be cis. The smallest bridged system so far prepared in which the bridge is trans is the [4.3.1] system; the trans ketone (**80**) has been prepared.²⁴⁴ In this case, there are four isomers, since both the trans and the cis, which has also been prepared, are pairs of enantiomers.

When one of the bridges contains a substituent, the question arises as to how to name the isomers involved. When the two bridges that do *not* contain the substituent are of unequal length, the rule generally followed is that the prefix *endo*- is used when the substituent is closer to the longer of the two unsubstituted bridges; the prefix *exo*- is used when the substituent is closer to the shorter bridge; for example, When the two bridges not containing the substituent are of equal length, this convention cannot be applied, but in some cases a decision can still be made. For example, if one of the two bridges contains a functional group, the *endo* isomer is the one in which the substituent is closer to the functional group:

4.K. OUT-IN ISOMERISM

Another type of stereoisomerism, called *out-in* isomerism (or *in-out*),²⁴⁵ is found in salts of tricyclic diamines with nitrogen at the bridgeheads. In medium-sized bicyclic ring systems, *in-out* isomerism is possible,²⁴⁶ and the bridgehead nitrogen atoms adopt the arrangement that is more stable.²⁴⁷ A focus on the nitrogen lone pairs reveals that 1,4-diazabicyclo[2.2.2]octane (**81**) favors the *out-out* isomer, that 1,6-diazabicyclo[4.4.4]tetradecane (**82**) the *in-in*,²⁴⁸ that 1,5-diazabicyclo[3.3.3]undecane (**83**) has nearly planar nitrogen atoms,²⁴⁹ and that 1,9-diazabicyclo[7.3.1]tridecane (**84**) is *in-out*.²⁵⁰ One can also focus on the NH unit in the case of ammonium salts.

²⁵⁰ Alder, R.W.; Heilbronner, E.; Honegger, E.; McEwen, A.B.; Moss, R.E.; Olefirowicz, E.; Petillo, P.A.; Sessions, R.B.; Weisman, G.R.; White, J.M.; Yang, Z.-Z. *J. Am. Chem. Soc.* **1993**, 115, 6580.

In the examples **85–87**, when k , l , and $m > 6$, the N—H bonds can be inside the molecular cavity or outside, giving rise to three isomers, as shown. Simmons and Park²⁵¹ isolated several such isomers with k , l , and m varying from 6 to 10. In the 9,9,9 compound, the cavity of the in-in isomer is large enough to encapsulate a

chloride ion that is hydrogen bonded to the two N—H groups. The species thus formed is a cryptate, but differs from the cryptates discussed at Section 3.C.ii in that there is a negative rather than a positive ion enclosed.²⁵² Even smaller ones (e.g., the 4,4,4 compound) have been shown to form mono-inside-protonated ions.²⁵³ In compound **88**, which has four quaternary nitrogen atoms, a halide ion has been encapsulated without a hydrogen being present on a nitrogen.²⁵⁴ This ion does not display *in-out* isomerism. *Out-in* and *in-in* isomers have also been prepared in analogous all-carbon tricyclic systems.²⁵⁵

It is known that chiral phosphanes are more pyramidal and that inversion is more difficult, usually requiring temperatures well over 100°C for racemization.²⁵⁶ Alder and Read²⁵⁷ found that deprotonation of bis(phosphorane) **89**, which is known to have an *in-out* structure with significant P—P bonding, leads to a rearrangement and the *out-out* diphosphane **90**. Reprotonation gives **89**,²⁵⁸ with inversion at the nonprotonated phosphorus atom occurring at room temperature.

4.L. ENANTIOTOPIC AND DIASTEREOTOPIC ATOMS, GROUPS, AND FACES²⁵⁹

Many molecules contain atoms or groups that appear to be equivalent, but a close inspection will show them to be actually different. We can test whether two atoms are equivalent by replacing each of them in turn with some other atom or group. If the new molecules created by this process are identical, the original atoms are equivalent; otherwise they are not. There are three cases.

1. In the case of malonic acid [$\text{CH}_2(\text{COOH})_2$], propane (CH_2Me_2), or any other molecule of the form CH_2Y_2 ,²⁶⁰ replacing either of the CH_2 hydrogens by a group Z will give the identical compound. The two hydrogens are thus equivalent. Equivalent atoms and groups need not, of course, be located on the same carbon atom. For example, all the chlorine atoms of hexachlorobenzene are equivalent as are the two bromine atoms of 1,3-dibromopropane.
2. In the case of ethanol, replacing one of the CH_2 hydrogens by a group Z will give one enantiomer of the compound ZCHMeOH (**91**), while replacement of the other hydrogen gives the *other* enantiomer (**92**). Since the two compounds that result upon replacement of H by Z (**91** and **92**) are not identical but enantiomeric, the hydrogens are *not* equivalent. Two atoms or groups that upon replacement with a third group give enantiomers are defined as *enantiotopic*. In any symmetrical environment, the two hydrogens behave as equivalent, but in a dissymmetrical environment they may behave differently. For example, in a reaction

with a chiral reagent they may be attacked at different rates. This has important consequences in enzymatic reactions,²⁶¹ since enzymes are capable of much greater discrimination than ordinary chiral reagents. An example is found in the Krebs

²⁵⁹ These terms were coined by Mislow. See Eliel, E.L. *Top. Curr. Chem.* **1982**, 105, 1; Mislow, K.; Raban, M. *Top. Stereochem.* **1967**, 1, 1. See also, Jennings, W.B. *Chem. Rev.* **1975**, 75, 307.

²⁶⁰ In the case where Y is itself a chiral group, this statement is only true when the two Y groups have the same configuration.

²⁶¹ For a review, see Benner, S.A.; Glasfeld, A.; Piccirilli, J.A. *Top. Stereochem.* **1989**, 19, 127. For a nonenzymatic example, see Job, R.C.; Bruce, T.C. *J. Am. Chem. Soc.* **1974**, 96, 809.

cycle, in biological organisms, where oxaloacetic acid (**93**) is converted to α -oxoglutaric acid (**95**) by a sequence that includes citric acid (**94**) as an intermediate. When **93** is labeled with ^{14}C at the 4 position, the label is found only at C-1 of **95**, despite the fact that **94** is not chiral. The two

CH_2COOH groups of **94** are enantiotopic and the enzyme easily discriminates between them.²⁶² Note that the X atoms or groups of any molecule of the form CX_2WY are always enantiotopic if neither W nor Y is chiral. However, enantiotopic atoms and groups may also be found in other molecules (e.g., the hydrogen atoms in 3-fluoro-3-chlorocyclopropene, **96**). In this case, substitution of an H by a group Z makes the C-3 atom asymmetric and substitution at C-1 gives the opposite enantiomer from substitution at C-2.

The term *prochiral*²⁶³ is used for a compound or group that has two enantiotopic atoms or groups (e.g., CX_2WY). That atom or group X that would lead to an R compound if preferred to the other is called *pro-(R)*. The other is *pro-(S)*; for example,

3. Where two atoms or groups in a molecule are in such positions that replacing each of them in turn by a group Z gives rise to diastereomers, the atoms or groups are called *diastereotopic*. Some examples are the CH_2 groups of 2-chlorobutane (**97**), vinyl chloride (**98**), and chlorocyclopropanone (**99**), as well as the two alkenyl hydrogens

of **100**. Diastereotopic atoms and groups are different in any environment, chiral or achiral. These hydrogens react at different rates with achiral reagents, but an even

²⁶² The experiments were carried out by Evans Jr., E.A.; Slotin, L. *J. Biol. Chem.* **1941**, 141, 439; Wood, H.G.; Werkman, C.H.; Hemingway, A.; Nier, A.O. *J. Biol. Chem.* **1942**, 142, 31. The correct interpretation was given by Ogston, A.G. *Nature (London)* **1948**, 162, 963. For discussion, see Eliel, E.L. *Top. Curr. Chem.* **1982**, 105, 1, pp. 5–7, 45–70.

²⁶³ Hirschmann, H.; Hanson, K.R. *Tetrahedron* **1974**, 30, 3649.

more important consequence is that in NMR spectra, diastereotopic hydrogens theoretically give different peaks and split each other. This is in sharp contrast to equivalent or enantiotopic hydrogens, which are indistinguishable in the NMR, except when chiral solvents are used, in which case enantiotopic (but not equivalent) protons give different peaks.²⁶⁴ The term *isochronous* is used for hydrogens that are indistinguishable in the NMR.²⁶⁵ In practice, the NMR signals from diastereotopic protons are often found to be indistinguishable, but this is merely because they are very close together. Theoretically they are distinct, and they have been resolved in many cases. When they appear together, it is sometimes possible to resolve them by the use of lanthanide shift reagents (Sec. 4.J) or by changing the solvent or concentration. Note that X atoms or groups (CX_2WY) are diastereotopic if either W or Y is chiral.

Just as there are enantiotopic and diastereotopic atoms and groups, *enantiotopic and diastereotopic faces* in trigonal molecules may be distinguished. Again, there are three cases: (1) In formaldehyde or acetone (**101**), attack by an achiral reagent A from either face of the molecule gives rise to the same transition state and product; the two faces are thus equivalent and there is only one product. (2) In 2-butanone (**102**) or acetaldehyde, attack by an achiral A at one face gives a chiral transition state and the enantiomeric products arise from attack at one or the other face. Such faces are *enantiotopic*. Attack at an enantiotopic face by a chiral reagent will generate another stereogenic center, which gives diastereomers that may not be formed in equal amounts. (3) In a case like **103**, the two faces are obviously not equivalent and are called *diastereotopic*. Enantiotopic and diastereotopic faces can be named by an extension of the CIP system (Sec. 4.E.i).²⁶³ If the three groups as arranged by the sequence rules have the order $X > Y > Z$, that face in which the groups in this sequence are clockwise (as in **104**) is the *Re* face (from Latin *rectus*), whereas **105** shows the *Si* face (from Latin *sinister*).

²⁶⁵ For a review of isochronous and nonisochronous nuclei in NMR, see van Gorkom, M.; Hall, G.E. *Q. Rev. Chem. Soc.* **1968**, 22, 14. For a discussion, see Silverstein, R.M.; LaLonde, R.T. *J. Chem. Educ.* **1980**, 57, 343.

Note that new terminology has been proposed.²⁶⁶ The concept of sphericity is used, and the terms homospheric, enantiospheric, and hemispheric have been coined to specify the nature of an orbit (an equivalent class) assigned to a coset representation.²⁶⁷ Using these terms, prochirality can be defined: If a molecule has at least one enantiospheric orbit, the molecule is defined as being prochiral.²⁵⁸

4.M. STEREOSPECIFIC AND STEREOSELECTIVE SYNTHESSES

Any reaction in which only one of a set of stereoisomers is formed predominantly is called a *stereoselective* synthesis.²⁶⁸ The same term is used when a mixture of two or more stereoisomers is exclusively or predominantly formed at the expense of other stereoisomers. In a *stereospecific* reaction, a given isomer leads to one product while another stereoisomer leads to the opposite product. All stereospecific reactions are necessarily stereoselective, but the converse is not true. These terms are best illustrated by examples. Thus, if maleic acid treated with bromine gives the *dl* pair of 2,3-dibromosuccinic acid while fumaric acid gives the meso isomer (this is the case), the reaction is stereospecific as well as stereoselective because two opposite isomers give two opposite isomers. However, if both maleic and fumaric acid gave the *dl* pair or a mixture in which the *dl* pair predominated, the reaction would be stereoselective, but not stereospecific. If more or less equal amounts of *dl* and meso forms were produced in each case, the reaction would be nonstereoselective. A consequence of these definitions is that if a reaction is carried out on a compound that has no stereoisomers, it cannot be stereospecific, but at most stereoselective. For example, addition of bromine to methylacetylene could (and does) result in preferential formation of *trans*-1,2-dibromopropene, but this can be only a stereoselective, not a stereospecific reaction.

4.N. CONFORMATIONAL ANALYSIS

For acyclic molecules with single covalent bonds, there is rotation about those bonds. As a practical matter, such rotation leads to different arrangements of the atoms with respect to a given bond, but all arrangements constitute the same molecule. The different

²⁶⁸ For a further discussion of these terms and of stereoselective reactions in general, see Eliel, E.L.; Wilen, S.H.; Mander, L.N. *Stereochemistry of Organic Compounds*, Wiley-Interscience, NY, **1994**, pp. 835–990.

arrangements for a molecule due to such rotation are called *rotamers*. In principle, there is rotation about every single bond and a near infinite number of rotamers. If two different 3D spatial arrangements of the atoms in an acyclic molecule are interconvertible merely by free rotation about bonds, they are called *conformations*.²⁶⁹ If they are not interconvertible, they are called *configurations*.²⁷⁰ Configurations represent *isomers* that can be separated, as previously discussed in this chapter. Conformations represent *conformers*, which are rapidly interconvertible and thus nonseparable. The terms “conformational isomer” or more commonly “rotamer”²⁷¹ are used to identify one of many structures that result from rotation about single covalent bonds. Typically, the conformation is the average of the collection of lower energy rotamers for an acyclic compound. A number of methods have been used to determine conformations.²⁷² These include X-ray and electron diffraction, IR, Raman, UV, NMR,²⁷³ and microwave spectra,²⁷⁴ PES,²⁷⁵ supersonic molecular jet spectroscopy,²⁷⁶ and ORD and CD measurements.²⁷⁷ Ring current NMR anisotropy has been applied to conformational analysis,²⁷⁸ as has chemical shift simulation.²⁷⁹ Some of these methods are useful only for solids. It must be kept in mind that the conformation of a molecule in the solid state is not necessarily the same as in solution.²⁸⁰ Conformations can be *calculated* by a method called molecular mechanics (Sec. 4.P). A method was reported that characterized six-membered ring conformations as a linear combination of ideal basic conformations.²⁸¹ The term absolute conformation has been introduced for molecules where

one conformation is optically inactive but, by internal rotation about a $C(sp^3)–C(sp^3)$ bond, optically active conformers are produced.²⁸²

Note that “free” rotation about single bonds is not possible in cyclic molecules, but rather pseudorotation that leads to different conformations. This discussion will therefore separate rotation in acyclic molecules from pseudorotation in cyclic molecules.

4.N.i. Conformation in Open-Chain Systems²⁸³

For any open-chain molecule with a single bond that connects two sp^3 carbon atoms, an infinite number of rotamers are possible, each of which has a certain energy associated with it, which leads to an infinite number of conformations. As a practical matter, the number of conformations is much less. If one ignores duplications due to symmetry, the number of conformations can be *estimated* as being $> 3^n$, where n = the number of internal C—C bonds. For example, *n*-pentane, has 11, *n*-hexane 35, *n*-heptane 109, *n*-octane 347, *n*-nonane 1101, and *n*-decane 3263.²⁸⁴ For ethane, there are two important rotamers that are taken as the extremes, a conformation of highest (marked eclipsed) and one of lowest (marked staggered) potential energy, depicted in two ways as sawhorse diagrams or Newman projections. In *Newman projection formulas*, the observer looks at the C—C bond head on. The three lines emanating from the center of the circle represent the bonds coming from the front carbon, with respect to the observer.

The staggered conformation is the conformation of lowest potential energy for ethane. As rotation about the bond occurs, the energy gradually increases until the eclipsed conformation is reached, when the energy is at a maximum. Further rotation decreases the energy again. Figure 4.4 illustrates this finding. The *angle of torsion*, which is a dihedral angle, is the angle between the X—C—C and the C—C—Y planes, as shown in the diagram. For ethane, the difference in energy is $\sim 2.9 \text{ kcal mol}^{-1}$ (12 kJ mol^{-1}).²⁸⁵ This difference is called the *energy barrier or rotational barrier*,²⁸⁶ since in free rotation about a single bond there must be enough rotational energy present to cross the barrier every time two hydrogen atoms are opposite each other. There was

FIG. 4.4. Conformational energy diagram for ethane.

much speculation about the cause of the barriers and many explanations have been suggested.²⁸⁷ It has been concluded from MO calculations (see Sec. 4.P) that the barrier is caused by repulsion between overlapping filled molecular orbitals.²⁸⁸ The staggered conformation of ethane is lowest in energy because the orbitals of the C—H bonds in this conformation have the least amount of overlap with the C—H orbitals of the adjacent carbon.

At ordinary temperatures, enough rotational energy is present for the ethane molecule to rotate rapidly, but it spends most of its time at or near the energy minimum. Groups larger than hydrogen cause larger barriers, presumably due to steric interactions between the larger units.²⁸⁹ When the barriers are large enough, as in the case of suitably substituted biphenyls (Sec. 4.C, category 5) or the diadamantyl compound mentioned (see **107** and **108**) rotation at room temperature is completely prevented, which is described as a *q* configuration not *a* conformations. Even for compounds with small barriers, cooling to low temperatures may remove enough rotational energy for what would otherwise be conformational isomers to become configurational isomers.

A 1,2-disubstituted ethane ($\text{YCH}_2\text{—CH}_2\text{Y}$ or $\text{YCH}_2\text{—CH}_2\text{X}$,²⁹⁰ e.g., *n*-butane),²⁹¹ is somewhat more complicated. There are four extremes: a fully staggered conformation, called *anti*, *trans*, or *antiperiplanar*; another staggered conformation, called *gauche* or *synclinal*; and two types of eclipsed conformations, called *synperiplanar* and *anticlinal*.

FIG. 4.5. Conformational energy for $\text{YCH}_2\text{—CH}_2\text{Y}$ or $\text{YCH}_2\text{—CH}_2\text{X}$. For *n*-butane, $\Delta E_1 = 4\text{--}6$, $\Delta E_2 = 0.9$, and $\Delta E_3 = 3.4 \text{ kcal mol}^{-1}$ (17–25, 3.8, 14 kJ mol^{-1} , respectively).

An energy diagram for this system is given in Fig. 4.5. Although there is constant rotation about the central bond, it is possible to estimate what percentage of the molecules are in each conformation at a given time. For example, a consideration of dipole moment and polarizability measurements led to the conclusion that for 1,2-dichloroethane in CCl_4 solution at 25°C $\sim 70\%$ of the molecules are in the *anti* and $\sim 30\%$ in the *gauche* conformation.²⁹² The corresponding figures for 1,2-dibromoethane are 89% *anti* and 11% *gauche*.²⁹³ The eclipsed conformations are unpopulated and serve only as pathways from one staggered conformation to another. Solids normally consist of a single conformer.

It may be observed that the *gauche* conformation of butane (see **106**), or any other similar molecule, appears to be chiral. It is not. The lack of optical activity in such compounds arises from the fact that **106** is not a static molecule, but is in dynamic equilibrium with many other conformations, including its mirror image. In effect, they interconvert too rapidly for separation.

For butane and for most other molecules of the forms $\text{YCH}_2\text{—CH}_2\text{Y}$ and $\text{YCH}_2\text{—CH}_2\text{X}$, the *anti* conformer is the most stable, but exceptions are known. One group of exceptions consists of molecules containing small electronegative atoms, especially

fluorine and oxygen. Thus 2-fluoroethanol,²⁹⁴ 1,2-difluoroethane,²⁹⁵ and 2-fluoroethyl trichloroacetate (FCH₂CH₂OCOCCL₃)²⁹⁶ exist predominantly in the *gauche* form and compounds, such as, 2-chloroethanol and 2-bromoethanol,²⁹⁴ also prefer the *gauche* form. It has been proposed that the preference for the *gauche* conformation in these molecules is an example of a more general phenomenon, known as the *gauche effect*; that is, a tendency to adopt that structure that has the maximum number of *gauche* interactions between adjacent electron pairs or polar bonds.²⁹⁷ It was believed that the favorable *gauche* conformation of 2-fluoroethanol was the result of intramolecular hydrogen bonding, but this explanation does not do for molecules like 2-fluoroethyl trichloroacetate. It has in fact been ruled out for 2-fluoroethanol as well.²⁹⁸ The effect of β -substituents in Y—C—C—OX systems where Y = F or SiR₃ has been examined and there is a small bond shortening effect on C—OX that is greatest when OX is a good leaving group. Bond lengthening was also observed with the β -silyl substituent.²⁹⁹ Other exceptions are known, where small electronegative atoms are absent. For example 1,1,2,2-tetrachloroethane and 1,1,2,2-tetrabromoethane both prefer the *gauche* conformation,³⁰⁰ even though 1,1,2,2-tetrafluoroethane prefers the *anti*.³⁰¹ Also, both 2,3-dimethylpentane and 3,4-dimethylhexane prefer the *gauche* conformation,³⁰² and 2,3-dimethylbutane shows no preference for either.³⁰³ Furthermore, the solvent can exert a powerful effect. For example, the compound 2,3-dinitro-2,3-dimethylbutane exists entirely in the *gauche* conformation in the solid state, but in benzene, the *gauche/anti* ratio is 79:21; while in CCl₄ the *anti* form is actually favored (*gauche/anti* ratio 42:58).³⁰⁴ In many cases, there are differences in the conformation of these molecules between the gas and the liquid phase (as when X = Y = OMe) because of polar interactions with the solvent.³⁰⁵

In one case, two conformational isomers of a single aliphatic hydrocarbon, 3,4-di(1-adamantyl)-2,2,5,5-tetramethylhexane, have proven stable enough for isolation at room temperature.³⁰⁶ The two isomers **107** and **108** were separately crystallized, and the structures were proven by X-ray crystallography. The actual dihedral angles are distorted from the 60° angles shown in the drawings, due to steric hindrance between the large adamantyl and *tert*-butyl groups.

All the conformations so far discussed have involved rotation about sp^3-sp^3 bonds. Many studies have also been made of compounds with sp^3-sp^2 bonds.³⁰⁷ For example, propanal (or any similar molecule) has four extreme conformations, two of which are called *eclipsing* and the other two *bisecting*. For propanal, the eclipsing conformations have lower energy than the other two, with **109** favored over **110** by ~ 1 kcal mol⁻¹ (4 kJ mol⁻¹).³⁰⁸ As already pointed out (Sec. 4.K.i), for a few of these compounds, rotation is slow enough to permit *cis-trans* isomerism, although for simple compounds rotation is rapid. The *cis* conformer of acetic acid was produced in solid Ar,³⁰⁹ and it was reported that acetaldehyde has a lower rotational barrier (~ 1 kcal mol⁻¹ or 4 kJ mol⁻¹) than ethane.³¹⁰ Calculations have examined the rotational barriers around the CO and CC bonds in formic acid, ethanedial, and glycolaldehyde molecules.³¹¹

Other carbonyl compounds exhibit rotation about sp^3-sp^3 bonds, including amides.³¹² In *N*-acetyl-*N*-methylaniline, the *cis*-conformation (**111**) is more stable than the *trans*-conformation (**112**) by 3.5 kcal mol⁻¹ (14.6 kJ mol⁻¹).³¹³ This is due to destabilization of (*S*) due to steric hindrance between two methyl groups, and to electronic repulsion between the carbonyl lone-pair electrons and the phenyl π -electrons in the twisted phenyl orientation.³¹³

A similar conformational analysis has been done with formamide derivatives,³¹⁴ with secondary amides,³¹⁵ and for hydroxamide acids.³¹⁶ It is known that thioformamide has a larger rotational barrier than formamide, which can be explained by a traditional picture of amide “resonance” that is more appropriate for the thioformamide than formamide itself.³¹⁷ Torsional barriers in α -keto amides have been reported,³¹⁸ and the C—N bond of acetamides,³¹⁹ thioamides,³²⁰ enamides³²¹ carbamates (R_2N-CO_2R'),³²² and enolate anions derived from amides³²³ have been examined. It is known that substituents influence rotational barriers.³²⁴

In Section 4.C, category 5, atropisomerism was possible when ortho substituents on biphenyl derivatives and certain other aromatic compounds prevented rotation about the $C^{sp^3}-C^{sp^3}$ bond. The presence of ortho-substituents can also influence the conformation of certain groups.³²⁵ In **113**, R = alkyl and the carbonyl unit is planar, with the *trans* C=O \cdots F conformer is more stable when X = F. When X = CF₃, the *cis* and *trans* are planar and the *trans* predominates.³²⁶ When R = alkyl, there is one orthogonal conformation, but there are two interconverting nonplanar conformations when R = *O*-alkyl.³²⁶ In 1,2-diacylbenzenes, the carbonyl units tend to adopt a twisted conformation to minimize steric interactions.³²⁷

4.N.ii. Conformation in Six-Membered Rings³²⁸

For cyclic compounds, complete rotation (360°) about a single bond is impossible. However, repulsion between atoms and groups leads to motion about each bond called pseudorotation. Pseudorotation leads to a variety of different conformations, depending on the size of the ring. In many such conformations, the ring is said to be puckered. For cyclohexane, there are two extreme conformations in which all the angles are tetrahedral (the C—C—C angles in cyclohexane are actually 111.5°).³²⁹ These are called the *boat* and the *chair* conformations. The chair conformation is the low-energy structure that participates in a dynamic equilibrium (there are two chair conformations that are

equivalent in energy for cyclohexane), and the boat form is a higher energy form³³⁰ in equilibrium with a somewhat more stable form

known as the *twist* conformation. The twist form is $\sim 1.5 \text{ kcal mol}^{-1}$ (6.3 kJ mol^{-1}) more stable than the boat because it has less eclipsing interaction (see below).³³¹ The chair form is more stable than the twist form by $\sim 5 \text{ kcal mol}^{-1}$ (21 kJ mol^{-1}).³³² In the vast majority of compounds containing a cyclohexane ring, the molecules exist almost entirely as equilibrating chair forms.³³³ It is known that the boat or twist form exists transiently. In some cases, chair and twist–boat conformations have actually been observed (*cis*-1,4-di-*tert*-butylcyclohexane, e.g.).³³⁴

Axial and equatorial bonds
in chair cyclohexane

An inspection of the chair form shows that six of its bonds are directed differently from the other six. On each carbon, one bond is directed up or down and the other more or less in the “plane” of the ring. The up or down bonds are called *axial* and the others are *equatorial*. The axial bonds point alternately up and down. If a molecule were frozen into a chair form, there would be isomerism in monosubstituted cyclohexanes. For example, there would be an equatorial methylcyclohexane and an axial isomer. This result is incorrect, however, as it has never been possible to isolate isomers of this type at room temperature.³³⁵ In order for the two types of methylcyclohexane to be nonseparable, there must be rapid inter-conversion of one chair form to another (in which all axial bonds become equatorial and vice versa) and this is possible only if the boat or twist conformations are transient species. Conversion of one chair form to another requires an activation energy of $\sim 10 \text{ kcal mol}^{-1}$ (42 kJ mol^{-1})³³⁶ and is very rapid at room temperature.³³⁷ However, by working at low temperatures, Jensen and Bushweller³³⁸ were able to obtain the pure equatorial conformers of chlorocyclohexane and trideuteriomethoxycyclohexane as solids and in solution. Equatorial chlorocyclohexane has a half-life of 22 years in solution at -160°C .

In some molecules, the twist conformation is actually preferred.³³⁹ Of course, in certain bicyclic compounds, the six-membered ring is forced to maintain a boat or twist conformation, as in norbornane or twistane.

In monosubstituted cyclohexanes, the substituent normally prefers the equatorial position because there is an interaction between the substituent and the axial hydrogens in the axial 3 and 5 positions, but the extent of this preference depends greatly on the nature of the group.³⁴⁰ Alkyl groups have a greater preference for the equatorial position than polar groups. For alkyl groups, the preference increases with size, although size seems to be unimportant for polar groups. Both the large HgBr ³⁴¹ and HgCl ³⁴² groups and the small F group have been reported to have little or no conformational preference (the HgCl group actually shows a slight preference for the axial position). Table 4.3 gives approximate values of the free energy required for various groups to go from the equatorial position to the axial (these are called *A* values),³⁴³ although it must be kept in mind that they vary somewhat with physical state, temperature, and solvent.³⁴⁴ Values for other groups in kcal mol^{-1} include D ³⁴⁵ (0.008), NH_2 ³⁴⁶ (1.4), $\text{CH}=\text{CH}_2$ ³⁴⁷ (1.7), CH_3 ³⁴⁸ (1.74), C_6H_{11} ³⁴⁹ (2.15), $\text{Si}(\text{CH}_3)$ ³⁵⁰ (2.4–2.6), OCH_3 ³⁵¹ (0.75), C_6H_5 ³⁵² (2.7), and $t\text{-(CH}_3)_3\text{C}$ ³⁵³ (4.9).

For alkyl groups in disubstituted compounds, the conformation is such that as many groups as possible adopt the equatorial position. This conformation will minimize the axial interactions (known as $\text{A}^{1,3}$ -strain), and will be the lower energy conformation. The preference for one chair conformation over the other depends on the groups attached to the cyclohexane ring, and their relative positions on that ring. In a *cis*-1,2-disubstituted cyclohexane, one substituent must be axial and the other equatorial. In a *trans*-1,2,

^bThe A values or A^{1,3}-strain.

compound both may be equatorial or both axial. This finding is also true for 1,4-disubstituted cyclohexanes, but the reverse holds for 1,3-compounds: the *trans* isomer must have the *age* conformation and the *cis* isomer may be *a* or *ee*. For alkyl groups, the *ee* conformation predominates over the *a*, but for other groups this is not necessarily so. For example, both *trans*-1,4-dibromocyclohexane and the corresponding dichloro compound have the *ee* and *a* conformations about equally populated³⁵⁴ and most *trans*-1,2-dihalo-cyclohexanes exist predominantly in the *a* conformation.³⁵⁵ Note that in the latter case the two halogen atoms are anti in the *a* conformation, but *gauche* in the *ee* conformation.³⁵⁶

Since compounds with alkyl equatorial substituents are generally more stable, *trans*-1,2 compounds, which can adopt the *ee* conformation, are thermodynamically more stable than their *cis*-1,2 isomers, which must exist in the *age* conformation. For the 1,2-dimethylcyclohexanes, the difference in stability is ~2 kcal mol⁻¹ (8 kJ mol⁻¹). Similarly, *trans*-1,4 and *cis*-1,3 compounds are more stable than their stereoisomers.

An interesting anomaly is *all-trans*-1,2,3,4,5,6-hexaisopropylcyclohexane, in which the six isopropyl groups prefer the axial position, although the six ethyl groups of the corresponding hexaethyl compound prefer the equatorial position.³⁵⁷ The alkyl groups of these compounds can of course only be all axial or all equatorial, and it is likely that the molecule prefers the all-axial conformation because of unavoidable strain in the other conformation.

³⁵⁶ For a case of a preferential diaxial conformation in 1,3 isomers, see Ochiai, M.; Iwaki, S.; Ukita, T.; Matsuura, Y.; Shiro, M.; Nagao, Y. *J. Am. Chem. Soc.* **1988**, *110*, 4606.

³⁵⁷ Golan, O.; Goren, Z.; Biali, S.E. *J. Am. Chem. Soc.* **1990**, *112*, 9300.

Incidentally, it is now apparent, at least in one case, why the correct number of stereoisomers could be predicted by assuming planar rings, even though they are not planar (Sec. 4.K.ii). In the case of both a *cis*-1,2-X,X-disubstituted and a *cis*-1,2-X,Y-disubstituted cyclohexane, the molecule is nonsuperimposable on its mirror image; neither has a plane of symmetry. However, in the former case (**114**) conversion of one chair form to the other which of course happens rapidly, turns the molecule into its mirror image, while in the latter case (**115**) rapid interconversion does not give the mirror image, but merely the conformer in which the original axial and equatorial substituents exchange places. Thus the optical inactivity of **114** is not due to a plane of symmetry, but to a rapid interconversion of the molecule and its mirror image. A similar situation holds for *cis*-1,3 compounds. However, for *cis*-1,4 isomers (both X,X and X,Y) optical inactivity arises from a plane of symmetry in both conformations. All *trans*-1,2- and *trans*-1,3-disubstituted cyclohexanes are chiral (whether X,X or X,Y), while *trans*-1,4 compounds (both X,X and X,Y) are achiral, since all conformations have a plane of symmetry. It has been shown that the equilibrium is very dependent on both the solvent and the concentration of the disubstituted cyclohexane.³⁵⁸ A theoretical study of the 1,2-dihalides showed a preference for the diaxial form with X = Cl, but predicted that the energy difference between diaxial and diequatorial was small when X = F.³⁵⁹

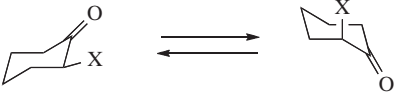

The conformation of a group can be frozen into a desired position by putting a large alkyl group into the ring (most often *tert*-butyl), which introduces significant $A^{1,3}$ -strain and leads to a preference for the chair with the groups in the equatorial position.³⁶⁰ It is known that silylated derivatives of *trans*-1,4- and *trans*-1,2-dihydroxycyclohexane, some monosilyloxycyclohexanes and some silylated sugars have unusually large populations of chair conformations with axial substituents.³⁶¹ Adjacent silyl groups in the 1,2-disubstituted series show a stabilizing interaction in all conformations, generally leading to unusually large axial populations.

The principles involved in the conformational analysis of six-membered rings containing one or two trigonal atoms. For example, cyclohexanone and cyclohexene, are similar.^{362–364} The barrier to interconversion in cyclohexane has been calculated to be 8.4–12.1 kcal mol^{−1} (35.2–50.7 kJ mol^{−1}).³⁶⁵ Cyclohexanone derivatives also assume a chair-conformation. Substituents at C-2 can assume an axial or equatorial position depending on steric and electronic influences. The proportion of the conformation with an axial X group is shown in Table 4.4 for a variety of substituents (X) in 2-substituted cyclohexanones.³⁶⁶

4.N.iii. Conformation in Six-Membered Rings Containing Heteroatoms

In six-membered rings containing heteroatoms,³⁶⁷ the basic principles are the same; that is, there are chair, twist, and boat forms, axial, and equatorial groups. The conformational equilibrium for tetrahydropyridines, for example, has been studied.³⁶⁸ In certain compounds, a number of new factors enter the picture. Only two of these will be examined.³⁶⁹

1. In 5-alkyl-substituted 1,3-dioxanes, the 5-substituent has a much smaller preference for the equatorial position than in cyclohexane derivatives;³⁷⁰ the $A^{1,3}$ -strain is much lower. This fact indicates that the lone pairs on the oxygens have a smaller steric requirement than the C—H bonds in the corresponding cyclohexane derivatives. There is some evidence of a homoanomeric interaction in these systems.³⁷¹ Similar behavior is found in the 1,3-dithianes,³⁷² and 2,3-disubstituted-1,4-dithianes have also been examined.³⁷³ With certain non-alkyl substituents (e.g., F, NO₂, SOMe,³⁷⁴ NMe₃⁺) the axial position is actually preferred.³⁷⁵

Substituted 1,3-dioxanes

2. An alkyl group located on a carbon α to a heteroatom prefers the equatorial position, which is of course the normally expected behavior, but a *polar* group in such a location prefers the *axial* position. An example of this phenomenon, known as the *anomeric effect*,³⁷⁶ is the greater stability of α -glucosides over β -glucosides. A number of explanations have been offered for the anomeric

effect.³⁷⁷ The one³⁷⁸ that has received the most acceptance³⁷⁹ is that one of the lone pairs of the polar atom connected to the carbon (an oxygen atom in the case of **117**) can be stabilized by overlapping with an antibonding orbital of the bond between the carbon and the other polar atom:

This can happen only if the two orbitals are in the positions shown. The situation can also be represented by this type of hyperconjugation (called “negative hyperconjugation,” see Sec. 2.M):

It is possible that simple repulsion between parallel dipoles in **116** also plays a part in the greater stability of **117**. It has been shown that aqueous solvation effects reduce anomeric stabilization in many systems, particularly for tetrahydropyrans. In contrast to cyclic acetals, simple acyclic acetals rarely adopt the anomeric conformation, apparently because the eclipsed conformation better accommodates steric interactions of groups linked by relatively short carbon–oxygen bonds.³⁸¹ In all *cis*-2,5-di-*tert*-butyl-1,4-cyclohexanediol, hydrogen bonding stabilizes the otherwise high-energy form³⁸² and 1,3-dioxane (**118**) exists largely as the twist conformation shown.³⁸³ The conformational preference of 1-methyl-1-silacyclohexane (**121**) has been studied.³⁸⁴ A strongly decreased activation barrier in

silacyclohexane was observed, as compared to that in the parent ring, and is explained by the longer endocyclic Si—C bonds.

Second-row heteroatoms are known to show a substantial anomeric effect.³⁸⁵ There appears to be evidence for a reverse anomeric effect in 2-aminotetrahydropyrans,³⁸⁶ but it has been called into question whether a reverse anomeric effect exists at all.³⁸⁷ In **119**, the lone-pair electrons assume an axial conformation and there is an anomeric effect.³⁸⁸ In **120**, however, the lone-pair electron orbitals are oriented *gauche* to both the axial and equatorial α -CH bond and there is no anomeric effect.³⁸⁸

4.N.iv. Conformation in Other Rings³⁸⁹

Three-membered saturated rings are usually planar, but other small rings can have some flexibility. Cyclobutane³⁹⁰ is not planar, but exists as in **122**, with an angle between the planes of $\sim 35^\circ$.³⁹¹ The deviation from planarity is presumably caused by eclipsing in the planar form (see Sec. 4.Q.i). Oxetane is closer to

planarity because there is less eclipsing, with an angle between the planes of $\sim 10^\circ$.³⁹² Cyclopentane might be expected to be planar, since the angles of a regular pentagon are 108° , but it is not so, also because of eclipsing effects.³⁹³ There are two puckered conformations for cyclopentane, the *envelope* and the *half-chair*. There is little energy difference between these two forms and many five-membered ring systems have

conformations somewhere in between them.³⁹⁴ Although in the envelope conformation one carbon is shown above the others,

ring motions cause each of the carbons in rapid succession to assume this position. The puckering rotates around the ring in what is called a *pseudorotation*³⁹⁵ (see Sec. 4.O.ii). In substituted cyclopentanes and five-membered rings in which at least one atom does not contain two substituents [e.g., tetrahydrofuran (THF), cyclopentanone, C₃- and C₇-monosubstituted and disubstituted hexahydroazepin-2-ones (caprolactams),³⁹⁶ tetrahydrothiophene *S*-oxide³⁹⁷], one conformer may be more stable than the others. The barrier to planarity in cyclopentane has been reported to be 5.2 kcal mol⁻¹ (22 kJ mol⁻¹).³⁹⁸ Contrary to previous reports, there is only weak stabilization (<2 kcal mol⁻¹; <8 kJ mol⁻¹) of three-, four-, and five-membered rings by *gem*-dialkoxycarbonyl substituents (e.g., COOR).³⁹⁹

Rings larger than six-membered are always puckered⁴⁰⁰ unless they contain a large number of *sp*² atoms (see the section on strain in medium rings, Sec. 4.Q.ii). The energy and conformations of the alkane series cycloheptane to cyclodecane has been reported.⁴⁰¹ The conformation shown for oxacyclooctane (**123**), for example, appears to be the most abundant one.⁴⁰² The conformations of other large-ring compounds have been studied, including cycloundecane,⁴⁰³ 11-membered ring lactones,⁴⁰⁴ 10- and 11-membered ring ketones,⁴⁰⁵ and 11- and 14-membered ring lactams.⁴⁰⁶ Dynamic NMR was used to determine the conformation large-ring cycloalkenes and lactones,⁴⁰⁷ and C—H coupling constants have been used for conformational analysis.⁴⁰⁸ Strain estimates have been made

for small-ring cyclic allenes and butatrienes.⁴⁰⁹ Note that axial and equatorial hydrogens are found only in the chair conformations of six-membered rings. In rings of other sizes, the hydrogens protrude at angles that generally do not lend themselves to classification in this way,⁴¹⁰ although in some cases the terms “pseudo-axial” and “pseudo-equatorial” have been used to classify hydrogens in rings of other sizes.⁴¹¹

4.O. MOLECULAR MECHANICS⁴¹²

Molecular Mechanics⁴¹³ describes a molecule in terms of a collection of bonded atoms that have been distorted from some idealized geometry due to nonbonded van der Waals (steric) and Coulombic (charge–charge) interactions. This approach is fundamentally different from MO theory that is based on quantum mechanics and that make no reference whatsoever to chemical bonding. The success of molecular mechanics depends on the ability to represent molecules in terms of unique valence structures, on the notion that bond lengths and angles may be transferred from one molecule to another and on a predictable dependence of geometrical parameters on the local atomic environment.

The molecular mechanics energy of a molecule is given as a sum of contributions arising from distortions from ideal bond distances (stretch contributions), bond angles (bend contributions) and torsion angles (torsion contributions), together with contributions from non-bonded interactions. This energy is commonly referred to as a *strain energy*, meaning that it reflects the inherent strain in a real molecule relative to a hypothetical idealized (strain-free) form.

$$E^{\text{strain}} = E_{\text{A}}^{\text{stretch}} + E_{\text{A}}^{\text{bend}} + E_{\text{A}}^{\text{torsion}} + E_{\text{AB}}^{\text{nonbonded}} \quad (4.1)$$

Stretch and bend terms are most simply given in terms of quadratic (Hooke's law) forms:

$$E^{\text{strain}}(r) = \frac{1}{2} k^{\text{stretch}} (r - r^{\text{eq}})^2 \quad (4.2)$$

$$E^{\text{bend}}(\alpha) = \frac{1}{2} k^{\text{bend}} (\alpha - \alpha^{\text{eq}})^2 \quad (4.3)$$

⁴¹³ For a review, see Rappe, A.K.; Casewit, C.J. *Molecular Mechanics Across Chemistry*, University Science Books, Sausalito, CA, **1997**.

r and α are the bond distance and angle, respectively, and r^{eq} and α^{eq} are the ideal bond length and angle, respectively.

Torsion terms need to properly reflect the inherent periodicity of the particular bond involved in a rotation. For example, the threefold periodicity of the carbon–carbon bond in ethane may be represented by a simple cosine form.

$$E^{\text{torsion}}(\omega) = k^{\text{torsion}3}[1 - \cos 3(\omega - \omega^{\text{eq}})] \quad (4.4)$$

Ω is the torsion angle, ω^{eq} is the ideal torsion angle and k^{torsion} is a parameter. Torsion contributions to the strain energy usually will also need to include contributions that are onefold and twofold periodic. These can be represented in the same manner as the threefold term.

$$E^{\text{torsion}}(\omega) = k^{\text{torsion}1}[1 - \cos(\omega - \omega^{\text{eq}})] + k^{\text{torsion}2}[1 - \cos 2(\omega - \omega^{\text{eq}})] + k^{\text{torsion}3}[1 - \cos 3(\omega - \omega^{\text{eq}})] \quad (4.5)$$

Nonbonded interactions involve a sum of van der Waals (VDW) interactions and Coulombic interactions. The Coulombic term accounts for charge–charge interactions.

$$E^{\text{nonbonded}}(r) = E^{\text{VDW}}(r) + E^{\text{Coulombic}}(r) \quad (4.6)$$

The VDW is made up of two parts, the first to account for strong repulsion on nonbonded atoms as they closely approach, and the second to account for weak long-range attraction, r is the nonbonded distance.

Molecular mechanics methods differ both in the form of the terms that make up the strain energy and in their detailed parameterization. Older methods (e.g., SYBYL⁴¹⁴) use very simple forms and relatively few parameters, while newer methods (e.g., MM3,⁴¹⁵ MM4,⁴¹⁶ and MMFF⁴¹⁷) use more complex forms and many more parameters. In general, the more complex the form of the strain energy terms and the more extensive the parameterization, the better the results. Of course, more parameters mean that more (experimental) data will be needed in their construction. Because molecular mechanics is not based on “physical fundamentals,” but rather is essentially an interpolation scheme, its success depends on the availability of either experimental or high-quality theoretical data for parameterization. A corollary is that molecular mechanics would not be expected to lead to good results for “new” molecules, that is, molecules outside the range of their parameterization.

The two most important applications of molecular mechanics are geometry calculations on very large molecules (e.g., on proteins) and conformational analysis on molecules for which there may be hundreds, thousands, or even tens of thousands of distinct structures. It is here that methods based on quantum mechanics are simply not (yet) practical. It should be no surprise that equilibrium geometries obtained from molecular mechanics are generally in good accord with experimental values. There are ample data with which to

⁴¹⁷ Halgren, T.A. *J. Computational Chem* **1996**, *17*, 490, and later papers in this series.

parameterize and evaluate the methods. However, because there are very few experimental data relating to the equilibrium conformations of molecules and energy differences among different conformations, molecular mechanics calculations for these quantities need to be viewed with a very critical eye. In time, high-quality data from quantum mechanics will provide the needed data and allow more careful parameterization (and assessment) than now possible.

The most important limitation of molecular mechanics is its inability to provide thermochemical data. The reason for this is that the mechanics strain energy is specific to a given molecule (it provides a measure of how much this molecule deviates from an ideal arrangement), and different molecules have different ideal arrangements. For example, acetone and methyl vinyl ether have different bonds and would be referenced to different standards. The only exception occurs for conformational energy differences or, more generally, for energy comparisons among molecules with exactly the same bonding (e.g., *cis*- and *trans*-2-butene).

Because a molecular mechanics calculation reveals nothing about the distribution of electrons or distribution of charge in molecules, and because mechanics methods have not (yet) been parameterized to reproduce transition state geometries, they are of limited value in describing either chemical reactivity or product selectivity. There are, however, situations where steric considerations associated with either the product or reactants are responsible for trends in reactivity and selectivity, and here molecular mechanics would be expected to be of some value.

Because of the different strengths and limitations of molecular mechanics and quantum chemical calculations, it is now common practice to combine the two, for example, to use molecular mechanics to establish conformation (or at least a set of reasonable conformations) and then to quantum calculations to evaluate energy differences.

In practical terms, molecular mechanics calculations may easily be performed on molecules comprising several thousand atoms. Additionally, molecular mechanics calculations are sufficiently rapid to permit extensive conformational searching on molecules containing upward of a hundred atoms. Modern graphical based programs for desktop computers make the methods available to all chemists.

4.P. STRAIN

Steric strain⁴¹⁸ exists in a molecule when bonds are forced to make abnormal angles, usually due to repulsion of large atoms or groups attached to those bonds, but not always. This repulsion results in a higher energy than would be the case in the absence of the angle distortions. It has been shown that there is a good correlation between the ¹³C—H coupling constants in NMR and the bond angles and bond force angles in strained organic molecules.⁴¹⁹ There are, in general, two kinds of structural features that result in sterically caused abnormal bond angles. One of these is found in small-ring compounds, where the angles must be less than those resulting from normal orbital overlap.⁴²⁰ Such strain is called *small-angle strain* or *Baeyer strain*. The other arises when nonbonded

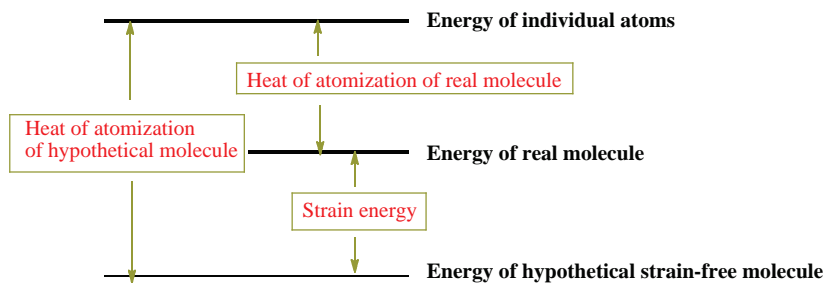

FIG. 4.6. Strain energy calculation.

atoms are forced into close proximity by the geometry of the molecule. These are called *nonbonded interactions*. This latter type of strain is most often associated with the term steric strain.

Strained molecules possess *strain energy*. That is, their potential energies are higher than they would be if strain were absent.⁴²¹ The strain energy for a particular molecule can be estimated from heat of atomization or heat of combustion data. A strained molecule has a lower heat of atomization than it would have if it were strain-free (Fig. 4.6). As in the similar case of resonance energies (Sec. 2.B), strain energies cannot be known exactly, because the energy of a real molecule can be measured, but not the energy of a hypothetical unstrained model. It is also possible to calculate strain energies by molecular mechanics, not only for real molecules, but also for those that cannot be made.⁴²²

4.P.i Strain in Small Rings

Three-membered rings have a great deal of angle strain (also called *Baeyer strain*), since 60° angles represent a large departure from the “normal” tetrahedral angles. Calculations have been interpreted to say that Baeyer strain in small ring systems originates from a decrease in nucleus–electron attraction compared to acyclic compounds,⁴²³ but this has been challenged in later work.⁴²⁴ However, in sharp contrast to other ethers, ethylene oxide is quite reactive, the ring being opened by many reagents (see Sec. 10.G.iii). Ring opening, of course, relieves the strain.⁴²⁵ Cyclopropane,⁴²⁶ which is even more strained⁴²⁷ than ethylene oxide, is also cleaved more easily than would be expected for an alkane.⁴²⁸ Thus,

pyrolysis at 450–500°C converts it to propene, bromination gives 1,3-dibromopropane,⁴²⁹ and it can be hydrogenated to propane (though at high pressure).⁴³⁰ Other three-membered rings are similarly reactive.⁴³¹ Alkyl substituents influence the strain energy of small ring compounds,⁴³² and carbonyl substitution also influences the strain energy.⁴³³ *gem*-Dimethyl substitution, for example, “lowers the strain energy of cyclopropanes, cyclobutanes, epoxides, and dimethyldioxirane by 6–10 kcal mol⁻¹ (25–42 kJ mol⁻¹) relative to an unbranched acyclic reference molecule.”⁴³² The CH bond dissociation energy also tends to increase ring strain in small-ring alkenes.⁴³⁴ Computation of the ring strain energy of 1,1-dimethylcyclobutane, however, shows “no significant enthalpic component of the *gem*-dimethyl effect as measured by the ring strain energy.”⁴³⁵

There is much evidence, chiefly derived from NMR coupling constants, that the bonding in cyclopropanes is not the same as in compounds that lack small-angle strain.⁴³⁶ For a normal carbon atom, one *s* and three *p* orbitals are hybridized to give four approximately equivalent *sp*³ orbitals, each containing ~25% *s* character. But for a cyclopropane carbon atom, the four hybrid orbitals are far from equivalent. The two orbitals directed to the outside bonds have more *s* character than a normal *sp*³ orbital, while the two orbitals involved in ring bonding have less, because the more *p*-like they are the more they resemble ordinary *p* orbitals, whose preferred bond angle is 90° rather than 109.5°. Since the small-angle strain in cyclopropanes is the difference between the preferred angle and the real angle of 60°, this additional *p* character relieves some of the strain. The external orbitals have ~33% *s* character, so that they are ~*sp*² orbitals, while the internal orbitals have ~17% *s* character, so that they may be called ~*sp*⁵ orbitals.⁴³⁷ Each of the three carbon–carbon bonds of cyclopropane is therefore formed by overlap of two *sp*⁵ orbitals. Molecular-orbital calculations show that such bonds are not completely *s* in character. In normal C—C bonds, *sp*³ orbitals overlap in such a way that the straight line connecting the nuclei becomes an axis about which the electron density is symmetrical. But in cyclopropane, the electron density is directed *away from the ring*.⁴³⁸ Figure 4.7 shows the direction of orbital overlap.⁴³⁹ For cyclopropane, the angle (marked θ) is 21°. Cyclobutane exhibits the same phenomenon but to a lesser extent, θ being 7°. ⁴³⁹ Molecular orbital calculations also show that the maximum electron densities of the C—C σ orbitals are bent away from the ring, with $\theta = 9.4^\circ$ for cyclopropane and 3.4° for cyclobutane.⁴⁴⁰ The bonds in cyclopropane are called *bent bonds* (sometimes, *banana bonds*), and are intermediate

FIG. 4.7. Orbital overlap in cyclopropane. The arrows point toward the center of electron density.

FIG. 4.8. Conformations of α -cyclopropylalkenes. Conformation (a) leads to maximum conjugation and conformation (b) to minimum conjugation

in character between σ and π , so that cyclopropanes behave in some respects like double-bond compounds.⁴⁴¹ For one thing, there is much evidence, chiefly from UV spectra,⁴⁴² that a cyclopropane ring is conjugated with an adjacent double bond. The conjugation is greatest for the conformation shown in Fig. 4.8a and is least or absent for the conformation shown in 4.8b, since overlap of the double-bond π orbital with two of the p -like orbitals of the cyclopropane ring is greatest in conformation a. However, the conjugation between a cyclopropane ring and a double bond is less than that between two double bonds.⁴⁴³ For other examples of the similarities in behavior of a cyclopropane ring and a double bond (see Sec. 4.O.iv).

Four-membered rings also exhibit angle strain, but much less than three-membered rings, and for that reason are less easily opened. Cyclobutane is more resistant than cyclopropane to bromination, and although it can be hydrogenated to butane, more strenuous conditions are required. Nevertheless, pyrolysis at 420°C gives two molecules of ethylene. As mentioned earlier (Sec. 4.O.iv), cyclobutane is not planar.

Many highly strained compounds containing small rings in fused systems have been prepared,⁴⁴⁴ showing that organic molecules can exhibit much more strain than simple cyclopropanes or cyclobutanes.⁴⁴⁵ Table 4.5 shows a few of these compounds.⁴⁴⁶

Perhaps the most interesting are cubane, prismane,⁴⁶⁰ and the substituted tetrahedrane, since preparation of these ring systems had been the object of much endeavor. Prismane is tetracyclo[2.2.0.0^{2,6}.0^{3,5}]hexane and many derivatives are known,⁴⁶¹ including bis (homohexaprismane) derivatives.⁴⁶² The bicyclobutane molecule is bent, with the angle θ between the planes equal to $126 \pm 3^\circ$.⁴⁶³ The rehybridization effect, described above for cyclopropane, is even more extreme in this molecule. Calculations have shown that the central bond is essentially formed by overlap of two p orbitals with little or no

s character.⁴⁶⁴ *Propellanes* are compounds in which two carbons, directly connected, are also connected by three other bridges. [1.1.1]Propellane is in the table and it is the smallest possible propellane.⁴⁶⁵ It is in fact more stable than the larger [2.1.1]propellane and [2.2.1]propellane, which have been isolated only in solid matrixes at low temperature.⁴⁶⁶ The bicyclo[1.1.1]pentanes are related to the propellanes except that the central connecting bond is missing, and several derivatives are known.⁴⁶⁷ Even more complex systems are known.⁴⁶⁸

In certain small-ring systems, including small propellanes, the geometry of one or more carbon atoms is so constrained that all four of their valences are directed to the same side of a plane (inverted tetrahedron), as in **124**.⁴⁶⁹ An example is 1,3-dehydroadamantane, **125**, which is also a propellane.⁴⁷⁰ X-ray crystallography of the 5-cyano derivative of **125** shows that the four carbon valences at C-1 and C-3 are all directed “into” the molecule and none point outside.⁴⁷¹ Compound **125** is quite reactive; it is unstable in air, readily adds hydrogen, water, bromine, or acetic acid to the C-1—C-3 bond, and is easily polymerized. When two such atoms are connected by a bond (as in **125**), the bond is very long (the C-1—C-3 bond length in the 5-cyano derivative of **125** is 1.64 Å), as the atoms try to compensate in this way for their enforced angles. The high reactivity of the C-1—C-3 bond of **125** is not only caused by strain, but also by the fact that reagents find it easy to approach these atoms since there are no bonds (e.g., C—H bonds on C-1 or C-3) to get in the way.

4.P.ii. Strain in Other Rings⁴⁷²

In rings larger than four-membered, there is no strain due to small bond angles, but there are three other kinds of strain. In the chair form of cyclohexane, which does not exhibit any of the three kinds of strain, all six carbon–carbon bonds have the two attached carbons in the *gauche* conformation. However, in five-membered rings and in rings containing from 7 to 13 carbons, any conformation in which all the ring bonds are *gauche* contains transannular interactions, that is, interactions between the substituents on C-1 and C-3 or C-1 and C-4, and so on. These interactions occur because the internal space is not large enough for all the quasi-axial hydrogen atoms to fit without coming into conflict. The molecule can adopt other conformations in which this *transannular strain* is reduced, but then some of the carbon–carbon bonds must adopt eclipsed or partially eclipsed conformations. The strain resulting from eclipsed conformations is called *Pitzer strain*. For saturated rings from 3- to 13-membered (except for the chair form of cyclohexane) there is no escape from at least one of these two types of strain. In practice, each ring adopts conformations that minimize both sorts of strain as much as possible. For cyclopentane, as seen in Section 4.O. iv, this means that the molecule is not planar. In rings larger than nine-membered, Pitzer strain seems to disappear, but transannular strain is still present.⁴⁷³ For 9- and 10-membered rings, some of the transannular and Pitzer strain may be relieved by the adoption of a third type of strain, *large-angle strain*. Thus, C—C—C angles of 115–120° have been found in X-ray diffraction of cyclononylamine hydrobromide and 1,6-diaminocyclodecane dihydrochloride.⁴⁷⁴

Strain can exert other influences on molecules. 1-Aza-2-adamantanone (**126**) is an extreme case of a twisted amide.⁴⁷⁵ The overlap of the lone-pair electrons on nitrogen with the π -system of the carbonyl is prevented.⁴⁷⁵ In chemical reactions, **126** reacts more or less like a ketone, giving a Wittig reaction (**16-44**) and it can form a ketal (**16-7**). A twisted biadamantylidene compound has been reported.⁴⁷⁶

The amount of strain in cycloalkanes is shown in Table 4.6,⁴⁷⁷ which lists heats of combustion per CH₂ group. As can be seen, cycloalkanes > 13-membered are as strain-free as cyclohexane.

[Reprinted with permission. Gol'dfarb, Ya.L.; Belen'kii, L.I. *Russ. Chem. Rev.* **1960**, 29, 214, p. 218].^aSee Ref. 472.

Transannular interactions can exist across rings from 8- to 11-membered and even larger.⁴⁷⁸ Such interactions can be detected by dipole and spectral measurements. For example, that the carbonyl group in **127a** is affected by the nitrogen (**127b** is probably another canonical form) has been demonstrated by photoelectron spectroscopy, which shows that the ionization potentials of the nitrogen *n* and C=O π orbitals in **127** differ from those of the two comparison molecules **128** and **129**.⁴⁷⁹ It is significant that when **127** donates electrons to a proton, it goes to the oxygen rather than to the nitrogen. Many examples of transannular reactions are known, including the following:

where DMF = *N*, *N*-dimethylformamide (Solvent)

⁴⁷⁸ For a review, see Cope, A.C.; Martin, M.M.; McKervey, M.A. *Q. Rev. Chem. Soc.* **1966**, 20, 119.

⁴⁷⁹ Spanka, G.; Rademacher, P. *J. Org. Chem.* **1986**, 51, 592. See also, Spanka, G.; Rademacher, P.; Duddeck, H. *J. Chem. Soc. Perkin Trans. 2* **1988**, 2119.

In summary, saturated rings may be divided into four groups, of which the first and third are more strained than the other two.⁴⁸²

1. *Small rings* (three- and four-membered). Small-angle strain predominates.
2. *Common rings* (five-, six-, and seven-membered). Largely unstrained. The strain that is present is mostly Pitzer strain.
3. *Medium rings* (8- to 11-membered). Considerable strain; Pitzer, transannular, and large-angle strain.
4. *Large rings* (12-membered and larger). Little or no strain.⁴⁸³

4.P.iii. Unsaturated Rings⁴⁸⁴

Double bonds can exist in rings of any size. As expected, the most highly strained are the three-membered rings (e.g., cyclopropene). Small-angle strain, which is so important in cyclopropane, is even greater in cyclopropene⁴⁸⁵ because the ideal angle is more distorted. In cyclopropane, the bond angle is forced to be 60° , $\sim 50^\circ$ smaller than the tetrahedral angle; but in cyclopropene, the angle, also $\sim 60^\circ$, is now $\sim 60^\circ$ smaller than the ideal angle of 120° for an alkene. Thus, the angle of cyclopropene is $\sim 10^\circ$ more strained than in cyclopropane. However, this additional strain is offset by a decrease in strain arising from another factor. Cyclopropene, lacking two hydrogens, has none of the eclipsing strain present in cyclopropane. Cyclopropene has been prepared⁴⁸⁶ and is stable at liquid-nitrogen temperatures, although on warming even to -80°C it rapidly polymerizes. Many other cyclopropenes are stable at room temperature and above.⁴⁶⁴ The highly strained benzocyclopropene,⁴⁸⁷ in which the cyclopropene ring is fused to a benzene ring, has been prepared⁴⁸⁸ and is stable for weeks at room temperature, although it decomposes on distillation at atmospheric pressure.

Benzocyclopropene

⁴⁸⁸ Vogel, E.; Grimme, W.; Korte, S. *Tetrahedron Lett.* **1965**, 3625. Also see Müller, P.; Bernardinelli, G.; Thi, H. C.G. *Chimia* **1988**, 42, 261; Neidlein, R.; Christen, D.; Poignée, V.; Boese, R.; Bläser, D.; Gieren, A.; Ruiz-Pérez, C.; Hübner, T. *Angew. Chem. Int. Ed.* **1988**, 27, 294.

As previously mentioned, double bonds in relatively small rings must be *cis*. A stable *trans* double bond⁴⁸⁹ first appears in an eight-membered ring (*trans*-cyclooctene, Sec. 4.C, category 6), although the transient existence of *trans*-cyclohexene and cycloheptene has been demonstrated.⁴⁹⁰ Above ~11 members, the *trans* isomer is more stable than the *cis*.²³² It has proved possible to prepare compounds in which a *trans* double bond is shared by two cycloalkene rings (e.g., **130**). Such compounds have been called [*m.n*] *betweenanenes*, and several have been prepared with *m* and *n* values from 8 to 26.⁴⁹¹ The double bonds of the smaller *betweenanenes*, as might be expected from the fact that they are deeply buried within the bridges, are much less reactive than those of the corresponding *cis*-*cis* isomers.

The smallest unstrained cyclic triple bond is found in cyclononyne.⁴⁹² Cyclooctyne has been isolated,⁴⁹³ but its heat of hydrogenation shows that it is considerably strained. There have been a few compounds isolated with triple bonds in seven-membered rings. 3,3,7,7-Tetramethylcycloheptyne (**131**) is known and dimerizes within 1 h at room temperature,⁴⁹⁴ but the thia derivative (**132**), in which the C—S bonds are longer than the corresponding C—C bonds in **131**, is indefinitely stable even at 140°C.⁴⁹⁵ Cycloheptyne itself has not been isolated, although its transient existence has been shown.⁴⁹⁶ Cyclohexyne⁴⁹⁷ and its 3,3,6,6-tetramethyl derivative⁴⁹⁸ have been trapped at 77 K, and in an Ar π matrix at 12 K, respectively. Its IR spectra have also been

obtained. Transient six- and even five-membered rings containing triple bonds have also been demonstrated.⁴⁹⁹ A derivative of cyclopentyne has been trapped in a matrix.⁵⁰⁰ Although cycloheptyne and cyclohexyne have not been isolated at room temperatures, Pt(0) complexes of these compounds have been prepared and are stable.⁵⁰¹ The smallest

cyclic allene⁵⁰² so far isolated is 1-*tert*-butyl-1,2-cyclooctadiene (**133**).⁵⁰³ The parent 1,2-cyclooctadiene has not been isolated. It has been shown to exist as a transient species, but rapidly dimerizes.⁵⁰⁴ Incorporation of the *tert*-butyl group apparently prevents this. The transient existence of 1,2-cycloheptadiene has also been shown,⁵⁰⁵ and both 1,2-cyclooctadiene and 1,2-cycloheptadiene have been isolated in Pt complexes.⁵⁰⁶ 1,2-Cyclohexadiene has been trapped at low temperatures, and its structure has been proved by spectral studies.⁵⁰⁷ Cyclic allenes in general are less strained than their acetylenic isomers.⁵⁰⁸ The cyclic cumulene 1,2,3-cyclononatriene also has been synthesized and is reasonably stable in solution at room temperature in the absence of air.⁵⁰⁹

There are many examples of polycyclic molecules and bridged molecules that have one or more double bonds. There is flattening of the ring containing the C=C unit, and this can have a significant effect on the molecule. Norbornene (bicyclo[2.2.1]hept-2-ene, **134**) is a simple example and it has been calculated that it contains a distorted π -face.⁵¹⁰ The double bond can appear away from the bridgehead carbon atoms, as in bicyclo[4.2.2]dec-3-ene (**135**), which flattens that part of the molecule. The C=C units in pentacyclo[8.2.1.1^{2,5}.1^{4,7}.1^{8,11}]hexadeca-1,7-diene (**136**) are held in a position where there is significant π - π interactions across the molecule.⁵¹¹

Double bonds at the bridgehead of bridged bicyclic compounds are impossible in small systems. This result is the basis of *Bredt's rule*,⁵¹² which states that elimination to give a double bond in a bridged bicyclic system (e.g., **137**) always leads away from the bridgehead. This rule no longer applies when the rings are large enough. In

determining whether a bicyclic system is large enough to accommodate a bridgehead double bond, the most reliable criterion is the size of the ring in which the double bond is located.⁵¹³ Bicyclo[3.3.1]non-1-ene⁵¹⁴ (**138**) and bicyclo[4.2.1]non-1(8)ene⁵¹⁵ (**139**) are stable compounds. Both can be looked upon as derivatives of *trans*-cyclooctene, which is of course a known compound. Compound **138** has been shown to have a strain

energy of the same order of magnitude as that of *trans*-cyclooctene.⁵¹⁶ On the other hand, in bicyclo[3.2.2]non-1-ene (**140**), the largest ring that contains the double bond is a *trans*-cycloheptene, which is as yet unknown. Compound **140** has been prepared, but dimerized before it could be isolated.⁵¹⁷ Even smaller systems ([3.2.1] and [2.2.2]), but with imine double bonds (**141–143**), have been obtained in matrixes at low temperatures.⁵¹⁸ These compounds are destroyed on warming. Compounds **141** and **142** are the first reported example of (*E–Z*) isomerism at a strained bridgehead double bond.⁵¹⁹

4.P.iv. Strain Due to Unavoidable Crowding⁵²⁰

In some molecules, large groups are so close to each other that they cannot fit into the available space in such a way that normal bond angles are maintained. It has proved possible to prepare compounds with a high degree of this type of strain. For example, success has been achieved in synthesizing benzene rings containing *ortho tert*-butyl groups. Two examples that have been prepared, of several, are 1,2,3-tri-*tert*-butyl compound **144**⁵²¹ and the 1,2,3,4-tetra-*tert*-butyl compound **145**.⁵²² That these molecules are strained is demonstrated by UV and IR spectra, which show that the ring is not planar in 1,2,4-tri-*tert*-butylbenzene, and by a comparison of the heats of reaction of this compound and its 1,3,5 isomer, which show that the 1,2,4 compound possesses $\sim 22 \text{ kcal mol}^{-1}$ (92 kJ mol^{-1}) more strain energy than its isomer⁵²³ (see also Reaction **18-27**). Although SiMe_3 groups are larger

than CMe_3 groups, it has proven possible to prepare $\text{C}_6(\text{SiMe}_3)_6$. This compound has a chair-shaped ring in the solid state, and a mixture of chair and boat forms in solution.⁵²⁴ Even smaller groups can sterically interfere in ortho positions. In hexaisopropylbenzene, the six isopropyl groups are so crowded that they cannot rotate, but are lined up around the benzene ring, all pointed in the same direction.⁵²⁵ This compound is an example of a *geared molecule*.⁵²⁶ The isopropyl groups fit into each other in the same manner as interlocked

gears. Another example is **146**, which is a stable enol.⁵²⁷ In this case, each ring can rotate about its C–aryl bond only by forcing the other to rotate as well. In the case of triptycene derivatives (e.g., **147**), a complete 360° rotation of the aryl group around the O–aryl bond requires the aryl group to pass over three rotational barriers; one of which is the C–X bond and the other two the “top” C–H bonds of the other two rings. As expected, the C–X barrier is the highest, ranging from $10.3 \text{ kcal mol}^{-1}$ (43.1 kJ mol^{-1}) for $\text{X} = \text{F}$ to $17.6 \text{ kcal mol}^{-1}$ (73.6 kJ mol^{-1}) for $\text{X} = \text{tert-butyl}$.⁵²⁸ In another instance, it has proved possible to prepare *cis* and *trans* isomers of 5-amino-2,4,6-triiodo-*N,N,N',N''*-tetramethylisophthalamide because there is no room for the CONMe_2 groups to rotate, caught as they are between two bulky iodine atoms.⁵²⁹ The *trans* isomer is chiral and has been resolved, while the *cis* isomer is a meso form. Another example of *cis-trans* isomerism resulting from restricted rotation about single bonds⁵³⁰ is found in 1,8-di-*o*-tolynaphthalene⁵³¹ (see also, Sec. 4.K.i).

There are many other cases of intramolecular crowding that result in the distortion of bond angles. Hexahelicene (Sec. 4.C, category 6) and bent benzene rings (Sec. 2.G) have been mentioned previously. The compounds tri-*tert*-butylamine, and tetra-*tert*-butylmethane are as yet unknown. In the latter, there is no way for the strain to be relieved and it is questionable whether this compound can ever be made. In tri-*tert*-butylamine, the crowding can be eased somewhat if the three bulky groups assume a planar instead of the normal pyramidal configuration. In tri-*tert*-butylcarbinol, coplanarity of the three *tert*-butyl groups is prevented by the presence of the OH group, and yet this compound has been prepared.⁵³² Tri-*tert*-butylamine should have less steric strain than tri-*tert*-butylcarbinol and it should be possible to prepare it.⁵³³ The tetra-*tert*-butylphosphonium cation (*t*-Bu)₄P⁺ has been prepared.⁵³⁴ Although steric effects are nonadditive in crowded molecules, a quantitative measure has been proposed by DeTar, based on molecular mechanics calculations. This is called *formal steric enthalpy* (FSE), and values have been calculated for alkanes, alkenes, alcohols, ethers, and methyl esters.⁵³⁵ For example, some FSE values for alkanes are butane 0.00; 2,2,3,3-tetramethylbutane 7.27; 2,2,4,4,5-pentamethylhexane 11.30; and tri-*tert*-butylmethane 38.53.

The two carbon atoms of a C=C double bond and the four groups attached to them are normally in a plane, but if the groups are large enough, significant deviation from planarity can result.⁵³⁶ The compound tetra-*tert*-butylethene (**148**) has not been prepared,⁵³⁷ but the tetraaldehyde (**149**), which should have about the same amount of strain, has been made. X-ray crystallography shows that **149** is twisted out of a planar shape by an angle of 28.6°.⁵³⁸ Also, the C=C double bond distance is 1.357 Å, significantly longer than normal C=C bond of 1.32 Å (Table 1.5). (*Z*)-1,2-Bis(*tert*-butyldimethylsilyl)-1,2-bis(trimethylsilyl)ethene (**150**) has an even greater twist, but could not be made to undergo conversion to the (*E*) isomer, probably because the groups are too large to slide past each other.⁵³⁹ A different kind of double-bond strain is found in tricyclo[4.2.2.2^{2,5}]dodeca-1,5-

diene (**151**),⁵⁴⁰ cubene (**152**),⁵⁴¹ and homocub-4(5)-ene (**153**).⁵⁴² In these molecules, the four groups on the

**148****149****150**

double bond are all forced to be on one side of the double-bond plane.⁵⁴³ In **151**, the angle between the line C1–C2 (extended) and the plane defined by C2, C3, and C11 is 27°. An additional source of strain in this molecule is the fact that the two double bonds are pushed into close proximity by the four bridges. In an effort to alleviate this sort of strain, the bridge bond distances (C-3—C-4) are 1.595 Å, which is considerably longer than the 1.53 Å expected for a normal sp^3 – sp^3 C—C bond (Table 1.5). Compounds **152** and **153** have *not* been isolated, but have been generated as intermediates that were trapped by reaction with other compounds.^{541,542}

Carbocations, Carbanions, Free Radicals, Carbenes, and Nitrenes

There are four types of organic species in which a carbon atom has a valence of only 2 or 3.¹ They are usually very short-lived, and most exist only as intermediates that are quickly converted to more stable molecules. However, some are more stable than others and fairly stable examples have been prepared for three of the four types. The four types of species are *carbocations (A)*, *carbon radicals (B)*, *carbanions (C)*, and *carbenes (D)*. Of the four, only carbanions have a complete octet around the carbon. There are many other organic ions and radicals with charges and unpaired electrons on atoms other than carbon, but only *nitrenes (E)*, the nitrogen analogues of carbenes, will be discussed. Each of these five types is discussed in a separate section, which in each case includes brief summaries of the ways in which the species form and react. These summaries are short and schematic. The generation and fate of the five types are more fully treated for the appropriate specific reactions in Part II.

5.A. CARBOCATIONS²

5.A.i. Nomenclature

First, the nomenclature of carbocations (A) is discussed. For many years, these species were called “carbonium ions,” although it was suggested³ as long ago as 1902 that this was

¹ For general references, see Isaacs, N.S. *Reactive Intermediates in Organic Chemistry*, Wiley, NY, **1974**; McManus, S.P. *Organic Reactive Intermediates*, Academic Press, NY, **1973**. Two serial publications devoted to review articles on this subject are *Reactive Intermediates (Wiley)* and *Reactive Intermediates (Plenum)*.

² See Olah, G.A.; Schleyer, P.v.R. *Carbonium Ions*, 5 Vols., Wiley, NY, **1968–1976**; Vogel, P. *Carbocation Chemistry*, Elsevier, NY, **1985**. See Saunders, M.; Jiménez-Vázquez, H.A. *Chem. Rev.* **1991**, *91*, 375; Arnett, E.M.; Hofelich, T.C.; Schriver, G.W. *React. Intermed. (Wiley)* **1987**, *3*, 189. ³ Gomberg, M. *Ber.* **1902**, *35*, 2397.

inappropriate because “-onium” usually refers to a covalency higher than that of the neutral atom. Nevertheless, the name “carbonium ion” was well established and created few problems⁴ until some years ago, when Olah and co-workers^{2,5} found evidence for another type of intermediate in which there is a positive charge at a carbon atom, but in which the formal covalency of the carbon atom is five rather than three. The simplest example is the methanonium ion (CH_5^+ ; see Reaction 12-01). Olah⁵ proposed that the name “carbonium ion” be henceforth reserved for pentacoordinated positive ions, and that **A** be called a “carbenium ions.” He also proposed the term “carbocation” to encompass both types. IUPAC has accepted these definitions.⁶ For the most part, intermediates such as **A** are called *carbenium ions* or *carbocations*, but the latter term will be used more often in this book.

5.A.ii. Stability and Structure of Carbocations

[Reprinted with permission from Kato, T.; Reed, C.A. *Angew. Chem. Int. Ed.* **2004**, 43, 2908, Wiley–VCH Verlag GmbH & Co. KGaA, Weinheim. Copyright © **2004** by Wiley–VCH Verlag]

Carbocations are intermediates in several kinds of reactions.⁷ The more stable ones have been prepared in solution and in some cases even as solid salts. X-ray crystallographic structures also have been obtained in some cases.⁸ The X-ray of the *tert*-butyl cation complexed with dichloromethane was reported,⁹ for example, and is presented as **1** with the solvent molecules removed for clarity. The IR spectrum of the *tert*-butyl cation has been recorded in the gas phase.¹⁰ An isolable dioxo-stabilized pentadienylium ion was isolated and its structure was determined by ¹H NMR, ¹³C NMR, mass spectrometry, and IR.¹¹ A β-fluoro substituted 4-methoxyphenethyl cation has been observed directly by laser flash photolysis.¹² In solution, the carbocation may be free (this is more likely in polar solvents,

in which it is solvated) or it may exist as an ion pair,¹³ which means that it is closely associated with a negative ion, called a *counterion* or *gegenion*. Ion pairs are more likely in nonpolar solvents.

Among simple alkyl carbocations,¹⁴ the order of stability is tertiary > secondary > primary. There are many known examples of rearrangements of primary or secondary carbocations to tertiary, both in solution and in the gas phase (see Sec. 18.A.ii). Since simple alkyl cations are unstable in ordinary strong-acid solutions (e.g., H₂SO₄), the study of these species was greatly facilitated by the discovery that many of them could be kept indefinitely as stable solutions in mixtures of fluorosulfuric acid and antimony pentafluoride. Such mixtures, usually dissolved in SO₂ or SO₂ClF, are among the strongest acidic solutions known and are often called *superacids*.¹⁵ The original experiments involved the addition of alkyl fluorides to SbF₅.¹⁶

Subsequently, it was found that the same carbocations could also be generated from alcohols in superacid-SO₂ at -60 °C¹⁷ and from alkenes by the addition of a proton from superacid or HF-SbF₅ in SO₂ or SO₂ClF at low temperatures.¹⁸ Even alkanes give carbocations in superacid by loss of H⁻. For example,¹⁹ 2-methylpropane gives the *tert*-butyl cation.

No matter how they are generated, study of the simple alkyl carbocations has provided dramatic evidence for the stability order.²⁰ Both propyl fluorides gave the isopropyl cation; all four butyl fluorides²¹ gave the *tert*-butyl cation, and all seven of the pentyl fluorides examined gave the *tert*-pentyl cation. *n*-Butane, in superacid, gave only the *tert*-butyl cation. To date, no primary cation has survived long enough for detection. Neither methyl nor ethyl fluoride gave the corresponding carbocations when treated with SbF₅. At low temperatures, methyl fluoride gave chiefly the methylated sulfur dioxide salt [(CH₃OSO)⁺SbF₆]⁻,²² while ethyl fluoride rapidly formed the *tert*-butyl and *tert*-hexyl cations by addition of the initially formed ethyl cation to ethylene molecules also formed.²³ At room temperature, methyl fluoride also gave the *tert*-butyl cation.²⁴ In accord with the

stability order, hydride ion is abstracted from alkanes by superacid most readily from tertiary and least readily from primary positions.

The stability order can be explained by the polar effect and by hyperconjugation (Sec. 2.M). In the polar effect, nonconjugated substituents exert an influence on stability through bonds (inductive effect) or through space (field effect). Since a tertiary carbocation has more carbon substituents on the positively charged carbon, relative to a primary, there is a greater polar effect that leads to great stability. In the hyperconjugation explanation,²⁵ a primary carbocation is compared with a tertiary, and “*the hyperconjugation concept arises from model-building procedures* (see Sec. 2.M). In general, this means that the model must be corrected by including some delocalization in order to get a good enough description.”²⁶ Evidence used to support the hyperconjugation explanation is that the equilibrium constant for this reaction involving **2** and **3** is 1.97, showing that **3** is more stable than **2**.²⁷ Due to a β secondary isotope effect, there is less hyperconjugation in **2** than in **3** (see Sec. 6.J.V.ii for isotope effects).²⁸ The field effect explanation is that the electron-donating effect of alkyl groups increases the electron density at the charge-bearing carbon, reducing the net charge on the carbon, and in effect spreading the charge over the α carbons. It is a general rule that the more concentrated any charge is, the less stable the species bearing it will be. There are several structural types of delocalization, as summarized in Table 5.1.²⁹

The most stable of the simple alkyl cations is the *tert*-butyl cation. Even the relatively stable *tert*-pentyl and *tert*-hexyl cations fragment at higher temperatures to produce the *tert*-butyl cation, as do all other alkyl cations with four or more carbons to date studied.³⁰ Methane,³¹ ethane, and propane, in superacid, also yield *tert*-butyl cations as the main product (see Reaction 12-20). Even paraffin wax and polyethylene give a *tert*-butyl cation. Solid salts of *tert*-butyl and *tert*-pentyl cations, [e.g., $\text{Me}_3\text{C}^+ \text{SbF}_6^-$], have been prepared from superacid solutions and are stable below -20°C .³²

²⁵ See Radom, L.; Poppinger, D.; Haddon, R.C. in Olah, G.A.; Schleyer, P.v.R. *Carbonium Ions*, Vol. 5, Wiley, NY, **1976**, pp. 2303–2426.

²⁷ Meot-Ner, M. *J. Am. Chem. Soc.* **1987**, 109, 7947.

²⁸ If only the field effect were operating, **2** would be more stable than **3**, since deuterium is electron-donating with respect to hydrogen (Sec. 1.J), assuming that the field effect of deuterium could be felt two bonds away.

^aSee Ref. 25.

In carbocations, where the positive carbon is in conjugation with a double bond, as in allylic cations (the allyl cation is **4**, R = H), the stability is greater because of increased delocalization due to resonance³³ where the positive charge is spread over several atoms instead of being concentrated on one (see the molecular orbital picture of **4** in Sec. 2.C, category 2). Each of the terminal atoms in **4** has a charge of $\frac{1}{2}$ (the charge is exactly $\frac{1}{2}$ if all of the R groups are the same). Stable cyclic and acyclic allylic-type carbocations³⁴ have been prepared by dissolving conjugated dienes in concentrated sulfuric acid; the cyclopentadienyl cation, (**5**) is an example.³⁵

Stable allylic carbocations have also been obtained by the reaction between alkyl halides, alcohols, or alkenes (by hydride extraction) and SbF₅ in SO₂ or SO₂ClF.³⁶ Bis(allylic) cations³⁷ are more stable than the simple allylic type, and some of these have been prepared in concentrated sulfuric acid.³⁸ Arenium ions (Sec. 11.A.i) are

familiar examples of this type. Propargyl cations ($\text{RC}\equiv\text{CC}^+\text{R}_2$) have also been prepared.³⁹

Canonical forms can be drawn for benzylic carbocations, as shown,⁴⁰ and they are similar to those shown above for allylic cations.

A number of benzylic carbocations have been obtained in solution as SbF_6^- salts.⁴¹ Diarylmethyl and triarylmethyl cations are even more stable because more canonical forms are possible (i.e., there is more extensive delocalization, hence greater stability). Chlorotriphenylmethane ionizes in polar solvents to give the stable triphenylmethyl cation (trityl cation, see **18**), for example, because the solvent does not react with the ion,

whereas water does react with the ion. In liquid SO_2 , for example, the ion remains stable for many years. Both triphenylmethyl and diphenylmethyl cations have been isolated as solid salts.⁴² In fact, $\text{Ph}_3\text{C}^+ \text{BF}_4^-$ and related salts are available commercially. Arylmethyl cations are further stabilized if they have electron-donating substituents in ortho or para positions.⁴³ Dications⁴⁴ and trications are also possible, including the particularly stable dication (**6**), where each positively charged benzylic carbon is stabilized by two azulene rings.⁴⁵ A related trication is known where two azulene rings stabilize each benzylic cationic center.⁴⁶

Cyclopropylmethyl carbocations⁴⁷ are even more stable than benzylic carbocations. Carbocations **7**, **8**, and similar ions have been prepared by dissolution of the alcohols in $\text{FSO}_3\text{H}-\text{SO}_2-\text{SbF}_5$,⁴⁸ and **9** has been prepared from the corresponding alcohol in

96% H_2SO_4 .⁴⁹ This special stability, which increases with each additional cyclopropyl group, is

a result of conjugation between the bent orbitals of the cyclopropyl rings (Sec. 4.Q.i) and the vacant p orbital of the cationic carbon (see **10**). Nuclear magnetic resonance and other studies have shown that the vacant p orbital lies parallel to the C-2—C-3 bond of the cyclopropane ring and not perpendicular to it.⁵⁰ In this respect, the geometry is similar to that of a cyclopropane ring conjugated with a double bond (Sec. 4.Q.i). Cyclopropylmethyl cations are further discussed in Section 10.C.i, category 4. The stabilizing effect just discussed is unique to cyclopropyl groups. Cyclobutyl and larger cyclic groups are about as effective at stabilizing a carbocation as ordinary alkyl groups.⁵¹

Another structural feature that increases carbocation stability is the presence, adjacent to the cationic center, of a heteroatom bearing an unshared pair⁵² (e.g., oxygen,⁵³ nitrogen,⁵⁴ or halogen).⁵⁵ Such ions are stabilized by resonance, as with the oxocarbenium ion ($\text{R}_2\text{C}=\text{O}^+\text{Me}$).

This methoxymethyl cation can be obtained as a stable solid, $\text{MeOCH}_2^+ \text{SbF}_6^-$.⁵⁶ Carbocations containing either α , β , or γ silicon atom are also stabilized,⁵⁷ relative to similar ions without the silicon atom. γ -Silyl cyclobutylcarbocations are known.⁵⁸ In superacid solution, ions [e.g., CX_3^+ ($\text{X} = \text{Cl}, \text{Br}, \text{I}$)] have been prepared.⁵⁹ Vinyl-stabilized halonium ions are also known.⁶⁰

Simple acyl cations (RCO^+) have been prepared⁶¹ in solution and the solid state.⁶² The acetyl cation (CH_3CO^+) is about as stable as the *tert*-butyl cation (see Table 5.1). The 2,4,6-trimethylbenzoyl and 2,3,4,5,6-pentamethylbenzoyl cations are especially stable (for steric reasons) and are easily formed in 96% H_2SO_4 .⁶³ These ions, often referred to as *acylium ions*, are stabilized by a canonical form containing a triple bond (**12**), although the positive charge is principally located on the carbon,⁶⁴ so that **11** contributes more than **12**.

The stabilities of many other stable carbocations can also be attributed to resonance. Among these are the tropylium, cyclopropenium,⁶⁵ and other aromatic cations discussed in Chapter 2. Where resonance stability is completely lacking, as in the phenyl (C_6H_5^+) or vinyl cations,⁶⁶ the ion, if formed at all, is usually very short lived.⁶⁷ Neither a vinyl⁶⁸ nor a phenyl cation has as yet been prepared as a stable species in solution.⁶⁹ However, stable alkenyl carbocations have been generated on Zeolite Y,⁷⁰ and the phenyl cation has been observed in cryogenic argon matrices.⁷¹

Various quantitative methods have been developed to express the relative stabilities of carbocations.⁷² One of the most common of these, although useful only for relatively stable carbocations that are formed by ionization of alcohols in acidic solutions, is based on the equation⁷³

$$H_{\text{R}} = \text{p}K_{\text{R}^+} - \log \frac{C_{\text{R}^+}}{C_{\text{ROH}}}$$

pK_{R^+} is the pK value for the reaction $R^+ + 2 H_2O \rightleftharpoons ROH + H_3O^+$ and is a measure of the stability of the carbocation. The H_R parameter is an easily obtainable measurement of the stability of a solvent (Sec. 8.C) and approaches pH at low concentrations of acid. In order to obtain pK_{R^+} , for a cation R^+ , one dissolves the alcohol ROH in an acidic solution of known H_R . Then, the concentration of R^+ and ROH are obtained, generally from spectra, and pK_{R^+} is easily calculated.⁷⁴ A measure of carbocation stability that applies to less stable ions is the dissociation energy [$D(R^+ - H^-)$] for the cleavage reaction $R-H \rightarrow R^+ + H^-$, which can be obtained from PES (Sec. 1.E) and other measurements. Some values of $D(R^+ - H^-)$ are shown in Table 5.2.⁷⁵⁻⁷⁸ Within a given class of ion, (primary, secondary, allylic, aryl, etc.), $D(R^+ - H^-)$ has been shown to be a linear function of the logarithm of the number of atoms in R^+ , with larger ions being more stable.⁷⁷

Since the central carbon of tricoordinated carbocations has only three bonds and no other valence electrons, the bonds are sp^2 and should be planar.⁷⁹ Raman, IR, and NMR spectroscopic data on simple alkyl cations show this to be so.⁸⁰ In methylcyclohexyl cations, there are two chair conformations where the carbon bearing the positive charge is planar (**13** and **14**), and there is evidence that **14** is more stable due to a difference in

hyperconjugation.⁸¹ Arenonium ions (**15**) are also known, and are relatively stable.⁸² Other evidence is that carbocations are difficult to form at bridgehead atoms in [2.2.1] systems,⁸³ where they cannot be planar (see Sec. 10.A.ii).⁸⁴ Bridgehead carbocations are known, however, as in [2.1.1]hexanes⁸⁵ and cubyl carbocations.⁸⁶ However, larger bridgehead ions can exist. For example, the adamantyl cation (**15**) has been synthesized, as the SF_6^- salt.⁸⁷ The relative stability of 1-adamantyl cations is influenced by the number and nature of substituents. For example, the stability of the 1-adamantyl cation increases with the number of isopropyl substituents at C-3, C-5, and C-7.⁸⁸ Among other bridgehead carbocations that have been prepared in superacid solution at -78°C are the dodecahydryl cation (**16**)⁸⁹ and the 1-trishomobarrellyl cation (**17**).⁹⁰ In the latter case, the instability of the bridgehead position is balanced by the extra stability gained from the conjugation with the three cyclopropyl groups.

Triarylmethyl cations (e.g., the triphenylmethyl carbocation, **18**),⁹¹ are propeller-shaped, although the central carbon and the three ring carbons connected to it are in a plane.⁹² The three benzene rings cannot be all in the same plane due to steric hindrance, although increased resonance energy would be gained if they could.

An important tool for the investigation of carbocation structure is measurement of the ^{13}C NMR chemical shift of the carbon atom bearing the positive charge.⁹³ This shift approximately correlates with electron density on the carbon. The ^{13}C chemical shifts for a

^aSee Ref. 94.

number of ions are given in Table 5.3.⁹⁴ As shown in Table 5.3, the substitution of an ethyl for a methyl or a methyl for a hydrogen atom causes a downfield shift, indicating that the central carbon becomes somewhat more positive. On the other hand, the presence of hydroxy or phenyl groups decreases the positive character of the central carbon. The ^{13}C chemical shifts are not always in exact order of carbocation stabilities, as determined in other ways. Thus the chemical shift shows that the triphenylmethyl cation has a more positive central carbon than diphenylmethyl cation, although the former is more stable. Also, the 2-cyclopropylpropyl and 2-phenylpropyl cations have shifts of -86.8 and -61.1, respectively, although we have seen that according to other criteria a cyclopropyl group is better than a phenyl group at stabilizing a carbocation.⁹⁵ The reasons for this discrepancy are not fully understood.^{88,96}

Nonclassical carbocations are discussed in section 10.C.i.

5.A.iii. The Generation and Fate of Carbocations

A number of methods are available to generate carbocations, stable or unstable.

1. A direct ionization, in which a leaving group attached to a carbon atom leaves with its pair of electrons, as in solvolysis reactions of alkyl halides (see Sec. 10.G.i) or sulfonate esters (Reaction 10-04):

⁹⁴ Olah, G.A.; White, A.M. *J. Am. Chem. Soc.* **1968**, *90*, 1884; **1969**, *91*, 5801. For ^{13}C NMR data for additional ions, see Olah, G.A.; Donovan, D.J. *J. Am. Chem. Soc.* **1977**, *99*, 5026; Olah, G.A.; Prakash, G.K.S.; Liang, G. *J. Org. Chem.* **1977**, *42*, 2666.

⁹⁶ See Brown, H.C.; Peters, E.N. *J. Am. Chem. Soc.* **1977**, *99*, 1712; Kitching, W.; Adcock, W.; Aldous, G. *J. Org. Chem.* **1979**, *44*, 2652. See also, Larsen, J.W.; Bouis, P.A. *J. Am. Chem. Soc.* **1975**, *97*, 4418; Volz, H.; Shin, J.; Streicher, H. *Tetrahedron Lett.* **1975**, 1297; Larsen, J.W. *J. Am. Chem. Soc.* **1978**, *100*, 330.

2. Ionization after an initial reaction that converts one functional group into a leaving group, as in protonation of an alcohol to give an oxonium ion (ROH_2^+) or conversion of a primary amine to a diazonium salt, both of which ionize to the corresponding carbocation:

Oxonium ions are also generated by protonation of ethers,⁹⁷ including epoxides.⁹⁸ However, these ions do not always lead to carbocations via ionization, but often undergo substitution reactions (see Chap 10). Oxatriquinane, (**19**) is a fused, tricyclic alkyl oxonium ion that is remarkably stable. Oxonium ion **19** has been heated to reflux in water, can be chromatographed, and does not react with alcohols or alkyl thiols.⁹⁹ The X-ray crystal structure shows longer C—O bond distances and more acute C—O—C bond angles than any reported alkyloxonium salt. Oxatriquinene (**20**) has also been synthesized.

3. A proton or other positive species adds to one atom of an alkene or alkyne, leaving the adjacent carbon atom with a positive charge (see Chapters 11 and 15).

4. A proton or other positive species adds to one atom of a $\text{C}=\text{X}$ bond, where $\text{X} = \text{O}, \text{S}, \text{N}$ in most cases, leaving the adjacent carbon atom with a positive charge (see Chapter 16). When $\text{X} = \text{O}, \text{S}$, this ion is a resonance stabilized oxocarbenium ion ($\text{X} = \text{O}$) or thiocarbenium ion ($\text{X} = \text{S}$), as shown. When $\text{X} = \text{NR}$, protonation leads to an iminium ion ($\text{X} = \text{N}$), with the charge localized on the nitrogen. A silylated carboxonium ion (e.g., **21**) has been reported.¹⁰⁰

When formed by any of the processes 1–3, carbocations are most often short-lived transient species and react further without being isolated. Oxocarbenium ions are more stable and may be longer lived, but even oxocarbenium ions are transient intermediates. The intrinsic barriers to formation and reaction of carbocations have been studied.¹⁰¹

⁹⁷ Peterson, P.E.; Slama, F.J. *J. Am. Chem. Soc.*, **1968**, 90, 6516.

⁹⁸ Carlier, P.R.; Deora, N.; Crawford, T.D. *J. Org. Chem.* **2006**, 71, 1592.

⁹⁹ Mascall, M.; Hafezi, N.; Meher N.K.; Fetting, J.C. *J. Am. Chem. Soc.* **2008**, 130, 13532.

¹⁰⁰ Prakash, G.K.S.; Bae, C.; Rasul, G.; Olah, G.A. *J. Org. Chem.* **2002**, 67, 1297.

There are two principal pathways by which carbocations react to give stable products that are effectively the reverse of the two pathways just described.

1. A carbocation may combine with a species possessing an electron pair (essentially a Lewis acid–base reaction, see Chapter 8). This reaction occurs by an atom or group donating electrons to the positive carbon of the carbocation. The atom or group that donates the electrons to carbon is called a *nucleophile* (see Chapter 10):

Any reasonable nucleophile will react with the carbocation, but the nucleophile may also be a neutral species with a pair to donate, in which case, of course, the immediate product must bear a positive charge (see Chapters 10, 13, 15, and 16). These reactions are very fast. A recent study measured k_s (the rate constant for reaction of a simple tertiary carbocation) to be $3.5 \times 10^{12} \text{ s}^{-1}$.¹⁰²

2. The carbocation may have a proton (or much less often, another positive ion) removed from the adjacent atom (see Chapters 11 and 17):

Carbocations can also adopt two other pathways that lead not to stable products, but to other carbocations:

3. *Rearrangement*. An alkyl or aryl group or a hydrogen atom (sometimes another group) migrates with its electron pair to the positive center, leaving another positive charge behind (see Chap 18):

A novel rearrangement has been observed. The 2-methyl-2-butyl-1-¹³C cation (¹³C-labeled *tert*-amyl cation) shows an interchange of the inside and outside carbons with a barrier of 19.5 kcal mol^{−1} (81.6 kJ mol^{−1}) (±2.0 kcal mol^{−1}, 8.4 kJ mol^{−1}).¹⁰³ Another unusual migratory process has been observed for the nonamethylcyclopentyl cation. It has been shown that “four methyl groups undergo rapid circumambulatory migration with a barrier <2 kcal mol^{−1} (8.4 kJ mol^{−1}) while five methyl groups are fixed to ring carbons. The process that equalizes the two sets of methyls has a barrier of 7.0 kcal mol^{−1} (29.3 kJ mol^{−1}).”¹⁰⁴

4. *Addition*. A carbocation may add to a double bond, generating a positive charge at a new position (see Chaps 11 and 15). This means that the π bond donates two electrons to a positive atom, generating positive charge on the carbon as shown:

¹⁰¹ Richard, J.P.; Amyes, T.L.; Williams, K.B. *Pure. Appl. Chem.* **1998**, 70, 2007.

¹⁰² Toteva, M.M.; Richard, J.P. *J. Am. Chem. Soc.* **1996**, 118, 11434.

¹⁰³ Vreck, V.; Saunders, M.; Kronja, O. *J. Am. Chem. Soc.* **2004**, 126, 13703.

¹⁰⁴ Kronja, O.; Kohli, T.-P.; Mayr, H.; Saunders, M. *J. Am. Chem. Soc.* **2000**, 122, 8067.

Whether formed by pathway 3 or 4, the new carbocation normally reacts further in an effort to stabilize itself, usually by pathway 1 or 2. However, **22** can add to another alkene molecule, and this product can add to still another, and so on. This is one of the mechanisms for vinyl polymerization.

5.B. CARBANIONS

5.B.i. Stability and Structure¹⁰⁵

Formally, a carbanion is a trivalent carbon atom with an unshared electron pair, and a formal charge of -1 . In fact, there are few carbanions that do not have an anion-stabilizing group attached to the carbon atom. Stabilization may be by resonance delocalization or by orbital participation of an atom with d orbitals or orbitals associated with a metal.

By definition, every carbanion possesses an unshared pair of electrons and is formally a base. When a carbanion donates an electron to a proton, it is converted to its conjugate acid (an acid–base reaction, see Chapter 8). If the carbanion ($R_3C:^-$) were available, reaction with an acid generates the conjugate acid (R_3C-H), an alkane. The stability of the carbanion is directly related to the strength of the conjugate acid. The weaker that conjugate acid, the greater the base strength of the carbanion, and the lower the stability of the carbanion.¹⁰⁶ Stability here is judged by diminished reactivity (lower electron-donating ability) with a proton. The greater the stability, the lower the electron-donating ability (lower reactivity) for reaction of the carbanion with a proton (any acid that is sufficiently strong), and hence the longer lived the carbanion. Thus the determination of the order of stability of a series of carbanions is equivalent to a determination of the inverse order of strengths of the conjugate acids, and one can obtain information about relative carbanion stability from a table of acid strengths (e.g., Table 8.1).

While formation of simple carbanions (e.g., CH_3^-) is rare, formation of a carbon–metal bond often generates a molecule (e.g., R_3C-M , where M = a metal atom) that has a polarized bond in which the carbon is electron rich (δ^-). An organic molecule that contains a carbon–metal bond is called an *organometallic compound*. Organometallic compounds where the metal is Mg, Li, or other metals are carbanion surrogates, and in much of their chemistry they react as if they were carbanions (see Reactions **12-22–12.39**). Many such compounds are known, and organometallic chemistry is a very large area, occupying a borderline region between organic and inorganic chemistry. This section will discuss carbanions with little reference to a metal. Section 5.B.ii will discuss the structures of organometallic compounds, which are often carbanion surrogates.

Carbanions are very strong bases, and the conjugate acids of simple unsubstituted carbanions are very weak acids, with very few exceptions. Unfortunately, it is not easy to measure acid strengths of very weak acids. There is little doubt that carbanions are very

¹⁰⁵ See Buncel, E.; Durst, T. *Comprehensive Carbanion Chemistry*, pts. A, B, and C; Elsevier, NY, **1980**, **1984**, **1987**; Bates, R.B.; Ogle, C.A. *Carbanion Chemistry*, Springer, NY, **1983**; Stowell, J.C. *Carbanions in Organic Synthesis*, Wiley, NY, **1979**; Cram, D.J. *Fundamentals of Carbanion Chemistry*, Academic Press, NY, **1965**; Staley, S.W. *React. ¹⁰⁶ See Reutov, O.A.; Beletskaya, I.P.; Butin, K.P. *CH-Acids*, Pergamon, Elmsford, NY, **1978**; Fischer, H.; Rewicki, D. *Prog. Org. Chem.* **1968**, 7, 116.

unstable in solution, and in contrast to the situation with carbocations, efforts to prepare solutions in which carbanions (e.g., ethyl or isopropyl) exist in a relatively free state have not yet been successful. It has also not been possible to form these carbanions in the gas phase. Indeed, there is evidence that simple carbanions (e.g., ethyl and isopropyl) are unstable, losing an electron, which converts them to radicals.¹⁰⁷ Nevertheless, there have been several approaches to the problem. Applequist and O'Brien¹⁰⁸ studied the position of equilibrium for the reaction:

This reaction was done in ether or an ether–pentane mixture. The reasoning in these experiments was that the R group that forms the more stable carbanion would be more likely to be bonded to lithium than to iodine. Carbanion stability was found to be in the order: vinyl > phenyl > cyclopropyl > ethyl > *n*-propyl > isobutyl > neopentyl > cyclobutyl > cyclopentyl. In a somewhat similar approach, Dessy et al.¹⁰⁹ treated a number of alkylmagnesium compounds with a number of alkylmercury compounds in THF, setting up the equilibrium:

where the group of greater carbanion stability is linked to magnesium. The carbanion stability determined this way was phenyl > vinyl > cyclopropyl > methyl > ethyl > isopropyl. The two stability orders are in fairly good agreement, and they show that stability of simple carbanions decreases in the order methyl > primary > secondary. It was not possible to determine the position of *tert*-butyl by the experiments reported by Dessy et al.¹⁰⁹, but there seems little doubt that it is still less stable. This stability order can be interpreted as solely a consequence of the field effect since resonance is absent. The electron-donating alkyl groups of isopropyl result in a greater negative charge density at the central carbon atom (compared with methyl), thus decreasing its stability. The results of Applequist and O'Brien¹⁰⁸ show that β branching also decreases carbanion stability. Cyclopropyl occupies an apparently anomalous position, but this is probably due to the large amount of *s* character in the carbanionic carbon (see Sec. 5.B.i, category 2). Strongly electron-withdrawing groups (e.g., trifluoromethylsulfonyl) provide exceptional stability to carbanions.¹¹⁰

A different approach to the problem of hydrocarbon acidity, and hence carbanion stability, is that of Shatenshtein and Shapiro, who treated hydrocarbons with deuterated potassium amide and measured the rates of hydrogen exchange.¹¹¹ The experiments did not measure *thermodynamic* acidity, since rates were measured, not positions of equilibria. They measured *kinetic* acidity; that is, which compounds gave up protons most rapidly (see Sec. 6.F for the distinction between thermodynamic and kinetic control of product). Measurements of rates of hydrogen exchange enable one to compare acidities of a series of acids against a given base even where the positions of the equilibria cannot be measured

¹¹¹ For reviews, see Jones, J.R. *Surv. Prog. Chem.* **1973**, *6*, 83; Shatenshtein, A.I.; Shapiro, I.O. *Russ. Chem. Rev.* **1968**, *37*, 845.

because they lie too far to the side of the starting materials; that is, where the acids are too weak to be converted to their conjugate bases in measurable amounts. Although the correlation between thermodynamic and kinetic acidity is far from perfect,¹¹² the results of the rate measurements, too, indicated that the order of carbanion stability is methyl > primary > secondary > tertiary.¹¹¹

Experiments described above were done in solution, and experiments in the gas phase gave different results. In reactions of OH^- with alkyltrimethylsilanes, it is possible to cleave either R or Me. Since the R or Me come off as a carbanion or incipient carbanion, the product ratio RH/MeH can be used to establish the relative stabilities of various R groups. From these experiments a stability order of neopentyl > cyclopropyl > *tert*-butyl > *n*-propyl > methyl > isopropyl > ethyl was found.¹¹³ On the other hand, in a different kind of gas-phase experiment, Graul and Squires¹¹⁴ were able to observe CH_3^- ions, but not the ethyl, isopropyl, or *tert*-butyl ions.

As mentioned above, carbanion-stabilizing groups can increase the stability of carbanions, which influences their ease of formation. Six structural features that lead to improved stability are listed:

1. *Conjugation of the Unshared Pair with an Unsaturated Bond.*

In cases where a double or triple bond is located α to the carbanionic carbon, the ion is stabilized by resonance in which the unshared pair overlaps with the π electrons of the double bond. This factor is responsible for the stability of the allylic¹¹⁵ and benzylic¹¹⁶ types of carbanions:

Diphenylmethyl and triphenylmethyl anions are still more stable due to extensive delocalization into the benzene rings, and can be kept in solution indefinitely if

¹¹⁶ See Bockrath, B.; Dorfman, L.M. *J. Am. Chem. Soc.* **1974**, 96, 5708.

water is rigidly excluded.¹¹⁷ X-ray crystallographic structures have been obtained for Ph_2CH^- and Ph_3C^- enclosed in crown ethers.¹¹⁸ Carbanion **23** has a lifetime of several minutes (hours in a freezer at -20°C) in dry THF.¹¹⁹ Condensed aromatic rings fused to a cyclopentadienyl anion are known to stabilize the carbanion.¹²⁰

Where the carbanionic carbon is conjugated with a carbon–oxygen or carbon–nitrogen multiple bond ($\text{Y}=\text{O}$ or N), the stability of the ion is greater than that of the triarylmethyl anions, since these electronegative atoms are more capable of bearing a negative charge than carbon. However, it is questionable whether ions of this type should be called a carbanion at all, since in the case of enolate ions, for example, **25** contributes more to the hybrid than **24** although such ions react more often at the carbon than at the oxygen. In benzylic enolate anions (e.g., **26**), the conformation of the enolate can be coplanar with the aromatic ring or bent out of plane if the strain is too great.¹²¹ Enolate ions can also be maintained in solution in many cases, at least for minutes or hours at lower temperatures. In the case of carbanions at a carbon α to a nitrile, the “enolate” resonance form would be a ketene imine nitrane, but the existence of this species has been called into question.¹²² A nitro group is particularly effective in stabilizing a negative charge on an adjacent carbon, and the anions of simple nitro alkanes can exist in water. Thus the $\text{p}K_a$ for nitromethane is 10.2. Dinitromethane is even more acidic ($\text{p}K_a = 3.6$). In contrast to the stability of cyclopropylmethyl cations (Sec. 5.A.ii), the cyclopropyl group exerts only a weak stabilizing effect on an adjacent carbanionic carbon.¹²³

By combining a very stable carbanion with a very stable carbocation, Okamoto et al.¹²⁴ were able to isolate the salt (**27**), as well as several similar salts, as stable solids. These are salts that consist entirely of carbon and hydrogen atoms.

2. *Carbanions Increase in Stability with an Increase in the Amount of s Character at the Carbanionic Carbon.* Thus the order of stability is

Acetylene, where the carbon is sp hybridized with 50% s character, is much more acidic than ethylene¹²⁵ (sp^2 , 33% s), which in turn is more acidic than ethane, with 25% s character. Increased s character means that the electrons are closer to the nucleus, and hence of lower energy. As previously mentioned, cyclopropyl carbanions are more stable than methyl, owing to the larger amount of s character as a result of strain (see Sec. 4.Q.i).

3. *Stabilization by Sulfur¹²⁶ or Phosphorus.* Attachment to the carbanionic carbon of a sulfur or phosphorus atom causes an increase in carbanion stability, although the reasons for this are in dispute. One theory is that there is overlap of the unshared pair with an empty d orbital¹²⁷ ($p\pi-d\pi$ bonding, see Sec. 2.H). For example, a carbanion containing the SO_2R group would be written as follows:

However, there is evidence against d -orbital overlap; and the stabilizing effects have been attributed to other causes.¹²⁸ In the case of a PhS substituent, carbanion stabilization is thought to be due to a combination of the inductive and polarizability effects of the group, and $d-p\pi$ resonance and negative hyperconjugation play a minor role, if any.¹²⁹ An α silicon atom also stabilizes carbanions.¹³⁰

4. *Field Effects.* Most of the groups that stabilize carbanions by resonance effects (either the kind discussed in paragraph 1 above or the kind discussed in paragraph 3) have electron-withdrawing field effects and thereby stabilize the carbanion further by spreading the negative charge, although it is difficult to separate the field effect from the resonance effect. However, in a nitrogen (ylid $\text{R}_3\text{N}^+-\text{CR}_2$, see Sec. 2.H), where a positive nitrogen is adjacent to the negatively charged carbon, only the field effect operates. Ylids are more stable than the corresponding simple carbanions. Carbanions are stabilized by a field effect if there is any heteroatom (O, N, or S) connected to the carbanionic carbon, provided that the heteroatom bears a positive charge in at least one important canonical form,¹³¹ for example,

5. Certain Carbanions Are Stable because They Are Aromatic. See the cyclopentadienyl anion in Section 2.I.ii, and other aromatic anions in Chapter 2.
6. *Stabilization by a Nonadjacent π Bond.*¹³² In contrast to the situation with carbocations (see Sec. 2.C.i), there have been fewer reports of carbanions stabilized by interaction with a nonadjacent π bond. One that may be mentioned is **30**, formed when optically active camphenilone (**28**) was treated with a strong base (potassium *tert*-butoxide).¹³³ That **30** was truly formed was shown by the following facts: (1) A proton was abstracted: ordinary CH_2 groups are not acidic enough for this base; (2) recovered **28** was racemized: **30** is symmetrical and can be attacked equally well from either side; (3) when the experiment was performed in deuterated solvent, the rate of deuterium uptake was equal to the rate of racemization; and (4) recovered **28** contained up to three atoms of deuterium per molecule, although if **29** were the only ion, no more than two could be taken up. Ions of this type, in which a negatively charged carbon is stabilized by a carbonyl group two carbons away, are called *homoenolate ions*.

Based on these four categories, functional groups in the α position stabilize carbanions in the following order: $\text{NO}_2 > \text{RCO} > \text{COOR} > \text{SO}_2 > \text{CN} \sim \text{CONH}_2 > \text{halogen} > \text{H} > \text{R}$.

It is unlikely that free carbanions exist in solution, although some of the stabilized carbanions noted above have reasonable lifetimes in solution. Like carbocations, they usually exist as either ion pairs or they are solvated.¹³⁴ Among experiments that demonstrate ion pairing or solvation was the treatment of $\text{PhCOCHMe}^- \text{M}^+$ with ethyl iodide, where M^+ was Li^+ , Na^+ , or K^+ . The half-lives of the reaction were¹³⁵ for Li, 31×10^{-6} ; Na, 0.39×10^{-6} ; and K, 0.0045×10^{-6} , demonstrating that the species involved were not identical. Similar results¹³⁶ were obtained with Li, Na, and Cs triphenylmethides ($\text{Ph}_3\text{C}^- \text{M}^+$).¹³⁷ Where ion pairs are unimportant, carbanions are solvated. Cram¹⁰⁵ demonstrated

solvation of carbanions in many solvents. There may be a difference in the structure of a carbanion depending on whether it is free (e.g., in the gas phase) or in solution. The negative charge may be more localized in solution in order to maximize the electrostatic attraction to the counterion.¹³⁸

The structure of simple unsubstituted carbanions is not known with certainty since they have not been isolated, but it is likely that the central carbon is sp^3 hybridized, with the unshared pair occupying one apex of the tetrahedron. Carbanions are expected to have pyramidal structures (e.g., **31**, similar to those of amines).

The methyl anion (CH_3^-) has been observed in the gas phase and reported to have a pyramidal structure.¹³⁹ If this is taken as a general structure for carbanions, then any carbanion in which the three R groups are different should be chiral and reactions in which it is an intermediate should give retention of configuration. Attempts have been made to demonstrate this principle, but without success.¹⁴⁰ A possible explanation is that pyramidal inversion takes place here, as in amines, so that the unshared pair and the central carbon rapidly oscillate from one side of the plane to the other. There is, however, other evidence for the sp^3 nature of the central carbon and for its tetrahedral structure. Carbons at bridgeheads, although extremely reluctant to undergo reactions in which they must be converted to carbocations, easily undergo reactions in which they must be carbanions and stable bridgehead carbanions are known.¹⁴¹ Also, reactions at vinylic carbons proceed with retention,¹⁴² indicating that the intermediate **32** has sp^2 hybridization and not the sp hybridization that would be expected in the analogous carbocation. A cyclopropyl anion can also hold its configuration.¹⁴³

Carbanions in which the negative charge is stabilized by resonance involving overlap of the unshared-pair orbital with the π electrons of a multiple bond are essentially planar, as would be expected by the necessity for planarity in resonance, although unsymmetrical solvation or ion-pairing effects may cause the structure to deviate somewhat from true planarity.¹⁴⁴ Cram¹⁴⁴ showed that where chiral carbanions possessing this type of resonance are generated, retention, inversion, or racemization can result, depending on the solvent (see Sec. 12.A.ii). This result is

¹⁴⁰ Retention of configuration has never been observed with simple carbanions. Cram has obtained retention with carbanions stabilized by resonance. However, these carbanions are known to be planar or nearly planar, and retention was caused by asymmetric solvation of the planar carbanions (see Sec. 12.A.ii).

explained by unsymmetrical solvation of planar or near-planar carbanions. However, some carbanions that are stabilized by adjacent sulfur or phosphorus, for example, are inherently chiral, since retention of configuration is observed where

they are generated, even in solvents that cause racemization or inversion with other carbanions.¹⁴⁵ It is known that in THF, PhCH(Li)Me behaves as a prochiral entity,¹⁴⁶ and **33** has been prepared as an optically pure α -alkoxyllithium reagent.¹⁴⁷ Cyclohexyllithium (**34**) shows some configurational stability, and it is known that isomerization is slowed by an increase in the strength of lithium coordination and by an increase in solvent polarity.¹⁴⁸ It is known that a vinyl anion is configurationally stable whereas a vinyl radical is not. This is due to the instability of the radical anion that must be an intermediate for conversion of one isomer of vinyl lithium to the other.¹⁴⁹ The configuration about the carbanionic carbon, at least for some of the α -sulfonyl carbanions, seems to be planar,¹⁵⁰ and the inherent chirality is caused by lack of rotation about the C—S bond.¹⁵¹

5.B.ii. The Structure of Organometallic Compounds¹⁵²

Whether a carbon–metal bond is ionic or polar-covalent is determined chiefly by the electronegativity of the metal and the structure of the organic part of the molecule. Ionic bonds become more likely as the negative charge on the metal-bearing carbon is decreased by resonance or field effects. Thus the sodium salt of acetoacetic ester has a more ionic carbon–sodium bond than methylsodium.

Most organometallic bonds are polar-covalent. Only the alkali metals have electronegativities low enough to form ionic bonds with carbon, and even here the behavior of lithium alkyls shows considerable covalent character. The simple alkyls and aryls of Na, K,

Rb, and Cs¹⁵³ are nonvolatile solids¹⁵⁴ insoluble in benzene or other organic solvents, while alkyllithium reagents are soluble, although they too are generally nonvolatile solids. Organolithium reagents with alkyl units (alkyllithium reagents) do not exist as monomeric species in hydrocarbon solvents or ether.¹⁵⁵ In benzene and cyclohexane, freezing-point-depression studies have shown that alkyllithium reagents are normally hexameric unless steric interactions favor tetrameric aggregates.¹⁵⁶ Nuclear magnetic resonance studies, especially measurements of ¹³C—⁶Li coupling, have also shown aggregation in hydrocarbon solvents.¹⁵⁷ Boiling-point-elevation studies have been performed in ether solutions, where alkyllithium reagents exist in two- to fivefold aggregates.¹⁵⁸ Even in the gas phase¹⁵⁹ and in the solid state,¹⁶⁰ alkyllithium reagents exist as aggregates. X-ray crystallography has shown that methylolithium has the same tetrahedral structure in the solid state as in ether solution.¹⁶⁰ However, *tert*-butyllithium is monomeric in THF, although dimeric in ether and tetrameric in hydrocarbon solvents.¹⁶¹ Neopentyllithium exists as a mixture of monomers and dimers in THF.¹⁶²

The C—Mg bond in *Grignard reagents* is covalent and not ionic. The actual structure of Grignard reagents in solution has been a matter of much controversy over the years.¹⁶³ In 1929, it was discovered¹⁶⁴ that the addition of dioxane to an ethereal Grignard solution precipitates all the magnesium halide and leaves a solution of R₂Mg in ether; (i.e., there can be no RMgX in the solution since there is no halide). The following equilibrium, now called the *Schlenk equilibrium*, was proposed as the composition of the Grignard solution:

in which **35** is a complex. Much work has demonstrated that the Schlenk equilibrium actually exists and that the position of the equilibrium depends on the identity of R, X, the

¹⁶⁴ Schlenk, W.; Schlenk, Jr., W. *Ber.* **1929**, 62B, 920.

solvent, the concentration, and the temperature.¹⁶⁵ It has been known for many years that the magnesium in a solution of a Grignard reagent, no matter whether it is RMgX , R_2Mg , or MgX_2 , can coordinate with two molecules of ether in addition to the two covalent bonds to generate the solvent-coordinated species shown.

Rundle and Guggenberger¹⁶⁶ performed X-ray diffraction studies on solid phenylmagnesium bromide dietherate and on ethylmagnesium bromide dietherate, which they obtained by cooling ordinary ethereal Grignard solutions until the solids crystallized. They found that the structures were magnesium bromides (e.g., **36**). These solids still contained ether. When ordinary ethereal Grignard solutions¹⁶⁷ prepared from bromomethane, chloromethane, bromoethane, and chloroethane were evaporated at $\sim 100^\circ\text{C}$ under vacuum so that the solid remaining contained no ether, X-ray diffraction showed *no* RMgX , but a mixture of R_2Mg and MgX_2 .¹⁶⁸ These results indicate that in the presence of ether, $\text{RMgX} \cdot 2\text{Et}_2\text{O}$ is the preferred structure, while the loss of ether drives the Schlenk equilibrium to $\text{R}_2\text{Mg} + \text{MgX}_2$. However, conclusions drawn from a study of the solid materials do not necessarily apply to the structures in solution.

Boiling-point-elevation and freezing-point-depression measurements have demonstrated that in THF at all concentrations and in ether at low concentrations (up to $\sim 0.1 \text{ M}$) Grignard reagents prepared from alkyl bromides and iodides are monomeric, (i.e., there are few or no molecules with two Mg atoms).¹⁶⁹ Thus, part of the Schlenk equilibrium is operating but not the other part (i.e., **35** is not present in measurable amounts). This was substantiated by ^{25}Mg NMR spectra of the ethyl Grignard reagent in THF, which showed the presence of three peaks, corresponding to EtMgBr , Et_2Mg , and MgBr_2 .¹⁷⁰ That the equilibrium between RMgX and R_2Mg lies far to the left for “ethylmagnesium bromide” in ether was shown by Smith and Becker,¹⁷¹ who mixed 0.1 M ethereal solutions of Et_2Mg and MgBr_2 and found that a reaction occurred with a heat evolution of $3.6 \text{ kcal mol}^{-1}$ (15 kJ mol^{-1}) of Et_2Mg , and that the product was *monomeric* (by boiling-point elevation measurements). When either solution was added little by little to the other, there was a linear output of heat until almost a 1 : 1 molar ratio was reached. Addition of an excess of either reagent gave no further heat output. These results show that at least under some conditions the Grignard reagent is largely RMgX .

(coordinated with solvent), but that the equilibrium can be driven to R_2Mg by evaporation of all the ether or by addition of dioxane.

For some aryl Grignard reagents, it is possible to distinguish separate NMR chemical shifts for $ArMgX$ and Ar_2Mg .¹⁷² From the area under the peaks, it is possible to calculate the concentrations of the two species, and from them, equilibrium constants for the Schlenk equilibrium. These data show¹⁷² that the position of the equilibrium depends very markedly on the aryl group and the solvent, but that conventional aryl Grignard reagents in ether are largely $ArMgX$. In THF the predominance of $ArMgX$ is less, and with some aryl groups there is actually more Ar_2Mg present. Separate NMR chemical shifts have also been found for alkyl $RMgBr$ and R_2Mg in HMPA¹⁷³ and in ether at low temperatures.¹⁷⁴ When Grignard reagents from alkyl bromides or chlorides are prepared in triethylamine the predominant species is $RMgX$.¹⁷⁵ Thus the most important factor determining the position of the Schlenk equilibrium is the solvent. For primary alkyl groups the equilibrium constant for the reaction as written above is lowest in Et_3N , higher in ether, and still higher in THF.¹⁷⁶

However, Grignard reagents prepared from alkyl bromides or iodides in ether at higher concentrations (0.5–1 M) contain dimers, trimers, and higher polymers, and those prepared from alkyl chlorides in ether at all concentrations are dimeric,¹⁷⁷ so that **35** is in solution, probably in equilibrium with $RMgX$ and R_2Mg (i.e., the complete Schlenk equilibrium seems to be present).

The Grignard reagent prepared from 1-chloro-3,3-dimethylpentane in ether undergoes rapid inversion of configuration at the Mg containing carbon (demonstrated by NMR; this compound is not chiral).¹⁷⁸ The mechanism of this inversion is not completely known. Despite the mechanistic ambiguity, in almost all cases, it is not possible to retain the configuration of a stereogenic carbon while forming a Grignard reagent.

Organolithium reagents (RLi) are very important reagents in organic chemistry. In recent years, a great deal has been learned about their structure¹⁷⁹ in both the solid state and in solution. X-ray analysis of complexes of *n*-butyllithium with tetramethylethylenediamine (TMEDA), THF, and 1,2-dimethoxyethane (DME) shows them to be dimers and tetramers [e.g., $(BuLi \cdot DME)_4$];¹⁸⁰ they are aggregates.¹⁸¹ X-ray analysis of isopropyllithium shows it to be a hexamer $[(iPrLi)_6]$,¹⁸² and unsolvated lithium aryls are tetramers.¹⁸³ α -Ethoxyvinyl lithium $[CH_2=C(OEt)Li]$ shows a polymeric structure with tetrameric subunits.¹⁸⁴ Aminomethyl aryllithium reagents have been shown to be

chelated and dimeric in solvents (e.g., THF).¹⁸⁵ There are several functionalized organolithium reagents.¹⁸⁶

The dimeric, tetrameric, and hexameric structures of organolithium reagents¹⁸⁷ in the solid state is often retained in solution, but this is dependent on the solvent and complexing additives, if any. A tetrahedral organolithium compound is known,¹⁸⁸ and the X-ray of an α,α -dilithio hydrocarbon has been reported.¹⁸⁹ Phenyllithium is a mixture of tetramers and dimers in diethyl ether, but stoichiometric addition of THF, DME, or TMEDA leads to the dimer.¹⁹⁰ The solution structures of mixed aggregates of butyllithium and amino-alkaloids has been determined¹⁹¹ as well as the solution structure of sulfur-stabilized allyllithium compounds.¹⁹² Vinylithium is an 8:1 mixture of tetramer/dimer in THF at -90°C , but addition of TMEDA changes the ratio of tetramer/dimer to 1:13 at -80°C .¹⁹³ Internally solvated allylic lithium compounds have been studied, showing the coordinated lithium to be closer to one of the terminal allyl carbons.¹⁹⁴ A relative scale of organolithium stability has been established,¹⁹⁵ and the issue of configurational stability of enantioenriched organolithium reagents has been examined.¹⁹⁶

Enolate anions are an important class of carbanions that appear in a variety of important reactions, including alkylation α to a carbonyl group and the aldol (**16-34**) and *Claisen condensation* (**16-85**) reactions. Metal enolate anions of aldehydes, ketones, esters, and other acid derivatives exist as aggregates in ether solvents.¹⁹⁷ There is evidence that the lithium enolate of isobutyrophenone is a tetramer in THF,¹⁹⁸ but a dimer in DME.¹⁹⁹ X-ray crystallography of ketone enolate anions have shown that they can exist as tetramers and hexamers.²⁰⁰ There is also evidence that the aggregate structure is preserved in solution and is probably the actual reactive species. Lithium enolate anions derived from esters are as dimers in the solid state²⁰¹ that contain four THF molecules. It has also been established that the reactivity of enolate anions in alkylation and condensation reactions is influenced by the aggregate state of the enolate. It is also true that the relative proportions of (*E*) and (*Z*) enolate anions are influenced by the extent of solvation and the aggregation state.

Addition of LiBr to a lithium enolate anion in THF suppresses the concentration of monomeric enolate.²⁰² *Ab initio* studies confirm the aggregate state of acetaldehyde.²⁰³ It is also known that α -Li benzonitrile [PhCH(Li)CN] exists as a dimer in ether and with TMEDA.²⁰⁴ Mixed aggregates of *tert*-butyllithium and lithium *tert*-butoxide are known to be hexameric.²⁰⁵

It might be mentioned that matters are much simpler for organometallic compounds with less-polar bonds. Thus Et₂Hg and EtHgCl are both definite compounds, the former is a liquid and the latter is a solid. Organocalcium reagents are also known, and are formed from alkyl halides via a single electron transfer (SET) mechanism with free radical intermediates.²⁰⁶

5.B.iii. The Generation and Fate of Carbanions

There are two principal ways in which most carbanions are generated.

1. A Group Attached to a Carbon Leaves Without Its Electron Pair

The “leaving group” is most often a proton. In fact, the proton is removed by a suitable base, and this is a simple acid–base reaction.²⁰⁷ However, other leaving groups are known (see Chap 12), such as carboxyl:

2. A Negative Ion Adds to a Carbon–Carbon Double or Triple Bond (see Chapter 15)

The addition of a negative ion to a carbon–oxygen double bond (C=O) does not give a carbanion, but an alkoxide (R–O[−]), since the negative charge resides on the oxygen.

The most common reaction of carbanions is to donate electrons to a positive species, often a proton, or with another species that has an empty orbital in its outer shell (a Lewis acid–base reaction):

This means that carbanions react with electrophilic atoms (those functionalized so there is a δ^+ carbon atom); see Chapter 16.

²⁰⁶ Walborsky, H.M.; Hamdouchi, C. *J. Org. Chem.* **1993**, *58*, 1187.

²⁰⁷ For a review of such reactions, see Durst, T. in Buncl, E.; Durst, T. *Comprehensive Carbanion Chemistry*, pt. B, Elsevier, NY, **1984**, pp. 239–291.

Carbanions may also form a bond with a carbon that already has four bonds, by displacing one of the four groups (S_N2 reaction, see Chapter 10):

Like carbocations, carbanions can also react in ways in which they are converted to species that are still charged. They can add to double bonds (usually C=O double bonds; see Chapters 10 and 16),

or rearrange, although this is rare (see Chapter 18),

or they are oxidized to free radicals.²⁰⁸ A system in which a carbocation [$\text{Ph}(p\text{-Me}_2\text{NC}_6\text{H}_4)_2\text{C}^+$] oxidizes a carbanion [$(p\text{-NO}_2\text{C}_6\text{H}_4)_3\text{C}^-$] to give two free radicals, reversibly, so that all four species are present in equilibrium, has been demonstrated.^{209,210}

Organometallic compounds that are not ionic but polar-covalent behave very much as if they were ionic and give similar reactions.

5.C. FREE RADICALS

5.C.i. Stability and Structure²¹¹

A *free radical* (usually just called a *radical*) may be defined as a species that contains one or more unpaired electrons. Note that this definition includes certain stable inorganic molecules (e.g., NO and NO₂), as well as many individual atoms (e.g., Na and Cl). As with carbocations and carbanions, simple alkyl radicals are very reactive and are usually transient species. For the most part, their lifetimes are extremely short in solution, but they can be kept frozen for relatively long periods of time within the crystal lattices of other

molecules.²¹² There are, however, many stable radicals,²¹³ some of which will be noted below. Many spectral²¹⁴ measurements have been made on radicals trapped in this manner. Even under these conditions the methyl radical decomposes with a half-life of 10–15 min in a methanol lattice at 77 K.²¹⁵ Since the lifetime of a radical depends not only on its inherent stability, but also on the conditions under which it is generated, the terms *persistent* and *stable* are usually used for the different senses. A stable radical is inherently stable; a persistent radical has a relatively long lifetime under the conditions at which it is generated, although it may not be very stable.

Radicals can be characterized by several techniques (e.g., mass spectrometry²¹⁶ or the characterization of alkoxycarbonyl radicals by Step–Scan Time-Resolved Infrared Spectroscopy).²¹⁷ Another technique makes use of the magnetic moment that is associated with the spin of an electron, which can be expressed by a quantum number of $+\frac{1}{2}$ or $-\frac{1}{2}$. According to the *Pauli principle*, any two electrons occupying the same orbital must have opposite spins, so the total magnetic moment is zero for any species in which all the electrons are paired. In radicals, however, one or more electrons are unpaired, so there is a net magnetic moment and the species is paramagnetic. Radicals can therefore be detected by magnetic-susceptibility measurements, but for this technique a relatively high concentration of radicals is required.

A much more important technique is *electron spin resonance* (ESR), also called *electron paramagnetic resonance* (EPR).²¹⁸ The principle of ESR is similar to that of NMR, except that electron spin is involved rather than nuclear spin. The two electron spin states ($m_s = \frac{1}{2}$ and $m_s = -\frac{1}{2}$) are ordinarily of equal energy, but in a magnetic field the energies are different. As in NMR, a strong external field is applied and electrons are caused to flip from the lower state to the higher by the application of an appropriate radio frequency signal. Inasmuch as two electrons paired in one orbital must have opposite spins that cancel, an ESR spectrum arises only from species that have one or more unpaired electrons (i.e., free radicals).

Since only free radicals give an ESR spectrum, the method can be used to detect the presence of radicals and to determine their concentration.²¹⁹ Furthermore, information concerning the electron distribution (and hence the structure) of free radicals can be obtained from the splitting pattern of the ESR spectrum (ESR peaks are split by nearby

protons).²²⁰ Fortunately (for the existence of most free radicals is very short), it is not necessary for a radical to be persistent for an ESR spectrum to be obtained. Electron spin resonance spectra have been observed for radicals with lifetimes considerably <1 s. Failure to observe an ESR spectrum does not prove that radicals are not involved, since the concentration may be too low for direct observation. In such cases, the *spin-trapping* technique can be used.²²¹ In this technique, a compound is added that is able to combine with very reactive radicals to produce more persistent radicals; the new radicals can be observed by ESR. Azulenyl nitrones have been developed as chromotropic spin-trapping agents.²²² An important class of spin-trapping compounds are nitroso compounds, which react with radicals to give stable nitroxide radicals:²²³ $RN=O + R'\cdot \rightarrow RR'N-O\cdot$. An *N*-oxide spin trap has been developed [37; 2(diethylphosphino)-5,5-dimethyl-1-pyrroline-*N*-oxide], and upon trapping a reactive free radical, ³¹P NMR can be used to identify it.²²⁴ This technique is effective, and short-lived species (e.g., the oxiranylmethyl radical) have been detected by spin trapping.²²⁵ Other molecules have been used to probe the intermediacy of radicals via SET processes. They are called SET probes.²²⁶

Because there is an equal probability that a given unpaired electron will have a quantum number of $+\frac{1}{2}$ or $-\frac{1}{2}$, radicals are observed as a single line in an ESR spectrum unless they interact with other electronic or nuclear spins or possess magnetic anisotropy, in which case two or more lines may appear in the spectrum.²²⁷

Another magnetic technique for the detection of free radicals uses an ordinary NMR instrument. It was discovered²²⁸ that if an NMR spectrum is taken during the course of a reaction, certain signals might be enhanced, either in a positive or negative direction; others may be reduced. When this type of behavior, called *chemically induced dynamic nuclear polarization*²²⁹ (CIDNP), is found in the NMR spectrum of the product of a reaction, it

FIG. 5.1.²³¹ (a) The NMR spectrum taken during reaction between EtI and EtLi in benzene (the region between 0.5 and 3.5 δ was scanned with an amplitude twice that of the remainder of the spectrum). The signals at 1.0–1.6 δ are due to butane, some of which is also formed in the reaction. (b) Reference spectrum of EtI. [Reprinted with permission from Ward, H.R.; Lawler, R.G.; Cooper, R.A. *J. Am. Chem. Soc.* **1969**, 91, 746. Copyright © 1969 American Chemical Society.]

means that *at least a portion of that product was formed via the intermediacy of a free radical*.²³⁰ For example, the question was raised whether radicals were intermediates in the exchange reaction between ethyl iodide and ethyllithium (Reaction 12-39):

Curve *a* in Fig. 5.1²³¹ shows an NMR spectrum taken during the course of the reaction. Curve *b* is a reference spectrum of ethyl iodide (CH_3 protons at $\delta = 1.85$; CH_2 protons at $\delta = 3.2$). Note that in curve *a* some of the ethyl iodide signals are enhanced; others go below the base line (*negative enhancement*; also called *emission*). Thus the ethyl iodide formed in the exchange shows CIDNP and so was formed via a free radical intermediate. Chemically induced dynamic nuclear polarization results when protons in a reacting molecule become dynamically coupled to an unpaired electron while traversing the path from reactants to products. Although the presence of CIDNP almost always means that a free radical is involved,²³² its absence does not prove that a free radical intermediate is

²³⁰ A related technique is called CIDEP. For a review, see Hore, P.J.; Joslin, C.G.; McLauchlan, K.A. *Chem. Soc. Rev.* **1979**, 8, 29.

²³¹ Ward, H.R.; Lawler, R.G.; Cooper, R.A. *J. Am. Chem. Soc.* **1969**, 91, 746.

²³² It has been shown that CIDNP can also arise in cases where para hydrogen (H_2 in which the nuclear spins are opposite) is present: Eisenschmid, T.C.; Kirss, R.U.; Deutsch, P.P.; Hommeltoft, S.I.; Eisenberg, R.; Bargon, J.; Lawler, R.G.; Balch, A.L. *J. Am. Chem. Soc.* **1987**, 109, 8089.

necessarily absent, since reactions involving free radical intermediates can also take place without observable CIDNP. Also, the presence of CIDNP does not prove that *all* of a product was formed via a free radical intermediate, only that some of it was. Note that dynamic nuclear polarization (DNP) enhances signal intensities in the NMR spectra of solids and liquids. In a contemporary DNP experiment, a diamagnetic sample is doped with a paramagnet and the large polarization of the electron spins is transferred to the nuclei via microwave irradiation of the EPR spectrum.²³³ Dynamic nuclear polarization has been used to examine biradicals.²³⁴

As with carbocations, the stability order of free radicals is tertiary > secondary > primary, explainable by field effects and hyperconjugation, analogous to that in carbocations (Sec. 5.A.ii).²³⁵

With resonance possibilities, the stability of free radicals increases,²³⁶ some can be kept indefinitely.²³⁷ Benzylic and allylic²³⁸ radicals for which canonical forms can be drawn similar to those shown for the corresponding cations (Sec. 5.A.ii) and anions (Sec. 5.B.i, category 1) are more stable than simple alkyl radicals, but still have only a transient existence under ordinary conditions. Note that 2-phenylethyl radicals have been shown to exhibit bridging of the phenyl group.²³⁹

The triphenylmethyl and similar radicals²⁴⁰ are stable enough to exist in solution at room temperature, although they are in equilibrium with a dimeric form. The concentration of triphenylmethyl radical in benzene solution is ~2% at room temperature. For many years, it was assumed that $\text{Ph}_3\text{C} \cdot$, the first stable free radical known,²⁴¹ dimerized to hexaphenylethane ($\text{Ph}_3\text{C}-\text{CPh}_3$),²⁴² but UV and NMR investigations have shown that the true structure is **38**.²⁴³ Although triphenylmethyl-type radicals are stabilized by resonance:

steric hindrance to dimerization and not resonance is the major cause of their stability.²⁴⁴ This was demonstrated by the preparation of the radicals **39** and **40**.²⁴⁵ These radicals are electronically very similar, but **39**, being planar, has much less steric hindrance to dimerization than $\text{Ph}_3\text{C}^\bullet$, while **40**, with six groups in ortho positions, has much more. On the other hand, the planarity of **35** means that it has a maximum amount of

resonance stabilization, while **40** must have much less, since its degree of planarity should be even less than $\text{Ph}_3\text{C}^\bullet$, which itself is propeller shaped and not planar. Thus if resonance is the chief cause of the stability of $\text{Ph}_3\text{C}^\bullet$, **40** should dimerize and **39** should not, but if steric hindrance is the major cause, the reverse should happen. It was found²³³ that **40** gave no evidence of dimerization, even in the solid state, while **39** existed primarily in the dimeric form, which is dissociated to only a small extent in solution.²⁴⁶ This result indicates that steric hindrance to dimerization is the major cause for the stability of triarylmethyl radicals. A similar conclusion was reached in the case of $(\text{NC})_3\text{C}^\bullet$, which dimerizes readily although it is considerably stabilized by resonance.²⁴⁷ Nevertheless, that resonance is still an important contributing factor to the stability of radicals is shown by the facts that (1) the radical $t\text{-Bu}(\text{Ph})_2\text{C}^\bullet$ dimerizes more than $\text{Ph}_3\text{C}^\bullet$, while $p\text{-PhCOC}_6\text{H}_4(\text{Ph}_2)\text{C}^\bullet$ dimerizes less.²⁴⁸ The latter has more canonical forms than $\text{Ph}_3\text{C}^\bullet$, but steric hindrance should be about the same (for attack at one of the two rings). (2) A number of radicals $(p\text{-XC}_6\text{H}_4)_3\text{C}^\bullet$, with $\text{X}=\text{F}$, Cl , O_2N , CN , and so on, do not dimerize, but are kinetically stable.²⁴⁹ Completely chlorinated triarylmethyl radicals are more stable than the unsubstituted kind, probably for steric reasons, and many are quite inert in solution and in the solid state.²⁵⁰

Allylic radical are relatively stable, and the pentadienyl radical is particularly stable, but (*E,E*)-, (*E,Z*)-, and (*Z,Z*)-stereoisomers can form. It has been calculated that the (*Z,Z*)-pentadienyl radical is 5.6 kcal mol^{-1} less stable than the (*E,E*)-pentadienyl radical.²⁵¹ Note that vinyl radicals have (*E*)- and (*Z*)-forms and the inversion barrier from one to the other increases as the electronegativity of substituents increase.²⁵² Conjugated propargylic radicals are calculated to have diminished stability as the

conjugation increases, in contrast to the behavior of alkenes.²⁵³ Cyclopropyl alkynes have been used as mechanistic probes to distinguish between vinyl radicals and ionic intermediates.²⁵⁴ Enolate radicals are also known.²⁵⁵

It has been postulated that the stability of free radicals is enhanced by the presence at the radical center of *both* an electron-donating and an electron-withdrawing group.²⁵⁶ This finding is called the *push–pull* or *captodative effect* (see also, Sec. 4.K.i). The effect arises from increased resonance, as in **41**.

There is some evidence in favor²⁵⁷ of the captodative effect, some of it from ESR studies.²⁵⁸ However, there is also experimental²⁵⁹ and theoretical²⁶⁰ evidence against it. There is evidence that while $\text{FCH}_2\cdot$ and $\text{F}_2\text{CH}\cdot$ are more stable than $\text{CH}_3\cdot$, the radical $\text{CF}_3\cdot$ is less stable; that is, the presence of the third F destabilizes the radical.²⁶¹

Certain radicals with unpaired electron on a carbon are also very stable.²⁶² Radicals can be stabilized by intramolecular hydrogen bonding.²⁶³ Diphenylpicrylhydrazyl (**42**) is a solid that can be kept for years, and stable neutral azine radicals have been prepared.²⁶⁴ Nitroxide radicals were mentioned previously,²⁶⁵ and the commercially available TEMPO (2,2,6,6-tetramethylpiperidine-1-oxyl) free radical (**43**) is a stable nitroxyl radical used in

^bFree radical stability is in the reverse order.

organic radical lacking resonance stabilization has been prepared (**48**), and its X-ray crystal structure was obtained.²⁷⁶ Dissociation energies (D values) of R—H bonds provide a measure of the relative inherent stability of free radicals R.²⁷⁷ Table 5.4 lists such values.^{278–281} The higher the D value, the less stable the radical. Bond-dissociation energies also have been reported for the C—H bond of alkenes and dienes²⁸² and for the C—H bond in radical precursors XYC—H, where X,Y can be H, alkyl, COOR, COR, SR, CN, NO₂, and so on.²⁸³ Bond dissociation energies for the C—O bond in hydroperoxide radicals (ROO[•]) have also been reported.²⁸⁴ However, note that basing radical

stabilization energy on the difference between the bond dissociation energy (BDE) of $\text{CH}_3\text{—H}$, as a reference point, and of R—H has been observed to have shortcomings.²⁸⁵ The problem is that these values are only applicable to carbon-centered radicals, and the stabilization energies are not transferable and cannot be used to estimate BDE of R—R' , R—R , or any R—X compounds.²⁸²

There are two possible structures for simple alkyl radicals.²⁸⁶ They might have sp^2 bonding, in which case the structure would be planar, with the odd electron in a p orbital, or the bonding might be sp^3 , which would make the structure pyramidal and place the odd electron in an sp^3 orbital. The ESR spectra of $\cdot\text{CH}_3$ and other simple alkyl radicals as well as other evidence indicate that these radicals have planar structures.²⁸⁷ This finding is in accord with the known loss of optical activity when a free radical is generated at a stereogenic carbon.²⁸⁸ In addition, electronic spectra of the CH_3 and CD_3 radicals (generated by flash photolysis) in the gas phase have definitely established that under these conditions the radicals are planar or near planar.²⁸⁹ The IR spectra of $\cdot\text{CH}_3$ trapped in solid argon led to a similar conclusion.²⁹⁰ Despite the usual loss of optical activity noted above, asymmetric radicals can be prepared in some cases. For example, asymmetric nitroxide radicals are known.²⁹¹ An anomeric effect was observed in alkoxy radical **49**, where the ratio of **49a**/**49b** was 1:1.78.²⁹²

Evidence from studies on bridgehead compounds shows that although a planar configuration is more stable, pyramidal structures are not impossible. In contrast to the situation with carbocations, free radicals have often been generated at bridgeheads, although studies have shown that bridgehead free radicals are less rapidly formed than the corresponding open-chain radicals.²⁹³ In sum, the available evidence indicates that

although simple alkyl free radicals prefer a planar, or near-planar shape, the energy difference between a planar and a pyramidal free radical is not great. However, free radicals in which the carbon is connected to atoms of high electronegativity (e.g., $\cdot\text{CF}_3$), prefer a pyramidal shape;²⁹⁴ increasing the electronegativity increases the deviation from planarity.²⁹⁵ Cyclopropyl radicals are also pyramidal.²⁹⁶ Free radicals with resonance are definitely planar, although triphenylmethyl-type radicals are propeller shaped,²⁹⁷ like the analogous carbocations (Sec. 5.A.i). Radicals possessing simple alkyl substituents attached to the radical carbon (C \cdot) that have C^{sp3}—C^{sp3} bonds, and rotation about those bonds is possible. The internal rotation barrier for the *tert*-butyl radical (Me₃C \cdot), for example, was estimated to be $\sim 1.4 \text{ kcal mol}^{-1}$ 6 kJ mol^{-1} .²⁹⁸

A number of diradicals (also called biradicals) are known,²⁹⁹ and the thermodynamic stability of diradicals has been examined.³⁰⁰ Orbital phase theory has been applied to the development of a theoretical model of localized 1,3-diradicals, and used to predict the substitution effects on the spin preference and S–T gaps, and to design stable localized carbon-centered 1,3-diradicals.³⁰¹ When the unpaired electrons of a diradical are widely separated, for example, as in $\cdot\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\cdot$, the species behaves spectrally like two doublets. When they are close enough for interaction or can interact through an unsaturated system (as in trimethylenemethane),³⁰² they can have total spin numbers of +1, 0, or -1, since each electron could be either $+\frac{1}{2}$ or $-\frac{1}{2}$. Spectroscopically they are called *triplets*,³⁰³ since each of the three possibilities is represented among the molecules and gives rise to its own spectral peak. In triplet molecules, the two unpaired electrons have the same spin. Not all diradicals have a triplet ground state. In 2,3-dimethylelecyclohexane-1,4-diyl (**50**), the singlet and triplet states were found to be almost degenerate.³⁰⁴ Diradicals (e.g., **51**) are very stable with a triplet ground state.³⁰⁵ Diradicals are generally short-lived species. The lifetime of **52** was measured to be $< 0.1 \text{ ns}$ and other diradicals were found to have lifetimes

in the 4–316-ns range.³⁰⁶ Diradical **53** [3,5-di-*tert*-butyl-3'-(*N*-*tert*-butyl-*N*-aminoxyl)-4-oxybiphenyl] was found to have a lifetime of weeks even in the presence of oxygen, and survived brief heating in toluene up to ~60 °C.³⁰⁷ Radicals with both unpaired electrons on the same carbon are discussed under carbenes. 1,4-Biradicals are known, and α -carbonyl substituents increase the lifetime of the radical, and negative α -hyperconjugation (see Sec. 2.M) has been suggested as the cause.³⁰⁸

5.C.ii. The Generation and Fate of Free Radicals³⁰⁹

Free radicals are formed from molecules by breaking a bond so that each fragment keeps one electron.^{310,311} The energy necessary to break the bond is supplied in one of two ways.

1. *Thermal Cleavage.* Subjection of any organic molecule to a high enough temperature in the gas phase results in the formation of free radicals. When the molecule contains bonds with *D* values or 20–40 kcal mol^{−1} (80–170 kJ mol^{−1}), cleavage can be caused in the liquid phase. Two common examples are cleavage of diacyl peroxides to acyl radicals that decompose to alkyl radicals³¹² and cleavage of azo compounds to alkyl radicals³¹³

2. *Photochemical Cleavage* (see Sec. 7.A.v). Light energy of 600–300 nm is 48–96 kcal mol⁻¹ (200–400 kJ mol⁻¹), which is on the order of magnitude of covalent-bond energies. Typical examples are photochemical cleavage of alkyl halides in the presence of triethylamine,³¹⁴ alcohols in the presence of mercuric oxide and iodine,³¹⁵ alkyl 4-nitrobenzenesulfonates,³¹⁶ chlorine and of ketones:

Photolytic decomposition of *N*-hydroxypyridin-2-thione is a method that generates hydroxyl radicals.³¹⁷ The photochemistry of radicals and biradicals has been reviewed.³¹⁸

Radicals are also formed from other radicals, either by the reaction between a radical and a molecule (which *must* give another radical, since the total number of electrons is odd) or by cleavage of a radical³¹⁹ to give another radical, for example, the decomposition of benzoyl peroxide to give the benzoyl radical:

Radicals can also be formed by oxidation or reduction, including electrolytic methods.

Reactions of free radicals either give nonradical products (termination reactions) or lead to other radicals, which themselves must usually react further (propagation reactions). The most common termination reactions are simple coupling of similar or different radicals:

Another termination process is disproportionation:³²⁰

A propagation reaction is one in which a radical reacts to give at least one radical product, which continues the radical reaction sequence. There are four principal propagation reactions, of which the first two are most common:

1. *Abstraction of Another Atom or Group, Usually a Hydrogen Atom (also see Chap 14).*

A radical may abstract hydrogen atoms from a second molecule, or by an intramolecular process. A bromine radical (Br^{\bullet}) reacts with an alkane, for example, to give HBr and a carbon radical. This type of reaction is known as hydrogen-atom transfer. Water is an excellent hydrogen atom source for many reactions involving metals.³²¹ The reduction of a carbon radical with Bu_3SnH is an example of a hydrogen-transfer reaction (see Sec. 14.A.i). Indeed, carbon radicals react as hydrogen-bond acceptors.³²² Other atoms may be removed by a radical via atom-transfer reactions. A halogen atom can be transferred in some cases, including the transfer of an iodine atom from an aryl iodide to give an aryl radical.³²³ Solvent effects play a role in hydrogen-atom transfer (hydrogen abstraction), and hydrogen-bonding plays a role.³²⁴

2. *Addition to a Multiple Bond (see Chap 15).*

The radical formed from an alkene may add to the double bond of a second equivalent of alkene, and so on. This is one of the chief mechanisms for vinyl polymerization.

3. *Decomposition.* This process can be illustrated by the decomposition of the benzyloxy radical (see 55).
4. *Rearrangement.*

This reaction is less common than rearrangement of carbocations, but it does occur (though not when R = alkyl or hydrogen; see Chapter 18). Perhaps the best-known rearrangement is that of cyclopropylcarbinyl radicals to a butenyl radical.³²⁵ The rate constant for this rapid ring opening has been measured in certain functionalized cyclopropylcarbinyl radicals by picosecond radical kinetics.³²⁶ Substituent effects on the kinetics of ring opening in substituted cyclopropylcarbinyl radicals have been studied.³²⁷ “The cyclopropylcarbinyl

radical (**56**) has found an important application as a radical clock.³²⁸ Various radical processes can be clocked by the competition of direct reaction with the cyclopropylcarbinyl radical (k_i) and opening of that radical to the 1-buten-4-yl radical (k_r) followed by trapping. Relative rates (k_i/k_r) can be determined from yields of 4-X-1-butene and cyclopropylcarbinyl products as a function of the radical trap³²⁹ (X—Y) concentration. Absolute rate constants have been determined for a number of radicals with various radical traps by laser flash photolysis methods.³³⁰ From these absolute rate constants, reasonably accurate values of k_i can be estimated, and with the relative rate (k_i/k_r), a value for k_r can be calculated. From the calibrated radical-clock reaction rate (k_r), rates (k_i) of other competing reactions can be determined from relative rate data (k_i/k_r).³²⁶ Other radical clocks are known.³³¹

Free radicals can also be oxidized to carbocations or reduced to carbanions.³³²

5.C.iii. Radical Ions³³³

Several types of radical anions are known with the unpaired electron or the charge or both on atoms other than carbon. Examples include semiquinones³³⁴ (**57**), acepentalenes (**58**),³³⁵ ketyls³³⁶ (**59**) and the radical anion of the isolable dialkylsilylene (**60**).³³⁷ Radical anions are formed by the reaction of carbene anions with chloromethanes.³³⁸ Reactions in

which alkali metals are reducing agents often involve radical anion intermediates (*Birch reduction*, e.g., Reaction **15-13**) that proceed via radical anion **61**.

Several types of radical cation are also known.³³⁹ Typical examples include alkyl azulene cation radicals (**62**),³⁴⁰ trialkyl amine radical cations,³⁴¹ 1,2-bis(dialkylamino)benzenes radical cations (e.g., **63**),³⁴² dimethylsulfonium cation radicals ($\text{Me}_2\text{S}^{\bullet+}$),³⁴³ *N*-alkyl substituted imine cation radicals ($\text{Ph}_2\text{C}=\text{NEt}^{\bullet+}$),³⁴⁴ dibenzo[*a,e*]cyclooctene (**64**, a non-planar cation radical),³⁴⁵ and [*n.n*]paracyclophane cation radicals.³⁴⁶ A twisted radical cation derived from bicyclo[2.2.2]oct-2-ene has been reported.³⁴⁷

5.D. CARBENES

5.D.i. Stability and Structure³⁴⁸

Carbenes are highly reactive species, and practically all have lifetimes considerably < 1 s. With exceptions noted below (Sec. 5.D.ii), carbenes have been isolated only by entrapment in matrices at low temperatures (77 K or less).³⁴⁹ The parent species (CH_2) is usually called *methylene*, although derivatives are more often named by the carbene nomenclature. Thus CCl_2 is generally known as dichlorocarbene, although it can also be called dichloromethylene.

The two nonbonded electrons of a carbene can be either paired or unpaired. If they are paired, the species is spectrally a *singlet*, while, as seen above (Sec. 5.C.i), two unpaired electrons appear as a *triplet*. An ingenious

method of distinguishing between the two possibilities was developed by Skell,³⁵⁰ based on the common reaction of addition of carbenes to double bonds to form cyclopropane derivatives (Reaction 15-51). If the singlet species adds to *cis*-2-butene, the resulting cyclopropane should be the *cis* isomer since the movements of the two pairs of electrons

should occur either simultaneously or with one rapidly succeeding another. However, if the attack is by a triplet species, the two unpaired electrons cannot both go into a new covalent bond, since by *Hund's rule* they have parallel spins. So one of the unpaired electrons will form a bond with the electron from the double bond that has the opposite spin, leaving two unpaired electrons that have the same spin and therefore cannot form a bond at once, but must wait until, by some collision process, one of the electrons can reverse its spin. During this time, there is free rotation about the C—C bond and a mixture of *cis*- and *trans*-1,2-dimethylcyclopropanes should result.³⁵¹

The results of this type of experiment show that CH₂ itself is usually formed as a singlet species, which can decay to the triplet state, which consequently has a lower energy (MO calculations³⁵² and experimental determinations show that the difference in energy between singlet and triplet CH₂ is ~8–10 kcal mol⁻¹ or 33–42 kJ mol⁻¹)³⁵³. However, it is possible to prepare triplet CH₂ directly by a photosensitized decomposition of diazomethane.³⁵⁴ The CH₂ group is so reactive³⁵⁵ that it generally reacts as the singlet before it has a chance to decay to the triplet state.³⁵⁶ As to other carbenes, some react as triplets, some as singlets, and others as singlets or triplets, depending on how they are generated. There are, however, molecules that generate persistent triplet carbenes.³⁵⁷

Indeed, remarkably stable diaryl triplet carbenes have been prepared,³⁵⁸ and protected diphenylcarbenes are particularly stable.³⁵⁹ There are also persistent singlet carbenes, although radical fragmentation is a problem.³⁶⁰

There is a limitation to the use of stereospecificity of addition as a diagnostic test for singlet or triplet carbenes.³⁶¹ When carbenes are generated by photolytic methods, they are often in a highly excited singlet state. When they add to the double bond, the addition is stereospecific; but the cyclopropane formed carries excess energy (i.e., it is in an excited state). It has been shown that under certain conditions (low pressures in the gas phase) the excited cyclopropane may undergo cis–trans isomerization *after* it is formed, so that triplet carbene may seem to be involved although in reality the singlet was present.³⁶²

Studies of the IR spectrum of CCl_2 trapped at low temperatures in solid argon indicate that the ground state for this species is the singlet.³⁶³ The geometrical structure of triplet methylene can be investigated by ESR measurements,³⁶⁴ since triplet species are diradicals. Such measurements made on triplet CH_2 trapped in matrices at very low temperatures (4 K) show that triplet CH_2 is a bent molecule, with an angle of $\sim 136^\circ$.³⁶⁵ The EPR measurements cannot be made on singlet species, but from electronic spectra of CH_2 formed in flash photolysis³⁶⁶ of diazomethane it was concluded that singlet CH_2 is also bent, with an angle of $\sim 103^\circ$.³⁶⁷ Singlet CCl_2 ³⁰⁰ and CBr_2 ³⁶⁸ are also bent, with angles of 100° and 114° , respectively. It has long been known that triplet aryl carbenes are bent.³⁶⁹

The most common carbenes are :CH_2 and :CCl_2 ,³⁷⁰ but many others have been reported,³⁷¹ including heterocyclic carbenes³⁷² diboron carbenes,³⁷³ **65** (stabilized by the steric constraints of the ring geometry),³⁷⁴ **66** (an aminocarbene without π conjugation),³⁷⁵ bicyclo[2.2.2]octylidene, (**67**),³⁷⁶ alkylidene carbenes (e.g., **68**),³⁷⁷ conformationally restricted cyclopropylcarbenes, (e.g., **69**),³⁷⁸ β -silylcarbenes (e.g., **70**),³⁷⁹ α -keto carbenes,³⁸⁰ vinyl carbenes,³⁸¹ and chiral carbenoids.³⁸² Fluoro(phenoxy)carbene is stable for several days if it is generated within the cavity of a hemicarcerand (see Sec. 3.C.iii).³⁸³ In the case of **65** ($\text{R} = \text{Ph}$),³⁸⁴ the precursor is a tetraaminoethylene, and when potassium hydride is present to preclude electrophilic catalysis, starting tetraaminoethylenes are recovered unchanged.

Flash photolysis of CHBr_3 produced the intermediate CBr ,³⁸⁵ which is a *carbyne*.

The intermediates CF and CCl were generated similarly from CHFBr_2 and CHClBr_2 , respectively. Triplet acetylenes have been reported as equivalents for 1,2-bicarbenes.³⁸⁶

5.D.ii. The Generation and Fate of Carbenes³⁸⁷

There are two primary methods to form carbenes, although other pathways are also known.

1. In α elimination, a carbon loses a group without its electron pair, usually a proton, and then a group with its pair, usually a halide ion:³⁸⁸

The most common example is formation of dichlorocarbene by treatment of chloroform with a base (see Reaction 10-3) and geminal alkyl dihalides with Me_3Sn^- ,³⁸⁹ but many other examples are known, such as

2. Disintegration of compounds containing certain types of double bonds:

The two most important ways of forming $:\text{CH}_2$ are examples: the photolysis of ketene

and the isoelectronic decomposition of diazomethane.³⁹²

³⁸⁷ See Jones, Jr., M. *Acc. Chem. Res.* **1974**, 7, 415; Kirmse, W. in Bamford, C.H.; Tipper, C.F.H. *Comprehensive Chemical Kinetics*, Vol. 9; Elsevier, NY, **1973**, pp. 373–415; Ref. 348; Petrosyan, V.E.; Niyazymbetov, M.E. *Russ. Chem. Rev.* **1989**, 58, 644.

³⁹² For a review, see Regitz, M.; Maas, G. *Diazo Compounds*, Academic Press, NY, **1986**, pp. 170–184.

Some diazoalkanes decompose to the corresponding carbene.³⁹³ Diazirines³⁹⁴ (isomeric with diazoalkanes) give carbenes,³⁹⁵ but arylmethyl radicals have also been generated from diazirines.³⁹⁶ In a different study, thermolysis of diarylox-ydiazirines (**71**) gave the anticipated carbene products, but photolysis gave both carbenes and aryloxy radicals by α -scission.³⁹⁷

Because most carbenes are so reactive, it is often difficult to prove that they are actually present in a given reaction. The lifetime of formylcarbene was measured to be 0.15–0.73 ns by transient absorption and transient grating spectroscopy in dichloromethane.³⁹⁸ In many instances, where a carbene is *apparently* produced by an α elimination or by disintegration of a double-bond compound, there is evidence that no free carbene is actually involved. The neutral term *carbenoid* is used where it is known that a free carbene is not present or in cases where there is doubt. α -Halo organometallic compounds, (R_2CXM) are often called *carbenoids* because they readily give elimination reactions³⁹⁹ (e.g., see Reaction **12-39**).

The reactions of carbenes are more varied than those of the species previously discussed in this chapter.⁴⁰⁰ Solvent effects have been observed in carbene reactions. The selectivity of certain carbenes is influenced by the nature of the solvent.⁴⁰¹ The distribution of rearrangement products (see below) from *tert*-butylcarbene⁴⁰² are influenced by changes in solvent.⁴⁰³ It is known that singlet methylene forms a charge-transfer complex with benzene.⁴⁰⁴ Solvent interactions for chlorophenylcarbene and fluorophenylcarbene, however, are weak.⁴⁰⁵

1. Additions to carbon–carbon double bonds have already been mentioned. Carbenes also add to aromatic systems, but the immediate products rearrange, usually with ring enlargement (see Reaction **15-65**). Additions of carbenes to other double bonds [e.g., $\text{C}=\text{N}$ (Reactions **16-46** and **16-48**), and to triple bonds], have also been reported.
2. An unusual reaction of carbenes is that of insertion into $\text{C}-\text{H}$ bonds (Reaction **12-21**). Thus $:\text{CH}_2$ reacts with methane to give ethane and with propane

to give *n*-butane and isobutane, as shown. Elimination to give an alkene is a competing side reaction in polar solvents, but this is suppressed in nonpolar solvents.⁴⁰⁶ Simple alkyl carbenes, such as this, are not very useful for synthetic purposes, but do illustrate the extreme reactivity of carbene. However, carbenoids generated by rhodium-catalyzed decomposition of diazoalkanes are very useful (see Reaction 12-23) and have been used in a variety of syntheses. Treatment in the liquid phase of an alkane (e.g., pentane) with carbene formed from the photolysis of diazomethane, gives the three possible products in statistical ratios⁴⁰⁷ demonstrating that carbene is displaying no selectivity. For many years, it was a generally accepted principle that the lower the selectivity the greater the reactivity; however, this principle is no longer regarded as general because many exceptions have been found.⁴⁰⁸ Singlet CH_2 generated by photolysis of diazomethane is probably the most reactive organic species known, but triplet CH_2 is somewhat less reactive, and other carbenes are still less reactive. The following series of carbenes of decreasing reactivity has been proposed on the basis of discrimination between insertion and addition reactions: $\text{CH}_2 > \text{HCCOOR} > \text{PhCH} > \text{BrCH} \sim \text{ClCH}$.⁴⁰⁹ Dihalocarbenes generally do not give insertion reactions at all. Insertion of carbenes into other bonds has also been demonstrated, although not insertion into C—C bonds.⁴¹⁰

Two carbenes that are stable at room temperature have been reported:⁴¹¹ **72** and **73**. In the absence of oxygen and moisture, **72** exists as stable crystals with a melting point of 240–241 °C.⁴¹² This structure was proved by X-ray crystallography.

3. It would seem that dimerization to form an alkene should be an important reaction of carbenes, but it is not.

Generally, the reactivity is so great that the carbene species do not have time to find each other and because the dimer generally has so much energy that it dissociates again. Apparent dimerization has been observed, but it is likely that the products in many reported instances of “dimerization” do not arise from an actual dimerization of two carbenes, but come from attack by a carbene on a molecule of a carbene precursor, for example,

4. Alkylcarbenes can undergo rearrangement, with migration of alkyl or hydrogen.⁴¹³ Indeed these rearrangements are generally so rapid⁴¹⁴ that additions to multiple bonds and insertion reactions, which are so common for CH_2 , are seldom encountered with alkyl or dialkyl carbenes. Unlike rearrangement of the species previously encountered in this chapter, most rearrangements of carbenes directly give stable molecules. A carbene intermediate has been suggested for the isomerization of cyclopropane.⁴¹⁵ Some examples of carbene rearrangement are

The rearrangement of acylcarbenes to ketenes is called the *Wolff rearrangement* (Reaction 18-8). A few rearrangements in which carbenes rearrange to other

carbenes are also known.⁴²⁰ Of course, the new carbene must stabilize itself in one of the ways mentioned.

5. The fragmentation reactions of alicyclic oxychlorocarbenes (e.g., **74** and **75**)⁴²¹ give substitution and elimination products. Menthylloxylchlorocarbene (**74**) gave primarily the substitution product, whereas neomenthylloxylchlorocarbene (**75**) gave primarily the elimination product, as shown. In this case, the substitution product is likely due to rearrangement of the chlorocarbene.⁴²² It is known that fragmentation of nortricycloxychlorocarbene in pentane occurs by an S_Ni-like process to give nortricycyl chloride.⁴²³ In more polar solvents, fragmentation leads to nortricycyl cation–chloride anion pair that gives nortricycyl chloride and a small amount of *exo*-2-norbornenyl chloride. Fragmentation can also lead to radicals.⁴²⁴

6. Triplet carbenes can abstract hydrogen or other atoms to give free radicals, for example,

This is not surprising, since triplet carbenes are free radicals. But singlet carbenes⁴²⁵ can also give this reaction, although in this case only halogen atoms are abstracted, not hydrogen.⁴²⁶

5.E. NITRENES

Nitrenes (R—N),⁴²⁷ are the nitrogen analogues of carbenes, and most of the comments about carbenes also applies to them. Nitrenes are too reactive for isolation under ordinary

conditions,⁴²⁸ although *ab initio* calculations show that nitrenes are more stable than carbenes with an enthalpy difference of 25–26 kcal mol⁻¹ (104.7–108.8 kJ mol⁻¹).⁴²⁹

Alkyl nitrenes have been isolated by trapping in matrices at 4 K,⁴³⁰ while aryl nitrenes, which are less reactive, can be trapped at 77 K.⁴³¹ The ground state of NH, and probably of most nitrenes,⁴³² is a triplet, although nitrenes can be generated in both triplet⁴³³ and singlet states. A quartet ground-state nitreno radical has been reported.⁴³⁴ In additions of EtOOC—N to C=C double bonds two species are involved, one of which adds in a stereospecific manner and the other not. By analogy with Skell's proposal involving carbenes (Sec. 5.D.i) these are taken to be the singlet and triplet species, respectively.⁴³⁵

The two principal means of generating nitrenes are analogous to those used to form carbenes.

1. *Elimination.* An example is

2. *Breakdown of Certain Double-Bond Compounds.* The most common method of forming nitrenes is photolytic or thermal decomposition of azides,⁴³⁶

The unsubstituted nitrene (NH) has been generated by photolysis of electric discharge through NH₃, N₂H₄, or HN₃.

The reactions of nitrenes are also similar to those of carbenes.⁴³⁷ As in that case, many reactions in which nitrene intermediates are suspected probably do not involve free nitrenes. It is often very difficult to obtain proof in any given case that a free nitrene is or is not an intermediate.

1. *Insertion (see Reaction 12-13).* Nitrenes, especially acyl nitrenes and sulfonyl nitrenes, can insert into C—H and certain other bonds, for example,

2. *Addition to C=C bonds (see Reaction 15-54):*

3. *Rearrangements.*⁴¹³ Alkyl nitrenes do not generally give either of the two preceding reactions because rearrangement is more rapid, for example,

Such rearrangements are so rapid that it is usually difficult to exclude the possibility that a free nitrene was never present at all; that is, that migration takes place at the same time the nitrene is formed⁴³⁸ (see Reaction 18-12). However, the rearrangement of naphthyl nitrenes to novel bond-shift isomers has been reported.⁴³⁹

4. *Abstraction.* For example,

5. *Dimerization.* One of the principal reactions of NH is dimerization to diimide (N_2H_2). Azobenzenes are often obtained in reactions where aryl nitrenes are implicated:⁴⁴⁰

It would thus seem that dimerization is more important for nitrenes than it is for carbenes, but again it has not been proven that free nitrenes are actually involved.

At least two types of *nitrenium ions*,⁴⁴¹ the nitrogen analogues of carbocations, can exist as intermediates, although much less work has been done in this area

Mechanisms and Methods of Determining Them

A mechanism is the actual process by which a reaction takes place: which bonds are broken, in what order, how many steps are involved, the relative rate of each step, and so on. In order to state a mechanism completely, the positions of all atoms should be specified, including those in solvent molecules, and the energy of the system, at every point in the process. A proposed mechanism must fit all the facts available. It is always subject to change as new facts are discovered. The usual course is that the gross features of a mechanism are the first to be known and then increasing attention is paid to finer details. The tendency is always to probe more deeply, to get more detailed descriptions.

Although for most reactions gross mechanisms can be written today with a good degree of assurance, no mechanism is known completely.¹ There is much about the fine details that is still puzzling, and for some reactions even the gross mechanism is not yet clear. The problems involved are difficult because there are so many variables. Many examples are known where reactions proceed by different mechanisms under different conditions. In some cases, there are several proposed mechanisms, each of which completely explains all the data.

6.A. TYPES OF MECHANISM

In most reactions of organic compounds, one or more covalent bonds are broken. Organic mechanisms may be divided into three basic types, depending on how the bonds break.

1. If a bond breaks in such a way that both electrons remain with one fragment, the mechanism is called *heterolytic*. Such reactions do not necessarily involve ionic intermediates, although they often do. The important thing is that the electrons are never unpaired. For most reactions, it is convenient to call one reactant the *attacking reagent* and the other the *substrate*. In this book, the substrate is always designated as that molecule that supplies carbon to the new bond. When carbon–carbon bonds are formed via heterolytic reactions, the reagent generally brings a pair of electrons

to the substrate or takes a pair of electrons from it. A reagent that brings an electron pair is called a *nucleophile* and the reaction is *nucleophilic*. A reagent that takes an electron pair is called an *electrophile* and the reaction is *electrophilic*. For a reaction in which the substrate molecule becomes cleaved, part of it (the part not containing the carbon) is usually called the *leaving group*. A leaving group that carries away an electron pair is called a *nucleofuge*. If it comes away without the electron pair, it is called an *electrofuge*.

2. If a bond breaks in such a way that each fragment gets one electron, free radicals are formed and such reactions are said to take place by *homolytic* or *free radical mechanisms*.
3. It would seem that all bonds must break in one of the two ways previously noted. But there is a third type of mechanism in which electrons (usually six, but sometimes some other number) move in a closed ring. There are no intermediates, ions or free radicals, and it is impossible to say whether the electrons are paired or unpaired. Reactions with this type of mechanism are called *pericyclic*² (see Reactions **15-58-15-61** and **18-29-18-33**).

Examples of all three types of mechanisms are given in Section 6.B.

6.B. TYPES OF REACTION

The number and range of organic reactions is so great as to seem bewildering, but actually almost all of them can be fitted into just six categories. In the description of the six types that follows, the immediate products are shown, although in many cases they then react with something else. All the species are shown without charges, since differently charged reactants can undergo analogous changes. The descriptions given here are purely for the purpose of classification and comparison. All are discussed in detail in Part II.

1. *Substitutions*. If heterolytic, these reactions can be classified as nucleophilic or electrophilic depending on which reactant is designated as the substrate and which as the attacking reagent (very often Y must first be formed by a previous bond cleavage).

- a. Nucleophilic substitution (Chaps 10 and 13).

- b. Electrophilic substitution (Chaps 11 and 12).

- c. Free radical substitution (Chap 14).

² For a classification of pericyclic reactions, see Hendrickson, J.B. *Angew. Chem. Int. Ed.* **1974**, 13, 47. Also see, Fleming, I. *Pericyclic Reactions*, Oxford University Press, Oxford, **1999**.

In free radical substitution, Y^\bullet is usually produced by a previous free radical cleavage, and X^\bullet goes on to react further.

2. *Additions to Double or Triple Bonds (Chaps 15 and 16).* These reactions can take place by all three of the mechanistic possibilities.

a. Electrophilic addition (heterolytic).

b. Nucleophilic addition (heterolytic).

c. Free-radical addition (homolytic).

d. Simultaneous addition (pericyclic).

The examples show Y and W coming from the same molecule, but very often (except in simultaneous addition) they come from different molecules, as illustrated by (b). Cleavage of the Y—W bond may occur at the same time that Y is bonding to B, but the cleavage may also occur earlier.

3. β Elimination (*Chap 17*).

These reactions can take place by either heterolytic or pericyclic mechanisms. Examples of the latter are shown in Section 17.C.i. Free radical β eliminations are extremely rare. In heterolytic eliminations, W and X may or may not leave simultaneously and may or may not combine afterwards.

4. *Rearrangement (Chap 18).* Many rearrangements involve migration of an atom or group from one atom to another. There are three types, depending on how many electrons the migrating atom or group carries with it.

a. Migration with electron pair (nucleophilic; common).

b. Migration with one electron (free radical; rare).

c. Migration without electrons (electrophilic; rare).

The generic examples show 1,2 rearrangements, in which the migrating group moves to the adjacent atom. These are the most common, although longer rearrangements are also possible. There are also some rearrangements that do not involve simple migration at all, but rather migration across a π -framework (see Chap 18). Some of the latter involve pericyclic mechanisms.

5. *Oxidation and Reduction (Chap 19)*. Many oxidation and reduction reactions fall naturally into one of the four types mentioned above, but many others do not. For a description of oxidation–reduction mechanistic types, see Section 19.A.
6. *Combinations of the Above*. Note that arrows are used to show movement of *electrons*. An arrow always follows the motion of electrons and never of a nucleus or anything else (it is understood that the rest of the molecule follows the electrons). Ordinary arrows (double-headed) follow electron pairs, while single-headed arrows follow unpaired electrons. Double-headed arrows are also used in pericyclic reactions for convenience, but in these reactions how or in which direction the electrons are moving is usually unknown.

While not mentioned here as a distinct category, it must be said that many reactions, including some examples of 1–6 are actually acid–base reactions. In other cases, an acid–base reaction initiates the process or sometimes ends the process. In 2a, for example, $\text{Y} = \text{H}$ and this is an acid–base reaction in which the π bond is the base and the proton is the acid. If $\text{W} = \text{H}$ in 3a, then the elimination process begins with an acid–base reaction in which a base donates two electrons to $\text{H} (= \text{W})$. In 2b, if A donates electrons to W and $\text{W} = \text{H}$, this is another example of an acid–base reaction. Always be mindful of the acid–base properties of reactions.

Many, if not most of the reactions, noted above are subject to modification of the reactivity by the introduction of π bonds. Most reactions involve the transfer of two electrons to make or break a bond. The presence of two electrons in a π bond allows this two- electron-transfer process to proceed through the intervening atoms. In effect, the reactivity of a given center is extended by the presence of π bonds. This is the concept of *vinylology*: the extension of points of reactivity by intervening π bonds. In other words, if a system $\text{X}-\text{C}-1-\text{C}-2$ undergoes a reaction at C-2 with loss of X from C-1, $\text{X}-\text{C}-1-\text{C}-2=\text{C}-3-\text{C}-4$ may undergo reaction at C-4. Reaction at C-4 initiates electron transfer via the π bond that is extended to C-1 for loss of X. Several examples of this type of reaction will be presented in later chapters.

6.C. THERMODYNAMIC REQUIREMENTS FOR REACTION

In order for a reaction to take place spontaneously, the free energy of the products must be lower than the free energy of the reactants (i.e., ΔG must be negative). Reactions can go the other way, of course, but only if free energy is added. Like water on the surface of the earth, which naturally flows only downhill and never uphill, molecules seek the lowest possible potential energy. Free energy is made up of two components, enthalpy (H) and entropy (S).

These quantities are related by the equation

$$\Delta G = \Delta H - T\Delta S$$

The enthalpy change in a reaction is essentially the difference in bond energies (including resonance, strain,³ and solvation energies) between the reactants and the products. The enthalpy change can be calculated by totaling the bond energies of all the bonds broken, subtracting from this the total of the bond energies of all the bonds formed, and adding any changes in resonance, strain, or solvation energies. Entropy changes are quite different, and refer to the disorder or randomness of the system. The lower the order in a system, the greater the entropy. The preferred conditions in Nature are *low* enthalpy and *high* entropy, and in reacting systems, enthalpy spontaneously decreases while entropy spontaneously increases.

For many reactions, entropy effects are small and it is the enthalpy that mainly determines whether the reaction can take place spontaneously. However, in certain processes entropy is important and can sometimes dominate enthalpy. Several examples will be discussed.

1. In general, liquids have lower entropies than gases, since the molecules of gas have much more freedom and randomness. Solids, of course, have still lower entropies. Any reaction in which the reactants are all liquids and one or more of the products is a gas is therefore thermodynamically favored by the increased entropy; the equilibrium constant for that reaction will be higher than it would otherwise be. Similarly, the entropy of a gaseous substance is higher than that of the same substance dissolved in a solvent.
2. In a reaction in which the number of product molecules is equal to the number of reactant molecules (e.g., $A + B \rightarrow C + D$), entropy effects are usually small, but if the number of molecules is increased, (e.g., $A \rightarrow B + C$), there is a gain in entropy because more arrangements in space are possible when more molecules are present. Reactions in which a molecule is cleaved into two or more parts are likely to be thermodynamically favored by the entropy factor. Conversely, reactions in which the number of product molecules is less than the number of reactant molecules show entropy decreases, and in such cases there must be a sizable decrease in enthalpy to overcome the unfavorable entropy change.
3. Although reactions in which molecules are cleaved into two or more pieces have favorable entropy effects, many potential cleavages do not take place because of large increases in enthalpy.⁴ An example is cleavage of ethane into two methyl radicals. In this case, a bond of $\sim 79 \text{ kcal mol}^{-1}$ (330 kJ mol^{-1}) is broken, and no new bond is formed to compensate for this enthalpy increase. However, ethane can be cleaved at very high temperatures, which illustrates the principle that *entropy becomes more important as the temperature increases*, as is obvious from the equation $\Delta G = \Delta H - T\Delta S$. The enthalpy term is independent of temperature, while the entropy term is directly proportional to the absolute temperature.

³ For a discussion of the activation strain model of chemical reactivity, see van Zeist, W.-J.; Bickelhaupt, F.M. *Org. Biomol. Chem.*, **2010**, 8, 3118.

⁴ For calculations of long-chain alkane energies see Song, J.-W.; Tsuneda, T.; Sato, T.; Hirao, K. *Org. Lett.* **2010**, 12, 1440.

4. An acyclic molecule has more entropy than a similar cyclic molecule because there are more conformations (cf. hexane and cyclohexane). Ring opening therefore correlates with a gain in entropy and ring closing a loss.

6.D. KINETIC REQUIREMENTS FOR REACTION

Just because a reaction has a negative ΔG does not necessarily mean that it will take place in a reasonable period of time. A negative ΔG is a *necessary*, but not a *sufficient*, condition for a reaction to occur spontaneously. For example, the reaction between H_2 and O_2 to give H_2O has a large negative ΔG , but mixtures of H_2 and O_2 can be kept at room temperature for many centuries without reacting to any significant extent. In order for a reaction to take place, *free energy of activation* (ΔG^\ddagger) must be added.⁵ This situation is illustrated in Fig. 6.1,⁶ which is an energy profile for a one-step reaction without an intermediate. In this type of diagram, the horizontal axis (called the *reaction coordinate*)⁷ signifies the progression of the reaction. The parameter ΔG_f^\ddagger is the free energy of activation for the forward reaction. If the reaction shown in Fig. 6.1 is reversible, ΔG_r^\ddagger must be $> \Delta G_f^\ddagger$, since it is the sum of ΔG and ΔG_f^\ddagger .

When a reaction between two or more molecules has progressed to the point corresponding to the top of the curve, the term *transition state* is applied to the positions of the nuclei and electrons. The transition state possesses a definite geometry and charge distribution, but has no finite existence; the system passes through it. The system at this point is called an *activated complex*.⁸

FIG. 6.1. Free energy profile of a reaction without an intermediate where the products have a lower free energy than the reactants.

⁵ To initiate a reaction of a mixture of H_2 and O_2 , energy must be added such as by striking a match.

⁶ Strictly speaking, this is an energy profile for a reaction of the type $\text{XY} + \text{Z} \rightarrow \text{X} + \text{YZ}$. However, it may be applied, in an approximate way, to other reactions.

⁷ For a review of reaction coordinates and structure–energy relationships, see Grunwald, E. *Prog. Phys. Org. Chem.* **1990**, 17, 55.

⁸ For a discussion of transition states, see Laidler, K.J. *J. Chem. Educ.* **1988**, 65, 540.

In *transition-state theory*,⁹ the starting materials and the activated complex are taken to be in equilibrium, the equilibrium constant being designated K^\ddagger . According to the theory, all activated complexes go on to product at the same rate (which, although at first sight is surprising, is not unreasonable since they are all “falling downhill”) so that the rate constant (see Sec. 6.J.vi) of the reaction depends only on the position of the equilibrium between the starting materials and the activated complex, (i.e., on the value of K^\ddagger). The parameter ΔG^\ddagger is related to K^\ddagger by

$$\Delta G^\ddagger = -2.3 RT \log K^\ddagger$$

so that a higher value of ΔG^\ddagger is associated with a smaller rate constant. The rates of nearly all reactions increase with increasing temperature because the additional energy thus supplied helps the molecules to overcome the activation energy barrier.¹⁰ Some reactions have no free energy of activation at all, meaning that K^\ddagger is essentially infinite and that virtually all collisions lead to reaction. Such processes are said to be *diffusion controlled*.¹¹

Like ΔG , ΔG^\ddagger is made up of enthalpy and entropy components

$$\Delta G^\ddagger = \Delta H^\ddagger - T\Delta S^\ddagger$$

ΔH^\ddagger , the *enthalpy of activation*, is the difference in bond energies, including strain, resonance, and solvation energies, between the starting compounds and the *transition state*. In many reactions, bonds have been broken or partially broken by the time the transition state is reached; the energy necessary for this is ΔH^\ddagger . It is true that additional energy will be supplied by the formation of new bonds, but if this occurs after the transition state, it can affect only ΔH and not ΔH^\ddagger .

Entropy of activation, (ΔS^\ddagger), which is the difference in entropy between the starting compounds and the transition state, becomes important when two reacting molecules must approach each other in a specific orientation in order for the reaction to take place. For example, the reaction between a simple non-cyclic alkyl chloride and hydroxide ion to give an alkene (Reaction 17-13) takes place only if, in the transition state, the reactants are oriented as shown. This is an acid–base reaction because the proton on the carbon β to the chlorine is polarized δ^+ , and is a weak acid. Removal of that proton initiates loss of the chlorine atom and formation of the alkene. The electrons in the C—H bond (the acidic proton) must align anti to the leaving groups (Cl) for the reaction to proceed.¹²

¹⁰ See Donahue, N.M. *Chem. Rev.* **2003**, *103*, 4593.

¹¹ For a monograph on diffusion-controlled reactions, see Rice, S.A. *Comprehensive Chemical Kinetics*, Vol. 25 (edited by Bamford, C.H.; Tipper, C.F.H.; Compton, R.G.); Elsevier: NY, **1985**.

¹² As will be seen in Chapter 17, elimination is also possible with some molecules if the hydrogen is oriented syn, instead of anti, to the chlorine atom. Of course, this orientation also requires a considerable loss of entropy.

When the two reacting molecules collide, if the ^-OH should approach the molecule, the chlorine atom, or near R^1 or R^2 , no reaction can take place. In order for a reaction to occur, the molecules must surrender the freedom they normally have to assume many possible arrangements in space because only one leads to reaction. Thus, a considerable loss in entropy is involved, (i.e., ΔS^\ddagger is negative).

Entropy of activation is also responsible for the difficulty in closing rings¹³ larger than six members. Consider a ring-closing reaction in which the two groups that must interact are situated on the ends of a 10-carbon chain. In order for reaction to take place, the groups must encounter each other. But a 10-carbon chain has many conformations, and in only a few of these are the ends of the chain near each other. Thus, forming the transition state requires a great loss of entropy.¹⁴ This factor is also present, although less so, in closing rings of six members or less (except three-membered rings), but with rings of this size the entropy loss is less than that of bringing two individual molecules together. For example, a reaction between an OH group and a COOH group in the same molecule to form a lactone with a five- or six-membered ring takes place much faster than the same reaction between a molecule containing an OH group and another containing a COOH group. Although ΔH^\ddagger is about the same, ΔS^\ddagger is much less for the cyclic case. However, if the ring to be closed has three or four members, small-angle strain is introduced and the favorable ΔS^\ddagger may not be sufficient to overcome the unfavorable ΔH^\ddagger change. Table 6.1 shows the relative rate constants for the closing of rings of 3–23 members all by the same reaction.¹⁵ Reactions in which the transition state has more disorder than the starting compounds, for example, the pyrolytic conversion of cyclopropane to propene, have positive ΔS^\ddagger values and are thus favored by the entropy effect.

Reactions with intermediates are two-step (or more) processes. In these reactions, there is an energy “well”. There are two transition states, each with an energy higher than the intermediate (Fig. 6.2). The deeper the well, the more stable the intermediate. In Fig. 6.2a, the second peak is higher than the first. The opposite situation is shown in Fig. 6.2b. Note that in reactions in which the second peak is higher than the first, the overall ΔG^\ddagger is less than the sum of the ΔG^\ddagger values for the two steps. Minima in free energy profile diagrams (*intermediates*) correspond to real species that have a finite though usually short existence.

These may be the carbocations, carbanions, free radicals, and so on., discussed in Chapter 5 or molecules in which all the atoms have their normal valences. In either case, under the reaction conditions they do not live long (because ΔG_2^\ddagger is small), but rapidly go on to products. Maxima in these curves, however, do not correspond to actual species, but only to

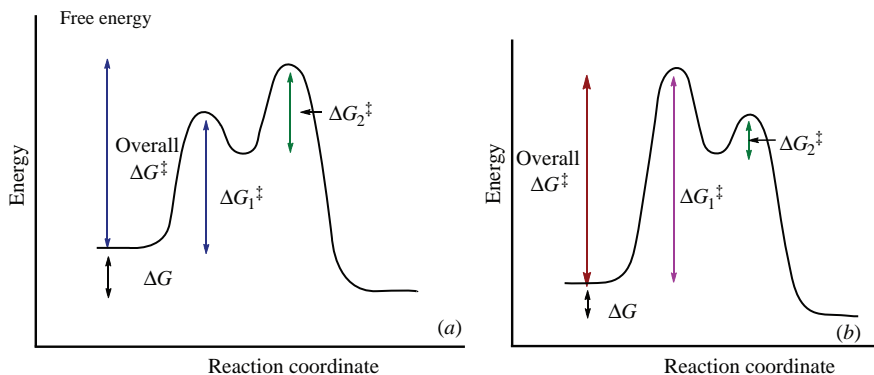

FIG. 6.2. (a) Free energy profile for a reaction with an intermediate ΔG_1^\ddagger and ΔG_2^\ddagger are the free energy of activation for the first and second stages, respectively. (b) Free energy profile for a reaction with an intermediate in which the first peak is higher than the second

transition states in which bond breaking and/or bond making have partially taken place. Transition states have only a transient existence with an essentially zero lifetime.¹⁶

6.E. THE BALDWIN RULES FOR RING CLOSURE¹⁷

In previous sections, the kinetic and thermodynamic aspects of ring-closure reactions were discussed in a general way. J.E. Baldwin¹⁸ supplied a more specific set of rules for certain closings of three seven-membered rings. These rules distinguish two types of ring closure, called *exo* and *endo*, and three kinds of atoms at the starred positions: *Tet* for sp^3 , *Trig* for sp^2 , and *Dig* for sp . The following are *Baldwin's rules* for closing rings of 3–7 members.

Rule 1. Tetrahedral systems

- a. 3-7-*Exo-Tet* are all favored processes
- b. 5-6-*Endo-Tet* are disfavored

Rule 2. Trigonal systems

- a. 3-7-*Exo-Trig* are favored
- b. 3-5-*Endo-Trig* are disfavored¹⁹
- c. 6-7-*Endo-Trig* are favored

Rule 3. Digonal systems

- a. 3-4-*Exo-Dig* are disfavored
- b. 5-7-*Exo-Dig* are favored
- c. 3-7-*Endo-Dig* are favored

“Disfavored” does not mean it cannot be done, only that it is more difficult than the favored cases. These rules are empirical and have a stereochemical basis. The favored pathways are those in which the length and nature of the linking chain will enable the terminal atoms to achieve the proper geometries for reaction. The disfavored cases require severe distortion of bond angles and distances. Many cases in the literature are in

Commun.* **1976**, 734; Baldwin, J.E. in *Further Perspectives in Organic Chemistry (Ciba Foundation Symposium 53)*, Elsevier, Amsterdam, The Netherlands, **1979**, pp. 85–99. See also, Baldwin, J.E.; Thomas, R.C.; Kruse, L.I.; Silberman, L. *J. Org. Chem.* **1977**, 42, 3846; Baldwin, J.E.; Lusch, M.J. *Tetrahedron* **1982**, 38, 2939; Fountain, K.R.; Gerhardt, G. *Tetrahedron Lett.* **1978**, 3985.

¹⁹ For some exceptions to the rule in this case, see Trost, B.M.; Bonk, P.J. *J. Am. Chem. Soc.* **1985**, 107, 1778; Torres, L.E.; Larson, G.L. *Tetrahedron Lett.* **1986**, 27, 2223.

substantial accord with these rules, and they are important in the formation of five- and six-membered rings.²⁰

Although Baldwin's rules can be applied to ketone enolates,²¹ additional rules were added to make the terminology more specific.²² The orientation of the orbital as it approaches the reactive center must be considered for determining the correct angle of approach. Diagrams that illustrate the enolate rules are shown.

The rules are

- 6-7 enolendo-exo-tet reactions are favored
- 3-5 enolendo-exo-tet reactions are disfavored
- 3-7 enolexo-exo-tet reactions are favored
- 3-7 enolexo-exo-trig reactions are favored
- 6-7 enolendo-exo-trig reactions are favored
- 3-5 enolendo-exo-trig reactions are disfavored

6.F. KINETIC AND THERMODYNAMIC CONTROL

There are many cases in which a compound under a given set of reaction conditions can undergo competing reactions to give different products. Starting material **A** may give either **B** or **C**, for example. Figure 6.3 shows a free energy profile for a reaction in which **B** is thermodynamically more stable than **C** (ΔG_{B} is $> \Delta G_{\text{C}}$), but **C** is formed faster (lower ΔG^{\ddagger}). If neither reaction is reversible, **C** will be formed in a larger amount because it is formed faster. The product is said to be *kinetically controlled*. However, if the reactions are reversible, this will not necessarily be the case. If such a process is stopped well before the

FIG. 6.3. Free energy profile illustrating kinetic versus thermodynamic control of products. The starting compounds (**A**) can react to give either **B** or **C**.

equilibrium has been established, the reaction will be kinetically controlled since more of the faster-formed product will be present. However, if the reaction is permitted to approach equilibrium, the predominant or even exclusive product will be **B**. Under these conditions the **C** that is first formed reverts to **A**, while the more stable **B** does so much less. We say the product is *thermodynamically controlled*.²³ Of course, Fig. 6.3 does not describe all reactions in which a compound **A** can give two different products. In many cases the more stable product is also the one that is formed faster. In such cases, the product of kinetic control is also the product of thermodynamic control.

6.G. THE HAMMOND POSTULATE

Transition states are not detectable and have zero lifetimes, so it is impossible to observe them directly. Information about their geometries must be obtained from inference and modeling. In some cases, the inferences can be very strong. For example, in the S_N2 reaction (Sec. 10.A.i) between CH_3I and I^- (a reaction in which the product is identical to the starting compound), the transition state should be perfectly symmetrical. In most cases, however, it is not possible to reach such easy conclusions, and conclusions are greatly aided by the *Hammond postulate*,²⁴ which states that for any single reaction step, *the geometry of the transition state for that step resembles the side to which it is closer in free energy*. Thus, for an exothermic reaction like that shown in Fig. 6.1, the transition state resembles the reactants more than the products, although not much more because there is a substantial ΔG^\ddagger on both sides.

The postulate is most useful in dealing with reactions with intermediates. In the reaction illustrated in Fig. 6.2a, the first transition state lies much closer in energy to the

²³ See Klumpp, G.W. *Reactivity in Organic Chemistry*, Wiley, NY, **1982**, pp. 36–89.

²⁴ Hammond, G.S. *J. Am. Chem. Soc.* **1955**, 77, 334. For a discussion, see Farcasiu, D. *J. Chem. Educ.* **1975**, 52, 76.

intermediate than to the reactants, and it is possible to predict that the geometry of the transition state resembles that of the intermediate more than it does that of the reactants. Likewise, the second transition state also has a free energy much closer to that of the intermediate than to the products, so that both transition states resemble the intermediate more than they do the products or reactants. This is generally the case in reactions that involve very reactive intermediates. More is usually known about the structure of intermediates than of transition states, so a knowledge of intermediates is used to draw conclusions about the transition states (e.g., see Sec. 10.G.i and 15.B.i).

6.H. MICROSCOPIC REVERSIBILITY

In the course of a reaction, the nuclei and electrons assume positions that at each point correspond to the lowest free energies possible. If the reaction is reversible, these positions must be the same in the reverse process, too. This means that the forward and reverse reactions (run under the same conditions) must proceed by the same mechanism. This is called the *principle of microscopic reversibility*. For example, if in a reaction $\mathbf{A} \rightarrow \mathbf{B}$ there is an intermediate \mathbf{C} , then \mathbf{C} must also be an intermediate in the reaction $\mathbf{B} \rightarrow \mathbf{A}$. This is a useful principle since it enables one to know the mechanism of reactions in which the equilibrium lies far over to one side. Reversible photochemical reactions are an exception, since a molecule that has been excited photochemically does not have to lose its energy in the same way (Chap 7).

6.I. MARCUS THEORY

It is often useful to compare the reactivity of one compound with that of similar compounds. The real goal is to find out how a reaction coordinate (and in particular the transition state) changes when one reactant molecule is replaced by a similar molecule. *Marcus theory* is a method for doing this.²⁵

In this theory, the activation energy (ΔG^\ddagger) is thought of as consisting of two parts.

1. An *intrinsic* free energy of activation, which would exist if the reactants and products had the same ΔG° .²⁶

This is a kinetic part, called the *intrinsic barrier* ($\Delta G_{\text{int}}^\ddagger$).

2. A thermodynamic part, which arises from the ΔG° for the reaction.

The Marcus equation says that the overall ΔG^\ddagger for a one-step reaction is²⁷

$$\Delta G^\ddagger = \Delta G_{\text{int}}^\ddagger + \frac{1}{2} \Delta G^\Delta + \frac{(\Delta G^\Delta)^2}{16(\Delta G_{\text{int}}^\ddagger - w^R)}$$

²⁵ See Albery, W.J. *Annu. Rev. Phys. Chem.* **1980**, *31*, 227; Kreevoy, M.M.; Truhlar, D.G. in Bernasconi, C.F. *Investigation of Rates and Mechanisms of Reactions*, 4th ed. (Vol. 6 of Weissberger, A. *Techniques of Chemistry*), pt. 1, Wiley, NY, **1986**, pp. 13–95.

²⁶ The parameter ΔG° is the standard free energy; that is, ΔG at atmospheric pressure.

²⁷ Albery, W.J.; Kreevoy, M.M. *Adv. Phys. Org. Chem.* **1978**, *16*, 87, pp. 98–99.

where the term ΔG^Δ stands for

$$\Delta G^\Delta = \Delta G^\circ - w^R + w^P$$

w^R , a work term, is the free energy required to bring the reactants together and w^P is the work required to form the successor configuration from the products.

For a reaction of the type $\mathbf{AX} + \mathbf{B} \rightarrow \mathbf{BX}$, the intrinsic barrier²⁸ $\Delta G_{\text{int}}^\ddagger$ is taken to be the average ΔG^\ddagger for the two symmetrical reactions

so that

$$\Delta G_{\text{int}}^\ddagger + \frac{1}{2}(\Delta G_{\mathbf{A},\mathbf{A}}^\ddagger + \Delta G_{\mathbf{B},\mathbf{B}}^\ddagger)$$

One type of process that can successfully be treated by the Marcus equation is the S_N2 mechanism (Sec. 10.A.i).

When R is CH_3 the process is called *methyl transfer*.²⁹ For such reactions, the work terms w^R and w^P are assumed to be very small compared to ΔG° , and can be neglected, so that the Marcus equation simplifies to

$$\Delta G^\ddagger = \Delta G_{\text{int}}^\ddagger + \frac{1}{2} \Delta G^\circ + \frac{(\Delta G)^\circ^2}{16 \Delta G_{\text{int}}^\ddagger}$$

The Marcus equation allows ΔG^\ddagger for $\mathbf{RX} + \mathbf{Y} \rightarrow \mathbf{RY} + \mathbf{X}$ to be calculated from the barriers of the two symmetrical reactions $\mathbf{RX} + \mathbf{X} \rightarrow \mathbf{RX} + \mathbf{X}$ and $\mathbf{RY} + \mathbf{Y} \rightarrow \mathbf{RY} + \mathbf{Y}$. The results of such calculations are generally in agreement with the *Hammond postulate*.

Marcus theory can be applied to any single-step process where something is transferred from one particle to another. It was originally derived for electron transfers,³⁰ and then extended to transfers of H^+ (see Sec. 8.D), H^- ,³¹ and H^\bullet ,³² as well as methyl transfers.

6.J. METHODS OF DETERMINING MECHANISMS³³

There are a number of commonly used methods for determining mechanisms.³⁴ In most cases, one method is not sufficient, and the problem is generally approached from several directions.

6.J.i. Identification of Products

Obviously any mechanism proposed for a reaction must account for all the products obtained and for their relative proportions, including products formed by side reactions. Incorrect mechanisms for the *von Richter reaction* (Reaction **13-30**) were accepted for many years because it was not realized that nitrogen was a major product. A proposed mechanism cannot be correct if it fails to predict the products in approximately the observed proportions. For example, any mechanism for the reaction

that fails to account for the formation of a small amount of ethane cannot be correct (see Reaction **14-1**), and any mechanism proposed for the *Hofmann rearrangement* (Reaction **18-13**):

must account for the fact that the carbonyl carbon is lost as CO_2 .

6.J.ii. Determination of the Presence of an Intermediate

Intermediates are postulated in many mechanisms, and the presence or absence of an intermediate is essential information. There are several methods, none of them foolproof,³⁵ for attempting to learn whether or not an intermediate is present and, if so, its structure. All methods are experimental, and an intermediate must be detected in one way or another, often by isolation or trapping.

1. *Isolation of an Intermediate.* It is sometimes possible to isolate an intermediate from a reaction mixture by stopping the reaction after a short time or by the use of very mild conditions. For example, in the *Neber rearrangement* (Reaction **18-12**) the intermediate **1** (an azirene)³⁶ has been isolated. If it can be shown that the isolated compound gives the same product when subjected to the reaction conditions, and at a rate no slower than the starting compound, this constitutes strong evidence that the reaction involves that intermediate, although it is not conclusive,

³⁵ For a discussion, see Martin, R.B. *J. Chem. Educ.* **1985**, 62, 789.

³⁶ See Gentilucci, L.; Grijzen, Y.; Thijs, L.; Zwanenburg, B. *Tetrahedron Lett.* **1995**, 36, 4665.

since the compound may arise by an alternate path and by coincidence give the same product.

2. *Detection of an Intermediate.* In many cases an intermediate cannot be isolated, but can be detected by normal IR, ReactIR,³⁷ NMR, or other spectra.³⁸ The detection by Raman spectra of NO_2^+ was regarded as strong evidence that this is an intermediate in the nitration of benzene (see Reaction 11-2). Free radical and triplet intermediates can often be detected by ESR and by CIDNP (see Chap 5). Free radicals (as well as radical ions and EDA complexes) can also be detected by a method that does not rely on spectra. In this method, a double-bond compound is added to the reaction mixture, and its fate traced.³⁹ One possible result is cis–trans conversion. For example, *cis*-stilbene is isomerized to the *trans* isomer in the presence of RS^\bullet radicals, by this mechanism:

Since the *trans* isomer is more stable than the *cis*, the reaction does not go the other way, and the detection of the isomerized product is evidence for the presence of the RS^\bullet radicals.

3. *Trapping of an Intermediate.* In some cases, the suspected intermediate is known to be one that reacts in a given way with a certain compound. The intermediate can then be trapped by running the reaction in the presence of that compound. For example, benzyne (Sec. 13.A.iii) react with dienes in the *Diels–Alder reaction* (15-60). In any reaction where a benzyne is a suspected intermediate, the addition of a diene and the detection of the *Diels–Alder* adduct indicate that the benzyne was probably present.
4. *Addition of a Suspected Intermediate.* If a certain intermediate is suspected, and if it can be obtained by other means, then under the same reaction conditions it should give the same products. This kind of experiment can provide conclusive negative evidence: if the correct products are not obtained, the suspected compound is not an intermediate. However, if the correct products are obtained, this is not conclusive since they may arise by coincidence. The *von Richter reaction* (Reaction 13-30) provides a good example here too. For many years, it had been assumed that an aryl cyanide was an intermediate, since cyanides are easily hydrolyzed to carboxylic acids (Reaction 16-4). Indeed, *p*-chlorobenzonitrile was shown to

³⁷ ReactIR uses mid-range IR spectroscopy for the identification and monitoring of critical reaction species and follows the changes in the reaction on a second-by-second basis. For applications, see Stead, D.; Carbone, G.; O'Brien, P.; Campos, K.R.; Coldham, I.; Sanderson, A. *J. Am. Chem. Soc.* **2010**, *132*, 7260; Pippel, D.J.; Weisenburger, G.A.; Faibish, N.C.; Beak, P. *J. Am. Chem. Soc.* **2001**, *123*, 4919.; Rutherford, J.L.; Hoffmann, D.; Collum, D.B. *J. Am. Chem. Soc.* **2002**, *124*, 264.

³⁹ For a review, see Todres, Z.V. *Tetrahedron* **1987**, *43*, 3839.

give *p*-chlorobenzoic acid under normal *von Richter* conditions.⁴⁰ However, when the experiment was repeated with 1-cyanonaphthalene, no 1-naphthoic acid was obtained, although 2-nitronaphthalene gave 13% 1-naphthoic acid under the same conditions.⁴¹ This proved that 2-nitronaphthalene must have been converted to 1-naphthoic acid by a route that does not involve 1-cyanonaphthalene. It also showed that even the conclusion that *p*-chlorobenzonitrile was an intermediate in the conversion of *m*-nitrochlorobenzene to *p*-chlorobenzoic acid must now be suspect, since it is not likely that the mechanism would substantially change in going from the naphthalene to the benzene system.

6.J.iii. The Study of Catalysis⁴²

Many organic reactions are slow in the absence of a catalyst. Acid-catalyzed reactions are prevalent for example. Once it is known that a reaction is subject to catalysis, much information about the mechanism of a reaction can be obtained from a knowledge of which substances catalyze the reaction, which inhibit it, and which do neither. Of course, just as a mechanism must be compatible with the products, so must it be compatible with its catalysts. In general, *catalysts perform their actions by providing an alternate pathway for the reaction* in which ΔG^\ddagger is less than it would be without the catalyst. Catalysts do not change ΔG .

6.J.iv. Isotopic Labeling⁴³

Molecules that have been isotopically labeled can be used to trace the path of the reaction, which may provide much useful mechanistic information. For example, in the reaction

does the CN group in the product come from the CN in the BrCN? The use of ¹⁴C supplied the answer, since $R^{14}CO_2^-$ gave *radioactive* RCN.⁴⁴ This surprising result saved a lot of labor, since it ruled out a mechanism involving the replacement of CO₂ by CN (see Reaction 16-94). Other radioactive isotopes are also frequently used as tracers, but even stable isotopes can be used. An example is the hydrolysis of esters

Which bond of the ester is broken, the acyl–O or the alkyl–O bond? The answer is found by the use of H₂¹⁸O. If the acyl–O bond breaks, the labeled oxygen will appear in the acid;

⁴⁴ Douglas, D.E.; Burditt, A.M. *Can. J. Chem.* **1958**, 36, 1256.

otherwise it will be in the alcohol (see Reaction **16-59**). Although neither compound is radioactive, the one that contains ^{18}O can be determined by submitting both to mass spectrometry. In a similar way, deuterium can be used as a label for hydrogen. In this case, mass spectrometry is not the only option since IR and ^1H and ^{13}C NMR⁴⁵ spectra can be used to determine when deuterium has been substituted for hydrogen.

In the labeling technique, it is not generally necessary to use completely labeled compounds. Partially labeled material is usually sufficient.

6.J.v. Stereochemical Evidence⁴⁶

If the products of a reaction are capable of existing in more than one stereoisomeric form, the form that is obtained may give information about the mechanism.⁴⁷ For example, Walden⁴⁸ discovered that (+)-malic acid gives (–)-chlorosuccinic acid when treated with PCl_5 and the (+) enantiomer when treated with SOCl_2 , showing that the mechanisms of these apparently similar conversions could not be the same (see Sec. 10.A.i and 10.D). Much useful information has been obtained about nucleophilic substitution, elimination, rearrangement, and addition reactions from this type of experiment. The isomers involved need not be enantiomers. Thus, the fact that *cis*-2-butene treated with KMnO_4 gives *meso*-2,3-butanediol and not the racemic mixture is evidence that the two OH groups attack the double bond from the same side (see Reaction **15-48**).

6.J.vi. Kinetic Evidence⁴⁹

The rate of a homogeneous reaction⁵⁰ is the rate of disappearance of a reactant or appearance of a product. The rate nearly always changes with time, since it is usually proportional to concentration and the concentration of reactants decreases with time. However, the rate is not always proportional to the concentration of all reactants. In some cases, a change in the concentration of a reactant produces no change at all in the rate, while in other cases the rate may be proportional to the concentration of a substance (a catalyst) that does not even appear in the stoichiometric equation. A study of which reactants affect the rate often tells a good deal about the mechanism.

If the rate is proportional to the change in concentration of only one reactant (**A**), the *rate law* (the rate of change of concentration of **A** with time *t*) is

$$\text{Rate} = \frac{-d[\text{A}]}{dt} = k[\text{A}]$$

⁵⁰ A homogeneous reaction occurs in one phase. Heterogeneous kinetics have been studied much less.

where k is the *rate constant* for the reaction.⁵¹ There is a minus sign because the concentration of **A** decreases with time. A reaction that follows such a rate law is called a *first-order reaction*. The units of k for a first-order reaction are reciprocal second (s^{-1}). The rate of a *second-order reaction* is proportional to the concentration of two reactants, or to the square of the concentration of one:

$$\text{Rate} = \frac{-d[\text{A}]}{dt} = k [\text{A}][\text{B}] \quad \text{or} \quad \text{Rate} = \frac{-d[\text{A}]}{dt} = k [\text{A}]^2$$

For a second-order reaction, the units are $\text{L mol}^{-1} \text{s}^{-1}$ or some other units expressing the reciprocal of concentration or pressure per unit time interval.

Similar expressions can be written for third-order reactions. A reaction whose rate is proportional to $[\text{A}]$ and to $[\text{B}]$ is said to be first order in **A** and in **B**, second order overall. A reaction rate can be measured in terms of any reactant or product, but the rates so determined are not necessarily the same. For example, if the stoichiometry of a reaction is $2\text{A} + \text{B} \rightarrow \text{C} + \text{D}$ then, on a molar basis, **A** must disappear twice as fast as **B**, so that $-d[\text{A}]/dt$ and $-d[\text{B}]/dt$ are not equal but the former is twice as large as the latter.

The rate law of a reaction is an experimentally determined fact. The rate law leads to an understanding of the *molecularity*, which may be defined as the number of molecules that come together to form the activated complex. It is obvious that if it is known how many (and which) molecules take part in the activated complex, a good deal is known about the mechanism. The experimentally determined rate order is not necessarily the same as the molecularity. Any reaction, no matter how many steps are involved, has only one rate law, but each step of the mechanism has its own molecularity. For reactions that take place in one step (reactions without an intermediate), the order is the same as the molecularity. A first-order, one-step reaction is always unimolecular; a one-step reaction that is second order in **A** always involves two molecules of **A**; if it is first order in **A** and in **B**, then a molecule of **A** reacts with one of **B**, and so on. For reactions that take place in more than one step, the order *for each step* is the same as the molecularity *for that step*. This fact enables us to predict the rate law for any proposed mechanism, although the calculations may get lengthy at times.⁵² If any one step of a mechanism is considerably slower than all the others (this is usually the case), the rate of the overall reaction is essentially the same as that of the slow step, which is consequently called the *rate-determining step*.⁵³

For reactions that take place in two or more steps, two broad cases can be distinguished:

1. The first step is slower than any subsequent step and is consequently rate determining. In such cases, the rate law simply includes the reactants that participate in the slow step. For example, if the reaction $\text{A} + 2\text{B} \rightarrow \text{C}$ has the mechanism

⁵¹ Colins, C.C.; Cronin, M.F.; Moynihan, H.A.; McCarthy, D.G. *J. Chem. Soc. Perkin Trans. 1* **1997**, 1267.

⁵² For a discussion of how order is related to *molecularity* in many complex situations, see Szabó, Z.G. in Bamford, C.H.; Tipper, C.F.H. *Comprehensive Chemical Kinetics*, Vol.2, Elsevier, NY, **1969**, pp. 1–80.

⁵³ Many chemists prefer to use the term *rate-limiting step* or *rate-controlling step* for the slow step, rather than *rate-determining step*. See the definitions in Gold, V.; Loening, K.L.; McNaught, A.D.; Sehmi, P. *IUPAC Compendium of Chemical Terminology*, Blackwell Scientific Publications, Oxford, **1987**, p. 337. For a discussion of rate-determining steps, see Laidler, K.J. *J. Chem. Educ.* **1988**, 65, 250.

where **I** is an intermediate, the reaction is second order, with the rate law

$$\text{Rate} = \frac{-d[\mathbf{A}]}{dt} = k [\mathbf{A}][\mathbf{B}]$$

2. When the first step is not rate determining, determination of the rate law is usually much more complicated. For example, consider the mechanism

where the first step is a rapid attainment of equilibrium, followed by a slow reaction to give **C**. The rate of disappearance of **A** is

$$\text{Rate} = \frac{-d[\mathbf{A}]}{dt} = k_1 [\mathbf{A}][\mathbf{B}] - k_{-1} [\mathbf{I}]$$

Both terms must be included because **A** is being formed by the reverse reaction, as well as being used up by the forward reaction. This equation is of very little help as it stands since the concentration of the intermediate cannot be measured. However, the combined rate law for the formation and disappearance of **I** is

$$\text{Rate} = \frac{-d[\mathbf{A}]}{dt} = k_1 [\mathbf{A}][\mathbf{B}] - k_{-1} [\mathbf{I}] - k_2 [\mathbf{I}][\mathbf{B}]$$

This equation is of little help unless the assumption is made that *the concentration of I does not change with time*, since it is an intermediate that is used up (going either to **A** + **B** or to **C**) as fast as it is formed. This assumption, called the assumption of the *steady state*,⁵⁴ enables $d[\mathbf{I}]/dt$ to be set equal to zero, and hence to solve for **[I]** in terms of the measurable quantities **[A]** and **[B]**:

$$[\mathbf{I}] = \frac{k_1 [\mathbf{A}][\mathbf{B}]}{k_2 [\mathbf{B}] + k_{-1}}$$

Inserting this value for **[I]** into the original rate expression gives

$$\frac{-d[\mathbf{A}]}{dt} = \frac{k_1 k_2 [\mathbf{A}][\mathbf{B}]^2}{k_2 [\mathbf{B}] + k_{-1}}$$

Note that this rate law is valid whatever the values of k_1 , k_{-1} , and k_2 . However, our original hypothesis was that the first step was faster than the second, or that

$$k_1 [\mathbf{A}][\mathbf{B}] \gg k_2 [\mathbf{I}][\mathbf{B}]$$

⁵⁴ For a discussion, see Raines, R.T.; Hansen, D.E. *J. Chem. Educ.* **1988**, 65, 757.

Since the first step is an equilibrium

$$k_1[\mathbf{A}][\mathbf{B}] = k_{-1}[\mathbf{I}]$$

this gives

$$k_{-1}[\mathbf{I}] \gg k_2[\mathbf{I}][\mathbf{B}]$$

Canceling $[\mathbf{I}]$ gives

$$k_{-1} \gg k_2[\mathbf{B}]$$

Neglecting $k_2[\mathbf{B}]$ in comparison with k_{-1} gives

$$\frac{-d[\mathbf{A}]}{dt} = \frac{k_1 k_2}{k_{-1}} [\mathbf{A}][\mathbf{B}]^2$$

The overall rate is thus third order: first order in \mathbf{A} and second order in \mathbf{B} . Incidentally, if the first step is rate determining (as was the case in the preceding paragraph), then

$$k_2[\mathbf{B}] \gg k_{-1} \quad \text{and} \quad \frac{-d[\mathbf{A}]}{dt} = k_1 [\mathbf{A}][\mathbf{B}]$$

which is the same rate law deduced from the rule that where the first step is rate determining, the rate law includes the reactants that participate in that step.

It is possible for a reaction to involve \mathbf{A} and \mathbf{B} in the rate-determining step, although only $[\mathbf{A}]$ appears in the rate law. This occurs when a large excess of \mathbf{B} is present, say 100 times the molar quantity of \mathbf{A} . In this case, the complete reaction of \mathbf{A} uses up only 1 equiv of \mathbf{B} , leaving 99 equiv. It is not easy to measure the change in concentration of \mathbf{B} with time in such a case, and it is seldom attempted, especially when \mathbf{B} is also the solvent. Since $[\mathbf{B}]$, for practical purposes, does not change with time, the reaction appears to be first order in \mathbf{A} although actually both \mathbf{A} and \mathbf{B} are involved in the rate-determining step. This is often referred to as a *pseudo-first-order* reaction. Pseudo-order reactions can also come about when one reactant is a catalyst whose concentration does not change with time because it is replenished as fast as it is used up and when a reaction is conducted in a medium that keeps the concentration of a reactant constant, for example, in a buffer solution where H^+ or OH^- is a reactant. Pseudo-first-order conditions are frequently used in kinetic investigations for convenience in experimentation and calculations.

What is actually being measured is the change in concentration of a product or a reactant with time. Many methods have been used to make such measurements.⁵⁵ The choice of a method depends on its convenience and its applicability to the reaction being studied. Among the most common methods are the following:

1. *Periodic or Continuous Spectral Readings.* In many cases, the reaction can be carried out in the cell while it is in the instrument. Then all that is necessary is that

⁵⁵ See Zuman, P.; Patel, R.C. *Techniques in Organic Reaction Kinetics*, Wiley, NY, **1984**. See Batt, L. in Bamford, C.H.; Tipper, C.F.H. *Comprehensive Chemical Kinetics*, Vol. 1, Elsevier, NY, **1969**, pp. 1–111.

the instrument be read, periodically or continuously. Among the methods used are IR and UV spectroscopy, polarimetry, NMR, and ESR.⁵⁶

2. *Quenching and Analyzing.* A series of reactions can be set up and each stopped in some way (perhaps by suddenly lowering the temperature or adding an inhibitor) after a different amount of time has elapsed. The materials are then analyzed by spectral readings, titrations, chromatography, polarimetry, or any other method.
3. *Removal of Aliquots at Intervals.* Each aliquot is then analyzed as in method 2.
4. *Measurement of Changes in Total Pressure, for Gas-Phase Reactions.*⁵⁷
5. *Calorimetric Methods.* The output or absorption of heat can be measured at time intervals.

Special methods exist for kinetic measurements of very fast reactions.⁵⁸

A graph is usually obtained that shows the change in concentration with time. Interpretation⁵⁹ is required to obtain a rate law and a value of k . If a reaction obeys simple first- or second-order kinetics, the interpretation is generally not difficult. For example, for a concentration at the start = A_0 , the first-order rate law

$$\frac{-d[A]}{dt} = k[A] \quad \text{or} \quad \frac{-d[A]}{[A]} = k dt$$

can be integrated between the limits $t=0$ and $t=t$ to give

$$-\ln \frac{[A]}{A_0} = kt \quad \text{or} \quad \ln [A] = -kt + \ln A_0$$

Therefore, if a plot of $\ln [A]$ against t is linear, the reaction is first order and k can be obtained from the slope. For first-order reactions, it is customary to express the rate not only by the rate constant k , but also by the *half-life*, which is the time required for one-half of any given quantity of a reactant to be used up. Since the half-life $t_{1/2}$ is the time required for $[A]$ to reach $A_0/2$:

$$\ln \frac{A_0}{2} = kt_{1/2} + \ln A_0$$

⁵⁹ See Connors, K.A. *Chemical Kinetics*, VCH, NY, **1990**, pp. 17–131; Ritchie, C.D. *Physical Organic Chemistry*, 2nd ed., Marcel Dekker, NY, **1990**, pp. 1–35; Zuman, P.; Patel, R.C. *Techniques in Organic Reaction Kinetics*, Wiley, NY, **1984**; Margerison, D. in Bamford, C.H.; Tipper, C.F.H. *Comprehensive Chemical Kinetics*, Vol. 1, Elsevier, NY, **1969**, pp. 343–421; Moore, J.W.; Pearson, R.G. *Kinetics and Mechanism*, 3rd ed., Wiley, NY, **1981**, pp. 12–82; in Bernasconi, C.F. *Investigation of Rates and Mechanisms of Reactions*, 4th ed. (Vol. 6 of Weissberger, A. *Techniques of Chemistry*), pt. 1, Wiley, NY, **1986**, the articles by Bunnett, J.F. pp. 251–372, Noyes Pub., pp. 373–423, Bernasconi, C.F. pp. 425–485, Wiberg, K.B. pp. 981–1019.

so that

$$t_{1/2} = \frac{\ln \left[\frac{A_0}{A_0/2} \right]}{k} = \frac{\ln 2}{k} = \frac{0.693}{k}$$

For the general case of a reaction first order in **A** and first order in **B**, second order overall, integration is complicated, but it can be simplified if equimolar amounts of **A** and **B** are used, so that $A_0 = B_0$. In this case,

$$\frac{-d[A]}{dt} = k [A][B]$$

is equivalent to

$$\frac{-d[A]}{dt} = k [A]^2 \quad \text{or} \quad \frac{-d[A]}{[A]^2} = k dt$$

Integrating as before gives

$$\frac{1}{[A]} - \frac{1}{A_0} = kt$$

Thus, under equimolar conditions, if a plot of $1/[A]$ against t is linear, the reaction is second order with a slope of k . It is obvious that the same will hold true for a reaction second order in **A**.⁶⁰

Although many reaction-rate studies do give linear plots, which are easily interpreted, the results in many other studies are not so simple. In some cases, a reaction may be first order at low concentrations but second order at higher concentrations. In other cases, fractional orders are obtained, and even negative orders. The interpretation of complex kinetics often requires much skill and effort. Even where the kinetic data are relatively simple, there is often a problem in interpreting the data because of the difficulty of obtaining sufficiently precise measurements.⁶¹

Nuclear magnetic resonance spectra can be used to obtain kinetic information in a completely different manner from that mentioned above. This method, which involves the study of NMR line shapes,⁶² depends on the fact that NMR spectra have an inherent time factor: If a proton changes its environment less rapidly than $\sim 10^3$ times s^{-1} , an NMR spectrum shows a separate peak for each position the proton assumes. For example, if the rate of rotation around the C—N bond of N,N-dimethylacetamide is slower than 10^3 rotations per second, the two N-methyl groups appear as a separate signal with different chemical shifts indicating that they are not equivalent, one being *cis* to the oxygen and the other *trans* to the acyl methyl group. However, if the environmental change takes place more rapidly than $\sim 10^3$ times per second, only one signal is found, at a chemical shift that is the weighted average of the two individual positions. In many cases, two or more signals

are found at low temperatures, but as the temperature is increased, the lines coalesce because the interconversion rate increases with temperature and passes the 10^3 per second mark. From studies of the way line shapes change with temperature it is often possible to calculate rates of reactions and of conformational changes. This method is not limited to changes in proton line shapes, but can also be used for other atoms that give NMR and ESR spectra (Sec. 5.C.i).

Several types of mechanistic information can be obtained from kinetic studies.

1. Information can be obtained from the order of a reaction. Which molecules and how many take part in the rate-determining step may be determined. Such knowledge is very useful and often essential in elucidating a mechanism. For any mechanism that can be proposed for a given reaction, a corresponding rate law can be calculated by the methods discussed in the beginning of this section. If the experimentally obtained rate law fails to agree with this, the proposed mechanism is wrong. However, it is often difficult to relate the order of a reaction to the mechanism, especially when the order is fractional or negative. It is frequently the case that two or more proposed mechanisms for a reaction are kinetically indistinguishable, that is, they predict the same rate law.
2. Probably the most useful data obtained kinetically are the rate constants themselves. They are important since they can relate the effect on the rate of a reaction of changes in the structure of the reactants (see Chapter 9), the solvent,⁶³ the ionic strength, the addition of catalysts, and so on.
3. If the rate is measured at several temperatures, in most cases a plot of $\ln k$ against $1/T$ (T stands for absolute temperature) is nearly linear⁶⁴ with a negative slope, and fits the equation

$$\ln k = \frac{-E_a}{RT} + \ln A$$

where R is the gas constant and A is a constant called the *frequency factor*. This permits the calculation of E_a , which is the *Arrhenius activation energy* of the reaction. Now ΔH^\ddagger can then be obtained by

$$E_a = \Delta H^\ddagger + RT$$

It is also possible to use these data to calculate ΔS^\ddagger by the formula⁶⁵

$$\frac{\Delta S^\ddagger}{4.576} = \log k - 10.753 - \log T + \frac{E_a}{4.576T}$$

for energies in calorie units. For joule units, the formula is

$$\frac{\Delta S^\ddagger}{19.15} = \log k - 10.753 - \log T + \frac{E_a}{19.15T}$$

One then obtains ΔG^\ddagger from $\Delta G^\ddagger = \Delta H^\ddagger - T\Delta S^\ddagger$.

FIG. 6.4. A C—D bond has a lower zero point than a corresponding C—H bond; thus the dissociation energy is higher.

6.J.vii. Isotope Effects

When a hydrogen atom in a reactant molecule is replaced by deuterium, there is often a change in the rate. Such changes are known as *deuterium isotope effects*⁶⁶ and are expressed by the ratio $k_{\text{H}}/k_{\text{D}}$. The ground-state vibrational energy (called the zero-point vibrational energy) of a bond depends on the mass of the atoms and is lower when the reduced mass is higher.⁶⁷ Therefore, D—C, D—O, D—N bonds, and so on, have lower energies in the ground state than the corresponding H—C, H—O, H—N bonds, and so on. Complete dissociation of a deuterium bond consequently requires more energy than that for a corresponding hydrogen bond in the same environment (Fig. 6.4). If a H—C, H—O, or H—N bond is not broken at all in a reaction or is broken in a non-rate-determining step, substitution of deuterium for hydrogen causes no change in the rate (see below for an exception to this statement), but if the bond is broken in the rate-determining step, the rate must be lowered by the substitution.

This provides a valuable diagnostic tool for determination of mechanism. For example, in the bromination of acetone (Reaction 12-4) the fact that the rate is independent of the bromine concentration led to the postulate that the rate-determining step was prior to

⁶⁶ See Melander, L.; Saunders, Jr., W.H. *Reaction Rates of Isotopic Molecules*, Wiley, NY, 1980. Chem.* 1973, 24, 407; Wolfsberg, M. *Annu. Rev. Phys. Chem.* 1969, 20, 449. Also see Kwart, H. *Acc. Chem. Res.* 1982, 15, 401; Isaacs, E.S. *Isot. Org. Chem.* 1984, 6, 67; Thibblin, A.; Ahlberg, P. *Chem. Soc. Rev.* 1989, 18, 209. See also, the series *Isotopes in Organic Chemistry*.

⁶⁷ The reduced mass μ of two atoms connected by a covalent bond is $\mu = m_1 m_2 / (m_1 + m_2)$.

tautomerization of the acetone:

In turn, the rate-determining step of the tautomerization involves cleavage of a C—H bond (see Reaction 12-3). Thus there should be a substantial isotope effect if deuterated acetone is brominated. In fact, $k_{\text{H}}/k_{\text{D}}$ was found to be ~ 7 .⁶⁸ Deuterium isotope effects usually range from 1 (no isotope effect at all) to ~ 7 or 8, although in a few cases, larger⁶⁹ or smaller values have been reported.⁷⁰ Values of $k_{\text{H}}/k_{\text{D}} < 1$ are called *inverse isotope effects*. Isotope effects are greatest when, in the transition state, the hydrogen is symmetrically bonded to the atoms between which it is being transferred.⁷¹ Also, calculations show that isotope effects are at a maximum when the hydrogen atom in the transition state is on the straight line connecting the two atoms between which it is being transferred, and that for sufficiently nonlinear configurations, they decrease to $k_{\text{H}}/k_{\text{D}} = 1$.⁷² Of course, in open systems there is no reason for the transition state to be nonlinear, but this is not the case in many intramolecular mechanisms, (e.g., in a 1,2-migration of a hydrogen)

To measure isotope effects, it is not always necessary to prepare deuterium-enriched starting compounds. It can also be done by measuring the change in deuterium concentration at specific sites between a compound containing deuterium in natural abundance and the reaction product, using a high field NMR instrument.⁷³

The substitution of tritium for hydrogen gives isotope effects that are numerically larger. Isotope effects have also been observed with other elements, but they are much smaller, ~ 1.02 – 1.10 . For example, $k_{12\text{C}}/k_{13\text{C}}$ for the reaction of methoxide with benzyl bromide is 1.053 .⁷⁴ Although they are small, heavy-atom isotope effects can be measured quite accurately and are often very useful.⁷⁵

⁷⁵ For a review of carbon isotope effects, see Willi, A.V. *Isot. Org. Chem.* **1977**, 3, 237.

Deuterium isotope effects have been found even where it is certain that the C—H bond does not break at all in the reaction. Such effects are called *secondary isotope effects*,⁷⁶ the term *primary isotope effect* being reserved for the type discussed previously. Secondary isotope effects can be divided into α and β effects. In a β secondary isotope effect, substitution of deuterium for hydrogen β to the position of bond breaking slows the reaction. An example is solvolysis of 2-bromopropane to 2-propanol, where k_H/k_D was found to be 1.34.⁷⁷ The cause of β isotope effects has been a matter of much controversy, but they are most likely due to hyperconjugation effects in the transition state. The effects are greatest when the transition state has considerable carbocation character.⁷⁸ Although the C—H bond in question is not broken in the transition state, the carbocation is stabilized by hyperconjugation (Sec. 2.M) involving this bond. Because of hyperconjugation, the difference in vibrational energy between the C—H bond and the C—D bond in the transition state is less than it is in the ground state, so the reaction is slowed by substitution of deuterium for hydrogen.

Support for hyperconjugation as the major cause of β isotope effects is the fact that the effect is greatest when D is anti to the leaving group⁷⁹ (because of the requirement that all atoms in a resonance system be coplanar, planarity of the D—C—C—X system would most greatly increase the hyperconjugation), and the fact that secondary isotope effects can be transmitted through unsaturated systems.⁸⁰ There is evidence that at least some β isotope effects are steric in origin⁸¹ (e.g., a CD_3 group has a smaller steric requirement than a CH_3 group) and a field-effect explanation has also been suggested (CD_3 is apparently a better electron donor than CH_3 ⁸²), but hyperconjugation is the most probable cause in most instances.⁸³ Part of the difficulty in attempting to explain these effects is their small size, ranging only as high as ~ 1.5 .⁸⁴ Another complicating factor is that they can change with temperature. In one case,⁸⁵ k_H/k_D was 1.00 ± 0.01 at 0°C , 0.90 ± 0.01 at 25°C , and 1.15 ± 0.09 at 65°C . Whatever the cause, there seems to be a good correlation between β secondary isotope effects and carbocation character in the transition state. They are thus a useful tool for probing mechanisms.

The other type of secondary isotope effect results from a replacement of hydrogen by deuterium at the carbon containing the leaving group. These so-called *secondary isotope*

effects are varied, with values so far reported⁸⁶ ranging from 0.87 to 1.26.⁸⁷ These effects are also correlated with carbocation character. Nucleophilic substitutions that do not proceed through carbocation intermediates (S_N2 reactions) have an isotope effect near unity.⁸⁸ Those that do involve carbocations (S_N1 reactions) have higher isotope effects, which depend on the nature of the leaving group.⁸⁹ The accepted explanation for a isotope effects is that one of the bending C—H vibrations is affected by the substitution of D for H more or less strongly in the transition state than in the ground state.⁹⁰ Depending on the nature of the transition state, this may increase or decrease the rate of the reaction. The α isotope effects on S_N2 reactions can vary with concentration,⁹¹ an effect attributed to a change from a free nucleophile to one that is part of an ion pair⁹² (see Sec. 10.G.ii). This illustrates the use of secondary isotope effects as a means of studying transition state structure. The γ secondary isotope effects have also been reported.⁹³

Another kind of isotope effect is the *solvent isotope effect*.⁹⁴ Reaction rates often change when the solvent is changed from H_2O to D_2O or from ROH to ROD. These changes may be due to any of three factors or a combination of all of them.

1. The solvent may be a reactant. If an O—H bond of the solvent is broken in the rate-determining step, there will be a primary isotope effect. If the molecules involved are D_2O or D_3O^+ there may also be a secondary effect caused by the O—D bonds that are not breaking.
2. The substrate molecules may become labeled with deuterium by rapid hydrogen exchange, and then the newly labeled molecule may become cleaved in the rate-determining step.
3. The extent or nature of solvent–solute interactions may be different in the deuterated and non-deuterated solvents; this may change the energies of the transition state, and hence the activation energy of the reaction. These are secondary isotope effects. Two physical models for this third factor have been constructed.⁹⁵

It is obvious that in many cases the first and third factors at least, and often the second, are working simultaneously. Attempts have been made to separate them.⁹⁶

The methods described in this chapter are not the only means of determining mechanisms. A detailed examination of the literature, coupled with well-planned experiments is the best way to devise an approach to the mechanism of a given reaction.

Irradiation Processes in Organic Chemistry

Most reactions carried out in organic chemistry laboratories take place between molecules, all of which are in their ground electronic states. In a *photochemical reaction*,¹ however, a reacting molecule has been previously promoted to an electronically excited state by absorption of light. A molecule in an excited state must lose its extra energy in some manner; it cannot remain in the excited state for long. The subject of electronic spectra is closely related to photochemistry. A chemical reaction is not the only possible means of relinquishing the extra energy in a photochemical process. In this chapter, electronically excited states and the processes of promotion to these states will be discussed. Reactions of such molecules are called photoreactions. There are enantioselective organocatalytic photoreactions, but they will not be discussed here.² Two other methods are available to facilitate chemical reactions: sonochemistry and microwave chemistry. Although the physical processes involved are not the same excitation processes observed in photochemistry, irradiation with ultrasound or with microwaves have a significant influence on chemical reactivity, and both are widely used. For that reason, they are included in this chapter.

7.A. PHOTOCHEMISTRY³

7.A.i. Excited States and the Ground State

Electrons can move from the ground-state energy level of a molecule to a higher level (i.e., an unoccupied orbital of higher energy) if outside energy is supplied. In a photochemical

FIG. 7.1. The UV, vis, and IR portions of the electromagnetic spectrum.

process, this energy is in the form of light. Light of any wavelength has an energy value associated with it given by $E = h\nu$, where ν is the frequency of the light ($\nu = \text{velocity of light } c \text{ divided by the wavelength } \lambda$), and h is Planck's constant. Since the energy levels of a molecule are quantized, the amount of energy required to raise an electron in a given molecule from one level to a higher one is a fixed quantity. Only light with exactly the frequency corresponding to this amount of energy will cause the electron to move to the higher level. If light of another frequency (too high or too low) is sent through a sample, it will pass out without a loss in intensity, since the molecules will not absorb it. However, if light of the correct frequency is passed into a sample, molecules will use that energy for electron promotion, and the light that leaves the sample will be diminished in intensity or altogether gone. A *spectrophotometer* is an instrument that allows light of a given frequency to pass through a sample and that detects (by means of a phototube) the amount of light that has been transmitted, that is, not absorbed. A spectrophotometer compares the intensity of the transmitted light with that of the incident light. Automatic instruments gradually and continuously change the frequency, and an automatic recorder plots a graph of absorption versus frequency or wavelength.

The energy of electronic transitions corresponds to light in the vis, UV, and far-UV regions of the spectrum (Fig. 7.1). Absorption positions are normally expressed in wavelength units, usually nanometers (nm).⁴ If a compound absorbs in the visible, it is colored, possessing a color complementary to that absorbed.⁵ Thus a compound absorbing in the violet has a yellow color. Organic chemists study the far-UV region less often than the vis or ordinary UV regions because special vacuum instruments are required, owing to the fact that oxygen and nitrogen absorb in these regions.

From these considerations it would seem that an electronic spectrum should consist of one or more sharp peaks, each corresponding to the transfer of an electron from one electronic level to another. Under ordinary conditions the peaks are seldom sharp. In order to understand why, it is necessary to realize that molecules are constantly vibrating and rotating and that these motions are also quantized. A molecule at any time is not only in a given electronic state, but also in a given vibrational and rotational state. The difference between two adjacent vibrational levels is much smaller than the difference between adjacent electronic levels, and the difference between adjacent rotational levels is smaller still. A typical situation is shown in Fig. 7.2. When an electron moves from one electronic level to another, it moves from a given vibrational and rotational level within that electronic level to some vibrational and rotational level at the next electronic level. A given sample contains a large number of molecules, and even if all of them are in the ground electronic state, they are still distributed

⁴ Formerly, millimicrons (mμ) were frequently used; numerically they are the same as nanometers.

FIG. 7.2. Energy curves for a diatomic molecule. Two possible transitions are shown. When an electron has been excited to the point marked A, the molecule may cleave (Sec. 7.A.v).

among the vibrational and rotational states (though the ground vibrational state, V_0 , is most heavily populated). This means that not just one wavelength of light will be absorbed, but a number of them close together, with the most probable transition causing the most intense peak. But in molecules containing more than a few atoms, there are so many possible transitions, and these are so close together that what is observed is a relatively broad band. The height of the peak depends on the number of molecules making the transition and is proportional to $\log \epsilon$, where ϵ is the *extinction coefficient*. The extinction coefficient can be expressed by $\epsilon = E/cl$, where c is the concentration in moles per liter, l is the cell length in centimeters, and $E = \log I_0/I$, where I_0 is the intensity of the incident light and I of the transmitted light. The wavelength is usually reported as λ_{\max} , meaning that this is the top of the peak. Purely vibrational transitions (e.g., between V_0 and V_1 of E_1), which require much less energy, are found in the IR region and are the basis of IR spectra. Purely rotational transitions are found in the far-IR and microwave (beyond the far-IR) regions.

A UV or vis absorption peak is caused by the promotion of an electron in one orbital (usually ground-state) to a higher orbital. Normally, the amount of energy necessary to make this transition depends mostly on the nature of the two orbitals involved and much less on the rest of the molecule. Therefore, a simple functional group (e.g., the C=C double bond) always causes absorption in the same general area. A group that causes absorption is called a *chromophore*.

7.A.ii. Singlet and Triplet States: "Forbidden" Transitions

In most organic molecules, all electrons in the ground state are paired, with each member of a pair possessing opposite spin, as demanded by the *Pauli principle*. When one of a pair of electrons is promoted to an orbital of higher energy, the two electrons no longer share an

orbital, and the promoted electron may, in principle, have the same spin as its former partner or the opposite spin. As seen in Chapter 5, a molecule in which two unpaired electrons have the same spin is called a *triplet*,⁶ while one in which all spins are paired is a *singlet*. Thus, at least in principle, for every excited singlet state there is a corresponding triplet state. In most cases, the triplet state has a lower energy than the corresponding singlet, which is in accord with *Hund's rule*. Therefore, a different amount of energy, and hence a different wavelength, is required to promote an electron from the ground state (which is almost always a singlet) to an excited singlet than to the corresponding triplet state.

It would thus seem that promotion of a given electron in a molecule could result either in a singlet or a triplet excited state depending on the amount of energy added. However, this is often not the case because transitions between energy levels are governed by selection rules, which state that certain transitions are “forbidden”. There are several types of “forbidden” transitions, two of which are more important than the others.

1. *Spin-Forbidden Transitions*. If the spin of an electron changes, transitions are not allowed, because a change from one spin to the opposite involves a change in angular momentum. Such a change would violate the law of conservation of angular momentum. Therefore, singlet–triplet and triplet–singlet transitions are forbidden, whereas singlet–singlet and triplet–triplet transitions are allowed.
2. *Symmetry-Forbidden Transitions*. Among the transitions in this class are those in which a molecule has a center of symmetry. In such cases, a $g \rightarrow g$ or $u \rightarrow u$ transition (see Sec. 1.A.) is “forbidden”, while a $g \rightarrow u$ or $u \rightarrow g$ transition is allowed.

The word “forbidden” is in quotation marks because these transitions are not actually forbidden, but only highly improbable. In most cases, promotions from a singlet ground state to a triplet excited state are so improbable that they cannot be observed, and it is safe to state that in most molecules only singlet–singlet promotions take place. However, this rule does break down in certain cases, most often when a heavy atom (e.g., iodine) is present in the molecule, in which cases it can be shown from spectra that singlet–triplet promotions are occurring.⁷ Symmetry-forbidden transitions can frequently be observed, though usually with low intensity.

7.A.iii. Types of Excitation

When an electron in a molecule is promoted (normally only one electron in any molecule), it usually goes into the lowest available vacant orbital, though promotion to higher orbitals is also possible. For most organic molecules, there are consequently four types of electronic excitation:

1. $\sigma \rightarrow \sigma^*$. Alkanes, which have no n or π electrons, can be excited only in this way.⁸
2. $n \rightarrow \sigma^*$. Alcohols, amines,⁹ ethers, and so on can also be excited in this manner.

⁶ See Kurreck, H. *Angew. Chem. Int. Ed.* **1993**, 32, 1409.

n	nm
2	227
3	263
6	352
9	413

3. $\pi \rightarrow \pi^*$. This pathway is open to alkenes as well as to aldehydes, carboxylic esters, and so on.
4. $n \rightarrow \pi^*$. Aldehydes, ketones, carboxylic esters, and so on can undergo this promotion, as well as the other three.

The four excitation types above are listed in what is normally the order of decreasing energy. Thus light of the highest energy (in the far-UV) is necessary for $\sigma \rightarrow \sigma^*$ excitation, while $n \rightarrow \pi^*$ promotions are caused by ordinary UV light. However, the order may sometimes be altered in some solvents.

In 1,3-butadiene (and other compounds with two conjugated double bonds), there are two π and two π^* orbitals (Sec. 2.C). The energy difference between the higher π (χ_2) and the lower π^* (χ_3) orbital is less than the difference between the π and π^* orbitals of ethylene. Therefore 1,3-butadiene requires less energy than ethylene, and thus light of a higher wavelength, to promote an electron. This is a general phenomenon, and it may be stated that, in general, *the more conjugation in a molecule, the more the absorption is displaced toward higher wavelengths* (see Table 7.1).¹⁰ When a chromophore absorbs at a certain wavelength and the substitution of one group for another causes absorption at a longer wavelength, a *bathochromic shift* is said to have occurred. The opposite kind of shift is called *hypsochromic*.

Of the four excitation types listed above, the $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ are far more important in organic photochemistry than the other two. Compounds containing C=O groups can be excited in both ways, giving rise to at least two peaks in the UV.

As seen above, a *chromophore* is a group that causes a molecule to absorb light. Examples of chromophores in the vis or UV are C=O, N=N,¹¹ Ph, and NO₂. Some chromophores in the far-UV (beyond 200 nm) are C=C, C≡C, Cl, and OH. An *auxochrome* is a group that displaces (through resonance) and usually intensifies the absorption of a chromophore present in the same molecule. Groups (e.g., Cl, OH, and NH₂) are generally regarded as auxochromes since they shift (usually bathochromically) the UV and vis bands of chromophores (e.g., Ph or C=O; see Table 7.2).¹² Since auxochromes are themselves chromophores (to be sure, generally in the far-UV), it is sometimes difficult to decide which group in a molecule is an auxochrome and which is a chromophore. For

example, in acetophenone (PhCOMe) is the chromophore Ph or C=O? In such cases, the distinction becomes practically meaningless.

7.A.iv. Nomenclature and Properties of Excited States

An excited state of a molecule can be regarded as a distinct chemical species, different from the ground state of the same molecule and from other excited states. It is obvious that some method of naming excited states is required. Unfortunately, there are several methods in use, depending on whether one is primarily interested in photochemistry, spectroscopy, or MO theory.¹³ One of the most common methods simply designates the original and newly occupied orbitals, with or without a superscript to indicate singlet or triplet. Thus the singlet state arising from promotion of a π to a π^* orbital in ethylene would be the $^1(\pi, \pi^*)$ state or the π, π^* singlet state. Another very common method can be used even in cases where one is not certain which orbitals are involved. The lowest-energy excited state is called S_1 , the next is S_2 , and so on. Triplet states are similarly labeled T_1 , T_2 , T_3 , and so on. In this notation, the ground state is S_0 . Other notational systems exist, but this text shall discuss only the two types just mentioned.

The properties of excited states are not easy to measure because of their generally short lifetimes and low concentrations, but enough work has been done for us to know that they often differ from the ground state in geometry, dipole moment, and acid or base strength.¹⁴

^aSee Table 1.7.

For example, acetylene, which is linear in the ground state, has a trans geometry in the excited state with $\sim sp^2$ carbons in the $^1(\pi, \pi^*)$ state.¹⁵ Similarly, the $^1(\pi, \pi^*)$ and the $^3(\pi, \pi^*)$ states of ethylene have a perpendicular and not a planar geometry,¹⁶ and the $^1(n, \pi^*)$ and $^3(n, \pi^*)$ states of formaldehyde are both pyramidal.¹⁷ Triplet species tend to stabilize themselves by distortion, which relieves interaction between the unpaired electrons. Obviously, if the geometry is different, the dipole moment will probably differ also and the change in geometry and electron distribution often results in a change in acid or base strength.¹⁸ For example, the S_1 state of 2-naphthol is a much stronger acid ($pK = 3.1$) than the ground state (S_0) of the same molecule ($pK = 9.5$).¹⁹

7.A.v. Photolytic Cleavage

As stated above, when a molecule absorbs a quantum of light it is promoted to an excited state. Actually, that is not the only possible outcome. Because the energy of vis and UV light is of the same order of magnitude as that of covalent bonds (Table 7.3), another possibility is that the molecule may cleave into two parts, a process known as *photolysis*. There are three situations that can lead to cleavage:

1. The promotion may bring the molecule to a vibrational level so high that it lies above the right-hand portion of the E_2 curve (line A in Fig. 7.2). In such a case, the excited molecule cleaves at its first vibration.
2. Even where the promotion is to a lower vibrational level, one that lies wholly within the E_2 curve (e.g., V_1 or V_2), the molecule may still cleave. As shown in Fig. 7.2, equilibrium distances are greater in excited states than in the ground state. The

FIG. 7.3. Promotion to a dissociative state results in bond cleavage.

Franck–Condon principle states that promotion of an electron takes place much faster than a single vibration (the promotion takes $\sim 10^{-15}$ s; a vibration $\sim 10^{-12}$ s). Therefore, when an electron is suddenly promoted, even to a low vibrational level, the distance between the atoms is essentially unchanged and the bond finds itself in a compressed condition like a pressed-in spring; this condition may be relieved by an outward surge that is sufficient to break the bond.

3. In some cases, the excited state is entirely dissociative (Fig. 7.3); that is, there is no distance where attraction outweighs repulsion, and the bond must cleave. An example is the hydrogen molecule, where a $\sigma \rightarrow \sigma^*$ promotion always results in cleavage.

A photolytic cleavage can break the molecule into two smaller molecules or into two free radicals (see Sec. 7.A.vii). Cleavage into two ions, though known, is rare. Once free radicals are produced by a photolysis, they behave like free radicals produced in any other way (Chap 5) except that they may be in excited states, and this can cause differences in behavior.²⁰

7.A.vi. The Fate of the Excited Molecule: Physical Processes

When a molecule has been photochemically promoted to an excited state, it does not remain in the excited state for long. Most promotions are from the S_0 to the S_1 state. As seen previously, promotions from S_0 to triplet states are “forbidden”. Promotions to S_2 and higher singlet states take place, but in liquids and solids these higher states usually drop very rapidly to the S_1 state ($\sim 10^{-13}$ to $\sim 10^{-11}$ s). The energy lost when an S_2 or S_3

²⁰ Lubitz, W.; Lendzian, F.; Bittl, R. *Acc. Chem. Res.* **2002**, *35*, 313.

FIG. 7.4. Modified Jablonski diagram showing transitions between the excited and the ground state. Radiative processes are shown by straight lines, radiationless processes by wavy lines. vc = vibrational cascade; $h\nu_f$ = fluorescence; $h\nu_p$ = phosphorescence.

molecule drops to S_1 is given up in small increments to the environment by collisions with neighboring molecules. Such a process is called an *energy cascade*. In a similar manner, the initial excitation and the decay from higher singlet states initially populate many of the vibrational levels of S_1 , but these also cascade, down to the lowest vibrational level of S_1 . Therefore, in most cases, the lowest vibrational level of the S_1 state is the only important excited singlet state.²¹ This state can undergo various physical and chemical processes. In the following list, we describe the physical pathways open to molecules in the S_1 and excited triplet states. These pathways are also shown in a modified *Jablonski diagram* (Fig. 7.4) and in Table 7.4.

1. A molecule in the S_1 state can cascade down through the vibrational levels of the S_0 state and thus return to the ground state by giving up its energy in small increments to the environment. This process is generally quite slow because the amount of energy is large and is called *internal conversion* (IC, see Fig. 7.4). Because it is slow, most molecules in the S_1 state adopt other pathways.²²

²¹ See Turro, N.J.; Ramamurthy, V.; Cherry, W.; Farneth, W. *Chem. Rev.* **1978**, 78, 125.

TABLE 7.4 Physical Processes Undergone by Excited Molecules^a

$S_0 + h\nu \rightarrow S_1^v$	Excitation
S_1^v	$\rightsquigarrow S_1 + \Delta$ Vibrational relaxation
$S_1 \rightarrow S_0 + h\nu$	Fluorescence
S_1	$\rightsquigarrow S_0 + \Delta$ Internal conversion
$S_1 \rightsquigarrow T_1^v$	Intersystem crossing
T_1^v	$\rightsquigarrow T_1 + \Delta$ Vibrational relaxation
$T_1^v \rightarrow S_0 + h\nu$	Phosphorescence
T_1	$\rightsquigarrow S_0 + \Delta$ Intersystem crossing
$S_1 + A_{(S_0)} \rightarrow S_0 + A_{(S_1)}$	Singlet–singlet transfer (photosensitization)
$T_1 + A_{(S_0)} \rightarrow S_0 + A_{(T_1)}$	Triplet–triplet transfer (photosensitization)

^aThe superscript *v* indicates vibrationally excited state; excited states higher than S_1 or T_1 are omitted.

2. A molecule in the S_1 state can drop to some low vibrational level of the S_0 state all at once by giving off the energy in the form of light. This process, which generally happens within 10^{-9} s, is called *fluorescence*. This pathway is not very common either (because it is relatively slow), except for small molecules (e.g., diatomic) and rigid molecules (e.g., aromatic). For most other compounds, fluorescence is very weak or undetectable. For compounds that do fluoresce, the fluorescence emission spectra are usually the approximate mirror images of the absorption spectra. This comes about because the fluorescing molecules all drop from the lowest vibrational level of the S_1 state to various vibrational levels of S_0 , while excitation is from the lowest vibrational level of S_0 to various levels of S_1 (Fig. 7.5). The only peak in common is the one that results from transitions between the lowest vibrational levels of the two states (called the 0–0 peak). In solution, even the 0–0 peak may be noncoincident because the two states are solvated differently. Fluorescence nearly always arises from a $S_1 \rightarrow S_0$ transition, although azulene (Sec. 2.I.iii) and its simple derivatives are exceptions,²³ emitting fluorescence from $S_2 \rightarrow S_0$ transitions.

Because of the possibility of fluorescence, any chemical reactions of the S_1 state must take place very fast, or fluorescence will occur before they can happen.

3. Most molecules (but by no means all) in the S_1 state can undergo an *intersystem crossing* (ISC, see Fig. 7.4) to the lowest triplet state T_1 .²⁴ An important example is benzophenone, of which 100% of the molecules that are excited to the S_1 state cross over to the T_1 .²⁵ Intersystem crossing from singlet to triplet is of course a “forbidden” pathway, since the angular-momentum problem (Sec. 7.A.ii) must

²³ For other exceptions, see Sugihara, Y.; Wakabayashi, S.; Murata, I.; Jinguji, M.; Nakazawa, T.; Persy, G.; Wirz, J. *J. Am. Chem. Soc.* **1985**, *107*, 5894, and references cited therein. See also, Turro, N.J.; Ramamurthy, V.; Cherry, W.; Farneth, W. *Chem. Rev.* **1978**, *78*, 125, see pp. 126–129.

²⁴ Also see Li, R.; Lim, E.C. *Chem. Phys.* **1972**, *57*, 605; Sharf, B.; Silbey, R. *Chem. Phys. Lett.* **1970**, *5*, 314; Schlag, E.W.; Schneider, S.; Fischer, S.F. *Annu. Rev. Phys. Chem.* **1971**, *22*, 465, pp. 490. There is evidence that ISC can also occur from the S_2 state of some molecules: Samanta, A. *J. Am. Chem. Soc.* **1991**, *113*, 7427; Ohsaku, M.; Koga, N.; Morokuma, K. *J. Chem. Soc. Perkin Trans. 2* **1993**, 71.

FIG. 7.5. Promotion and fluorescence between S_1 and S_0 states.

be taken care of, but this often takes place by compensations elsewhere in the system. Intersystem crossings take place without loss of energy. Since a singlet state usually has a higher energy than the corresponding triplet, this means that energy must be given up. One way for this to happen is for the S_1 molecule to cross to a T_1 state at a high vibrational level and then for the T_1 to cascade down to its lowest vibrational level (see Fig. 7.4). This cascade is very rapid (10^{-12} s). When T_2 or higher states are populated, they too rapidly cascade to the lowest vibrational level of the T_1 state.

4. A molecule in the T_1 state may return to the S_0 state by giving up heat (ISC) or light (this is called *phosphorescence*).²⁶ Of course, the angular momentum difficulty exists here, so that both ISC and phosphorescence are very slow ($\sim 10^{-3}$ – 10^1 s). This means that T_1 states generally have much longer lifetimes than S_1 states. When they occur in the same molecule, phosphorescence is found at lower frequencies than fluorescence (because of the higher difference in energy between S_1 and S_0 than between T_1 and S_0) and is longer-lived (because of the longer lifetime of the T_1 state).
5. If nothing else happens to it first, a molecule in an excited state (S_1 or T_1) may transfer its excess energy all at once to another molecule in the environment, in a process called *photosensitization*.²⁷ The excited molecule, which we will call D for donor, thus drops to S_0 while the other molecule (A for acceptor) becomes excited:

²⁶ See Lower, S.K.; El-Sayed, M.A. *Chem. Rev.* **1966**, 66, 199. For a review of physical and chemical processes of triplet states see Wagner, P.J.; Hammond, G.S. *Adv. Photochem.* **1968**, 5, 21.

²⁷ See Albini, A. *Synthesis*, **1981**, 249; Turro, N.J.; Dalton, J.C.; Weiss, D.S. *Org. Photochem.* **1969**, 2, 1. Ionic liquids may be soluble photosensitizers. See Hubbard, S.C.; Jones, P.B. *Tetrahedron* **2005**, 61, 7425.

Thus there are *two* ways for a molecule to reach an excited state: by absorption of a quantum of light or by transfer from a previously excited molecule.²⁸ The donor D is also called a *photosensitizer*. This energy transfer is subject to the *Wigner spin-conservation rule*, which is actually a special case of the law of conservation of momentum we encountered previously. According to the Wigner rule, the total electron spin does not change after the energy transfer. For example, when a triplet species interacts with a singlet these are some allowed possibilities:²⁹

In all these cases, the products have three electrons spinning “up” and the fourth “down” (as do the starting molecules). However, formation of, say, two triplets ($\uparrow\downarrow + \uparrow\downarrow$) or two singlets ($\uparrow\downarrow + \uparrow\downarrow$), whether ground states or excited, would violate the rule.

In the two most important types of photosensitization, both of which are in accord with the Wigner rule, a triplet excited state generates another triplet and a singlet generates a singlet:

Singlet–singlet transfer can take place over relatively long distances (e.g., 40 Å), but triplet transfer normally requires a collision between the molecules.³⁰ Both types of photosensitization can be useful for creating excited states when they are difficult to achieve by direct irradiation. Photosensitization is therefore an important method for carrying out photochemical reactions when a molecule cannot be brought to the desired excited state by direct absorption of light. Triplet–triplet transfer is especially important because triplet states are usually much more difficult to prepare by direct irradiation than singlet states (often impossible) and because triplet states, having longer lifetimes, are much more likely than singlets to transfer energy by photosensitization. Photosensitization can also be accomplished by electron transfer.³¹

In choosing a photosensitizer,³² one should avoid a compound that absorbs in the same region as the acceptor because the latter will then compete for the light.³³ For

²⁸ In certain cases excited states can be produced directly in ordinary reactions. See White, E.H.; Miano, J.D.; Watkins, C.J.; Breaux, E.J. *Angew. Chem. Int. Ed.* **1974**, 13, 229.

examples of the use of photosensitization to accomplish reactions, see Reactions **15-62** and **15-63**.

6. An excited species can be quenched. Quenching is the deactivation of an excited molecular entity intermolecularly by an external environmental influence (e.g., a quencher), or intramolecularly by a substituent through a nonradiative process.³⁴ When the external environmental influence (quencher) interferes with the behavior of the excited state after its formation, the process is referred to as dynamic quenching. Common mechanisms include energy transfer, charge transfer, and so on. When the environmental influence inhibits the excited state formation, the process is referred to as static quenching. A quencher is defined as a molecular entity that deactivates (quenches) an excited state of another molecular entity, either by energy transfer, electron transfer, or by a chemical mechanism.³⁴

An example is the rapid triplet quenching of aromatic ketone triplets³⁵ by amines, which is well known.³⁶ Alkyl and aryl thiols and thioethers also serve as quenchers in this system.³⁷ In this latter case, the mechanism involves electron transfer from the sulfur atom to the triplet ketone, and this is supported by theoretical calculations.³⁸ Aromatic ketone triplets are quenched by phenols, and the photochemical reaction between aromatic ketones and phenols is efficient only in the presence of an acid catalyst.³⁹ Indirect evidence has been provided for involvement of the hydrogen-bonded triplet exciplex and for the role of electron transfer in this reaction.⁴⁰

7.A.vii. The Fate of the Excited Molecule: Chemical Processes

Although both excited singlet and triplet species can undergo chemical reactions, they are much more common for triplets, simply because these generally have much longer lifetimes. Excited singlet species, in most cases, have a lifetime of $<10^{-10}$ s and undergo one of the physical processes already discussed before they have a chance to react chemically. Therefore, photochemistry is largely the chemistry of triplet states.⁴¹ Table 7.5⁴² lists many of the possible chemical pathways that can be taken by an excited molecule.⁴³ The first four of these are unimolecular reactions; the others are bimolecular. TABLE 7.5 Primary Photochemical Reactions^a of an Excited Molecule A—B—C^b

Reactions	Reaction Type	Example Number
(A—B—C) → A—B• + C•	Simple cleavage into radicals ⁴⁶	(1)
(A—B—C) → E + F	Decomposition into molecules	(2)
(A—B—C) → A—C—B	Intramolecular rearrangement	(3)
(A—B—C) → A—B—C'	Photoisomerization	(4)
(A—B—C) + RH → A—B—C—H + R•	Hydrogen-atom abstraction	(5)
(A—B—C) → (ABD) ₂	Photodimerization	(6)
(A—B—C) + A → ABX + A*	Photosensitization	(7)

^aExamples are given in the text; the most common are (1), (2), and, in the presence of a suitable acceptor molecule (7).

^bSee Ref. 42.

the case of bimolecular reactions, it is rare for two excited molecules to react with each other (because the concentration of excited molecules at any one time is generally low); reactions are between an excited molecule and an unexcited molecule of either the same or another species. The reactions listed in Table 7.5 are primary processes. Secondary reactions often follow, since the primary products are frequently radicals or carbenes; even if they are ordinary molecules, they are often in upper vibrational levels and so have excess energy. In almost all cases, the primary products of photochemical reactions are in their ground states, though exceptions are known.⁴⁴ Of the reactions listed in Table 7.5, the most common are cleavage into radicals (1), decomposition into molecules (2), and (in the presence of a suitable acceptor molecule) photosensitization (7), which we have already discussed. The following are some specific examples of reaction categories (1)–(6). Other examples are discussed in Part II.^{45,46}

*Category 1. Simple Cleavage into Radicals.*⁴⁷ Aldehydes and ketones absorb in the 230–330-nm region. This is assumed to result from an $n \rightarrow \pi^*$ singlet–singlet transition. The excited aldehyde or ketone can then cleave.⁴⁸

When applied to ketones, this is called *Norrish Type I cleavage* or often just *Type I cleavage*. In a secondary process, the acyl radical ($R'-CO\bullet$) can then lose CO to give $R'\bullet$ radicals. Another example of a category 1 process is cleavage of Cl_2 to give two Cl atoms. Other bonds that are easily cleaved by photolysis are the O—O bonds of peroxy compounds and the C—N bonds of aliphatic azo compounds ($R-N=N-R$).⁴⁹ The latter is an important source of radicals $R\bullet$, since the other product is the very stable N_2 .

Category 2. Decomposition into Molecules. Aldehydes (though not generally ketones) can also cleave in this manner:

This is an extrusion reaction (see Chapter 17). In another example of a process in category 2, aldehydes and ketones with an γ hydrogen can cleave in still another way (a β -elimination, see Chap 17):

This reaction, called *Norrish Type II cleavage*,⁵⁰ involves intramolecular abstraction of the γ hydrogen followed by cleavage of the resulting diradical⁵¹ (a secondary reaction) to give an enol that tautomerizes to the aldehyde or ketone product.⁵²

Both singlet and triplet n,π^* states undergo the reaction.⁵³ The intermediate diradical can also cyclize to a cyclobutanone, which is often a side product. Carboxylic esters, anhydrides, and other carbonyl compounds can also give this reaction.⁵⁴ The

photolysis of ketene to CH_2 (Sec. 5.D.ii) is still another example of a reaction in category 2. Both singlet and triplet CH_2 are generated, the latter in two ways:

Reactions are known where *both* Norrish Type I and Type II reactions compete, and the substituents on and nature of the substrate will determine which leads to the major product.⁵⁵

Category 3. Intramolecular Rearrangement. Two examples are the rearrangement of the trimesityl compound **1** to the enol ether (**2**),⁵⁶ and irradiation of *o*-nitrobenzaldehydes (**3**) to give *o*-nitrosobenzoic acids (**4**).⁵⁷

Category 4. Photoisomerization. The most common reaction in this category is photochemical *cis*–*trans* isomerization.⁵⁸ For example, *cis*-stilbene can be converted to the *trans* isomer,⁵⁹ and the photoisomerization of *O*-methyl oximes is known.⁶⁰

The isomerization takes place because the excited states, both S_1 and T_1 , of many alkenes have a perpendicular instead of a planar geometry (Sec. 7.A.iv), so *cis*–*trans* isomerism disappears upon excitation. When the excited molecule drops back to the S_0 state, either isomer can be formed. A useful example is the photochemical

conversion of *cis*-cyclooctene to the much less stable *trans* isomer.⁶¹ Another interesting example of this isomerization involves azo crown ethers. The crown ether **5**, in which the N=N bond is *anti*, preferentially binds NH_4^+ , Li^+ , and Na^+ , but the *syn* isomer preferentially binds K^+ and Rb^+ (see Sec. 3.C.ii). Thus, ions can be selectively put in or taken out of solution merely by turning a light source on or off.⁶²

In another example, the *trans* azo compound (**6**) is converted to its *cis* isomer when exposed to light. In this case⁶³ the *cis* isomer is a stronger acid than the *trans*. The *trans* isomer is dissolved in a system containing a base, wherein a liquid membrane separates two sides, one of which is illuminated, the other kept dark. On the illuminated side, the light converts the *trans* isomer to the *cis*. The *cis* isomer, being a stronger acid, donates its proton to the base, converting *cis*-ArOH to *cis*-ArO[−]. This ion migrates to the dark side, where it rapidly reverts to the *trans* ion, which reacquires a proton. Because each cycle forms one H_3O^+ ion in the illuminated compartment and one [−]OH ion in the dark compartment, the process reverses the normal reaction whereby these ions neutralize each other.⁶⁴ Thus the energy of light is used to do chemical work.⁶⁵ Another example of a category 4 reaction is the conversion of bicyclo[2.2.1]hept-2,5-diene to **7**.⁵⁸ The thermal isomerization of dibenzosubvalene (**9**) to the corresponding dibenzodihydropentalenofuran (**8**) in quantitative yield was known,⁶⁶ but in another example of a category 4 reaction the photochemical isomerization of **8** to **9** has now been reported.⁶⁷

These examples illustrate that the use of photochemical reactions can make it very easy to obtain compounds that would be difficult to get in other ways. Reactions similar to these are discussed in Reaction 15-63.

Category 5. Hydrogen-Atom Abstraction. When benzophenone is irradiated in isopropyl alcohol, the initially formed S_1 state crosses to the T_1 state, which abstracts hydrogen from the solvent to give the radical **10**. Radical **10** then abstracts another hydrogen to give benzhydrol (**11**) or dimerizes to benzpinacol (**12**):

An example of intramolecular abstraction has already been given (see category 2 in this section).

Category 6. Photodimerization. An example is dimerization of cyclopentenone:⁶⁸

See Reaction 15-63 for a discussion of this and similar reactions.

7.A.viii. The Determination of Photochemical Mechanisms⁶⁹

The methods used for the determination of photochemical mechanisms are largely the same as those used for organic mechanisms in general (Chapter 6): product identification, isotopic tracing, the detection and trapping of intermediates, and kinetics. There are, however, a few new factors: (1) there are generally many products in a photochemical reaction, as many as 10 or 15; (2) in measuring kinetics, there are more variables, since it is possible to study the effect on the rate of the intensity or the wavelength of light; (3) in the detection of intermediates by spectra the technique of *flash photolysis* can be used, which can detect extremely short-lived intermediates.

In addition to these methods, there are two additional techniques.

1. The use of emission (fluorescence and phosphorescence), as well as absorption spectroscopy. From these spectra the presence of as well as the energy and lifetime of singlet and triplet excited states can often be calculated.
2. The study of quantum yields. The *quantum yield* is the fraction of absorbed light that goes to produce a particular result. There are several types. A *primary quantum yield* for a particular process is the fraction of molecules absorbing light that undergo that particular process. Thus, if 10% of all the molecules that are excited to

⁶⁹ For a review, see Calvert, J.G.; Pitts, Jr., J.N. *Photochemistry*, Wiley, NY, **1966**, pp. 580–670.

the S_1 state cross over to the T_1 state, the primary quantum yield for that process is 0.10. However, primary quantum yields are often difficult to measure. A *product quantum yield* (usually designated Φ) for a product P that is formed from a photoreaction of an initially excited molecule A can be expressed as:

$$\Phi = \frac{\text{number of molecules of P formed}}{\text{number of quanta absorbed by A}}$$

Product quantum yields are much easier to measure. The number of quanta absorbed can be determined by an instrument called an *actinometer*, which is actually a standard photochemical system whose quantum yield is known. An example of the information that can be learned from quantum yields is the following. If the quantum yield of a product is finite and invariant with changes in experimental conditions, it is likely that the product is formed in a primary rate-determining process. Another example: In some reactions, the product quantum yields are found to be well over 1 (perhaps as high as 1000). Such a finding indicates a chain reaction (see Sec. 14.A.i for a discussion of chain reactions).

7.B. SONOCHEMISTRY

Sonochemistry (chemical events induced by exposure to ultrasound) occupies an important place in organic chemistry.⁷⁰ The chemical effects of high-intensity ultrasound were extensively studied in aqueous solutions for many years,⁷¹ but are now applied to a variety of organic solvents. The origin of sonochemistry is acoustic cavitation: the creation, growth, and implosive collapse of gas vacuoles in solution by the sound field. Acoustic cavitation is the phenomenon by which intense ultrasonic waves induce the formation, oscillation, and implosion of gas bubbles in liquids.⁷² Liquids irradiated with high-power ultrasound undergo chemical decomposition and emit light.⁷³ These phenomena occur near the end of the collapse of bubbles expanded many times their equilibrium sizes. Chemistry (sonochemistry), light emission (sonoluminescence), and cavitation noise often accompany the process of acoustic cavitation.⁷⁴

Sonochemistry generates gas vacuoles *in situ*. The collapse of gas vacuoles generates transient hot spots with local temperatures of several thousand Kelvin, and pressures of hundreds of atmospheres. A sonochemical hot spot forms where the gas- and liquid-phase

reaction zones have effective temperatures of 5200 and 1900 K, respectively.⁷⁵ The high temperatures and pressures that are achieved in the bubbles during the quasiadiabatic collapse⁷⁶ lead to the generation of chemistry and to the emission of light, most probably coming from molecular excited states and molecular recombination. Note that work has been done that shows the commonly held view that bubbles are filled with saturated gas is inconsistent with a realistic estimate of condensation rates.⁷⁷ The alternative view of extensive solvent vapor supersaturation in bubbles uniformly heated to a few thousand kelvin, depending on the conditions, is in accord with sonochemical rates and products.⁷⁸

There is a correlation between sonochemical and sonoluminescence measurements, which is usually not observed. Sonoluminescence is the consequence that both the sonochemical production (under air) of oxidizing species, and the emission of light reflect the variations of the primary sonochemical acts, which are themselves due to variations of the number of "active" bubbles.⁷⁹ Pulsed ultrasound in the high-frequency range (>1 MHz) is extensively used in medical diagnosis, and the effects of pulsed ultrasound in the 20-kHz range using an immersed titanium horn has been reported.⁸⁰

The chemical effects of ultrasound have been studied for >50 years,⁸¹ and applied to colloid chemistry in the 1940s.⁸² Modern interest in the chemical uses of ultrasound involves chemistry in both homogeneous⁸³ and heterogeneous⁸⁴ systems. Organic solvents (e.g., alkanes) support acoustic cavitation and the associated sonochemistry. This leads to carbon-carbon bond cleavage and radical rearrangements, with the peak temperatures reached in such cavities controlled by the vapor pressure of the solvent.⁸⁵

It is often difficult to compare the sonochemical results reported from different laboratories (the reproducibility problem in sonochemistry).⁸⁶ The sonochemical power irradiated into the reaction system can be different for different instruments. Several methods are available to estimate the amount of ultrasonic power entered into a sonochemical reaction,⁸⁶ the most common being calorimetry. This experiment involves measurement of the initial rate of a temperature rise produced when a system is irradiated by power ultrasound. It has

been shown that calorimetric methods combined with the Weissler reaction can be used to standardize the ultrasonic power of individual ultrasonic devices.⁸⁷

Sonochemistry has been used to facilitate or assist many organic reactions,⁸⁸ and there are other applications.⁸⁹ The scope of reactions studied is beyond this work, but some representative examples will be listed. Ultrasound has been used to promote lithiation of organic compounds,⁹⁰ for the generation of carbenes,⁹¹ and reactions of metal carbonyls where sonochemical ligand dissociation has been observed, which often produces multiple CO substitution.⁹² The influence of ultrasound on phase-transfer catalyzed thioether synthesis has been studied.⁹³

Sonochemistry has been applied to acceleration of the *Reformatsky reaction*,⁹⁴ *Diels–Alder reactions*,⁹⁵ the arylation of active methylene compounds⁹⁶ nucleophilic aromatic substitution of haloarenes,⁹⁷ and to hydrostannation and tin hydride reduction.⁹⁸ Other sonochemical applications involve the reaction of benzyl chloride and nitrobenzene,⁹⁹ an S_{RN}1 reaction in liquid ammonia at room temperature,¹⁰⁰ and *Knoevenagel condensation* of aromatic aldehydes.¹⁰¹ Iodination of aliphatic hydrocarbons can be accelerated,¹⁰² and oxyallyl cations have been prepared from α,α' -diiodoketones using sonochemistry.¹⁰³ Sonochemistry has been applied to the preparation of carbohydrate compounds.¹⁰⁴ When sonochemistry is an important feature of a chemical reaction, this fact will be noted in the reactions presented in Chapters 10–19.

7.C. MICROWAVE CHEMISTRY

In 1986, independent work by Gedye et al.,¹⁰⁵ as well as Majetich and co-workers¹⁰⁶ reported the use of microwave irradiation for organic reactions. Gedye described four different types of reactions, including the hydrolysis of benzamide to benzoic acid under acidic conditions, and all reactions showed significant rate enhancements when

compared to the same reactions done at reflux conditions.¹⁰⁷ Majetich, Giguere and co-workers¹⁰⁶ reported rate enhancements for microwave-promoted *Diels–Alder*, *Claisen*, and ene reactions. Many publications¹⁰⁸ have appeared that describe chemical synthesis promoted by microwave irradiation, including many review articles¹⁰⁹ and books.¹¹⁰

Microwaves are electromagnetic waves (see Sec. 7.A.i) and there are electric and magnetic field components. Charged particles start to migrate or rotate as the electric field is applied,¹¹¹ which leads to further polarization of polar particles. Because the concerted forces applied by the electric and magnetic components of microwaves are rapidly changing in direction ($2.4 \times 10^9 \text{ s}^{-1}$), warming occurs.¹¹¹ In general, the most common frequencies used for microwave dielectric heating¹¹² are 918 MHz and 2.45 GHz¹¹³ (wavelengths of 33.3 and 12.2 cm, respectively), which are in the region between the IR and radiowave wavelengths in the electromagnetic spectrum. For chemical reactions done with microwave irradiation, rapid heating is usually observed,¹¹⁴ and if a solvent is used superheating of that solvent was always observed.¹¹² Agitation is usually important.¹¹⁵ In the early days of microwave chemistry, reactions were often done in open vessels, but also in sealed Teflon or glass vessels using unmodified domestic household ovens.¹¹⁶ Dielectric heating is direct so if the reaction matrix has a sufficiently large dielectric loss tangent, and contains molecules possessing a dipole moment, a solvent is not required. The use of dry-reaction microwave chemistry is increasingly popular.¹¹⁷

Microwave dielectric heating was initially categorized by thermal effects and nonthermal effects.¹¹⁸ “Thermal effects are those which are caused by the different temperature regime which can be created due to microwave dielectric heating. Nonthermal effects are effects,¹¹⁹ which are caused by effects specifically inherent to the microwaves and are not caused by

different temperature regimes.”¹¹¹ Some claimed special effects¹²⁰ in microwave chemistry, such as lowering of Gibbs energy of activation, but later study under careful temperature control indicated no special rate effects.¹²¹ When conventional microwave ovens were used, temperature control was difficult, particularly when reactions are carried out in closed reaction vessels. The main contributing factor to any rate acceleration caused by microwave dielectric heating seems to be due to a thermal effect. The thermal effect may be due to a faster initial heating rate or to the occurrence of local regions with higher temperatures.¹¹¹

Conventional microwave ovens are used less often for microwave chemistry today. Microwave reactors for chemical synthesis are commercially available and widely used in academia and in industry. These instruments have built-in magnetic stirring, direct temperature control of the reaction mixture, shielded thermocouples or IR sensors, and the ability to control temperature and pressure by regulating microwave output power.

The applications of microwave chemistry to organic chemistry are literally too numerous to mention. A few representative examples will be given to illustrate the scope and utility. The combined use of microwaves and ultrasound is important in process chemistry and organic synthesis.¹²² Microwave chemistry is widely used in synthesis,¹²³ including organocatalyzed asymmetric reactions.¹²⁴ Examples include the *Heck reaction* (Reaction 13-10),¹²⁵ the *Suzuki reaction* (Reaction 13-12),¹²⁶ the *Sonogashira reaction* (Reaction 13-13),¹²⁷ *Ullman-type couplings* (Reaction 13-3),¹²⁸ cycloaddition reactions (Reactions 15-58–15-66),¹²⁹ dihydroxylation (Reaction 15-48),¹³⁰ and the *Mitsunobu reaction* (Reaction 10-23).¹³¹ There are a multitude of other reactions types from earlier literature that can be found in the cited review articles. When microwave chemistry is an important feature of a chemical reaction, this fact will be noted in the reactions presented in Chapters 10–19.

Acids and Bases

Two acid–base theories are used in organic chemistry today: the Brønsted theory and the Lewis theory.¹ These theories are quite compatible and are used for different purposes.² However, the Lewis-based idea of electron-donating species (bases) and electron-accepting species (acids) is often the more useful for organic chemistry. Remember also that most organic reactions are not done in an aqueous medium, and focus on electron transfer rather than proton transfer is far more useful.

8.A. BRØNSTED THEORY

According to this theory, an acid is defined as a *proton donor*³ and a base as a *proton acceptor*. However, a base must have a pair of electrons available to share with the proton; this is usually present as an unshared pair, but sometimes is in a π orbital. By this definition, an acid–base reaction is the transfer of a proton from an acid to a base. However, protons do not exist free in solution, but must be attached to an electron pair. In fact, the acid does not “give up” a proton, but rather the base donates electrons to the proton, “pulling it away” to form the conjugate acid. After removal of the proton, the species remaining (the *conjugate base*) still retains the electron pair to which the proton was formerly attached. The conjugate base, in theory at least, can reacquire a proton and is therefore a base. All acids will generate a conjugate base upon reaction with a suitable base, and all bases will generate a *conjugate acid* by reaction with a suitable acid. All acid–base reactions fit the equation

¹ For monographs on acids and bases, see Stewart, R. *The Proton: Applications to Organic Chemistry*, Academic Press, NY, **1985**; Bell, R.P. *The Proton in Chemistry*, 2nd ed., Cornell University Press, Ithaca, NY, **1973**; Finston, H.L.; Rychman, A.C. *A New View of Current Acid–Base Theories*, Wiley, NY, **1982**.

² For discussion of the historical development of acid–base theory, see Bell, R.P. *Q. Rev. Chem. Soc.* **1947**, *1*, 113; Bell, R.P. *The Proton in Chemistry*, 1st ed., Cornell University Press, Ithaca, NY, **1959**, pp. 7–17.

³ According to IUPAC terminology (Bunnett, J.F.; Jones, R.A.Y. *Pure Appl. Chem.* **1988**, *60*, 1115), an acid is a *hydron* donor. The IUPAC recommends that the term *proton* be restricted to the nucleus of the hydrogen isotope of mass 1, while the nucleus of the naturally occurring element, which contains ~0.015% deuterium, be called the *hydron* (the nucleus of mass 2 has always been known as the *deuteron*). This accords with the naturally occurring negative ion, which has long been called the *hydride* ion. In this book, however, we will continue to use *proton* for the naturally occurring form, because most of the literature uses this term.

No charges are shown in this equation, but an acid always has a charge one positive unit higher than that of its conjugate base.

8.A.i Brønsted Acids

According to the Brønsted definition, *acid strength* may be defined as the tendency to give up a proton and *base strength* as the tendency to accept a proton. All acid–base reactions are reversible, and both an acid and a conjugate acid are present in the equilibrium mixture. In one sense, acid–base reactions occur because the acid and the conjugate acid are not of equal strength (i.e., the equilibrium can be shifted to one side or the other). If an acid, say HCl, is placed in contact with the conjugate base of a weaker acid, say acetate ion, the conjugate acid in this reaction would be acetic acid. Since HCl is a stronger acid than acetic acid (see Table 8.1), the equilibrium lies well to the right. As the reaction is written, if the equilibrium lies to the right (higher concentration of acetic acid and a lower concentration of HCl), HCl is the stronger acid. Likewise, acetate is taken to be a stronger base than the chloride ion. If this is a correct statement, treatment of acetic acid with chloride ion should give essentially no reaction, since the weaker acid already has the proton. This is found to be correct.

For a comparison of two different acids, the position of the equilibrium in reaction with a common base allows the relative strengths of acids to be determined.⁴ Likewise, the strength of two different bases will be determined by comparing the equilibrium established when they react with a common acid. By definition, the acid and base are always drawn on the left side of the equation, and the conjugate acid and conjugate base are assumed to be on the right side of the equation.

Of course, if the two acids involved are close to each other in strength, a measurable reaction will occur from both sides. This finding really means that the concentration of acid and base at equilibrium will be close to that of the concentration of the conjugate acid and conjugate base. However, the position of equilibrium will still be over to the side of the weaker acid (unless the acidities are equal within experimental limits). If the concentration of acid and base is higher, the reaction of conjugate acid and conjugate base is more facile, and the compound labeled as the acid is considered to be a weaker acid. If the concentration of the conjugate acid and conjugate base is higher, the reaction of the acid and base is more facile, and the compound labeled as the acid is a stronger acid.

Using these protocols as the definition of acid strength, it is possible to construct a table in which acids are listed in order of acid strength⁵ (Table 8.1).⁶ The conjugate base is shown next to each acid in Table 8.1. Using the axiom that a strong acid generates a weak conjugate base and a weak acid will generate a strong conjugate base, it is clear that if the acids in such a table are listed in *decreasing* order of acid strength, the bases must be listed in *increasing* order of base strength. The $\text{p}K_a$ values⁷ in Table 8.1 are most accurate in the middle of the table.^{8–67}

⁴ Although equilibrium is reached in most acid–base reactions extremely rapidly (see Sec. 8.B), some are slow (especially those in which the proton is lost from a carbon) and in these cases time must be allowed for the system to come to equilibrium.

⁵ For a review of stronger Brønsted acids, see Akiyama, T. *Chem. Rev.* **2007**, *107*, 5744.

⁶ Table 8.1 is a thermodynamic acidity scale and applies only to positions of equilibria. For the distinction between thermodynamic and kinetic acidity (see Sec. 8.B).

⁷ For a first principles calculation of $\text{p}K$ values in nonaqueous solution, see Ding, F.; Smith, J.M.; Wang, H. *J. Org. Chem.* **2009**, *74*, 2679.

Chem.* **1969**, 20, 133.⁶⁶ Gillespie, R.J. *Acc. Chem. Res.* **1968**, 1, 202.⁶⁷ For discussions of pK_a determinations for the conjugate acids of ketones, see Bagno, A.; Lucchini, V.; Scorrano, G. *Bull. Soc. Chim. Fr.* **1987**, 563; Toullec, J. *Tetrahedron Lett.* **1988**, 29, 5541.

The pK_a values are much harder to measure⁶⁸ for very strong and very weak acids, and these values must be regarded as approximate. If one did not have the pK_a values available, it can be determined experimentally that HClO_4 is a stronger acid than H_2SO_4 . A mixture of HClO_4 and H_2SO_4 in 4-methyl-2-pentanone can be titrated to an HClO_4 end point without interference by H_2SO_4 .⁶⁹ Similarly, HClO_4 can be shown to be stronger than HNO_3 or HCl . However, this is not quantitative, and the value of -10 in the table is not much more than an educated guess. The values for RNO_2H^+ , ArNO_2H^+ , HI , RCNH^+ and RSH_2^+ must also be regarded as highly speculative.⁷⁰ A wide variety of pK_a values have been reported for the conjugate acids of even such simple bases as acetone⁶⁷ (-0.24 to -7.2), diethyl ether (-0.30 to -6.2), ethanol (-0.33 to -4.8), methanol (-0.34 to -4.9), and 2-propanol (-0.35 to -5.2), depending on the method used to measure them.⁷¹ Very accurate values can be obtained only for acids weaker than hydronium ion and stronger than water.

A crystallographic scale of acidity has been developed, including the acidity of $\text{C}-\text{H}$ compounds. Measuring the mean $\text{C}-\text{H} \cdots \text{O}$ distances in crystal structures correlated well with conventional $pK_{a(\text{DMSO})}$ values,⁷² where DMSO is dimethyl sulfoxide. An *ab initio* study was able to correlate ring strain in strained hydrocarbons with hydrogen-bond acidity.⁷³ The kinetic acidity of aliphatic hydrocarbons has been determined.⁷⁴

The bottom portion of Table 8.1 consists of very weak acids (pK_a above that of water ≈ 15.8).⁷⁵ In most of these acids, the proton is lost from a carbon atom, and such acids are known as *carbon acids*. The pK_a values for such weak acids are often difficult to measure and are known only approximately. The methods used to determine the relative positions of these acids are discussed in Chapter 5.⁷⁶ The acidity of carbon acids is proportional to the stability of the carbanions that are their conjugate bases (see Sec. 5.B.i).

The extremely strong acids at the top of the table are known as *superacids* (see Sec. 5.A. ii).⁷⁷ The actual species present in the $\text{FSO}_3\text{H}-\text{SbF}_5$ mixture are probably $\text{H}[\text{SbF}_5(\text{SO}_3\text{F})]$

and $\text{H}[\text{SbF}_2(\text{SO}_3\text{F})_4]$.⁶⁶ The addition of SO_3 causes formation of the still stronger $\text{H}[\text{SbF}_4(\text{SO}_3\text{F})_2]$, $\text{H}[\text{SbF}_3(\text{SO}_3\text{F})_3]$, and $\text{H}[(\text{SbF}_5)_2(\text{SO}_3\text{F})]$.⁶⁶ There is a study of electrophilic intermediates that are generated in superacids⁷⁸ (also see Chapter 10).

By the use of tables (e.g., Table 8.1), it is possible to determine whether a given acid will react with a given base to give reasonable concentrations of the conjugate acid and base. For tables in which acids are listed in order of decreasing strength, the rule is that *any acid will react with any base in the table that is below it but not with any above it*.⁷⁹ The greater the separation in the table, the better the reaction. It must be emphasized that the order of acid strength in Table 8.1 separation applies when a given acid and base react without a solvent or, when possible, in water. In other solvents, the order may be greatly different (see Sec. 8.G). In the gas phase, where solvation effects are completely or almost completely absent, acidity orders may also differ greatly.⁸⁰ For example, in the gas phase, toluene is a stronger acid than water and *tert*-butoxide ion is a weaker base than methoxide ion⁸¹ (see also Sec. 8.G). It is also possible for the acidity order to change with temperature. For example, $>50^\circ\text{C}$ the order of base strength is $\text{BuOH} > \text{H}_2\text{O} > \text{Bu}_2\text{O}$; from 1 to 50°C the order is $\text{BuOH} > \text{Bu}_2\text{O} > \text{H}_2\text{O}$; while $<1^\circ\text{C}$ the order becomes $\text{Bu}_2\text{O} > \text{BuOH} > \text{H}_2\text{O}$.⁸²

8.A.ii. Brønsted Bases

Basicity may be measured by a parameter known as proton affinity of an anion. The dissociation of a hydrogen ion for a molecule in the gas phase is called the *proton affinity* of the conjugate base.⁸³ A hydrogen-bond basicity scale has been developed that can be used to determine the relative basicity of molecules. Table 8.2 gives the $\text{p}K_{\text{HB}}$ values for several common heteroatom-containing molecules.⁸⁴ This is obtained from the protonated form (conjugated acid) of the base in question. The larger the number, the more basic is that compound. The basicity of aliphatic amines has been calculated,⁸⁵ the ion-pair basicity of amines in THF ⁸⁶ and in water⁸⁷ has been determined, and the basicity of pyridine was examined.⁸⁸ There are secondary deuterium isotope effects for measuring the basicity of secondary amines, and deuteration was found to increase the basicity.⁸⁹ Weaker bases have

⁷⁸ Prakash, G.K.S. *J. Org. Chem.* **2006**, *71*, 3661.

⁷⁹ These reactions are equilibria. What the rule actually says is that the position of equilibrium will be such that the weaker acid predominates. However, this needs to be taken into account only when the acid and base are close to each other in the table (within ~ 2 pK units).

⁹⁵ Besseau, F.; Luçon, M.; Laurence, C.; Berthelot, M. *J. Chem. Soc. Perkin Trans. 2* **1998**, 101.

⁹⁶ Laurence, C.; Berthelot, M.; Luçon, M.; Morris, D.G. *J. Chem. Soc. Perkin Trans. 2* **1994**, 491.

also been examined, and the basicity of carbonyl compounds in carbon tetrachloride has been determined.⁹⁷ Alkenes are weak bases⁹⁸ that react with strong acids (e.g., HCl or HBr, Reaction **15-02**). Note that extremely twisted amides (Sec. 4.Q.ii) exhibit high basicity.⁹⁹

A class of organic compounds termed *superbases* has been developed.¹⁰⁰ Vinamidine type or *Schwesinger proton sponges* (see Sec. 8.F), **1**,¹⁰¹ are dubbed superbases and are probably the most powerful organic neutral bases known. The pK_a (pK_{BH}^+) in MeCN was measure as 31.94. It has been shown that the pK_a values of strong neutral organic (super) bases in acetonitrile are well described by the density functional theory.¹⁰² The fundamental type of proton sponge is 1,8-bis(dimethylamino)naphthalene (**2**, see Sec. 8.F), with a pK_{BH}^+ of 18.18.¹⁰³ Other superbase-type compounds include amidinazines [e.g., N^1, N^1 -dimethyl- N^2 -β-(2-pyridylethyl)-formamidine (**3**)], pK_{BH}^+ in DMSO = 25.1,¹⁰⁴ 1,8-bis(tetramethylguanidino)naphthalene, (**4**),¹⁰⁵ and quinolino[7,8-*h*]quinolines (e.g., **5**) with a pK_{BH}^+ = 12.8.¹⁰⁶

It is important to note that organometallic compounds, such as *Grignard reagents* (RMgX) and organolithium reagents (RLi),¹⁰⁷ are powerful bases. The conjugate bases of both of these bases are alkanes, (R—H), which are very weak acids indeed (see Table 8.1).

8.B. THE MECHANISM OF PROTON-TRANSFER REACTIONS

Proton transfers between a base and an oxygen or nitrogen acid are usually extremely fast.¹⁰⁸ Such reactions are generally diffusion controlled in the thermodynamically favored direction.¹⁰⁹ In fact, a *normal acid* is defined¹¹⁰ as one whose proton-transfer reactions are completely diffusion controlled, except when the conjugate acid of the base to which the proton is transferred has a *pK* value very close (differs by less than ~ 2 *pK* units) to that of the acid. The normal acid–base reaction mechanism consists of three steps:

The actual proton transfer takes place in the second step the first step is formation of a hydrogen-bonded complex. The product of the second step is another hydrogen-bonded complex, which dissociates in the third step.

However, not all such proton transfers are diffusion controlled. For example, if an internal hydrogen bond exists in a molecule, reaction with an external acid or base is often much slower.¹¹¹ In a case such as 3-hydroxypropanoic acid, the OH^- ion can form a hydrogen bond with the acidic hydrogen only if the internal hydrogen bond breaks. Therefore only some of the collisions between OH^- ions and 3-hydroxypropanoic acid molecules result in proton transfer. In many collisions, the OH^- ions will come away “empty-handed”, resulting in a lower reaction rate. Note that this affects only the rate, not the equilibrium. Other systems are capable of hydrogen bonding (e.g., 1,2-diols). In the case of cyclohexane-1,2-diols, hydrogen bonding, ion–dipole interactions, polarizability, and stereochemistry all play a role in determining the acidity.¹¹² The presence of halogen atoms (e.g., chlorine) can lead to hydrogen-bonding effects.¹¹³ Another factor that can create lower rates is a molecular structure in which the acidic proton is protected within a molecular cavity (e.g., the in–in and out–in isomers shown in Sec. 4.L). See also the proton sponges mentioned in Section 8.F. Proton transfers between an acidic and a basic group within the same molecule can also be slow, if the two groups are too far apart for hydrogen bonding. In such cases, participation of solvent molecules may be necessary.

¹⁰⁸ For reviews of such proton transfers, see Hibbert, F. *Adv. Phys. Org. Chem.* **1986**, 22, 113; Crooks, J.E. in Bamford, C.H.; Tipper, C.F.H. *Chemical Kinetics*, Vol. 8; Elsevier, NY, **1977**, pp. 197–250. See Bernasconi, C.F.; Fairchild, D.E.; Montañez, R.L.; Aleshi, P.; Zheng, H.; Lorange, E. *J. Org. Chem.* **2005**, 70, 7721.

¹¹¹ See Ritchie, C.D.; Lu, S. *J. Am. Chem. Soc.* **1989**, 111, 8542.

¹¹² Chen, X.; Walthall, D.A.; Brauman, J.I. *J. Am. Chem. Soc.* **2004**, 126, 12614.

¹¹³ Abraham, M. H.; Enomoto, K.; Clarke, E. D.; Sexton, G. *J. Org. Chem.* **2002**, 67, 4782.

Proton transfers to or from a carbon atom¹¹⁴ in most cases are much slower than those strictly between oxygen or nitrogen atoms. At least three factors can be responsible for this,¹¹⁵ not all of them applying in every case.

1. Hydrogen bonding is very weak or altogether absent for carbon (Chap 3).
2. Loss of a proton from many carbon acids leads to carbanions that are stabilized by resonance. Calculations show that carbon acidity is influenced by coordination based on electrophile coordination geometry.¹¹⁶ Structural reorganization (movement of atoms to different positions within the molecule) may accompany this process. Chloroform, HCN, and 1-alkynes do not form resonance-stabilized carbanions, and these¹¹⁷ behave kinetically as normal acids.¹¹⁸ It has been reported that carborane acids [e.g., H(CHB₁₁H₅Cl₆)] are the strongest isolable (Lewis-free) Brønsted acids known.¹¹⁹
3. There may be considerable reorganization of solvent molecules around the ion as compared to the neutral molecule.¹²⁰

In connection with factors 2 and 3, it has been proposed¹¹⁵ that any factor that stabilizes the product (e.g., by resonance or solvation) lowers the rate constant if it develops late on the reaction coordinate, but increases the rate constant if it develops early. This is called the *Principle of Imperfect Synchronization*.

Mechanisms of proton transfer have been studied for many compounds, including the reactions of acids with lactams,¹²¹ amides with various bases,¹²² and amines with alkoxide bases.¹²³

8.C. MEASUREMENTS OF SOLVENT ACIDITY¹²⁴

When a solute is added to an acidic solvent it may become protonated by the solvent. This effect can lead to an enhancement of acidity, as in the effect of using formic acid rather than methanol.¹²⁵ An acidity scale has been reported for ionic liquids¹²⁶ (see Sec. 9.D.iii for a discussion of ionic liquids), and the Lewis acidity of ionic liquids has been established

using IR.¹²⁷ If the solvent is water and the concentration of solute is not very great, then the pH of the solution is a good measure of the proton-donating ability of the solvent. Unfortunately, this is no longer true in concentrated solutions because activity coefficients are no longer unity. A measurement of solvent acidity is needed that works in concentrated solutions and applies to mixed solvents as well. The *Hammett acidity function*¹²⁸ is a measurement that is used for acidic solvents of high dielectric constant.¹²⁹ For any solvent, including mixtures of solvents (but the proportions of the mixture must be specified), a value H_0 is defined as

$$H_0 = \text{p}K_{\text{BH}^+_{\text{w}}} - \log \frac{[\text{BH}^+]}{[\text{B}]}$$

H_0 is measured by using “indicators” that are weak bases (B) and so are partly converted, in these acidic solvents, to the conjugate acids BH^+ . Typical indicators are *o*-nitroanilinium ion, with a $\text{p}K$ in water of -0.29 , and 2,4-dinitroanilinium ion, with a $\text{p}K$ in water of -4.53 . For a given solvent, $[\text{BH}^+]/[\text{B}]$ is measured for one indicator, usually by spectrophotometric means and with the known $\text{p}K$ in water ($\text{p}K_{\text{BH}^+_{\text{w}}}$) for that indicator, H_0 can be calculated for that solvent system. In practice, several indicators are used, so that an average H_0 is taken. Once H_0 is known for a given solvent system, $\text{p}K_a$ values in it can be calculated for any other acid–base pair.

The symbol H_0 is defined as

$$h_0 = \frac{a_{\text{H}^+} f_{\text{I}}}{f_{\text{HI}^+}}$$

where a_{H^+} is the activity of the proton and f_{I} and f_{HI^+} are the activity coefficients of the indicator and conjugate acid of the indicator,¹³⁰ respectively. The parameter H_0 is related to H_0 by

$$H_0 = -\log h_0$$

so that H_0 is analogous to pH and H_0 to $[\text{H}^+]$, and indeed in dilute aq solution $H_0 = \text{pH}$.

The parameter H_0 reflects the ability of the solvent system to donate protons, but it can be applied only to acidic solutions of high dielectric constant, mostly mixtures of water with acids (nitric, sulfuric, perchloric, etc.). It is apparent that the H_0 treatment is valid only when $f_{\text{I}}/f_{\text{HI}^+}$ is independent of the nature of the base (the indicator). Since this is so only when the bases are structurally similar, the treatment is limited. Even when similar bases are compared, many deviations are found.¹³¹ Other acidity scales¹³² have been set up,

including a scale for C—H acids,¹³³ among them H_- for bases with a charge of -1 , H_R for aryl carbinols,¹³⁴ H_C for bases that protonate on carbon,¹³⁵ and H_A for unsubstituted amides.¹³⁶ It is now clear that there is no single acidity scale that can be applied to a series of solvent mixtures, irrespective of the bases employed.¹³⁷

Although most acidity functions have been applied only to acidic solutions, some work has also been done with strongly basic solutions.¹³⁸ The H_- function, which is used for highly acidic solutions when the base has a charge of -1 , can also be used for strongly basic solvents, in which case it measures the ability of these solvents to abstract a proton from a neutral acid (BH).¹³⁹ When a solvent becomes protonated, its conjugate acid is known as a *lyonium ion*.

Another approach to the acidity function problem was proposed by Bunnett et al.,¹⁴⁰ who derived the equation

$$\log \frac{[\text{SH}^+]}{[\text{S}]} + H_0 = \phi(H_0 + \log [\text{H}^+]) + \text{p}K_{\text{SH}^+}$$

where S is a base that is protonated by an acidic solvent. Thus the slope of a plot of $\log ([\text{SH}^+]/[\text{S}]) + H_0$ against $H_0 + \log [\text{H}^+]$ is the parameter ϕ , while the intercept is the $\text{p}K_a$ of the lyonium ion (SH^+ , referred to infinite dilution in water). The value of ϕ expresses the response of the equilibrium

to changing acid concentration. A negative ϕ indicates that the log of the ionization ratio $[\text{SH}^+]/[\text{S}]$ increases, as the acid concentration increases, more rapidly than $-H_0$. A positive ϕ value indicates the reverse. The *Bunnett–Olsen equation* given above is a linear free–energy relationship (see Sec. 9.C) that pertains to acid–base equilibria. A corresponding equation that applies to kinetic data is

$$\log k_\psi + H_0 = \Phi(H_0 + \log [\text{H}^+]) + \log k_2^0$$

where k_ψ is the pseudo-first-order rate constant for a reaction of a weakly basic substrate taking place in an acidic solution and k_2^0 is the second-order rate constant at infinite dilution in water. In this case, ϕ characterizes the response of the reaction rate to changing acid concentration of the solvent. The *Bunnett–Olsen treatment* has also been applied to basic media, where, in a group of nine reactions in concentrated NaOMe solutions, no correlation

was found between reaction rates and either H_- or stoichiometric base concentration, but where the rates were successfully correlated by a linear free energy equation similar to those given above.¹⁴¹

A treatment partially based on the *Bunnett–Olsen treatment* is that of Bagno et al.,¹⁴² which formulates medium effects (changes in acidity of solvent) on acid–base equilibria. An appropriate equilibrium is chosen as reference, and the acidity dependence of other reactions compared with it, by use of the linear free energy equation

$$\log \frac{K'}{K_0} = m^* \log \frac{K}{K_0}$$

where the K values are the equilibrium constants for the following: K for the reaction under study in any particular medium; K' for the reference reaction in the same medium; K_0 for the reaction under study in a reference solvent; K'_0 for the reference reaction in the same reference solvent; and m^* is the slope of the relationship [corresponding to $(1 - \phi)$ of the *Bunnett–Olsen treatment*]. This equation has been shown to apply to many acid–base reactions.

Another type of classification system was devised by Bunnett¹⁴³ for reactions occurring in moderately concentrated acid solutions. $\log k_\psi + H_0$ is plotted against $\log a_{\text{H}_2\text{O}}$, where k_ψ is the pseudo-first-order rate constant for the protonated species and $a_{\text{H}_2\text{O}}$ is the activity of water. Most such plots are linear or nearly so. According to Bunnett, the slope of this plot w tells something about the mechanism. Where w is between -2.5 and 0 , water is not involved in the rate-determining step; where w is between 1.2 and 3.3 , water is a nucleophile in the rate-determining step; where w is between 3.3 and 7 , water is a proton-transfer agent. These rules hold for acids in which the proton is attached to oxygen or nitrogen.

A new acidity scale has been developed based on calorimetric measurement of *N*-methylimidazole and *N*-methylpyrrole in bulk solvents.¹⁴⁴ A revised version of this method was shown to give better results in some cases.¹⁴⁵ Another scale of solvent acidities was developed based on the hydrogen-bond donor acidities in aq DMSO.¹⁴⁶ Note that bond energies, acidities, and electron affinities are related in a thermodynamic cycle, and Fattahi and Kass¹⁴⁷ show that by measuring two of these quantities the third can be found.

8.D. ACID AND BASE CATALYSIS¹⁴⁸

Many reactions are catalyzed by acids or bases. Some are catalyzed by both acids and bases. In such cases, the catalyst is involved in a fundamental way in the mechanism. The

first step of such a reaction is nearly always a proton transfer between the catalyst and the substrate.

Reactions can be catalyzed by acid or base in two different ways, called *general* and *specific catalysis*. If the rate of an acid-catalyzed reaction run in a solvent (S) is proportional to its conjugate acid [SH⁺], the reaction is said to be subject to *specific acid catalysis*, the acid being the lyonium ion (SH⁺). The acid that is put into the solvent may be stronger or weaker than SH⁺, but the rate is proportional only to the [SH⁺] that is actually present in the solution derived from the equilibrium

The identity of HA is important only to the extent that it determines the position of equilibrium, and hence the [SH⁺]. Most measurements have been made in water, where SH⁺ is H₃O⁺.

In *general acid catalysis*, the rate is increased not only by an increase in [SH⁺], but also by an increase in the concentration of other acids (e.g., in water by phenols or carboxylic acids). These other acids increase the rate even when [SH⁺] is held constant. In this type of catalysis the strongest acids catalyze best, so that, in the example given, an increase in the phenol concentration catalyzes the reaction much less than a similar increase in [H₃O⁺]. This relationship between acid strength of the catalyst and its catalytic ability can be expressed by the *Brønsted catalysis equation*¹⁴⁹

$$\log k = \alpha \log K_{\alpha} + C$$

where k is the rate constant for a reaction catalyzed by an acid of ionization constant K_{α} . According to this equation, when $\log k$ is plotted against $\log K_{\alpha}$ for catalysis of a given reaction by a series of acids, a straight line should be obtained with slope and intercept C . Straight lines are obtained in many cases, but not always. The relationship usually fails when acids of different types are compared. For example, it is much more likely to hold for a group of substituted phenols than for a collection of acids that contains both phenols¹⁵⁰ and carboxylic acids. The Brønsted equation is another linear free energy relationship (see Sec. 9.C).

Analogously, there are *general* and *specific* (S[−] from an acidic solvent SH) *base-catalyzed reactions*. The Brønsted law for bases is

$$\log k = \beta \log K_b + C$$

The Brønsted equations relate a rate constant k to an equilibrium constant K_e . In Chapter 6, the *Marcus equation* was seen to relate a rate term (in that case ΔG^{\ddagger}) to an equilibrium term (ΔG°). When the Marcus treatment is applied to proton transfers¹⁵¹ between a carbon and an oxygen (or a nitrogen), the simplified¹⁵² equation (Sec. 6.I)

$$\Delta G^{\ddagger} = \Delta G_{\text{int}}^{\ddagger} + \frac{1}{2} \Delta G^{\circ} + \frac{(\Delta G^{\circ})^2}{16 \Delta G_{\text{int}}^{\ddagger}}$$

¹⁴⁹ See Klumpp, G.W. *Reactivity in Organic Chemistry*, Wiley, NY, **1982**, pp. 167–179; Bell, R.P. in Chapman, N. B.; Shorter, J. *Correlation Analysis in Chemistry: Recent Advances*, Plenum Press, **1978**, pp. 55–84; Kresge, A.J. *Chem. Soc. Rev.* **1973**, 2, 475.

¹⁵⁰ See Silva, P.J. *J. Org. Chem.* **2009**, 74, 914.

¹⁵¹ See Marcus, R.A. *J. Phys. Chem.* **1968**, 72, 891; Kresge, A.J. *Chem. Soc. Rev.* **1973**, 2, 475.

¹⁵² Omitting the work terms.

where

$$\Delta G_{\text{int}}^{\ddagger} = \frac{1}{2} (\Delta G_{\text{O},\text{O}}^{\ddagger} + \Delta G_{\text{C},\text{C}}^{\ddagger})$$

can be further simplified: Because proton transfers between oxygen and oxygen (or nitrogen and nitrogen) are much faster than those between carbon and carbon, $\Delta G_{(\text{O},\text{O})}^{\ddagger}$ is much smaller than $\Delta G_{(\text{C},\text{C})}^{\ddagger}$ and one can write¹⁵³

$$\Delta G^{\ddagger} = \frac{1}{2} \Delta G_{\text{C},\text{C}}^{\ddagger} + \frac{1}{2} \Delta G^{\circ} + \frac{(\Delta G^{\circ})^2}{8 \Delta G_{\text{C},\text{C}}^{\ddagger}}$$

Thus, if the carbon part of the reaction is kept constant and only the A of HA is changed (where A is an oxygen or nitrogen moiety), then ΔG^{\ddagger} is dependent only on ΔG° . Differentiation of this equation yields the Brønsted α :

$$\frac{d\Delta G^{\ddagger}}{d\Delta G^{\circ}} = \alpha = \frac{1}{2} \left(1 + \frac{\Delta G^{\circ}}{2 \Delta G_{\text{C},\text{C}}^{\ddagger}} \right)$$

The *Brønsted law* is therefore a special case of the *Marcus equation*.

A knowledge of whether a reaction is subject to general or specific acid catalysis supplies information about the mechanism. For any acid-catalyzed reaction we can write

If the reaction is catalyzed only by the specific acid SH^+ , it means that step 1 is rapid and step 2 is rate controlling. This means that an equilibrium has been rapidly established between A and the strongest acid present in the solution, namely, SH^+ (since this is the strongest acid that can be present in S). On the other hand, if step 2 is faster, there is no time to establish equilibrium and the rate-determining step must be step 1. This step is affected by all the acids that may be present, and the rate reflects the sum of the effects of each acid (general acid catalysis). General acid catalysis is also observed if the slow step is the reaction of a hydrogen-bond complex ($\text{A} \cdots \text{HB}$), since each complex reacts with a base at a different rate. A comparable discussion can be used for general and specific base catalysis.¹⁵⁴ Further information can be obtained from the values α and β in the Brønsted catalysis equations, since these are approximate measures of the extent of proton transfer in the transition state. In most cases, values of α and β are between 1 and 0. A value of α or β near 0 is generally taken to mean that the transition state resembles the reactants; that is, the proton has been transferred very little when the transition state has been reached. A value of α or β near 1 is taken to mean the opposite; that is, in the transition state the proton has been almost completely transferred. However, cases are known in which these generalizations are not followed,¹⁵⁵ and their theoretical basis has been challenged.¹⁵⁶ In general, the proton in the transition state lies closer to the weaker base.

8.E. LEWIS ACIDS AND BASES

At about the same time that Brønsted proposed his acid–base theory, Lewis put forth a broader theory. A base in the Lewis theory is the same as in the Brønsted one, namely, a compound with an available pair of electrons, either unshared or in a π orbital. However, a *Lewis base* donates electrons to an atom other than H or C.¹⁵⁷ A *Lewis acid* is any species with a vacant orbital.¹⁵⁸ In a Lewis acid–base reaction, the unshared pair of the base forms a covalent bond with the vacant orbital of the acid, as represented by the general equation

in which charges are not shown, since they may differ. A specific example is

In the Brønsted picture, the acid is a proton donor, but in the Lewis picture the proton itself is the acid since it has a vacant orbital. A Brønsted acid becomes, in the Lewis picture, the compound that gives up the actual acid. The advantage of the Lewis theory is that it correlates the behavior of many more processes. For example, AlCl_3 and BF_3 are Lewis acids because they have only six electrons in the outer shell and have room for eight. Lewis acids SnCl_4 and SO_3 have eight, but their central elements, not being in the first row of the periodic table, have room for 10 or 12. Other Lewis acids are simple cations, like Ag^+ . The simple reaction $A + \bar{B} \longrightarrow A-B$ is not very common in organic chemistry, but the scope of the Lewis picture is much larger because reactions of the types shown here, which are very common in organic chemistry, are also Lewis acid–base reactions. In fact, all reactions in which a covalent bond is formed through one species contributing a filled and the other a vacant orbital may be regarded as Lewis acid–base reactions. An *ab initio* analysis of the factors that determine Lewis versus Lowry–Brønsted acidity–basicity is available.¹⁵⁹

When a Lewis acid combines with a base to give a negative ion in which the central atom has a higher than normal valence, the resulting salt is called an *ate complex*.¹⁶⁰ Examples are

¹⁵⁷ Lewis bases are useful catalysts in organic synthesis. See Denmark, S.E.; Beutner, G.L. *Angew. Chem. Int. Ed.* **2008**, 47, 1560.

¹⁵⁸ For a monograph on Lewis acid–base theory, see Jensen, W.B. *The Lewis Acid–Base Concept*, Wiley, NY, **1980**. For a discussion of the definitions of Lewis acid and base, see Jensen, W.B. *Chem. Rev.* **1978**, 78, 1.

¹⁵⁹ Rauk, A.; Hunt, I.R.; Keay, B.A. *J. Org. Chem.* **1994**, 59, 6808.

¹⁶⁰ For a review of ate complexes, see Wittig, G. *Q. Rev. Chem. Soc.* **1966**, 20, 191.

Ate complexes are analogous to the onium salts formed when a Lewis base expands its valence, for example,

Far fewer quantitative measurements have been made of Lewis acid strength compared to that of Brønsted acids.¹⁶¹ A simple table of Lewis acidities based on some quantitative measurement (e.g., that given for Brønsted acids in Table 8.1) is not feasible because Lewis acidity depends on the nature of the base and any solvent that can function as a base. For example, lithium perchlorate functions as a weak Lewis acid in ether.¹⁶² Qualitatively, the following approximate sequence of acidity of Lewis acids of the type MX_n has been suggested, where X is a halogen atom or an inorganic radical: $\text{BX}_3 > \text{AlX}_3 > \text{FeX}_3 > \text{GaX}_3 > \text{SbX}_5 > \text{SnX}_4 > \text{AsX}_5 > \text{ZnX}_2 > \text{HgX}_2$.

8.E.i Hard–Soft Acids–Bases

The facility with which an acid–base reaction takes place depends, of course, on the strengths of the acid and the base. But it also depends on quite another quality, called the *hardness*¹⁶³ or *softness* of the acid or base.¹⁶⁴ Hard and soft acids and bases have these characteristics:

Soft Bases. The donor atoms are of low electronegativity and high polarizability, and are easy to oxidize. They hold their valence electrons loosely.

Hard Bases. The donor atoms are of high electronegativity and low polarizability, and are hard to oxidize. They hold their valence electrons tightly.

Soft Acids. The acceptor atoms are large, have low positive charge, and contain unshared pairs of electrons (*p* or *d*) in their valence shells. They have high polarizability and low electronegativity.

Hard Acids. The acceptor atoms are small, have high positive charge, and do not contain unshared pairs in their valence shells. They have low polarizability and high electronegativity.

A qualitative listing of the hardness of some acids and bases is given in Table 8.3.¹⁶⁵ The treatment has also been made quantitative,¹⁶⁶ with the following operational

definition:

$$\eta = \frac{I - A}{2}$$

In this equation, η , the *absolute hardness*, is half the difference between I , the ionization potential, and A , the electron affinity.¹⁶⁷ The softness (σ), is the reciprocal of η . Values of η for some molecules and ions are given in Table 8.4.¹⁶⁸ Note that the proton, which is involved in all Brønsted acid–base reactions, is the hardest acid listed, with $\eta = \infty$ (it has no ionization potential). The above equation cannot be applied to anions, because electron affinities cannot be measured for them. Instead, the assumption is made that η for an anion X⁻ is the same as that for the radical X[•].¹⁶⁹ Other methods are also needed to apply the treatment to polyatomic cations.¹⁶⁹

Once acids and bases have been classified as hard or soft, a simple rule can be given: *hard acids prefer to bond to hard bases, and soft acids prefer to bond to soft bases [the HSAB (hard–soft acid–base) principle]*.¹⁷⁰ The rule has nothing to do with acid or base *strength* but merely says that the product A—B will have extra stability if both A and B are hard or if both are soft. Another rule is that a soft Lewis acid and a soft Lewis base tend to form a covalent bond, while a hard acid and a hard base tend to form ionic bonds.

One application of the first rule given above is found in complexes between alkenes or aromatic compounds and metal ions (see above). Alkenes and aromatic rings are soft bases and should prefer to complex with soft acids. Thus, Ag⁺, Pt²⁺, and Hg²⁺ complexes are common, but complexes of Na⁺, Mg²⁺, or Al³⁺ are rare. Chromium complexes are also common, but in such complexes the chromium is in a low or zero oxidation state (which

^cFor singlet state.

softens it) or attached to other soft ligands. Another application is the reaction:

The HSAB principle predicts that the equilibrium should lie to the right, because the hard acid CH_3CO^+ should have a greater affinity for the hard base (RO^-) than for the soft base (RS^-). Indeed, thiol esters are easily cleaved by RO^- or hydrolyzed by dilute base (^-OH is also a hard base).¹⁷¹ Another application of the rule is discussed in Section 10.G.ii.¹⁷² The

HSAB principles have been applied to analyze the reactivity of ketone and ester enolate anions,¹⁷³ and in analyzing catalyst selectivity in synthesis.¹⁷⁴

8.F. THE EFFECTS OF STRUCTURE ON THE STRENGTHS OF ACIDS AND BASES¹⁷⁵

The structure of a molecule can affect its acidity or basicity in a number of ways. Unfortunately, in most molecules two or more of these effects (as well as solvent effects) are operating, and it is usually very difficult or impossible to say how much each effect contributes to the acid or base strength.¹⁷⁶ Small differences in acidity or basicity between similar molecules are particularly difficult to interpret. It is well to be cautious when attributing them to any particular effect.

1. *Field Effects.* These effects were discussed in Section 1.I. In general, changes in substituents can have an effect on acidity. As an example of the influence of field effects on acidity, compare the acidity of acetic acid and 2-nitroacetic acid:

The only difference in the structure of these molecules is the substitution of NO₂ for H. Since NO₂ is a strongly electron-withdrawing group, it withdraws electron density from the negatively charged COO[−] group in the anion of 2-nitroacetic acid (compared with the anion of acetic acid). As the pK_a values indicate, 2-nitroacetic acid is ~1000 times stronger than acetic acid.¹⁷⁷ Any effect that results in electron withdrawal from a negatively charged center (−I effect) is a stabilizing effect because it spreads the charge. Thus, −I groups increase the acidity of uncharged acids (e.g., acetic) because they spread the negative charge of the anion. However, −I groups also increase the acidity of any acid, no matter what the charge. For example, if the acid has a charge of +1 (and its conjugate base is therefore uncharged), a −I group destabilizes the positive center (by increasing and concentrating the positive charge) of the acid, a destabilization that will be relieved when the proton is lost. In general, *groups that withdraw electrons by the field effect increase acidity and decrease basicity, while electron-donating groups act in the opposite direction.* Another example is the molecule (C₆F₅)₃CH, which has three strongly electron-withdrawing C₆F₅ groups and a pK_a of 16,¹⁷⁸ compared with

^aSee Ref. 47.

Ph₃CH, with a pK_a of 31.5 (Table 8.1), an acidity enhancement of $\sim 10^{15}$. Table 8.5 shows pK_a values for some acids. An approximate idea of field effects can be obtained from this table. In the case of the chlorobutyric acids, the effect decreases with distance. It must be remembered, however, that field effects are not the sole cause of the acidity differences noted and that in fact solvation effects may be more important in many cases (see Sec. 8.G).¹⁷⁹ The influence of various substituents on the acidity of acetic acid has been calculated,¹⁸⁰ Substituent effects for weak acids (e.g., phenols and benzyl alcohols) have been discussed.¹⁸¹

Field effects are important in benzoic acid derivatives, and the pK_a of the acid will vary with the nature and placement of the “X” group in **6**.¹⁸² The pK_a of 3-OMe (**6**) is 5.55, but 4-OMe (**6**) is 6.02 in 50% aq methanol,¹⁸³ compared with a pK_a of 5.67 when X = H. When X = 4-NO₂, the pK_a is 4.76 and 4-Br is 5.36.¹⁷² The pK_a of 2,6-diphenylbenzoic acid is 6.39.¹⁸⁴

2. *Resonance Effects.* Resonance that stabilizes a base, but not its conjugate acid, results in the acid having a higher acidity than otherwise expected and vice versa. An example is found in the higher acidity of carboxylic acids¹⁸⁵ compared with primary alcohols.

The RCOO^- ion is stabilized by resonance not available to the RCH_2O^- ion (or to RCOOH).¹⁸⁶ Note that the RCOO^- is stabilized not only by the fact that there are 2 equiv canonical forms, but also by the fact that the negative charge is spread over both oxygen atoms, and is therefore less concentrated than in RCH_2O^- . The same effect is found in other compounds containing a $\text{C}=\text{O}$ or $\text{C}\equiv\text{N}$ group. Thus amides (RCONH_2) are more acidic than amines (RCH_2NH_2); esters ($\text{RCH}_2\text{COOR}'$) more than ethers ($\text{RCH}_2\text{CH}_2\text{OR}'$); and ketones ($\text{RCH}_2\text{COR}'$) more than alkanes ($\text{RCH}_2\text{CH}_2\text{R}'$) (Table 8.1). The effect is enhanced when two carbonyl groups are attached to the same carbon (because of additional resonance and spreading of charge); for example, β -keto esters (see **7**) are more acidic than simple ketones or carboxylic esters (Table 8.1). Compounds such as (**7**) are generically referred to as *active methylene compounds* ($\text{X}-\text{CH}_2-\text{X}$), where X is an electron-withdrawing group (a carbonyl, cyano, sulfonyl, etc.).¹⁸⁷ The influence of substituents in the α -position of substituted ethyl acetate derivatives has been studied.¹⁸⁸ Extreme examples of this effect are found in the molecules tricyanomethane $[(\text{NC})_3\text{CH}]$, with a $\text{p}K_a$ of -5 (Table 8.1), and 2-(dicyanomethylene)-1,1,3,3-tetracyanopropene $(\text{NC})_2\text{C}=\text{C}[\text{CH}(\text{CN})_2]_2$, whose first $\text{p}K_a$ is below -8.5 and whose second $\text{p}K_a$ is -2.5 .

Resonance effects are also important in aromatic amines. *m*-Nitroaniline is a weaker base than aniline, a fact that can be accounted for by the $-I$ effect of the nitro group. But *p*-nitroaniline is weaker still, though the $-I$ effect should be less because of the greater distance. This result is obtained by taking the canonical form **A** into account. Because **A** contributes to the resonance hybrid,¹⁸⁹ the electron density of

¹⁸⁵ See Exner, O.; Čárský, P. *J. Am. Chem. Soc.* **2001**, *123*, 9564. See also, Liptak, M.D.; Shields, G.C. *J. Am. Chem. Soc.* **2001**, *123*, 7314.

¹⁸⁶ It has been contended that resonance delocalization plays only a minor role in the increased strength of carboxylic acids compared to alcohols, and the "... higher acidity of acids arises principally because the electrostatic potential of the acidic hydrogens is more positive in the neutral acid molecule...": Siggel, M.R.; Streitwieser, Jr., A.; Thomas, T.D. *J. Am. Chem. Soc.* **1988**, *110*, 8022; Thomas, T.D.; Carroll, T.X.; Siggel, M.R. *J. Org. Chem.* **1988**, *53*, 1812. For contrary views, see Exner, O. *J. Org. Chem.* **1988**, *53*, 1810; Perrin, D.D. *J. Am. Chem. Soc.* **1991**, *113*, 2865. See also, Godfrey, M. *Tetrahedron Lett.* **1990**, *31*, 5181.

¹⁸⁷ Copper complexes of active methylene compounds show large $\text{p}K_a$ shifts. See Zhong, Z.; Postnikova, B.J.; Hanes, R.E.; Lynch, V.M.; Anslyn, E.V. *Chemistry: European J.* **2005**, *11*, 2385.

¹⁸⁸ Goumont, R.; Magnier, E.; Kizilian, E.; Terrier, F. *J. Org. Chem.* **2003**, *68*, 6566.

¹⁸⁹ See, however, Krygowski, T.M.; Maurin, J. *J. Chem. Soc. Perkin Trans. 2* **1989**, 695.

the unshared pair is lower in *p*-nitroaniline than in *m*-nitroaniline, where a canonical form (e.g., **A**) is impossible. Note that the pK_a values reported are those of the conjugate acid, the ammonium ion.¹⁹⁰ The basicity is lower in the para compound for two reasons, both caused by the same effect: (1) the unshared pair is less available for attack by a proton, and (2) when the conjugate acid is formed, the resonance stabilization afforded by **A** is no longer available because the previously unshared pair is now being shared by the proton. The acidity of phenols is affected by substituents in a similar manner.¹⁹¹

In general, resonance effects lead to the same result as field effects. That is, here too, electron-withdrawing groups increase acidity and decrease basicity, and electron-donating groups act in the opposite manner. As a result of both resonance and field effects, charge dispersal leads to greater stability.

3. *Periodic Table Correlations.* When comparing Brønsted acids and bases that differ in the position of an element in the periodic table:

- Acidity increases and basicity decreases in going from left to right across a row of the periodic table. Thus acidity increases in the order $\text{CH}_4 < \text{NH}_3 < \text{H}_2\text{O} < \text{HF}$, and basicity decreases in the order $^-\text{CH}_3 > ^-\text{NH}_2 > ^-\text{OH} > \text{F}^-$. This behavior can be explained by the increase in electronegativity upon going from left to right across the table. It is this effect that is responsible for the great differences in acidity between carboxylic acids, amides, and ketones: $\text{RCOOH} \gg \text{RCONH}_2 \gg \text{RCOCH}_3$.
- Acidity increases and basicity decreases in going down a column of the periodic table, despite the decrease in electronegativity. Thus acidity increases in the order $\text{HF} < \text{HCl} < \text{HBr} < \text{HI}$ and $\text{H}_2\text{O} < \text{H}_2\text{S}$, and basicity decreases in the order $\text{NH}_3 > \text{PH}_3 > \text{AsH}_3$. This behavior is related to the size of the species involved. Thus, for example, F^- , which is much smaller than I^- , attracts a proton much more readily because its negative charge occupies a smaller volume, and is therefore more concentrated (note that F^- is also much harder than I^- and is thus more attracted to the hard proton; see Sec. 8.E). This rule does not always hold for positively charged acids. Thus, although the order of acidity for the group 16 hydrides is $\text{H}_2\text{O} < \text{H}_2\text{S} < \text{H}_2\text{Se}$, the acidity order for the positively charged ions is $\text{H}_3\text{O}^+ > \text{H}_3\text{S}^+ > \text{H}_3\text{Se}^+$.¹⁹²

Lewis acidity is also affected by periodic table considerations. In comparing acid strengths of Lewis acids of the form MX_n ¹⁶¹:

- Acids that require only one electron pair to complete an outer shell are stronger than those that require two. Thus GaCl_3 is stronger than ZnCl_2 . This results from the relatively smaller energy gain in adding an electron pair that does not

¹⁹⁰ Smith, J.W. in Patai, S. *The Chemistry of the Amino Group*; Wiley, NY, **1968**, pp. 161–204.

¹⁹¹ Liptak, M.D.; Gross, K.C.; Seybold, P.G.; Feldus, S.; Shields, G.C. *J. Am. Chem. Soc.* **2002**, *124*, 6421.

complete an outer shell and from the buildup of negative charge if two pairs come in.

- d. Other things being equal, the acidity of MX_n decreases in going down the periodic table because as the size of the molecule increases, the attraction between the positive nucleus and the incoming electron pair is weaker. Thus BCl_3 is a stronger acid than AlCl_3 .¹⁹³
4. *Statistical Effects.* In a symmetrical diprotic acid, the first dissociation constant is twice as large as expected since there are 2 equiv ionizable hydrogens, while the second constant is only one-half as large as expected because the conjugate base can accept a proton at 2 equiv sites. So K_1/K_2 should be 4, and approximately this value is found for dicarboxylic acids where the two groups are sufficiently far apart in the molecule that they do not influence each other. A similar argument holds for molecules with 2 equiv basic groups.¹⁹⁴
5. *Hydrogen Bonding.* Internal hydrogen bonding can greatly influence acid or base strength. For example, the $\text{p}K$ for *o*-hydroxybenzoic acid is 2.98, while the value for the para isomer is 4.58. Internal hydrogen bonding between the ^-OH and COO^- groups of the conjugate base of the ortho isomer stabilizes it and results in an increased acidity.
6. *Steric Effects.* The proton itself is so small that direct steric hindrance is seldom encountered in proton transfers. Steric effects are much more common in Lewis acid–base reactions in which larger acids are used. Spectacular changes in the order of base strength have been demonstrated when the size of the acid was changed. Table 8.6 shows the order of base strength of simple amines when compared against acids of various size.¹⁹⁵ It can be seen that the usual order of basicity of amines (when the proton is the reference acid) can be completely inverted by using a large enough acid. The strain caused by formation of a covalent bond when the two atoms involved each have three large groups is called *face strain* or *F strain*.

Steric effects can indirectly affect acidity or basicity by affecting the resonance (Sec. 2.F). For example, *o*-*tert*-butylbenzoic acid is ~ 10 times as strong as the para isomer, because the carboxyl group is forced out of the plane by the *tert*-butyl group. Indeed, virtually all ortho benzoic acids are stronger than the corresponding para isomers, regardless of whether the group on the ring is electron donating or electron withdrawing.

Steric effects can also be caused by other types of strain. 1,8-Bis(diethylamino)-2,7-dimethoxynaphthalene (**8**) is an extremely strong base for a tertiary amine ($\text{p}K_a$ of the conjugate acid = 16.3; cf. *N,N*-dimethylaniline, $\text{p}K_a = 5.1$), but proton transfers to and from the nitrogen are exceptionally slow; slow enough to be

¹⁹³ Note that Lewis acidity *decreases*, whereas Brønsted acidity *increases*, going down the table. There is no contradiction here when we remember that in the Lewis picture the actual acid in all Brønsted acids is the same, namely, the proton. In comparing, say, HI and HF, we are not comparing different Lewis acids but only how easily F^- and I^- give up the proton.

¹⁹⁴ The effect discussed here is an example of a symmetry factor. For an extended discussion, see Ebersson, L. in Patai, S. *The Chemistry of Carboxylic Acids and Esters*, Wiley, NY, **1969**, pp. 211–293.

followed by a UV spectrophotometer.¹⁹⁶ Compound **8** is severely strained because the two nitrogen lone pairs are forced to be near each other.¹⁹⁷ Protonation relieves the strain: one lone pair is now connected to a hydrogen, which forms a hydrogen

bond to the other lone pair (shown in **9**). The same effects are found in 4,5-bis(dimethylamino)fluorene (**10**)¹⁹⁸ and 4,5-bis(dimethylamino)phenanthrene (**11**).¹⁹⁹ Compounds (e.g., **8**, **10**, and **11**), are known as *proton sponges*.²⁰⁰ The basicity of a proton sponge has been calculated as the sum of the proton affinity¹⁵² of an appropriate reference monoamine, the strain released on protonation, and the energy of the intramolecular hydrogen bond formed on protonation.²⁰¹ Another type of proton sponge is quino[7,8-*h*]quinoline (**12**).²⁰² Protonation of this compound also gives a stable mono protonated ion similar to **9**, but the steric hindrance found in **8**, **10**, and **11** is absent. Therefore, **12** is a much stronger base than quinoline (**13**) (p*K_a* values of the conjugate acids are 12.8 for **12** and 4.9 for **13**), but proton transfers are not abnormally slow. A cyclam-like macrocyclic tetramine (**15**) was prepared by a coupling reaction of bispidine, and was shown to be a new class of

proton sponge.²⁰³

Chiral Lewis acids are known. Indeed, an air stable and storable chiral Lewis acid catalyst has been prepared, a chiral zirconium catalyst combined with molecular sieves powder.²⁰⁴ Association of a bulky silicon group with the bis (trifluoromethanesulfonyl)imide (known as triflimide) anion leads to enhancement of the electrophilic character of R_3SiNTf_2 . The presence of a chiral substituent derived from (–)-myrtenal on the silicon atom led to a chiral silicon Lewis acid.²⁰⁵

Another type of steric effect is the result of an entropy effect. The compound 2,6-di-*tert*-butylpyridine is a weaker base than either pyridine or 2,6-dimethylpyridine.²⁰⁶ The reason is that the conjugate acid **14** is less stable than the conjugate acids of nonsterically hindered pyridines. In all cases, the conjugate acids are hydrogen bonded to a water molecule, but in the case of **14** the bulky *tert*-butyl groups restrict rotations in the water molecule, lowering the entropy.²⁰⁷

The conformation of a molecule can also affect its acidity. The following pK_a values were determined for compounds **16–19**.²⁰⁸

Since ketones are stronger acids than carboxylic esters (Table 8.1), it is not surprising that **16** is a stronger acid than **18**.²⁰⁹ A comparison of **16** with cyclic diketone **17** shows an increase in acidity of only 2.1 pK units, while a comparison of **18** with cyclic diester **19** shows an increase of 8.6 units. Indeed, **19** (called *Meldrum's acid*) is an unusually strong acid for a 1,3-diester. In order to account for this very large effect of a ring, MO calculations were carried out for two conformations of methyl acetate and of its enolate ion.²¹⁰ Loss of a proton is easier by ~ 5 kcal mol^{–1} (21 kJ mol^{–1}) for the syn than for the anti conformer of the ester.

In an acyclic molecule like **18**, the preferred conformations are anti, but in *Meldrum's acid* (**19**) the conformation on both sides is constrained to be syn.

Facial differences in proton reactivity can lead to enantioselective deprotonation. Enantioselective deprotonation is also achieved by using a chiral base and/or a chiral complexing agent. Enantioselective deprotonation in cyclic ketones,²¹¹ and with heterodimer bases has been studied.²¹² When a Lewis acid coordinates to a base, the resulting complex can have conformational properties that influence reactivity. Coordination of SnCl_4 with aldehydes and esters, for example, leads to a complex where the conformation is determined by interactions of the $\text{C}=\text{O} \cdots \text{SnCl}_4$ unit with substituents attached to the carbonyl.²¹³

7. *Hybridization*. An s orbital has a lower energy than a p orbital. Therefore, the more s character a hybrid orbital contains, the lower the energy of that orbital. It follows that a carbanion at an sp carbon is more stable than a corresponding carbanion at an sp^2 carbon. Thus $\text{HC}\equiv\text{C}^-$, which has more s character in its unshared pair than $\text{CH}_2=\text{CH}^-$ or CH_3CH_2^- (sp vs sp^2 vs sp^3 , respectively), is a much weaker base. This explains the relatively high acidity of acetylenes and HCN. Another example is that alcohol and ether oxygen atoms, where the unshared pair is sp^3 , are more strongly basic than carbonyl oxygen atoms, where the unshared pair is sp^2 (Table 8.1).

An understanding of the reactivity of bases arises from the study of their structures in solution and in the crystalline state. Due to the importance of dialkylamide bases, there is a significant body of work, led by independent work by Williard and by Collum, that has attempted to understand the structures of these reactive molecules. It is clear that the dialkylamide bases are aggregates. Note that the simplest member of the amide base family, lithium amide (LiNH_2), was shown to be monomeric and unsolvated, as determined using a combination of gas-phase synthesis and millimeter/submillimeter-wave spectroscopy.²¹⁴ Both monomeric LiNH_2 and LiNMe_2 are planar.²¹⁵ Lithium diisopropylamide (LiNiPr_2 , LDA) was isolated from a THF solution and X-ray crystallography revealed a dimeric structure (**20**; $\text{R} = i\text{Pr}$, $\text{S} = \text{THF}$) in the solid state.²¹⁶ Lithium diisopropylamide was also shown to be a dimer in solutions of THF²¹⁷ and/or HMPA (see **20**, $\text{R} = i\text{Pr}$ and $\text{S} = \text{THF}$, HMPA).²¹⁸ In the presence of HMPA, many derivatives of **20** tend to be mixed aggregates.²¹⁹ Extremely hindered LiNR_2 ($\text{R} = 2\text{-adamantyl}$) are

monomeric under all conditions.²²⁰ In hydrocarbon solvents, lithium tetramethylpiperidide [LTMP, $\text{RR}'\text{NLi}$, where $\text{RR}' = -\text{CMe}_2(\text{CH}_2)_3\text{C}(\text{Me}_2)-$] forms cyclic trimers and tetramers, with the tetrameric species predominating.²²¹ In THF, lithium hexamethyldisilazide [LHMDS, $(\text{Me}_3\text{Si})_2\text{NLi}$] forms a five-coordinate tetrasolvate $[(\text{Me}_3\text{Si})_2\text{NLi}(\text{thf})_4]$,²²² but in ether there is an equilibrium mixture of monomer and dimer.²²³ A review is available that discusses the solution structures of amide bases LiNR_2 .²²⁴ Chiral lithium amide bases are known and they show similar behavior in solution.²²⁵ Chelation effects are common in enantioenriched amide bases, which also form aggregates.²²⁶ The aggregation state of lithium phenylacetonitrile has been studied.²²⁷ Dianion aggregates can be generated, and in the case of the lithiation reaction of *N*-silyl allylamine, X-ray structure determination showed the presence of three uniquely different aggregates.²²⁸ A mixed aggregate is formed when the lithium enolate of a ketone is mixed with a lithium amide.²²⁹

Similar information is available for other bases. Lithium phenoxide (LiOPh) is a tetramer in THF.²³⁰ Lithium 3,5-dimethylphenoxide is a tetramer in ether, but addition of HMPA leads to dissociation to a monomer.²³¹

Enolate anions are nucleophiles in reactions with alkyl halides (Reaction **10-68**), with aldehydes and ketones (Reactions **16-34** and **16-36**) and with acid derivatives (Reaction **16-85**). Enolate anions are also bases, reacting with water, alcohols and other protic solvents, and even the carbonyl precursor to the enolate anion. Enolate anions exist as aggregates, and the effect of solvent on aggregation and reactivity of lithium enolate anions has been studied.²³² Alkyl substitution has a significant influence on the energetics of enolate anions.²³³

8.G. THE EFFECTS OF THE MEDIUM ON ACID AND BASE STRENGTH

Structural features are not the only factors that affect acidity or basicity. The same compound can have its acidity or basicity changed when the reaction conditions are changed. The effect of temperature (Sec. 8.A) has already been mentioned. More important is the effect of the solvent, which can exert considerable influence on acid and base strengths by differential solvation.²³⁴ If a base is more solvated than its conjugate acid, its stability is increased relative to the conjugate acid. For example, Table 8.6 shows that in reactions with a proton, where steric effects are absent, methylamine is a stronger base than ammonia and dimethylamine is stronger still.²³⁵ These results are easily explainable if one assumes that methyl groups are electron donating. However, trimethylamine, which should be even stronger, is a weaker base than dimethylamine or methylamine. This apparently anomalous behavior can be explained by differential hydration.²³⁶ Thus, NH_4^+ is much better hydrated (by hydrogen bonding to the water solvent) than NH_3 because of its positive charge.²³⁷ It has been estimated that this effect contributes ~ 11 pK units to the base strength of ammonia.²³⁸ When methyl groups replace hydrogen, this difference in hydration decreases²³⁹ until, for trimethylamine, it contributes only ~ 6 pK units to the base strength.¹⁹⁵ Thus two effects act in opposite directions, the field effect increasing the basicity as the number of methyl groups increases and the hydration effect decreasing it. Taken together, the strongest base is dimethylamine and the weakest is ammonia in solution. If alkyl groups are electron donating, one would expect that in the gas phase,²⁴⁰ where the solvation effect does not exist, the basicity order of amines toward the proton should be $\text{R}_3\text{N} > \text{R}_2\text{NH} > \text{RNH}_2 > \text{NH}_3$, and this has indeed been confirmed, for $\text{R} = \text{Me}$, as well as $\text{R} = \text{Et}$ and Pr .²⁴¹ Aniline too, in the gas phase, is a stronger base than NH_3 ,²⁴² so

its much lower basicity in aqueous solution (pK_a of PhNH_3^+ 4.60 compared with 9.24 for aq NH_4^+) is caused by similar solvation effects and not by resonance and field electron-withdrawing effects of a phenyl group. Similarly, pyridine²⁴³ and pyrrole²⁴⁴ are both much less basic than NH_3 in aqueous solution (pyrrole²⁴⁵ is neutral in aqueous solution), but *more* basic in the gas phase. Care must be taken in attributing relative acidities or basicities to any particular effect. Solvent has a significant influence on the *Hammett reaction constant* (Sec. 11.D), which influences the acidity of substituted benzoic acids.²⁴⁶

In the case of Lewis acids, protic solvents (e.g., water or alcohol) can strongly influence their reactivity, cause it to react via an alternative path to the one desired, or even cause decomposition. Rare earth metal triflates have been used to develop water tolerant Lewis acids that can be used in many organic reactions.²⁴⁷

For simple alcohols, the order of gas-phase *acidity* is completely reversed from that in aqueous solution. In solution, the acidity is in the order $\text{H}_2\text{O} > \text{MeCH}_2\text{OH} > \text{Me}_2\text{CHOH} > \text{Me}_3\text{COH}$, but in the gas phase the order is precisely the opposite.²⁴⁸ Once again solvation effects can be invoked to explain the differences. Comparing the two extremes, H_2O and Me_3COH , we see that the OH^- ion is very well solvated by water while the bulky Me_3CO^- is much more poorly solvated because the water molecules cannot get as close to the oxygen. Thus in solution H_2O gives up its proton more readily. When solvent effects are absent, however, the intrinsic acidity is revealed and Me_3COH is a stronger acid than H_2O . This result demonstrates that simple alkyl groups cannot be simply regarded as electron donating. If methyl is an electron-donating group, then Me_3COH should be an intrinsically weaker acid than H_2O , yet it is stronger. A similar pattern is found with carboxylic acids, where simple aliphatic acids (e.g., propanoic) are stronger than acetic acid in the gas phase,²⁴⁹ although weaker in aqueous solution (Table 8.5). The evidence in these and other cases²⁵⁰ is that alkyl groups can be electron donating when connected to unsaturated systems, but may have either no effect or may actually be electron withdrawing in other systems. It appears that the intrinsic gas-phase acidity order of alcohols as well as the basicity order of amines is due to the effect of alkyl groups, because of their polarizability, which can spread both positive and negative charges.²⁵¹ It has been calculated that even in the case of alcohols the field effects of the alkyl groups are still operating normally, but are swamped by the greater polarizability effects.²⁵² Polarizability effects on anionic centers

are a major factor in gas-phase acid–base reactions.²⁵³ It has been shown (by running reactions on ions that are solvated in the gas phase) that solvation by even one molecule of solvent can substantially affect the order of basicities.²⁵⁴

The effect on the orientation of solvent molecules when an acid or base is converted to its conjugate is an important aspect of solvent effects. For example, consider an acid (RCOOH) converted to RCOO⁻ in aqueous solution. The solvent molecules, by hydrogen bonding, arrange themselves around the COO⁻ group in a much more orderly fashion than they had been arranged around the COOH group (because they are more strongly attracted to the negative charge). This leads to a considerable loss of freedom and a decrease in entropy. Thermodynamic measurements show that for simple aliphatic and halogenated aliphatic acids in aqueous solution at room temperature, the entropy ($T\Delta S$) usually contributes much more to the total free energy change ΔG than does the enthalpy ΔH .²⁵⁵ Two examples are shown in Table 8.7.²⁵⁶ Resonance and field effects of functional groups therefore affect the acidity of RCOOH in two distinct ways. They affect the enthalpy (electron-withdrawing groups increase acidity by stabilizing RCOO⁻ by charge dispersal), but they also affect the entropy (by lowering the charge on the COO⁻ group and by changing the electron-density distribution in the COOH group, electron-withdrawing groups alter the solvent orientation patterns around both the acid and the ion, and consequently change ΔS).

A change from a protic to an aprotic solvent can also affect the acidity or basicity, since there is a difference in solvation of anions by a protic solvent (which can form hydrogen bonds) and an aprotic one.²⁵⁷ The effect can be extreme: In DMF, picric acid is stronger than HBr,²⁵⁸ though in water HBr is far stronger. This particular result can be attributed to size. That is, the large ion (O₂N)₃C₆H₂O⁻ is better solvated by DMF than the smaller

ion Br^- .²⁵⁹ The ionic strength of the solvent also influences acidity or basicity, since it has an influence on activity coefficients.

In summary, solvation can have powerful effects on acidity and basicity. In the gas phase, the effects discussed in Section 8.F, especially resonance and field effects, operate unhindered by solvent molecules. Electron-withdrawing groups generally increase acidity (and decrease basicity); electron-donating groups act in the opposite way. In solution, especially aqueous solution, these effects still largely persist (which is why $\text{p}K$ values in Table 8.5 do largely correlate with resonance and field effects), but in general are much weakened, and occasionally reversed.¹⁷⁹

Effects of Structure and Medium on Reactivity

When the equation for a reaction of, say, carboxylic acids, is written, it is customary to use the formula RCOOH , where R is a generic alkyl group, which implies that all carboxylic acids undergo the reaction. Since most compounds with a given functional group usually give more or less the same reactions, the custom is useful, and the practice is used in this text. It allows a large number of individual reactions to be classified together and serves as an aid both for memory and understanding. Nevertheless, it must be borne in mind that a given functional group does not always react the same way, regardless of what molecule it is a part of. In other words, a reaction at the functional group is influenced by the rest of the molecule. This influence may be great enough to stop the reaction completely or to make it take an entirely different course. Even when two compounds with the same functional group undergo the same reaction, the rates and/or the positions of equilibrium are usually different, sometimes slightly, sometimes greatly, depending on the structures of the compounds. The greatest variations may be expected when additional functional groups are present.

The effects of structure on reactivity can be divided into three major types: field, resonance (or mesomeric), and steric.¹ In most cases, two or all three of these are operating, and it is usually not easy to tell how much of the rate enhancement (or decrease) is caused by each of the three effects.

9.A. RESONANCE AND FIELD EFFECTS

It is often particularly difficult to separate resonance and field effects; they are frequently grouped together under the heading of *electrical effects*.² Field effects were discussed in Section 1.I. Table 1.3 contains a list of some $+I$ and $-I$ groups. As for resonance effects, in Section 2.F it was shown how the electron density distribution in aniline is not the same as it would be if there were no resonance interaction between the ring and the NH_2 group. Most groups that contain an unshared pair on an atom connected to an unsaturated system display a similar effect; that is, the electron density on the group is less than expected, and the density on the unsaturated system is greater. Such groups are said to be electron donating by the

^aArgon (Ar) appears in both lists because it is capable of both kinds of effect.

resonance effect ($+M$ groups). Alkyl groups, which do not have an unshared pair, are also $+M$ groups, presumably because of hyperconjugation (see Sec. 2.M).

On the other hand, groups that have a multiple-bonded electronegative atom directly connected to an unsaturated system are $-M$ groups. In such cases, canonical forms can be drawn in which electrons are delocalized from the unsaturated system into the group, as in nitrobenzene (**1**). Table 9.1 contains a list of some $+M$ and $-M$ groups.

The resonance effect of a group, whether $+M$ or $-M$, operates only when the group is directly connected to an unsaturated system, so that, for example, in explaining the effect of the CH_3O group on the reactivity of the $COOH$ in $CH_3OCH_2CH_2COOH$, only the field effect of the CH_3O need be considered. This is one way of separating the two effects. In *p*-methoxybenzoic acid both effects must be considered. The field effect operates through space, solvent molecules, or the σ bonds of a system, while the resonance effect operates through π electrons.

It must be emphasized once again that neither by the resonance nor by the field effect are any electrons actually being donated or withdrawn, though these terms are convenient (and we will use them). As a result of both effects, the electron-density distribution is not the same as it would be without the effect (see Sec. 1.I, 2.F). Complicating the study of these effects on the reactivity of compounds is the fact that a given group may have an effect in the transition state that is considerably more or less than it has in the molecule that does not react.

In the alkaline hydrolysis of aromatic amides (Reaction 16-60), the rate-determining step is the attack of hydroxide ion at the carbonyl carbon. The conversion of **2** to **3**

TABLE 9.2 Relative Rates of Reaction of RBr with Ethanol^a

R	Relative Rate
CH ₃	17.6
CH ₃ CH ₂	1
CH ₃ CH ₂ CH ₂	0.28
(CH ₃) ₂ CHCH ₂	0.030
(CH ₃) ₃ CCH ₂	4.2×10^{-6}

^aSee Ref. 3.

illustrates the nature of electrical effects (resonance and field) on reactivity. In the transition state, which has a structure somewhere between that of the starting amide (2) and the intermediate (3), the electron density on the carbonyl carbon is increased. Therefore, electron-withdrawing groups ($-I$ or $-M$) on the aromatic ring will lower the free energy of the transition state (by spreading the negative charge). These groups have much less effect on the free energy of 2. Since G is lowered for the transition state, but not substantially for 2, ΔG^\ddagger is lowered and the reaction rate is increased (Chapter 6). Conversely, electron-donating groups ($+I$ or $+M$) should decrease the rate of this reaction. Of course, many groups are $-I$ and $+M$, and for these it is not always possible to predict which effect will predominate.

9.B. STERIC EFFECTS

It occasionally happens that a reaction proceeds much faster or much slower than expected on the basis of electrical effects alone. In these cases, it can often be shown that steric effects have a significant influence on the rate. For example, Table 9.2 lists relative rates for the S_N2 ethanolysis of certain alkyl halides (see Sec. 10.A.i).³ All these compounds are primary bromides; the branching is on the second carbon, so that field-effect differences should be small. As Table 9.2 shows, the rate decreases with increasing branching and reaches a very low value for neopentyl bromide. This reaction is known to involve an attack by the nucleophile from a position opposite to that of the bromine (see Sec. 10.A.i). The great decrease in rate can be attributed to *steric hindrance* in the transition state of the reaction, which makes attack of the nucleophile more difficult. Another example of steric hindrance is found in 2,6-disubstituted benzoic acids, which are difficult to esterify no matter what the resonance or field effects of the groups in the 2 or the 6 positions. Similarly, once 2,6-disubstituted benzoic acids are esterified, the esters are difficult to hydrolyze.

Not all steric effects decrease reaction rates. In the hydrolysis of RCl by an S_N1 mechanism (see Sec. 10.A.ii), the first step, which is rate determining, involves ionization of the alkyl chloride to a carbocation:

³ Hughes, E.D. *Q. Rev. Chem. Soc.* **1948**, 2, 107.

TABLE 9.3 Rates of Hydrolysis of Tertiary Alkyl Chlorides at 25 °C in 80% Aqueous Ethanol^a

^aSee Ref. 6.

The central carbon in the alkyl chloride is sp^3 hybridized, with angles of $\sim 109.5^\circ$, but when it is converted to the carbocation, the hybridization becomes sp^2 and the preferred angle is 120° . If the halide is tertiary and the three alkyl groups are large enough, they will be pushed together by the enforced tetrahedral angle, resulting in strain (see Sec. 4.Q.iv). This type of strain is called *B strain*⁴ (for back strain), and can be relieved by ionization to the carbocation.⁵

The rate of ionization (and hence the solvolysis rate) of a molecule in which there is B strain is expected to be larger than in cases where B strain is not present. Table 9.3 shows that this is so.⁶ Substitution of ethyl groups for the methyl groups of *tert*-butyl chloride does not cause B strain; the increase in rate is relatively small, and the rate smoothly rises with the increasing number of ethyl groups. The increase is caused by normal field and resonance (hyperconjugation) effects. Substitution by one isopropyl group is not greatly different. But with the second isopropyl group the crowding is now great enough to cause B strain, and the rate is increased 10-fold. Substitution of a third isopropyl group increases the rate still more. Another example where B strain increases the rate of solvolysis is found with the highly crowded molecules tri-*tert*-butylcarbinol, di-*tert*-butylneopentylcarbinol, *tert*-butyldineopentylcarbinol, and trineopentylcarbinol, where rates of solvolysis of the *p*-nitrobenzoate esters are faster than that of *tert*-butyl nitrobenzoate by factors of 13,000, 19,000, 68,000, and 560, respectively.⁷

Another type of strain, which can affect rates of cyclic compounds, is called *I strain* (internal strain).⁸ This type of strain results from changes in ring strain in going from a tetrahedral to a trigonal carbon or vice versa. For example, as mentioned above, S_N1 solvolysis of an alkyl halide involves a change in the bond angle of the central carbon from $\sim 109.5^\circ$ to $\sim 120^\circ$. This change is highly favored in 1-chloro-1-methylcyclopentane because it relieves eclipsing strain (Sec. 4.Q.iv); thus this compound undergoes solvolysis in 80% ethanol at 25 °C, 43.7 times faster than the reference compound *tert*-butyl chloride.⁹ In the corresponding cyclohexyl compound, this factor is absent because the substrate does not have eclipsing strain (Sec. 4.Q.iv), and this compound undergoes the reaction at about one-third the rate of *tert*-butyl chloride. The reasons for this small decrease in rate are not clear. Corresponding behavior is found in the other direction, in changes from a trigonal to a tetrahedral carbon. Thus cyclohexanone undergoes addition reactions faster than cyclopentanone. Similar considerations apply to larger rings. Rings of

7–11 members exhibit eclipsing and transannular strain; and in these systems reactions in which a tetrahedral carbon becomes trigonal generally proceed faster than in open-chain systems.¹⁰ *I*-Strain has been shown to be a factor in other reactions as well.¹¹

Conformational effects on reactivity can be considered under the heading of steric effects,¹² but in these cases the effect of a group X and that of another group X' upon reactivity at a site Y are not considered. But the effect of the conformation of the molecule must be considered. Many reactions fail entirely unless the molecules are able to assume the proper conformation. An example is the rearrangement of *N*-benzoylnorephedrine. The two diastereomers of this compound (**4** and **5**) behave very differently when treated with alcoholic HCl. In one of the isomers, nitrogen-to-oxygen migration takes place, while the other does not react at all.¹³ In order for the migration to take place, the nitrogen must be near the oxygen (*gauche* to it). When **4** assumes this conformation, the methyl and phenyl groups are anti to each other, which is a favorable position, but when **5** has the nitrogen *gauche* to the oxygen, the methyl must be *gauche* to the phenyl, which is so unfavorable that the reaction does not occur. Other examples are electrophilic additions to C=C double bonds (see Sec. 15.A.i) and E2 elimination reactions (see Sec. 17.A.i.). Also, many examples are known where axial and equatorial groups behave differently.¹⁴

In steroids and other rigid systems, a functional group in one part of the molecule can strongly affect the rate of a reaction taking place at a remote part of the same molecule by altering the conformation of the whole skeleton. An example of this effect, called *conformational transmission*, is found in ergost-7-en-3-one (**6**) and cholest-6-en-3-one (**7**), where **7** condenses with benzaldehyde 15 times faster than **6**.¹⁵ The reaction site in both cases is the carbonyl group, and the rate increases because moving the double bond from the 7 to the 6 position causes a change in conformation at the carbonyl group (the difference in the side chain at C-17 does not affect the rate). Molecular models of **6** and **7** are provided for illustration.

9.C. QUANTITATIVE TREATMENTS OF THE EFFECT OF STRUCTURE ON REACTIVITY¹⁶

Suppose a reaction is performed on a substrate molecule that can be represented as XGY, where Y is the site of the reaction, X a variable substituent, and G is a skeleton group to which X and Y are attached. In such a molecule, changing X from H to CH₃ results in a rate increase by a factor, of say, 10. What part of the increase is due to each of the effects previously mentioned? The obvious way to approach such a problem is to try to find compounds in which one or two of the factors are absent or at least negligible. This is difficult because factors that seem negligible to one investigator do not always appear so to another. The first attempt to give numerical values was that of Hammett.¹⁷ For the cases of *m*- and *p*-XC₆H₄Y, Hammett set up the equation

$$\log \frac{k}{k_0} = \sigma \rho$$

where k_0 is the rate constant or equilibrium constant for X = H, k is the constant for the group X, ρ is a constant for a given reaction under a given set of conditions, and σ is a constant characteristic of the group X. The equation is called the *Hammett equation*.

The value of ρ was set at 1.00 for ionization of XC₆H₄COOH in water at 25°C. The values of σ_m and σ_p were then calculated for each group (for a group X, σ is different for the meta and para positions). Once a set of σ values was obtained, ρ values could be obtained for other reactions from the rates of just two X-substituted compounds, if the σ values of the X groups were known (in practice, at least four well-spaced values are used to calculate ρ because of experimental error and because the treatment is not exact). With the ρ value calculated and the known σ values for other groups, rates can be predicted for reactions that have not yet been run.

The σ values are numbers that sum up the total electrical effects (resonance plus field) of a group X when attached to a benzene ring. The treatment usually fails for the ortho position. The Hammett treatment has been applied to many reactions and to many functional groups. It correlates an enormous amount of data quite well. Jaffé's review article¹⁷ listed ρ values for 204 reactions,¹⁸ many of which have different ρ values for different conditions. Among them are reactions as disparate as the following reactions.

Rate constants for the following:

¹⁶ See Exner, O. *Correlation Analysis of Chemical Data*, Plenum, NY, **1988**; Johnson, C.D. *The Hammett Equation*, Cambridge University Press, Cambridge, **1973**; Shorter, J. *Correlation Analysis of Organic Reactivity*, Wiley, NY, **1982**; Chapman, N.B.; Shorter, J. *Correlation Analysis in Chemistry: Recent Advances*, Plenum, NY, **1978**. Also see Connors, K.A. *Chemical Kinetics*, VCH, NY, **1990**, pp. 311–383; Lewis, E.S. in Bernasconi, C.F. *Investigation of Rates and Mechanisms of Reactions* (Vol. 6 of Weissberger, A. *Techniques of Chemistry*), 4th ed., Wiley, NY, **1986**, pp. 871–901; Jones, R.A.Y. *Physical and Mechanistic Organic Chemistry*, 2nd ed., Cambridge University Press, Cambridge, **1984**, pp. 38–68; Hine, J. *Structural Effects in Organic Chemistry*, Wiley, NY, **1975**, pp. 55–102. For a historical perspective, see Grunwald, E. *CHEMTECH* **1984**, 698.

¹⁷ For a review, see Jaffé, H.H. *Chem. Rev.* **1953**, 53, 191.

¹⁸ Additional ρ values are given in Wells, P.R. *Chem. Rev.* **1963**, 63, 171 and van Bekkum, H.; Verkade, P.E.; Wepster, B.M. *Recl. Trav. Chim. Pays-Bas* **1959**, 78, 821.

Equilibrium constants for

The *Hammett equation* also has been shown to apply to many physical measurements, including IR frequencies and NMR chemical shifts.¹⁹ The treatment is reasonably successful whether the substrates are attacked by electrophilic, nucleophilic, or free radical reagents, the important thing being that the mechanism be the same *within* a given reaction series.

However, there are many reactions that do not fit the treatment. These are mostly reactions where the attack is directly on the ring and where the X group can enter into direct resonance interaction with the reaction site in the transition state (i.e., the substrate is XY rather than XGY). For these cases, two new sets of σ values have been devised: σ^+ values (proposed by H.C. Brown) for cases in which an electron-donating group interacts with a developing positive charge in the transition state (this includes the important case of electrophilic aromatic substitutions; see Chapter 11), and σ^- values, where electron-withdrawing groups interact with a developing negative charge. Table 9.4 gives σ , σ^+ , and σ^- values for some common X groups.²⁰ As shown in the table, σ is not very different from σ^+ for most electron-withdrawing groups. The values of σ_m^- are not shown in the table, since they are essentially the same as the σ_m values.

A positive value of σ indicates an electron-withdrawing group and a negative value an electron-donating group.²¹ The constant ρ measures the susceptibility of the reaction to electrical effects.²² Reactions with a positive ρ are helped by electron-withdrawing groups and vice versa. The following ρ values for the ionization of some carboxylic acids illustrate this.²³

$\text{XC}_6\text{H}_4\text{—CH}_2\text{—COOH}$	0.49	$\text{XC}_6\text{H}_4\text{—CH}_2\text{CH}_2\text{—COOH}$	0.21

This example shows that the insertion of a CH_2 or a CH=CH group diminishes electrical effects to about the same extent, while a CH_2CH_2 group diminishes them much more. A $\rho > 1$ would mean that the reaction is more sensitive to electrical effects than is the ionization of $\text{XC}_6\text{H}_4\text{COOH}$ ($\rho = 1.00$).

Similar calculations have been made for compounds with two groups X and X' on one ring, where the σ values are sometimes additive and sometimes not,³⁶ for other ring systems, (e.g., naphthalene)³⁷ and heterocyclic rings,³⁸ and for ethylenic and acetylenic systems.³⁹

The *Hammett equation* is a *linear free energy relationship* (LFER). This relationship can be demonstrated as follows for the case of equilibrium constants (for rate constants a similar demonstration can be made with ΔG^\ddagger instead of ΔG). For each reaction, where X is any group,

$$\Delta G = -RT \ln K$$

For the unsubstituted case,

$$\Delta G_0 = -RT \ln K_0$$

The Hammett equation can be rewritten

$$\log K - \log K_0 = \sigma \rho$$

so that

$$\frac{-\Delta G}{2.3 RT} = \frac{\Delta G_0}{2.3 RT} = \sigma \rho$$

and

$$-\Delta G = \sigma \rho 2.3 RT - \Delta G_0$$

For a given reaction under a given set of conditions, σ , R , T , and ΔG_0 are all constant, so that σ is linear with ΔG .

The Hammett equation is not the only LFER.⁴⁰ Some, like the Hammett equation, correlate structural changes in reactants, but the *Grunwald–Winstein relationship*

(see Sec. 10.G.iv) correlates changes in solvent and the *Brønsted relation* (see Sec. 8.D) relates acidity to catalysis. The *Taft equation* is a structure–reactivity equation that correlates only field effects.⁴¹

Taft, following Ingold,⁴² assumed that for the hydrolysis of carboxylic esters, steric and resonance effects will be the same whether the hydrolysis is catalyzed by acid or base (see the discussion of ester-hydrolysis mechanisms, Reaction **16-59**). Rate differences would therefore be caused only by the field effects of R and R'

in RCOOR'. This system is presumably good to use for this purpose because the transition state for acid-catalyzed hydrolysis (**8**) has a greater positive charge (and is hence destabilized by $-I$ and stabilized by $+I$ substituents) than the starting ester, while the transition state for base-catalyzed hydrolysis (**9**) has a greater negative charge than the starting ester. Field effects of substituents X could therefore be determined by measuring the rates of acid- and base-catalyzed hydrolysis of a series XCH₂COOR',⁴³ where R' is held constant.³⁸ From these rate constants, a value σ_I could be determined by the equation⁴⁴

$$\sigma_I + 0.181 \left[\log \left(\frac{k}{k_0} \right)_B - \log \left(\frac{k}{k_0} \right)_A \right]$$

In this equation, $(k/k_0)_B$ is the rate constant for basic hydrolysis of XCH₂COOR' divided by the rate constant for basic hydrolysis of CH₃COOR', $(k/k_0)_A$ is the similar rate-constant ratio for acid catalysis, and 0.181 is an arbitrary constant. The substituent constant σ_I is for a group X, substituted at a saturated carbon, which reflects only field effects.⁴⁵ Once a set of σ_I values was obtained, it was found that the equation

$$\sigma_I + 0.181 \left[\log \left(\frac{k}{k_0} \right)_B - \log \left(\frac{k}{k_0} \right)_A \right]$$

⁴¹ For reviews of the separation of resonance and field effects, see Charton, M. *Prog. Phys. Org. Chem.* **1981**, 13, 119; Shorter, J. *Q. Rev. Chem. Soc.* **1970**, 24, 433; *Chem. Ber.* **1969**, 5, 269. For a review of field and inductive effects, see Reynolds, W.F. *Prog. Phys. Org. Chem.* **1983**, 14, 165. For a review of field effects on reactivity, see Grob, C.A. *Angew. Chem. Int. Ed.* **1976**, 15, 569.

⁴² Ingold, C.K. *J. Chem. Soc.* **1930**, 1032.

⁴³ Also see Draffehn, J.; Ponsold, K. *J. Prakt. Chem.* **1978**, 320, 249.

⁴⁴ The symbol σ_F is also used in the literature; sometimes in place of σ_I , and sometimes to indicate only the field (not the inductive) portion of the total effect (Sec. 1.G).

⁴⁵ There is another set of values (called σ^* values) that are also used to correlate field effects. These are related to σ_I values by $\sigma_{I(X)} = 0.45\sigma$. Only σ_I , and not σ^* values are discussed.

TABLE 9.5 The σ_I and σ_R^0 Values for Some Groups^a

Group (R)	σ_I	σ_R^0	Group (R)	σ_I	σ_R^0

holds for a number of reactions, among them:⁴⁶

As with the Hammett equation, σ_I is constant for a given reaction under a given set of conditions. For very large groups, the relationship may fail because of the presence of steric effects, which are not constant. The equation also fails when X enters into resonance with the reaction center to different extents in the initial and transition states. A list of some σ_I values is given in Table 9.5.⁴⁷ The σ_I values are about what is expected for pure field-effect values (see Sec. 1.I) and are additive, as field effects (but not resonance or

⁴⁶ Wells, P.R. *Chem. Rev.* **1963**, *63*, 171, p. 196.

⁴⁷ These values are from Bromilow, J.; Brownlee, R.T.C.; Lopez, V.O.; Taft, R.W. *J. Org. Chem.* **1979**, *44*, 4766, but the values for NHAc, OH, and I are from Wells, P.R.; Ehrenson, S.; Taft, R.W. *Prog. Phys. Org. Chem.* **1968**, *6*, 147, the values for Ph and NMe₃⁺ are from Taft, R.W.; Ehrenson, S.; Lewis, I.C.; Glick, R. *J. Am. Chem. Soc.* **1959**, *81*, 5352; Taft, R.W.; Deno, N.C.; Skell, P.S. *Annu. Rev. Phys. Chem.* **1958**, *8*, 287, and the value for CMe₃ is from Seth-Paul, W.A.; de Meyer-van Duyse, A.; Tollenaere, J.P. *J. Mol. Struct.* **1973**, *19*, 811. The values for the CH₂Ph and CH₂COCH₃ groups were calculated from σ^* values by the formula given in ref. 45. Also see Charton, M. *Prog. Phys. Org. Chem.* **1981**, *13*, 119; Taylor, P.J.; Wait, A.R. *J. Chem. Soc. Perkin Trans. 2* **1986**, 1765.

⁴⁸ For σ_R^0 values for some other NR₂ groups, see Korzhenevskaya, N.G.; Titov, E.V.; Chotii, K.Yu.; Chekhuta, V.G. *J. Org. Chem. USSR* **1987**, *28*, 1109.

⁴⁹ It has been shown that charged groups (called polar substituents) cannot be included with uncharged groups (dipolar substituents) in one general scale of electrical substituent effects: Marriott, S.; Reynolds, J.D.; Topsom, R. D. *J. Org. Chem.* **1985**, *50*, 741.

steric effects) would be expected to be. Thus, in moving a group one carbon down the chain, there is a decrease by a factor of 2.8 ± 0.5 (cf. the values of R in Table 9.5 for $R = \text{Ph}$ and CH_3CO). An inspection of Table 9.5 shows that σ_I values for most groups are fairly close to the σ_m values (Table 9.4) for the same groups. This result is not surprising, since σ_m values would be expected to arise almost entirely from field effects, with little contribution from resonance.

Since σ_p values represent the sum of resonance and field effects, these values can be divided into resonance and field contributions if σ_I is taken to represent the field-effect portion.⁵⁰ The resonance contribution σ_R ⁵¹ is defined as:

$$\sigma_R = \sigma_p - \sigma_I$$

As it stands, however, this equation is not very useful because the σ_R value for a given group, which should be constant if the equation is to have any meaning, is actually not constant, but depends on the nature of the reaction.⁵² In this respect, the σ_I values are much better. Although they vary with solvent in some cases, σ_I values are essentially invariant throughout a wide variety of reaction series. However, it is possible to overcome⁵³ the problem of varying σ_R values by using a special set of σ_R values, called σ_R^0 ,⁵⁴ that measure the ability to delocalize π electrons into or out of an unperturbed or "neutral" benzene ring. Several σ_R^0 scales have been reported; the most satisfactory values are obtained from ^{13}C chemical shifts of substituted benzenes.⁵⁵ Table 9.5 lists some values of σ_R^0 , most of which were obtained in this way.⁵⁶

An equation, for example,

$$\log \frac{k}{k_0} = \rho_I \sigma_I + \rho_R \sigma_R^0$$

which treats resonance and field effects separately, is known as a *dual substituent parameter equation*.⁵⁷

The only groups in Table 9.5 with negative values of σ_I are the alkyl groups methyl and *tert*-butyl. There has been some controversy on this point.⁵⁸ One opinion is that σ_I values decrease in the series methyl, ethyl, isopropyl, *tert*-butyl (respectively, -0.046 , -0.057 , -0.065 , -0.074).⁵⁹ Other evidence, however, has led to the belief that all alkyl groups have

approximately the same field effect and that the σ_I values are invalid as a measure of the intrinsic field effects of alkyl groups.⁶⁰

Another attempt to divide σ values into resonance and field contributions⁶¹ is that of Swain and Lupton, who show that the large number of sets of σ values (σ_m , σ_p , σ_{p-} , σ_{p+} , σ_I , σ_R^0 , etc., as well as others we have not mentioned) are not entirely independent and that linear combinations of two sets of new values F (which expresses the field-effect contribution) and R (the resonance contribution) satisfactorily express 43 sets of values.⁶² Each set is expressed as:

$$\sigma = f_F + r_R$$

where f and r are weighting factors. Some F and R values for common groups are given in Table 9.6.⁶³ From the calculated values of f and r , Swain and Lupton⁶³ calculated that the importance of resonance, % R , is 20% for σ_m , 38% for σ_p , and 62% for σ_p^+ .⁶⁴ This is another dual substituent parameter approach.

Taft and co-workers⁶⁵ were also able to isolate steric effects.⁶⁵ For the acid-catalyzed hydrolysis of esters in aqueous acetone, long (k/k_0) was shown to be insensitive to polar effects.⁶⁶ In cases where resonance interaction was absent, this value was proportional only

^aSee Ref. 68.

to steric effects (and any others⁶⁷ that are not field or resonance). The equation is

$$\log \frac{k}{k_0} = E_s$$

Some E_s values are given in Table 9.7,⁶⁸ where hydrogen is taken as standard, with a value of 0.⁶⁹ This treatment is more restricted than those previously discussed, since it requires more assumptions, but the E_s values are approximately in order of the size of the groups. Charton⁷⁰ show that E_s values for substituents of types CH₂X, CHX₂, and CX₃ are linear functions of the *van der Waals radii* for these groups.

Two other steric parameters are independent of any kinetic data. Charton's v values are derived from *van der Waals radii*,⁷¹ and Meyer's V^a values from the volume of the portion of the substituent that is within 0.3 nm of the reaction center.⁷² The V^a values are obtained by molecular mechanics calculations based on the structure of the molecule. Table 9.7 gives v and V^a values for some groups.⁷³ As can be seen in the table, there is a fair, but not perfect, correlation among the E_s , v , and V^a values. Other sets of steric values (e.g., E_S^1 ,⁷⁴ E_S^* ,⁷⁵ Ω_s ,⁷⁶ and δ_f ,⁷⁷ have also been proposed.⁷³

Since the *Hammett equation* has been so successful in the treatment of the effects of groups in the meta and para positions, it is not surprising that attempts have been made to apply it to ortho positions also.⁷⁸ The effect on a reaction rate or equilibrium constant of a group in the ortho position is called the *ortho effect*.⁷⁹ Despite the many attempts made to quantify ortho effects, no set of values has so far commanded general agreement. However, the Hammett treatment is successful for ortho compounds when the group Y in *o*-XC₆H₄Y is separated from the ring; for example, ionization constants of *o*-XC₆H₄OCH₂CO₂H can be successfully correlated.⁸⁰

Linear free energy relationships can have mechanistic implications. If $\log k/k_0$ is linear with the appropriate σ , it is likely that the same mechanism operates throughout the series. If not, a smooth curve usually indicates a gradual change in mechanism, while a pair of intersecting straight lines indicates an abrupt change,⁸¹ although nonlinear plots can also be due to other causes (e.g., complications arising from side reactions). If a reaction series follows σ^+ or σ^- better than σ it generally means that there is extensive resonance interaction in the transition state.⁸²

Information can also be obtained from the magnitude and sign of ρ . For example, a strongly negative ρ value indicates a large electron demand at the reaction center, from which it may be concluded that a highly electron-deficient center, perhaps an incipient carbocation, is involved. Conversely, a positive ρ value is associated with a developing negative charge in the transition state.⁸³ The $\sigma\rho$ relationship even applies to free radical reactions, because free radicals can have some polar character (Sec. 14.A.ii), though ρ values here are usually small (less than ~ 1.5) whether positive or negative. Reactions involving cyclic transition states (Sec. 6.B) also exhibit very small ρ values.

9.D. EFFECT OF MEDIUM ON REACTIVITY AND RATE

There is no question that the solvent chosen for a given reaction has a profound influence on the course of that reaction. Protic versus aprotic solvents, as well as polar versus nonpolar solvents, can have effects ranging from solubility to solvent assisted ionization or stabilization of transition states. Reactions can also be done neat in one of the reactants, in the gas phase, on solid support, or in the solid phase. Environmental friendly chemistry (green chemistry) is becoming increasingly important, and chemical reactions in non-polluting (often non-organic) solvents are of particular interest.⁸⁴ This section will describe alternative reaction media as well as other medium-related things that influence chemical reactions.

⁷⁸ See Fujita, T.; Nishioka, T. *Prog. Phys. Org. Chem.* **1976**, *12*, 49; Charton, M. *Prog. Phys. Org. Chem.* **1971**, *8*, 235. See also, Robinson, C.N.; Horton, J.L.; Fosheé, D.O.; Jones, J.W.; Hanissian, S.H.; Slater, C.D. *J. Org. Chem.* **1986**, *51*, 3535.

⁷⁹ This is not the same as the ortho effect discussed in Section 11.B.iv.

9.D.i High Pressure

Acceleration of some chemical reactions is possible when high-pressure techniques are employed.^{85,86} The effects on a given reaction can be predicted to a certain extent because the thermodynamic properties of solutions are well known. The rate of a reaction can be expressed in terms of the activation volume, (ΔV^\ddagger)

$$\frac{\delta \ln k}{\delta p} = \frac{\Delta V^\ddagger}{RT}$$

so rate constants vary with pressure.⁸⁶ “The activation volume⁸⁷ is the difference in partial molal volume between the transition state and the initial state. From a synthetic point of view, this could be approximated by the molar volume.”⁸⁶ If the volume of activation is negative, the rate of the reaction will be accelerated by increasing pressure. As the pressure increases, the value of ΔV^\ddagger decreases and the system does not strictly obey the equation shown above at pressures > 10 kbar (1 bar = 0.986924 atm = 1.1019716 kg cm⁻²). If the transition state of a reaction involves bond formation, concentration of charge, or ionization, a negative volume of activation often results. There is a correlation between pressure and steric interactions in organic reactions.⁸⁸ Cleavage of a bond, dispersal of charge, or neutralization of the transition state and diffusion control lead to a positive volume of activation. Matsumoto et al. summarized the reactions for which rate enhancement is expected at high pressure.⁸⁶

1. Reactions in which the molecularity number (number of molecules) decreases when starting materials are converted to products: cycloadditions and condensations.
2. Reactions that proceed via cyclic transition states.
3. Reactions that take place through dipolar transition states.
4. Reactions with steric hindrance.

Many high-pressure reactions are done neat, but if a solvent is used, the influence of pressure on that solvent is important. The melting point generally increases at elevated pressures, and this influences the viscosity of the medium (the viscosity of liquids increases approximately two times per kilobar increase in pressure). Controlling the rate of diffusion of reactants in the medium is also important, leading to another influence of high pressure on reactivity.^{86,89} In most reactions, pressure is applied (5–20 kbar) at room temperature and then the temperature is increased until reaction takes place. The temperature is lowered and the pressure is reduced to isolate the products.

9.D.ii Water and Other Non-Organic Solvents

Although some reactions may be done in water,⁹⁰ chemical reactions of organic substrates usually employ an organic solvent (e.g., a hydrocarbon, ether, dichloromethane, small molecular weight alcohols, and so on), but other more exotic solvents are available. For example, poly(ethylene glycol), or PEG, has been used as a solvent medium for catalytic hydrogenation (Reaction **15-11**).⁹¹ For some reactions in organic solvents, the presence of water may cause unwanted side reactions, and methods have been developed to detect the presence of water in those solvents.⁹²

With the exception of small molecular weight molecules with polar functional groups and polyfunctional molecules or salts, organic chemicals have poor solubility in water. Nonetheless, some reactions show a faster rate of reaction in water or in aqueous media.⁹³ The first indication that water accelerated a reaction was in a patent by Hopff and Rautenstrauch in 1939,⁹⁴ who reported that yields in the *Diels–Alder Reaction* (**15-60**) were enhanced in aqueous detergent solutions. In an early study, Berson et al.⁹⁵ showed a clear relationship between the endo/exo product ratio and solvent polarity, in the Diels–Alder reaction of cyclopentadiene and acrylates. Breslow and Rideout.⁹⁶ showed there was a hydrophobic acceleration for an intermolecular *Diels–Alder reaction* in which cyclopentadiene reacted with methyl vinyl ketone. Clearly, there is an accelerating effect on some chemical reactions when done in water that is useful in organic chemistry.⁹⁷

When nonpolar compounds are suspended in water, their relative insolubility causes them to associate, diminishing the water–hydrocarbon interfacial area (a hydrophobic effect).⁹⁸ This association is greater in water than in methanol and brings the reactive partners into close proximity, increasing the rate of reaction. Any additive that increases the hydrophobic effect will increase the rate.⁹⁶

Organic chemical reactions have been done in supercritical fluids, including supercritical water.⁹⁹ A supercritical fluid can be either liquid or gas, but it is used in a state above the temperature and pressure where gases and liquids can coexist. The properties of a supercritical fluid are different from those of either gases or liquids under standard conditions, with no distinct liquid and gas phases at temperatures and pressures above its critical point. The critical point is the temperature, pressure, and so on, at which there are no phase boundaries. Carbon dioxide can be used as a reaction solvent when pressurized (supercritical carbon dioxide, scCO₂). Carbon dioxide is nontoxic,

inexpensive, abundant, and easily recycled. These properties have made it attractive as an extraction solvent.¹⁰⁰ The low critical temperature of CO₂ (T_c) 31.1 °C ensures that scCO₂ is a safe solvent for many applications.¹⁰¹ There are solubility issues that suggest scCO₂ is a rather polar solvent.¹⁰² For example, many systems with hydrocarbon chains are not very soluble in CO₂.¹⁰³ Water/carbon dioxide emulsions have also been employed.¹⁰⁴ The use of (scCO₂) has been explored in many reactions,¹⁰⁵ including catalysis.¹⁰⁶ Some applications of this technique include the electrochemical synthesis of conducting polymers¹⁰⁷ and highly cross-linked polymers¹⁰⁸ in scCO₂, the synthesis of octyl palmitate,¹⁰⁹ of carbonated fatty methyl esters,¹¹⁰ and of methyl carbamates.¹¹¹ A carbonylation reaction was done in scCO₂ in the course of a synthesis of trisubstituted cyclopentanes and cyclohexanes as key components of substance P antagonists.¹¹² A continuous flow acid-catalyzed dehydration of alcohols was accomplished in scCO₂.¹¹³ Supercritical fluids are playing an increasingly important role in synthetic organic chemistry.¹¹⁴

Other supercritical fluids can be used for chemical reactions, such as supercritical ammonia in the synthesis of labeled guanidines.¹¹⁵

9.D.iii Ionic Solvents

Environmentally friendly solvents,¹¹⁶ which include ionic liquids, are of great interest.¹¹⁷ An ionic liquid is a salt in which the ions are poorly coordinated, usually leading to their being liquid at <100 °C and sometimes at room temperature.¹¹⁸ In such ionic species, there is usually at least one ion with a delocalized charge, whereas the other component is usually organic. This combination inhibits the formation of a stable crystal lattice. The structure and solvation properties of solutes in ionic liquids have been studied.¹¹⁹ It was discovered

that some ionic liquids are suitable as a medium for chemical reactions.¹²⁰ Both methylimidazolium and pyridinium ions form the basis of common ionic liquids that have been used in organic chemistry.¹²¹ One of the most common ionic liquids used as a solvent is 1-butyl-3-methylimidazolium as the hexafluorophosphate, (**10**, Bmim PF₆).¹²² Hydrogenbutylimidazolium tetrafluoroborate (HBuIm, **11**) and 1,3-dibutylimidazolium, tetrafluoroborate (DiBuIm, **12**), for example,¹²³ have been reported to facilitate *Diels–Alder Reactions* (**15–60**).¹²⁴ It is known that a proton on C-2 of imidazolium cations (e.g., **10–12**) is relatively acidic.¹²⁵ Carbene formation is common and the anion generated by treatment with base can undergo substitution reactions.¹²⁵ These facts lead to a caution that undesired side reactions are possible when these ionic liquids are employed as solvents.^{125,126} Pyridinium-based ionic liquids [e.g., ethylpyridinium tetrafluoroborate (**13**)] have also been used.¹²⁷ Several room temperature ionic liquids have been synthesized from amino acids.¹²⁸

Ionic solvents have been used to facilitate heterocyclic reactions,¹²⁹ several catalytic reactions,¹³⁰ the *Heck Reaction* (**13–9**)¹³¹ and other Pd catalyzed C—C bond-forming reactions,¹³² the oxidation of alcohols with hypervalent iodine reagents (**19–3**),¹³³ and the catalytic asymmetric dihydroxylation of alkenes (**15–48**) using a recoverable and reusable Os/ligand complex.¹³⁴ The camphorsulfonate anion has been used as a counterion for imidazolium salts, and shown to increase the number of unsolvated imidazolium cations.¹³⁵ This ionic liquid was then shown to influence the endo/exo ratio in a stereoselective *Diels–Alder Reaction* (**15–60**).¹³⁵ Other catalytic reactions in ionic liquids are known.¹³⁶ Other chiral ionic

liquids are known.¹³⁷ Reactions performed in an ionic liquid are a rapidly growing area of organic chemistry, and has been expanded to include microwave reactions (see Sec. 7.C) in ionic solvents.¹³⁸ The development and use of ionic solvents is a growth area of organic chemistry.¹³⁹ Also note that some ionic liquids are categorized as Lewis base (Sec. 8.E), which will influence the acidity of dissolved compounds.¹⁴⁰ There are also acidic Brønsted ionic liquids.¹⁴¹

9.D.iv. Solventless Reactions

In some cases, it should be possible to accomplish a chemical transformation without the use of a solvent. Dry media reaction under microwave irradiation is an important area of study (see Sec. 7.C).¹⁴² There are several advantages of solventless reactions: (1) the possibility of direct formation of high-purity compounds, (2) the possibility of sequential reactions, (3) fast kinetics, (4) lower energy usage, (5) minimal need for preformed salts and metal–metalloid complexes, (6) simplicity and low equipment cost, and (7) the possibility of avoiding functional group protection–deprotection.¹⁴³ Potential difficulties include the possibility of hot spots and runaway reactions, and difficulties in handling solid or highly viscous materials.¹⁴⁴ An example of this approach is the aldol condensation, where a single aldol product was obtained in high yield.¹⁴⁵ 3-Carboxylcoumarins have been produced via a solventless aldol.¹⁴³

INTRODUCTION

Part II of this book will be directly concerned with organic reactions and their mechanisms. The reactions have been classified into 10 chapters, based primarily on reaction type: substitutions, additions to multiple bonds, eliminations, rearrangements, and oxidation–reduction reactions. Substitutions are classified on the basis of mechanism as well as substrate. Chapters 10 and 13 include nucleophilic substitutions at aliphatic and aromatic substrates, respectively. Chapters 12 and 11 deal with electrophilic substitutions at aliphatic and aromatic substrates, respectively. All free radical substitutions are discussed in Chapter 14. Additions to multiple bonds are classified not according to mechanism, but according to the type of multiple bond. Additions to carbon–carbon multiple bonds are dealt with in Chapter 15; additions to other multiple bonds in Chapter 16. One chapter is devoted to each of the three remaining reaction types: Chapter 17, eliminations; Chapter 18, rearrangements; Chapter 19, oxidation–reduction reactions. This last chapter covers only those oxidation–reduction reactions that could not be conveniently treated in any of the other categories (except for oxidative eliminations).

Each chapter in Part II consists of two main sections. The first section of each chapter (except Chapter 19) deals with mechanism and reactivity. For each reaction type the various mechanisms are discussed in turn, with particular attention given to the evidence for each mechanism and to the factors that cause one mechanism rather than another to prevail in a given reaction. Following this, each chapter contains a section on reactivity, including, where pertinent, a consideration of orientation and the factors affecting it.

The second main section of each chapter is a treatment of the reactions belonging to the category indicated by the title of the chapter. It is not possible to discuss in a book of this nature all or nearly all known reactions. However, an attempt has been made to include all the important reactions of standard organic chemistry that can be used to prepare relatively pure compounds in reasonable yields. In order to present a well-rounded picture and to include some reactions that are traditionally discussed in textbooks, a number of reactions that do not fit into the above category have been included. However, certain special areas have been covered only lightly or not at all. Among these are polymerization reactions, and the preparation and reactions of heterocyclic compounds, carbohydrates, steroids, and compounds containing phosphorus, silicon, arsenic, boron, and mercury. The basic principles involved in these areas are of course no different from those in the areas more fully treated.

Each reaction is discussed in its own numbered section.¹ These are numbered consecutively within a chapter, each section number is preceded by the chapter number, so that Reaction **16-1** is the first reaction of Chapter 16 and Reaction **13-21** is the 21st reaction of Chapter 13. The order in which the reactions are presented is not arbitrary, but is based on an orderly outline that depends on the type of reaction. Within each section, the scope and utility of the reaction are discussed and references are given to review articles, if any. If there are features of the mechanism that especially pertain to that reaction, these are also discussed within the section rather than in the first part of the chapter where the discussion of mechanism is more general.

II.A. IUPAC NOMENCLATURE FOR TRANSFORMATIONS

There has long been a need for a method of naming reactions. Many reactions have been given the names of their discoverers or those who popularized them (e.g., *Claisen*, *Diels–Alder*, *Stille*, *Wittig*, *Cope*, *Dess–Martin*). In the past, this was necessary because mechanisms were not well understood, and a *named reaction* was a convenient way to identify certain transformations. Nowadays, the reasons for assigning a name are less clear and there may be as many as 800–1000 named reactions. Some believe that this practice has gotten out of hand, while others believe it to be the best way to organize key reactions. Named reactions are useful to a point, but each name must be individually memorized, and there are many reactions that do not have such names. The IUPAC Commission on Physical Organic Chemistry produced a *system* for naming, not reactions, but transformations (a reaction includes all reactants; a transformation shows only the substrate and product, omitting the reagents). The advantages of a systematic method are obvious. Once the system is known, no memorization is required; the name can be generated directly from the equation. The system includes rules for naming eight types of transformation: substitutions, additions, eliminations, attachments and detachments, simple rearrangements, coupling and uncoupling, insertions and extrusions, and ring opening and closing. Only the most basic rules are given for the first three of these types, which, however, will suffice for naming many transformations.²

II.A.i. Substitutions

A name consists of the entering group, the syllable “de”, and the leaving group. If the leaving group is hydrogen, it may be omitted (in all examples, the substrate is written on the left).

¹ The classification of reactions into sections is, of course, to some degree arbitrary. Each individual reaction is different, and custom generally decides how we group them together. Individual preferences also play a part. No claim is made that the classification system used in this book is more valid than any other. For another way of classifying reactions, see Fujita, S. *J. Chem. Soc., Perkin Trans. 2* **1988**, 597.

² For a more complete set of rules, see Jones, R.A.Y.; Bunnett, J.F. *Pure Appl. Chem.* **1989**, 61, 725.

Multivalent substitutions are named by a modification of this system that includes suffixes (e.g., “bisubstitution” and “tersubstitution”).

(Note: The nitrilo group is $\equiv\text{N}$.)

II.A.ii. Additions

For simple 1,2-additions, the names of both addends are given followed by the suffix “addition”. The addends are named in order of priority in the *Cahn–Ingold–Prelog system* (Sec. 4.E.i), the lower-ranking addend coming first. Multivalent addition is indicated by “biaddition”, and so on,

Eliminations are named the same way as additions, except that “elimination” is used instead of “addition”.

In the reaction sections of this book, IUPAC names are used for most transformations (these names will be printed in the same typeface used above), including examples of all eight types.³ As will become apparent, some transformations require more rules than we have given here.² However, it is hoped that the simplicity of the system will also be apparent.

³ For some examples, see: attachments (18-27, 19-29), detachments (19-72), simple rearrangements (18-7, 18-29), coupling (10-56, 19-34), uncoupling (19-9, 19-75), insertions (12-21, 18-9), extrusions (17-35, 17-38), ring opening (10-14, 10-35), ring closing (10-9, 15-60).

Two further notes: (1) Many transformations can be named using either of two reactants as the substrate. For example, the transformation methylene-de-oxo-bisubstitution above, can also be named ethylidene-de-triphenylphosphorandiyl-bisubstitution. In this book, unless otherwise noted, we will show only those names in which the substrate is considered to undergo the reactions indicated by the titles of the chapters. Thus the name we give to Reaction **11-11** ($\text{ArH} + \text{RCI} \rightarrow \text{ArR}$) is alkyl-de-hydrogenation, not aryl-de-chlorination, although the latter name is also perfectly acceptable under the IUPAC system. (2) The IUPAC rules recognize that some transformations are too complex to be easily fitted into the system, so they also include a list of names for some complex transformations, which are IUPAC approved, but nonsystematic (for some examples, see Reactions **12-44**, **18-34**).

II.B. IUPAC SYSTEM FOR SYMBOLIC REPRESENTATION OF MECHANISMS

In addition to providing a system for naming transformations, the IUPAC Commission on Physical Organic Chemistry has also produced one for representing mechanisms.⁴ As will be seen, many mechanisms (but by no means all) are commonly referred to by designations (e.g., $\text{S}_{\text{N}}2$, $\text{A}_{\text{AC}}2$, E1_{cB} , and $\text{S}_{\text{RN}}1$), many of them devised by C.K. Ingold and co-workers. While these designations have been useful (and we will continue to use them in this book), the sheer number of them can be confusing, especially since the symbols do not give a direct clue to what is happening. For example, there is no way to tell directly from the symbols how $\text{S}_{\text{N}}2'$ is related to $\text{S}_{\text{N}}2$ (see Sec. 10.A.i). The IUPAC system is based on a very simple description of bond changes.⁵ The letter A represents formation of a bond (association); D the breaking of a bond (dissociation). These are *primitive changes*. The basic description of a mechanism consists of these letters, with subscripts to indicate where the electrons are going. In any mechanism, the *core atoms* are defined as (1) the two atoms in a multiple bond that undergoes addition, or (2) the two atoms that will be in a multiple bond after elimination, or (3) the single atom at which substitution takes place.

As an example of the system, this is how an E1_{cB} mechanism (Sec. 17.A.iii) would be represented:

Overall designation: $\text{A}_{\text{n}}\text{D}_{\text{E}} + \text{D}_{\text{N}}$ (or $\text{A}_{\text{xh}}\text{D}_{\text{H}} + \text{D}_{\text{N}}$). In this case, the overall reaction is

and the core atoms are the two carbons in boldface.

⁴ Guthrie, R.D. *Pure Appl. Chem.* **1989**, *61*, 23. For a briefer description, see Guthrie, R.D.; Jencks, W.P. *Acc. Chem. Res.* **1989**, *22*, 343.

⁵ There are actually two IUPAC systems. The one used in this book (Ref. 4) is intended for general use. A more detailed system, which describes every conceivable change happening in a system, and which is designed mostly for computer handling and storage, is given by Littler, J.S. *Pure Appl. Chem.* **1989**, *61*, 57. The two systems are compatible; the Littler system uses the same symbols as the Guthrie system, but has additional symbols.

Step 1, First Symbol.

A bond is being formed between O and H. Bond formation is represented by A. For this particular case, the system gives two choices for subscript. In any process, the subscript is N if a core atom is forming a bond to a nucleophile (A_N) or breaking a bond to a nucleofuge (D_N). If a noncore atom is doing the same thing, lowercase n is used instead. Since H and O are noncore atoms, the lowercase n is used, and the formation of the O—H bond is designated by A_n . However, because involvement of H^+ is so common in organic mechanisms, the rules allow an alternative. The subscript H or h may replace N or n. The symbol xh denotes that the H^+ comes from or goes to an unspecified carrier atom X. Thus the term A_{xh} means that a bond is being formed between H (moving without electrons) and an outside atom, in this case O. The same subscript, xh, would be used if the outside atom were any other nucleophilic atom, say, N or S.

Step 1, Second Symbol.

A bond is being broken between C and H. The symbol is D. In any process, the subscript is E if a core atom is forming a bond to an electrophile (A_E) or breaking a bond to an electrofuge (D_E). Since C is a core atom, the symbol here is D_E . Alternatively, the symbol could be D_H . The rules allow A_H or D_H to replace A_E or D_E if the electrophile or electrofuge is H^+ . Because a core atom is involved in this primitive change the H in the subscript is capitalized.

Step 1. Combined Symbols.

In Step 1, two bond changes take place simultaneously. In such cases, they are written together with no space or punctuation: A_nD_E or $A_{xh}D_H$

Step 2.

Only one bond is broken in this step and no bonds are formed. (The movement of a pair of unshared electrons into the C—C bond, forming a double bond, is not designated by any symbol. In this system, bond multiplicity changes are understood without being specified.) Thus the symbol is D. The broken bond is between a core atom (C) and a nucleofuge (Cl), so the designation is D_N .

The overall designation can be either $A_nD_N + D_N$ or $A_{xh}D_H + D_N$. The + symbol shows that there are two separate steps. If desired, rate-limiting steps can be shown by the symbol. In this case, if the first step is the slow step [old designation ($E1_{cB}$)_I], the designation would be $A_nD_E + D_N$ or $A_{xh}D_H + D_N$.

For most mechanisms (other than rearrangements), there will be only two A or D terms with uppercase subscripts, and the nature of the reaction can be immediately recognized by looking at them. If both are A, the reaction is an addition; if both are D (as in $A_nD_E + D_N$) it is an elimination. If one is A and the other D, the reaction is a substitution.

Here, we have given only a brief description of the system. Other IUPAC designations will be shown in Part II, where appropriate. For more details, further examples, and additional symbols, see Ref. 4.

II.C. ORGANIC SYNTHESSES REFERENCES

At the end of many numbered sections there is a list of *Organic Syntheses* references (abbreviated OS). With the exception of a few very common reactions (12-3, 12-23, 12-24,

and 12–38), and to the extent that it is possible, the list includes *all* OS references for each reaction. The volumes of OS that have been covered are Collective Volumes I–XI. There are indices to OS.⁶ Organic Syntheses can now be accessed online.⁷ Certain ground rules were followed in assembling these lists. A reaction in which two parts of a molecule independently undergo simultaneous reaction is listed under both reactions. Similarly, if two reactions happen (or might happen) rapidly in succession without the isolation of an intermediate, the reactions are listed in both places. For example, at OS IV, 266 is

This reaction is treated as Reaction 10–49 followed by Reaction 10–12 and is listed in both places. However, certain reactions are not listed because they are trivial examples. An instance of this is the reaction found at OS III, 468:

This is a chloromethylation reaction and is consequently listed in Reaction 11–14. However, in the course of the reaction formaldehyde is generated from the acetal. This reaction is not listed in Reaction 10–6 (hydrolysis of acetals), because it is not really a preparation of formaldehyde.

Fieser and Fieser's Reagents for Organic Synthesis: Collective Index for, Volumes 1–12, Wiley, New York, **1990**; Liotta, D.C.; Volmer, M. Organic Syntheses Reaction Guide, Wiley: NY, **1991**, which covers the series through Vol. 68. For an older index to Organic Syntheses (through Vol. 45), see Sugawara, S.; Nakai, S. Reaction Index of Organic Syntheses, Wiley: NY, **1967**.

⁷ Available at <http://www.orgsyn.org/>.

Aliphatic Substitution, Nucleophilic and Organometallic

In nucleophilic aliphatic substitution the attacking (electron donating) reagent (the nucleophile) brings an electron pair to the substrate, using this pair to form the new bond, and the leaving group (the nucleofuge) comes away with an electron pair:

As written, this equation says nothing about charges. Nucleophile Y may be neutral or negatively charged; RX may be neutral or positively charged; so there are four charge types, examples of which follows:

In all cases, Y must have an unshared pair of electrons, so that all nucleophiles are Lewis bases. When Y is the solvent, the reaction is called *solvolysis*. Nucleophilic substitution at an aromatic carbon is considered in Chapter 13.

Nucleophilic substitution at an alkyl carbon is said to *alkylate* the nucleophile. For example, the above reaction between RI and NMe₃ is an *alkylation* of trimethylamine. Nucleophilic substitution at an acyl carbon is an *acylation* of the nucleophile, and such reactions are found in Chapter 16.

10.A. MECHANISMS

Several distinct mechanisms are possible for aliphatic nucleophilic substitution reactions, depending on the substrate, nucleophile, leaving group, and reaction conditions. In all of them, however, the *attacking* reagent carries the electron pair with it. Mechanisms that

occur at a saturated carbon atom are considered first.¹ By far the most common are the S_N1 and S_N2 mechanisms.

10.A.i. The S_N2 Mechanism

The designation S_N2 stands for *substitution nucleophilic bimolecular*. The IUPAC designation (Sec. 9.F) is A_ND_N. In this mechanism, there is *backside attack*,² which means that the nucleophile approaches the substrate from a position 180° away from the leaving group. This approach will minimize steric and electronic repulsion of the substrate and the incoming nucleophile. The reaction is a one-step process with no intermediate (see below, and Sec. 10.A.iv). The C—Y bond is formed as the C—X bond is broken to generate *pentacoordinate transition state 1*.

The energy necessary to break the C—X bond is supplied by the collision of the nucleophile (Y) with the carbon bearing the leaving group (X). The top of the curve of free energy of activation is taken to be the transition state, and the position of the atoms for this reaction are shown in transition state **1**. The transition state is not a real structure, of course, but the energetic midpoint of the reaction. There are various computational methods to ascertain characteristics of a given transition state, and the experimental examination of kinetic isotope effects has been used to infer information about the transition state.³ The group X must leave as the group Y comes in, because at no time can the carbon have more than eight electrons in its outer shell. When the transition state is reached, the central carbon atom has gone from its initial *sp*³ hybridization to essentially *sp*² with an approximately perpendicular *p* orbital. One lobe of this *p* orbital overlaps with the nucleophile and the other with the leaving group. This is the reason a frontside S_N2 mechanism has never been observed. In a hypothetical frontside transition state, both the nucleophile and the leaving group would have to overlap with the same lobe of the *p* orbital. The backside mechanism involves the maximum amount of overlap throughout the course of the reaction. At the energy point of the transition state, the three nonreacting substituents and the central carbon are approximately coplanar. They will be exactly coplanar if both the entering and leaving group are the same.

There is a large amount of evidence for the S_N2 mechanism. First, there is the kinetic evidence.⁴ Since both the nucleophile and the substrate are involved in the rate-determining step (the only step, in this case), the reaction should be first order

¹ See Hartshorn, S.R. *Aliphatic Nucleophilic Substitution*, Cambridge University Press, Cambridge, **1973**; Katritzky, A.R.; Brycki, B.E. *Chem. Soc. Rev.* **1990**, 19, 83; Richard, J.P. *Adv. Carbocation Chem.* **1989**, 1, 121; Streitwieser, A. *Solvolytic Displacement Reactions*, McGraw-Hill, NY, **1962**.

² See Sun, L.; Hase, W. L.; Song, K. *J. Am. Chem. Soc.* **2001**, 123, 5753. Nucleophilicity and leaving group ability for frontside and backside attack have been studied. See Bento, A.P.; Bickelhaupt, F.M. *J. Org. Chem.* **2008**, 73, 7290.

³ Hasanayn, F.; Streitwieser, A.; Al-Rifai, R. *J. Am. Chem. Soc.* **2005**, 127, 2249. See also Cruickshank, F.R.; Hyde, A.J.; Pugh, D. *J. Chem. Ed.* **1977**, 54, 288.

⁴ For a theoretical investigation of a kinetic isotope effect, see Matsson, O.; Dybala-Defratyka, A.; Rostkowski, M.; Paneth, P.; Westaway, K.C. *J. Org. Chem.* **2005**, 70, 4022.

in each component, second order overall, and satisfy the rate expression shown in Eq. (10-1).

$$\text{Rate} = k[\text{RX}][\text{Y}] \quad (10-1)$$

This rate law has been found to apply. Note that the 2 in S_N2 stands for bimolecular. It must be remembered that this is not always the same as second order (see Sec. 6.J.vi). If a large excess of nucleophile is present (e.g., if it is the solvent⁵) the mechanism may still be bimolecular, although the experimentally determined kinetics will be first order, Eq. (10-2).

$$\text{Rate} = k[\text{RX}] \quad (10-2)$$

As previously mentioned (Sec. 6.J.vi), such kinetics are called *pseudo-first order*.

The kinetic evidence is a necessary but not a sufficient condition; other mechanisms will be encountered that are also consistent with these data. Much more convincing evidence is obtained from the fact that the mechanism predicts inversion of configuration when substitution occurs at a chiral carbon and this has been observed many times. This inversion of configuration (see Sec. 4.E.ii) that proceeds through transition state **1** is called the *Walden inversion* and was observed long before the S_N2 mechanism was formulated by Hughes and Ingold.⁶

At this point, it is useful to see just how it was originally proved that a given substitution reaction proceeds with inversion of configuration, even before the mechanism was known. Walden presented a number of examples⁷ in which inversion *must* have taken place. For example, (+)-malic acid (**2**) could be converted to (+)-chlorosuccinic acid by thionyl chloride and to (–)-chlorosuccinic acid by phosphorus pentachloride.

One was an inversion and the other a retention of configuration, but the question was which was which? The signs of rotation are of no help in answering this question since rotation need not be related to configuration (Sec. 4.F). Another example discovered by Walden is formation of **3** from **4**.⁸

⁵ For a discussion of this type of solvent effect, see Arnaut, L.G.; Formosinho, S.J. *Chemistry: European J.* **2007**, *13*, 8018.

⁶ Cowdrey, W.A.; Hughes, E.D.; Ingold, C.K.; Masterman, S.; Scott, A.D. *J. Chem. Soc.* **1937**, 1252. The idea that the addition of one group and removal of the other are simultaneous was first suggested by Lewis, G.N. in *Valence and the Structure of Atoms and Molecules*, Chemical Catalog Company, NY, **1923**, p. 113. The idea that a one-step substitution leads to inversion was proposed by Olsen, A.R. *J. Chem. Phys.* **1933**, *1*, 418.

⁷ Walden, P. *Ber.* **1893**, *26*, 210; **1896**, *29*, 133; **1899**, *32*, 1855.

⁸ For a discussion of these cycles, see Kryger, L.; Rasmussen, S.E. *Acta Chem. Scand.* **1972**, *26*, 2349.

A series of experiments designed to settle the matter of exactly where inversion takes place was performed by Phillips,⁹ Kenyon,¹⁰ and co-workers. In 1923, Phillips and co-workers⁹ carried out the following cycle based on (+)-1-phenyl-2-propanol. In this cycle, (+)-1-phenyl-2-propanol is converted to its ethyl ether by two routes, path *AB* giving the (–) ether, and path *CD* giving the (+) ether. Therefore, at least one of the four steps must be an inversion. It is extremely unlikely that there is inversion in step *A*, *C*, or *D*, since in all these steps the C—O bond is unbroken, and in none of them could the oxygen of the bond have come from the reagent. There is a high probability that *A*, *C*, and *D* proceeded with retention, leaving *B* as the inversion. A number of other such cycles were carried out, always with nonconflicting results.¹⁰ These experiments not only definitely showed that certain specific reactions proceed with inversion, but also established the configurations of many compounds.

Walden inversion has been found at a primary carbon atom by the use of a chiral substrate containing a deuterium and a hydrogen atom at the carbon bearing the leaving group.¹¹ Inversion of configuration has also been found for $\text{S}_{\text{N}}2$ reactions proceeding in the gas phase.¹² High-pressure mass spectrometry has been used to probe the energy surface for gas-phase $\text{S}_{\text{N}}2$ reactions, which have two transition states (a “loose” and a “tight” transition state).¹³

Another kind of evidence for the $\text{S}_{\text{N}}2$ mechanism comes from compounds with potential leaving groups at bridgehead carbons. If the $\text{S}_{\text{N}}2$ mechanism is correct, these compounds should not be able to react by this mechanism, since the nucleophile cannot approach from the rear. Among the many known examples of unsuccessful reaction attempts at bridgeheads under $\text{S}_{\text{N}}2$ conditions¹⁴ are treatment of the [2.2.2] system (**5**) with ethoxide

ion¹⁵ and treatment of the [3.3.1] system (6) with sodium iodide in acetone.¹⁶ In these cases, open-chain analogues underwent the reactions readily. As a final example of evidence for the S_N2 mechanism, the reaction between optically active 2-octyl iodide and radioactive iodide ion may be mentioned:

Racemization is expected in this reaction, since if the pure *R* isomer is the starting material each exchange will produce an (*S*) isomer. With increasing concentration of (*S*) isomer, it will begin to compete for I[−] with the *R* isomer, until at the end a racemic mixture is left. The point investigated was a comparison of the rate of inversion with the rate of uptake of radioactive ^{*}I[−]. It was found¹⁷ that the rates were identical within experimental error:

$$\text{Rate of inversion} \quad 2.88 \pm 0.03 \times 10^{-5}$$

$$\text{Rate of exchange} \quad 3.00 \pm 0.25 \times 10^{-5}$$

The rate of racemization was the parameter actually measured, which is twice the rate of inversion, since each inversion creates, in effect, two racemic molecules. The significance of this result is that it shows that every act of exchange is an act of inversion.

Eschenmoser and co-workers¹⁸ provided strong evidence that the transition state in an S_N2 reaction must be linear. Base treatment of methyl α-tosyl-*o*-toluenesulfonate (7) gives the *o*-(1-tosylethyl)benzenesulfonate ion (9). The role of the base is to remove the benzylic proton α- to the tosyl group to give the ion 8. It might be supposed that the negatively charged carbon of 8 attacks the methyl group in an internal S_N2 process, but this is not the case. Crossover experiments¹⁸ (See 11-27) have shown that the negatively charged carbon attacks the methyl group of another molecule rather than the nearby one in the same molecule; that is, the reaction is intermolecular (see 8) and not intramolecular, despite the more favorable entropy of the latter pathway (Sec. 6.D). It is likely that intramolecular attack does not take place because complete linearity cannot be attained. This behavior is in sharp contrast to that in cases in which the leaving group is not constrained (Sec. 10.C), where intramolecular S_N2 mechanisms operate freely.

There is evidence, both experimental and theoretical, that there are intermediates in at least some S_N2 reactions in the gas phase, in charge-type I reactions, where a negative ion nucleophile attacks a neutral substrate.¹⁹ Two energy minima, one before and one after the

¹⁵ Doering, W. von E.; Levitz, M.; Sayigh, A.; Sprecher, M.; Whelan, Jr., W.P. *J. Am. Chem. Soc.* **1953**, 75, 1008. Actually, a slow substitution was observed in this case, but not by an S_N2 mechanism.

transition state, appear in the reaction coordinate (Fig. 10.1).²⁰ The energy surface for the S_N2 *Menshutkin* reaction (**10-31**) has been examined. It was shown that charge separation was promoted by the solvent.²¹ An *ab initio* study of the S_N2 reaction at primary and secondary carbon centers has looked at the energy barrier (at the transition state) to the reaction.²² These minima correspond to unsymmetrical ion-dipole complexes.²³ Theoretical calculations also show such minima in certain solvents (e.g., *N,N*-dimethylformamide DMF), but not in water.²⁴ In general, polar aprotic solvents (those that do not have an acidic hydrogen $X-H$, where $X=O, S, N$, etc.), favor polarized transition state 1.²⁵ The rate of the reaction is generally slower in protic solvents (e.g., alcohol or water).

The S_N2 reactions can occur at atoms other than carbon, X (e.g., nitrogen or sulfur²⁶), and analogous to the phenomenon observed for S_N2 reactions at carbon.²⁷ the valence of the element X, controls the intrinsic barrier for the reaction in accord with the properties seen in the periodic table.²⁸

For a list of some of the more important reactions that operate by the S_N2 mechanism, see Table 10.7.

Note that in some reactions, (e.g., bromine transfer between carbanions via nucleophilic attack on bromine), anomalous kinetic behavior is observed. The largest rate constants are associated with bromine transfer between cyano-activated carbanions and the smallest relate to the removal of bromine from the nitromethane and nitroethane moieties.²⁹ The Brønsted plot (log *k* vs Δ*pK_a*) for this reaction shows that unlike any normal Brønsted plot, which by definition displays a positive slope, the plot for MeNO₂ and EtNO₂ is negative. In deprotonation reactions of carbon compounds, the reactivity of nitroethane and nitromethane were shown to be anomalous.³⁰ In the series nitromethane, ethane, and isopropane, compounds with higher acidity undergo slower deprotonation (i.e., the Brønsted plot displays a negative slope), contrary to expectations.³¹

10.A.ii. The S_N1 Mechanism

The most ideal version of the S_N1 mechanism (*substitutional nucleophilic unimolecular*) consists of two steps³² (once again, possible charges on the substrate and nucleophile are not shown):

The first step is a slow ionization of the substrate and is the rate-determining step. The second is a rapid reaction between the intermediate carbocation and the nucleophile. There are, of course, transition states for both step 1 (R···X) and step 2 (R⁺···Y).³³ The reactive nature of the carbocation can be expressed by its electrophilic character, or *electrophilicity*. A theoretical discussion concerning the origin of the electrophilicity concept was proposed by Parr et al.³⁴ In general, a good electrophile was characterized by having a high value of electronegativity (or a high value of electronic chemical potential), and a low value of chemical hardness (Sec. 8.E.i). The effect of substitution has been studied³⁵ in the context of superelectrophilicity (where carbocations are generated in superacidic media). Solvent effects have also been studied.³⁶ Electrophilicity scales

have been proposed using other carbocations,³⁷ and there is an electrophilicity index.³⁸ Carbocation intermediates have been studied for the reaction $\text{Ar}_2\text{CH}-\text{O}_2\text{CR} \rightarrow \text{Ar}_2\text{CH}^+$, and the relative ionization rates with the same anionic leaving group does not correlate with the corresponding relative reactivities of the carbocation toward a common nucleophile.³⁹

Returning to the $\text{S}_{\text{N}}1$ mechanism, ionization of a leaving group to form the carbocation is always assisted by the solvent,⁴⁰ since the energy necessary to break the bond is largely recovered by solvation of R^+ and of X. For example, the ionization of $t\text{-BuCl}$ to $t\text{-Bu}^+$ and Cl^- in the gas phase without a solvent requires $150 \text{ kcal mol}^{-1}$ (630 kJ mol^{-1}). In the absence of a solvent, such a process simply would not take place, except at very high temperatures. In water, this ionization requires only 20 kcal mol^{-1} (84 kJ mol^{-1}). The difference is solvation energy. This means that the water is effectively “pulling” the leaving group away from the substrate. In cases where the role of the solvent is solely to assist in departure of the leaving group from the frontside the mechanism is called *limiting* $\text{S}_{\text{N}}1$. In other words, there is a complete absence of backside ($\text{S}_{\text{N}}2$) participation by solvent molecules. There is kinetic and other evidence⁴¹ that two molecules of a protic solvent form weak hydrogen bonds with X in order to pull the leaving group X away from RX.

In the IUPAC system, the $\text{S}_{\text{N}}1$ mechanism is $\text{D}_{\text{N}} + \text{A}_{\text{N}}$ or $\text{D}_{\text{N}}^{\ddagger} + \text{A}_{\text{N}}$ (where \ddagger denotes the rate-determining step). The IUPAC designations for the $\text{S}_{\text{N}}1$ and $\text{S}_{\text{N}}2$ mechanisms thus clearly show the essential differences between them: $\text{A}_{\text{N}}\text{D}_{\text{N}}$ indicates that bond breaking is concurrent with bond formation; $\text{D}_{\text{N}} + \text{A}_{\text{N}}$ shows that the former happens first.

In looking for evidence for the $\text{S}_{\text{N}}1$ mechanism, the first thought is that it should be a first-order reaction following the rate law:

$$\text{Rate} = k[\text{RX}] \quad (10-3)$$

Since the slow step involves only the substrate, the rate should be dependent only on the concentration of that. Although the solvent is necessary to assist in the process of ionization, it does not enter the rate expression, because it is present in large excess. However, the simple rate law given in Eq. (10-3) is not sufficient to account for all the data. Many cases are known where pure first-order kinetics are followed, but in many other cases more complicated kinetics are found. This fact can be explained by taking into account the

⁴¹ Blandamer, M.J.; Burgess, J.; Duce, P.P.; Symons, M.C.R.; Robertson, R.E.; Scott, J.M.W. *J. Chem. Res. (S)* **1982**, 130.

reversibility of the first step. The X formed in this step competes with Y for the cation and the rate law must be modified as shown (see Chap 6).

At the beginning of the reaction, when the concentration of X is very small, $k_{-1}[\text{X}]$ is negligible compared with $k_2[\text{Y}]$ and the rate law is reduced to Eq. (10-3). Indeed, $\text{S}_{\text{N}}1$ reactions generally do display simple first-order kinetics in their initial stages. Most kinetic studies of $\text{S}_{\text{N}}1$ reactions fall into this category. In the later stages of $\text{S}_{\text{N}}1$ solvolyses, $[\text{X}]$ becomes large and Eq. (10-4) predicts that the rate should decrease. This is found to be the case for diarylmethyl halides,⁴² although not for *tert*-butyl halides, which follow Eq. (10-3) for the entire reaction.⁴³ An explanation for this difference is that *tert*-butyl cations are less selective than the relatively stable diarylmethyl type (Sec. 5.A.ii). Although halide ion is a much more powerful nucleophile than water, there is much more water available since it is the solvent.⁴⁴ The selective diphenylmethyl cation survives many collisions with solvent molecules before combining with a reactive halide. However, some of the collisions with solvent lead to product, so despite the fact that the halide ion is more reactive, the slower reaction with solvents leads to product because of the overwhelming number of solvent molecules.

If the X formed during the reaction can decrease the rate, at least in some cases, it should be possible to *add* X from the outside and further decrease the rate in that way. This retardation of rate by addition of X is called *common-ion effect* or the *mass-law effect*. Once again, addition of halide ions decreases the rate for diphenylmethyl, but not for *tert*-butyl halides.

One factor that complicates the kinetic picture is the *salt effect*. An increase in ionic strength of the solution usually increases the rate of an $\text{S}_{\text{N}}1$ reaction (Sec. 10.G.iv). But when the reaction is of charge type II, where both Y and RX are neutral, so that X is negatively charged (and most solvolyses are of this charge type), the ionic strength increases as the reaction proceeds and this increases the rate. This effect must be taken into account in studying the kinetics. Incidentally, the fact that the addition of outside ions *increases* the rate of most $\text{S}_{\text{N}}1$ reactions makes especially impressive the *decrease* in rate caused by the common ion.

Note that the pseudo-first-order rate law for an $\text{S}_{\text{N}}2$ reaction in the presence of a large excess of Y [Eq. (10-1)] is the same as that for an ordinary $\text{S}_{\text{N}}1$ reaction [Eq. (10-3)]. It is thus not possible to tell these cases apart by simple kinetic measurements. However, they can often be distinguished by the common-ion effect mentioned above. Addition of a common ion will not markedly affect the rate of an $\text{S}_{\text{N}}2$ reaction beyond the effect caused by other ions. Unfortunately, as seen above, not all $\text{S}_{\text{N}}1$ reactions show the common-ion effect, and this test fails for *tert*-butyl and similar cases.

⁴³ Bateman, L.C.; Hughes, E.D.; Ingold, C.K. *J. Chem. Soc.* **1940**, 960.

⁴⁴ In the experiments mentioned, the solvent was actually "70" or "80%" aq acetone. The "80%" aq acetone consists of 4 vol of dry acetone and 1 vol of water.

Kinetic studies also provide other evidence for the S_N1 mechanism. One technique used ^{19}F NMR to follow the solvolysis of trifluoroacetyl esters.⁴⁵ If this mechanism operates essentially as shown above, the rate should be the same for a given substrate under a given set of conditions, *regardless of the identity of the nucleophile or its concentration*. In one experiment, benzhydryl chloride (Ph_2CHCl) was treated in SO_2 with the nucleophiles fluoride ion, pyridine, and triethylamine at several concentrations of each nucleophile.⁴⁶ In each case, the initial rate of the reaction was approximately the same when corrections were made for the salt effect. The same type of behavior has been shown in a number of other cases, even when the reagents are as different in their nucleophilicities (see Sec. 10.G.ii) as H_2O and HO^- .

It is normally not possible to detect the carbocation intermediate of an S_N1 reaction directly, because its lifetime is very short. However, in the case of 3,4-dimethoxydiphenylmethyl acetate (**10**), and certain other substrates in polar solvents, it was possible to initiate the reaction photolytically, and under these conditions the UV spectra of the intermediate carbocations could be obtained,⁴⁷ providing additional evidence for the S_N1 mechanism. Further, addition of water to a colorless solution of $\text{Ar}_2\text{CH}-\text{OAc}$ (Ar = morpholinophenyl) in acetone, leads to direct observation of the intermediate carbocation.⁴⁸

Further evidence for the S_N1 mechanism is that reactions run under S_N1 conditions fail or proceed very slowly at the bridgehead positions¹³ of [2.2.1] (norbornyl) systems⁴⁹ (e.g., 1-chloroapocamphane, **8**). If S_N1 reactions require carbocations and if carbocations must be planar or nearly planar, then it is no surprise that bridgehead 1-norbornyl carbon atoms, which cannot assume planarity, do not become the seat of carbocations. As an example, **11**, boiled 21 h with 30% KOH in 80% ethanol or 48 h with aq ethanolic silver nitrate, gave no reaction in either case,⁵⁰ although analogous open-chain systems reacted readily. According to this theory, S_N1 reactions should be possible with larger rings, since near-planar carbocations might be expected there. This turns out to be the case. For example, [2.2.2] bicyclic systems undergo S_N1 reactions much faster than smaller bicyclic systems, although the reaction is still slower than with open-chain systems.⁵¹ Proceeding to a still larger system, the bridgehead [3.2.2] cation (**12**) is actually stable enough to be kept in solution in $\text{SbF}_5\text{-SO}_3\text{ClF}$ at temperatures below -50°C ⁵² (see also, Sec. 10.G, category 6). Other small bridgehead systems that undergo S_N1 reactions are the [3.1.1] (e.g., **13**)⁵³ and

the cubyl (e.g., **14**)⁵⁴ systems. *Ab initio* calculations show that the cubyl cation, although it cannot be planar, requires less energy to form than the 1-norbornyl cation.⁵⁵ There are reactions where the cationic carbon is not coplanar with conjugating substituents (e.g., phenyl), and formation of the carbocation is more difficult but the reaction proceeds.⁵⁶

Certain nucleophilic substitution reactions that normally involve carbocations can take place at norbornyl bridgeheads⁵⁷ (though it is not certain that carbocations are actually involved in all cases) if the leaving group used is of the type that cannot function as a nucleophile (and thus come back) once it has gone, and in the displacement of ClCO_2 in **15**. In this example,⁵⁸ chlorobenzene is the nucleophile (see Reaction **11-10**).

Additional evidence for the $\text{S}_{\text{N}}1$ mechanism, in particular, for the intermediacy of carbocations, is that solvolysis rates of alkyl chlorides in ethanol parallel carbocation stabilities, as determined by heats of ionization measured in superacid solutions (Sec. 5.A.ii).⁵⁹ It is important to note that some solvolysis reactions proceed by an $\text{S}_{\text{N}}2$ mechanism.⁶⁰

10.A.iii. Ion Pairs in the $\text{S}_{\text{N}}1$ Mechanism⁶¹

Like the kinetic evidence, the stereochemical evidence for the $\text{S}_{\text{N}}1$ mechanism is less clear-cut than it is for the $\text{S}_{\text{N}}2$ mechanism.⁶² If there is a free carbocation, it is planar (Sec. 5.A.ii), and the nucleophile should attack with equal facility from either side of the plane, resulting in complete racemization. Although many first-order substitutions do give complete racemization, many others do not. Typically there is 5–20% inversion, although in a few cases, a small amount of retention of configuration has been found. These and other results have led to the conclusion that in many $\text{S}_{\text{N}}1$ reactions at least some of the products are not formed from free carbocations, but rather from *ion pairs*. According to this

concept,⁶³ S_N1 reactions proceed in this manner:

where **16** (an *intimate, contact, or tight ion pair*), **17** (a *loose, or solvent-separated ion pair*),⁶⁴ or **18** (the dissociated ions, which means that each is surrounded by molecules of solvent).⁶⁵ The reaction in which the intimate ion pair recombines to give the original substrate is referred to as *internal return*. The reaction products can result from attack by the nucleophile at any stage. In the intimate ion pair (**16**), R⁺ does not behave like the free cation of **18**. There is probably significant bonding between R⁺ and X⁻ and asymmetry may well be maintained.⁶⁶ Here, X⁻ “solvates” the cation on the side from which it departed, while solvent molecules near **16** can only solvate it from the opposite side. Nucleophilic attack by a solvent molecule on **16** thus leads to inversion. Note that there is evidence for concerted pathways in some ion pairing reactions.⁶⁷

Ignoring the possibilities of elimination or rearrangement (see Chapters 17 and 18), a complete picture of the possibilities for solvolysis reactions⁶⁸ in a solvent SH is represented by the following scheme,⁶⁹ although in any particular case it is unlikely that all these reactions occur:

In this scheme, (RS) and (SR) represent enantiomers, and so on, and δ represents some fraction. The following are the possibilities: (1) Direct attack by SH on RX gives SR (complete inversion) in a straight S_N2 process. (2) If the intimate ion pair R⁺X⁻ is formed, the solvent can attack at this stage. This can lead to total inversion if reaction A does not take place or to a combination of inversion and racemization if there is competition between A and B. (3) If the solvent-separated ion pair is formed, SH can attack here. The stereochemistry is not maintained as tightly and more racemization (perhaps total) is expected. (4) Finally, if free R⁺ is formed, it is planar, and attack by SH gives complete racemization.

The ion-pair concept thus predicts that S_N1 reactions can display either complete racemization or partial inversion. The fact that this behavior is generally found is evidence

that ion pairs are involved in many S_N1 reactions. There is much other evidence for the intervention of ion pairs,⁷⁰ including ion–molecule pairs.⁷¹

1. The compound 2-octyl brosylate was labeled at the sulfone oxygen with ^{18}O and solvolyzed. The unreacted brosylate recovered at various stages of solvolysis had the ^{18}O considerably, although not completely, scrambled:⁷²

In an intimate ion pair, the three oxygen atoms become equivalent:

Similar results were obtained with several other sulfonate esters.⁷³ The possibility must be considered that the scrambling resulted from ionization of one molecule of ROSO_2Ar to R^+ and ArSO_2O^- followed by attack by the ArSO_2O^- ion on *another* carbocation or perhaps on a molecule of ROSO_2Ar in an S_N2 process. However, this was ruled out by solvolyzing unlabeled substrate in the presence of labeled HOSO_2Ar . These experiments showed that there was some intermolecular exchange (3–20%), but not nearly enough to account for the amount of scrambling found in the original experiments. Similar scrambling was found in solvolysis of labeled carboxylic esters ($\text{R}-^{18}\text{O}-\text{COR}'$), where the leaving group is $\text{R}'\text{COO}^-$.⁷⁴ Also in this case, the external addition of RCOO^- did not result in significant exchange. However, it has been proposed that the scrambling could result from a concerted process, not involving ion-pair intermediates, and there is some evidence for this view.⁷⁵

2. The *special salt effect*. The addition of LiClO_4 or LiBr in the acetolysis of certain tosylates produced an initial steep rate acceleration that then decreased to the normal linear acceleration (caused by the ordinary salt effect).⁷⁶ This result is interpreted as: the ClO_4^- (or Br^-) traps the solvent-separated ion pair to give $\text{R}^+ \parallel \text{ClO}_4^-$ which, being unstable under these conditions, goes to product. Hence, the amount of solvent-separated ion pair that would have returned to the starting material is reduced, and the rate of the overall reaction is increased. The special salt effect has been directly observed by the use of picosecond absorption spectroscopy.⁷⁷

3. The possibilities of racemization or inversion of the *product* (*RS*) of a solvolysis reaction were discussed previously. However, the formation of an ion pair followed by internal return can also affect the stereochemistry of the *substrate* molecule *RX*. Cases have been found where internal return racemizes an original optically active *RX*, an example being solvolysis in aq acetone of α -*p*-anisylethyl *p*-nitrobenzoate,⁷⁸ while in other cases partial or complete retention is found (e.g., solvolysis in aq acetone of *p*-chlorobenzhydryl *p*-nitrobenzoate).⁷⁹ Racemization of *RX* is presumably caused by the equilibrium pathway:

Evidence for ion pairs includes some cases where internal return involves racemization, it has been shown that such racemization is *faster* than solvolysis. For example, optically active *p*-chlorobenzhydryl chloride racemizes ~ 30 times faster than it solvolyzes in acetic acid.⁸⁰

Molecular orbital calculations⁸¹ on *tert*-BuCl show that the C—Cl distance in the intimate ion pair is 2.9 Å and the onset of the solvent-separated ion pair takes place at ~ 5.5 Å (cf. the C—Cl bond length of 1.8 Å).

In a few cases, S_N1 reactions have been found to proceed with partial retention (20–50%) of configuration. Ion pairs have been invoked to explain some of these.⁸² For example, it has been proposed that the phenolysis of optically active α -phenylethyl chloride, in which the ether of net retained configuration is obtained, involves a four-center mechanism:

This conclusion is strengthened by the fact that partial retention was obtained in this system only with chloride or other neutral leaving groups; with leaving groups bearing a positive charge, which are much less likely to form hydrogen bonds with the solvent, no retention was found.⁸³ Partial retention can also arise when the ion pair is shielded at the backside by an additive (e.g., acetonitrile, acetone, or aniline).⁸⁴

The difference between the S_N1 and S_N2 mechanisms is in the timing of the steps. In the S_N1 mechanism, first *X* leaves, then *Y* attacks. In the S_N2 case, the two

things happen simultaneously. One could imagine a third possibility: first the attack of Y and then the removal of X. This is not possible at a saturated carbon, since it would mean that there are more than eight electrons in the outer shell of carbon. However, this type of mechanism is possible and indeed occurs at other types of substrate (Sec. 10.F and Chap 13).

10.A.iv. Mixed S_N1 and S_N2 Mechanisms

Some reactions of a given substrate under a given set of conditions display all the characteristics of S_N2 mechanisms; other reactions seem to proceed by S_N1 mechanisms, but cases are found that cannot be characterized so easily. There seems to be something in between, a mechanistic “borderline” region.⁸⁵ At least two broad theories have been devised to explain these phenomena. One theory holds that intermediate behavior is caused by a mechanism that is neither “pure” S_N1 nor “pure” S_N2, but some “in-between” type. According to the second theory, there is no intermediate mechanism at all, and borderline behavior is caused by simultaneous operation, in the same flask, of both the S_N1 and S_N2 mechanisms; that is, some molecules react by the S_N1, while others react by the S_N2 mechanism.

One formulation of the intermediate-mechanism theory is that of Sneen et al.⁸⁶ The formulation is in fact very broad and applies not only to borderline behavior, but to all nucleophilic substitutions at a saturated carbon.⁸⁷ According to Sneen, et al.⁸⁸ all S_N1 and S_N2 reactions can be accommodated by one basic mechanism (the *ion-pair mechanism*). The substrate first ionizes to an intermediate ion pair that is then converted to products:

The difference between the S_N1 and S_N2 mechanisms is that in the former case the *formation* of the ion pair (k_1) is rate determining, while in the S_N2 mechanism its *destruction* (k_2) is rate determining. Borderline behavior is found where the rates of formation and destruction of the ion pair are of the same order of magnitude.⁸⁸ However, a number of investigators have asserted that these results could also be explained in other ways.⁸⁹

There is evidence for the Sneen formulation where the leaving group has a positive charge. In this case, there is a cation–molecule pair ($\text{RX}^+ \rightarrow \text{R}^+ \text{X}^-$).⁹⁰ instead of the ion pair that would be present if the leaving group were uncharged. Katritzky et al.⁹¹ found that

when such a reaction was run at varying high pressures, there was a minimum in the plot of rate constant versus pressure. A minimum of this sort usually indicates a change in mechanism, and the interpretation in this case was that the normal S_N2 mechanism operates at higher pressures and the cation–molecule mechanism at lower pressures.

An alternative view that also favors an intermediate mechanism is that of Schleyer and co-workers,⁹² who believe that the key to the problem is varying degrees of nucleophilic solvent assistance to ion-pair formation. They have proposed an S_N2 (intermediate) mechanism.⁹³

Among the experiments that have been cited for the viewpoint that borderline behavior results from simultaneous S_N1 and S_N2 mechanisms is the behavior of 4-methoxybenzyl chloride in 70% aq acetone.⁹⁴ In this solvent, hydrolysis⁹⁵ (i.e., conversion to 4-methoxybenzyl alcohol) occurs by an S_N1 mechanism. When azide ions are added, the alcohol is still a product, but now 4-methoxybenzyl azide is another product. Addition of azide ions increases the rate of ionization (by the salt effect), but *decreases* the rate of hydrolysis. If more carbocations are produced, but fewer go to the alcohol, then some azide must be formed by reaction with carbocations: an S_N1 process. However, the rate of ionization is always *less* than the total rate of reaction, so some azide must also form by an S_N2 mechanism.⁹⁴ Thus, the conclusion is that S_N1 and S_N2 mechanisms operate simultaneously.⁹⁶

Some nucleophilic substitution reactions that seem to involve a “borderline” mechanism actually do not. Thus, one of the principal indications that a “borderline” mechanism is taking place has been the finding of partial racemization and partial inversion. However, this type of stereochemical behavior is quite consistent with a strictly S_N2 process.⁹⁷ The reaction of optically active 2-octyl brosylate in 75% aq dioxane, gave inverted 2-octanol in 77% optical purity.⁹⁷ When sodium azide was added, 2-octyl azide was obtained along with the 2-octanol, *but the latter was now 100% inverted*. It is apparent that, in the original case, 2-octanol was produced by two different processes: An S_N2 reaction leading to inverted product, and another process in which some intermediate leads to racemization or retention. When azide ions were added, they scavenged this intermediate, so that the entire second process now went to produce azide, while the S_N2 reaction, unaffected by addition of azide, still went on to give inverted 2-octanol. What is the nature of the intermediate in the second process? At first thought, it is a carbocation, so that this would be another example of simultaneous S_N1 and S_N2 reactions. However, solvolysis of 2-octyl brosylate in pure methanol or of 2-octyl methanesulfonate in pure water, in the absence of azide ions, gave methyl 2-octyl ether or 2-octanol, respectively, *with 100% inversion of configuration*, indicating that the mechanism in these solvents was pure S_N2 . Since methanol and water are more polar than 75% aq dioxane and since an increase in polarity of solvent increases the rate of S_N1 reactions at the expense of S_N2 (Sec. 10.G.iii), it is

⁹⁵ The relationship between electrophilicity and rate coefficients is discussed in Aizman, A.; Contreras, R.; Pérez, P. *Tetrahedron* **2005**, 61, 889.

⁹⁶ See, however, Sneen, R.A.; Larsen, J.W. *J. Am. Chem. Soc.* **1969**, 91, 6031.

⁹⁷ Weiner, H.; Sneen, R.A. *J. Am. Chem. Soc.* **1965**, 87, 287.

extremely unlikely that any S_N1 process could occur in 75% aq dioxane. The intermediate in the second process is thus not a carbocation. Its nature is suggested by the fact that, in the absence of azide ions, the amount of inverted 2-octanol decreased with an increasing percentage of dioxane in the solvent. Thus the intermediate is an oxonium ion (**19**) formed by an S_N2 attack *by dioxane*. This ion is not a stable product, but reacts with water in another S_N2 process to produce 2-octanol with retained configuration.

That part of the original reaction that resulted in retention of configuration⁹⁸ is thus seen to stem from two successive S_N2 reactions and not from any “borderline” behavior.⁹⁹

10.B. SET MECHANISMS

In certain reactions, where nucleophilic substitutions would seem obviously indicated, there is evidence that radicals and/or radical ions are actually involved.¹⁰⁰ The first step in such a process is transfer of an electron from the nucleophile to the substrate to form a radical anion:

Mechanisms that begin this way are called *SET mechanisms*.¹⁰¹ Once formed, the radical ion cleaves:

The radicals formed in this way can go on to product by reacting with the Y^\bullet produced in Step 1 or with the original nucleophilic ion Y^- , in which case an additional step is necessary:

In the latter case, the radical ion $\text{R-X}^{\bullet-}$ is formed by Step 4, as well as by Step 1, so that a chain reaction (Sec. 14.A.i) can take place.

⁹⁸ According to this scheme, the configuration of the isolated RN_3 should be retained. It was, however, largely inverted, owing to a competing S_N2 reaction where N_3^- directly attacks ROBs.

One type of evidence for an SET mechanism is the finding of some racemization. A free radical would likely result in a completely racemized product RY, but it has been suggested¹⁰² that inversion can also take place in some SET processes. The suggestion is that in Step 1 the Y[−] still approaches from the back side, even though an ordinary S_N2 mechanism will not follow, and that the radical R[•], once formed, remains in a solvent cage with Y[•] still opposite X[−], so that Steps 1–3 can lead to inversion.

Reactions with SET mechanisms typically show predominant, although not 100%, inversion.

Other evidence cited¹⁰³ for SET mechanisms has been detection of radical or radical-ion intermediates by ESR¹⁰⁴ or CIDNP; the finding that such reactions can take place at 1-norbornyl bridgeheads;¹⁰⁵ and the formation of cyclic side products when the substrate has a double bond in the 5,6-position (such substrates are called *radical probes*).

Free radicals with double bonds in this position are known to cyclize readily (Sec. 15.A.iii).¹⁰⁶

The SET mechanism is chiefly found where X = I or NO₂ (see Reaction 10-67). A closely related mechanism, the S_{RN}1, takes place with aromatic substrates (Chap 13).¹⁰⁷ In that mechanism, the initial attack is by an electron donor, rather than a nucleophile. The S_{RN}1 mechanism has also been invoked for reactions of enolate anions with 2-iodobicyclo[4.1.0]heptane.¹⁰⁸ An example is the reaction of 1-iodobicyclo[2.2.1]heptane (**20**) with NaSnMe₃ or LiPPh₂, and some other nucleophiles, to give the substitution product.¹⁰⁹ Another is the reaction of bromo 4-bromoacetophenone (**21**) with Bu₄NBr in cumene.¹¹⁰ The two mechanisms, S_N2 versus SET, have been compared and contrasted.¹¹¹ There are

also reactions where it is reported that radical, carbanion, and carbene pathways occur simultaneously.¹¹²

The mechanisms so far considered can, in theory at least, operate on any type of saturated (or for that matter unsaturated) substrate. There are other mechanisms that are more limited in scope.

10.C. THE NEIGHBORING-GROUP MECHANISM¹¹³

It is occasionally found with certain substrates that (1) the rate of reaction is greater than expected, and (2) the configuration at a chiral carbon is *retained* and not inverted or racemized. In these cases, there is usually a group with an unshared pair of electrons β to the leaving group (or sometimes farther away). The mechanism operating in such cases is called the *neighboring-group mechanism* and consists essentially of two S_N2 substitutions, each causing an inversion so the net result is retention of configuration.¹¹⁴ In the first step of this reaction, the neighboring group acts as a nucleophile, pushing out the leaving group, but still retaining attachment to the molecule. In the second step, the external nucleophile displaces the neighboring group by a backside attack:

The reaction obviously must go faster than if Y were attacking directly, since if the latter process were faster, it would be happening. The neighboring group Z is said to be lending *anchimeric assistance*. The rate law followed in the neighboring-group mechanism is the first-order law shown in Eq. (10-2) or (10-3); that is, Y does not take part in the rate-determining step.

The reason attack by Z is faster than that by Y is that the group Z is more available. In order for Y to react, it must collide with the substrate, but Z is immediately available by virtue of its position. A reaction between the substrate and Y involves a large decrease in entropy of activation (ΔS^\ddagger), since the reactants are far less free in the transition state than before. Reaction of Z involves a much smaller loss of ΔS^\ddagger (see Sec. 6.D).¹¹⁵

It is not always easy to determine when a reaction rate has been increased by anchimeric assistance. In order to be certain, it is necessary to know what the rate would be without participation by the neighboring group. An obvious way to examine this question is to compare the rates of the reaction with and without the neighboring group, (e.g., $\text{HOCH}_2\text{CH}_2\text{Br}$ vs $\text{CH}_3\text{CH}_2\text{Br}$). However, this will certainly not give an accurate determination of the extent of participation, since the steric and field effects of H and OH are not the same. Furthermore, no matter what the solvent, the shell of solvent molecules that surrounds the polar protic OH group must differ greatly from that which surrounds the

¹¹⁵ See Page, M.I. *Chem. Soc. Rev.* **1973**, 2, 295.

nonpolar H. Because of these considerations, it is desirable to have a large increase in the rate, preferably > 50-fold, before a rate increase is attributed to neighboring-group participation.

The first important evidence for the existence of this mechanism was the demonstration that retention of configuration can occur if the substrate is suitable. It was shown that the threo *dl* pair of 3-bromo-2-butanol when treated with HBr gave *dl*-2,3-dibromobutane, while the erythro pair gave the meso isomer (**22**).¹¹⁶

This result indicated that retention had taken place. Note that both products are optically inactive and so cannot be told apart by differences in rotation. The meso and *dl* dibromides have different boiling points and indexes of refraction and were identified by these properties. Even more convincing evidence was that either of the two threo isomers alone gave not just one of the enantiomeric dibromides, but the *dl* pair. The reason for this is that the intermediate present after the attack by the neighboring group (**23**) is symmetrical, so the external nucleophile Br[−] can attack both carbon atoms equally well. Intermediate **23** is a *bromonium ion*, the existence of which has been demonstrated in several types of reactions (see Reaction 15-39).

Although **23** is symmetrical, intermediates in most neighboring-group mechanisms are not, and it is therefore possible to get not a simple substitution product, but a rearrangement. This will happen if Y attacks not the carbon atom from which X left, but the one to which Z was originally attached:

In such cases, substitution and rearrangement products are often produced together. For a discussion of rearrangements, see Chapter 18.

Another possibility is that the intermediate may be stable or may find some other way to stabilize itself. In such cases, Y never attacks at all and the product is cyclic. These are simple internal S_N2 reactions.¹¹⁷ Two examples are formation of epoxides and lactones:

¹¹⁶ Winstein, S.; Lucas, H.J. *J. Am. Chem. Soc.* **1939**, 61, 1576, 2845.

¹¹⁷ For a theoretical treatment of strain energy release and intrinsic barriers for internal S_N2 reactions, see Wolk, J.L.; Rozental, E.; Basch, H.; Hoz, S. *J. Org. Chem.* **2006**, 71, 3876.

The fact that acetolysis of both 4-methoxy-1-pentyl brosylate (**24**) and 5-methoxy-2-pentyl brosylate (**25**) gave the same mixture of products is further evidence for participation by a neighboring group.¹¹⁸ In this case, the intermediate **26** is common to both substrates.

The neighboring-group mechanism operates only when the ring size is right for a particular type of Z. For example, for $\text{MeO}(\text{CH}_2)_n\text{OBs}$, neighboring-group participation was important for $n = 4$ or 5 (corresponding to a five- or six-membered intermediate), but not for $n = 2, 3$, or 6 .¹¹⁹ However, optimum ring size is not the same for all reactions, even with a particular Z. In general, the most rapid reactions occur when the ring size is three, five, or six, depending on the reaction type. The likelihood of four-membered ring neighboring-group participation is increased when there are alkyl groups α or β to the neighboring group.¹²⁰

The following are some of the more important neighboring groups: COO^- (but not COOH), COOR , COAr , OCOR ,¹²¹ OR , OH , O^- ,¹²² NH_2 , NHR , NR_2 , NHCOR , SH , SR , S^- ,¹²³ SO_2Ph ,¹²⁴ I , Br , and Cl . The effectiveness of halogens as neighboring groups decreases in the order $\text{I} > \text{Br} > \text{Cl}$.¹²⁵ The Cl substituents is a very weak neighboring group, and can be shown to act in this way only when the solvent does not interfere. For example, when 5-chloro-2-hexyl tosylate is solvolyzed in acetic acid, there is little participation by the Cl , but when the solvent is changed to trifluoroacetic acid, which is much less nucleophilic, neighboring-group participation by the Cl becomes the major reaction

pathway.¹²⁶ Thus, Cl acts as a neighboring group *only when there is need for it* (for other examples of the *principle of increasing electron demand*, see Sec. 10.C.i).

A number of intermediates of halogen participation (halonium ions),¹²⁷ (e.g., **27** and **28**), have been prepared as stable salts in $\text{SbF}_5\text{—SO}_2$ or $\text{SbF}_5\text{—SO}_2\text{ClF}$ solutions.¹²⁸ Some have even been crystallized. Attempts to prepare four-membered homologues of **27** and **28** were not successful.¹²⁹ There is no evidence that F can act as a neighboring group.¹²³

The principle that a neighboring group lends assistance in proportion to the need for such assistance also applies to differences in leaving-group ability. Thus, $p\text{-NO}_2\text{C}_6\text{H}_4\text{SO}_2\text{O}$ (the nosylate group) is a better leaving group than $p\text{-MeC}_6\text{H}_4\text{SO}_2\text{O}$ (the tosylate group). Experiments have shown that the OH group in *trans*-2-hydroxycyclopentyl arenesulfonates (**29**) acts as a neighboring group when the leaving group is tosylate, but not when it is nosylate, apparently because the nosylate group leaves so rapidly that it does not require assistance.¹³⁰

10.C.i. Neighboring-Group Participation by π and σ Bonds: Nonclassical Carbocations¹³¹

For all the neighboring groups listed in Section 10.C, the nucleophilic attack is made by an atom with an unshared pair of electrons. In this section, neighboring-group participation by $\text{C}=\text{C}$ π bonds and C—C and C—H σ bonds will be considered. There has been a great deal of controversy over whether such bonds can act as neighboring groups and about the existence and structure of the intermediates involved. These intermediates are called *nonclassical* (or *bridged*) carbocations. In *classical carbocations* (Chap 5), the positive charge is *localized* on one carbon atom or delocalized by resonance involving an unshared pair of electrons or a double or triple bond in the allylic position. In a *nonclassical carbocation*,¹³² the positive charge is *delocalized* by a double or triple bond that is not in the allylic position or by a single bond. Examples are

the 7-norbornenyl cation (**30**), the norbornyl cation (**31**),¹³³ and the cyclopropylmethyl cation (**32**). A cyclopropyl group (as in **33**) is capable of stabilizing the norbornyl cation, inhibiting this rearrangement.¹³⁴ Carbocation **30** is called a *homoaallylic* carbocation, because in **30a** there is one carbon atom between the positively charged carbon and the double bond. Many of these carbocations can be produced in more than one way if the proper substrates are chosen. For example, **31** can be generated by the departure of a leaving group

from **34** or from **35**.¹³⁵ The first of these pathways is called the σ route to a nonclassical carbocation, because participation of a σ bond is involved. The second is called the π route.¹³⁶ The argument against the existence of nonclassical carbocations is essentially that the structures **30a–30c** (or **31a**, **31b**, etc.) are not canonical forms, but real structures and that there is rapid equilibration among them. This debate remained an active area of interest for some reactions for many years.¹³⁷ In one study, the solvolysis and rearrangement of 2-bicyclo[3.2.2]nonanyl tosylate in methanol generated ethers derived from the 2-bicyclo[3.2.2]nonanyl and 2-bicyclo[3.3.1]nonanyl systems that were rationalized in terms of a classical carbocation.¹³⁸ Density functional and *ab initio* calculations indicated that the products of the 2-bicyclo[3.2.2]nonanyl tosylate solvolysis were found to have nonclassical structures.¹³⁹

In discussing nonclassical carbocations, care must be taken to make the distinction between neighboring-group participation and the existence of nonclassical carbocations.¹⁴⁰ If a nonclassical carbocation exists in any reaction, then an ion with electron delocalization, as shown in the above examples, is a discrete reaction intermediate. If a carbon–carbon double or single bond participates in the departure of the leaving group to

form a carbocation, it may be that a nonclassical carbocation is involved, but there is no necessary relation. In any particular case, either or both of these possibilities are possible.

In the following pages, some of the evidence bearing on the questions of the participation of π and σ bonds is considered, which bears on the existence of nonclassical carbocations,¹⁴¹ although a thorough discussion is beyond the scope of this book.¹⁰⁰

1. **C=C as a Neighboring Group.**¹⁴² The most striking evidence that C=C can act as a neighboring group is that acetolysis of **36**-OTs is 10^{11} times faster than that of **37**-OTs and *proceeds with retention of configuration*.¹⁴³ The rate data alone do not necessarily prove that acetolysis of **36**-OTs involves a nonclassical intermediate (**30d**), but it is certainly strong evidence that the C=C group assists in the departure of the OTs.

Evidence that **30** is indeed a nonclassical ion comes from an NMR study of the relatively stable norbornadienyl cation (**38**). The ^1H NMR spectrum shows that the 2 and 3 protons are not equivalent to the 5 and 6 protons.¹⁴⁴ Thus there is interaction between the charged carbon and one double bond, which is evidence for the existence of **30d**.¹⁴⁵ In the case of **36**, the double bond is geometrically fixed in an especially favorable position for backside attack on the carbon bearing the leaving group (hence the very large rate enhancement), but there is much evidence that other double bonds in the homoallylic position,¹⁴⁶ as well as in positions farther away,¹⁴⁷ can also lend anchimeric assistance, although generally with much lower rate ratios. One example of the latter is the compound β -(*syn*-7-norbornenyl)ethyl brosylate (**39**), which at 25°C undergoes acetolysis $\sim 140,000$ times faster than the saturated analogue **40**.¹⁴⁸ Triple bonds¹⁴⁹ and allenes¹⁵⁰ can also act as neighboring groups.

Evidence has been presented to show that participation by a potential neighboring group can be reduced or eliminated if an outside nucleophile is present that is more effective than the neighboring group in attacking the central carbon (see above), or if a sufficiently good leaving group is present (see above). In another example of the principle of increasing electron demand, Gassman et al.¹⁵¹ showed that neighboring-group participation can also be reduced if the stability of the potential carbocation is increased. They found that the presence of a *p*-anisyl group at the 7 position of **36** and **37** exerts a powerful leveling effect on the rate differences. Thus, solvolysis in acetone–water at 85 °C of **38** was only ~ 2.5 times faster than that of the saturated compound **42**. Furthermore, both **41** and its stereoisomer **43** gave the same mixture of solvolysis products, showing that the stereoselectivity in the solvolysis of **36** is not present here. The difference between **41** and **36** is that in the case of **41** the positive charge generated at the 7 position in the transition state is greatly stabilized by the *p*-anisyl group. Apparently, the stabilization by the *p*-anisyl group is so great that further stabilization that would come from participation by the C=C bond is not needed.¹⁵² The use of a phenyl instead of a *p*-anisyl group is not sufficient to stop participation by the double bond completely, although it does reduce it.¹⁵³ These results essentially emphasize the previous conclusion that *a neighboring group lends anchimeric assistance only when there is sufficient demand for it*.¹⁵⁴ The π -bond of a neighboring alkene group can assist solvolysis via π -participation.¹⁵⁵

The ability of C=C to serve as a neighboring group can depend on its electron density. When the strongly electron-withdrawing CF₃ group was attached to a double-bond carbon of **44**, the solvolysis rate was lowered by a factor of ~ 10⁶.¹⁵⁶ A second CF₃ group had an equally strong effect. In this case, two CF₃ groups decrease the electron density of the C=C bond to the point that the solvolysis rate for **44** (R¹ = R² = CF₃) was about the same as (actually ~ 17 times slower than) the rate for the saturated substrate **37** (X = OMos). Thus, the two CF₃ groups completely remove the ability of the C=C bond to act as a neighboring group.

2. *Cyclopropyl¹⁵⁷ as a Neighboring Group.*¹⁵⁸ In Section 4.Q.i, the properties of a cyclopropane ring were shown to be similar to those of a double bond in some ways. Therefore it is not surprising that a suitably placed

cyclopropyl ring can also be a neighboring group. Thus *endo-anti*-tricyclo[3.2.1.0^{2,4}]octan-8-yl *p*-nitrobenzoate (**45**) solvolyzed $\sim 10^{14}$ times faster than the *p*-nitrobenzoate of **37-OH**.¹⁵⁹ Obviously, a suitably placed cyclopropyl ring can be even more effective¹⁶⁰ as a neighboring group than a double bond.¹⁶¹ The need for suitable placement is emphasized by the fact that **47** solvolyzed only about five times faster than **37-OBs**,¹⁶² while **46** solvolyzed three times *slower* than **37-OBs**.¹⁶³ In the case of **45** and of all other cases known where cyclopropyl lends considerable anchimeric assistance, the developing *p* orbital of the carbocation is orthogonal to the participating bond of the cyclopropane ring.¹⁶⁴ An experiment designed to test whether a developing *p* orbital that would be parallel to the participating bond would be assisted by that bond showed no rate enhancement.¹⁶⁴ This result is in contrast to the behavior of cyclopropane rings directly attached to positively charged carbons, where the *p* orbital is parallel to the plane of the ring (Sec. 5.A.ii, and category 4.b below). Rate enhancements, although considerably smaller, have also been reported for suitably placed cyclobutyl rings.¹⁶⁵

3. *Aromatic Rings as Neighboring Groups.*¹⁶⁶ There is a great deal of evidence that aromatic rings in the β position can function as neighboring groups.¹⁶⁷

¹⁵⁷ In this section, systems are considered in which at least one carbon separates the cyclopropyl ring from the carbon bearing the leaving group. For a discussion of systems in which the cyclopropyl group is directly attached to the leaving-group carbon, see below, category 4.b.

Stereochemical evidence was obtained by solvolysis of L-*threo*-3-phenyl-2-butyl tosylate (**48**) in acetic acid.¹⁶⁸ Of the acetate product, 96% was the *threo* isomer and only ~ 4% was *erythro*. Moreover, both the (+) and (-) *threo* isomers (**49** and **50**) were produced in

approximately equal amounts (a racemic mixture). When solvolysis was conducted in formic acid, even less *erythro* isomer was obtained. This result is similar to that found on reaction of 3-bromo-2-butanol with HBr (Sec. 10.C) and leads to the conclusion that configuration is retained because phenyl acts as a neighboring group. However, evidence from rate studies is not so simple. If β -aryl groups assist the departure of the leaving group, solvolysis rates should be enhanced. In general, they are not. However, solvolysis rate studies in 2-arylethyl systems are complicated by the fact that, for primary and secondary systems, two pathways can exist.¹⁶⁹ In one of these (designated k_{Δ}), the aryl, behaving as a neighboring group, pushes out the leaving

group to give a bridged ion, called a *phenonium ion* (**51**), and is in turn pushed out by the solvent (SOH), so the net result is substitution with retention of configuration (or rearrangement, if **51** is opened from the other side). The other pathway (k_s) is simple S_N2 attack by the solvent at the leaving-group carbon. The net result is substitution with inversion and no possibility of rearrangement. Whether the leaving group is located at a primary or a secondary carbon, there is no cross over between these pathways; they are completely independent.¹⁷⁰ Both the k_{Δ} and k_s pathways are unimportant when the leaving group is at a tertiary carbon. In these cases, the mechanism is S_N1 and open carbocations $\text{ArCH}_2\text{CR}_2^+$ are intermediates. This pathway is designated k_c . Which of the two pathways (k_s or k_{Δ}) predominates in any given case depends on the solvent and on the nature of the aryl group. As expected from the results we have seen for Cl as a neighboring group (see above), the k_{Δ}/k_s ratio is highest for solvents that are poor nucleophiles and so compete very poorly with the aryl group. For several common solvents, the k_{Δ}/k_s ratio increases in the order $\text{EtOH} < \text{CH}_3\text{CO}_2\text{H} < \text{HCO}_2\text{H} < \text{CF}_3\text{CO}_2\text{H}$.¹⁷¹ In accord with this, the following percentages of retention were obtained in solvolysis of 1-phenyl-2-propyl tosylate at 50 °C: solvolysis in EtOH 7%, $\text{CH}_3\text{CO}_2\text{H}$ 35%, and HCO_2H 85%.¹⁷¹ This finding indicates that k_s predominates in EtOH (phenyl participates very little),

while k_{Δ} predominates in HCO₂H. Trifluoroacetic acid is a solvent of particularly low nucleophilic power, and in this solvent the reaction proceeds entirely by k_{Δ} .¹⁷² Deuterium labeling showed 100% retention.¹⁷³ This case provides a clear example of neighboring-group rate enhancement by phenyl. The rate of solvolysis of PhCH₂CH₂OTs at 75 °C in CF₃COOH is 3040 times the rate for CH₃CH₂OTs.¹⁷²

With respect to the aromatic ring, the k_{Δ} pathway is electrophilic aromatic substitution (Chapter 11). Groups on the ring that activate that reaction (Sec. 11.B.i) are predicted to increase, and deactivating groups will decrease the rate of this pathway. This prediction has been borne out by several investigations. The p -nitro derivative of **48** solvolyzed in acetic acid 190 times slower than **48**, and there was much less retention of configuration; the acetate produced was only 7% threo and 93% erythro.¹⁷⁴ At 90 °C, acetolysis of p -ZC₆H₄CH₂CH₂OTs gave the rate ratios shown in Table 10.1.¹⁷⁵ Throughout this series k_s is fairly constant, as it should be since it is affected only by the rather remote field effect of Z. It is k_{Δ} that changes substantially as Z is changed from activating to deactivating. The evidence is thus fairly clear that participation by aryl groups depends greatly on the nature of the group. For some groups (e.g., p -nitrophenyl), in some solvents (e.g., acetic acid), there is essentially no neighboring-group participation at all,¹⁷⁶ while for others (e.g., p -methoxyphenyl), neighboring-group participation is substantial. The combined effect of solvent and structure is shown in Table 10.2, where the figures shown were derived by three different methods.¹⁷⁷ The decrease in neighboring-group effectiveness when aromatic rings are substituted by electron-withdrawing groups is reminiscent of the similar case of C=C bonds substituted by CF₃ groups (see above, category 1).

^aSee Ref. 177.

Several phenonium ions have been prepared as stable ions in solution where they can be studied by NMR, among them **52**,¹⁷⁸ **53**,¹⁷⁹ and the unsubstituted **51**.¹⁸⁰ These were prepared¹⁸¹ by the method shown for **51**: treatment of the corresponding β -arylethyl chloride with SbF₅—SO₂ at low temperatures. These conditions are even more

extreme than the solvolysis in CF₃COOH mentioned earlier. The absence of any nucleophile eliminates not only the k_s pathways but also nucleophilic attack on **51**. Although **51** is not in equilibrium with the open-chain ion PhCH₂CH₂⁺, which is primary and hence unstable, **53** is in equilibrium with the open-chain tertiary ions PhCMe₂C⁺Me₂ and PhC⁺MeCMe₃, although only **53** is present in appreciable concentration. Proton and ¹³C NMR show that **51**–**53** are classical carbocations where the only resonance is in the six-membered ring. The three-membered ring is a normal cyclopropane ring that is influenced only to a relatively small extent by the positive charge on the adjacent ring. Nuclear magnetic resonance spectra show that the six-membered rings have no aromatic character, but are similar in structure to the arenium ions (e.g., **54**), that are intermediates in electrophilic aromatic substitution (Chapter 11). A number of phenonium ions, including **51**, have also been reported to be present in the gas phase, where their existence has been inferred from reaction products and from ¹³C labeling.¹⁸²

It is thus clear that β -aryl groups can function as neighboring groups.¹⁸³ Much less work has been done on aryl groups located in positions farther away from the leaving group, but there is evidence that these too can lend anchimeric assistance.¹⁸⁴

4. *The Carbon–Carbon Single Bond as a Neighboring Group.*¹⁸⁵

- a. *The 2-Norbornyl System.* In the investigations to determine whether a C—C σ bond can act as a neighboring group, by far the greatest attention has been paid to the 2-norbornyl system.¹⁸⁶ Winstein et al.¹⁸⁷ found that solvolysis in acetic acid of optically active *exo*-2-norbornyl brosylate (**55**, OB = brosylate) gave a racemic mixture of the two *exo* acetates; no *endo* isomers were formed:

Furthermore, **55** solvolyzed ~ 350 times faster than its *endo* isomer (**58**). Similar high *exo/endo* rate ratios have been found in many other [2.2.1] systems. These two results [(1) that solvolysis of an optically active *exo* isomer gave only racemic *exo* isomers and (2) the high *exo/endo* rate ratio] were interpreted by Winstein et al.¹⁸⁷ as indicating that the 1,6-bond assists in the departure of the leaving group and that a nonclassical intermediate (**59**) is involved. They reasoned that solvolysis of the *endo* isomer (**58**) is not assisted by the 1,6-bond because it is not in a favorable position for backside attack, and that consequently solvolysis of **58** takes place at a “normal” rate. Therefore the much faster rate for the solvolysis of **55** must be caused by anchimeric assistance. The stereochemistry of the product is also explained by the intermediacy of **59**, since in **59** the 1 and 2 positions are equivalent and would be attacked by the nucleophile with equal facility, but only from the *exo* direction in either case. Incidentally, acetolysis of **58** also leads exclusively to the *exo* acetates (**56** and **57**), so that in this case Winstein et al.¹⁸⁷ postulated that a classical ion (**60**) is first formed and then converted to the more stable **59**. Evidence for this interpretation is that the product from solvolysis of **58** is not racemic, but contains somewhat more **57** than **56** (corresponding to 3–13% inversion, depending on the solvent), suggesting that when **60** is formed, some of it goes to give **57** before it can collapse to **59**.

The concepts of σ participation and the nonclassical ion **59** were challenged by H.C. Brown,¹⁴¹ who suggested that the two results can also be explained by postulating that **55** solvolyzes without participation of the 1,6 bond to give the classical ion **60**, which is in rapid equilibrium with **61**. This rapid interconversion has been likened to the action of a windshield wiper.¹⁸⁸ Obviously, in going from **60** to **61** and back again, **59** must be present, but in Brown's view it is a transition state and not an intermediate. Brown's explanation for the stereochemical result was that exclusive exo attack is a property to be expected from any 2-norbornyl system, not only for the cation but even for reactions not involving cations, because of steric hindrance to attack from the endo side. There is a large body of data showing that exo attack on norbornyl systems is fairly general in many reactions. A racemic mixture will be obtained if **60** and **61** are present in equal amounts, since they are equivalent and exo attack on **60** and **61** gives, respectively, **57** and **56**. Brown explained the high exo/endo rate ratios by contending that it is not the endo rate that is normal and the exo rate abnormally high, but the exo rate that is normal and the endo rate abnormally *low*, because of steric hindrance to removal of the leaving group in that direction.¹⁸⁹

A vast amount of work has been done¹⁹⁰ on solvolysis of the 2-norbornyl system in an effort to determine whether the 1,6-bond participates and whether **59** is an intermediate. Most,¹⁹¹ although not all,¹⁹² chemists now accept the intermediacy of **59**.

Besides the work done on solvolysis, of 2-norbornyl compounds, the 2-norbornyl cation has also been extensively studied at low temperatures; there is much evidence that under these conditions the ion is definitely nonclassical. Olah and co-workers prepared the 2-norbornyl cation in stable solutions at temperatures below -150°C in $\text{SbF}_5\text{--SO}_2$ and $\text{FSO}_3\text{H--SbF}_5\text{--SO}_2$, where the structure is static

and hydride shifts are absent.^{193,194} Studies by ^1H and ^{13}C NMR, as well as by laser Raman spectra and X-ray electron spectroscopy, led to the conclusion¹⁹⁴ that under these conditions the ion is nonclassical.¹⁹⁵ A similar result has been reported for the 2-norbornyl cation in the solid state, where at 77 and even 5 K, ^{13}C NMR spectra gave no evidence of the freezing out of a single classical ion.¹⁹⁶

Olah and co-workers represented the nonclassical structure as a corner-protonated nortricyclane (**62**); the symmetry is better seen when the ion is drawn, as in **63**. Almost all the positive charge resides on C-1 and C-2 and very little on the bridging carbon C-6. Other evidence for the nonclassical nature of the 2-norbornyl cation in stable solutions comes from heat of reaction measurements showing that the 2-norbornyl cation is more stable (by $\sim 6\text{--}10\text{ kcal mol}^{-1}$ or $25\text{--}40\text{ kJ mol}^{-1}$) than would be expected without the bridging.¹⁹⁷ Studies of IR spectra of the 2-norbornyl cation in the gas phase also show the nonclassical structure.¹⁹⁸ *Ab initio* calculations show that the nonclassical structure corresponds to an energy minimum.¹⁹⁹

The spectra of other norbornyl cations have also been investigated at low temperatures. Spectra of the tertiary 2-methyl- and 2-ethylnorbornyl cations show less delocalization,²⁰⁰ and the 2-phenylnorbornyl cation (**64**) is essentially classical,²⁰¹ as are the 2-methoxy-²⁰² and 2-chloronorbornyl cations.²⁰³ Recall (Sec. 5.A.ii) that methoxy and halo groups also stabilize a positive charge. The ^{13}C NMR data show that electron-withdrawing groups on the benzene ring of **64** cause the ion to become less classical, while electron-donating groups enhance the classical nature of the ion.²⁰⁴

b. *The Cyclopropylmethyl System.* Apart from the 2-norbornyl system, the greatest amount of effort in the search for C—C participation has been devoted to the

¹⁹³ The presence of hydride shifts (Reaction 18-01) under solvolysis conditions has complicated the interpretation of the data.

cyclopropylmethyl system.²⁰⁵ It has long been known that cyclopropylmethyl substrates solvolyze with abnormally high rates and that the products often include not only unrearranged cyclopropylmethyl, but also cyclobutyl and homoallylic compounds. An example is²⁰⁶

Cyclobutyl substrates also solvolyze abnormally rapidly and give similar products. Indeed, computational studies on the cyclobutylmethyl cation suggest it is nonclassical (Sec. 10.C.i). Furthermore, when the reactions are carried out with labeled substrates, considerable, although not complete, scrambling is observed. For these reasons, it has been suggested that a common intermediate (some kind of nonclassical intermediate, e.g., **32**) is present in these cases. This common intermediate could then be obtained by three routes:

In recent years, much work has been devoted to the study of these systems, and it is apparent that matters are not so simple, although there is much that is still not completely understood, some conclusions can be drawn.

- i. In the solvolysis of simple primary cyclopropylmethyl systems, the rate is enhanced because of participation by the σ bonds of the ring.²⁰⁷ The ion that forms initially is an unrearranged cyclopropylmethyl cation²⁰⁸ that is *symmetrically* stabilized; that is, both the 2,3 and 2,4 σ bonds help stabilize the positive charge. As seen previously (Sec. 5.A.ii) that a cyclopropyl group stabilizes an adjacent positive charge even better than a phenyl group. One way of representing the structure of this cation is as shown in **65**. Among the evidence that **65** is a symmetrical ion is that substitution of one or more methyl groups in the 3 and 4 positions increases the rate of solvolysis of cyclopropylcarbonyl 3,5-dinitrobenzoates by approximately a factor of 10 for *each* methyl group.²⁰⁹ If only one of the σ bonds (say, the 2,3 bond) stabilizes the cation, then methyl substitution at the 3 position should increase the rate, and a second methyl group at the 3 position should increase it still more, but a second methyl group at the 4 position should have little effect.²¹⁰

- ii. The most stable geometry of simple cyclopropylmethyl cations is the bisected one shown in Section 5.A.ii. There is much evidence that in systems where this geometry cannot be obtained, solvolysis is greatly slowed.²¹¹
- iii. Once a cyclopropylmethyl cation is formed, it can rearrange to two other cyclopropylmethyl cations:

This rearrangement, which accounts for the scrambling, is completely stereospecific.²¹² The rearrangements probably take place through a non-planar cyclobutyl cation intermediate or transition state. The formation of cyclobutyl and homoallylic products from a cyclopropylmethyl cation is also completely stereospecific. These products may arise by direct attack of the nucleophile on **65** or on the cyclobutyl cation intermediate.²¹³ A planar cyclobutyl cation is ruled out in both cases because it would be symmetrical and the stereospecificity would be lost.

- iv. The rate enhancement in the solvolysis of secondary cyclobutyl substrates is probably caused by participation by a bond leading directly to **65**, which accounts for the fact that solvolysis of cyclobutyl and of cyclopropylmethyl substrates often gives similar product mixtures. There is no evidence that requires cyclobutyl cations to be intermediates in most secondary cyclobutyl systems, although tertiary cyclobutyl cations can be solvolysis intermediates.

- v. The unsubstituted cyclopropylmethyl cation has been generated in superacidic solutions at low temperatures, where ¹³C NMR spectra have led to the conclusion that it consists of a mixture of the bicyclobutonium ion (**32**) and the bisected cyclopropylmethyl cation (**65**), in equilibrium with **32**.²¹⁴ Molecular orbital calculations show that these two species are energy minima, and that both have nearly the same energy.²¹³

c. *Methyl as a Neighboring Group.* Both the 2-norbornyl and cyclopropylmethyl system contain a σ bond that is geometrically constrained to be in a particularly favorable position for participation as a neighboring group. However, there have been a number of investigations to determine whether a C—C bond can lend anchimeric assistance even in a simple open-chain compound, (e.g., neopentyl tosylate). On solvolysis, neopentyl systems undergo almost exclusive rearrangement and **66** must lie on the reaction path, but the two questions

that have been asked are (1) Is the departure of the leaving group concerted with the formation of the $\text{CH}_3\text{—C}$ bond (e.g., does the methyl participate)? (2) Is **66** an intermediate or only a transition state? With respect to the first question, there is evidence, chiefly from isotope effect studies, which indicates that the methyl group in the neopentyl system does indeed participate,²¹⁵ although it may not greatly enhance the rate. As to the second question, evidence that **66** is an intermediate is that small amounts of cyclopropanes (10–15%) can be isolated in these reactions.²¹⁶ Cation **66** is a protonated cyclopropane and would give cyclopropane on loss of a proton.²¹⁷ In an effort to isolate a species that has structure **66**, the 2,3,3-trimethyl-2-butyl cation was prepared in superacid solutions at low temperatures.²¹⁸ However, ^1H and ^{13}C NMR, as well as Raman spectra, showed this to be a pair of rapidly equilibrating open ions. Of course, **67** must lie on the reaction path connecting the two open ions, but it is evidently a transition state and not an intermediate. However, evidence from X-ray photoelectron spectroscopy (XPS) has shown that the 2-butyl cation is substantially methyl bridged.²¹⁹

d. *Silylalkyl as a Neighboring Group.* Rates of solvolysis are enhanced in molecules that contain a silylalkyl or silylaryl group β -to the carbon bearing the leaving group. This is attributed to formation of a cyclic transition state involving the silicon.²²⁰

²²⁰ Fujiyama, R.; Munechika, T. *Tetrahedron Lett.* **1993**, 34, 5907.

5. *Hydrogen as a Neighboring Group.* The questions relating to hydrogen are similar to those relating to methyl. There is no question that hydride can migrate, but the two questions are (1) Does the hydrogen atom

participate in the departure of the leaving group? (2) Is **68** an intermediate or only a transition state? There is some evidence that a β hydrogen can participate.²²¹ Evidence that **68** can be an intermediate in solvolysis

reactions comes from a study of the solvolysis in trifluoroacetic acid of deuterated *sec*-butyl tosylate **69**. In this solvent of very low nucleophilic power, the products were an equimolar mixture of **70** and **71**,²²² but

no **72** or **73** was found. If this reaction did not involve neighboring hydrogen at all (pure $\text{S}_{\text{N}}2$ or $\text{S}_{\text{N}}1$), the product would be only **70**. On the other hand, if hydrogen does migrate, but only open cations are involved, then there should be an equilibrium among these four cations:

leading not only to **70** and **71**, but also to **72** and **73**. The results are most easily compatible with the intermediacy of the bridged ion **74**, which can then be attacked by the solvent equally at the 2 and 3 positions. Attempts to prepare **68** as a stable ion in superacid solutions at low temperatures have not been successful.²²¹

10.D. THE $\text{S}_{\text{N}}\text{i}$ MECHANISM

In a few reactions, nucleophilic substitution proceeds with retention of configuration, even where there is no possibility of a neighboring-group effect. In the $\text{S}_{\text{N}}\text{i}$ mechanism (*substitution nucleophilic internal*), part of the leaving group must be able to attack the substrate, detaching itself from the rest of the leaving group in the process. The IUPAC

²²¹ See Buzek, P.; Schleyer, P.v.R.; Sieber, S.; Koch, W.; Carneiro, J.W. de M.; Vancik, H.; Sunko, D.E. *J. Chem. Soc., Chem. Commun.* **1991**, 671; Imhoff, M.A.; Ragain, R.M.; Moore, K.; Shiner, V.J. *J. Org. Chem.* **1991**, 56, 3542.

designation is $D_N + A_N D_e$. The first step is the same as the very first step of the S_N1 mechanism: dissociation into an intimate ion pair.²²³ But in the second step part of the leaving group attacks, necessarily from the front since it is unable to get to the rear, which results in retention of configuration.

The example shown is the most important case of this mechanism yet discovered, since the reaction of alcohols with thionyl chloride to give alkyl halides usually proceeds in this way, with the first step in this case being $ROH + SOCl_2 \rightarrow ROSOCl$ (these alkyl chlorosulfites can be isolated).

Evidence for this mechanism is as follows: The addition of pyridine to the mixture of alcohol and thionyl chloride results in the formation of alkyl halide with *inverted* configuration. Inversion results because the pyridine reacts with $ROSOCl$ to give $ROSONC_5H_5$ before anything further can take place. The Cl^- freed in this process now attacks from the rear. The reaction between alcohols and thionyl chloride is second order, which is predicted by this mechanism, but the decomposition by simple heating of $ROSOCl$ is first order.²²⁴

The S_Ni mechanism is relatively rare. Another example is the decomposition of $ROCOCl$ (alkyl chloroformates) into RCI and CO_2 .²²⁵

10.E. NUCLEOPHILIC SUBSTITUTION AT AN ALLYLIC CARBON: ALLYLIC REARRANGEMENTS

Allylic substrates rapidly undergo nucleophilic substitution reactions (see Sec. 10.G.i, category 3), but we discuss them in a separate section because they are commonly accompanied by a certain kind of rearrangement known as an *allylic rearrangement*.²²⁶ When allylic substrates are treated with nucleophiles under S_N1 conditions, two products are usually obtained: the normal one and a rearranged one.

Two products are formed because an allylic type of carbocation is a resonance hybrid

²²⁶ See DeWolfe, R.H. in Bamford, C.H.; Tipper, C.F.H. *Comprehensive Chemical Kinetics*, Vol. 9, Elsevier, NY, **1973**, pp. 417–437. For comprehensive older reviews, see DeWolfe, R.H.; Young, W.G. *Chem. Rev.* **1956**, *56*, 753; in Patai, S. *The Chemistry of Alkenes*, Wiley, NY, **1964**, the sections by Mackenzie, K. pp. 436–453 and DeWolfe, R.H.; Young, W.G. pp. 681–738.

so that C-1 and C-3 each carry a partial positive charge and both are attacked by Y. Of course, an allylic rearrangement is undetectable in the case of symmetrical allylic cations, as in the case where R = H, unless isotopic labeling is used. This mechanism has been called the S_N1' mechanism. The IUPAC designation is $1/D_N + 3/A_N$, the numbers 1 and 3 signifying the *relative* positions where the nucleophile attacks and from which the nucleofuge leaves.

As with other S_N1 reactions, there is clear evidence that S_N1' reactions can involve ion pairs. If the intermediate attacked by the nucleophile is a completely free carbocation, then, say,

should give the same mixture of alcohols when reacting with hydroxide ion, since the carbocation from each should be the same. When treated with 0.8 M aq NaOH at 25 °C, **75** gave 60% $\text{CH}_3\text{CH}=\text{CHCH}_2\text{OH}$ and 40% $\text{CH}_3\text{CHOHCH}=\text{CH}_2$, while **76** gave the products in yields of 38 and 62%, respectively.²²⁷ This phenomenon is called the *product spread*. In this case, and in most others, the product spread is in the direction of the starting compound. With increasing polarity of solvent,²²⁸ the product spread decreases and in some cases is entirely absent. It is evident that in such cases the high polarity of the solvent completely stabilizes free carbocations. There is other evidence for the intervention of ion pairs in many of these reactions. When $\text{H}_2\text{C}=\text{CHCMe}_2\text{Cl}$ was treated with acetic acid, both acetates were obtained, but also some $\text{ClCH}_2\text{CH}=\text{CMe}_3$,²²⁹ and the isomerization was faster than the acetate formation. This could not have arisen from a completely free Cl^- returning to the carbon, since the rate of formation of the rearranged chloride was unaffected by the addition of external Cl^- . All these facts indicate that the first step in these reactions is the formation of an unsymmetrical intimate ion pair that undergoes a considerable amount of internal return and in which the counterion remains close to the carbon from which it departed. Thus, **75** and **76**, for example, give rise to two *different* intimate ion pairs. The field of the anion polarizes the allylic cation, making the nearby carbon atom more electrophilic, so that it has a greater chance of attracting the nucleophile.²³⁰

Nucleophilic substitution at an allylic carbon can also take place by an S_N2 mechanism, in which case no allylic rearrangement usually takes place. However, allylic rearrangements can also take place under S_N2 conditions, by the following mechanism, in which the nucleophile attacks at the γ carbon rather than the usual position:²³¹

²²⁷ DeWolfe, R.H.; Young, W.G. *Chem. Rev.* **1956**, 56, 753 give several dozen such examples.

²²⁸ Katritzky, A.R.; Fara, D.C.; Yang, H.; Tamm, K.; Tamm, T.; Karelson, M. *Chem. Rev.* **2004**, 104, 175.

²²⁹ Young, W.G.; Winstein, S.; Goering, H.L. *J. Am. Chem. Soc.* **1951**, 73, 1958.

²³⁰ See Kantner, S.S.; Humski, K.; Goering, H.L. *J. Am. Chem. Soc.* **1982**, 104, 1693; Thibblin, A. *J. Chem. Soc. Perkin Trans. 2* **1986**, 313.

²³¹ See Magid, R.M. *Tetrahedron* **1980**, 36, 1901, see pp. 1901–1910.

The IUPAC designation is 3/1/A_ND_N. This mechanism is a second-order allylic rearrangement; it usually comes about where S_N2 conditions hold but where a substitution sterically retards the normal S_N2 mechanism.²³² There are few well-established cases of the S_N2' mechanism on substrates of the type C=C—CH₂X, but compounds of the form C=C—CR₂X give the S_N2' rearrangement almost exclusively²³³ when they give bimolecular reactions at all. Increasing the size of the nucleophile can also increase the extent of the S_N2' reaction at the expense of the S_N2.²³³ In certain cases, the leaving group can also have an effect on whether the rearrangement occurs. Thus PhCH=CHCH₂X, treated with LiAlH₄, gave 100% S_N2 reaction (no rearrangement) when X = Br or Cl, but 100% S_N2' when X = PPh₃⁺ Br[−].²³⁴ The solvent also plays a role in some cases, with more polar solvents giving more S_N2' product.²³⁵

The S_N2' mechanism, as shown above, involves the simultaneous movement of three pairs of electrons. However, Bordwell et al.²³⁶ contended that there is no evidence requiring that this bond making and bond breaking be in fact concerted, and that a true S_N2' mechanism is a myth. There is evidence both for²³⁷ and against²³⁸ this proposal. There is also a review of the S_N' reaction.²³⁹

The stereochemistry of S_N2' reactions has been investigated. It has been found that both syn²⁴⁰ (the nucleophile enters on the side from which the leaving group departs) and anti²⁴¹ reactions can take place, depending on the nature of X and Y,²⁴² although the syn pathway predominates in most cases.

When a molecule has a nucleofuge capable of giving the S_Ni reaction in an allylic position, it is possible for the nucleophile to attack at the γ position instead of the α position. This reaction is called the S_Ni' mechanism and has been demonstrated on 2-buten-1-ol and 3-buten-2-ol, both of which gave 100% allylic rearrangement

when treated with thionyl chloride in ether.²⁴³ Ordinary allylic rearrangements (S_N1') or S_N2' mechanisms could not be expected to give 100% rearrangement in *both* cases. In the case shown, the nucleophile is only part of the leaving group, not the whole. But it is also possible to have reactions in which a simple leaving group, (e.g., Cl) comes off to form an ion pair²⁴⁴ and then returns not to the position where it originated but to the allylic position:

Most S_N1' reactions are of this type.

Allylic rearrangements have also been demonstrated in propargyl systems, for example,²⁴⁵

The product in this case is an allene,²⁴⁶ but such shifts can also give triple-bond compounds or, if Y = OH, an enol will be obtained that tautomerizes to an α,β -unsaturated aldehyde or ketone.

When X = OH, this conversion of acetylenic alcohols to unsaturated aldehydes or ketones is called the *Meyer-Schuster rearrangement*.²⁴⁷ The propargyl rearrangement can also go the other way; that is, 1-haloalkenes, treated with organocopper compounds, give alkynes.²⁴⁸

The S_N2' reaction has been shown to predominate in reactions of mixed cuprates (Reaction 10-58) with allylic mesylates,²⁴⁹ and in ring-opening reactions of aziridines.²⁵⁰ A related reaction is the opening of cyclopropylcarbinyl halides with organocuprates where the cyclopropane ring reacts similarly to the C=C unit of an alkene to give a homoallylic substituted product.²⁵¹ This latter reaction is interesting since the reaction of **77** with piperidine leads to the S_N2' product (**78**) in ~ 87% yield, but there is ~ 8% of the direct substitution product, (**79**). Since the carbon bearing the bromine is very hindered,

formation of **72** is somewhat unusual under these conditions. As Bordwell has suggested (see above), this may not be a true S_N2 process.

10.F. NUCLEOPHILIC SUBSTITUTION AT AN ALIPHATIC TRIGONAL CARBON: THE TETRAHEDRAL MECHANISM

All the mechanisms so far discussed take place at a saturated carbon atom. Nucleophilic substitution is also important at trigonal carbons, especially when the carbon is double bonded to an oxygen, a sulfur, or a nitrogen. These reactions are discussed in Chapter 16. Nucleophilic substitution at vinylic carbons is considered in Section 10.6 and at aromatic carbons in Chapter 13.

Nucleophilic substitution at a vinylic carbon²⁵² is difficult (see Sec. 10.G.i), but many examples are known. The most common mechanisms are the tetrahedral mechanism and the closely related *addition–elimination mechanism*. Both of these mechanisms are impossible at a saturated substrate. The addition–elimination mechanism has been demonstrated for the reaction between 1,1-dichloroethene (**80**) and ArS^- catalyzed by ^-OEt .²⁵³ The product was not the 1,1-dithiophenoxy compound (**81**), but the “rearranged” compound **84**. Isolation of **82** and **83** showed that an addition–elimination mechanism had taken place. In the first step, ArSH adds to the double bond (nucleophilic addition, Sec. 15.A.ii) to give the saturated **82**. The second step is an E2 elimination reaction (Sec. 17.A.i) to give the alkene **83**. A second elimination and addition give **84**.

The tetrahedral mechanism, often also called addition–elimination (*AdN-E*), takes place with much less facility than with carbonyl groups, since the negative charge of the intermediate must be borne by a carbon, which is less electronegative than oxygen, sulfur, or nitrogen:

Such an intermediate can also stabilize itself by combining with a positive species. When it does, the reaction is nucleophilic addition to a $\text{C}=\text{C}$ double bond (see Chap 15). It

²⁵² See Rappoport, Z. *Recl. Trav. Chim. Pays-Bas* **1986**, 104, 309; Shainyan, B.A. *Russ. Chem. Rev.* **1986**, 55, 511; Modena, G. *Acc. Chem. Res.* **1971**, 4, 73.

²⁵³ Truce, W.E.; Boudakian, M.M. *J. Am. Chem. Soc.* **1956**, 78, 2748.

is not surprising that with vinylic substrates addition and substitution often compete. For chloroquinones, where the charge is spread by resonance, tetrahedral intermediates have been isolated:²⁵⁴

In the case of $\text{Ph}(\text{MeO})\text{C}=\text{C}(\text{NO}_2)\text{Ph} + \text{RS}^-$, the intermediate lived long enough to be detected by UV spectroscopy.²⁵⁵

Since both the tetrahedral and addition–elimination mechanisms begin the same way, it is usually difficult to tell them apart, and often no attempt is made to do so. The strongest kind of evidence for the addition–elimination sequence is the occurrence of a “rearrangement”, but of course the mechanism could still take place even if no rearrangement is found. Evidence²⁵⁶ that a tetrahedral or an addition–elimination mechanism takes place in certain cases (as opposed, e.g., to an $\text{S}_{\text{N}}1$ or $\text{S}_{\text{N}}2$ mechanism) is that the reaction rate increases when the leaving group is changed from Br to Cl to F (this is called the *element effect*).²⁵⁷ This finding clearly demonstrates that the carbon–halogen bond does not break in the rate-determining step (as it would in both the $\text{S}_{\text{N}}1$ and $\text{S}_{\text{N}}2$ mechanisms), because fluorine is by far the poorest leaving group among the halogens in both the $\text{S}_{\text{N}}1$ and $\text{S}_{\text{N}}2$ reactions (Sec. 10.G.iii). The rate is faster with fluorides in the cases cited, because the superior electron-withdrawing character of the fluorine makes the carbon of the C–F bond more positive, and hence more susceptible to nucleophilic attack.

Ordinary vinylic substrates react very poorly if at all by these mechanisms, but substitution is greatly enhanced in substrates of the type $\text{ZCH}=\text{CHX}$, where Z is an electron-withdrawing group (HCO , RCO ,²⁵⁸ EtOOC , ArSO_2 , NC , F , etc.), since these β groups stabilize the carbanion:

Many such examples are known. In most cases, where the stereochemistry has been investigated, retention of configuration is observed,²⁵⁹ but stereoconvergence [the same product mixture from an (*E*) or (*Z*) substrate] has also been observed,²⁶⁰ especially where the carbanionic carbon bears two electron-withdrawing groups. Although rare, nucleophilic substitution with inversion has also been reported as in the intramolecular substitution of the C–Br bond of 2-bromobut-2-enylamines by the pendant nitrogen atom, giving

2-ethylene aziridines by way of stereochemical inversion.²⁶¹ It is not immediately apparent why the tetrahedral mechanism should lead to retention, but this behavior has been ascribed, on the basis of MO calculations, to hyperconjugation involving the carbanionic electron pair and the substituents on the adjacent carbon.²⁶²

Vinylc substrates are in general very reluctant to undergo S_N1 reactions, but they can be made to do so in two ways:²⁶³ (1) By the use of a group that stabilizes the vinylic cation. For example, α -aryl vinylic halides $\text{ArBrC}=\text{CR}'_2$ have often been shown to give S_N1 reactions.²⁶⁴ The S_N1 reactions have also been demonstrated with other stabilizing groups: cyclopropyl,²⁶⁵ vinylic,²⁶⁶ alkynyl,²⁶⁷ and an adjacent double-bond ($\text{R}_2\text{C}=\text{C}=\text{CR}'\text{X}$).²⁶⁸ (2) Even without a stabilization, by the use of a very good leaving group [e.g., OSO_2CF_3 (triflate)].²⁶⁹ The stereochemical outcome of S_N1 reactions at a vinylic substrate is often randomization,²⁷⁰ that is, either a cis or a trans substrate gives a 1:1 mixture of cis and trans products, indicating that vinylic cations are linear. Another indication that vinylic cations prefer to be linear is the fact that reactivity in cycloalkenyl systems decreases with decreasing ring size.²⁷¹ However, a linear vinylic cation need not give random products.²⁷² The empty p orbital lies in the plane of the double bond, so entry of the nucleophile can be and often is influenced by the relative size of R^1 and R^2 .²⁷³ It must be emphasized that even where vinylic substrates do give S_N1 reactions, the rates are generally lower than those of the corresponding saturated compounds.

Alkynyl cations are so unstable that they cannot be generated even with very good leaving groups. However, one way in which they have been generated was by formation of a tritiated substrate.

Vinyl halides can react by a $S_{RN}1$ mechanism (Sec. 13.A.iv) in some cases. An example is the $FeCl_2$ catalyzed reaction of 1-bromo-2-phenylethene and the enolate anion of pinacolone ($t\text{-BuCOCH}_2^-$), which gave a low yield of substitution products along with alkynes.²⁸¹

10.G. REACTIVITY

A large amount of work has been done on this subject. Although a great deal is known, much is still poorly understood, and many results are anomalous and hard to explain. In this section, only approximate generalizations are attempted. The work discussed here, and the conclusions reached, pertain to reactions taking place in solution. Some investigations have also been carried out in the gas phase.²⁸²

10.G.i. The Effect of Substrate Structure

The effect on the reactivity of a change in substrate structure depends on the mechanism.

1. *Branching at the α and β Carbons.* For the S_N2 mechanism, branching at either the α or the β carbon decreases the rate. Tertiary systems seldom²⁸³ react by the S_N2 mechanism and neopentyl systems react so slowly as to make such reactions, in general, synthetically useless.²⁸⁴ Experiments show that methyl halide reacts 30 times faster than ethyl, whereas isopropyl halides react 40 times slower than ethyl.²⁸⁵ The presence of π bonds accelerates the rate, as illustrated by the fact that allyl halides react 40 times faster than ethyl halides, and benzyl halides react 120 times faster.²⁸⁵ The reason for the low rates for secondary and especially tertiary is almost certainly steric. This statement includes the primary neopentyl halides, which react 20,000 times slower than ethyl halides.²⁸⁶ The transition state **1** is more crowded when larger groups are close to the central carbon.²⁸⁷

The tetrahedral mechanism for substitution at a carbonyl carbon (Chapter 16) is also slowed or blocked completely by α or β branching for similar reasons. Solvolysis in such systems is linked to relief of B-strain, but solvent participation can overshadow this as steric hindrance increases.²⁸⁸ Severe steric strain can cause distortion from coplanarity in the carbocation intermediate,²⁸⁹ although there seems to be no loss of

resonance stability.²⁹⁰ Adding electron-donating substituents to such molecules improves coplanarity in the cation.²⁹¹ For example, esters of the formula R_3CCOOR' cannot generally be hydrolyzed by the tetrahedral mechanism (see Reaction 16-59), and R_3CCO_2H acids cannot be easily esterified.²⁹² Synthetic advantage can be taken of this fact, for example, with a molecule containing two ester groups only the less hindered one is hydrolyzed.

For the S_N1 mechanism, branching as the α carbon increases the rate, as shown by rate data for alkyl bromides.²⁹³ The secondary bromide isopropyl bromide reacts 11.6 times faster than bromoethane in water at 50 °C, and *tert*-butyl bromide (a tertiary halide) reacts 1.2×10^6 times faster.²⁹³ This result is explained by the stability order of alkyl cations (tertiary > secondary > primary). Of course, the rates are not actually dependent on the stability of the ions, but on the difference in free energy between the starting compounds and the transition states. The *Hammond postulate* (Sec. 6.G) is used to make the assumption that the transition states resemble the cations and that anything (e.g., branching) that lowers the free energy of the ions also lowers it for the transition states. For simple alkyl groups, the S_N1 mechanism is important under all conditions only for tertiary substrates.²⁹⁴ As previously indicated (Sec. 10.A.iv), secondary substrates generally react by the S_N2 mechanism,²⁹⁵ except that the S_N1 mechanism may become important at high solvent polarities. Isopropyl bromide reacts less than twice as fast as ethyl bromide in the relatively nonpolar 60% ethanol (cf. this with the 10^4 ratio for *tert*-butyl bromide, where the mechanism is certainly S_N1), but in the more polar water the rate ratio is 11.6.²⁹³ The 2-adamantyl system is an exception; it is a secondary system that reacts by the S_N1 mechanism because backside attack is hindered for steric reasons.²⁹⁶ Because there is no S_N2 component, this system provides an opportunity for comparing the pure S_N1 reactivity of secondary and tertiary substrates. It has been found that substitution of a methyl group for a hydrogen of 2-adamantyl substrates (thus changing a secondary to a tertiary system) increases solvolysis rates by a factor of $\sim 10^8$.²⁹⁷ Simple primary substrates react by the S_N2 mechanism (or with participation by neighboring alkyl or hydrogen), but not by the

S_N1 mechanism, even when solvolyzed in solvents of very low nucleophilicity²⁹⁸ (e.g., trifluoroacetic acid or trifluoroethanol²⁹⁹), and even when very good leaving groups (e.g., OSO_2F) are present³⁰⁰ (see, however, Sec. 10.G.iii).

For some tertiary substrates, the rate of S_N1 reactions is greatly increased by the relief of B strain in the formation of the carbocation (see Sec. 9.B). Except where B strain is involved, β branching has little effect on the S_N1 mechanism, except that carbocations with β branching undergo rearrangements readily. Of course, isobutyl and neopentyl are primary substrates, and for this reason react very slowly by the S_N1 mechanism, but not more slowly than the corresponding ethyl or propyl compounds.

To sum up, primary and secondary substrates generally react by the S_N2 mechanism and tertiary by the S_N1 mechanism. However, tertiary substrates seldom undergo nucleophilic substitution at all. Elimination is always a possible side reaction of nucleophilic substitutions (wherever a β hydrogen is present), and with tertiary substrates it usually predominates. With a few exceptions, nucleophilic substitutions at a tertiary carbon have little or no preparative value. However, tertiary substrates that can react by the SET mechanism (e.g., $p\text{-NO}_2\text{C}_6\text{H}_4\text{CMe}_2\text{Cl}$) give very good yields of substitution products when treated with a variety of nucleophiles.³⁰¹

2. *Unsaturation at the α Carbon.* Vinylic, acetylenic,³⁰² and aryl substrates are very unreactive toward nucleophilic substitutions. For these systems, both the S_N1 and S_N2 mechanisms are greatly slowed or stopped altogether. One reason that has been suggested for this is that sp^2 (and even more, sp) carbon atoms have a higher electronegativity than sp^3 carbons and thus a greater attraction for the electrons of the bond. As seen previously (Sec. 8.F, category 7), an $sp\text{-H}$ bond has a higher acidity than an $sp^3\text{-H}$ bond, with that of an $sp^2\text{-H}$ bond in between. This is reasonable; the carbon retains the electrons when the proton is lost and an sp carbon, which has the greatest hold on the electrons, loses the proton most easily. But in nucleophilic substitution, the leaving group *carries off* the electron pair, so the situation is reversed and it is the sp^3 carbon that loses the leaving group and the electron pair most easily. Recall (Sec. 1.J) that bond distances decrease with increasing s character. Thus the bond length for a vinylic or aryl C—Cl bond is 1.73 Å compared with 1.78 Å for a saturated C—Cl bond. Other things being equal, a shorter bond is a stronger bond.

Of course, it has been seen (Sec. 10.F) that S_N1 reactions at vinylic substrates can be accelerated by α substituents that stabilize that cation, and that reactions by the tetrahedral mechanism can be accelerated by β substituents that stabilize the carbanion. Also, reactions at vinylic substrates can in certain cases proceed by addition–elimination or elimination–addition sequences (Sec. 10.F).

In contrast to such systems, substrates of the type RCOX are usually much *more* reactive than the corresponding RCH_2X . Of course, the mechanism here is almost always the tetrahedral one. Three reasons can be given for the enhanced reactivity of RCOX : (1) The carbonyl carbon has a sizable partial positive charge that makes it very attractive to nucleophiles. (2) In an $\text{S}_{\text{N}}2$ reaction, a σ bond must break in the rate-determining step, which requires more energy than the shift of a pair of π electrons, which is what happens in a tetrahedral mechanism. (3) A trigonal carbon offers less steric hindrance to a nucleophile than a tetrahedral carbon.

For reactivity in aryl systems, see Chapter 13.

3. *Unsaturation at the β Carbon.* The $\text{S}_{\text{N}}1$ rates are increased when there is a double bond in the β position, so that allylic and benzylic substrates react rapidly (allylic tosylates react more than 30 times faster than ethyl tosylate).³⁰³ The reason is that allylic (Sec. 5.A.ii) and benzylic³⁰⁴ (Sec. 5.A.ii) cations are stabilized by resonance. The presence of a second or a third phenyl group increases the rate still more (10^5 and 10^{10} times faster, respectively), because these carbocations are more stable yet.³⁰³ Remember that allylic rearrangements are possible with allylic systems.

In general, $\text{S}_{\text{N}}1$ rates at an allylic substrate are increased by any substituent in the 1 or 3 position that can stabilize the carbocation by resonance or hyperconjugation.³⁰⁵ Among these are alkyl, aryl, and halo groups.

The $\text{S}_{\text{N}}2$ rates for allylic and benzylic systems are also increased (see above), probably owing to resonance possibilities in the transition state. Evidence for this in benzylic systems is that the rate of the reaction was 8000 times slower than the rate with $(\text{PhCH}_2)_2\text{SEt}^+$.³⁰⁶ The cyclic **86** does not have the proper geometry for conjugation in the transition state.

Triple bonds in the β position (in propargyl systems) have about the same effect as double bonds.³⁰⁷ Alkyl, aryl, halo, and cyano groups, among others, in the 3 position of allylic substrates increase $\text{S}_{\text{N}}2$ rates, owing to increased resonance in the transition state, but alkyl and halo groups in the 1 position decrease the rates because of steric hindrance.

4. *α Substitution.* Compounds of the formula 2X , where $\text{Z} = \text{RO}$, RS , or R_2N undergo $\text{S}_{\text{N}}1$ reactions very rapidly,³⁰⁸ because of the increased resonance in the carbocation.

These groups have an unshared pair on an atom directly attached to the positive carbon, which stabilizes the carbocation (Sec. 5.A.ii). The field effects of these groups would be expected to decrease S_N1 rates (see Sec. 10.G.i, category 6), so the resonance effect is far more important.

When Z in $2X$ is RCO ,³⁰⁹ HCO , $ROCO$, NH_2CO , NC , or F_3C ,³¹⁰ S_N1 rates are decreased compared to CH_3X , owing to the electron-withdrawing field effects of these groups. Furthermore, carbocations³¹¹ with a CO or CN group are greatly destabilized because of the partial positive charge on the adjacent carbon (**87**). The S_N1 reactions have been carried out on such compounds,³¹² but the rates are very low. For example, from a comparison of the solvolysis rates of **88** and **89**, a rate-retarding effect of 10^{76}

was estimated for the $C=O$ group.³¹³ However, when a different kind of comparison is made: $RCOCR'_2X$ versus HCR'_2X (where X = a leaving group), the RCO had only a small or negligible rate-retarding effect, indicating that resonance³¹⁴ may be offsetting the inductive destabilization for this group.³¹⁵ For a CN group also, the rate-retarding effect is reduced by this kind of resonance.³¹⁶ A carbocation with a COR group has been isolated.³¹⁷ When S_N2 reactions are carried out on these substrates, rates are greatly increased for certain nucleophiles (e.g., halide or halide-like ions), but decreased or essentially unaffected by others.³¹⁸ For example, α -chloroacetophenone ($PhCOCH_2Cl$) reacts with KI in acetone at $75^\circ C \sim 32,000$ times faster than 1-chlorobutane,³¹⁹ but α -bromoacetophenone reacts with the nucleophile triethylamine 0.14 times as fast as iodomethane.³¹⁸ The reasons

for this varying behavior are not clear, but those nucleophiles that form a “tight” transition state (one in which bond making and breaking have proceeded to about the same extent) are more likely to accelerate the reaction.³²⁰

When Z is SOR or SO₂R (e.g., α-halo sulfoxides and sulfones), nucleophilic substitution is retarded.³²¹ The S_N1 mechanism is slowed by the electron-withdrawing effect of the SOR or SO₂R group,³²² and the S_N2 mechanism presumably by the steric effect.

5. *β Substitution.* For compounds of the type ZCH₂CH₂X, where Z is any of the groups listed in Section 10.F, as well as halogen³²³ or phenyl, S_N1 rates are lower than for unsubstituted systems, because the resonance effects mentioned in item 4 are absent, but the field effects are still there, although smaller. These groups in the β position do not have much effect on S_N2 rates unless they behave as neighboring groups and enhance the rate through anchimeric assistance,³²⁴ or unless their size causes the rates to decrease for steric reasons.³²⁵ It has been shown that silicon exerts a β-effect, and that tin exerts a γ-effect.³²⁶ Silicon also exerts a γ-effect.³²⁷
6. *The Effect of Electron-Donating and Electron-Withdrawing Groups.* If substitution rates for a series of compounds *p*-ZC₆H₄CH₂X are measured, it is possible to study the electronic effects of groups Z on the reaction. Steric effects of Z are minimized or eliminated, because Z is so far from the reaction site. For S_N1 reactions, electron-withdrawing Z decrease the rate and electron-donating Z increase it,³²⁸ because the latter decrease the energy of the transition state (and of the carbocation) by spreading the positive charge, for example,

while electron-withdrawing groups concentrate the charge. The Hammett σ relationship³²⁹ (Sec. 9.C) fairly successfully correlates the rates of many of these reactions (with σ^+ instead of σ). The ρ values are generally about -4 , which is expected for a reaction where a positive charge is created in the transition state.

For S_N2 reactions, no such simple correlations are found.³³⁰ In this mechanism, bond breaking is about as important as bond making in the rate-determining step,

and substituents have an effect on both processes, often in opposite directions. The unsubstituted benzyl chloride and bromide solvolyze by the S_N2 mechanism.³²²

For $Z = \text{alkyl}$, the *Baker–Nathan order* (Sec. 2.M) is usually observed both for S_N1 and S_N2 reactions.

In para-substituted benzyl systems, steric effects have been removed, but resonance and field effects are still present. However, Holtz and Stock³³¹ studied a system that removes not only steric effects, but also resonance effects. This is the 4-substituted bicyclo[2.2.2]octylmethyl tosylate system (**90**). In this system, steric effects are completely absent owing to the rigidity of the molecules, and only field effects operate. By this means, Holtz and Stock showed that electron-withdrawing groups increase the rate of S_N2 reactions. This can be ascribed to stabilization of the transition state by withdrawal of some of the electron density.

For substrates that react by the tetrahedral mechanism, electron-withdrawing groups increase the rate and electron-donating groups decrease it.

7. *Cyclic Substrates.* Cyclopropyl substrates are extremely resistant to nucleophilic attack.³³² For example, cyclopropyl tosylate solvolyzes $\sim 10^6$ times more slowly than cyclobutyl tosylate in acetic acid at 60°C .³³³ When such attack does take place, the result is generally not normal substitution (though exceptions are known,³³⁴ especially when a stabilizing group, e.g., aryl or alkoxy, is present), but ring opening:³²⁶

There is much evidence that the ring opening is usually concerted with the departure of the leaving group³³⁵ (as in the similar case of cyclobutyl substrates, Sec. 10.C.i, category 4.b.iv), from which we can conclude that if the 2,3-bond of the cyclopropane ring did not assist, the rates would be lower still. Strain plays a role in the ring-opening process.³³⁶ It has been estimated³³⁷ that without this

assistance the rates of these already slow reactions would be further reduced by a factor of perhaps 10^{12} . For a discussion of the stereochemistry of the ring opening, see Reaction **18-27**, Section B. For larger rings, we have seen (Sec. 9.A) that, because of I strain, cyclohexyl substrates solvolyze slower than analogous compounds in which the leaving group is attached to a ring of 5 or of from 7 to 11 members.

8. *Bridgeheads*.¹⁴ The S_N2 mechanism is impossible at most bridgehead compounds (Sec. 10.A.i). Nucleophilic attack in [1.1.1]propellane has been reported, however.³³⁸ In general, a relatively large ring is required for an S_N1 reaction to take place (Sec. 10.A.ii).³³⁹ The S_N1 reactions have been claimed to occur for 1-iodobicyclo[1.1.1]pentane via the bicyclo[1.1.1]pentyl cation,³⁴⁰ but this has been disputed and the bicyclo[1.1.0]butylcarbiny cation was calculated to be the real intermediate.³⁴¹ Solvolytic reactivity at

bridgehead positions spans a wide range; for example, from $k = 4 \times 10^{-17} \text{ s}^{-1}$ for **91** (very slow) to $3 \times 10^6 \text{ s}^{-1}$ for the [3.3.3] compound **92** (very fast);³⁴² a range of 22 orders of magnitude. Molecular mechanics calculations show that S_N1 bridgehead reactivity is determined by strain changes between the substrate and the carbocation intermediate.³⁴³

9. *Deuterium Substitution*. Both α and β secondary isotope effects affect the rate in various ways (Sec. 6.J.vii). The measurement of a secondary isotope effect provides a means of distinguishing between S_N1 and S_N2 mechanisms, since for S_N2 reactions the values range from 0.95 to 1.06 per α D, while for S_N1 reactions the values are higher.³⁴⁴ This method is especially good because it provides the minimum of perturbation of the system under study; changing from α H to α D hardly affects the reaction, while other probes (e.g., changing a substituent or the polarity of the solvent) may have a much more complex effect.

Table 10.3 is an approximate listing of groups in order of S_N1 and S_N2 reactivity. Table 10.4 shows the main reactions that proceed by the S_N2 mechanism (if R = primary or, often, secondary alkyl).

^bCatalysts are not shown. This is a schematic list only. Some of these reactions may also take place by other mechanisms and the scope may vary greatly. See the discussion of each reaction for details.

10.G.ii The Effect of the Attacking Nucleophile³⁴⁵

Any species that has an unshared pair (i.e., any Lewis base) can, in principle, be a nucleophile, whether it is neutral or has a negative charge. The rates of S_N1 reactions

³⁴⁵ Harris, J.M.; McManus, S.P. *Nucleophilicity*, American Chemical Society, Washington, **1987**; Klumpp, G.W. *Reactivity in Organic Chemistry*, Wiley, NY, **1982**, pp. 145–167, 181–186; Hudson, R.F. in Klopman, G. *Chemical Reactivity and Reaction Paths*, Wiley, NY, **1974**, pp. 167–252.

are independent of the identity of the nucleophile, since it does not appear in the rate-determining step.³⁴⁶ This may be illustrated by the effect of changing the nucleophile from H_2O to OH^- for a primary and a tertiary substrate. For methyl bromide, which reacts by an $\text{S}_{\text{N}}2$ mechanism, the rate is multiplied > 5000 by the change to the more powerful nucleophile OH^- , but for *tert*-butylbromide, which reacts by an $\text{S}_{\text{N}}1$ mechanism, the rate is unaffected.³⁴⁷ A change in nucleophile can, however, change the *product* of an $\text{S}_{\text{N}}1$ reaction. Thus solvolysis of benzyl tosylate in methanol gives benzyl methyl ether (the nucleophile is the solvent methanol). If the more powerful nucleophile Br^- is added, the rate is unchanged, but the product is now benzyl bromide.

Note that the so-called *cation affinity* is used to measure the ability of a cation to interact with an electron-donating species. While this is not formally used to describe $\text{S}_{\text{N}}1$ reactions, it is important for catalytic activity due to different ligands.³⁴⁸

For $\text{S}_{\text{N}}2$ reactions in solution, there are four main principles that govern the effect of the nucleophile on the rate. The nucleophilicity order is not invariant, but depends on substrate, solvent, leaving group, and so on.

1. A nucleophile with a negative charge is always a more powerful nucleophile than its conjugate acid (assuming the latter is also a nucleophile). Thus OH^- is more powerful than H_2O , NH_2^- is more powerful than NH_3 , and so on
2. In comparing nucleophiles whose attacking atom is in the same row of the periodic table, nucleophilicity is approximately the same as the order of basicity,³⁴⁹ although *basicity is thermodynamically controlled and nucleophilicity is kinetically controlled*. So an approximate order of nucleophilicity is $\text{NH}_2^- > \text{RO}^- > \text{OH}^- > \text{R}_2\text{NH} > \text{ArO}^- > \text{NH}_3 > \text{pyridine} > \text{F}^- > \text{H}_2\text{O} > \text{ClO}_4^-$, and another is $\text{R}_3\text{C}^- > \text{R}_2\text{N}^- > \text{RO}^- > \text{F}^-$ (see Table 8.1). This type of correlation works best when the structures of the nucleophiles being compared are similar, as with a set of substituted phenoxides. Within such a series, linear relationships can often be established between nucleophilic rates and $\text{p}K$ values.³⁵⁰
3. Going down the periodic table, nucleophilicity increases, although basicity decreases. Thus the usual order of halide nucleophilicity is $\text{I}^- > \text{Br}^- > \text{Cl}^- > \text{F}^-$ (as seen below, this order is solvent dependent). Similarly, any sulfur nucleophile is more powerful than its oxygen analogue. The same is true for phosphorus versus nitrogen. The main reason for this distinction between basicity and nucleophilic power is that the smaller negatively charged nucleophiles are more solvated by the usual polar protic solvents; that is, because the negative charge of Cl^- is more concentrated than the charge of I^- , the former is more tightly surrounded by a shell of solvent molecules that constitute a barrier between it and the substrate. This finding is most important for protic polar solvents in which the solvent may be hydrogen bonded to small nucleophiles. Evidence for this is that many nucleophilic substitutions with small negatively charged nucleophiles are much more rapid in aprotic polar solvents than in protic ones.³⁵¹ Also, in DMF, an aprotic solvent, the

order of nucleophilicity was $\text{Cl}^- > \text{Br}^- > \text{I}^-$.³⁵² Another experiment was the use of $\text{Bu}_4\text{N}^+ \text{X}^-$ and LiX as nucleophiles in acetone, where X^- was a halide ion. The halide ion in the former salt is much less associated than in LiX . The relative rates with LiX were Cl^- , 1; Br^- , 5.7; I^- , 6.2, which is in the normal order, while with $\text{Bu}_4\text{N}^+ \text{X}^-$, where X^- is much freer, the relative rates were Cl^- , 68; Br^- , 18; I^- , 3.7.³⁵³ In a further experiment, halide ions were allowed to react with the molten salt $(n\text{-C}_5\text{H}_{11})_4\text{N}^+ \text{X}^-$ at 180°C in the absence of a solvent.³⁵⁴ Under these conditions, where the ions are unsolvated and unassociated, the relative rates were Cl^- , 620; Br^- , 7.7; I^- , 1. In the gas phase (no solvent), an approximate order of nucleophilicity was found to be $^-\text{OH} > \text{F}^- \sim \text{MeO}^- > \text{MeS}^- \gg \text{Cl}^- > ^-\text{CN} > \text{Br}^-$,³⁵⁵ providing further evidence that solvation³⁵⁶ is responsible for the effect in solution.

However, solvation is not the entire answer since, even for *uncharged* nucleophiles, nucleophilicity increases going down a column in the periodic table. These nucleophiles are not so greatly solvated and changes in solvent do not greatly affect their nucleophilicity.³⁵⁷ To explain these cases, the principle of hard and soft acids and bases (Sec. 8.E) may be used.³⁵⁸ The proton is a hard acid, but an alkyl substrate (which may be considered to act as a Lewis acid toward the nucleophile considered as a base) is a good deal softer. According to the principle given in Section 8.F, an alkyl group is expected to prefer softer nucleophiles than the proton. Thus the larger, more polarizable (softer) nucleophiles have a greater (relative) attraction toward an alkyl carbon than toward a proton.

4. The freer the nucleophile, the greater the rate.³⁵⁹ One instance of this has already been discussed.³⁵³ Another is that the rate of attack by $(\text{EtOOC})_2\text{CBu}^- \text{Na}^+$ in benzene was increased by the addition of substances (e.g., 1,2-dimethoxyethane, adipamide) that specifically solvated the Na^+ and thus left the anion freer.³⁶⁰ In a nonpolar solvent (e.g., benzene), salts, [e.g., $(\text{EtOOC})_2\text{CBu}^- \text{Na}^+$], usually exist as ion-pair aggregations of large molecular weights.³⁶¹ Similarly, it was shown that the half-life of the reaction between $\text{C}_6\text{H}_5\text{COCHEt}^-$ and ethyl bromide depended on the positive ion: K^+ , 4.5×10^{-3} ; Na^+ , 3.9×10^{-5} ; Li^+ , 3.1×10^{-7} .³⁶² Presumably, the potassium ion leaves

the negative ion freest to attack most rapidly. Further evidence is that in the gas phase,³⁶³ where nucleophilic ions are completely free, without solvent or counterion, reactions take place orders of magnitude faster than the same reactions in solution.³⁶⁴ It has proven possible to measure the rates of reaction of ^-OH with methyl bromide in the gas phase, with ^-OH either unsolvated or solvated with one, two, or three molecules of water.³⁶⁵ The rates were, with the number of water molecules in parentheses: (0) 1.0×10^{-9} ; (1) 6.3×10^{-10} ; (2) 2×10^{-12} ; (3) $2 \times 10^{-13} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$, evidence that solvation of the nucleophile decreases the rate. The rate of this reaction in aqueous solution is $2.3 \times 10^{-25} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$. Similar results were found for other nucleophiles and other solvents.³⁶⁶ Also, solution studies have been made of the effect of solvation of the nucleophile by a specific number of water molecules. Indeed, hydrogen bonding lowers the intrinsic nucleophilicity.³⁶⁷ When the salt $(n\text{-C}_6\text{H}_{13})_4\text{N}^+\text{F}^-$ reacted with n -octyl methanesulfonate, the relative rate fell from 822 for no water molecules to 96 for 1.5 water molecules to 1 for 6 water molecules.³⁶⁸

In Chapter 3, cryptands were seen to specifically solvate the alkali metal portion of salts like KF, KOAc, and so on. Synthetic advantage can be taken of this fact to allow anions to be freer, thus increasing the rates of nucleophilic substitutions and other reactions (see Sec. 10.G.v).

However, the four rules given above do not always hold. One reason is that steric influences often play a part. For example, the *tert*-butoxide ion Me_3CO^- is a stronger base than ^-OH or ^-OEt , but a much poorer nucleophile because its large bulk hinders it from closely approaching a substrate.

The following overall nucleophilicity order for $\text{S}_{\text{N}}2$ mechanisms (in protic solvents) was given by Edwards and Pearson³⁶⁹: $\text{RS}^- > \text{ArS}^- > \text{I}^- > \text{CN}^- > ^-\text{OH} > \text{N}_3^- > \text{Br}^- > \text{ArO}^- > \text{Cl}^- > \text{pyridine} > \text{AcO}^- > \text{H}_2\text{O}$. A quantitative relationship³⁷⁰ (the *Swain-Scott equation*, which can be derived from *Marcus theory*³⁷¹) has been worked out similar to the linear free-energy equations considered in Chapter 9:³⁷²

$$\log(k, k_0) = sn$$

where n is the nucleophilicity of a given group, s is the sensitivity of a substrate to nucleophilic attack, and k_0 is the rate for H_2O , which is taken as the standard and for which n is assigned a value of zero. The parameter s is defined as 1.0 for bromomethane.

Table 10.5 contains values of *n* for some common nucleophiles.³⁷³ The order is similar to that of Edwards and Pearson.

It is now evident that there is *no* absolute order of either nucleophilicity³⁷⁴ or leaving-group ability, even in the gas phase where solvation is not a factor because they have an effect on each other. When the nucleophile and leaving group are both hard or both soft, the reaction rates are relatively high, but when one is hard and the other soft, rates are reduced.³⁶³ Although this effect is smaller than the effects in paragraphs one and four above, it still prevents an absolute scale of either nucleophilicity or leaving-group ability.³⁷⁵ There has been controversy as to whether the selectivity of a reaction should increase with decreasing reactivity of a series of nucleophiles, or whether the opposite holds. There is evidence for both views.³⁷⁶

For substitution at a carbonyl carbon, the nucleophilicity order is not the same as it is at a saturated carbon, but follows the basicity order more closely. The reason is presumably that the carbonyl carbon has a partial positive charge. That is, a carbonyl carbon is a much harder acid than a saturated carbon. The following nucleophilicity order for these substrates has been determined:³⁷⁷ Me₂C=NO[−] > EtO[−] > MeO[−] > [−]OH > [−]OAr > N₃[−] > F[−] > H₂O > Br[−] ~ I[−]. Soft bases are ineffective at a carbonyl carbon.³⁷⁸ In a reaction carried out in the gas phase with alkoxide nucleophiles OR[−] solvated by only one molecule of an alcohol R'OH, it was found that both RO[−] and R'O[−] attacked the formate substrate (HCO₂R'') about equally, although in the unsolvated case, the more basic alkoxide is the better nucleophile.³⁷⁹ In this study, the product ion R²O[−] was also solvated by one molecule of ROH or R'OH.

If an atom containing one or more unshared pairs is adjacent to the attacking atom on the nucleophile, the nucleophilicity is enhanced.³⁸⁰ Examples of such nucleophiles are HO₂[−],

$\text{Me}_2\text{C}=\text{NO}^-$, NH_2NH_2 , and so on. This is called the *alpha effect* (α -effect),³⁸¹ and a broader definition is a positive deviation exhibited by an α -nucleophile from a Brønsted-type nucleophilicity plot,³⁸² where the reference (or normal) nucleophile is one that possesses the same basicity as the α -nucleophile, but does not deviate from the Brønsted-type plot. Several reviews of the α -effect have been published previously.^{72,383} Several possible explanations have been offered.³⁸⁴ One is that the ground state of the nucleophile is destabilized by repulsion between the adjacent pairs of electrons;³⁸⁵ another is that the transition state is stabilized by the extra pair of electrons;³⁸⁶ a third is that the adjacent electron pair reduces solvation of the nucleophile.³⁸⁷ Evidence supporting the third explanation is that there was no alpha effect in the reaction of HO_2^- with methyl formate in the gas phase,³⁸⁸ although HO_2^- shows a strong alpha effect in solution. The α -effect has been demonstrated to be remarkably dependent on the nature of the solvent.³⁸⁹ The α -effect is substantial for substitution at a carbonyl or other unsaturated carbon, at some inorganic atoms,³⁹⁰ and for reactions of a nucleophile with a carbocation,³⁹¹ but is generally smaller or absent entirely for substitution at a saturated carbon.³⁹²

Attempts have been made to establish a general scale of nucleophilicity,³⁹³ and the nucleophilic reactivity of other moieties have been determined, including alcohols and alkoxides,³⁹⁴ carbanions,³⁹⁵ amines,³⁹⁶ pyridines,³⁹⁷ pyrroles,³⁹⁸ indoles,³⁹⁹ imides and amides,⁴⁰⁰ amino acids and peptides,⁴⁰¹ and sulfur ylids.⁴⁰²

10.G.iii. The Effect of the Leaving Group

The leaving group at the saturated carbon comes off more easily the more stable it is as a free entity. This is usually inverse to its basicity, and the best leaving groups are the weakest bases. Thus iodide is the best leaving group among the halides and fluoride is the poorest. Since XH is always a weaker base than X^- , nucleophilic substitution is always easier at a substrate RXH^+ than at RX . An example of this effect is that OH and OR are not leaving groups from ordinary alcohols and ethers, but can come off when the groups are protonated (i.e., converted to ROH_2^+ or RORH^+).⁴⁰³ Reactions in which the leaving group does not come off until it has been protonated have been called $\text{S}_{\text{N}}1\text{cA}$ or $\text{S}_{\text{N}}2\text{cA}$, depending on whether after protonation the reaction is an $\text{S}_{\text{N}}1$ or $\text{S}_{\text{N}}2$ process (these designations are often shortened to $\text{A}1$ and $\text{A}2$). The cA stands for conjugate acid, since the substitution takes place on the conjugate acid of the substrate. The IUPAC designations for these mechanisms are, respectively, $\text{A}_{\text{h}} + \text{D}_{\text{N}} + \text{A}_{\text{N}}$ and $\text{A}_{\text{h}} + \text{A}_{\text{N}}\text{D}_{\text{N}}$; that is, the same designations as $\text{S}_{\text{N}}1$ and $\text{S}_{\text{N}}2$, with A_{h} to show the preliminary step. When another electrophile assumes the role of the proton, the symbol A_{e} is used instead. The ions ROH_2^+ and RORH^+ can be observed as stable entities at low temperatures in superacid solutions.⁴⁰⁴ At higher temperatures, they cleave to give carbocations.

It is obvious that the best nucleophiles (e.g., NH_2^- , $^- \text{OH}$) cannot take part in $\text{S}_{\text{N}}1\text{cA}$ or $\text{S}_{\text{N}}2\text{cA}$ processes, because they would be converted to their conjugate acids under the acidic conditions necessary to protonate the leaving groups.⁴⁰⁵ Because $\text{S}_{\text{N}}1$ reactions do not require powerful nucleophiles, but do require good leaving groups, most of them take place under acidic conditions. In contrast, $\text{S}_{\text{N}}2$ reactions, which do require powerful nucleophiles, which are generally strong bases, most often take place under basic or neutral conditions.

Another circumstance that increases leaving-group power is ring strain. Ordinary ethers do not cleave at all and protonated ethers only under strenuous conditions, but epoxides⁴⁰⁶ (**93**) are cleaved quite easily and protonated epoxides (**94**) even more easily. Aziridines (**95**)⁴⁰⁷ and episulfides (**96**) are also easily cleaved (see Sec. 10.G.viii).⁴⁰⁸

Although halides are common leaving groups in nucleophilic substitution for synthetic purposes, it is often more convenient to use alcohols. Since OH does not leave from ordinary alcohols, it must be converted to a group that does leave. One way is protonation, mentioned above. Another is conversion to a reactive ester, most commonly a sulfonic ester. The sulfonic ester groups *tosylate*, *brosylate*, *nosylate*, and *mesylate* are better

leaving groups than halides and are frequently used.⁴⁰⁹ Other leaving groups are still better, and compounds containing these groups make powerful alkylating agents. Among them are oxonium ions (ROR_2^+),⁴¹⁰ and the

fluorinated compounds *triflates*⁴¹¹ and *nonaflates*.⁴¹¹ *Tresylates* are ~ 400 times less reactive than triflates, but still ~ 100 times more reactive than tosylates.⁴¹² Halonium ions (RCIR^+ , RBrR^+ , RIR^+), which can be prepared in superacid solutions (Sec. 5.A.ii) and isolated as solid SbF_6^- salts, are also extremely reactive in nucleophilic substitution.⁴¹³ Of the above types of compound, the most important in organic synthesis are tosylates, mesylates, oxonium ions, and triflates. The others have been used mostly for mechanistic purposes.

The leaving group ability of NH_2 , NHR , and NR_2 are extremely poor,⁴¹⁴ but the leaving-group ability of NH_2 can be greatly improved by converting a primary amine (RNH_2) to the ditosylate (RNTs_2). The NTs_2 group has been successfully replaced by a number of nucleophiles.⁴¹⁵ Another way of converting NH_2 into a good leaving group has been extensively developed by Katritzky et al.⁴¹⁶ In this method, the amine is converted to a pyridinium compound (**98**) by treatment with a pyrylium salt (frequently a 2,4,6-triphenylpyrylium salt, **97**).⁴¹⁷ When the salt is heated, the counterion acts as a nucleophile. In some cases, a non-nucleophilic ion (e.g., BF_4^-), is used as the counterion for the conversion **97** \rightarrow **98**, and then Y^- is added to **98**. Among the nucleophiles that have been used successfully in this reaction are I^- , Br^- , Cl^- , F^- , OAc^- , N_3^- , NHR_2 , and H^- . Ordinary NR_2 groups are good leaving groups when the substrate is a *Mannich base* (these are compounds of the form $\text{RCOCH}_2\text{CH}_2\text{NR}_2$; see Reaction 16-19).⁴¹⁸ The elimination-addition mechanism applies in this case.

Probably the best leaving group is N_2 from the species RN_2^+ , which can be generated in several ways,⁴¹⁹ of which the two most important are the treatment of primary amines with nitrous acid (see Reaction **13-19**)

and the protonation of diazo compounds⁴²⁰

No matter how produced, RN_2^+ are usually too unstable to be isolable,⁴²¹ reacting presumably by the $\text{S}_{\text{N}}1$ or $\text{S}_{\text{N}}2$ mechanism.⁴²² The simplest aliphatic diazonium ion (CH_2N_2^+) has been prepared at -120°C in superacid solution, where it lived long enough for an NMR spectrum to be taken.⁴²³ Actually, the exact mechanisms are in doubt because the rate laws, stereochemistry, and products have proved difficult to interpret.⁴²⁴ If there are free carbocations they should give the same ratio of substitution to elimination to rearrangements, and so on, as carbocations generated in other $\text{S}_{\text{N}}1$ reactions, but they often do not. "Hot" carbocations (unsolvated and/or chemically activated) that can hold their configuration have been postulated,⁴²⁵ as have ion pairs, in which ^-OH (or ^-OAc , etc., depending on how the diazonium ion is generated) is the counterion.⁴²⁶ One class of aliphatic diazonium salts of which several members have been isolated as stable salts are the cyclopropenyldiazonium salts:⁴²⁷

Diazonium ions generated from ordinary aliphatic primary amines are usually useless for preparative purposes, since they lead to a mixture of products giving not only substitution by any nucleophile present, but also elimination and rearrangements if the substrate permits. For example, diazotization of *n*-butylamine gave 25% 1-butanol, 5.2% 1-chlorobutane, 13.2% 2-butanol, 36.5% butenes (consisting of 71% 1-butene, 20% *trans*-2-butene, and 9% *cis*-2-butene), and traces of butyl nitrites.⁴²⁸

In the S_N1cA and S_N2cA mechanisms (see above) there is a preliminary step, the addition of a proton, before the normal S_N1 or S_N2 process occurs. There are also reactions in which the substrate *loses* a proton in a preliminary step. In these reactions, there is a carbene intermediate.

Once formed by this process, the carbene may undergo any of the normal carbene reactions (see Sec. 5.D.ii). When the net result is substitution, this mechanism has been called the S_N1cB (for conjugate base) mechanism.⁴²⁹ Although the slow step is an S_N1 step, the reaction is second order; first order in substrate and first order in base.

Table 10.6 lists some leaving groups in approximate order of ability to leave.^{430–432} The order of leaving-group ability is about the same for S_N1 and S_N2 reactions.

10.G.iv. The Effect of the Reaction Medium⁴³³

The effect of solvent polarity⁴³⁴ on the rate of S_N1 reactions depends on whether the substrate is neutral or positively charged.⁴³⁵ For neutral substrates, which constitute the majority of cases, the more polar the solvent, the faster the reaction, since there is a greater charge in the transition state than in the starting compound (Table 10.7⁴³⁶) and the energy of an ionic transition state is reduced by polar solvents. However, when the substrate is positively charged, the charge is more spread out in the transition state than in the starting ion, and a greater solvent polarity slows the reaction. Even for solvents with about the same

calculate dielectric screening effects in solvents.⁴⁴¹ The S_N2 reactions have been done in ionic liquids (see Sec. 9.D.iii)⁴⁴² and in supercritical carbon dioxide (see Sec. 9.D.ii).⁴⁴³

For S_N2 reactions, the effect of the solvent⁴⁴⁴ depends on which of the four charge types the reaction belongs to (preceding Sec. 10.A). In types I and IV, an initial charge is dispersed in the transition state, so the reaction is hindered by polar solvents. In type III, initial charges are *decreased* in the transition state, so that the reaction is even more hindered by polar solvents. Only type II, where the reactants are uncharged but the transition state has built up a charge, is aided by polar solvents. These effects are summarized in Table 10.7.⁴³⁶ Westaway⁴⁴⁵ proposed a “solvation rule” for S_N2 reactions, which states that changing the solvent will not change the structure of the transition state for type I reactions, but will change it for type II reactions. The difference between protic and aprotic solvents must be considered for S_N2 reactions as well.⁴⁴⁶ For reactions of types I and III the transition state is more solvated in polar aprotic solvents than in protic ones,⁴⁴⁷ while (as seen in Sec. 10.G.ii) the original charged nucleophile is less solvated in aprotic solvents⁴⁴⁸ (the second factor is generally much greater than the first⁴⁴⁹). So the change from, say, methanol to DMSO should greatly increase the rate. As an example, the relative rates at 25 °C for the reaction between MeI and Cl[−] were in MeOH, 1;³⁵¹ in HCONH₂ (still protic although a weaker acid), 12.5; in HCONHMe, 45.3; and HCONMe₂, 1.2×10^6 . The change in rate in going from a protic to an aprotic solvent is also related to the *size* of the

^aSee Ref. 450.

attacking anion. Small ions are solvated best in protic solvents, since hydrogen bonding is most important for them, while large anions are solvated best in aprotic solvents (protic solvents have highly developed structures held together by hydrogen bonds; aprotic solvents have much looser structures, and it is easier for a large anion to be fitted in). So the rate of attack by small anions is most greatly increased by the change from a protic to an aprotic solvent. This may have preparative significance. The review articles in Ref. 431 have lists of several dozen reactions of charge types I and III in which yields are improved and reaction times reduced in polar aprotic solvents. Reaction types II and IV are much less susceptible to the difference between protic and aprotic solvents.

Since for most reactions S_N1 rates go up and S_N2 rates go down in solvents of increasing polarity, it is quite possible for the same reaction to go by the S_N1 mechanism in one solvent and the S_N2 in another. Table 10.8 is a list of solvents in order of ionizing power;⁴⁵⁰ a solvent high on the list is a good solvent for S_N1 reactions. Trifluoroacetic acid, which was not studied by Smith et al.,⁴⁵⁰ has greater ionizing power⁴⁵¹ than any solvent listed in Table 10.8. Because it also has very low nucleophilicity, it is an excellent solvent for S_N1 solvolyses. Other good solvents for this purpose are 1,1,1-trifluoroethanol (CF₃CH₂OH), and 1,1,1,3,3,3-hexafluoro-2-propanol [(F₃C)₂CHOH].⁴⁵²

Previously, the influence of the polarity of the solvent on the rates of S_N1 and S_N2 reactions was discussed. The ionic strength of the medium has similar effects. In general, the addition of an external salt affects the rates of S_N1 and S_N2 reactions in the same way as an increase in solvent polarity, although this is not quantitative; different salts have different effects.⁴⁵³ However, there are exceptions: Although the rates of S_N1 reactions are usually increased by the addition of salts (this is called the *salt effect*), addition of the leaving-group ion often decreases the rate (the common-ion effect, Sec. 10.A.ii). There is also the special salt effect of LiClO₄, mentioned on Section 10.A.iii, category 2. In addition

to these effects, S_N1 rates are also greatly accelerated when there are ions present that specifically help in pulling off the leaving group.⁴⁵⁴ Especially important are Ag^+ , Hg^{2+} , and Hg_2^{2+} , but H^+ helps to pull off F (hydrogen bonding).⁴⁵⁵ Even primary halides have been reported to undergo S_N1 reactions when assisted by metal ions.⁴⁵⁶ This does not mean, however, that reactions in the presence of metallic ions invariably proceed by the S_N1 mechanism. It has been shown that alkyl halides can react with $AgNO_2$ and $AgNO_3$ by the S_N1 or S_N2 mechanism, depending on the reaction conditions.⁴⁵⁷

The effect of solvent has been treated quantitatively (for S_N1 mechanisms, in which the solvent pulls off the leaving group) by a linear free energy relationship⁴⁵⁸

$$\log(k, k_0) = m Y$$

where m is characteristic of the substrate (defined as 1.00 for t -BuCl) and is usually near unity, Y is characteristic of the solvent and measures its “ionizing power”, and k_0 is the rate in a standard solvent, 80% aq ethanol at 25 °C. This is known as the *Grunwald–Winstein equation*, and its utility is at best limited. The Y values can of course be measured for solvent mixtures as well. This is one of the principal advantages of the treatment, since it is not easy otherwise to assign a polarity arbitrarily to a given mixture of solvents.⁴⁵⁹ The treatment is most satisfactory for different proportions of a given solvent pair. For wider comparisons, the treatment is not so good quantitatively, although the Y values do give a reasonably good idea of solvolyzing power.⁴⁶⁰ Table 10.9 contains a list of some Y values.⁴⁶¹

Ideally, Y should measure only the ionizing power of the solvent, and should not reflect any backside attack by a solvent molecule in helping the nucleofuge to leave (nucleophilic assistance; k_s , Sec. 10.C.i, category 3). Actually, there is evidence that many solvents do

lend some nucleophilic assistance,⁴⁶² even with tertiary substrates.⁴⁶³ It was proposed that a better measure of solvent “ionizing power” would be a relationship based on 2-adamantyl substrates, rather than *t*-BuCl, since the structure of this system completely prevents backside nucleophilic assistance (Sec. 10.G.i). Such a scale, called Y_{OTs} , was developed,

⁴⁶² A scale of solvent nucleophilicity (as opposed to ionizing power), called the N_{T} scale, has been developed: Kevill, D.N.; Anderson, S.W. *J. Org. Chem.* **1991**, 56, 1845.

⁴⁶³ See Kevill, D.N.; Anderson, S.W. *J. Am. Chem. Soc.* **1986**, 108, 1579; McManus, S.P.; Neamati-Mazreah, N.; Karaman, R.; Harris, J.M. *J. Org. Chem.* **1986**, 51, 4876; Abraham, M.H.; Doherty, R.M.; Kamlet, M.J.; Harris, J. M.; Taft, R.W. *J. Chem. Soc. Perkin Trans. 2* **1987**, 913.

with m defined as 1.00 for 2-adamantyl tosylate.⁴⁶⁴ Some values of Y_{OTs} are given in Table 10.9. These values, which are actually based on both 1- and 2-adamantyl tosylates (both are equally impervious to nucleophilic assistance and show almost identical responses to solvent ionizing power⁴⁶⁵) are called Y_{OTs} because they apply only to tosylates. It has been found that solvent “ionizing power” depends on the leaving group, so separate scales⁴⁶⁶ have been set up for OTf,⁴⁶⁷ Cl,⁴³³ Br,⁴⁶⁸ I,⁴⁶⁹ and other nucleofuges,⁴⁷⁰ all based on the corresponding adamantyl compounds. A new Y scale has been established based on benzylic bromides.⁴⁷¹ In part, this was done because benzylic tosylates did not give a linear correlation with the 2-adamantyl Y_{OTs} parameter.⁴⁷² This is substrate dependent, since solvolysis of 2,2-dimethyl-1-phenyl-1-propanol tosylate showed no nucleophilic solvent participation.⁴⁷³

In order to include a wider range of solvents than those in which any of the Y values can be conveniently measured, other attempts have been made at correlating solvent polarities.⁴⁷⁴ Kosower et al.⁴⁷⁵ found that the position of the charge-transfer peak (see Sec. 3.C.i) in the UV spectrum of the complex (**99**) between iodide ion and 1-methyl- or 1-ethyl-4-carbomethoxypyridinium ion was dependent on the polarity of the solvent.⁴⁷⁵ From these peaks, which are very easy to measure, Kosower et al.⁴⁷⁵ calculated transition energies that he called Z values. These values are thus measures of solvent polarity analogous to Y values. Another scale is based on the position of electronic spectra peaks of the pyridinium- N -phenolbetaine (**100**) in various solvents.⁴⁷⁶ Solvent polarity values on this scale are called $E_{\text{T}}(30)$ ⁴⁷⁷ values. The $E_{\text{T}}(30)$ values are related to Z values by the expression⁴⁷⁸

$$Z = 1.41 E_{\text{T}}(30) + 6.92$$

Table 10.9 shows that Z and $E_T(30)$ values are generally in the same order as Y values. Other scales, the π^* scale,⁴⁷⁹ the π^*_{azo} scale,⁴⁸⁰ and the Py scale,⁴⁸¹ are also based on spectral data.⁴⁸²

Carbon dioxide can be liquefied under high pressure (supercritical CO_2). Several reactions have been done using supercritical CO_2 as the medium (Sec. 9.D.ii), but special apparatus is required. This medium offers many advantages,⁴⁸³ and some disadvantages, but is an interesting new area of research.

The effect of solvent on nucleophilicity has already been discussed (Sec. 10.G.ii).

10.G.v. Phase-Transfer Catalysis

A difficulty that occasionally arises when carrying out nucleophilic substitution reactions is that the reactants do not mix. For a reaction to take place, the reacting molecules must collide. In nucleophilic substitutions, the substrate is usually insoluble in water and other polar solvents, while the nucleophile is often an anion, which is soluble in water, but not in the substrate or other organic solvents. Consequently, when the two reactants are brought together, their concentrations in the same phase are too low for convenient reaction rates. One way to overcome this difficulty is to use a solvent that will dissolve both species. As seen in Section 10.G.iv, a dipolar aprotic solvent may serve this purpose. Another way, which is used very often, is *phase-transfer catalysis*.⁴⁸⁴

In this method, a catalyst is used to carry the nucleophile from the aqueous into the organic phase. As an example, simply heating and stirring a two-phase mixture of 1-chlorooctane for several days with aq. NaCN gives essentially no yield of 1-cyanooctane. But if a small amount of an appropriate quaternary ammonium salt is added, the product is quantitatively formed in ~ 2 h.⁴⁸⁵ There are two principal types of phase-transfer catalyst, although the action of the two types is somewhat different, the effects are the same. Both get the anion into the organic phase and allow it to be relatively free to react with the substrate.

1. *Quaternary Ammonium or Phosphonium Salts*. In the above-mentioned case of NaCN, the uncatalyzed reaction does not take place because the ^-CN ions

cannot cross the interface between the two phases, except in very low concentration. The reason is that the Na^+ ions are solvated by the water, and this solvation energy would not be present in the organic phase. The CN^- ions cannot cross without the Na^+ ions because that would destroy the electrical neutrality of each phase. In contrast to Na^+ ions, quaternary ammonium (R_4N^+)⁴⁸⁶ and phosphonium (R_4P^+) ions with sufficiently large R groups are poorly solvated in water and prefer organic solvents. If a small amount of such a salt is added, three equilibria are set up:

The Na^+ ions remain in the aqueous phase; they cannot cross. The Q^+ ions do cross the interface and carry an anion with them. At the beginning of the reaction, the chief anion present is CN^- . This gets carried into the organic phase (equilibrium 1) where it reacts with RCl to produce RCN and Cl^- . The Cl^- then gets carried into the aqueous phase (equilibrium 2). Equilibrium 3, taking place entirely in the aqueous phase, allows Q^+CN^- to be regenerated. All the equilibria are normally reached much faster than the actual conversion of RCl to RCN , so the latter is the rate-determining step.

In some cases, the Q^+ ions have such a low solubility in water that virtually all remain in the organic phase.⁴⁸⁷ In such cases, the exchange of ions (equilibrium 3) takes place across the interface. Still another mechanism (*the interfacial mechanism*) can operate where OH^- extracts a proton from an organic substrate.⁴⁸⁸ In this mechanism, the OH^- ions remain in the aqueous phase and the substrate in the organic phase; the deprotonation takes place at the interface.⁴⁸⁹ Thermal stability of the quaternary ammonium salt is a problem, limiting the use of some catalysts. The trialkylacetyl ammonium halide (**101**) is thermally stable, however, even at high reaction temperatures.⁴⁹⁰ The use of molten quaternary ammonium salts as ionic reaction media for substitution reactions has also been reported.⁴⁹¹

2. *Crown Ethers and Other Cryptands*.⁴⁹² As seen in Section 3.C.ii, certain cryptands are able to surround certain cations. In effect, a salt like KCN is converted by

dicyclohexano-18-crown-6 into a new salt (**102**) whose anion is the same, but whose cation is now a much larger species with the positive charge spread over a large volume, and hence much less concentrated. This larger cation is much less solubilized by water than K^+ and much more attracted to organic solvents. Although KCN is generally insoluble in organic solvents, the cryptate salt is soluble in many of them. In these cases, we do not need an aqueous phase at all but simply add the salt to the organic phase. Suitable cryptands have been used to increase the rates of reactions where F^- , Br^- , I^- , ^-OAc , and ^-CN are nucleophiles.⁴⁹³ Certain compounds that are not cryptands can act in a similar manner. One example is the podand tris(3,6-dioxaheptyl)amine (**103**), also called TDA-1.⁴⁹⁴ Another, not related to the crown ethers, is the pyridyl sulfoxide (**104**).⁴⁹⁵

Both of the above-mentioned catalyst types get the anions into the organic phase, but there is another factor as well. There is evidence that sodium and potassium salts of many anions, even if they could be dissolved in organic solvents, would undergo reactions very slowly (dipolar aprotic solvents are exceptions) because in these solvents the anions exist as ion pairs with Na^+ or K^+ and are not free to react with the substrate (Sec. 10.G.ii, category 4). Fortunately, ion pairing is usually much less with the quaternary ions and with the positive cryptate ions, so the anions in these cases are quite free to attack. Such anions are sometimes referred to as “naked” anions.

Not all quaternary salts and cryptands work equally well in all situations. Some experimentation is often required to find the optimum catalyst.

Although phase-transfer catalysis has been most often used for nucleophilic substitutions, it is not confined to these reactions. Any reaction that needs an insoluble anion dissolved in an organic solvent can be accelerated by an appropriate phase-transfer catalyst. Some examples will be seen in later chapters. In fact, in principle, the method is not even limited to anions, and a small amount of work has been done in transferring cations,⁴⁹⁶ radicals, and molecules.⁴⁹⁷ The reverse type of phase-transfer catalysis has also been reported: transport into the aqueous phase of a reactant that is soluble in organic solvents.⁴⁹⁸ Microwave activated phase-transfer catalysis has been reported.⁴⁹⁹

The catalysts mentioned above are soluble. Certain cross-linked polystyrene resins, as well as alumina⁵⁰⁰ and silica gel, have been used as insoluble phase-transfer catalysts. These, called *triphasic catalysts*,⁵⁰¹ have the advantage of simplified product work up and easy and quantitative catalyst recovery, since the catalyst can easily be separated from the product by filtration.

10.G.vi. Influencing Reactivity by External Means

In many cases, reactions are slow. This is sometimes due to poor mixing or the aggregation state of one or more reactants. A powerful technique used to increase reaction rates is *ultrasound* (see Sec. 7.B). In this technique, the reaction mixture is subjected to high-energy sound waves, most often 20 KHz, but sometimes higher (a frequency of 20 KHz is about the upper limit of human hearing). When these waves are passed through a mixture, small bubbles form (*cavitation*). Collapse of these bubbles produces powerful shock waves that greatly increase the temperatures and pressures within these tiny regions, resulting in an increased reaction rate.⁵⁰² In an instance where a metal, as a reactant or catalyst, is in contact with a liquid phase, a further effect is that the surface of the metal is cleaned and/or eroded by the ultrasound, allowing the liquid-phase molecules to come into closer contact with the metal atoms. Among the advantages of ultrasound is that it may increase yields, reduce side reactions, and permit the use of lower temperatures and/or pressures. The reaction of pyrrolidinone (**105**) with allyl bromide, under phase-transfer conditions, gave < 10% of the *N*-allyl product, (**106**). When the reaction was done under identical conditions, but with exposure to ultrasound (in an ultrasonic bath), the yield of **106** was 78%.⁵⁰³ It has been postulated that ultrasound has its best results with reactions that proceed, at least partially, through free radical intermediates.⁵⁰⁴

As noted in Chapter 7 (see Sec. 7.C), microwave irradiation is used extensively. Reaction times are greatly accelerated in many reactions, and reactions that took hours to be complete in refluxing solvents are done in minutes. Benzyl alcohol was converted to benzyl bromide, for example, using microwave irradiation (650 W) in only 9 min on a doped K-10 Montmorillonite clay.⁵⁰⁵ This technique is growing and very useful.

The rate of many reactions can be increased by application of high pressure.⁵⁰⁶ In solution, the rate of a reaction can be expressed in terms of the activation volume (ΔV^\ddagger).⁵⁰⁷

$$\frac{\delta \ln k}{\delta p} = \frac{\Delta V^\ddagger}{RT}$$

The value of ΔV^\ddagger is the difference in partial molal volume between the transition state and the initial state, but it can be approximated by the molar volume.⁵⁰⁷ Increasing pressure decreases the value of ΔV^\ddagger and ΔV^\ddagger is negative as the reaction rate is accelerated. This equation is not strictly obeyed > 10 kbar. If the transition state of a reaction involves bond formation, concentration of charge, or ionization, a negative volume of activation often results. Cleavage of a bond, dispersal of charge, neutralization of the transition state, and diffusion control lead to a positive volume of activation. Reactions for which rate enhancement is expected at high pressure include⁵⁰⁷:

1. Reactions in which the number of molecules decreases when starting materials are converted to products: cycloadditions [e.g., the *Diels–Alder* (Reaction **15-60**)] and condensations, [e.g., the *Knoevenagel condensation* (**16-38**)].
2. Reactions that proceed via cyclic transition states: *Claisen* (Reaction **18-33**) and *Cope* (Reaction **18-32**) rearrangements.
3. Reactions that take place through dipolar transition states: *Menshutkin reaction* (Reaction **10-31**), electrophilic aromatic substitution.
4. Reactions with steric hindrance.

Many high-pressure reactions are done neat, but if a solvent is used, the influence of pressure on that solvent is important. The melting point generally increases at elevated pressures, which influences the viscosity of the medium (viscosity of liquids increases approximately two times per kilobar increase in pressure). Controlling the rate of diffusion of reactants in the medium is also important.⁵⁰⁸ In most reactions, pressure is applied (5–20 kbar) at room temperature and then the temperature is increased until reaction takes place.

10.G.vii. Ambident (Bidentant) Nucleophiles: Regioselectivity

Some nucleophiles have a pair of electrons on each of two or more atoms, or canonical forms can be drawn in which two or more atoms bear an unshared pair. In these cases, the nucleophile may attack in two or more different ways to give different products. Such reagents are called *ambident nucleophiles*.⁵⁰⁹ In most cases, a nucleophile with two potentially attacking atoms can attack with either of them, depending on conditions, and mixtures are often obtained, although this is not always the case. For example, the

nucleophile (NCO^-) usually gives only isocyanates (RNCO) and not the isomeric cyanates (ROCN).⁵¹⁰ When a reaction can potentially give rise to two or more structural isomers (e.g., ROCN or RNCO), but actually produces only one, the reaction is said to be *regioselective*⁵¹¹ (cf. the definitions of stereoselective, Sec. 4.N and enantioselective, Sec. 4.H., category 2). Some important ambident nucleophiles follow:

1. *Ions of the Type* $-\text{CO}-\text{CR}^--\text{CO}-$. These ions, which are derived by removal of a proton from malonic esters, β -keto esters, β -diketones, and so on, are resonance hybrids:

Attack is therefore possible at a saturated carbon via the carbon atoms (*C*-alkylation) or the oxygen atoms (*O*-alkylation):

With unsymmetrical ions, three products are possible, since either oxygen can attack. With a carbonyl substrate the ion can analogously undergo *C*- or *O*-acylation.

2. *Compounds of the Type* $\text{CH}_3\text{CH}-\text{CH}_2-\text{CO}-$. *Can Give Up Two Protons*, if treated with 2 molar equivalents of a strong enough base, to give dicarbanions:

Such ions are ambident nucleophiles, since they have two possible attacking carbon atoms, aside from the possibility of attack by oxygen. In such cases, the attack is virtually always by the more basic carbon.⁵¹² Since the hydrogen of a carbon bonded to two carbonyl groups is more acidic than that of a carbon bonded to just one (see Chap 8), the CH group of **107** is less basic than the CH_2 group, so the latter attacks the substrate. This gives rise to a useful general principle: Whenever the goal is to remove a proton at a given position for use as a nucleophile, but there is a stronger acidic group in the molecule, it may be possible to take off both protons; if it is, then attack is always by the desired position since it is the ion of the weaker acid. On the other hand, if the goal is to attack with the more acidic position, all that is necessary is to remove just one proton.⁵¹³ For example, ethyl acetoacetate can be

⁵¹² For an exception, see Trimitsis, G.B.; Hinkley, J.M.; TenBrink, R.; Faburada, A.L.; Anderson, R.; Poli, M.; Christian, B.; Gustafson, G.; Erdman, J.; Rop, D. *J. Org. Chem.* **1983**, 48, 2957.

⁵¹³ See Hauser, C.R.; Harris, C.M. *J. Am. Chem. Soc.* **1958**, 80, 6360. For reviews, see Thompson, C.M.; Green, D. L.C. *Tetrahedron* **1991**, 47, 4223; Harris, T.M.; Harris, C.M. *Org. React.* **1969**, 17, 155.

alkylated at either the methyl or the methylene group (Reaction 10-67):

3. *The CN^- Ion.* This nucleophile can give nitriles (RCN , Reaction 10-75) or isocyanides ($\text{RN}\equiv\text{C}$).
4. *The Nitrite Ion.* This ion can give nitrite esters $\text{R}-\text{O}-\text{N}=\text{O}$ (Reaction 10-22) or nitro compounds RNO_2 (Reaction 10-76), which are not esters.
5. *Phenoxide ions.* These ions, (which are analogous to enolate anions) can undergo C- or O-alkylation:

6. *Removal of a Proton from an Aliphatic Nitro Compound.* This reaction gives a carbanion ($\text{R}_2\text{C}^- - \text{NO}_2$) that can be alkylated at oxygen or carbon.⁵¹⁴ O-Alkylation gives a nitronic ester, and such compounds are generally unstable to heat and break down to give an oxime and an aldehyde or ketone.

There are many other ambident nucleophiles.

It would be useful to have general rules as to which atom of an ambident nucleophile will attack a given substrate under a given set of conditions.⁵¹⁵ Unfortunately, the situation is complicated by the large number of variables. It might be expected that the more electronegative atom would always attack, but this is often not the case. Where the products are determined by thermodynamic control (Sec. 6.F), the principal product is usually the one in which the atom of higher basicity has attacked (i.e., $\text{C} > \text{N} > \text{O} > \text{S}$).⁵¹⁶ However, in most reactions, the products are kinetically controlled and matters are much less simple. Nevertheless, the following generalizations can be made, while recognizing that there are many exceptions and unexplained results. As in the discussion of nucleophilicity in general (Sec. 10.G.ii), there are two major factors: the polarizability (hard-soft character) of the nucleophile and solvation effects.

1. The principle of hard and soft acids and bases states that hard acids prefer hard bases and soft acids prefer soft bases (Sec. 8.E.i). In an $\text{S}_{\text{N}}1$ mechanism, the nucleophile attacks a carbocation, which is a hard acid. In an $\text{S}_{\text{N}}2$ mechanism, the nucleophile

⁵¹⁶ See Bégué, J.; Charpentier-Morize, M.; Née, G. *J. Chem. Soc., Chem. Commun.* **1989**, 83.

attacks the carbon atom of a molecule, which is a softer acid. The more electronegative atom of an ambident nucleophile is a harder base than the less electronegative atom. Therefore, as the character of a given reaction changes from S_N1 to S_N2 like, an ambident nucleophile becomes more likely to attack with its less electronegative atom.⁵¹⁷ Thus, changing from S_N1 to S_N2 conditions should favor C attack by ^-CN , N attack by NO_2^- , C attack by enolate or phenoxide ions, and so on. As an example, primary alkyl halides are attacked (in protic solvents) by the carbon atom of the anion of $CH_3COCH_2CO_2Et$, while α -chloro ethers, which react by the S_N1 mechanism, are attacked by the oxygen atom. However, this does not mean that attack is by the less electronegative atom in all S_N2 reactions and by the more electronegative atom in all S_N1 reactions. The position of attack also depends on the nature of the nucleophile, the solvent, the leaving group, and other conditions. The rule merely states that increasing the S_N2 character of the transition state makes attack by the less electronegative atom more likely.

2. All negatively charged nucleophiles must of course have a positive counterion. If this ion is Ag^+ (or some other ion that specifically helps in removing the leaving group, Sec. 10.G.iv), rather than the more usual Na^+ or K^+ , then the transition state is more S_N1 like. Therefore the use of Ag^+ promotes attack at the more electronegative atom. For example, alkyl halides treated with $NaCN$ generally give mostly RCN , but the use of $AgCN$ increases the yield of isocyanides (RNC).⁵¹⁸
3. In many cases, the solvent influences the position of attack. The freer the nucleophile, the more likely it is to attack with its more electronegative atom, but the more this atom is encumbered by either solvent molecules or positive counterions, the more likely it is to attack by the less electronegative atom. In protic solvents, the more electronegative atom is better solvated by hydrogen bonds than the less electronegative atom. In polar aprotic solvents, neither atom of the nucleophile is greatly solvated, but these solvents are very effective in solvating cations. Thus in a polar aprotic solvent the more electronegative end of the nucleophile is freer from entanglement by both the solvent and the cation, so that a change from a protic to a polar aprotic solvent often increases the extent of attack by the more electronegative atom. An example is attack by sodium β -naphthoxide on benzyl bromide, which resulted in 95% O-alkylation in DMSO and 85% C-alkylation in 2,2,2-trifluoroethanol.⁵¹⁹ Changing the cation from Li^+ to Na^+ to K^+ (in nonpolar solvents) also favors O- over C-alkylation⁵²⁰ for similar reasons (K^+ leaves the nucleophile much freer than Li^+), as does the use of crown ethers, which are good at solvating cations (Sec. 3.C.ii).⁵²¹ Alkylation of the enolate anion of cyclohexanone in the gas phase,

⁵¹⁷ This principle, sometimes called *Kornblum's rule*, was first stated by Kornblum, N.; Smiley, R.A.; Blackwood, R.K.; Iffland, D.C. *J. Am. Chem. Soc.* **1955**, 77, 6269.

where the nucleophile is completely free, showed only O-alkylation and no C-alkylation.⁵²²

4. In extreme cases, steric effects can govern the regioselectivity.⁵²³

10.G.viii. Ambident Substrates

Some substrates (e.g., 1,3-dichlorobutane) can be attacked at two or more positions, and these may be called *ambident substrates*. In the example given, there happen to be two leaving groups in the molecule. Apart from dichlorobutane, and in general, there are two kinds of substrates that are inherently ambident (unless symmetrical). One of these, the allylic type, has already been discussed (Sec. 10.E). The other is the epoxy (or the similar aziridine⁵²⁴ or episulfide) substrate.⁵²⁵ Selectivity for one or the other position is usually called regioselectivity.

Substitution of the free epoxide, which generally occurs under basic or neutral conditions, usually involves an S_N2 mechanism. Since primary substrates undergo S_N2 attack more readily than secondary, unsymmetrical epoxides are attacked in neutral or basic solution at the less highly substituted carbon, and stereospecifically, with inversion at that carbon. Under acidic conditions, it is the protonated epoxide that undergoes the reaction. Under these conditions the mechanism can be either S_N1 or S_N2 . In S_N1 mechanisms, which favor tertiary carbons, attack may be expected to be at the more highly substituted carbon, and this is indeed the case. However, even when protonated epoxides react by what is expected to be an S_N2 mechanism, attack is usually at the more highly substituted position.⁵²⁶ This result probably indicates significant carbocation character at the carbon (ion pairing, for example). Thus, it is often possible to change the direction of ring opening by changing the conditions from basic to acidic or vice versa. In the ring opening of 2,3-epoxy alcohols, the presence of $Ti(OiPr)_4$ increases both the rate and the regioselectivity, favoring attack at C-3 rather than C-2.⁵²⁷ When an epoxide ring is fused to a cyclohexane ring, S_N2 ring opening invariably gives diaxial rather than diequatorial ring opening.⁵²⁸

Cyclic sulfates (**108**), prepared from 1,2-diols, react in the same manner as epoxides, but usually more rapidly.⁵²⁹

10.H. REACTIONS

The reactions in this chapter are classified according to the attacking atom of the nucleophile in the order O, S, N, halogen, H, C. For a given nucleophile, reactions are classified by the substrate and leaving group. For the most part, only alkyl substrates are considered, since acyl substrates are considered in Chapter 16. Nucleophilic substitutions at a sulfur atom are treated at the end.

Not all the reactions in this chapter are actually nucleophilic substitutions. In some cases, the mechanisms are not known with enough certainty even to decide whether a nucleophile, an electrophile, or a free radical is attacking. In other cases, conversion of one compound to another can occur by two or even all three of these possibilities, depending on the reagent and reaction conditions. However, one or more of the nucleophilic mechanisms previously discussed do hold for the overwhelming majority of the reactions in this chapter. For the alkylations, the S_N2 is by far the most common mechanism, as long as R is primary or secondary alkyl. For the acylations, the tetrahedral mechanism is the most common.

10.H.i. Oxygen Nucleophiles

A. Attack by OH at an Alkyl Carbon

10-1 Hydrolysis of Alkyl Halides

Hydroxy-de-halogenation

Alkyl halides can be converted to alcohols. Hydroxide ion is usually required, although particularly active substrates (e.g., allylic or benzylic alcohols) can be hydrolyzed by water. Ordinary halides can be hydrolyzed by water,⁵³⁰ if the solvent is HMPA or *N*-methyl-2-pyrrolidinone,⁵³¹ or if the reaction is done in an ionic solvent.⁵³² If the hydrolysis (solvolysis) reaction proceeds via ionization, by an S_N1 type mechanism, this reaction can be performed on tertiary substrates without significant interference from elimination side reactions. Tertiary alkyl α -halocarbonyl compounds can be converted to the corresponding alcohol with silver oxide in aq acetonitrile.⁵³³ The reaction is not frequently used for synthetic purposes, because alkyl halides are usually obtained from alcohols.

Vinyl halides are unreactive (Sec. 10.F), but they can be hydrolyzed to ketones at room temperature with mercuric trifluoroacetate, or with mercuric acetate in either trifluoroacetic acid or acetic acid containing BF_3 etherate.⁵³⁴ Primary bromides and iodides give alcohols when treated with bis(tributyltin)oxide ($\text{Bu}_3\text{Sn}-\text{O}-\text{SnBu}_3$) in the presence of silver salts.⁵³⁵

OS **II**, 408; **III**, 434; **IV**, 128; **VI**, 142, 1037.

10-2 Hydrolysis of gem-Dihalides

Oxo-de-dihalo-bisubstitution

gem-Dihalides can be hydrolyzed using either acid or basic catalysis to give aldehydes or ketones.⁵³⁶ Formally, the reaction may be regarded as giving $\text{R}-\text{C}(\text{OH})\text{XR}'$, which is unstable and loses HX to give the carbonyl compound. For aldehydes derived from RCHX_2 , strong bases cannot be used, because the product undergoes the *aldol reaction* (**16-34**) or the *Cannizzaro reaction* (**19-81**). A mixture of calcium carbonate and sodium acetate is effective,⁵³⁷ and heating to 100°C in DMSO gives good yields.⁵³⁸ A simple method heats a *gem*-dibromide with pyridine, and subsequent treatment with water gives the aldehyde.⁵³⁹ Heating 1,1-dihaloalkenes ($\text{C}=\text{CX}_2$) with zinc and water leads to the corresponding methyl ketone.⁵⁴⁰

10-3 Hydrolysis of 1,1,1-Trihalides

Hydroxy,oxo-de-trihalo-tersubstitution

This reaction is similar to **10-2**. The utility of the method is limited by the lack of availability of trihalides, although these compounds can be prepared by addition of CCl_4 and similar compounds to double bonds (Reaction **15-38**) and by the free radical halogenation of methyl groups on aromatic rings (Reaction **14-1**). When the reaction is carried out in the presence of an alcohol, a carboxylic ester can be obtained directly.⁵⁴¹ 1,1-Dichloroalkenes

can also be hydrolyzed to carboxylic acids, by treatment with aq H_2SO_4 . In general 1,1,1-trifluorides do not undergo this reaction,⁵⁴² although exceptions are known.⁵⁴³

Aryl 1,1,1-trihalomethanes can be converted to acyl halides by treatment with sulfur trioxide.⁵⁴⁴ Hydrolysis of the acid chloride gives the carboxylic acid (Reaction 16-57).

Chloroform is more rapidly hydrolyzed with base than dichloromethane or carbon tetrachloride and gives not only formic acid, but also carbon monoxide.⁵⁴⁵ Hine⁵⁴⁶ showed that the mechanism of chloroform hydrolysis is quite different from that of dichloromethane or carbon tetrachloride, although superficially the three reactions appear similar. The first step is the loss of a proton to give CCl_3^- , which then loses Cl^- to give dichlorocarbene (CCl_2), which is hydrolyzed to formic acid or carbon monoxide.

This is an example of an $\text{S}_{\text{N}}1\text{CB}$ mechanism (Sec. 10.G.iii, category 1). The other two compounds react by the normal mechanisms. Carbon tetrachloride cannot give up a proton and dichloromethane is not acidic enough.

OS III, 270; V, 93. Also see, OS I, 327.

10-4 Hydrolysis of Alkyl Esters of Inorganic Acids

Hydroxy-de-sulfonyloxy-substitution, and so on

Esters of inorganic acids, including those given above and others, can be hydrolyzed to alcohols. The reactions are most successful when the ester is that of a strong acid, but it can be done for esters of weaker acids by the use of hydroxide ion (a more powerful nucleophile) or acidic conditions (which make the leaving group come off more easily). When vinylic substrates are hydrolyzed, the products are enols, which tautomerize to aldehydes or ketones (Sec. 2.N), as shown.

These reactions are all considered at one place because they are formally similar. Although some of them involve $\text{R}-\text{O}$ cleavage and are thus nucleophilic substitutions at

a saturated carbon, others involve cleavage of the bond between the inorganic atom and oxygen and are thus nucleophilic substitutions at a sulfur, nitrogen, and so on. It is even possible for the same ester to be cleaved at either position, depending on the conditions. Thus benzhydryl *p*-toluenesulfate ($\text{Ph}_2\text{CHOSOC}_6\text{H}_4\text{CH}_3$) was found to undergo C—O cleavage in HClO_4 solutions and S—O cleavage in alkaline media.⁵⁴⁷ In general, the weaker the corresponding acid, the less likely is C—O cleavage. Thus, sulfonic acid esters ($\text{ROSO}_2\text{R}'$) generally give C—O cleavage,⁵⁴⁸ while nitrous acid esters (RONO) usually give N—O cleavage.⁵⁴⁹ Esters of sulfonic acids that are frequently hydrolyzed are mentioned in Section 10.G.iii. For hydrolysis of sulfonic acid esters (see also, Reaction 16-100).

OS VI, 852. See also, VIII, 50.

10-5 Hydrolysis of Diazoketones

Hydro, hydroxy-de-diazo-bisubstitution

Diazoketones are relatively easy to prepare (see Reaction 16-89). When treated with acid, they add a proton to give α -keto diazonium salts, which are hydrolyzed to the alcohols by the $\text{S}_{\text{N}}1$ or $\text{S}_{\text{N}}2$ mechanism.⁵⁵⁰ Relatively good yields of α -hydroxy ketones can be prepared in this way, since the diazonium ion is somewhat stabilized by the presence of the carbonyl group, which discourages N_2 from leaving because that would result in an unstable α -carbonyl carbocation.

10-6 Hydrolysis of Acetals, Enol Ethers, and Similar Compounds⁵⁵¹

The alkoxyl group (OR) is not a leaving group in these reactions, so these compounds must be converted to the conjugate acids before they can be hydrolyzed. Although 100% sulfuric acid and other concentrated strong acids readily cleave simple ethers,⁵⁵² the only

acids used preparatively for this purpose are HBr and HI (Reaction 10-49). However, acetals, ketals, and ortho esters⁵⁵³ are easily cleaved by dilute acids. These compounds are hydrolyzed with greater facility because carbocations of type $R_2(RO)C^+$ are greatly stabilized by resonance (Sec. 5.A.ii). The reactions therefore proceed by the S_N1 mechanism,⁵⁵⁴ as shown for acetals:⁵⁵⁵

This mechanism, which is an S_N1 or $A1$ mechanism, is the reverse of that for acetal formation by reaction of an aldehyde and an alcohol (Reaction 16-5). Among the facts supporting the mechanism are⁵⁵⁶ (1) The reaction proceeds with *specific* H_3O^+ catalysis (see Sec. 8.D). (2) It is faster in D_2O . (3) Optically active ROH are not racemized. (4) Even with *tert*-butyl alcohol the R—O bond does not cleave, as shown by ^{18}O labeling.⁵⁵⁷ (5) In the case of acetophenone ketals, the intermediate corresponding to **109** [$\text{ArCMe}(\text{OR})_2$] could be trapped with sulfite ions (SO_3^{2-}).⁵⁵⁸ (6) Trapping of this ion did not affect the hydrolysis rate,⁵⁵⁸ so the rate-determining step must come earlier. (7) In the case of 1,1-dialkoxyalkanes, intermediates corresponding to **109** were isolated as stable ions in superacid solution at -75°C , where their spectra could be studied.⁵⁵⁹ (8) Hydrolysis rates greatly increase in the order $\text{CH}_2(\text{OR}')_2 < \text{RCH}(\text{OR}')_2 < \text{R}_2\text{C}(\text{OR}')_2 < \text{RC}(\text{OR}')_3$, as would be expected for a carbocation intermediate.⁵⁶⁰ Formation of **109** is usually the rate-determining step (as marked above), but there is evidence that at least in some cases this step is fast, and the rate-determining step is loss of R'OH from the protonated hemiacetal.⁵⁶¹ Rate-determining addition of water to **109** has also been reported.⁵⁶²

While the $A1$ mechanism shown above operates in most acetal hydrolyses, it has been shown that at least two other mechanisms can take place with suitable substrates.⁵⁶³ In one of these mechanisms, the second and third of the above steps are concerted, so that the

mechanism is S_N2cA (or $A2$). This has been shown, for example, in the hydrolysis of 1,1-diethoxyethane, by isotope effect studies:⁵⁶⁴

In the second mechanism, the first and second steps are concerted. In the case of hydrolysis of 2-(*p*-nitrophenoxy)tetrahydropyran, *general* acid catalysis was shown⁵⁶⁵ demonstrating that the substrate is protonated in the rate-determining step (Sec. 8.D). Reactions in which a substrate is protonated in the rate-determining step are called $A-S_E2$ reactions.⁵⁶⁶ However, if protonation of the substrate were all that happens in the slow step, then the proton in the transition state would be expected to lie closer to the weaker base (Sec. 8.D). Because the substrate is a much weaker base than water, the proton should be largely transferred. Since the Brønsted coefficient was found to be 0.5, the proton was actually transferred only about halfway. This can be explained if the basicity of the substrate is increased by partial breaking of the C—O bond. The conclusion drawn is that steps 1 and 2 are concerted. The hydrolysis of ortho esters in most cases is also subject to general acid catalysis.⁵⁶⁷

The hydrolysis of acetals and ortho esters is governed by the stereoelectronic control factor discussed in Section 16.A.i, category 4,⁵⁶⁸ although the effect can generally be seen only in systems where conformational mobility is limited, especially in cyclic systems. There is evidence for synplanar stereoselection in the acid hydrolysis of acetals.⁵⁶⁹ The mechanism of Lewis acid mediated cleavage of chiral acetals is also known.⁵⁷⁰

Convenient reagents for the hydrolysis of acetals are wet silica gel⁵⁷¹ and Amberlyst-15 (a sulfonic acid based polystyrene cation exchange resin).⁵⁷² Both cyclic and acyclic acetals and ketals can be converted to aldehydes or ketones under nonaqueous conditions by treatment with TESOTf-2,6-lutidine (or 2,4,6-collidine) in dichloromethane followed by treatment with water,⁵⁷³ with Lewis acids e.g., 0.8% $\text{In}(\text{OTf})_3$ in acetone,⁵⁷⁴ ceric ammonium nitrate in aq acetonitrile,⁵⁷⁵ or $\text{Bi}(\text{OTf})_3 \cdot x\text{H}_2\text{O}$.⁵⁷⁶

Although acetals, ketals, and ortho esters are easily hydrolyzed by acids, they are extremely resistant to hydrolysis by bases. An aldehyde or ketone can therefore be protected from attack by a base by conversion to the acetal or ketal (Reaction 16-5), and then can be cleaved with acid. Pyridine–HF has also been used for this conversion.⁵⁷⁷

Thioacetals, thioketals, *gem*-diamines, and other compounds that contain any two of the groups OR, OCOR, NR₂, NHCOR, SR, and halogen on the same carbon can also be hydrolyzed to aldehydes or ketones, in most cases, by acid treatment. Thioacetals [RCH(SR')₂] and thioketals [R₂C(SR')₂] are among those compounds generally resistant to acid hydrolysis.⁵⁷⁸ Because conversion to these compounds (Reaction 16-11) serves as an important method for protection of aldehydes and ketones, many methods have been devised to cleave them to the parent carbonyl compounds. Among reagents⁵⁷⁹ used for this purpose are HgCl₂,⁵⁸⁰ FeCl₂•6 H₂O,⁵⁸¹ cetyltrimethylammonium tribromide in dichloromethane,⁵⁸² *m*-chloroperoxybenzoic acid, the *Dess–Martin periodinane*⁵⁸³ (see Reaction 19-03), and sodium nitrite in aqueous acetyl chloride.⁵⁸⁴ Mixed acetals and ketals (RO—C—SR) can be hydrolyzed with most of the reagents mentioned above, including *N*-bromosuccinimide (NBS) in aq acetone,⁵⁸⁵ and glyoxylic acid on Amberlyst-15 with microwave irradiation.⁵⁸⁶

Enol ethers (vinyl ethers) are readily hydrolyzed by acids; the rate-determining step is protonation of the substrate.⁵⁸⁷ However, protonation does not take place at the oxygen, but at the β carbon,⁵⁸⁸ because that gives rise to the stable carbocation (110).⁵⁸⁹ After that, the mechanism is similar to the A1 mechanism given above for the hydrolysis of acetals.

Among the facts supporting this mechanism, which is an A-S_E2 mechanism because the substrate is protonated in the rate-determining step, are (1) the ¹⁸O labeling shows that in ROCH=CH₂ it is the vinyl–oxygen bond and not the RO bond that cleaves;⁵⁹⁰ (2) the

reaction is subject to general acid catalysis;⁵⁹¹ (3) there is a solvent isotope effect when D₂O is used.⁵⁹¹ A method has been developed to determine primary kinetic isotope effects relating to proton transfer in the hydrolysis of enol ethers.⁵⁹² Enantioselective protonation is possible in some cases. Cyclic silyl enol ethers are converted to chiral α -substituted ketones, for example, with high enantioselectivity using a chiral Brønsted acid.⁵⁹³

Enamines are also hydrolyzed by acids (see Reaction 16-2); the mechanism is similar. Ketene dithioacetals [R₂C=C(SR')₂] also hydrolyze by a similar mechanism, except that the initial protonation step is partially reversible.⁵⁹⁴ Furans represent a special case of enol ethers that are cleaved by acid to give 1,4-diones.⁵⁹⁵ Thus oxonium ions are cleaved by water to give an alcohol and an ether:

10-7 Hydrolysis of Epoxides

(3) *OC-seco*-hydroxy-de-alkoxy substitution

The hydrolysis of epoxides is a convenient method for the preparation of *vic*-diols. The reaction is catalyzed by acids or bases. A basic reagent will attack the polarized carbon of the epoxide unit to open the ring, whereas an acid-catalyzed reaction leads to a protonated epoxide (an oxonium ion),⁵⁹⁶ which is opened by nucleophilic attack at an adjacent carbon. Among acid catalysts, perchloric acid leads to minimal side reactions,⁵⁹⁷ and 10% Bu₄NHSO₄ in water is effective.⁵⁹⁸ However, water reacts directly with epoxides at 60 °C.⁵⁹⁹ Dimethyl sulfoxide is a superior solvent for the alkaline hydrolysis of epoxides.⁶⁰⁰

Cobalt salen [salen = bis(salicylidene)ethylenediamine] catalysts, in the presence of water, open epoxides with high stereoselectivity.⁶⁰¹ The enzyme *epoxide hydrolase* opens epoxides with high enantioselectivity.⁶⁰²

10.H.ii Attack by OR at an Alkyl Carbon

10-8 Alkylation with Alkyl Halides: The Williamson Reaction

Alkoxy-de-halogenation

The *Williamson reaction* (*Williamson ether synthesis*), discovered in 1850, is still the best general method for the preparation of unsymmetrical or symmetrical ethers.⁶⁰³ The reaction can also be carried out with aromatic R', although C-alkylation is sometimes a side reaction (see Sec. 10.G.vii).⁶⁰⁴ The normal method involves treatment of a primary or secondary alkyl halide with alkoxide or aroxide ion prepared from an alcohol or phenol by reaction with a suitable base, although methylation using dimethyl carbonate has been reported.⁶⁰⁵ The solvent is usually an aprotic solvent (THF, ether, etc.) rather than an alcohol solvent, which typically promotes elimination reactions in the presence of alkoxides (see Chap. 17). It is also possible to mix the halide and alcohol or phenol directly with Cs₂CO₃ in acetonitrile,⁶⁰⁶ or with NaH in the presence of DMF.⁶⁰⁷ The reaction can also be carried out in a dry medium,⁶⁰⁸ neat,⁶⁰⁹ or in solvents using microwave irradiation.⁶¹⁰ Williamson ether synthesis in ionic liquids has also been reported.⁶¹¹ The reaction is *not* successful for tertiary R (elimination predominates), and low yields are often obtained with secondary R. Monoethers can be formed from diols and alkyl halides.⁶¹² It is possible to selectively alkylate the primary hydroxyl in a diol [HOCH₂CH(OH)R] using a tin complex.⁶¹³

Many other functional groups can be present in the molecule without interference. Ethers with one tertiary group *can* be prepared by treatment of an alkyl halide or sulfate ester (Reaction 10-10) with a tertiary alkoxide (R'O⁻). Di-*tert*-butylether was prepared in high yield by direct attack by *t*-BuOH on reaction with the *tert*-butyl cation (at -80 °C in SO₂ClF).⁶¹⁴ Di-*tert*-alkyl ethers in general have proved difficult to make, but they can be prepared in low-to-moderate yields by treatment of a tertiary halide with Ag₂CO₃ or Ag₂O.⁶¹⁵ Alcohols react with Mg(ClO₄)₂ and an excess of Boc (Boc = *t*-butoxycarbonyl) anhydride (Boc₂O) to give the *tert*-butyl ether.⁶¹⁶

Active halides (e.g., Ar_3CX) may react directly with the alcohol.⁶¹⁷ Hindered alcohols may react as well.⁶¹⁸ The mechanism for these cases is of course $\text{S}_{\text{N}}1$. *tert*-Butyl halides can be converted to aryl *tert*-butyl ethers by treatment with phenols and an amine (e.g., pyridine).⁶¹⁹ Aryl alkyl ethers can be prepared from alkyl halides by treatment with an aryl acetate (instead of a phenol) in the presence of K_2CO_3 and a crown ether.⁶²⁰ The Pd-catalyzed displacement of allylic acetates with aliphatic alcohols has been shown to give the corresponding alkyl allyl ether.⁶²¹ A Rh-catalyst⁶²² Ir catalyst,⁶²³ and an In-Si combined Lewis acid catalyst⁶²⁴ have been used in ether forming reactions. Aryl ethers have been prepared using *Mitsunobu conditions* (see Reaction 10-17).⁶²⁵

Vinyl ethers have been formed by coupling tetravinyl tin with phenols, in the presence of cupric acetate and oxygen.⁶²⁶ The Pd-catalyzed coupling of vinyl triflates and phenols has also been reported.⁶²⁷

Both aryl alkyl and dialkyl ethers can be efficiently prepared with the use of phase-transfer catalysis (Sec. 10.G.v)⁶²⁸ and with micellar catalysis.⁶²⁹ Symmetrical benzylic ethers have been prepared by reaction of benzylic alcohols with Mg/I_2 followed by triflic anhydride.⁶³⁰

A slight variation of the *Williamson ether synthesis* has been used for the protection of hydroxy groups⁶³¹ by reaction of their salts with chloromethyl methyl ether.

This protecting group is known as MOM (methoxymethyl) and such compounds are called MOM ethers. The resulting acetals are stable to bases and are easily cleaved with mild acid treatment (Reaction 10-7). Another protecting group, the 2-methoxyethoxymethyl group (the MEM group), is formed in a similar manner. Both MOM and MEM groups can be cleaved with dialkyl- and diarylboron halides (e.g., Me_2BBr).⁶³²

Another common method for the protection of alcohols is conversion to the silyl ether ($R-O-SiR'_3$). The alcohol is generally treated with a base (e.g., trimethylamine or imidazole) and then with a chlorotrialkylsilane (R_3SiCl), or the analogous bromide.⁶²⁹ There are many variations of this basic procedure. Iodine promotes the reaction, for example.⁶³³ There are also many ways to remove the silyl group to regenerate the alcohol, although fluoride ion, including tetrabutylammonium fluoride in THF, is probably the most common method.⁶²⁹

Most Williamson reactions proceed by the S_N2 mechanism, but there is evidence (see Sec. 10.C) that in some cases the SET mechanism can take place, especially with alkyl iodides.⁶³⁴ Secondary alcohols have been converted to the corresponding methyl ether by reaction with methanol in the presence of ferric nitrate nonahydrate.⁶³⁵

10-9 Epoxide Formation (Internal Williamson Ether Synthesis)

(3)OC-cyclo-Alkoxy-de-halogenation

This is a special case of Reaction 10-8. The base removes the proton from the OH group of a halohydrin (chlorohydrin or bromohydrin), and the resulting alkoxide subsequently attacks in an internal S_N2 reaction.⁶³⁶ Many epoxides have been made in this way.⁶³⁷ The course of the reaction can be influenced by neighboring group effects.⁶³⁸ Enantioselective epoxide-forming reactions are known, using chiral additives (e.g., dihydrocinchonidines).⁶³⁹ Epoxidation of alkenes has also been accomplished using HOF—MeCN in a continuous flow system.⁶⁴⁰

Larger cyclic ethers can be prepared, including five- and six-membered rings (tetrahydrofurans and tetrahydropyrans, respectively).⁶⁴¹ Additional treatment with base yields the glycol (Reaction 10-7). Thiiranes can be prepared by the reaction of α -chloro ketones with $(EtO)_2P(=O)-SH$ and $NaBH_4-Al_2O_3$ with microwave irradiation.⁶⁴²

1,2-Diols can be converted to epoxides by treatment with DMF dimethyl acetal, $[(MeO)_2CHNMe_2]$,⁶⁴³ with diethyl azodicarboxylate ($Et_2OCN=NCO_2Et$),

10-10 Alkylation with Inorganic Esters

Alkoxy-de-sulfonyloxy substitution

The reaction of alkyl sulfates with alkoxide ions is quite similar to Reaction **10-8** in mechanism and scope. Other inorganic esters can also be used. Methyl ethers of alcohols and phenols are commonly formed by treatment of alkoxides or aroxides with methyl sulfate. The alcohol or phenol can be methylated directly with dimethyl sulfate under various conditions.⁶⁴⁷ Carboxylic esters sometimes give ethers when treated with alkoxides ($\text{B}_{\text{AL}}2$ mechanism, Reaction **16-59**) in a very similar process (see also, Reaction **16-64**). A related reaction heated **111** with alumina to give the corresponding benzofuran, (**112**).⁶⁴⁸ The reaction of aliphatic alcohols and potassium organotrifluoroborate salts also gives ethers.⁶⁴⁹

tert-Butyl ethers (**113**) can be prepared by treating the compound *tert*-butyl-2,2,2-trichloroacetimidate with an alcohol or phenol in the presence of boron trifluoride etherate.⁶⁵⁰ Trichloroimidates can be used to prepare other ethers as well.⁶⁵¹ *tert*-Butyl ethers can be cleaved by acid-catalyzed hydrolysis.⁶⁵²

Alcohols react with diazo compounds to form ethers, but diazomethane and diazo ketones are most readily available, giving methyl ethers or α -keto ethers,⁶⁵³ respectively. With diazomethane⁶⁵⁴ the method is expensive and requires great caution, but the conditions are mild and high yields are obtained. Diazomethane is used chiefly to methylate alcohols and phenols that are expensive or available in small amounts. Hydroxy compounds react better as their acidity increases; ordinary alcohols do not react at all unless a catalyst (e.g., HBF_4 ⁶⁵⁵ or silica gel)⁶⁵⁶ is present. The more acidic phenols react very well in the absence of a catalyst. The reaction of oximes, and ketones that have substantial enolic contributions, give O-alkylation to form, respectively, O-alkyl oximes and enol ethers. The mechanism⁶⁵⁷ is as in Reaction 10-5. Note that O-aryloximes are prepared from oximes and aryl halides, mediated by CuI .⁶⁵⁸

Diazoalkanes can also be converted to ethers by thermal or photochemical cleavage in the presence of an alcohol. These are carbene or carbenoid reactions.⁶⁵⁹ Enantioselective insertion into phenolic O—H bond leads to highly substituted ethers.⁶⁶⁰ Similar intermediates are involved when diazoalkanes react with alcohols in the presence of *t*-BuOCl to give acetals.⁶⁶¹

OS V, 245. Also see, OS V, 1099.

10-12 Dehydration of Alcohols

Alkoxy-de-hydroxylation

The dehydration of alcohols to form symmetrical ethers⁶⁶² is analogous to Reactions 10-8 and 10-10, but the species from which the leaving group departs is ROH_2^+ or ROSO_2OH . The former is obtained directly on treatment of alcohols with sulfuric acid and may go, by an $\text{S}_{\text{N}}1$ or $\text{S}_{\text{N}}2$ pathway, directly to the ether if attacked by another molecule of alcohol. On the other hand, it may, again by either an $\text{S}_{\text{N}}1$ or $\text{S}_{\text{N}}2$ route, be attacked by the nucleophile HSO_4^- , in which case it is converted to ROSO_2OH , which in turn may be attacked by an alcohol molecule to give ROR. Elimination is always a side reaction and, in the case of tertiary alkyl substrates, completely predominates. Good yields of ethers were obtained by heating diarylcarbinols [$\text{ArAr}'\text{CHOH} \rightarrow (\text{ArAr}'\text{CH})_2\text{O}$] with TsOH in the solid

state.⁶⁶³ Acids (e.g., Nafion-H with silyl ethers)⁶⁶⁴ can be used in this transformation, and Lewis acids can be used with alcohols in some cases.⁶⁶⁵

Mixed (unsymmetrical) ethers can be prepared if one group is tertiary alkyl and the other primary or secondary, since the latter group is not likely to compete with the tertiary group in the formation of the carbocation, while a tertiary alcohol is a very poor nucleophile.⁶⁶⁶ If one group is not tertiary, the reaction of a mixture of two alcohols leads to all three possible ethers. Unsymmetrical ethers have been formed by treatment of two different alcohols with MeReO_3 ⁶⁶⁷ or with BiBr_3 .⁶⁶⁸ Unsymmetrical ethers have been prepared under *Mitsunobu conditions* (Reaction **10-17**) with a polymer-supported phosphine and diethyl azadicarboxylate (DEAD).⁶⁶⁹ Symmetrical ethers are formed by heating benzylic alcohols with the polymer poly(3,4-ethylenedioxythiophene) in toluene or heptane (a two-phase system), with no other additives.⁶⁷⁰ Diols can be converted to cyclic ethers,⁶⁷¹ although the reaction is most successful for five-membered rings, but five-, six-, and seven-membered rings have been prepared.⁶⁷² Thus, 1,6-hexanediol gives mostly 2-ethyltetrahydrofuran. This reaction is also important in preparing furfural derivatives from aldoses, with concurrent elimination.

Phenols and primary alcohols form ethers when heated with dicyclohexylcarbodiimide⁶⁷³ (see Reaction **16-63**).

10-13 Transesterification

Hydroxy-de-alkoxylation and Alkoxy-de-hydroxylation

The exchange of one alkoxy group for another is rare for *ethers* without a reactive R group (e.g., diphenylmethyl),⁶⁷⁴ or by treatment of alkyl aryl ethers with alkoxide ions: $\text{ROAr} + \text{R}'\text{O}^- \rightarrow \text{ROR}' + \text{ArO}^-$.⁶⁷⁵ 3-(2-Benzyloxyethyl)-3-methyl-oxetane was transformed into 3-benzyloxymethyl-3-methyltetrahydrofuran by an internal transesterification catalyzed by $\text{BF}_3 \cdot \text{OEt}_2$.⁶⁷⁶

Acetals and ortho esters undergo transesterification readily,⁶⁷⁷ as with the transformation of **114** to **115**.⁶⁷⁸ As seen in Reaction **10-6**, departure of the leaving group from an acetal gives a particularly stable carbocation. It is also possible to convert a dimethylketal directly to a dithiane by reaction with butane 1,4-dithiol on clay.⁶⁷⁹ These are equilibrium reactions, and most often the equilibrium is shifted by removing the lower-boiling alcohol by distillation. Enol ethers can be prepared by treating an alcohol with an enol ester or a different enol ether, with mercuric acetate as a catalyst,⁶⁸⁰ as shown in the example. *N,N*-Diethylaminoethylthiol reacts with aryl ethers to give the phenol derivative and the corresponding sulfide in what is effectively a transesterification.⁶⁸¹

1,2-Diketones can be converted to α -keto enol ethers by treatment with an alkoxytrimethylsilane (ROSiMe_3).⁶⁸²

media.⁶⁸⁹ Many of the β -hydroxy ethers produced in this way are valuable solvents, [e.g., diethylene glycol and Cellosolve (2-ethoxyethanol)]. Reaction with thiols leads to hydroxy thioethers.⁶⁹⁰ Other nucleophilic oxygen or sulfur species have been shown to open epoxides, including thiols⁶⁹¹ (catalyzed by Sc⁶⁹² or In⁶⁹³). (Phenylseleno)silanes react with epoxides to give β -hydroxy selenides.⁶⁹⁴

Opening an epoxide by an alkoxide moiety can be done intramolecularly, and a new cyclic ether is generated. Ethers of various ring sizes can be produced depending on the length of the tether between the alkoxide unit and the epoxide. Specialized conditions are common, as in the conversion of **116** to **117**.⁶⁹⁵ Another variant of this transformation used a Co-salen catalyst.⁶⁹⁶ A specialized version has the alkoxide moiety on the carbon adjacent to the epoxide, leading to the *Payne rearrangement* where a 2,3-epoxy alcohol is converted to an isomeric one, by treatment with aqueous base, as shown in the example.⁶⁹⁷

The reaction results in inverted configuration at C-2. Of course, the product can also revert to the starting material by the same pathway, so a mixture of epoxy alcohols is generally obtained.

The reaction of alcohols with aziridines leads to β -amino ethers,⁶⁹⁸ and reaction with thiols gives β -amino thioethers.⁶⁹⁹ It has been shown that ring opening of aziridines by

been shown that a strained four-membered ring silane (a siletane) also gives the corresponding alcohol upon oxidation.⁷¹⁴ Treatment with a fluorinating agent (e.g., tetrabutylammonium fluoride or CsF) replaces Ar or SiR₃ with F, which is oxidized with hydrogen peroxide or a peroxyacid to give the alcohol. This sequence is often called the *Tamao–Fleming oxidation*.⁷¹² There are several variations in substrate that allow versatility in the initial incorporation of the silyl unit.⁷¹⁵ Hydroperoxide oxidation of a cyclic silane leads to a diol.⁷¹⁶

C. Attack by OCOR at an Alkyl Carbon

10-17 Alkylation of Carboxylic Acid Salts

Acyloxy-de-halogenation

Sodium salts of carboxylic acids, including hindered acids (e.g., mesitoic), rapidly react with primary and secondary bromides and iodides at room temperature in dipolar aprotic solvents, especially HMPA, to give high yields of carboxylic esters.⁷¹⁷ The mechanism is S_N2. Several bases or basic media have been used to generate the carboxylate salt.⁷¹⁸ Sodium salts are often used, but K, Ag, Cs,⁷¹⁹ and substituted ammonium salts have also been used. An important variation uses phase transfer catalysis,⁷²⁰ and good yields of esters have been obtained from primary, secondary, benzylic, allylic, and phenacyl halides.⁷²¹ Without phase-transfer catalysts and in protic solvents, the reaction is useful only for fairly active R [e.g., benzylic and allylic (S_N1 mechanism)], but not for tertiary alkyl, since elimination occurs instead.⁷²² Solid-state procedures are available. Addition of the dry carboxylate salt and the halide to alumina as a solid support, and microwave irradiation gives the ester in a procedure that is applicable to long-chain primary halides.⁷²³ A similar reaction of hexanoic acid and benzyl bromide on solid benzyltributylammonium chloride

gave the ester with microwave irradiation.⁷²⁴ Ionic liquid solvents have been shown to facilitate this alkylation reaction.⁷²⁵

The reaction of an alcohol and a carboxylate anion with diethyl azodicarboxylate ($\text{EtOOCN}=\text{NCOOEt}$) and Ph_3P ⁷²⁶ is called the *Mitsunobu reaction*.⁷²⁷ Other azocarboxylates may be used in this reaction, including diisopropyl azodicarboxylate (DIAD), and di-2-methoxyethyl azodicarboxylate (DMEAD).⁷²⁸ Other Mitsunobu catalysts are available,⁷²⁹ including organocatalysts,⁷³⁰ and polymer-supported reagents have been used.⁷³¹ A renewable phosphine ligand has been developed.⁷³² Note that other functional groups, including azides⁷³³ and thiocyanates⁷³⁴ can be generated from alcohols using Mitsunobu conditions. This reaction can also be considered as an $\text{S}_{\text{N}}2$ mechanism. Phenol esters can also be formed.⁷³⁵ Mitsunobu cyclodehydration of 1,2-diols leads to epoxides.⁷³⁶

Lactones can be prepared from halo acids by treatment with base (see Reaction 16-63). This has most often been accomplished with γ and δ lactones, but macrocyclic lactones (e.g., 11-17-members) have also been prepared in this way.⁷³⁷ An interesting variation treated 2-ethylbenzoic acid with hypervalent iodine and then $\text{I}_2/h\nu$ to give the five-membered ring lactone.⁷³⁸

Copper(I) carboxylates give esters with primary (including neopentyl without rearrangement), secondary, and tertiary alkyl, allylic, and vinylic halides.⁷³⁹ A simple S_{N} mechanism is obviously precluded in this case. Vinylic halides can be converted to vinylic acetates by treatment with sodium acetate if palladium(II) chloride is present.⁷⁴⁰

A carboxylic acid (not the salt) can be the nucleophile if F^- is present.⁷⁴¹ Mesylates are readily displaced, for example, by benzoic acid/ CsF .⁷⁴² Dihalides have been converted to

diesters by this method.⁷⁴¹ A COOH group can be conveniently protected by reaction of its ion with a phenacyl bromide (ArCOCH₂Br).⁷⁴³ The resulting ester is easily cleaved when desired with zinc and acetic acid. Dialkyl carbonates can be prepared without phosgene (see Reaction **16-61**) by phase-transfer catalyzed treatment of primary alkyl halides with dry KHCO₃ and K₂CO₃.⁷⁴⁴

Other leaving groups can also be replaced by OCOR. Alkyl chlorosulfites (ROSOCI) and other derivatives of sulfuric, sulfonic, and other inorganic acids can be treated with carboxylate ions to give the corresponding esters. Treatment with oxalyl chloride allows displacement by carboxylate salts.⁷⁴⁵ The use of dimethyl sulfate⁷⁴⁶ or trimethyl phosphate⁷⁴⁷ allows sterically hindered COOH groups to be methylated. The reaction of benzoic acid with aq lithium hydroxide, and then dimethyl sulfate gave methyl benzoate.⁷⁴⁸ Dimethyl carbonate in the presence of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU, see Reaction **17-13**) has been used to prepare methyl esters.⁷⁴⁹ With certain substrates, carboxylic acids are strong enough nucleophiles for the reaction. Examples of such substrates are trialkyl phosphites [P(OR)₃]⁷⁵⁰ and acetals of DMF.⁷⁵¹

This is an S_N2 process, since inversion is found at R. Another good leaving group is NTs₂ and ditosylamines react quite well with acetate ion in dipolar aprotic solvents:⁷⁵² RNTs₂ + OAc[−] → ROAc. Ordinary primary amines have been converted to acetates and benzoates by the *Katritzky pyrylium–pyridinium method* (Sec. 10.G.iii).⁷⁵³ Quaternary ammonium salts can be cleaved by heating with AcO[−] in an aprotic solvent.⁷⁵⁴ Oxonium ions can also be used as substrates:⁷⁵⁵ R₃O⁺ + R'COO[−] → R'COOR + R₂O. The reaction of potassium thioacetate with alkyl halides give dithiocarboxylic esters.⁷⁵⁶

In a variation of this reaction, alkyl halides can be converted to carbamates, by treatment with a secondary amine and K₂CO₃ under phase transfer conditions.⁷⁵⁷ The reaction of alcohols and alkyl halides can lead to carbonates.⁷⁵⁸

10-18 Cleavage of Ethers with Acetic Anhydride or Acid Halides

Acyloxy-de-alkoxylation

Dialkyl ethers can be cleaved by treatment with anhydrous ferric chloride in acetic anhydride,⁷⁵⁹ or with Me_3SiOTf in acetic anhydride.⁷⁶⁰ In this reaction, both R groups are converted to acetates and yields are moderate to high. Ethers can also be cleaved by the mixed, anhydride acetyl tosylate.⁷⁶¹

Epoxides give β -hydroxyalkyl carboxylates when treated with a carboxylic acid or a carboxylate ion and a suitable catalyst.⁷⁶² Tetrahydrofuran was opened to give *O*-acetyl-4-iodo-1-butanol by treatment with acid chlorides and samarium halides⁷⁶³ or BCl_3 .⁷⁶⁴ In a highly specialized transformation, the reaction of an epoxide with CO_2 and ZnCl_2 in an ionic liquid leads to a cyclic carbonate.⁷⁶⁵ Epoxides react with CO and CH_3OH in the presence of 10% of 3-hydroxypyridine and 5% of $\text{Co}_2(\text{CO})_8$ to give a β -hydroxy methyl ester.⁷⁶⁶

OS VIII, 13.

10-19 Alkylation of Carboxylic Acids with Diazo Compounds

Hydro, acyloxy-de-diazo-bisubstitution

Carboxylic acids can be converted to esters with diazo compounds in a reaction essentially the same as 10-11. In contrast to alcohols, carboxylic acids undergo the reaction quite well at room temperature, since the reactivity of the reagent increases with acidity. The reaction is used where high yields are important or where the acid is sensitive to higher temperatures. Because of availability, diazomethane (CH_2N_2)⁶⁵⁴ is commonly used to prepare methyl esters, and diazo ketones are common. The mechanism is as shown in Reaction 10-11.

D. Other Oxygen Nucleophiles

10-20 Formation of Oxonium Salts

Dialkyloxonio-de-halogenation

Alkyl halides can be alkylated by ethers or ketones to give oxonium salts, if a very weak, negatively charged nucleophile is present to serve as a counterion and a Lewis acid is present to combine with X^- .⁷⁶⁷ A typical procedure consists of treating the halide with the ether or the ketone in the presence of AgBF_4 or AgSbF_6 . The Ag^+ serves to remove X^- and the BF_4^- or SbF_6^- acts as the counterion. Another method involves treatment of the halide with a complex formed between the oxygen compound and a Lewis acid (e.g., $\text{R}_2\text{O} \cdot \text{BF}_3 + \text{RX} \rightarrow \text{R}_3\text{O}^+ \text{ } ^-\text{BF}_4^-$), although this method is most satisfactory when the oxygen and halogen atoms are in the same molecule so that a cyclic oxonium ion is obtained. Ethers and oxonium ions also undergo exchange reactions:

OS V, 1080, 1096, 1099; VI, 1019.

10-21 Preparation of Peroxides and Hydroperoxides

Hydroperoxy-de-halogenation

Hydroperoxides can be prepared by treatment of alkyl halides, esters of sulfuric or sulfonic acids, or alcohols with hydrogen peroxide in basic solution, where it is actually HO_2^- .⁷⁶⁸ Sodium peroxide is similarly used to prepare dialkyl peroxides ($2\text{RX} + \text{Na}_2\text{O}_2 \rightarrow \text{ROOR}$). Another method, which gives primary, secondary, or tertiary hydroperoxides and peroxides, involves treatment of the halide with H_2O_2 or a peroxide in the presence of silver trifluoroacetate.⁷⁶⁹ Peroxides can also be prepared⁷⁷⁰ by treatment of alkyl bromides or tosylates with potassium superoxide (KO_2) in the presence of crown ethers (though alcohols may be side products⁷⁷¹) and by the reaction between alkyl triflates and germanium or tin peroxide.⁷⁷²

Diacyl peroxides and acyl hydroperoxides can similarly be prepared⁷⁷³ from acyl halides or anhydrides and from carboxylic acids.⁷⁷⁴ Diacyl peroxides can also be prepared by the

treatment of carboxylic acids with hydrogen peroxide in the presence of dicyclohexylcarbodiimide,⁷⁷⁵ Sulfuric acid, methanesulfonic acid, or some other dehydrating agent. Mixed alkyl–acyl peroxides (peresters) can be made from acyl halides and hydroperoxides.

OS III, 619, 649; V, 805, 904; VI, 276.

10-22 Preparation of Inorganic Esters

Nitrosooxy-de-hydroxylation, and so on.

The above transformations show a few of the many inorganic esters that can be prepared by the reaction of an alcohol with an inorganic acid or, better, its acid halide or anhydride⁷⁷⁶ These similar reactions are grouped together for convenience, but not all involve nucleophilic substitutions at R. The other possible pathway is nucleophilic substitution at the inorganic central atom, such as the attack of the alcohol oxygen at the electrophilic sulfur atom in **118**,⁷⁷⁷ or a corresponding S_N2 type process (see Sec. 16.B.v). In such cases, there

is no alkyl–O cleavage. Mono esters of sulfuric acid (alkylsulfuric acids), which are important industrially because their salts are used as detergents, can be prepared by treating alcohols with SO₃, H₂SO₄, ClSO₂OH, or SO₃ complexes.⁷⁷⁸ It is possible to prepare a primary sulfonate ester (e.g., tosylate), in the presence of a secondary alcohol unit when tosic acid reacts with a 1,2-diol in the presence of Fe³⁺-Montmorillonite.⁷⁷⁹ Polymer-bound reagents have been used to prepare sulfonate esters.⁷⁸⁰ Phenolic triflates have been prepared using *N,N*-ditriflylaniline and K₂CO₃ under microwave irradiation.⁷⁸¹ Sulfinic esters are readily prepared from alcohols and sulfinyl chlorides, and in the presence of Cinchona alkaloids the reaction is enantioselective.⁷⁸²

Alkyl nitrites⁷⁸³ can be conveniently prepared by an exchange reaction $\text{ROH} + \text{R}'\text{ONO} \rightarrow \text{RONO} + \text{R}'\text{OH}$, where $\text{R} = t\text{-Bu}$.⁷⁸⁴ Primary amines can be converted to alkyl nitrates ($\text{RNH}_2 \rightarrow \text{RONO}_2$) by treatment with N_2O_4 at -78°C in the presence of an excess of amidine base.⁷⁸⁵ *Mitsunobu* conditions (Reaction **10-17**) can be used to prepare phosphate ester or phosphonate esters. The reaction can be done intramolecularly for prepare cyclic phosphonate esters.⁷⁸⁶

Alkyl halides are often used as substrates instead of alcohols. In such cases, the *salt* of the inorganic acid is usually used and the mechanism is nucleophilic substitution at the carbon atom. An important example is the treatment of alkyl halides with silver nitrate to form alkyl nitrates. This is used as a test for alkyl halides. In some cases, there is competition from the central atom. Thus nitrite ion is an ambident nucleophile that can give nitrites or nitro compounds (see Reaction **10-42**).⁷⁸⁷ Dialkyl or aryl alkyl ethers can be cleaved with anhydrous sulfonic acids.⁷⁸⁸

Here R'' may be alkyl or aryl. For dialkyl ethers, the reaction does not end as indicated above, since $\text{R}'\text{OH}$ is rapidly converted to $\text{R}'\text{OR}'$ by the sulfonic acid (Reaction **10-12**), which in turn is further cleaved to $\text{R}'\text{OSO}_2\text{R}''$ so that the product is a mixture of the two sulfonates. For aryl alkyl ethers, cleavage always takes place to give the phenol, which is not converted to the aryl ether under these conditions. Ethers can also be cleaved in a similar manner by mixed anhydrides of sulfonic and carboxylic acids⁷⁸⁹ (prepared as in Reaction **16-68**). β -Hydroxyalkyl perchlorates⁷⁹⁰ and sulfonates can be obtained from epoxides.⁷⁹¹ Epoxides and oxetanes give α,ω -dinitrates when treated with N_2O_5 .⁷⁹² Aziridines and azetidines react similarly, giving nitramine nitrates (e.g., *N*-butylazetidine gave $\text{NO}_2\text{OCH}_2\text{CH}_2\text{CH}_2\text{N}(\text{Bu})\text{NO}_2$).⁷⁹²

Phosphinate esters are prepared by transesterification-type reactions (**16-64**) from alcohols and other phosphinates.⁷⁹³

(*S*)-phenethylamine and the bis-(sulfonyl chloride) of 1,2-benzenesulfonic acid, followed by KNO_2 and 18-crown-6 gave (*R*)-phenethyl alcohol in 70% yield and 40% enantiomeric excess (ee).⁷⁹⁵

10-24 Alkylation of Oximes⁷⁹⁶

Oximes can be alkylated by alkyl halides or sulfates. *N*-Alkylation is a side reaction, yielding a nitron.⁷⁹⁷ The relative yield of oxime ether and nitron depends on the nature of the reagents, including the configuration of the oxime, and on the reaction conditions.⁷⁹⁸ For example, *anti*-benzaloximes give nitrones, while the *syn* isomers give oxime ethers.⁷⁹⁹

10.H.iii. Sulfur Nucleophiles

Sulfur compounds⁸⁰⁰ are better nucleophiles than their oxygen analogues (Sec. 10.G.ii), so in most cases these reactions take place faster and more smoothly than the corresponding reactions with oxygen nucleophiles. There is evidence that some of these reactions take place by SET mechanisms.⁸⁰¹

10-25 Attack by SH at an Alkyl Carbon: Formation of Thiols⁸⁰²

Mercapto-de-halogenation

Sodium sulfhydryde (NaSH) is a much better reagent for the formation of thiols (mercaptans) from alkyl halides than H_2S and is used much more often. It is easily prepared by bubbling H_2S into an alkaline solution, but hydrosulfide on a supported polymer resin has also been used.⁸⁰³ The reaction is most useful for primary halides. Secondary substrates give much lower yields, and the reaction fails completely for tertiary

halides because elimination predominates. Sulfuric and sulfonic esters can be used instead of halides. Thioethers (RSR) are often side products.⁸⁰⁴ The conversion can also be accomplished under neutral conditions by treatment of a primary halide with F^- and a tin sulfide (e.g., $Ph_3SnSSnPh_3$).⁸⁰⁵ An indirect method for the preparation of a thiol is the reaction of an alkyl halide with thiourea to give an isothiuronium salt (**119**), and subsequent treatment with alkali or a high-molecular-weight amine gives cleavage to the thiol.

Other indirect methods are treatment of the halide with silyl-thiols and KH, followed by treatment with fluoride ion and water,⁸⁰⁶ and hydrolysis of *Bunte salts* (see Reaction **10-28**) is another method.

Thiols have also been prepared from alcohols. One method involves treatment with H_2S and a catalyst (e.g., Al_2O_3),⁸⁰⁷ but this is limited to primary alcohols. Another method involves treatment with *Lawesson's reagent* (see Reaction **16-10**).⁸⁰⁸ Tertiary nitro compounds give thiols ($RNO_2 \rightarrow RSH$) when treated with sulfur and sodium sulfide, followed by amalgamated aluminum.⁸⁰⁹

10-26 Attack by S at an Alkyl Carbon: Formation of Thioethers

Alkylthio-de-halogenation; Alkylthio-de-hydroxylation

Thioethers (sulfides) can be prepared by treatment of alkyl halides with salts of thiols (thiolate anions).⁸¹⁰ The R' group may be alkyl or aryl and organolithium bases can be used to deprotonate the thiol.⁸¹¹ As in Reaction **10-25**, RX cannot be a tertiary halide, and sulfuric and sulfonic esters can be used instead of halides. As in the *Williamson Reaction* (**10-8**), yields are often improved by phase-transfer catalysis.⁸¹² Thiols react directly with alkyl halides in the presence of bases (e.g., DBU; see Reaction **17-13**)⁸¹³ or CsF .⁸¹⁴ Leaving groups other than chloride can be used, as in the Ru catalyzed reaction of thiols

with propargylic carbonates.⁸¹⁵ Vinylic sulfides can be prepared by treating vinylic bromides with PhS^- in the presence of a Ni complex,⁸¹⁶ or in the presence of $\text{Pd}(\text{PPh}_3)_4$. Alternatively, the Ag salt of an enethiol reacts with iodomethane to give the corresponding methyl vinyl sulfide.⁸¹⁷

In some cases, alcohols can be converted to thioethers by reaction with thiols. Tertiary alcohols react with thiols in the presence of sulfuric acid to give thioethers, and the reaction works best with tertiary substrates.⁸¹⁸ This reaction is analogous to Reaction 10-12. Thiophenol reacts with propargylic alcohols in the presence of a Ru catalyst to give propargylic thioethers.⁸¹⁹ Primary and secondary alcohols can be converted to alkyl aryl sulfides ($\text{ROH} \rightarrow \text{RSAr}$) in high yields by treatment with Bu_3P and an *N*-(arylthio)succinimide in benzene.⁸²⁰ Iodine catalyzes the allylic alkylation of thiols.⁸²¹ Thioethers (RSR') can be prepared from an alcohol ROH and a halide $\text{R}'\text{Cl}$ by treatment with tetramethylthiourea $\text{Me}_2\text{NC}(=\text{S})\text{NMe}_2$ followed by NaH .⁸²²

Thiolate ions are also useful for the demethylation of certain ethers,⁸²³ esters, amines, and quaternary ammonium salts. Aryl methyl ethers⁸²⁴ can be cleaved by heating with EtS^- in the dipolar aprotic solvent DMF: $\text{ROAr} + \text{EtS}^- \rightarrow \text{ArO}^- + \text{EtSR}$.⁸²⁵ Allylic sulfides have been prepared by treating allylic carbonates ROCO_2Me (R = an allylic group) with a thiol and a $\text{Pd}(0)$ catalyst.⁸²⁶ A good method for the demethylation of quaternary ammonium salts consists of refluxing them with PhS^- in 2-butanone to give the amine and methyl phenyl sulfide.⁸²⁷

A methyl group is cleaved more readily than other simple alkyl groups (e.g., ethyl), although loss of these groups competes. Benzylic and allylic groups cleave even more easily, and this is a useful procedure for the cleavage of benzylic and allylic groups from quaternary ammonium salts, even if methyl groups are also present.⁸²⁸

Symmetrical thioethers ($\text{R}-\text{S}-\text{R}$) can also be prepared by treatment of an alkyl halide ($\text{R}-\text{X}$) with sodium sulfide (Na_2S).⁸²⁹ Symmetrical thioethers have also been prepared by the reaction of $\text{S}(\text{MgBr})_2$ with allylic halides.⁸³⁰ This reaction can be carried out internally, by treatment of sulfide ions with 1,4-, 1,5-, or 1,6-dihalides, to prepare five-, six-, and

10-27 Formation of Disulfides⁸⁵⁶

Dithio-de-dihalo- *aggre* -substitution

Disulfides can be prepared by treatment of alkyl halides with disulfide ions and also indirectly by the reaction of *Bunte salts* (see Reaction 10-28) with acid solutions of iodide, thiocyanate ion, or thiourea,⁸⁵⁷ or by pyrolysis or treatment with hydrogen peroxide. Alkyl halides also give disulfides when heated to reflux with sulfur and NaOH.⁸⁵⁸ Some molybdenum compounds convert alkyl halides to disulfides, including (BnNEt₃)₆Mo₇S₂₄.⁸⁵⁹

There are no OS references, but a similar preparation of a polysulfide may be found in OS IV, 295.

10-28 Formation of Bunte Salts

Sulfonatothio-de-halogenation

Primary and secondary, but not tertiary, alkyl halides are easily converted to *Bunte salts* (RSSO₃[−]) by treatment with thiosulfate ion.⁸⁶⁰ Bunte salts can be hydrolyzed with acids to give the corresponding thiols⁸⁶¹ or converted to disulfides, tetrasulfides, or pentasulfides.⁸⁶²

OS VI, 235.

10-29 Alkylation of Sulfinic Acid Salts**Alkylsulfonyl-de-halogenation**

Alkyl halides or alkyl sulfates, treated with the salts of sulfinic acids, give sulfones.⁸⁶³ A Pd catalyzed reaction with a chiral complexing agent led to sulfones with modest asymmetric induction.⁸⁶⁴ Alkyl sulfinates ($\text{R}'\text{SO}-\text{OR}$) may be side products.⁸⁶⁵ Sodium tosylsulfinate reacted with allylic acetates in the presence of a Pd catalyst to give the corresponding sulfone.⁸⁶⁶ Sulfonic acids themselves can be used, if DBU (see Reaction 17-13) is present.⁸⁶⁷ Sulfonyl halides react with allylic halides in the presence of AlCl_3-Fe ⁸⁶⁸ and with benzyl halides in the presence of Sm/HgCl_2 .⁸⁶⁹ Sulfones have also been prepared by treatment of alkyl halides with tosylhydrazide.⁸⁷⁰ The copper(II)-catalyzed cross-coupling of organoboronic acids and sulfinic acid salts leads to sulfones.⁸⁷¹ Vinyl sulfones were prepared from PhSO_2Na and vinyl iodonium salts $\text{C}=\text{C}-\text{I}^+\text{Ph BF}_4^-$.⁸⁷² OS IV, 674; IX, 497. See also, OS VI, 1016.

10-30 Formation of Alkyl Thiocyanates**Thiocyanato-de-halogenation**

Alkyl halides⁸⁷³ or sulfuric or sulfonic esters can be heated with sodium or potassium thiocyanate to give alkyl thiocyanates,⁸⁷⁴ although the attack by the analogous cyanate ion (Reaction 10-44) gives exclusive *N*-alkylation. Primary amines can be converted to thiocyanates by the *Katritzky pyrylium-pyridinium method* (Sec. 10.G.iii).⁸⁷⁵ Tertiary chlorides are converted to tertiary thiocyanates with $\text{Zn}(\text{SCN})_2$ in pyridine and ultrasound.⁸⁷⁶

10.H.iv. Nitrogen Nucleophiles

A. Attack by NH₂, NHR, or NR₂ at an Alkyl Carbon

10-31 Alkylation of Amines

Amino-de-halogenation (alkyl)

The reaction between alkyl halides and ammonia or primary amines is not usually a feasible method for the preparation of primary or secondary amines, since they are stronger bases than ammonia and preferentially attack the substrate. However, the reaction is very useful for the preparation of tertiary amines⁸⁷⁷ and quaternary ammonium salts. If ammonia is the nucleophile,⁸⁷⁸ the three or four alkyl groups on the nitrogen of the product must be identical. If a primary, secondary, or tertiary amine is used, then different alkyl groups can be placed on the same nitrogen atom. The conversion of tertiary amines to quaternary salts is called the *Menshutkin reaction*.⁸⁷⁹ It is sometimes possible to use this method for the preparation of a primary amine by the use of a large excess of ammonia or a secondary amine by the use of a large excess of primary amine. Metal-catalyzed methods are available to convert primary amines to secondary amines,⁸⁸⁰ and secondary amines can be converted to tertiary amines.⁸⁸¹ Ionic liquids have been used to facilitate amination reactions.⁸⁸² The use of ammonia in methanol with microwave irradiation has also been effective.⁸⁸³ Microwave irradiation has also been used in reactions of aniline with allyl iodides.⁸⁸⁴ Bromides react faster than chlorides, and secondary amines reaction with 3-chloro-1-bromopropane via the bromide, in the presence of Zn and THF.⁸⁸⁵ N-Alkylation has been accomplished using alkyl halides in aqueous media.⁸⁸⁶

Bases other than amine can be used. Both sodium carbonate⁸⁸⁷ and lithium hydroxide⁸⁸⁸ have been used. Cesium hydroxide was successfully used as a base in the presence of

molecular sieve 4 Å,⁸⁸⁹ and cesium fluoride has been used with benzylic halides.⁸⁹⁰ Potassium carbonate in DMSO has been used for the alkylation of aniline.⁸⁹¹

The limitations of this approach can be seen in the reaction of a saturated solution of ammonia in 90% ethanol with ethyl bromide in a 16:1 molar ratio, which gave 34.2% of the primary amine (at a 1:1 ratio the yield was 11.3%).⁸⁹² α -Halo acids are one type of substrate that give reasonable yields of primary amine (provided a large excess of NH_3 is used) and are subsequently converted to amino acids. *N*-Chloromethyl lactams also react with amines to give good yields to the *N*-aminomethyl lactam.⁸⁹³ An indirect method to prepare primary amines from alkyl halides uses Reaction **10-43**, followed by reduction of the azide (**19-32**),⁸⁹⁴ and the *Gabriel synthesis* (**10-41**) is effective.

The immediate product in any particular step is the protonated amine, but it rapidly loses a proton to another molecule of ammonia or amine in an equilibrium process, for example,

When a primary or secondary amine must be converted directly to the quaternary salt (*exhaustive alkylation*), the rate can be increased by the addition of a non-nucleophilic strong base that serves to remove the proton from $\text{RR}'\text{NH}_2^+$ or $\text{RR}'\text{R}^2\text{NH}^+$ and thus liberates the amine to attack another molecule of RX .⁸⁹⁵

The conjugate bases of ammonia and of primary and secondary amines (NH_2^- , RNH^- , R_2N^-) are generically known as *amide bases*, and are sometimes used as nucleophiles,⁸⁹⁶ including amide bases generated from organolithium reagents and amines (R_2NLi).⁸⁹⁷ This is in contrast to analogous methods **10-1**, **10-8**, **10-25**, and **10-26**. Primary alkyl, allylic, and benzylic bromides, iodides, and tosylates react with sodium bis(trimethylsilyl)amide to give derivatives that are easily hydrolyzed to produce amine salts in high overall yields.⁸⁹⁸ Primary arylamines are easily alkylated, but diaryl- and triaryl amines are very poor nucleophiles. However, the reaction has been carried out with diarylamines.⁸⁹⁹ Sulfates or sulfonates can be used instead of halides. *N*-Alkylation of heterocycles is sometimes problematic, but pyrrole is converted to *N*-methylpyrrole with KOH, iodomethane in ionic liquids.⁹⁰⁰

The reaction can be carried out intramolecularly to give cyclic amines, with three-, five-, and six-membered (but not four-membered) rings being easily prepared. Thus, 4-chloro-1-aminobutane treated with base gives pyrrolidine, and 2-chloroethylamine gives

aziridine⁹⁰¹ (analogous to Reaction 10-9):

Reduction of *N*-(3-bromopropyl) imines gives a bromoamine *in situ*, which cyclizes to the aziridine.⁹⁰² Five-membered ring amines (pyrrolidines) can be prepared from alkenyl amines via treatment with *N*-chlorosuccinimide (NCS) and then Bu₃SnH.⁹⁰³ The Pd catalyzed internal addition of amine to allylic acetates leads to cyclic products via a S_N2' reaction.⁹⁰⁴ Three-membered cyclic amines (aziridines) can be prepared from chiral conjugated amides via bromination and reaction with an amine.⁹⁰⁵ Four-membered cyclic amines (azetidines) have been prepared from the ditosylate of 1,3-propanediol⁹⁰⁶ and from 1,3-dichloropropane.⁹⁰⁷ This reaction was also used to close five-, six-, and seven-membered rings.

As usual, tertiary substrates do not give the reaction at all, but undergo preferential elimination upon treatment with a basic amine. However, tertiary (but not primary or secondary) halides (e.g., R₃CCl) can be converted to primary amines (R₃CNH₂) by treatment with NCl₃ and AlCl₃⁹⁰⁸ in a reaction related to Reaction 10-39. Ruthenium(II) complexes have been used for the alkylation of aryl amines.⁹⁰⁹

Primary amines can be prepared from alkyl halides by the use of hexamethylenetetramine⁹¹⁰ followed by cleavage of the resulting salt with ethanolic HCl. The method called the *Delépine reaction* is most successful for active halides (e.g., allylic and benzylic halides and α-halo ketones).

A convenient way of obtaining secondary amines without contamination by primary or tertiary amines involves treatment of alkyl halides with the sodium or calcium salt of cyanamide (NH₂—CN) to give disubstituted cyanamides, which are then hydrolyzed and decarboxylated to secondary amines. Good yields are obtained when the reaction is carried out under phase-transfer conditions.⁹¹¹ The R group may be primary, secondary, allylic, or benzylic. 1,ω-Dihalides give cyclic secondary amines. Aminoboranes react with sulfonate esters to give a derivative that can be hydrolyzed to a tertiary amine.⁹¹² An aminyl-radical

cyclization process was used to prepare cyclic amines.⁹¹³ *N*-Silylalkyl amines are formed from amines by reaction with halotrialkylsilanes and a suitable base.⁹¹⁴ Amines react directly with triarylsilanes in the presence of Yb catalysts.⁹¹⁵

Palladium compounds react with allylic halides, acetates, or carbonate derivatives to generate π -allyl Pd intermediates that react with amines to give an allylic amine (see the reaction below).⁹¹⁶ The same reaction is discussed in Reaction 10-60 with other nucleophiles. Propargylic amines can be prepared by similar methodology.⁹¹⁷ Boronic acid derivatives leads to methylation of aniline derivatives in the presence of cupric acetate.⁹¹⁸ *tert*-Butylamines can be prepared from isobutylene, HBr, and the amine by heating a sealed tube.⁹¹⁹

Phosphines behave similarly to amines, and compounds, such as R_3P and $\text{R}_4\text{P}^+ \text{X}^-$, can be prepared.⁹²⁰ The reaction between triphenylphosphine and quaternary salts of nitrogen heterocycles in an aprotic solvent is probably the best way of dealkylating the heterocycles, for example,⁹²¹

Other phosphorus compounds can be alkylated. Phosphinate esters, for example, react with a suitable base and then an alkyl halide to give the P-substituted product.⁹²²

10-32 Replacement of a Hydroxy or Alkoxy by an Amino Group

Amino-de-hydroxylation and Amino-de-alkoxylation

Alcohols can be converted to alkyl halides, which then react with amines (Reaction 10-43). Alcohols react with various amine reagents that give products convertible to the amine.⁹²³ The conversion $\text{ROH} \rightarrow \text{RNH}_2$ can be accomplished for primary and secondary alcohols by treatment with hydrazoic acid (HN_3), diisopropyl azodicarboxylate ($i\text{Pr}-\text{OOCN}=\text{NCOO}-i\text{Pr}$), and excess Ph_3P in THF, followed by water or aq acid.⁹²⁴ This is a type of *Mitsunobu Reaction* (see 10-17).⁹²⁵ Primary and secondary alcohols (ROH , but not methanol) can be converted to tertiary amines.⁹²⁶ Primary amines can be generated directly from primary alcohols and ammonia.⁹²⁷ Formation of $\text{R}'_2\text{NR}$ required treatment with the secondary amine ($\text{R}'_2\text{NH}$) with the $(t\text{-BuO})_3\text{Al}$ compound in the presence of Raney nickel.⁹²⁸

Allylic alcohols (ROH) react with amines in the presence of Pt^{929} or Pd^{930} complexes, to give allylic amines.⁹³¹ Amines can be *N*-alkylated by reaction with alcohols, in a sealed tube with microwave irradiation,⁹³² and also by Ru -,⁹³³ Ir -,⁹³⁴ or Au catalyzed⁹³⁵ reactions, or by Ti mediated⁹³⁶ reactions. Copper–aluminum hydrotalcite can also be used to generate amines from alcohols.⁹³⁷ The use of aniline gives secondary amines (PhNHR). Phenols can be converted to aniline derivatives.^{938,939} Heating indoles with benzylic alcohols in the presence of $\text{Me}_3\text{P}=\text{CH}(\text{CN})$ gives the *N*-benzylindole.⁹⁴⁰ Heating an alcohol on $\gamma\text{-Al}_2\text{O}_3$

leads to an amine,⁹⁴¹ as does treatment with the amine, SnCl₂, and Pd(PPh₃)₄.⁹⁴² The Ru catalyzed reaction of amines and diols leads to cyclic amines.⁹⁴³

β-Amino alcohols give aziridines (**120**) when treated with triphenylphosphine dibromide in the presence of triethylamine.⁹⁴⁴ The fact that inversion takes place at the OH carbon indicates that an S_N2 mechanism is involved, with OPPh₃ as the leaving group.

Alcohols can be converted to amines in an indirect manner.⁹⁴⁵ The alcohols are converted to alkylphosphonium perchlorates, which in DMF successfully *monoalkylate* not only secondary but also primary amines.⁹⁴⁶

Thus by this means secondary as well as tertiary amines, can be prepared in good yields. Benzylic alcohols can be converted to an azide and then treated with triphenylphosphine to give the amine (Reaction **19-50**).⁹⁴⁷

Cyanohydrins can be converted to amines by treatment with ammonia. The use of primary or secondary amines instead of ammonia leads to secondary and tertiary cyanoamines, respectively. It is more common to perform the conversion of an aldehyde or ketone directly to the cyanoamine without isolation of the cyanohydrin (see Reaction **16-52**). α-Hydroxy ketones (acyloins and benzoin)s behave similarly.⁹⁴⁸

A solution of the sodium salt of *N*-methylaniline in HMPA can be used to cleave the methyl group from aryl methyl ethers.⁹⁴⁹ ArOMe + PhNMe[−] → ArO[−] + PhNMe₂. This reagent also cleaves benzylic groups. In a similar reaction, methyl groups of aryl methyl ethers can be cleaved with lithium diphenylphosphide (Ph₂PLi).⁹⁵⁰ This reaction is specific for methyl ethers and can be carried out in the presence of ethyl ethers with

10-33 Transamination

Alkylamino-de-amination

Where the nucleophile is the conjugate base of a primary amine, NH_2 can be a leaving group. The method has been used to prepare secondary amines.⁹⁵² In another process, primary amines are converted to secondary amines in which both R groups are the same ($2 \text{RNH}_2 \rightarrow \text{R}_2\text{NH} + \text{NH}_3$)⁹⁵³ by refluxing in xylene in the presence of Raney nickel.⁹⁵⁴ Quaternary salts can be dealkylated with ethanolamine.⁹⁵⁵

In this reaction, methyl groups are cleaved in preference to other saturated alkyl groups. A similar reaction takes place between a *Mannich base* (see Reaction 16-19) and a secondary amine, where the mechanism is elimination–addition (see Sec. 10.F). Transamination has been accomplished using yeast alcohol dehydrogenase.⁹⁵⁶

See also, Reaction 19-5.

OS V, 1018.

10-34 Alkylation of Amines With Diazo Compounds

Hydro, dialkylamino-de-diazo-bisubstitution

The reaction of diazo compounds with amines is similar to Reaction 10-11.⁹⁵⁷ The acidity of amines is not great enough for the reaction to proceed without a catalyst, but BF_3 , which converts the amine to the $\text{F}_3\text{B}-\text{NHR}'_2$ complex, enables the reaction to take place. Cuprous cyanide can also be used as a catalyst.⁹⁵⁸ Ammonia has been used rather than an amine but, as in the case of Reaction 10-31, mixtures of primary, secondary, and tertiary amines are obtained. However, a highly chemoselective reaction of amines in water has been reported.⁹⁵⁹ Primary aliphatic amines give mixtures of secondary and tertiary amines. Secondary amines give successful alkylation. Primary aromatic amines also give the reaction, but diaryl or arylalkylamines react very poorly.

10-35 Reaction of Epoxides with Nitrogen Reagents⁹⁶⁰(3) *OC-seco-Amino-de-alkoxylation*

The reaction between epoxides and ammonia⁹⁶¹ (or ammonium hydroxide)⁹⁶² is a general and useful method for the preparation of β -hydroxyamines. With epoxides derived from terminal alkenes, the reaction with ammonia gives largely the primary amine, but secondary and tertiary amine products are possible from the appropriate epoxide. The reaction of **121** with ammonium hydroxide with microwave irradiation, for example,

gave **122**.⁹⁶³ Ethanolamines, which are useful solvents, as well as synthetic precursors, are prepared by this reaction. Similar ring-opening occurs with alkyl and aromatic amines.⁹⁶⁴ For another way of accomplishing this conversion, see Reaction 10-40. Ring opening has been accomplished with aniline on silica gel,⁹⁶⁵ and with aromatic amines in the presence of heteropoly acids in water.⁹⁶⁶

Primary and secondary amines give, respectively, secondary and tertiary amines (**121**). Aniline reacts with epoxides in the presence of aq β -cyclodextrin⁹⁶⁷ in 5 M LiClO₄ in ether,⁹⁶⁸ or in fluoro-alcohol solvents.⁹⁶⁹ Aniline reacts with epoxides in the presence of a VCl₃ catalyst⁹⁷⁰ or a Cu(II) catalyst.⁹⁷¹ *N*-Boc-amine (H₂N—CO₂*t*-Bu) reacted with epoxides in the presence of a cobalt–salen catalyst to give the amido alcohol.⁹⁷² Solvent-free reactions using a catalytic amount of SnCl₄ are known.⁹⁷³ Other metal-catalyzed

ring-opening reactions of epoxides with amines have been reported,⁹⁷⁴ often with high enantioselectivity.

Enantioselective ring-opening reactions typically use a metal catalyst in the presence of a chiral additive. Amines react with epoxides using a catalytic amount of a Nb complex, in the presence of a 1,1-bi-2-naphthol (BINOL) derivative, to give chiral amino alcohols.⁹⁷⁵ Other enantioselective ring-opening reactions include a V–salen-catalyzed reaction,⁹⁷⁶ and a Mg–BINOL complex.⁹⁷⁷

Tetrahydropyrimidones can be used to mediate the addition of indole to epoxides.⁹⁷⁸ Amide bases react differently with epoxides. Lithium 2,2,6,6-tetramethylpiperidide (LTMP), for example, reacted with epoxides, but the product was the corresponding enamine.⁹⁷⁹ This latter reaction follows a very different mechanism. Initial formation of the lithio-epoxide is followed by rearrangement to give the aldehyde,⁹⁸⁰ and subsequent reaction with the amine byproduct of the lithiation leads to the enamine.

An indirect method for generating an amino alcohol (**124**) is to open an epoxide with azide to give the azido-alcohol (**123**),⁹⁸¹ and subsequent reduction (Reaction **19-50**) gives the amine group.⁹⁸² The cerium ammonium nitrate catalyzed reaction of epoxides and sodium azide, for example, gave the azido alcohol with selectivity for the azide group on the more substituted position.⁹⁸³ Cerium chloride has also been used, giving the azide on the less substituted carbon.⁹⁸⁴ Under *Mitsunobu conditions* (Reaction **10-17**), epoxides are converted to 1,2-diazides with HN₃.⁹⁸⁵ The reaction of trimethylsilyl azide and an epoxide was reported using an ionic solvent.⁹⁸⁶ In the presence of AlCl₃ in water at pH 4, sodium azide reacts with epoxy acids to give the β -azido- α -hydroxycarboxylic acid.⁹⁸⁷ Silylazides can be used as well.⁹⁸⁸

Sodium nitrate (NaNO_2) reacts with epoxides in the presence of MgSO_4 to give the nitro alcohol.⁹⁸⁹ The nitro group can also be reduced to give the amine (Reaction **19-45**).⁹⁹⁰

Episulfides (thiiranes), which can be generated *in situ* in various ways, react similarly to give β -amino thiols,⁹⁹¹ and aziridines react with amines to give 1,2-diamines (Reaction **10-38**). Triphenylphosphine similarly reacts with epoxides to give an intermediate that undergoes elimination to give alkenes (see the *Wittig Reaction*, **16-44**).

OS X, 29. See OS VI, 652 for a related reaction.

10-36 Formation of Aziridines from Epoxides

Amino-de-alkoxylation

It is possible to prepare aziridines, which are synthetically important molecules, directly from the corresponding epoxide. Reaction of $\text{Ph}_3\text{P}=\text{NPh}$ with an epoxide in the presence of ZnCl_2 gives the *N*-phenyl aziridine.⁹⁹² Guanidines have also been used to prepare aziridines from epoxides.⁹⁹³ Tosylamines react with epoxides to give the *N*-tosylaziridine.⁹⁹⁴

Various methods are available to convert an aminomethyl epoxide to a hydroxymethyl aziridine (**125**).⁹⁹⁵

10-37 Amination of Oxetanes

(4)OC-homoseco-Amino-de-alkoxylation

Oxetanes are significantly less reactive with nucleophiles due to diminished ring strain. Under certain conditions, however, amines can open oxetanes to give amino alcohols. *tert*-Butyl amine reacts with oxetanes in the presence of $\text{Yb}(\text{OTf})_3$, for example, to give 3-hydroxy amines.⁹⁹⁶ Lithium tetrafluoroborate has also been used for this purpose.⁹⁹⁷

10-38 Reaction of Aziridines with Nitrogen

(3)NC-*seco*-Amino-de-aminoalkylation

Just as epoxides can be opened by amines to give hydroxy amines, aziridines can be opened to give diamines.⁹⁹⁸ With bicyclic aziridines, the major product is usually the *trans* diamine. *N*-Aryl or *N*-alkyl aziridines react with amines in the presence of T-Binolate,⁹⁹⁹ $\text{Sn}(\text{OTf})_2$ ¹⁰⁰⁰ or $\text{B}(\text{C}_6\text{F}_5)_3$ ¹⁰⁰¹ to give the diamine. Activated aziridines undergo regioselective ring opening with organoalanes.¹⁰⁰² Amines react with *N*-tosylaziridines, in the presence of various catalysts or additives to give the corresponding diamine derivative.¹⁰⁰³ This reaction also takes place on activated silica.¹⁰⁰⁴ The reaction of LiNTf_2 and an amine, in the presence of an *N*-alkyl aziridine gives the diamine.¹⁰⁰⁵

Tosyl-aziridines react with azide ion to generate azido tosylamines,¹⁰⁰⁶ and a clay-catalyzed variation¹⁰⁰⁷ has been reported. Reduction of the azide (Reaction 19-50) gives the diamine. Silylazides (e.g., Me_3SiN_3) also react with aziridine derivatives to give the azido-amine.¹⁰⁰⁸ This latter reaction can be catalyzed by InCl_3 .¹⁰⁰⁹

10-39 Amination of Alkanes

Amino-de-hydrogenation or Amination

Alkanes, arylalkanes, and cycloalkanes can be aminated, at tertiary positions only, by treatment with trichloroamine and aluminum chloride at 0–10 °C.¹⁰¹⁰ For example, *p*- $\text{MeC}_6\text{H}_4\text{CHMe}_2$ gives *p*- $\text{MeC}_6\text{H}_4\text{CMe}_2\text{NH}_2$, methylcyclopentane gives 1-amino-1-methylcyclopentane, and adamantane gives 1-aminoadamantane, all in good yields.

A Ag catalyzed reaction has also been reported.¹⁰¹¹ There are not many other methods for the preparation of *tert*-alkyl amines. The mechanism has been rationalized as an S_N1 process with H⁺ as the leaving group.¹⁰¹⁰

Note that under photochemical conditions, ammonia opens cyclopropane derivatives to give the corresponding alkyl amine.¹⁰¹² See also Reaction, **12-12**.

OS V, 35.

10-40 Formation of Isonitriles (Isocyanides)

Haloform-isonitrile transformation

There are several methods available for the preparation of isonitriles, otherwise known as isocyanides.¹⁰¹³ Reaction with chloroform under basic conditions is a common test for primary amines, both aliphatic and aromatic, since isonitriles (**126**) have very strong bad odors. The reaction probably proceeds by an S_N1cB mechanism with dichlorocarbene (**127**) as an intermediate.

Yields are generally not high,¹⁰¹⁴ but an improved procedure has been reported.¹⁰¹⁵ When secondary amines are involved, the adduct **128** cannot lose two molar equivalents of HCl. Instead it is hydrolyzed to an *N,N*-disubstituted formamide.¹⁰¹⁶

A completely different way of preparing isocyanides involves the reaction of epoxides or oxetanes with trimethylsilyl cyanide and zinc iodide to give the isocyanide **129**.¹⁰¹⁷

B. Attack by NHCOR

10-41 N-Alkylation or N-Arylation of Amides and Imides

Acylamino-de-halogenation

Amides are very weak nucleophiles,¹⁰¹⁸ far too weak to attack alkyl halides, so they first must be converted to their conjugate bases, the anion. By this method, unsubstituted amides can be converted to *N*-substituted, or *N*-substituted to *N,N*-disubstituted, amides.¹⁰¹⁹ Esters of sulfuric or sulfonic acids can also be substrates. Tertiary substrates give elimination and O-Alkylation is at times a side reaction.¹⁰²⁰ Both amides and sulfonamides have been alkylated under phase-transfer conditions.¹⁰²¹ Metal-catalyzed amidations are known, including an Ir(I) catalyzed allylic amidation.¹⁰²²

Lactams can be alkylated using similar procedures. Ethyl pyrrolidone (5-carboethoxy 2-pyrrolidinone) and related lactams were converted to *N*-alkyl derivatives via treatment with NaH (short contact time) followed by addition of the halide.¹⁰²³ Other 2-pyrrolidinone derivatives can be alkylated using a similar procedure.¹⁰²⁴ *N*-Cyclopropyl lactams are prepared using a Bi reagent in the presence of cupric acetate.¹⁰²⁵ *N*-Aryl lactams can be prepared using Ph₃Bi and Cu(OAc)₂.¹⁰²⁶ *N*-Arylation of sulfonamides has been reported using a Pd catalyst,¹⁰²⁷ and this method has been applied to an intramolecular arylation leading to bicyclic lactams.¹⁰²⁸

N-Alkenyl amides have been prepared from vinyl iodides and primary amides, using 10% CuI and two molar equivalents of cesium carbonate.¹⁰²⁹ A related Pd catalyzed vinylation of lactams was repeated using vinyl ethers as a substrate.¹⁰³⁰ Oxazolidin-2-ones (a cyclic carbamate) can be *N*-alkylated using an alkyl halide with KF/Al₂O₃.¹⁰³¹

The *Gabriel synthesis*¹⁰³² for converting halides to primary amines is based on this reaction. The halide is treated with potassium phthalimide and the resulting product hydrolyzed (Reaction 16-60)

It is obvious that the primary amines formed in this reaction will be uncontaminated by secondary or tertiary amines (unlike Reaction 10-31). The reaction is usually rather slow, but the rate can be conveniently increased by the use of a dipolar aprotic solvent (e.g., DMF)¹⁰³³ or with a crown ether.¹⁰³⁴ Hydrolysis of the phthalimide, whether acid or base catalyzed (acid catalysis is used far more frequently), is also usually very slow, and better procedures are generally used. A common one is the *Ing-Manske procedure*,¹⁰³⁵ in which the phthalimide is heated with hydrazine in an exchange reaction,¹⁰³⁶ but other methods have been introduced, using Na₂S in aq THF or acetone,¹⁰³⁷ and 40% aq methylamine.¹⁰³⁸ *N*-Aryl imides can be prepared from ArPb(OAc)₃ and NaH.¹⁰³⁹

An alternative to the Gabriel synthesis, in which alkyl halides can be converted to primary amines in good yields, involves treatment of the halide with the strong base guanidine followed by alkaline hydrolysis.¹⁰⁴⁰ There are several other alternative procedures.¹⁰⁴¹

N-Alkyl amides or imides can also be prepared starting from alcohols by treatment of the latter with equimolar amounts of the amide or imide (Ph₃P) and diethyl azodicarboxylate (EtO₂CN=NCO₂Et) at room temperature (the *Mitsunobu Reaction*, 10-17).¹⁰⁴² A related reaction treats an alcohol with ClCH=NMe₂⁺Cl⁻, followed by potassium phthalimide and treatment with hydrazine give the amine.¹⁰⁴³ Metal-catalyzed syntheses of amides via oxidative coupling of alcohols and amines are known. Variations include the use

of a Ru complex,¹⁰⁴⁴ a RuCl₃ catalyzed reaction,¹⁰⁴⁵ an FeCl₃ catalyzed reaction,¹⁰⁴⁶ an Ir complex catalyzed reaction,¹⁰⁴⁷ and an InCl₃ catalyzed coupling of alcohols with ToSMIC (ToSMIC = toluene sulfonyl methyl cyanide).¹⁰⁴⁸

Amides can also be alkylated with diazo compounds, as in Reaction 10-34. Salts of sulfonamides (ArSO₂NH[−]) can be used to attack alkyl halides to prepare *N*-alkyl sulfonamides (ArSO₂NHR) that can be further alkylated to ArSO₂NRR'. Hydrolysis of the latter is a good method for the preparation of secondary amines. Secondary amines can also be made by crown-ether assisted alkylation of F₃CCONHR (R = alkyl or aryl) and hydrolysis of the resulting F₃CCONRR'.¹⁰⁴⁹

The reaction of a primary amide and benzaldehyde, in the presence of a silane and trifluoroacetic acid, leads to the corresponding *N*-benzylamide.¹⁰⁵⁰ This transformation is a reductive alkylation (Reaction 16-17). *N*-Alkynyl amides have been prepared by the copper-catalyzed reaction of 1-bromoalkynes and secondary amides.¹⁰⁵¹ 1-Haloalkynes are typically prepared by base-induced elimination of 1,1-dihaloalkenes¹⁰⁵² or by direct halogenation of an alkyne with sodium or potassium hypohalite, prepared by reaction of the appropriate base with the halogen.¹⁰⁵³

Internal *N*-alkylation has been used to prepare the highly strained compounds α-lactams.¹⁰⁵⁴

Sodium nitrite can be used to prepare nitro compounds from primary or secondary alkyl bromides or iodides, but the method is of limited scope. Silver nitrite gives nitro compounds only when RX is a primary bromide or iodide.¹⁰⁵⁶ Nitrite esters are an important side product in all these cases (Reaction **10-22**) and become the major product (by an S_N1 mechanism) when secondary or tertiary halides are treated with silver nitrite. Alkyl nitro compounds can be prepared from the alkyl halide via the corresponding azide, by treatment with HOF in acetonitrile.¹⁰⁵⁷

Nitro compounds can be prepared from alcohols using NaNO₂/AcOH/HCl.¹⁰⁵⁸

OS I, 410; IV, 368, 454, 724.

10-43 Formation of Azides

Azido-de-halogenation

Alkyl azides can be prepared by treatment of the appropriate halide with azide ion.¹⁰⁵⁹ Phase-transfer catalysis,¹⁰⁶⁰ ultrasound,¹⁰⁶¹ and the use of reactive clays¹⁰⁶² are important variations. Substrates with leaving groups other than halogen have been used,¹⁰⁶³ including OMs (Ms = methanesulfonyl), OTs (Ts = tosyl),¹⁰⁶⁴ and OAc (Ac = acetyl).¹⁰⁶⁵ There are protocols for the conversion of alcohols to azides.¹⁰⁶⁶ Boronic acids are precursors to azides.¹⁰⁶⁷ Aryl azides are prepared from aryl amines by reaction with *t*-BuONO and moist NaN₃ in *t*-BuOH.¹⁰⁶⁸

Ring-opening reactions of epoxides with nitrogen nucleophiles were discussed in Reaction **10-35**. However, it is appropriate to discuss epoxide-opening reactions involving azides. Epoxides react with NaN₃ (**10-35**), under various conditions and media, including in ionic liquids.¹⁰⁶⁹ Other reagents include TMSN₃ (TMS = trimethylsilyl) and Ph₄SbOH¹⁰⁷⁰ or SmI₂¹⁰⁷¹ or (i-Bu)₂AlHN₃Li¹⁰⁷² to give β-azido alcohols; these are easily converted to aziridines (**131**).¹⁰⁷³

produced $\text{RN}(\text{NO}_2)\text{CN}$.¹⁰⁸⁸ When alkyl halides are treated with NCO^- in the presence of ethanol, carbamates can be prepared directly (see Reaction **16-8**).¹⁰⁸⁹ Acyl halides give the corresponding acyl isocyanates and isothiocyanates.¹⁰⁹⁰ For the formation of isocyanides (isonitriles), see Reaction **10-75**. Isonitriles, in the presence of sulfur and a Rh catalyst, are converted to isothiocyanate,¹⁰⁹¹ as are amines.¹⁰⁹²

OS **III**, 735.

10-45 Formation of Azoxy Compounds

Alkyl-*NNO*-azoxy-de-halogenation

The reaction between alkyl halides and alkanediazotates (**132**) gives azoxyalkanes.¹⁰⁹³ The R and R' groups may be the same or different, but neither may be aryl or tertiary alkyl. The reaction is regioselective; only the isomer shown is obtained.

10.H.v. Halogen Nucleophiles¹⁰⁹⁴

10-46 Halide Exchange

Halo-de-halogenation

Halide exchange, sometimes call the *Finkelstein reaction*, is an equilibrium process, but it is often possible to shift the equilibrium.¹⁰⁹⁵ The reaction is most often applied to the preparation of iodides and fluorides. Iodides can be prepared from chlorides or bromides by taking advantage of the fact that sodium iodide, but not the bromide or chloride, is soluble in acetone. When an alkyl chloride or bromide is treated with a solution of sodium iodide in acetone, the equilibrium is shifted by the precipitation of sodium chloride or bromide. Since the mechanism is $\text{S}_{\text{N}}2$, the reaction is much more successful for primary halides than for secondary or tertiary halides; sodium iodide in acetone can be used as a test for primary bromides or chlorides. Tertiary chlorides can be converted to iodides by treatment with excess NaI in CS_2 , and ZnCl_2 as catalyst.¹⁰⁹⁶ Vinylic bromides give vinylic iodides with

retention of configuration when treated with KI and a nickel bromide-zinc catalyst,¹⁰⁹⁷ or with KI and CuI in hot HMPA.¹⁰⁹⁸

Fluorides¹⁰⁹⁹ are prepared by treatment of other alkyl halides with any of a number of fluorinating agents,¹¹⁰⁰ among them anhydrous HF (which is useful only for reactive substrates, e.g., benzylic or allylic), AgF, KF,¹¹⁰¹ HgF₂, Et₃N·2HF,¹¹⁰² 4-Me—C₆H₄IF₂,¹¹⁰³ and Me₃SiF₂Ph⁺—NBu₄.¹¹⁰⁴ The Pd catalyzed conversion of chlorides to fluorides has also been reported.¹¹⁰⁵ The equilibria in these cases are shifted because the alkyl fluoride once formed has little tendency to react, owing to the extremely poor leaving-group ability of fluorine. Phase-transfer catalysis of the exchange reaction is a particularly effective way of preparing both fluorides and iodides.¹¹⁰⁶

Primary alkyl chlorides can be converted to bromides with ethyl bromide, *N*-methyl-2-pyrrolidinone and a catalytic amount of NaBr,¹¹⁰⁷ with LiBr under phase-transfer conditions,¹¹⁰⁸ and with Bu₄N⁺ Br[−].¹¹⁰⁹ Primary bromides were converted to chlorides with TMSCl/imidazole in hot DMF.¹¹¹⁰ For secondary and tertiary alkyl chlorides, treatment with excess gaseous HBr and an anhydrous FeBr₃ catalyst in CH₂Cl₂ has given high yields¹¹¹¹ (this procedure is also successful for chloride-to-iodide conversions). Alkyl chlorides or bromides can be prepared from iodides by treatment with HCl or HBr in the presence of HNO₃, making use of the fact that the leaving I[−] is oxidized to I₂ by the HNO₃.¹¹¹² Primary iodides give the chlorides when treated with PCl₅ in POCl₃.¹¹¹³ Primary alkyl halides are converted to the corresponding fluoride with tetrabutylammonium fluoride in *tert*-butanol.¹¹¹⁴ Alkyl fluorides and chlorides are converted to the bromides and iodides (and alkyl fluorides to the chlorides) by heating with the corresponding HX in excess amounts.¹¹¹⁵

10-47 Formation of Alkyl Halides from Esters of Sulfuric and Sulfonic Acids**Halo-de-sulfonyloxy-substitution**, and so on

Alkyl sulfates, tosylates, and other esters of sulfuric and sulfonic acids can be converted to alkyl halides with any of the four halide ions.¹¹¹⁶ Neopentyl tosylate, for example, reacts with Cl^- , Br^- , or I^- without rearrangement in HMPA.¹¹¹⁷ Similarly, allylic tosylates can be converted to chlorides without allylic rearrangement by reaction with LiCl in the same solvent.¹¹¹⁸ Inorganic esters are intermediates in the conversion of alcohols to alkyl halides with SOCl_2 , PCl_5 , PCl_3 , and so on (Reaction **10-48**), but those esters are seldom isolated.

OS **I**, 25; **II**, 111, 404; **IV**, 597, 753; **V**, 545.

10-48 Formation of Alkyl Halides from Alcohols**Halo-de-hydroxylation**

Alcohols can be converted to alkyl halides with several reagents,¹¹¹⁹ the most common of which are halogen acids (HX) and inorganic acid halides, (e.g., SOCl_2 ,¹¹²⁰ PCl_5 , PCl_3 , and POCl_3).¹¹²¹ When the reagent is HX, the mechanism is $\text{S}_{\text{N}}1\text{cA}$ or $\text{S}_{\text{N}}2\text{cA}$; that is, the leaving group is not $^- \text{OH}$, but OH_2 (Sec. 10.G.iii). The leaving group is not $^- \text{OH}$ with the other reagents either, since in these cases the alcohol is first converted to an inorganic ester (e.g., ROSOCl) with SOCl_2 (Reaction **10-22**). The leaving group is therefore $^- \text{OSOCl}$ or a similar group (Reaction **10-47**). These may react by the $\text{S}_{\text{N}}1$ or $\text{S}_{\text{N}}2$ mechanism and, in the case of ROSOCl , by the $\text{S}_{\text{N}}\text{i}$ mechanism¹¹²² (Sec. 10.D).

The reagent HBr is usually used for alkyl bromides¹¹²³ and HI for alkyl iodides. These reagents are often generated *in situ* from the halide ion and an acid (e.g., phosphoric or sulfuric). The use of HI sometimes results in reduction of the alkyl iodide to the alkane (Reaction **19-53**) and, if the substrate is unsaturated, can also reduce the double bond.¹¹²⁴ The reaction can be used to prepare primary, secondary, or tertiary halides, but alcohols of the isobutyl or neopentyl type often give large amounts of rearrangement products.¹¹²⁵ Tertiary chlorides are easily made with concentrated HCl, but primary and secondary

alcohols react with HCl so slowly that a catalyst, usually zinc chloride, is required.¹¹²⁶ Primary alcohols give good yields of chlorides upon treatment with HCl in HMPA.¹¹²⁷

The inorganic acid chlorides (SOCl₂,¹¹²⁸ PCl₃, etc.) give primary, secondary, or tertiary alkyl chlorides with much less rearrangement than is observed with HCl. Inorganic bromides and iodides, especially PBr₃, have also been used, but they are more expensive and used less often than HBr or HI, although some of them may also be generated *in situ* (e.g., PBr₃ from phosphorous and bromine). Secondary alcohols always give *some* rearranged bromides if another secondary position is available, even with PBr₃, PBr₅, or SOBr₂; thus 3-pentanol gives both 2- and 3-bromopentane. Such rearrangement can be avoided by converting the alcohol to a sulfonate and then using Reaction 10-47,¹¹²⁹ or by the use of phase-transfer catalysis.¹¹³⁰ Tertiary alcohols can be converted to the bromide with BBr₃ at 0 °C.¹¹³¹ Iodides have been prepared by simply heating the alcohol with iodine.¹¹³² Trichloroisocyanuric acid (1,3,5-trichlorohexahydrotriazin-2,4,6-trione) and triphenylphosphine converts primary alcohols to the corresponding chloride.¹¹³³ Pivaloyl chloride–DMF has been used to convert alcohols to chlorides.¹¹³⁴ Sodium iodide and Amberlyst-15¹¹³⁵ or tosic acid and KI with microwave irradiation¹¹³⁶ converts primary alcohols to the iodide.

The preparation of alkyl fluorides can be problematic, and specialized reagents are usually required. Hydrogen fluoride does not generally convert alcohols to alkyl fluorides.¹¹³⁷ The most important reagent for this purpose is the commercially available diethylaminosulfur trifluoride (Et₂NSF₃, DAST),¹¹³⁸ which converts primary, secondary, tertiary, allylic, and benzylic alcohols to fluorides in high yields under mild conditions.¹¹³⁹ Fluorides have also been prepared from alcohols by treatment with nonaflyl fluoride,¹¹⁴⁰ tetrabutylammonium difluoride,¹¹⁴¹ CsI/BF₃,¹¹⁴² TMSI/ZnCl₂,¹¹⁴³ and indirectly, by conversion to a sulfate or tosylate, and so on (Reaction 10-47). A mixture of IF₅, NEt₃, and excess KF¹¹⁴⁴ or (Cl₃CO)₂C=O [bis(trichloromethyl)carbonate] and KF (which gives COF₂ *in situ*) with 18-crown-6¹¹⁴⁵ also converts primary alcohols to primary fluorides.

Primary, secondary, and tertiary alcohols can be converted to any of the four halides by treatment with the appropriate NaX, KX, or NH₄X in polyhydrogen fluoride–pyridine solution.¹¹⁴⁶ This method is even successful for neopentyl halides. Ionic liquids can be used for halogenation, and bmim-Cl (1-*n*-butyl-3-methylimidazolium chloride) generates the chloride directly from the alcohol without any additional reagent.¹¹⁴⁷ Triphenylphosphine and iodine will convert alcohols to iodides in ionic liquids, under solvent-free conditions.¹¹⁴⁸ *tert*-Butyl halides halogenate alcohols in the ionic liquid [pmim]Br with sonication.¹¹⁴⁹

Other reagents¹¹⁵⁰ have also been used, including ZrCl₄/NaI,¹¹⁵¹ Me₃SiCl and BiCl₃,¹¹⁵² or Me₃SiCl and InCl₃¹¹⁵³ or GaCl₃–tartrate,¹¹⁵⁴ or simply Me₃SiCl in DMSO.¹¹⁵⁵ 1,2-Dipyridiniumdibromide ethane is an efficient brominating agent, and simply grinding the reagent and an alcohol in a porcelain mortar at room temperature with no solvent gives the product.¹¹⁵⁶ Other specialized reagents include (RO)₃PRX¹¹⁵⁷ and R₃PX₂¹¹⁵⁸, which give good yields for primary (including neopentyl), secondary, and tertiary halides without rearrangements.¹¹⁵⁹ Similarly, a mixture of PPh₃ and CCl₄¹¹⁶⁰ (or CBr₄¹¹⁶¹) give good results, and PPh₃/Cl₃CCONH₂ is an efficient chlorinating reagent.¹¹⁶² The compound PPh₃—CCl₃CN converts neopentyl alcohol to neopentyl chloride, in 95% yield.¹¹⁶³

The $\text{PPh}_3\text{—CCl}_4$ or CBr_4 method converts allylic alcohols¹¹⁶⁴ to the corresponding halides without allylic rearrangements,¹¹⁶⁵ and also cyclopropylcarbinyl alcohols to the halides without ring opening.¹¹⁶⁶ A mixture of triphenylphosphine and iodine converts alcohols to iodides under solvent-free conditions, using microwave irradiation.¹¹⁶⁷ Hexabromoacetone–ethyltribromoacetate is an efficient brominating reagent.¹¹⁶⁸ *N*-Bromosaccharin and *N*-iodosaccharin in the presence of PPh_3 gives the corresponding bromide or iodide.¹¹⁶⁹

Allylic and benzylic alcohols can also be converted to bromides or iodides with NaX—BF_3 etherate,¹¹⁷⁰ and to iodides with AlI_3 .¹¹⁷¹ A mixture of methanesulfonic acid and NaI also converts benzylic alcohols to benzylic iodides.¹¹⁷² Allylic alcohols are converted to allylic halides in a procedure that uses acetyl halides, but the reaction proceeds with allylic rearrangement.¹¹⁷³ A simple method that is specific for benzylic and allylic alcohols (and does not give allylic rearrangement) involves reaction with NCS or NBS and methyl sulfide.¹¹⁷⁴ A mixture of NBS, $\text{Cu}(\text{OTf})_2$, and diisopropylcarbodiimide converted primary alcohols to the corresponding bromide.¹¹⁷⁵ The use of NCS gave the chloride and *N*-iodosuccinimide (NIS) gave the iodide under identical conditions. Thiols are converted to alkyl bromides by a similar procedure using PPh_3 and NBS.¹¹⁷⁶

Trialkylsilyl ethers (e.g., ROSiMe_3) are converted to the corresponding iodide with $\text{SiO}_2\text{—Cl/NaI}$.¹¹⁷⁷ Hydroxy ketones are converted to the iodide with iodine and iodic acid.¹¹⁷⁸ Propargylic fluorides can be prepared from allenylsilanes by treatment with Selectfluor.¹¹⁷⁹

10-49 Formation of Alkyl Halides from Ethers**Halo-de-alkoxylation**

Ethers can be cleaved by heating with concentrated HI or HBr.¹¹⁸⁰ Hydrogen chloride is seldom successful,¹¹⁸¹ and HBr reacts more slowly than HI, but is often a superior reagent, since it causes fewer side reactions. Phase-transfer catalysis has also been used,¹¹⁸² and 47% HBr in ionic liquids has proven effective.¹¹⁸³ Dialkyl ethers and alkyl aryl ethers can be cleaved. In the latter case, the alkyl–oxygen bond is the one broken. As in Reaction **10-48**, the actual leaving group is not OR'^- , but $^-\text{OHR}'$. Although alkyl aryl ethers always cleave so as to give an alkyl halide and a phenol, there is no general rule for dialkyl ethers. Often cleavage occurs from both sides, and a mixture of two alcohols and two alkyl halides is obtained. However, methyl ethers are usually cleaved so that methyl iodide or bromide is a product. An excess of HI or HBr converts the alcohol product into alkyl halide, so that dialkyl ethers (but not alkyl aryl ethers) are converted to 2 equiv of alkyl halide. This procedure is often carried out so that a mixture of only two products is obtained instead of four.

O-Benzyl ethers are readily cleaved to the alcohol and the hydrocarbon via hydrogenolysis, and the most common methods are hydrogenation¹¹⁸⁴ or dissolving metal conditions (Na or K in ammonia).¹¹⁸⁵ Heating in anisole with 3% $\text{Sc}(\text{NTf}_2)_3$ ¹¹⁸⁶ or with In metal in aq ethanol¹¹⁸⁷ also cleaves benzyl ethers. Isoprenyl alkyl ethers are cleaved using iodine in dichloromethane,¹¹⁸⁸ and allyl alkyl ethers are cleaved with Lewis acids under various conditions.¹¹⁸⁹ The $\text{OCH}_2\text{CH}=\text{CHPh}$ unit of mixed allyl ethers ($\text{O}-\text{CH}_2\text{CH}=\text{CH}_2$ and $\text{OCH}_2\text{CH}=\text{CHPh}$) can be cleaved selectively under electrolytic conditions.¹¹⁹⁰

Cyclic ethers (usually THF derivatives) can be similarly cleaved (see Reaction **10-50** for epoxides). Treatment of 2-methyltetrahydrofuran with acetyl chloride and ZnCl_2 gave primarily *O*-acetyl-4-chloro-1-pentanol.¹¹⁹¹ A mixture of $\text{Et}_2\text{NSiMe}_3/2 \text{ MeI}$ cleaved THF to give the *O*-trimethylsilyl ether of 4-iodo-1-butanol.¹¹⁹² Ethers have also been cleaved

with Lewis acids [e.g., BF_3 , $\text{Ce}(\text{OTf})_4$,¹¹⁹³ $\text{SiCl}_4/\text{LiI}/\text{BF}_3$,¹¹⁹⁴ BBr_3 ,¹¹⁹⁵ or AlCl_3].¹¹⁹⁶ In such cases, the departure of the OR is assisted by complex formation with the Lewis acid (see **133**). The reagent $\text{NaI}-\text{BF}_3$ etherate selectively cleaves ethers in the order benzylic ethers > alkyl methyl ethers > aryl methyl ethers.¹¹⁹⁷

Dialkyl and alkyl aryl ethers are cleaved with Me_3SiI ¹¹⁹⁸: $\text{ROR}' + \text{Me}_3\text{SiI} \rightarrow \text{RI} + \text{Me}_3\text{SiOR}$.¹¹⁹⁹ A more convenient and less expensive alternative, which gives the same products, is a mixture of chlorotrimethylsilane and NaI .¹²⁰⁰ Triphenyldibromophosphorane (Ph_3PBr_2) cleaves dialkyl ethers to give 2 molar equivalents of alkyl bromide.¹²⁰¹ Alkyl aryl ethers can also be cleaved with LiI to give alkyl iodides and salts of phenols¹²⁰² in a reaction similar to Reaction **10-51**. Allyl aryl ethers¹²⁰³ are efficiently cleaved with $\text{NaI}/\text{Me}_3\text{SiCl}$,¹²⁰⁴ or NbCl_5 .¹²⁰⁵ Aryl benzyl ethers are cleaved with BCl_3 using pentamethylbenzene as a non-Lewis basic cation scavenger.¹²⁰⁶ Cleavage in ionic liquids is also known.¹²⁰⁷

A closely related reaction is cleavage of oxonium salts.

For these substrates, HX is not required, and X can be any of the four halide ions.

tert-Butyldimethylsilyl ethers ($\text{ROSiMe}_2\text{CMe}_3$) can be converted to bromides (RBr) by treatment with Ph_3PBr_2 ,¹²⁰⁸ $\text{Ph}_3\text{P}-\text{CBr}_4$,¹²⁰⁹ BBr_3 ,¹²¹⁰ and CuBr_2 .¹²¹¹ Alcohols are often protected by conversion to this kind of silyl ether.¹²¹²

10-50 Formation of Halohydrins from Epoxides

(3) *OC-seco-Halo-de-alkoxylation*

This is a special case of Reaction **10-49** and is frequently used for the preparation of halohydrins.¹²¹³ In contrast to the situation with open-chain ethers and with larger rings, many epoxides react with all four hydrohalic acids, although with HF¹²¹⁴ the reaction is unsuccessful with simple aliphatic and cycloalkyl epoxides.¹²¹⁵ Hydrogen fluoride does react with more rigid epoxides, such as those in steroid systems. The reaction can be applied to simple epoxides¹²¹⁶ if polyhydrogen fluoride–pyridine is the reagent. The reagent $\text{NEt}_3 \cdot 3\text{HF}$ converts epoxides to fluorohydrins with microwave irradiation.¹²¹⁷ Organocatalysts have been used to convert epoxides to fluorohydrins using an acetyl fluoride/fluorous alcohol combination.¹²¹⁸ Chloro-, bromo-, and iodohydrins can also be prepared¹²¹⁹ by treating epoxides with Ph_3P and X_2 ,¹²²⁰ with $3/\text{NaBr}/\text{H}_2\text{O}$,¹²²¹ LiBr on Amberlyst-15 resin,¹²²² ceric ammonium nitrate/ KBr ,¹²²³ I_2 with a SmI_2 catalyst,¹²²⁴ and LiI on silica gel.¹²²⁵ Epoxides can be converted directly to 1,2-dichloro compounds by treatment with SOCl_2 and pyridine,¹²²⁶ or with Ph_3P and CCl_4 .¹²²⁷ These are two-step reactions: a halohydrin is formed first and is then converted by the reagents to the dihalide (Reaction **10-48**). As expected, inversion is found at both carbons. Meso epoxides were cleaved enantioselectively with the chiral B-halodiisopinocampheylboranes (see Reaction **15-16**), where the halogen was Cl, Br, or I.¹²²⁸ Diatomic iodine gives an iodohydrin with a 2,6-bis[2-(*o*-aminophenoxy)methyl]-4-bromo-1-methoxybenzene catalyst.¹²²⁹

Epoxides are converted to the corresponding chlorohydrin upon treatment with the ionic liquid [AcMIm]Cl.¹²³⁰

Bicyclic epoxides are usually opened to the *trans*-halohydrin. Unsymmetrical epoxides are usually opened to give mixtures of regioisomers. In a typical reaction, the halogen is delivered to the less sterically hindered carbon of the epoxide. In the absence of this structural feature, and in the absence of a directing group, relatively equal mixtures of regioisomeric halohydrins are expected. The phenyl is such a group, and in 1-phenyl-2-alkyl epoxides reaction with POCl₃/DMAP (DMAP = 4-dimethylaminopyridine) leads to the chlorohydrin with the chlorine on the carbon bearing the phenyl.¹²³¹ When done in an ionic liquid with Me₃SiCl, styrene epoxide gives 2-chloro-2-phenylethanol.¹²³² The reaction of thionyl chloride and poly(vinylpyrrolidinone) converts epoxides to the corresponding 2-chloro-1-carbinol.¹²³³ Bromine with a phenylhydrazine catalyst, however, converts epoxides to the 1-bromo-2-carbinol.¹²³⁴ An alkenyl group also leads to a halohydrin with the halogen on the carbon bearing the C=C unit.¹²³⁵ Epoxy carboxylic acids are another example. When NaI reacts at pH 4, the major regioisomer is the 2-iodo-3-hydroxy compound, but when InCl₃ is added, the major product is the 3-iodo-2-hydroxy carboxylic acid.¹²³⁶

Acyl chlorides react with ethylene oxide in the presence of NaI to give 2-iodoethyl esters.¹²³⁷

Acyl chlorides react with epoxides in the presence of a Eu(dpm)₃ catalyst¹²³⁸ [dpm = 1,1-bis(diphenylphosphino)methane] or a YCp₂Cl catalyst¹²³⁹ to give chloro esters.

A related reaction with episulfides leads to 2-chlorothio-esters.¹²⁴⁰ Aziridines have been opened with PPh₃ and halogenating agents,¹²⁴¹ and also by MgBr₂ to give 2-haloamides in a related reaction.¹²⁴² *N*-Tosyl aziridines react with KF•2 H₂O to give the 2-fluoro tosylamine product.¹²⁴³ Aziridinium salts are opened by bromide ion.¹²⁴⁴

10-51 Cleavage of Carboxylic Esters with Lithium Iodide**Iodo-de-acyloxy-substitution**

Carboxylic esters, where R is methyl or ethyl, can be cleaved by heating with lithium iodide in refluxing pyridine or a higher-boiling amine.¹²⁴⁵ The reaction is useful where a molecule is sensitive to acid and base (so that Reaction 16-59 cannot be used) or where it is desired to cleave selectively only one ester group in a molecule containing two or more. For example, refluxing *O*-acetyloleanolic acid methyl ester with LiI in *s*-collidine

cleaved only the 17-carbomethoxy group, not the 3-acetyl group.¹²⁴⁶ Esters ($\text{RCO}_2\text{R}'$) and lactones can also be cleaved with a mixture of Me_3SiCl and NaI to give $\text{R}'\text{I}$ and RCO_2H .¹²⁴⁷ The reaction of acetyl chloride and an allylic acetate leads to the allylic chloride.¹²⁴⁸

10-52 Conversion of Diazo Ketones to α -halo Ketones**Hydro, halo-de-diazo bisubstitution**

When diazo ketones are treated with HBr or HCl , they give the respective α -halo ketones. Hydrogeniodide does not give the reaction, since it reduces the product to a methyl ketone (Reaction 19-67). α -Fluoro ketones can be prepared by addition of the diazo ketone to polyhydrogen fluoride–pyridine.¹²⁴⁹ This method is also successful for diazoalkanes.

Diazotization of α -amino acids in the above solvent at room temperature gives α -fluoro carboxylic acids.¹²⁵⁰ If this reaction is run in the presence of excess KCl or KBr , the corresponding α -chloro or α -bromo acid is obtained instead.¹²⁵¹

10-53 Conversion of Amines to Halides

Halo-de-amination

Primary alkyl amines (RNH_2) can be converted¹²⁵² to alkyl halides by (1) conversion to RNTs_2 (Sec. 10.G.ii) and treatment of this with I^- or Br^- in DMF,⁴¹⁵ or to $\text{N}(\text{Ts})-\text{NH}_2$ derivatives followed by treatment with NBS under photolysis conditions,¹²⁵³ (2) diazotization with *tert*-butylnitrite and a metal halide (e.g., TiCl_4 in DMF),¹²⁵⁴ or (3) the *Katritzky pyrylium-pyridinium method* (Sec. 10.G.ii).¹²⁵⁵ Alkyl groups can be cleaved from secondary and tertiary aromatic amines by concentrated HBr in a reaction similar to Reaction 10-49, for example,¹²⁵⁶

Tertiary aliphatic amines are also cleaved by HI , but useful products are seldom obtained. Tertiary amines can be cleaved by reaction with phenyl chloroformate¹²⁵⁷: $\text{R}_3\text{N} + \text{ClCOOPh} \rightarrow \text{RCI} + \text{R}_2\text{NCOOPh}$. α -Chloroethyl chloroformate behaves similarly.¹²⁵⁸ Alkyl halides may be formed when quaternary ammonium salts are heated: $\text{R}_4\text{N}^+ \text{X}^- \rightarrow \text{R}_3\text{N} + \text{RX}$.¹²⁵⁹

10-54 Conversion of Tertiary Amines to Cyanamides: The von Braun Reaction

Bromo-de-dialkylamino substitution

The *von Braun reaction* involves the cleavage of tertiary amines by cyanogen bromide to give an alkyl bromide and a disubstituted cyanamide, and can be applied to many tertiary amines.¹²⁶⁰ Usually, the R group that cleaves is the one that gives the most reactive halide (e.g., benzyl or allyl). For simple alkyl groups, the smallest are the most readily cleaved. One or two of the groups on the amine may be aryl, but they do not cleave. Cyclic amines have been frequently cleaved by this reaction. Secondary amines also give the reaction, but the results are usually poor.¹²⁶¹

The mechanism consists of two successive nucleophilic substitutions, with the tertiary amine as the first nucleophile and the liberated bromide ion as the second:

The intermediate *N*-cyanoammonium bromide has been trapped, and its structure confirmed by chemical, analytical, and spectral data.¹²⁶² The BrCN in this reaction has been called a *counterattack reagent*; that is, a reagent that accomplishes, in one flask, two transformations designed to give the product.¹²⁶³

OS III, 608.

10.H.vi. Carbon Nucleophiles

In any heterolytic reaction in which a new carbon–carbon bond is formed,¹²⁶⁴ one carbon atom attacks as a nucleophile and the other as an electrophile. The classification of a given reaction as nucleophilic or electrophilic is a matter of convention and is usually based on analogy. Although not discussed in this chapter, Reactions **11-8–11-25** and **12-16–12-21** are nucleophilic substitutions with respect to one reactant, but following convention, we classify them with respect to the other. Similarly, all the reactions in this section would be called electrophilic substitution (aromatic or aliphatic) if we were to consider the reagent as the substrate.

In Reactions **10-56–10-65**, the nucleophile is a “carbanion” part of an organometallic compound, often a *Grignard reagent*. There is much that is still not known about the mechanisms of these reactions and many of them are not nucleophilic substitutions at all. In those reactions that are nucleophilic substitutions, the attacking carbon brings a pair of electrons with it to the new C—C bond, whether or not free carbanions are actually involved. The connection of two alkyl or aryl groups is called *coupling*. Reactions **10-56–10-65** include both symmetrical and unsymmetrical coupling reactions. The latter are also called *cross-coupling reactions*. Other coupling reactions are considered in later chapters.

10-55 Coupling with Silanes

De-silylalkyl-coupling

Organosilanes (RSiMe₃ or RSiMe₂F, where R can be vinylic, allylic, or alkynyl) couple with vinylic, allylic, and aryl bromides and iodides (R'X), in the presence of certain catalysts, to give RR' in good yields.¹²⁶⁵ Allylsilanes react with allylic acetates in the presence of iodine.¹²⁶⁶ The transition metal catalyzed coupling of silanes, particularly allyl

10-56 Coupling of Alkyl Halides: The Wurtz Reaction

De-halogen-coupling

The coupling of alkyl halides by treatment with sodium to give a symmetrical product is called the *Wurtz reaction*. Side reactions (elimination and rearrangement) are so common that the reaction is seldom used. Mixed Wurtz reactions of two alkyl halides are even less feasible because of the number of products obtained. A somewhat more useful reaction (but still not very good) takes place when a mixture of an alkyl and an aryl halide is treated with sodium to give an alkylated aromatic compound (the *Wurtz–Fittig reaction*).¹²⁸⁸ However, the coupling of two aryl halides with sodium is impractical (but see Reaction 13-11). Other metals have also been used to effect *Wurtz reactions*,¹²⁸⁹ notably Ag, Zn,¹²⁹⁰ Fe,¹²⁹¹ activated Cu,¹²⁹² In,¹²⁹³ La,¹²⁹⁴ and Mn compounds.¹²⁹⁵ Lithium, under the influence of ultrasound, has been used to couple alkyl, aryl, and benzylic halides.¹²⁹⁶

In a related reaction, *Grignard reagents* (Reaction 12-38) have been coupled in the presence of trifluorosulfonic anhydride.¹²⁹⁷ Tosylates and other sulfonates and sulfates couple with *Grignard reagents*,¹²⁹⁸ most often those prepared from aryl or benzylic halides.¹²⁹⁹ Alkyl sulfates and sulfonates generally make better substrates in reactions with *Grignard reagents* than the corresponding halides (Reaction 10-57). The method is useful for primary and secondary R.

One type of *Wurtz reaction* that is quite useful is the closing of small rings, especially three-membered rings.¹³⁰⁰ For example, 1,3-dibromopropane can be converted to cyclopropane by Zn and NaI.¹³⁰¹ Two highly strained molecules prepared this way are bicyclobutane¹³⁰² and tetracyclo[3.3.1.1^{3,7}.0^{1,3}]decane.¹³⁰³ Three- and four-membered rings can also be closed in this manner with certain other reagents,¹³⁰⁴ including benzoyl peroxide,¹³⁰⁵ *t*-BuLi,¹³⁰⁶ and lithium amalgam,¹³⁰⁷ as well as electrochemically.¹³⁰⁸ The Pd or Ni catalyzed cross-coupling reaction of a *Grignard reagent* and an alkyl halide, is often called *Kumada coupling*.¹³⁰⁹

Vinyl halides can be coupled to give 1,3-butadienes (**134**) by treatment with activated Cu powder in a reaction analogous to the *Ullmann Reaction* (**13-11**).¹³¹⁰ This reaction is stereospecific, with retention of configuration at both carbons. Vinyl halides can also be coupled¹³¹¹ with Zn—NiCl₂,¹³¹² and with *n*-BuLi in ether in the presence of MnCl₂.¹³¹³ The coupling reaction with vinyltin reagents and vinyl halides occurs with a Pd catalyst.¹³¹⁴

It seems likely that the mechanism of the *Wurtz reaction* consists of two basic steps. The first is halogen-metal exchange to give an organometallic compound (RX + M → RM), which in many cases can be isolated (Reaction **12-38**). Following this, the organometallic compound reacts with a second molecule of alkyl halide (RX + RM → RR). This reaction and its mechanism are considered in Section (Reaction **10-57**).

A variation of the *Wurtz coupling* uses other metals to mediate or facilitate the coupling. In certain cases, such variations can be synthetically useful. Because of the presence of the 1,5-diene moiety in many naturally occurring compounds, methods that couple¹³¹⁵ allylic groups¹³¹⁶ are quite important. In one of these methods, allylic halides, tosylates, and acetates can be symmetrically coupled by treatment with nickel carbonyl¹³¹⁷ to give 1,5-dienes.¹³¹⁸ The order of halide reactivity is $I > Br > Cl$. With unsymmetrical allylic substrates, coupling nearly always takes place at the less-substituted end.

The reaction can be performed intramolecularly; large (11–20-membered) rings can be made in good yields (60–80%) by the use of high dilution.¹³¹⁹ The mechanism of coupling likely involves reaction of the allylic compound with Ni(CO)_4 to give one or more π -allyl complexes, one of which may be the η^3 -complex **135**. Loss of CO to give a π -allylnickel bromide (**136**) and ligand transfer leads to coupling and the final product. In some cases, the η^3 -complexes (**136**) can be isolated from the solution and crystallized as stable solids.

Unsymmetrical coupling can be achieved by treating an alkyl halide directly with **136**, in a polar aprotic solvent,¹³²⁰ and coupling occurs at the less substituted end. There is evidence that free radicals are involved in such couplings.¹³²¹ Hydroxy or carbonyl groups in the alkyl halide do not interfere. When **136** reacts with an allylic halide, a mixture of three products is obtained because of halogen–metal interchange. For example, allyl bromide treated with **136** prepared from methallyl bromide gave an approximately statistical mixture of 1,5-hexadiene, 2-methyl-1,5-hexadiene, and 2,5-dimethyl-1,5-hexadiene.¹³²² A symmetrical coupling of allylic tosylates used Ni(CO)_4 .

Symmetrical coupling of allylic halides occurs by heating with magnesium in ether.¹³²³ The coupling of two different allylic groups has been achieved by treatment of an allylic bromide with an allylic *Grignard reagent* in THF containing HMPA,¹³²⁴ or with an allylic tin reagent.¹³²⁵ This type of coupling can be achieved with almost no allylic rearrangement in the substrate (and almost complete allylic rearrangement in the reagent) by treatment of allylic halides with lithium allylic boron ate complexes ($\text{RCH}=\text{CHCH}_2\text{B}-\text{R}'_2\text{Li}^+$).¹³²⁶ The reaction between primary and secondary halides and allyltributylstannane provides another method for unsymmetrical coupling $\text{RX} + \text{CH}_2=\text{CHCH}_2\text{SnBu}_3 \rightarrow \text{RCH}_2\text{CH}=\text{CH}_2$.¹³²⁷

In another method for the coupling of two different allylic groups,¹³²⁸ a carbanion derived from a β,γ -unsaturated thioether couples with an allylic halide to give **137**.¹³²⁹ The product (**137**) contains an SPh group that must be removed (with Li in ethylamine) to give the 1,5-diene. Unlike most of the methods previously discussed, this method has the advantage that the coupling preserves the original positions and configurations of the two double bonds; no allylic rearrangements take place.

Treatment of conjugated ketones with SmI_2 in HMPA gave the coupled diketone via *Wurtz-type coupling*.¹³³⁰

organolithium compounds with alkyl halides¹³³⁴ or aryl halides¹³³⁵ is possible.¹³³⁶ Unactivated aryl halides couple with alkylolithium reagents in THF.¹³³⁷ The reaction of *n*-butyllithium/TMEDA with a homoallylic alcohol [CH₂=C(Me)CH₂CH₂OH] leads to the allyllithium reagent, and subsequent reaction with an alkyl halide gives the substituted homoallylic alcohol [CH₂=C(CH₂R)CH₂CH₂OH].¹³³⁸ Organolithium reagents exhibit an important side reaction: They react with ether solvents, and their half-life in such solvents is known.¹³³⁹ With highly reactive organolithium reagents, preparing and keeping them long enough for the alkyl halide to be added is sometimes a problem (but usually not with simple primary organolithium reagents). Alkenes can be prepared by the coupling of vinylic lithium compounds with primary halides¹³⁴⁰ or of vinylic halides with alkylolithium reagents in the presence of a Pd or Ru catalyst.¹³⁴¹ α -Lithioepoxides can also be formed, and reaction with an alkyl halide gives the substituted epoxide.¹³⁴² Arylsilanes (e.g., 2-trimethylsilylpyridine) undergo a deprotonation reaction of a silyl methyl group when treated with *tert*-butyllithium to give the corresponding ArMe₂SiCH₂Li reagent.¹³⁴³ Subsequent reaction with an alkyl halide leads to the substituted silane. Organolithium reagents formed by Li–H exchange in the presence of (–)-sparteine couple with alkyl halides with high asymmetric induction.¹³⁴⁴ Exchange of organotin compounds with organolithium reagents generates a new organolithium, and in one case intramolecular coupling in the presence of (–)-sparteine led to chiral pyrrolidine derivatives.¹³⁴⁵ Propargyl lithium reagents formed in the presence of mercuric salts couple with halides.¹³⁴⁶ Note that 1-lithioalkynes were coupled to alkyl halides in the presence of a palladium catalyst.¹³⁴⁷

Aryllithium reagents are formed by metal–halogen exchange with aryl halides or H–metal exchange with various aromatic compounds, and they react with alkyl halides. The reaction of **138** with *n*-butyllithium, for example, generated the aryllithium (**139**), which reacted with iodomethane to give **140**.¹³⁴⁸ When an aromatic ring has an attached heteroatom or an heteroatom-containing substituent, reaction with a strong base (e.g., an

organolithium reagent) usually leads to an *ortho* lithiated species.¹³⁴⁹ Subsequent reaction with an electrophilic species gives the *ortho* substituted product. This phenomenon is known as *directed ortho metalation* (See **13-17**). This selectivity was discovered independently by Gilman and by Wittig in 1939–1940, when anisole was found to give *ortho* deprotonation in the presence of butyllithium.¹³⁵⁰ Alkylation *ortho* to a carbonyl is possible, and treatment of the acyl hydrazide [PhC(=O)NHNMe₂] with *sec*-butyllithium and then iodoethane gave the *ortho* ethyl derivative.¹³⁵¹ Note that aminonaphthalene derivatives were reacted with *tert*-butyllithium and aryllithium formation occurred on the ring distal to the amino group, and subsequent reaction with iodomethane gave methylation on that ring.¹³⁵²

In a method for propargylating an alkyl halide without allylic rearrangement, the halide is treated with lithio-1-trimethylsilylpropyne (**141**), which is a lithium compound protected by an SiMe₃ group.¹³⁵³ Reaction at its 1 position (which gives an allene) takes place only to a small extent, because of steric blockage by the large SiMe₃ group. The SiMe₃ group is easily removed by treatment with Ag⁺ followed by CN[−]. Propargyl derivative **141** is prepared by treating propynyllithium with Me₃SiCl to give MeC≡CSiMe₃ from which a proton is removed with BuLi. The R group may be primary or allylic.¹³⁵⁴ On the other hand, propargylic halides can be alkylated with essentially complete allylic rearrangement, to give allenes, by treatment with *Grignard reagents* and metallic salts,¹³⁵⁵ or with dialkylcuprates (R₂Cu).¹³⁵⁶

Grignard reagents are generally unreactive with alkyl halides unless allylic and benzylic reagents and substrates are used.¹³⁵⁷ *Grignard reagents* have the advantage that they are usually simpler to prepare than the corresponding R'₂CuLi (see Reaction **10-58**), but the reaction is much narrower in scope. *Grignard reagents* couple only with active halides: allylic (though allylic rearrangements are common) and benzylic. They also couple with tertiary alkyl halides, but generally in low or moderate yields.¹³⁵⁸

Allylic halides are more reactive than aliphatic alkyl halides, but Cu salts have been used to facilitate coupling with alkylmagnesium halides.¹³⁵⁹ Indeed, *Grignard reagents*

may react with alkyl halides in the presence of certain metal catalysts,¹³⁶⁰ and stereocontrol is possible in these reactions.¹³⁶¹ These catalysts include Cu(I) compounds (see Reaction 10-58),¹³⁶² Ag compounds,¹³⁶³ Pd¹³⁶⁴ complexes, Co compounds,¹³⁶⁵ Fe compounds,¹³⁶⁶ and an Fe–amine complex was shown to catalyze Grignard coupling reactions.¹³⁶⁷ Iron nanoparticles have also been employed to facilitate this type of coupling.¹³⁶⁸ Alkyl triflates have been used rather than alkyl halides.¹³⁶⁹ Chiral Cu complexes have been used with allylic halides to give rearranged alkylated products, with high enantioselectivity.¹³⁷⁰ A similar reaction was reported using a *Grignard reagent* and a chiral imidazolium carbene complex.¹³⁷¹ As noted above, *Grignard reagents* react with allylic substrates, but if there is steric hindrance at the carbon bearing the leaving group, the reaction may proceed by an S_N2' pathway (Sec. 10.E).¹³⁷²

Aryl halides, even when activated, generally do not couple with *Grignard reagents*, although certain transition metal catalysts do effect this reaction in variable yields,¹³⁷³ including V compounds.¹³⁷⁴ The reaction with *Grignard reagents* proceeds better when OR can be the leaving group, providing that activating groups are present in the ring. Aryl triflates couple with arylmagnesium halides in the presence of a Pd catalyst,¹³⁷⁵ as do vinyl halides with RMgX with a Pd¹³⁷⁶ or Ni catalyst.¹³⁷⁷ Alkyl halides are coupled to arylmagnesium bromides in the presence of a Co catalyst.¹³⁷⁸ It is also possible to couple alkynylmagnesium halides with aryl iodides in the presence of Pd catalysts.¹³⁷⁹ A silica-supported phosphine–Pd complex was used to couple arylmagnesium halides with aryl iodides.¹³⁸⁰ Aryl *Grignard reagents* couple with alkyl halides, including neopentyl iodide, in the presence of ZnCl₂ and a Ni catalyst.¹³⁸¹

Vinyl¹³⁸² and aryl halides¹³⁸³ also couple with alkyl *Grignard reagents* in the presence of a catalytic amount of an Fe catalyst,¹³⁸⁴ as do vinyl triflates with CuI¹³⁸⁵ or vinyl halides with a Co catalyst.¹³⁸⁶ *Grignard reagents* prepared from primary or secondary¹³⁸⁷ alkyl or aryl halides can be coupled with vinylic or aryl halides (see Reaction 13-9) in high yields in the presence of a Ni(II) catalyst.¹³⁸⁸ When a chiral Ni(II) catalyst is used, optically active hydrocarbons can be prepared from achiral reagents.¹³⁸⁹ The Pd catalyzed coupling of arylmagnesium halides and vinyl bromides has also been reported.¹³⁹⁰

Because *Grignard reagents* react with the C=O group (Reaction 16-24 and 16-82), they cannot be used to couple with halides containing ketone, CO₂R, or amide functions. Although the coupling of *Grignard reagents* with ordinary alkyl halides is usually not useful for synthetic purposes, small amounts of symmetrical coupling product are commonly formed while *Grignard reagents* are being prepared.

For symmetrical coupling of organometallic reagents (2RM → RR), see Reaction 14-24 and 14-25.

Much study has been devoted to the mechanisms of these reactions,¹³⁹¹ but firm conclusions are still lacking, in part because the mechanisms vary depending on the metal, the R group, the catalyst, if any, and the reaction conditions. Two basic pathways can be envisioned: a nucleophilic substitution process (which might be S_N1 or S_N2) and a free radical mechanism. This could be an SET pathway, or some other route that provides radicals. In either case, the two radicals R• and R'• would be in a solvent cage:

It is necessary to postulate the solvent cage because, if the radicals were completely free, the products would be ~ 50% RR', 25% RR, and 25% R'R'. This is generally not the case; in most of these reactions RR' is the predominant or exclusive product.¹³⁹² An example where an S_N2 mechanism has been demonstrated (by the finding of inversion of configuration at R) is the reaction between allylic or benzylic lithium reagents with secondary halides.¹³⁹³ The fact that in some of these cases the reaction can be successfully applied to aryl and vinylic substrates indicates that a simple S_N process cannot be the only

¹³⁹² When a symmetrical distribution of products is found, this is evidence for a free-radical mechanism: the solvent cage is not efficient and breaks down.

¹³⁹³ Sommer, L.H.; Korte, W.D. *J. Org. Chem.* **1970**, 35, 22; Korte, W.D.; Kinner, L.; Kaska, W.C. *Tetrahedron Lett.* **1970**, 603. See also, Schlosser, M.; Fouquet, G. *Chem. Ber.* **1974**, 107, 1162, 1171.

mechanism. One possibility is that the reagents first undergo an exchange reaction: $\text{ArX} + \text{RM} \rightarrow \text{RX} + \text{ArM}$, and then a nucleophilic substitution takes place. On the other hand, there is much evidence that many coupling reactions involving organometallic reagents with simple alkyl groups occur by free radical mechanisms. Among the evidence¹³⁹⁴ is the observation of CIDNP in reactions of alkyl halides with simple organolithium reagents¹³⁹⁵ (see Sec. 5.C.i), the detection of free radicals by ESR spectroscopy¹³⁹⁶ (Sec. 5.C.i), and the formation of 2,3-dimethyl-2,3-diphenylbutane when the reaction was carried out in the presence of cumene¹³⁹⁷ (this product is formed when a free radical abstracts a hydrogen from cumene to give PhCMe_2 , which dimerizes). Evidence for free radical mechanisms has also been found for the coupling of alkyl halides with simple organosodium compounds (Wurtz),¹³⁹⁸ with *Grignard reagents*,¹³⁹⁹ and with lithium dialkylcopper reagents (see Reaction 10-58).¹⁴⁰⁰ Free radicals have also been implicated in the metal-ion catalyzed coupling of alkyl and aryl halides with *Grignard reagents*.¹⁴⁰¹

to the thermal instability of any dialkyl cuprate that has a hydrogen atom on a carbon that is β - to the Cu.

The reaction with alkyl halides is of wide scope¹⁴⁰⁶ and R in R_2CuLi may be primary alkyl, allylic, benzylic, aryl, vinylic, or allenic, and may contain keto, CO_2H , CO_2R , or $CONR_2$ groups.¹⁴⁰⁷ The mechanism of these reactions probably involves formation of a Cu(II) intermediate.¹⁴⁰⁸ Reaction with allylic substrates usually proceeds with high selectivity for the γ -position,¹⁴⁰⁹ in S_N2' -type reactions.¹⁴¹⁰

Inversion of configuration has been shown in the reaction of 2-bromobutane with Ph_2CuLi ,¹⁴¹¹ but the same reaction with 2-iodobutane was reported to proceed with racemization.¹⁴¹² The reaction at a vinylic substrate occurs stereospecifically, with retention of configuration.¹⁴¹³ Many *gem*-dihalides do not react, but when the two halogens are on a carbon α to an aromatic ring¹⁴¹⁴ or on a cyclopropane ring,¹⁴¹⁵ both halogens can be replaced by R (e.g., $PhCHCl_2 \rightarrow PhCHMe_2$). However, 1,2-dibromides give exclusive elimination (Reaction 17-22).¹⁴¹⁶ Vinylmagnesium halides, upon addition of a catalytic amount of Li_2CuCl_4 , couple to alkyl halide.¹⁴¹⁶

Lithium dialkylcopper reagents couple with alkyl tosylates.¹⁴¹⁷ High yields are obtained with primary tosylates; secondary tosylates give lower yields,¹⁴¹⁸ but aryl tosylates do not react. Vinylic triflates¹⁴¹⁹ couple very well to give alkenes¹⁴²⁰ and they also couple with allylic cuprates, to give 1,4-dienes.¹⁴²¹ Propargylic tosylates couple with vinylic cuprates to give vinylic allenes.¹⁴²²

The R' in R'_2CuLi may be primary alkyl, vinylic, allylic, or aryl. Thus, in the reaction so far described, the alkyl groups on the organocuprate or the alkyl halide may *not* be secondary or tertiary alkyl. However, secondary and tertiary alkyl coupling can be achieved

(on primary RX) by the use of $R'_2CuLi \bullet P Bu_2$ ¹⁴²³ (but this procedure introduces problems in the workup) or by the use of $PhS(R')CuLi$,¹⁴²⁴ which selectively couples a secondary or tertiary R' with a primary iodide (RI) to give RR' .¹⁴²⁵ It is possible to prepare mixed cuprates, where one ligand is tightly bound to the copper, allowing the other ligand to be transferred in a coupling reaction. A common example is adds a 2-thienyl group to the cuprate to give $R(Th)CuLi$, where the R group is transferred in lieu of the thienyl unit.¹⁴²⁶ A lithium neopentyl aryl cuprate selectively transferred from an aryl group to an allylic halide.¹⁴²⁷

Coupling to a secondary alkyl halide (R in RX above = secondary) can be achieved in high yield with the reagents $R'_2Cu(CN)Li_2$,¹⁴²⁸ where R' is primary alkyl or vinylic (but not aryl).¹⁴²⁹ This modified reagent is commonly known as a *higher order mixed cuprate*. The reagents $RCu(PPh_2)Li$, $RCu(NR'_2)Li$, and $RCu(PR'_2)Li$ (R' = cyclohexyl) are more stable than R_2CuLi and can be used at higher temperatures.¹⁴³⁰ These reagents are rather reactive. Unactivated aryl triflates¹⁴³¹ ($ArOSO_2CF_3$) react to give ArR in good yields when treated with $R_2Cu(CN)Li_2$,¹⁴³² with R_3Al ,¹⁴³³ or with R_3SnR and a Pd complex catalyst.¹⁴³⁴ See Reaction 10-59 for other examples involving Al, Sn, and Pd coupling reactions. Both OTf units in $RCH(OTf)_2$ can be replaced with $Me_2(CN)CuLi_2$.¹⁴³⁵ With an allenic substrate, reaction with $R(CN)CuLi$ can give ordinary displacement (with retention of configuration)¹⁴³⁶ or an S_N2' reaction to produce an alkyne.¹⁴³⁷ In the latter case, a chiral allene (see Sec. 4.C, category 5) gave a chiral alkyne. The structures of these “higher order mixed” cuprates has been called into question¹⁴³⁸ by Bertz,¹⁴³⁹ who suggested the reagent actually existed as $R_2CuLi \bullet LiCN$ in THF. This was contradicted by Lipshutz and James.¹⁴⁴⁰

The fact that R'_2CuLi do not react with ketones provides a method for the alkylation of ketones via the organocuprate coupling with α -haloketones (e.g., **142**¹⁴⁴¹; see also, Reactions **10-68** and **10-73**). Note that halogen-metal exchange (Reaction **12-39**) is a side reaction and can become the main reaction.¹⁴⁴² When α,α' -dibromo ketones are treated with Me_2CuLi in ether at $-78^\circ C$ and the mixture quenched with methanol, monomethylation takes place¹⁴⁴³ (no dimethylation is observed). It has been suggested that the reaction involves cyclization (**10-56**) to a cyclopropanone followed by nucleophilic attack to give the enolate anion, which is protonated by the methanol. If iodomethane is added instead of methanol, an α,α' -dimethyl ketone is obtained, presumably from S_N2 attack (Reaction **10-68**). Primary, secondary, and tertiary monoalkylation can be achieved with a lithium *tert*-butoxy(alkyl)copper reagent¹⁴⁴⁴ instead of Me_2CuLi , one of the few methods for introducing a tertiary alkyl group to a carbonyl group.

When dialkylcopperzinc reagents ($R_2CuZnCl$) couple with allylic halides, allylic rearrangement occurs (S_N2') almost completely, and the reaction is diastereoselective if the allylic halide contains a δ alkoxy group.¹⁴⁴⁵ Another type of copper reagent was prepared from $RZnI/CuCN$, and was shown to couple with alkenyl halides.¹⁴⁴⁶ Diethylzinc in the presence of a catalytic amount of $CuBr$ coupled to allylic chlorides.¹⁴⁴⁷ When treated with organocopper compounds and Lewis acids (e.g., $n-BuCu \bullet BF_3$), allylic halides give substitution with almost complete allylic rearrangement, independently of the degree of substitution at the two ends of the allylic system.¹⁴⁴⁸

OS IX, 502.

10-59 Reaction of Alkyl Halides and Sulfonate Esters with Other Organometallic Reagents

Alkyl-de-halogenation

In addition of Mg, Li, and Cu, other metals and metal complexes can be used to catalyze or mediate coupling reactions. Organoaluminum compounds couple very well with tertiary (to give products containing a quaternary carbon) and benzylic halides at $-78^\circ C$.¹⁴⁴⁹ This reaction can also be applied to allylic, secondary, and some primary halides, but several days standing at room temperature is required (see also, Reaction **10-63**). Vinylic aluminum compounds (in the presence of a suitable transition metal catalyst) couple

with allylic halides, acetates, and alcohol derivatives to give 1,4-dienes,¹⁴⁵⁰ and with vinylic and benzylic halides to give 1,3-dienes and allylic arenes, respectively.¹⁴⁵¹ Note that alkylboronic acids are coupled in the presence of Ag₂O and a catalytic amount of CrCl₂ to give the symmetrical alkyl derivative.¹⁴⁵²

Products containing a quaternary carbon can also be obtained by treatment of tertiary halides with dialkyl or diaryl zinc reagents in CH₂Cl₂,¹⁴⁵³ with Me₃Si and AlCl₃,¹⁴⁵⁴ or with alkyltitanium reagents (RTiCl₃ and R₂TiCl₂).¹⁴⁵⁵ Alkyl or aryl triflates (halides) couple with alkyl or ArZn(halide) reagents in the presence of a Pd catalyst.¹⁴⁵⁶ This organozinc coupling reaction has been done in ionic liquids.¹⁴⁵⁷ Vinyl halides can be coupled with vinyltin reagents in the presence of CuI,¹⁴⁵⁸ and aryl tin compounds couple with vinyl halides¹⁴⁵⁹ or vinyl triflates when a Pd catalyst is present.¹⁴⁶⁰ When the vinyltin reagent is coupled with a vinyl triflate in the presence of a Pd catalyst, the reaction is known as the *Stille reaction* (Reaction 12-15). In the *Stille reaction*, vinylic triflates, in the presence of a Pd catalyst and LiCl, couple with organotin compounds (R'SnMe₃), where R' can be alkyl, allylic, vinylic, or alkynyl.¹⁴⁶¹ The reaction has been performed intramolecularly, to prepare large-ring lactones.¹⁴⁶²

The coupling of alkyl or alkenyl halides and an organozinc compound with a Ni complex has come to be known as *Negishi coupling*.¹⁴⁶³ Several variations have been reported over the years. Arylzinc compounds¹⁴⁶⁴ have been used, and also arylvinyl iodides.¹⁴⁶⁵ The structure of bis(iodozincio)methane in THF solution has been reported.¹⁴⁶⁶ Pyridylzinc compounds have been used in *Negishi coupling*.¹⁴⁶⁷

Carbonylative cross coupling reactions have been reported.¹⁴⁶⁸ Palladium-catalyzed variations are also known for alkyl or vinyl halides with organozinc compounds.¹⁴⁶⁹ Dialkylzinc compounds can be coupled to alkyl halides in the presence of a nickel catalyst,¹⁴⁷⁰ but with geminal diiodo compounds without a catalyst.¹⁴⁷¹ Asymmetric variations are known using various chiral additives or chiral catalysts,¹⁴⁷² including the example shown for an allylic chloride (DMA = dimethylacetamide).¹⁴⁷³ Coupling with propargylic substrates has also been reported.¹⁴⁷⁴

Copper compounds can also be used as catalysts with dialkylzinc reagents.¹⁴⁷⁵ The reaction of aryl halides with Me_4ZnLi_2 and then $\text{VO}(\text{OEt})\text{Cl}_2$ leads to the methylated aryl.¹⁴⁷⁶ Isopropylzinc ($i\text{PrZn}$) displaces the iodide in γ -iodo ketones to give the alkyl substitution product, without reaction at the carbonyl.¹⁴⁷⁷ Reactions of organozinc reagents with a carbonyl compound via acyl addition is presented in **16-31** (the *Reformatsky reaction*). Tertiary halides have also been coupled to allyltin reagents in the presence of AIBN.¹⁴⁷⁸ Alkyl halides can be treated with SmI_2 and then CuBr to give a reactive species that couples with other alkyl halides.¹⁴⁷⁹ Trialkylindium compounds couple to allylic bromides in the presence of $\text{Cu}(\text{OTf})_2 \cdot \text{P}(\text{OEt})_3$ ¹⁴⁸⁰ and vinyl indium compounds are coupled to α -halo esters with a BEt_3 catalyst.¹⁴⁸¹ Arylsulfonyl chlorides couple with allyl halides in the presence of bismuth to give allyl-aryls.¹⁴⁸² Vinyl iodides couple with RMnCl with an iron catalyst¹⁴⁸³ and Bu_3MnMgBr reacted with a geminal dibromocyclopropane to give a dialkylated cyclopropane.¹⁴⁸⁴ α -Haloketones are coupled with aryl halides using a

Ni catalyst.¹⁴⁸⁵ Allylgallium reagents have been coupled to α -bromo esters in the presence of BEt_3/O_2 .¹⁴⁸⁶

Arylpalladium salts (ArPdX) prepared from arylmercury compounds and lithium palladium chloride couple with allylic chlorides in moderate yields, although allylic rearrangements can occur.¹⁴⁸⁷ In most cases, better yields are obtained by addition of a Pd complex to the substrate, sometimes in conjunction with another metal, to facilitate coupling. Under these conditions, any arylpalladium species is generated *in situ*. Allylic, benzylic, vinylic, and aryl halides or triflates (trifluoromethylsulfonates) couple with organotin reagents in a reaction catalyzed by Pd complexes.¹⁴⁸⁸ The advantage of this procedure is that the aryl group may contain nitro, ester, or aldehyde groups, and so on, which cannot be present in a *Grignard reagent*. Such functional groups as CO_2R , CN , OH , and CHO may be present in either reagent, but the substrate may not bear a β hydrogen on an sp^3 carbon, because that results in elimination. Indium metal has been used to mediate the coupling of an allylic halide and an arylpalladium complex.¹⁴⁸⁹ Organoindium compounds were coupled to 1-iodonaphthalene with a Pd catalyst.¹⁴⁹⁰ Aryl halides were also coupled to allylic silanes in the presence of a Pd catalyst.¹⁴⁹¹

Dimethylzinc was coupled to aryl halides with a Pd catalyst,¹⁴⁹² and *Reformatsky-type* zinc derivatives (see Reaction **16-28**) have been coupled to aryl halides using a Pd catalyst and microwave irradiation.¹⁴⁹³ Alkyl halides couple with ArMnCl or RMnCl in the presence of a Pd catalyst.¹⁴⁹⁴ Cobalt-catalyzed coupling reactions are known.¹⁴⁹⁵

In many cases, the organometallic reagent is prepared from the corresponding organolithium reagent (Reaction **10-57**), as in the conversion of an aryllithium to an arylzirconium reagent, which was subsequently coupled to an aryl halide in the presence of a Pd catalyst.¹⁴⁹⁶ Vinylzirconium reagents can be coupled to allylic halides in the presence of Cu(I) compounds.¹⁴⁹⁷

Alkylboranes are coupled to alkyl halides in the presence of a Ni catalyst.¹⁴⁹⁸

10-60 Coupling of Organometallic Reagents with Carboxylic Esters

Alkyl-de-acyloxy-substitution

Several organometallic reagents react with allylic esters and carbonates to give the coupling product. Lithium dialkylcopper reagents couple with allylic acetates to give normal coupling products or those resulting from allylic rearrangement, depending on the substrate.¹⁴⁹⁹ A mechanism involving a σ -allylic copper(III) complex has been suggested.¹⁵⁰⁰ Silyl cuprates have also been used, with benzoate esters, to give allyl silanes.¹⁵⁰¹ Interestingly, allylic silanes have been coupled to acetates using $\text{B}(\text{C}_6\text{F}_5)_3$ ¹⁵⁰² or BF_3 .¹⁵⁰³

Allenes are obtained when propargyl acetates are treated with methylmagnesium iodide.¹⁵⁰⁴ Lithium dialkylcopper reagents give normal coupling products with enol acetates of β -dicarbonyl compounds.¹⁵⁰⁵ It is also possible to carry out the coupling of allylic acetates with *Grignard reagents*, if catalytic amounts of cuprous salts are present.¹⁵⁰⁶ Yields are better with this method, and regioselectivity can be controlled by the choice of cuprous salts.

Several metal-catalyzed coupling reactions are known. Allylic, benzylic, and cyclopropylmethyl acetates couple with trialkylaluminums,¹⁵⁰⁷ and allylic acetates couple with aryl and vinylic tin reagents, in the presence of a Pd catalyst¹⁵⁰⁸ (see below). Allylic acetates can be symmetrically coupled by treatment with $\text{Ni}(\text{CO})_4$ (Reaction 10-56) or with Zn and a Pd—complex catalyst,¹⁵⁰⁹ or converted to unsymmetrical 1,5-dienes by treatment with an allylic stannane ($\text{R}_2\text{C}=\text{CHCH}_2\text{SnR}_3$) in the presence of a Pd complex.¹⁵¹⁰ Other Ni(0) coupling reactions are known.¹⁵¹¹ Titanium-mediated¹⁵¹² coupling, Ir catalyzed,¹⁵¹³

and Fe catalyzed¹⁵¹⁴ reactions are also known. Aryl halides can be coupled to allylic acetates with $\text{CoBr}_2/\text{Mn}/\text{FeBr}_2$.¹⁵¹⁵ Allylic phosphonates have been used as substrates for displacement by higher order cuprates¹⁵¹⁶ (see Reaction **10-58**) or dialkylzinc reagents.¹⁵¹⁷

A common method is the reaction of η^3 - π -allyl palladium complexes¹⁵¹⁸ (see Sec 3.C.i) with various nucleophiles,¹⁵¹⁹ where the complex is obtained from allylic esters (acetate is the most common) or allylic carbonates (also see Reaction **10-31**). This coupling reaction is often called the *Tsuji-Trost* reaction.¹⁵²⁰ The mechanism of such π -allyl palladium reactions has been discussed.¹⁵²¹ The structure and nature of the ligands associated with the metal are important to the reaction, particularly with respect to stereoselectivity of a given reaction.¹⁵²² A typical transformation is shown for the reaction of **143** with diethyl malonate, BSA (N,O-bis(trimethylsilyl)acetamide), and potassium acetate, which gives coupling product **144** in the presence of the Pd catalyst.¹⁵²³ This reaction is a variation of the basic transformation reported several years ago by Trost et al.¹⁵²⁴ Enolate anions of active methylene compounds¹⁵²⁵ and also sulfone anions¹⁵²⁶ have been used as nucleophiles most of the time. In most reported cases, the $\text{R}'\text{M}$ species is the anion of an active methylene compound (e.g., sodium, potassium, or lithium dimethylmalonate) or *Knoevenagel-type* carbanions (see Reaction **16-38**) or amino acid surrogates.¹⁵²⁷ Enolate

anions (see Reaction 10-68) have also been used.¹⁵²⁸ Other nucleophiles can be used to displace allylic acetates.¹⁵²⁹ The Pd catalyst used, the reaction conditions, and the nature of the organometallic compounds varies widely. Although two allylic coupling products are possible via the π -allyl intermediate, attack at the less substituted position is generally favored. This transformation has been done in ionic liquids¹⁵³⁰ and ionic liquids have been used as additives in catalytic amounts in other solvents.¹⁵³¹ Palladium nanoparticles have been used to catalyze the reaction.¹⁵³² The S_N2' reactions with allylic substrates have been reported.¹⁵³³ Benzoate esters have been used successfully in lieu of the acetate.¹⁵³⁴ Catalyst metals other than Pd have been used for this reaction with allylic acetates.¹⁵³⁵

The use of chiral ligands¹⁵³⁶ or chiral additives that may act as ligands¹⁵³⁷ lead to asymmetric induction in the coupling product.¹⁵³⁸

As mentioned above, a common variation is to replace the acetate leaving group with a carbonate ($-\text{OCO}_2\text{R}$), where methyl carbonate ($-\text{OCO}_2\text{Me}$) is most common.¹⁵³⁹ A representative reaction is the transformation of **145** to **146**,¹⁵⁴⁰ where the use of a chiral ligand led to modest asymmetric induction. Indeed, as with allylic acetates, chiral ligands and chiral additives lead to asymmetric induction.¹⁵⁴¹ A variety of active

methylene compounds can be used as nucleophiles,¹⁵⁴² including enolate anions.¹⁵⁴³ Other nucleophiles can be used to displace allylic carbonates,¹⁵⁴⁴ often in conjunction with chiral ligands to give the product with enantioselectivity. Polymer-supported phosphine ligands have been used successfully,¹⁵⁴⁵ and catalyst systems other than Pd have been used for this reaction with allylic carbonates.¹⁵⁴⁶ Potassium vinyltrifluoroborates (Reaction **10-73**) have also been used in Pd catalyzed coupling reactions with allylic acetates.¹⁵⁴⁷

Intramolecular cyclization is possible when the active methylene compound and an allylic acetate or carbonate is incorporated into the same molecule.¹⁵⁴⁸ Propargylic esters have been used in Pd catalyzed coupling reactions, including a reaction with trialkylindium reagents.¹⁵⁴⁹

10-61 Coupling of Organometallic Reagents with Sulfate Esters, Sulfoxides, Sulfones, Nitro, and Acetals

Alkyl-de-sulfonyl and de-sulfonyloxy-substitution, and so on; **Alkyl-de-alkoxy-substitution**, and so on; **Alkyl-de-nitration**, and so on

Leaving groups other than halide, esters or carbonate, or sulfonate esters are sometimes used. Sulfates, sulfonates, and epoxides give the expected products. The reactions of sodium sulfonates and alkyl halides in ionic liquids have been reported.¹⁵⁵⁰ The SO₂Ph group of allylic sulfones can be a leaving group if a Pd complex is present.¹⁵⁵¹ The NR₂ group from *Mannich bases* (e.g., RCOCH₂CH₂NR₂), can also act as a leaving group

in this reaction (elimination–addition mechanism, Sec. 10.F). A nitro group can be displaced¹⁵⁵² from α -nitro esters, ketones, nitriles, and α,α -dinitro compounds,¹⁵⁵³ and even from simple tertiary nitro compounds of the form R_3CNO_2 ¹⁵⁵⁴ or ArR_2CNO_2 ¹⁵⁵⁵ by salts of nitroalkanes, for example,

These reactions take place by SET mechanisms.¹⁵⁵⁶ However, with α -nitro sulfones it is the sulfone group that is displaced, rather than the nitro group.¹⁵⁵⁷ The SO_2R group of allylic sulfones can be replaced by CHZZ' ($\text{C}=\text{CCH}_2\text{---SO}_2\text{R} \rightarrow \text{C}=\text{CCH}_2\text{---CHZZ'}$) if a $\text{Mo}(\text{CO})_6$ catalyst is used.¹⁵⁵⁸

tert-Butylsulfones react with organolithium reagents, in the presence of a catalytic amount of an iron complex, to give coupling.¹⁵⁵⁹ In this case the *t*-BuSO₂ unit becomes a “leaving group”. A sulfoxide was a “leaving group” in the cyclization of a carboxylic acid that contains a sulfoxide unit at C-4. Treatment with phenyliodonium bis(trifluoroacetate) gave the five-membered ring lactone.¹⁵⁶⁰ Similar displacement of ToISO_2 was observed with tolylsulfones and diethylzinc.¹⁵⁶¹

Phosphonic esters, $\text{ROPO}(\text{OR})_2$, react with allylic *Grignard reagents* to give the coupling product.¹⁵⁶²

10-62 The Bruylants Reaction

Alkyl-de-cyanation

The *Bruylants reaction* is the reaction of an aminonitrile with a *Grignard reagent* to give a substituted amine.¹⁵⁶³ This reaction is most often used for the preparation of aliphatic amines via aliphatic *Grignard reagents*. In a few cases, vinylic *Grignard reagents* can be used to prepare allylic amines.¹⁵⁶⁴ The use of AgBF_4 to convert amino nitriles to the

corresponding iminium ion facilitates the *Bruylants reaction* with vinylic *Grignard reagents*.¹⁵⁶⁵ Replacement of the cyano group in a tertiary nitrile is also possible.¹⁵⁶⁶

Displacement of a cyano group in α -cyanoketones is possible. Treatment of the α -cyanoketone with SmI_2 followed by addition of an excess of allyl bromide gave the α -allyl ketone derivative.¹⁵⁶⁷ α -Cyano amines react with allyl bromide and then zinc metal to give homoallylic amines after treatment with dilute acetic acid in THF.¹⁵⁶⁸

10-63 Coupling Involving Alcohols

De-hydroxyl-coupling

In some cases, it is possible to couple an alcohol in the presence of an organometallic compound.¹⁵⁶⁹ Allylic alcohols are coupled with alkylmagnesium bromides in the presence of $\text{Ti}(\text{O}i\text{Pr})_4$, for example.¹⁵⁷⁰ Allylic alcohols can be coupled with arylboronic acids in an ionic liquid solvent and a Rh catalyst.¹⁵⁷¹ The Pd catalyzed reaction of active methylene compounds with allylic alcohols¹⁵⁷² or benzylic alcohols¹⁵⁷³ is also known. The coupling of an alcohol to the α carbon of a ketone ($\text{RCOMe} + \text{R}'\text{OH}$) to give a β -substituted alcohol [$\text{RCH}(\text{OH})\text{CH}_2\text{R}'$] is possible in the presence of a Ru catalyst.¹⁵⁷⁴ Alcohols are coupled to allenes in the presence of an Ir catalyst.¹⁵⁷⁵ Allylic carbonates are coupled to allylic alcohols with a Ni catalyst.¹⁵⁷⁶

Allylic or benzylic alcohols can be symmetrically coupled¹⁵⁷⁷ by treatment with methyllithium and titanium trichloride at -78°C ¹⁵⁷⁸ or by refluxing with TiCl_3 and LiAlH_4 (as shown).¹⁵⁷⁹ When the substrate is an allylic alcohol, the reaction is not regiospecific, but a mixture of normal coupling and allylic-rearranged products is found. A free radical mechanism is involved.¹⁵⁸⁰ The TiCl_3 — LiAlH_4 reagent can also convert 1,3-diols to cyclopropanes, provided that at least one phenyl group is present.¹⁵⁸¹

Tertiary alcohols (R_3C-OH) react with trimethylaluminum at 80–200 °C to give methylation (R_3C-Me).¹⁵⁸² The presence of side products from elimination and rearrangement, as well as the lack of stereospecificity,¹⁵⁸³ indicate an S_N1 mechanism. The reaction can also be applied to primary and secondary alcohols if these contain an aryl group in the α position. Higher trialkylaluminums are far less suitable, because reduction competes with alkylation [see also, reactions of Me_3Al with ketones (**16-24**) and with carboxylic acids (**16-82**)]. The Me_2TiCl_2 compound reacts with tertiary alcohols in the same way.¹⁵⁸⁴ β -Alkylation of secondary alcohols has been reported using alcohol substrates in the presence of an Ir complex.¹⁵⁸⁵

Allylic alcohols couple with a reagent prepared from $MeLi$, CuI , or $R'Li$ in the presence of $(Ph_3PNMePh)^+ I^-$ to give alkenes (e.g., **147**) that are products of allylic rearrangement.¹⁵⁸⁶

The reaction gives good yields with primary, secondary, and tertiary alcohols, and with alkyl and aryllithium reagents.¹⁵⁸⁷ Allylic alcohols also couple with certain *Grignard reagents*¹⁵⁸⁸ in the presence of a nickel complex to give both normal products and the products of allylic rearrangement.

Allenic alcohols couple with allyl indium reagents at 140 °C to give allylic alcohol products.¹⁵⁸⁹ Similarly, ω -hydroxy lactones couple with organoindium reagents.¹⁵⁹⁰ Phenols react with vinyl boronates and a copper catalyst to give aryl vinyl ethers.¹⁵⁹¹

Alcohols react with allylsilanes, in the presence of an $InCl_3$ ¹⁵⁹² or $InBr_3$ ¹⁵⁹³ catalyst to give the corresponding coupling product ($R_2CHOH \rightarrow R_2CH-CH_2CH=CH_2$). Silyl ethers are also coupled to allylsilanes in the presence of $InCl_3$.¹⁵⁹⁴ Propargylic alcohols have been coupled to allylic silanes using an Au catalyst¹⁵⁹⁵ or a Rh catalyst.¹⁵⁹⁶

10-64 Coupling of Organometallic Reagents with Compounds Containing the Ether Linkage¹⁵⁹⁷**Alkyl-de-alkoxy-substitution**

Acetals,¹⁵⁹⁸ ketals, and ortho esters¹⁵⁹⁹ react with *Grignard reagents* to give, respectively, ethers and acetals (or ketals). The latter can be hydrolyzed to aldehydes or ketones (Reaction **10-6**). This procedure is a way of converting a halide ($\text{R}''\text{X}$, which may be alkyl, aryl, vinylic, or alkynyl) to an aldehyde ($\text{R}''\text{CHO}$), increasing the length of the carbon chain by one carbon (see also, Reaction **10-76**). The ketone synthesis generally gives lower yields. Acetals, including allylic acetals, also give this reaction with organocopper compounds and BF_3 .¹⁶⁰⁰ Dihydropyrans react with *Grignard reagents* in the presence of a Ni catalyst.¹⁶⁰¹ Acetals also undergo substitution when treated with silyl enol ethers or allylic silanes, with a Lewis acid catalyst,¹⁶⁰² for example,

ω -Ethoxy lactams react with *Grignard reagents* to give ω -substituted lactams.¹⁶⁰³ Tertiary amines can be prepared by the reaction of amino ethers with *Grignard reagents*,¹⁶⁰⁴ ($\text{R}_2\text{NCH}_2\text{—OR}' + \text{R}^2\text{MgX} \rightarrow \text{R}_2\text{NCH}_2\text{—R}^2$) or with lithium dialkylcopper reagents.¹⁶⁰⁵

Ordinary ethers are not cleaved by *Grignard reagents* (in fact, diethyl ether and THF are the most common solvents for *Grignard reagents*), although more active organometallic compounds often do cleave them.¹⁶⁰⁶ However, methyl ethers have been replaced with a methyl group ($\text{MeMgX} + \text{ROMe} \rightarrow \text{R—Me}$) via a Ni catalyzed coupling reaction with MeMgBr .¹⁶⁰⁷ Oxetanes have been opened with organolithium reagents and $\text{BF}_3 \bullet \text{OEt}_2$ ¹⁶⁰⁸ and also with excess Li metal with a biphenyl catalyst.¹⁶⁰⁹ Allylic ethers can be cleaved by

Grignard reagents in THF if CuBr is present.¹⁶¹⁰ The reaction can take place either with or without allylic rearrangement.¹⁶¹¹ Propargylic ethers give allenes.¹⁶¹² Vinylic ethers can also be cleaved by *Grignard reagents* in the presence of a catalyst, in this case, a Ni complex.¹⁶¹³ Silyl enol ethers $R_2C=CROSiMe_3$ behave similarly.¹⁶¹⁴ Bicyclic benzo-furans can be opened by dialkylzinc reagents in the presence of a Pd catalyst.¹⁶¹⁵

Certain acetals and ketals can be dimerized in a reaction similar to Reaction 10-56 by treatment with $TiCl_4-LiAlH_4$, for example,¹⁶¹⁶

Also see, Reaction 10-65.

10-65 The Reaction of Organometallic Reagents with Epoxides

3(OC)-seco-Alkyl-de-alkoxy-substitution

The reaction between *Grignard reagents* or organolithium reagents and epoxides is very valuable and is often used to increase the length of a carbon chain by two carbons.¹⁶¹⁷ The *Grignard reagent* may be aromatic or aliphatic, although tertiary *Grignard reagents* give low yields. As expected for an S_N2 process, attack is at the less substituted carbon. With allylic *Grignard reagents*, the addition of a catalytic amount of $Yb(OTf)_3$ facilitated alkylation.¹⁶¹⁸ Organolithium reagents,¹⁶¹⁹ in the presence of chiral additives, lead to the 2-substituted alcohol with good enantioselectivity. Similar reaction with a chiral *Schiff base* gave the same type of product, with excellent enantioselectivity.¹⁶²⁰

Lithium dialkylcopper reagents also give the reaction,¹⁶²¹ as do higher order cuprates,¹⁶²² often producing higher yields. They have the additional advantage that they do not react with ester, ketone, or carboxyl groups so that the epoxide ring of epoxy esters, ketones, and carboxylic acids can be selectively attacked, often in a regioselective manner.¹⁶²³ The use of BF_3 increases the reactivity of R_2CuLi , enabling it to be used with thermally unstable epoxides.¹⁶²⁴ Lithium diaminocyno cuprates have also been used.¹⁶²⁵

The reaction has also been performed with other organometallic compounds.¹⁶²⁶ Trialkylaluminum reagents open epoxides with delivery of the alkyl group to carbon.¹⁶²⁷ In the presence of a Lewis acid catalyst (e.g., BF_3), alkylation can occur at the more substituted carbon.¹⁶²⁸ *Friedel–Crafts type alkylation* (see Reaction 11-11) is possible when an aromatic compound reacts with an epoxide and AlCl_3 .¹⁶²⁹ Epoxides react with allyl bromide in the presence of In metal, with the expected delivery of allyl to the less substituted carbon.¹⁶³⁰ When a substituted epoxide was treated with CO , $\text{BF}_3 \cdot \text{OEt}_2$, and a Co catalyst, carbonylation occurred and the final product was a β -lactone.¹⁶³¹ Similar β -lactone forming reactions were reported using substituted epoxides, CO , and a metal compound– BF_3 complex.¹⁶³² A double carbonylation reaction was reported in the presence of an Al complex, generating an anhydride.¹⁶³³ Five-membered ring lactams were formed from substituted epoxides using $\text{BF}_3 \cdot \text{OEt}_2$ followed by treatment with KHF_2 .¹⁶³⁴ Ring opening of epoxides with Ti compounds has been shown to be selective for the more substituted carbon.¹⁶³⁵ Epoxides react with Ag salts of alkynes, in the

presence of Zr compounds, to give the rearrangement product, a propargylic alcohol.¹⁶³⁶ A Ga/Sm induced ring opening with alkyl halides has been reported.¹⁶³⁷

In the presence of a Sc catalyst, chiral allylic boranes open epoxides at the less substituted position to generate chiral, homoallylic alcohols.¹⁶³⁸

When *gem*-disubstituted epoxides (**148**), and sometimes other epoxides, are treated with *Grignard reagents*, the product may be **149**, that is, the new alkyl group may appear on the same carbon as the OH. In such cases, the epoxide is isomerized to an aldehyde or a ketone before reacting with the *Grignard reagent*. Halohydrins are often side products.

When the substrate is a vinylic epoxide,¹⁶³⁹ *Grignard reagents* generally give a mixture of the normal product and the product of allylic rearrangement (**150**).¹⁶⁴⁰ Butyllithium reacted with a *gem*-difluoroalkylidene epoxide ($\text{F}_2\text{C}=\text{CR}$ -epoxide) and $\text{S}_{\text{N}}2'$ displacement gave alkylation at the difluoro carbon and opened the epoxide.¹⁶⁴¹ The latter often predominates. In the case of R_2CuLi ,¹⁶⁴² acyclic substrates give mostly allylic rearrangement ($\text{S}_{\text{N}}2'$).¹⁶³⁹ The double bond of the “vinylic” epoxide can be part of an enolate anion. In this case, R_2CuLi give exclusive allylic rearrangement ($\text{S}_{\text{N}}2'$) to **151** after hydrolysis, while *Grignard* and organolithium reagents opened the epoxide directly ($\text{S}_{\text{N}}2$) to give **152** after hydrolysis.¹⁶⁴³

An organometallic equivalent that opens epoxides is a hydrosilane, for example, Me_3SiH , and CO, catalyzed by dicobalt octacarbonyl:¹⁶⁴⁴ See Reaction 10-55 for other coupling reactions with organosilanes. Silyl enol ethers react with epoxides in a related reaction, but a Lewis acid (e.g., TiCl_4) is required.¹⁶⁴⁵

10-66 Reaction of Organometallics with Aziridines

Aziridines have been opened by organometallic reagents to give amines.¹⁶⁴⁶ It is also possible to open aziridines, although they are less reactive than epoxides,¹⁶⁴⁷ with organometallic reagents particularly when there is an *N*-sulfonyl group (e.g., tosyl, formally making it a sulfonamide). *Grignard reagents* react with *N*-tosyl 2-phenylaziridine to give the corresponding *N*-tosylamine.¹⁶⁴⁸ Organocuprates (**10-58**) reaction with *N*-allylaziridines to give the corresponding amine.¹⁶⁴⁹ In a *Friedel–Crafts type reaction* (**11-11**), aziridines react with benzene, in the presence of $\text{In}(\text{OTf})_3$, to give the β -aryl amine.¹⁶⁵⁰

N-Tosyl aziridines have also been opened with enolate anions, which led to a pyrroline derivative,¹⁶⁵¹ and with $\text{Me}_2\text{S}=\text{CHCO}_2\text{Et}$ (see Reaction **16-46**) to generate a *N*-tosyl azetidine.¹⁶⁵² Allylic alcohols open *N*-tosylaziridines with KSF–Montmorillonite clay.¹⁶⁵³ *C*-Arylation is possible with a $\text{Ag}(\text{I})$ catalyst.¹⁶⁵⁴ *N*-Sulfonyl aziridines react with the enolate anions of β -keto esters under phase-transfer conditions.¹⁶⁵⁵ *N*-Tosylaziridines react with InCl_3 to give the chloro *N*-tosylamine.¹⁶⁵⁶

Aziridines react with nucleophiles other than carbon nucleophiles. In the presence of tetrabutylammonium fluoride (TBAF), trimethylsilyl azide reacts with *N*-tosylaziridines to give the azido *N*-tosylamine.¹⁶⁵⁷ *N*-Benzylic aziridines are opened by trimethylsilyl azide in the presence of a Cr catalyst.¹⁶⁵⁸ Acetic anhydride reacts with *N*-tosylaziridines, in the presence of PBu_3 , to give the *N*-tosylamino acetate.¹⁶⁵⁹ Mediated by Lewis bases, aziridines react with silylated nucleophiles.¹⁶⁶⁰

10-67 Alkylation at a Carbon Bearing an Active Hydrogen

Bis(ethoxycarbonyl)methyl-de-halogenation, and so on

The metal-catalyzed displacement of allylic acetates and carbonates (Reaction **10-60**) clearly falls into this category. However, this section will focus on the more general reaction of active methylene compounds with substrates bearing a leaving group, not

necessarily allylic substrates or metal catalyzed. When compounds contain two or three strong electron-withdrawing groups on a carbon atom bearing a proton (the so-called α -proton), that proton is more acidic than compounds without such groups (Sec. 5.B.i, category 1). Treatment with a suitable base (a base that has a conjugate acid with a pK_a greater than the α -proton) removes the α -proton and generates the corresponding enolate anion (Reaction 10-68). These enolate anions react as carbon nucleophiles and attack alkyl halides, resulting in their alkylation.¹⁶⁶¹ Both Z and Z' may be COOR', CHO, COR',¹⁶⁶² CONR'₂, COO⁻, CN,¹⁶⁶³ NO₂, SOR', SO₂R',¹⁶⁶⁴ SO₂OR', SO₂NR'₂ or similar groups.¹⁶⁶⁵ Some commonly used bases are sodium ethoxide and potassium *tert*-butoxide, each in its respective alcohol as solvent. With particularly acidic compounds (e.g., β -diketones—Z, Z' = COR'), sodium hydroxide in water or aq alcohol or acetone, or even sodium carbonate,¹⁶⁶⁶ is a strong enough base for the reaction. If at least one Z group is COOR', saponification is a possible side reaction. In addition to the groups listed above, Z may also be phenyl, but if two phenyl groups are on the same carbon, the acidity is less than in the other cases and a stronger base must be used. However, the reaction can be successfully carried out with diphenylmethane with NaNH₂ as the base.¹⁶⁶⁷ If the solvent used in the reaction is acidic enough to protonate either the enolate anion or the base, an equilibrium will be established leading to only small amounts of the enolate anion (thermodynamic conditions). Such protic solvents include water, alcohols, or amines. To avoid this reaction, solvents that do not contain an acidic proton (aprotic solvents) are used, but protic solvents can be used in some cases. The use of polar aprotic solvents (e.g., DMF or DMSO), markedly increases the rate of alkylation¹⁶⁶⁸ but also increases the extent of alkylation at the oxygen rather than the carbon with highly reactive species (e.g., iodomethane, Sec. 10. G.viii). In general, enolate anions, such as those described here, react with alkyl halides via C-alkylation, although trialkylsilyl halides and anhydrides tend to react via O-alkylation. Phase-transfer catalysis has also been used,¹⁶⁶⁹ and the use of chiral phase-transfer catalysts led to enantioselectivity in the alkylated product.¹⁶⁷⁰ The reaction is successful for primary and secondary alkyl, allylic (with allylic rearrangement possible), and benzylic RX, but fails for tertiary halides, since these undergo elimination under the reaction conditions (see, however, Reaction 10-67). Various functional groups may be present in RX as long as they are not sensitive to base. Side reactions that may cause problems are the above-mentioned competing O-alkylation, elimination (if the enolate anion is a strong enough base), and dialkylation.

With substrates (e.g., ZCH₂Z') it is possible to alkylate twice. Initial removal of the proton with a base followed by alkylation of the resulting enolate anion with RX, can be

β -Keto sulfoxides [e.g., **156** or sulfones ($-\text{SO}_2-$)] are easily prepared (Reaction **16-86**). When one group attached to the sulfur atom is chiral, the alkylation proceeds with reasonable enantioselectivity.¹⁶⁷⁸

Other examples of the reaction are the *cyanoacetic ester synthesis*, in which Z is CO_2Et and Z' is CN (as in the malonic ester synthesis, the product here can be hydrolyzed and decarboxylated), and the *Sorensen* method of amino acid synthesis, using *N*-acetylamino malonic esters, $(\text{EtO}_2\text{C})_2\text{CHNHCOCH}_3$. Hydrolysis and decarboxylation of the product in this case gives an α -amino acid. The amino group is also frequently protected by conversion to a phthalimido group.

The reaction is not limited to $\text{Z}-\text{CH}_2-\text{Z}'$ compounds. Other compounds have acidic CH hydrogens. Some examples are the methyl hydrogens of α -aminopyridines, the methyl hydrogens of ynamines of the form $\text{CH}_3\text{C}\equiv\text{CNR}_2$ ¹⁶⁷⁹ (the product in this case can be hydrolyzed to an amide $\text{RCH}_2\text{CH}_2\text{CONR}_2$), the CH_2 hydrogens of cyclopentadiene and its derivatives (Sec. 2.I.ii), hydrogens connected to a triple-bond carbon (Reaction **10-74**), and the hydrogen of HCN (Reaction **10-75**) can also be removed with a base and the resulting ion alkylated (see also, Reactions **10-68–10-72**). α -Imino esters have been used since treatment with a strong base with a titanium catalyst followed by an aldehyde leads to hydroxy amino esters.¹⁶⁸⁰

Alkylation takes place at the most acidic position of a reagent molecule; for example, acetoacetic ester ($\text{CH}_3\text{COCH}_2\text{COOEt}$) is alkylated at the methylene and not at the methyl group, because the former is more acidic than the latter, and hence gives up its proton to the base. However, if 2 molar equivalents of base are used, then not only is the most acidic proton removed but also the second most acidic. Alkylation of this doubly charged anion (a dianion) occurs at the less acidic position, in this case the second most acidic position¹⁶⁸¹ (see Sec. 10.G.vii). The first and second ion pair acidities of β -diketones has been studied.¹⁶⁸²

When ω,ω' -dihalides are used, ring closures can be effected.¹⁶⁸³

This method has been used to close rings of three ($n=0$) to seven members, although five-membered ring closures proceed in highest yields. Another ring-closing method involves internal alkylation.¹⁶⁸⁴

This method has been shown to be applicable to medium rings (10–14 members) without the use of high-dilution techniques.¹⁶⁸⁵

The mechanism of these reactions is usually S_N2 with inversion taking place at a chiral RX, although an SET¹⁶⁸⁶ mechanism may be involved in certain cases,¹⁶⁸⁷ especially where the nucleophile is an α -nitro carbanion¹⁶⁸⁸ and/or the substrate contains a nitro or cyano¹⁶⁸⁹ group. Tertiary alkyl groups can be introduced by an S_N1 mechanism if the ZCH_2Z' compound (not the enolate anion) is treated with a tertiary carbocation generated *in situ* from an alcohol or alkyl halide and BF_3 or $AlCl_3$,¹⁶⁹⁰ or with a tertiary alkyl perchlorate.¹⁶⁹¹

Alkylation α to a nitro group can be achieved with the *Katritzky pyrylium–pyridinium reagents*.¹⁶⁹² This reaction probably has a free radical mechanism.¹⁶⁹³

10-68 Alkylation of Ketones, Aldehydes, Nitriles, and Carboxylic Esters

α -Acylalkyl-de-halogenation, and so on

Ketones,¹⁶⁹⁴ nitriles,¹⁶⁹⁵ and carboxylic esters¹⁶⁹⁶ can be alkylated in the α position in a reaction similar to **10-67**.¹⁶⁵² The pK_a of the proton α to the carbonyl or CN is in the range of 19–25 depending on the number of substituents (see Table 8.1), and a base that has a conjugate acid with a pK_a greater than that proton must be employed. Note that since only one activating group is present, compared with two activating groups for the substrates in Reaction **10-67**, the pK_a of the α -proton is higher (a weaker acid) and a stronger base is required. Reaction of the α -proton with the base generates the key nucleophilic

intermediate, an enolate anion (**157**). The most common bases¹⁶⁹⁷ are lithium diethylamide (Et_2NLi), lithium diisopropylamide [$(\text{Me}_2\text{CH})_2\text{NLi}$, LDA],¹⁶⁹⁸ lithium hexamethyldisilazide [$\text{LiN}(\text{SiMe}_3)_2$], $t\text{-BuOK}$, NaNH_2 , and KH . The base lithium N -isopropyl- N -cyclohexylamide (LICA) is particularly successful for carboxylic esters¹⁶⁹⁹ and nitriles.¹⁷⁰⁰ Enolate anion formation with lithium amides can also be regioselective (see Reaction **12-22**).¹⁷⁰¹ Lithium enolate anions exist as aggregates in solution.¹⁷⁰² The mechanism for this deprotonation reaction has been studied,¹⁷⁰³ as has the rate of deprotonation.¹⁷⁰⁴

Solid KOH in Me_2SO has been used to methylate ketones, in high yields.¹⁷⁰⁵ Some of these bases are strong enough to convert the ketone, nitrile, or ester completely to its enolate anion conjugate base; others (especially $t\text{-BuOK}$) convert a significant fraction of the molecules. In the latter case, the *aldol reaction* (**16-34**) or *Claisen condensation* (**16-85**) may be side reactions, since under the thermodynamic conditions associated with this base both the free molecule and its conjugate base are present at the same time. Both lactones¹⁷⁰⁶ and lactams are similarly alkylated.¹⁷⁰⁷ Protic solvents are generally not suitable because they protonate the base (though of course this is not a problem with a conjugate pair, e.g., $t\text{-BuOK}$ in $t\text{-BuOH}$). Some common solvents are DME, THF, DMF, and liquid NH_3 . Phase-transfer catalysis has been used to alkylate many nitriles, as well as some esters and ketones.¹⁷⁰⁸ Amino acid surrogates (**158**, $\text{R}=\text{N}$ derivative) can be alkylated, often under phase-transfer conditions.¹⁷⁰⁹

Direct alkylation of aldehydes is difficult when bases (e.g., KOH and NaOMe) are used, due to rapid aldol reaction (**16-34**), but aldehydes bearing only one α hydrogen have been alkylated with allylic and benzylic halides in good yields using the base KH to prepare the potassium enolate,¹⁷¹⁰ or in moderate yields, by the use of a phase-transfer catalyst.¹⁷¹¹

Even the use of amide bases (e.g., lithium diisopropylamide, LDA), lithium hexamethyl disilazide (LHMDS), or lithium tetramethylpiperidide (LTMP) to generate the enolate anion in an aprotic solvent (e.g., ether or THF) cannot completely suppress rapid aldol side reactions.

As in Reaction **10-67**, the alkyl halide that reacts with the enolate anion may be primary or secondary. Tertiary halides give elimination. Even primary and secondary halides may give predominant elimination if the enolate anion is a strong enough base (e.g., the enolate anion from Me_3CCOMe).¹⁷¹² Tertiary alkyl groups, as well as other groups that normally give $\text{S}_{\text{N}}1$ reactions, can be introduced if the reaction is performed on a silyl enol ether¹⁷¹³ of a ketone, aldehyde, or ester (see **158**) with a Lewis acid catalyst.¹⁷¹⁴ Tertiary alkyl fluorides were coupled to silyl enol ethers with $\text{BF}_3 \cdot \text{etherate}$.¹⁷¹⁵ Note that tin enolates ($\text{C}=\text{C}-\text{OSnR}_3$) react with halides in the presence of a Zn catalyst.¹⁷¹⁶ A chiral variation of this latter reaction was reported involving generation of the enolate anion in the presence of Me_3SnCl , a Pd catalyst, and a chiral ligand.¹⁷¹⁷

Metal-catalyzed alkylations that are related to this reaction are known. 1,3-Diketones are benzylated or allylated using Bi catalysts.¹⁷¹⁸ Monoalkylation is possible using Pd catalysts,¹⁷¹⁹ and Pd catalyzed asymmetric allylic alkylation is known.¹⁷²⁰ α -Alkylation of ketones with alcohols uses a Ru catalyst,¹⁷²¹ or Ni nanoparticles.¹⁷²² A recyclable Pd catalyst is available.¹⁷²³ Zinc enolate anions have been used in enantioselective Pd catalyzed alkylation reactions.¹⁷²⁴

Silyl enol ethers can be converted to the enolate anion, which can then be alkylated in the usual manner. The reaction of silyl enol ether (**159**) with KOEt followed by LiBr and a catalytic amount of *n*-butyllithium with allyl iodide gave **160**.¹⁷²⁵ Metal-catalyzed alkylation reactions are known with silyl enol ethers, including an In catalyzed¹⁷²⁶ reaction. An Ir catalyzed regioselective and enantioselective alkylation of silyl enol ethers using allylic carbonates as a substrate has been reported.¹⁷²⁷

The metal-catalyzed (usually Ni) coupling reaction of an alkyl halide or an electrophilic substrate with a silane¹⁷²⁸ is known as *Hiyama coupling*.¹⁷²⁹ A Ni catalyzed Hiyama cross-coupling with a chiral additive leads to a chiral alkylated ketone.¹⁷³⁰ The nature of the ligand has an important impact on the reaction.¹⁷³¹ There is a Pd catalyzed Hiyama cross-coupling.¹⁷³² Aryl siloxanes have been used in this reaction.¹⁷³³

Enol carbonates react with alkylating agents in the presence of a Pd catalyst. The decarboxylative alkylation of allyl enol carbonates to the corresponding allylcyclohexanone derivatives is known.¹⁷³⁴ An asymmetric version of this reaction has been reported.¹⁷³⁵ The same reaction can be done using enolate anion and allylic acetates with a Pd catalyst.¹⁷³⁶

Vinyllic and aryl halides can be used to vinylate or arylate carboxylic esters (but not ketones) by the use of NiBr₂ as a catalyst.¹⁷³⁷ Ketones have been vinylated by treating their enol acetates with vinyllic bromides in the presence of a Pd catalyst,¹⁷³⁸ but direct reaction of a ketone, a vinyl halide, sodium *tert*-butoxide and a Pd catalyst also give the α -vinyl ketone.¹⁷³⁹ Also as in Reaction 10-67, this reaction can be used to close rings.¹⁷⁴⁰ Rings have been closed by treating a dianion of a dialkyl succinate with a 1, ω -dihalide or ditosylate.¹⁷⁴¹ This was applied to the synthesis of three-, four-, five-, and six-membered rings. When the attached groups were chiral (e.g., menthyl) the product was formed with > 90% ee.¹⁷⁴⁰

Efficient enantioselective alkylations are known,¹⁷⁴² including the use of a chiral base to form the enolate anion.¹⁷⁴³ Alternatively, a chiral auxiliary can be attached. Many auxiliaries are based on the use of chiral amides¹⁷⁴⁴ or esters.¹⁷⁴⁵ Subsequent formation of the enolate anion allows alkylation to proceed with high enantioselectivity. A subsequent step is required to convert the chiral amide or ester to the corresponding carboxylic acid. Chiral additives can also be used,¹⁷⁴⁶ and the influence of chelating ligands and hydrocarbon cosolvents has been studied for $\text{LiN}(\text{TMS})_2$ mediated enolization reactions.¹⁷⁴⁷ The addition of triethylamine influences the (*E/Z*) selectivity of the enolate anion.¹⁷⁴⁸ Dynamic kinetic resolution has been used for the asymmetric alkylation of malonate derivatives using allenyl acetates.¹⁷⁴⁹

When the compound to be alkylated is an unsymmetrical ketone, the question arises as to which side will be alkylated (regioselectivity). If a phenyl or a vinylic group is present on one side, alkylation goes predominantly on that side. When only alkyl groups are present, the reaction is generally not regioselective; mixtures are obtained in which sometimes the more alkylated and sometimes the less alkylated side is predominantly alkylated. Which product is found in higher yield depends on the nature of the substrate, the base,¹⁷⁵⁰ the cation, and the solvent. In any case, di- and trisubstitution are frequent¹⁷⁵¹ and it is often difficult to stop with the introduction of just one alkyl group.¹⁷⁵²

Several methods have been developed for ensuring that alkylation takes place regioselectively on the *desired* side of a ketone.¹⁷⁵³ Among these are the following:

1. Block one side of the ketone by introducing a removable group. Alkylation takes place on the other side; the blocking group is then removed. A common reaction for this purpose is formylation with ethyl formate (Reaction **16-86**). This generally blocks the less hindered side. The formyl group is easily removed by alkaline hydrolysis (Reaction **12-43**).
2. Introduce an activating group on one side. Alkylation then takes place on that side (Reaction **10-67**). The activating group is then removed.

3. Prepare the desired one of the two possible enolate anions.¹⁷⁵⁴ The two ions (e.g., **161** and **162**) for

2-heptanone, interconvert rapidly only in the presence of the parent ketone or any stronger acid.¹⁷⁵⁵ In the absence of such acids, it is possible to prepare either **161** or **162** and thus achieve selective alkylation on either side of the ketone.¹⁷⁵⁶ The desired enolate anion can be obtained by treatment of the corresponding enol acetate with 2 equiv of methyllithium in 1,2-dimethoxyethane. Each enol acetate gives the corresponding enolate, for example,

The enol acetates, in turn, can be prepared by treatment of the parent ketone with an appropriate reagent.¹⁷⁴⁵ Such treatment generally gives a mixture of the two enol acetates in which one or the other predominates, depending on the reagent. The mixtures are easily separable.¹⁷⁵⁵ An alternate procedure involves conversion of a silyl enol ether¹⁷⁵⁷ (see Reaction 12-17) or a dialkylboron enol ether¹⁷⁵⁸ (an enol borinate, see Reaction 10-73) to the corresponding enolate anion. If the less hindered enolate anion is desired (e.g., **161**), it can be prepared directly from the ketone by treatment with LDA in THF or DME at -78°C .¹⁷⁵⁹

4. Begin not with the ketone itself, but with an α,β -unsaturated ketone in which the double bond is present on the side where alkylation is desired. Upon treatment with lithium in liquid NH_3 , such a ketone is reduced to an enolate anion. When the alkyl halide is added, it must react with the enolate anion on the side where the double bond was.¹⁷⁶⁰ Of course, this method is not actually an alkylation of the ketone, but of the α,β -unsaturated ketone, although the product is the same as if the saturated ketone had been alkylated on the desired side.

Both sides of acetone have been alkylated with different alkyl groups, in one operation, by treatment of the *N,N*-dimethylhydrazone of acetone with *n*-BuLi, followed by a primary alkyl, benzylic, or allylic bromide or iodide; then another mole of *n*-BuLi, a second halide, and finally hydrolysis of the hydrazone.¹⁷⁶¹ Alkylation of an unsymmetrical ketone at the more substituted position was reported using an alkyl bromide, NaOH, and a calix[*n*]arene catalyst (see Sec. 4.H. category 2 for calixarenes).¹⁷⁶²

Among other methods for the preparation of alkylated ketones are (1) Alkylation of silyl enol ethers using various reagents as noted above, (2) the *Stork enamine reaction* (Reaction 10-69), (3) the acetoacetic ester synthesis (Reaction 10-67), (4) alkylation of β -keto sulfones or sulfoxides (Reaction 10-67), (5) acylation of $\text{CH}_3\text{SOCH}_2^-$ followed by reductive cleavage (Reaction 16-86), (6) treatment of α -halo ketones with lithium dialkylcopper reagents (Reaction 10-57), and (7) treatment of α -halo ketones with trialkylboranes (Reaction 10-73).

Aldehydes can be indirectly alkylated via an imine derivative of the aldehyde.¹⁷⁶³ The derivative is easily prepared (Reaction 16-13) and the product easily hydrolyzed to the aldehyde (Reaction 16-2). Either or both R groups may be hydrogen, so that mono-, di-, and trisubstituted acetaldehydes can be prepared by this method. The R' group may be primary alkyl, allylic, or benzylic. Imine alkylation can also be applied to the preparation of substituted amine derivatives. An amino acid surrogate (e.g., $\text{Ph}_2\text{C}=\text{NCH}_2\text{CO}_2\text{R}$), when treated with KOH and an alkyl halide gives the C-alkylated product.¹⁷⁶⁴ When a chiral additive is used, good enantioselectivity was observed. This reaction has also been done in the ionic liquid Bmim tetrafluoroborate (see Sec. 9.D.iii).¹⁷⁶⁵ It is possible to alkylate α -amino amides directly.¹⁷⁶⁶

Hydrazones and other compounds with C=N bonds can be similarly alkylated.¹⁷⁴³ The use of chiral amines or hydrazines¹⁷⁶⁷ [followed by hydrolysis (Reaction 16-2) of the alkylated imine] can lead to chiral alkylated ketones in high optical yields¹⁷⁶⁸ (for an example, see Sec. 4.J). Lithiated imines are generated by the treatment of an imine with a

suitable base, and reaction with an alkyl halide gives the alkylated imine.¹⁷⁶⁹ α -Magnesio imines also react with alkyl halides.¹⁷⁷⁰

In α,β -unsaturated ketones, nitriles, and esters (e.g., **163**), the γ hydrogen assumes the acidity normally held by the position α to the carbonyl group, especially when R is not hydrogen and so cannot compete. This principle, called *vinylity* (see Sec. 6.B), operates because the resonance effect is transmitted through the double bond. However, because of the resonance, alkylation at the α position (with allylic rearrangement) competes with alkylation at the γ position and usually predominates.

α -Hydroxynitriles (cyanohydrins), protected by conversion to acetals with ethyl vinyl ether (Reaction **15-5**), can be easily alkylated with primary or secondary alkyl or allylic halides.¹⁷⁷¹ The R group can be aryl or a saturated or unsaturated alkyl. Since the cyanohydrins¹⁷⁷² are easily formed from aldehydes (Reaction **16-52**) and the product is easily hydrolyzed to a ketone, this is a method for converting an aldehyde (RCHO) to a ketone (RCOR')¹⁷⁷³ (for other methods, see Reactions **10-71**, **16-82**, and **18-9**).¹⁷⁷⁴ In this procedure, the normal mode of reaction of a carbonyl carbon is reversed. The C atom of an aldehyde molecule is normally electrophilic and is attacked by nucleophiles (Chapter 16), but by conversion to the protected cyanohydrin this carbon atom has been induced to perform as a nucleophile.¹⁷⁷⁵ The German word *Umpolung*¹⁷⁷⁶ is used to describe this kind of reversal (another example is found in Reaction **10-71**). Since the ion **164** serves as a substitute for the unavailable $\text{R}(\text{C}=\text{O})^-$ anion, it is often called a “masked” $\text{R}(\text{C}=\text{O})^-$ ion.

This method fails for formaldehyde ($R = H$), but other masked formaldehydes have proved successful.¹⁷⁷⁷ In an interesting variation of nitrile alkylation, a quaternary bromide [$\text{PhC}(\text{Br})(\text{Me})\text{CN}$] reacted with allyl bromide, in the presence of a *Grignard reagent*, to give the alkylated product [$\text{PhC}(\text{CN})(\text{Me})\text{CH}_2\text{CH}=\text{CH}_2$].¹⁷⁷⁸

A coupling reaction of two ketones to form a 1,4-diketone has been reported, using $\text{ZnCl}_2/\text{Et}_2\text{NH}$.¹⁷⁷⁹ An interesting allylic substitution at a 3° center involves the reaction of 3° 2-bromonitriles with $i\text{PrMgBr}$ and allyl bromide to give the 2-allyl nitrile.¹⁷⁸⁰

α -Alkylation of ketones with primary alcohols is possible using polymer-associated nanoparticulate Pd.¹⁷⁸¹

Protonation of enolate anions is discussed in Reaction 16-34, in connection with the aldol condensation.

10-69 The Stork Enamine Reaction

α -Acylalkyl-de-halogenation¹⁷⁸²

When enamines are treated with alkyl halides, an alkylation occurs to give an iminium salt via electron transfer from the electron pair on nitrogen, through the $\text{C}=\text{C}$ to the electrophilic carbon of the alkyl halide.¹⁷⁸³ In effect, an enamine behaves as a “nitrogen enolate anion” and generally reacts as carbon nucleophiles.¹⁷⁸⁴ Hydrolysis of the iminium salt gives a ketone. Since the enamine is normally formed from a ketone (Reaction 16-13), the net result is alkylation of the ketone at the α position. The method, known as the *Stork enamine reaction*,¹⁷⁸⁵ is an alternative to the ketone alkylation considered in Reaction 10-68, generally giving monoalkylation of the ketone. Alkylation usually takes place on the less substituted side of the original ketone. The most commonly used amines are the cyclic amines piperidine, morpholine, and pyrrolidine. There are metal-catalyzed enamine alkylation reactions, including the use of Ir catalysts.¹⁷⁸⁶ There are reactions that are catalyzed by enamines, including asymmetric reactions.¹⁷⁸⁷

The method is quite useful for particularly active alkyl halides, (e.g., allylic, benzylic, and propargylic halides), and for α -halo ethers and esters. Other primary and secondary halides can show sluggish reactivity. The reaction of enamines with benzotriazole derivatives has been reported.¹⁷⁸⁸ Tertiary halides do not give the reaction at all since, with respect to the halide, this is nucleophilic substitution and elimination predominates. The reaction can also be applied to activated aryl halides (e.g., 2,4-dinitrochlorobenzene; see Chapter 13), to epoxides,¹⁷⁸⁹ and to activated alkenes (e.g., acrylonitrile). The latter is a *Michael-type reaction* (**15-24**) with respect to the alkene.

Acylation¹⁷⁹⁰ can be accomplished with acyl halides or with anhydrides. Hydrolysis of the resulting iminium salt leads to a 1,3-diketone. A COOEt group can be introduced by treatment of the enamine with ethyl chloroformate (ClCOOEt;¹⁷⁹¹ a CN group with cyanogen chloride¹⁷⁹² (not cyanogen bromide or iodide, which leads to halogenation of the enamine); a CHO group with the mixed anhydride of formic and acetic acids¹⁷⁹¹ or with DMF and phosgene,¹⁷⁹³ and a C(R)=NR' group with a nitrilium salt RC \equiv N⁺R'.¹⁷⁹⁴ The acylation of the enamine can take place by the same mechanism as alkylation, but another mechanism is also possible, if the acyl halide has an α hydrogen and if a tertiary amine is present, as it often is (it is added to neutralize the HX given off). In this mechanism, the acyl halide is dehydrohalogenated by the tertiary amine, producing a ketene (Reaction **17-14**), which adds to the enamine to give a cyclobutanone (Reaction **15-63**). This compound can be cleaved in the solution to form the same acylated imine salt (that would form by the more direct mechanism, or it can be isolated (in the case of enamines derived from aldehydes), or it may cleave in other ways.¹⁷⁹⁵

N-Alkylation can be a problem, particularly with enamines derived from aldehydes. An alternative method, which gives good yields of alkylation with primary and secondary halides, is alkylation of enamine *salts*, which are prepared by treating an imine with ethylmagnesium bromide in THF:¹⁷⁹⁶

The imines are prepared by the reaction of secondary amines with aldehydes or ketones, mainly ketones (**16-13**). The enamine salt method has also been used to give good yields of mono α alkylation of α,β -unsaturated ketones.¹⁷⁹⁷ Enamines prepared from aldehydes and

butylisobutylamine can be alkylated by simple primary alkyl halides in good yields.¹⁷⁹⁸ N-Alkylation in this case is presumably prevented by steric hindrance.

When the nitrogen of the substrate contains a chiral R group, both the *Stork enamine synthesis* and the enamine salt method can be used to perform enantioselective syntheses.¹⁷⁹⁹ The use of *S*-proline can generate a chiral enamine *in situ*, thus allowing alkylation to occur, giving alkylated product with good enantioselectivity. The reaction has been done intramolecularly.¹⁸⁰⁰

Conjugate addition (*Michael addition*) occurs when enamines react with conjugated ketones. This reaction is discussed in Reaction **15-24**.

OS V, 533, 869; VI, 242, 496, 526; VII, 473.

10-70 Alkylation of Carboxylic Acid Salts

α -Carboxyalkyl-de-halogenation

Carboxylic acids can be alkylated in the α position by conversion of their salts to dianions, which have resonance contributors,¹⁸⁰¹ by treatment with a strong base (e.g., LDA).¹⁸⁰² The use of Li^+ as the counterion increases the solubility of the dianionic salt. The reaction has been applied¹⁸⁰³ to primary alkyl, allylic, and benzylic halides, and to carboxylic acids of the form $\text{RCH}_2\text{CO}_2\text{H}$ and $\text{RR}^2\text{CHCO}_2\text{H}$.¹⁶⁹⁵ Alkylation occurs at carbon, the more nucleophilic site relative to the carboxylate oxygen anion (see Sec. 10.G.vii). This procedure is an alternative to the malonic ester synthesis (Reaction **10-67**) as a means of preparing carboxylic acids and has the advantage that acids of the form $\text{RR}'\text{R}^2\text{CCO}_2\text{H}$ can also be prepared. In a related reaction, methylated aromatic acids can be alkylated at the methyl group by a similar procedure.¹⁸⁰⁴

The presence of a sulfur atom on a carbon enhances the acidity of a proton on that carbon, and in dithioacetals and dithioketals that proton RSCH_2SR is even more acidic. 1,3-Dithianes can be alkylated¹⁸⁰⁵ if a proton is first removed by treatment with butyllithium in THF.¹⁸⁰⁶ Since 1,3-dithianes can be prepared by treatment of an aldehyde or its acetal (see OS VI, 556) with 1,3-propanedithiol (Reaction 16-11) and can be hydrolyzed (Reaction 10-7), this is a method for the conversion of an aldehyde to a ketone¹⁸⁰⁷ (see also, Reactions 10-68 and 18-9):

This is another example of Umpolung (see Reaction 10-68);¹⁷⁷³ the normally electrophilic carbon of the aldehyde is made to behave as a nucleophile. The reaction can be applied to the unsubstituted dithiane ($\text{R}=\text{H}$) and one or two alkyl groups can be introduced, so a wide variety of aldehydes and ketones can be made starting with formaldehyde.¹⁸⁰⁸ The R' group may be a primary or secondary alkyl or benzylic. Iodides give the best results. The reaction has been used to close rings.¹⁸⁰⁹ A similar synthesis of aldehydes can be performed starting with ethyl ethylthiomethyl sulfoxide ($\text{EtSOCH}_2\text{SEt}$).¹⁸¹⁰

Group **A** may be regarded as a structural equivalent for carbonyl group **B**, since introduction of **A** into a molecule is actually an indirect means of introducing **B**. It is convenient to have a word for units within molecules. Such a word is *synthon*, introduced by Corey,¹⁸¹¹ which is defined as a structural unit within a molecule that can be formed and/or assembled by known or conceivable synthetic operations. There are many other synthons equivalent to **A** and **B** (e.g., **C**; by Reactions 19-36 and 19-3) and **D** (by Reactions 10-2 and 16-23).¹⁸¹²

Carbanions generated from 1,3-dithianes also react with epoxides¹⁸¹³ to give the expected products. Reaction with epoxides leads to intermediates that undergo the *Brook rearrangement* (Reaction 18-44), which is synthetically useful in what is known as *anion relay chemistry*.

Another useful application of this reaction stems from the fact that dithianes can be desulfurated with *Raney nickel* (Reaction **14-27**). Aldehydes can therefore be converted to chain-extended hydrocarbons:¹⁸¹⁴

Similar reactions have been carried out with other thioacetals, as well as with compounds containing three thioether groups on a carbon.¹⁸¹⁵

If a stabilizing group other than sulfur is attached to the S—CH₂ unit of a thioether (RSCH₂X, where X is a stabilizing group), formation of the anion and alkylation can be facile. For example, benzylic and allylic thioethers (RSCH₂Ar and RSCH₂CH=CH₂)¹⁸¹⁶ and thioethers of the form RSCH₃ (R = tetrahydrofuranyl or 2-tetrahydropyranyl)¹⁸¹⁷ have been successfully alkylated at the carbon adjacent to the sulfur atom.¹⁸¹⁸ Stabilization by one thioether group has also been used in a method for the homologation of primary halides.¹⁸¹⁹ Thioanisole is treated with BuLi to give the corresponding anion,¹⁸²⁰ which reacts with the halide to give the thioether, which is then refluxed with a mixture of methyl iodide and sodium iodide in DMF to give the alkyl iodide as the final product (via an intermediate sulfonium salt). By this sequence, an alkyl halide (RX) is converted to its homologue RCH₂X by a pathway involving two laboratory steps (see also, Reaction **10-64**).

Vinylic sulfides containing an α hydrogen can also be alkylated¹⁸²¹ by alkyl halides or epoxides. This method is for converting an alkyl halide (RX) to an α,β-unsaturated aldehyde, which is the synthetic equivalent of the unknown [−]HC=CH—CHO ion.¹⁸²² Even simple alkyl aryl sulfides (RCH₂SAr and RR'CHSAr) have been alkylated α to the sulfur.¹⁸²³

Sulfones¹⁸²⁴ and sulfonic esters can also be alkylated in the α position if strong enough bases are used.¹⁸²⁵ Alkylation at the α position of selenoxides allows the formation of alkenes, since selenoxides easily undergo elimination (Reaction **17-12**).¹⁸²⁶

Alkylation can also be carried out, in certain compounds, at positions α to other heteroatoms,¹⁸²⁷ for example, at a position α to the nitrogen of tertiary amines.¹⁸²⁸ Alkylation α to the nitrogen of primary or secondary amines is not generally feasible because an NH hydrogen is usually more acidic than a CH hydrogen.

α-Lithiation of *N*-Boc amines has been accomplished and these react with halides in the presence of a Pd catalyst.¹⁸²⁹ Alkylation α to the nitrogen atom of a carbamate occurs when the carbamate is treated with a *Grignard reagent* under electrolysis conditions.¹⁸³⁰ α-Methoxy amides also react with allyl halides and zinc metal to give alkylation via replacement of the OMe unit.¹⁸³¹ It has been accomplished, however, by replacing the NH hydrogens with other (removable) groups.¹⁸³² In one example, a secondary amine is converted to its *N*-nitroso derivative (Reaction **12-50**).¹⁸³³ The *N*-nitroso product is easily hydrolyzed to the product amine (Reaction **19-51**).¹⁸³⁴ Alkylation of secondary and primary amines has also been accomplished with > 10 other protecting groups, involving conversion of amines to amides, carbamates,¹⁸³⁵ formamidines,¹⁸³⁶ and phosphoramides.¹⁸³¹ In the case of formamidines (**165**), use of a chiral R' leads to a chiral amine, in high ee, even when R is not chiral.¹⁸³⁷ The reaction of hydrazones with aryl halides, in the presence of a Pd catalyst leads to replacement of H with an aryl group (R'NH—N=CRH → R'NHC=NRR").¹⁸³⁸

A proton can be removed from an allylic ether by treatment with an alkyllithium at about -70°C (at higher temperatures the *Wittig rearrangement*, **18-22**, takes place) to give the ion **166**, which reacts with alkyl halides

to give the two products shown.¹⁸³⁹ Similar reactions¹⁸⁴⁰ have been reported for allylic¹⁸⁴¹ and vinylic tertiary amines. In the latter case, enamines (**167**), treated with a strong base, are converted to anions that are then alkylated, generally at C-3.¹⁸⁴² (For direct alkylation of enamines at C-2, see Reaction **10-69**.)

It is also possible to alkylate a methyl, ethyl, or other primary group of an aryl ester (ArCO_2R), where Ar is a 2,4,6-trialkylphenyl group.¹⁸⁴³ Since esters can be hydrolyzed to alcohols, this constitutes an indirect alkylation of primary alcohols. Methanol has also been alkylated by converting it to $^-\text{CH}_2\text{O}^-$.¹⁸⁴⁴

10-72 Alkylation of Dihydro-1,3-Oxazine. The Meyers Synthesis of Aldehydes, Ketones, and Carboxylic Acids

A synthesis of aldehydes¹⁸⁴⁵ developed by Meyers et al.¹⁸⁴⁶ begins with the commercially available dihydro-1,3-oxazine derivatives (**168**; A = H, Ph, or COOEt).¹⁸⁴⁷ Removal of a proton from the indicated carbon in **168** leads to the resonance stabilized and bidentate anion (**169**). Alkylation occurs regioselectively at carbon using many alkyl bromides and iodides. The R group of RX can be primary or secondary alkyl, allylic, or benzylic and can carry another halogen or a CN group.¹⁸⁴⁸ The alkylated oxazine (**170**) is then reduced and hydrolyzed to give an aldehyde containing two more carbons than the starting RX. This method thus complements Reaction **10-71**, which converts RX to an aldehyde containing

one more carbon. Since A can be H, mono- or disubstituted acetaldehydes can be produced by this method.

The ion **169** also reacts with epoxides, to form γ -hydroxy aldehydes after reduction and hydrolysis,¹⁸⁴⁹ and with aldehydes and ketones (Reaction **16-38**). Similar aldehyde synthesis has also been carried out with thiazoles¹⁸⁵⁰ and thiazolines¹⁸⁵¹ (five-membered rings containing N and S in the 1 and 3 positions).

The reaction has been extended to the preparation of ketones:¹⁸⁵² Treatment of a dihydro-1,3-oxazine (**171**) with iodomethane forms the iminium salt (Reaction **10-31**) which, when treated with a *Grignard reagent* or organolithium compound (**16-31**), produces **172**, which can be hydrolyzed to a ketone. The R group can be alkyl, cycloalkyl, aryl, benzylic, and so on, and R' of the *Grignard reagent* can be alkyl, aryl, benzylic, or allylic. Note that the heterocycles **168**, **170**, or **171** do not react directly with *Grignard reagents*. In another procedure, 2-oxazolines¹⁸⁵³ (**173**) can be alkylated to give **174**,¹⁸⁵⁴ which are easily converted directly to the esters **175** by heating in 5–7% ethanolic sulfuric acid.

2-Oxazolines (**173** and **174**) are thus synthons for carboxylic acids; this is another indirect method for the α alkylation of a carboxylic acid,¹⁸⁵⁵ representing an alternative to the malonic ester synthesis (**10-67**) and to Reactions **10-70** and **10-73**. The method can be adapted to the preparation of optically active carboxylic acids by the use of a chiral reagent.¹⁸⁵⁶ Note that, unlike **168**, **173** can be alkylated even if R is alkyl. However, the C=N bond of **173** and **174** cannot be effectively reduced, so that aldehyde synthesis is not feasible here.¹⁸⁵⁷

10-73 Alkylation with Boranes, Boronic Acids, and Boronates

Alkyl-de-halogenation

Trialkylboranes react rapidly and in high yields with α -halo ketones,¹⁸⁵⁸ α -halo esters,¹⁸⁵⁹ α -halo nitriles,¹⁸⁶⁰ and α -halo sulfonyl derivatives (sulfones, sulfonic esters, sulfonamides)¹⁸⁶¹ in the presence of a base to give, respectively, alkylated ketones, esters, nitriles, and sulfonyl derivatives.¹⁸⁶² Potassium *tert*-butoxide is often a suitable base, but potassium 2,6-di-*tert*-butylphenoxide at 0 °C in THF gives better results in most cases, possibly because the large bulk of the two *tert*-butyl groups prevents the base from coordinating with the R_3B .¹⁸⁶³ The trialkylboranes are prepared by treatment of 3 equiv of an alkene with 1 equiv of BH_3 (Reaction 15-16).¹⁸⁶⁴ With appropriate boranes, the R group transferred to α -halo ketones, nitriles, and esters can be vinylic,¹⁸⁶⁵ or (for α -halo ketones and esters) aryl.¹⁸⁶⁶

The reaction can be extended to α,α -dihalo esters¹⁸⁶⁷ and α,α -dihalo nitriles.¹⁸⁶⁸ It is possible to replace just one halogen or both. In the latter case, the two alkyl groups can be the same or different. When dialkylation is applied to dihalo nitriles, the two alkyl groups can be primary or secondary, but with dihalo esters, dialkylation is limited to primary R. Another extension is the reaction of boranes (BR_3) with γ -halo- α,β -unsaturated esters.¹⁸⁶⁹ Alkylation takes place in the γ position, but the double bond migrates out of conjugation with the CO_2Et unit [$\text{BrCH}_2\text{CH}=\text{CHCO}_2\text{Et} \rightarrow \text{RCH}=\text{CHCH}_2\text{CO}_2\text{Et}$]. In this case, however, double-bond migration is an advantage, because nonconjugated β,γ -unsaturated esters are usually much more difficult to prepare than their α,β -unsaturated isomers.

The alkylation of activated halogen compounds is one of several reactions of trialkylboranes developed by H.C. Brown¹⁸⁷⁰ (see also, Reactions 15-16, 15-27, 18-31–18-40, etc.). These compounds are extremely versatile and can be used for the preparation of many types of compounds. In this reaction, for example, an alkene (via the BR_3) can be coupled to a ketone, a nitrile, a carboxylic ester, or a sulfonyl derivative. Note that this is still

another indirect way to alkylate a ketone (see Reaction 10-68) or a carboxylic acid (see Reaction 10-70), and provides an additional alternative to the malonic ester and acetoacetic ester syntheses (Reaction 10-67).

Although superficially this reaction resembles Reaction 10-57, it is likely that the mechanism is quite different, involving migration of an R group from boron to carbon (see also, Reactions 18-23–18-26). The mechanism is not known with certainty,¹⁸⁷¹ but it may be tentatively shown as (illustrated for an α -halo ketone):

The first step is removal of the acidic proton by the base to give an enolate anion that combines with the borane (Lewis acid–base reaction). An R group then migrates, displacing the halogen leaving group.¹⁸⁷² Another migration follows, this time of BR_2 from carbon to oxygen to give the enol borinate (**176**),¹⁸⁷³ which is hydrolyzed. Configuration at the alkyl group R is retained.¹⁸⁷⁴

Alkenylboranes ($\text{R}'_2\text{C}=\text{CHBZ}_2$; Z = various groups) couple in high yields with vinylic,¹⁸⁷⁵ alkynyl, aryl, benzylic, and allylic halides or triflates in the presence of a Pd catalyst and a base to give $\text{R}'_2\text{C}=\text{CHR}$.¹⁸⁷⁶ 9-Alkyl-9-BBN compounds (Reaction 15-16) also couple with vinylic and aryl halides,¹⁸⁷⁷ as well as with α -halo ketones, nitriles, and esters.¹⁸⁷⁸

The reaction has also been applied to compounds with other leaving groups. Diazo ketones, diazo esters, diazo nitriles, and diazo aldehydes (**177**)¹⁸⁷⁹ react with trialkylboranes in a similar manner.

The mechanism is probably also similar. In this case, a base is not needed, since the carbon already has an available pair of electrons. The reaction with diazo aldehydes¹⁸⁸⁰ is

especially notable, since successful reactions cannot be obtained with α -halo aldehydes.¹⁸⁸¹

Alkyl¹⁸⁸² and aryl¹⁸⁸³ boronic acids $[\text{RB}(\text{OH})_2]$ react with allylic acetates to give the alkylated product in the presence of a Pd catalyst.¹⁸⁸⁴ A cyclopropylboronic acid was coupled to an allylic bromide with silver oxide/KOH and a Pd catalyst.¹⁸⁸⁵ Arylboronic acids undergo a coupling reaction with epoxides in the presence of a Pd catalyst.¹⁸⁸⁶ Alkylboronic acids can also be coupled to aromatic compounds in the presence of $\text{Cu}(\text{OAc})_2$ and a Pd catalyst.¹⁸⁸⁷ The Pd catalyzed coupling of vinyl halides and alkylboronic acids,¹⁸⁸⁸ which gives substituted alkenes, is related to the *Suzuki coupling* (Reaction **13-12**). Vinyl zirconium reagents were coupled to alkyl halides with a Pd catalyst.¹⁸⁸⁹ Arylation of sp^3 C—H positions can be done using arylboronates and a Rh catalyst.¹⁸⁹⁰ In a related but metal-free reaction, activated epoxides and aziridines are opened by borates.¹⁸⁹¹

Potassium aryl- and 1-alkenyltrifluoroborates (ArBF_3K and RBF_3K) are easily prepared from organoboronic acids or esters. In general, the trifluoroborates have greater air stability and greater nucleophilicity¹⁸⁹² when compared to the corresponding organoboranes and organoboronic acid derivatives. Potassium alkyltrifluoroborates undergo the Pd catalyzed coupling reaction with arenediazonium tetrafluoroborates,¹⁸⁹³ diaryliodonium salts,¹⁸⁹⁴ aryl halides,¹⁸⁹⁵ as well as with aryl triflates. An example of the latter reaction converted **178** to diphenylmethane via coupling with phenyl triflate.¹⁸⁹⁶ Alkenyltrifluoroborates can be coupled to aryl halides.¹⁸⁹⁷

10-74 Alkylation at an Alkynyl Carbon

Alkynyl-de-halogenation

The reaction between alkyl halides and acetylide ions is useful, but of limited scope.¹⁸⁹⁸ Only primary halides unbranched in the β -position give good yields, although allylic halides can be used if CuI is present.¹⁸⁹⁹ If acetylene is the reagent, two different groups can be successively attached. Sulfates, sulfonates, and epoxides¹⁹⁰⁰ are sometimes used as substrates. The acetylide ion is often prepared by treatment of an alkyne with a strong base (e.g., NaNH₂). Magnesium acetylides (prepared as in Reaction 12-22) are also frequently used, although they react only with active substrates (e.g., allylic, benzylic, and propargylic halides) and not with primary alkyl halides. Alternatively, the alkyl halide can be treated with a lithium acetylide–ethylenediamine complex.¹⁹⁰¹ If 2 equiv of a very strong base are used, alkylation can be effected at a carbon α to a terminal triple bond: $\text{RCH}_2\text{C}\equiv\text{CH} + 2\text{BuLi} \rightarrow \text{RCHC}(\text{C}^- + \text{R}'\text{Br}) \rightarrow \text{RR}'\text{CHC}\equiv\text{C}^-$.¹⁹⁰² For another method of alkylating at an alkynyl carbon, see Reaction 18-26. An alternative method for generating an alkyne anion treated a trialkylsilyl alkyne with potassium carbonate in methanol, and then methyllithium/LiBr.¹⁹⁰³ In the presence of an alkyl iodide, alkylation at the alkynyl carbon occurred. Terminal alkynes react with alkylzinc reagents in the presence of a Pd catalyst.¹⁹⁰⁴

Other metalated terminal alkynes can be coupled to substrates with a leaving group, and even with other organometallics. In the presence of a Pd catalysts, an alkynyltin reagent reacts with an alkylzinc compound to give the corresponding alkyne.¹⁹⁰⁵ Terminal alkynes react with allylic bromides in the presence of a Ni catalyst.¹⁹⁰⁶ The reaction of a terminal alkyne with Zn(II) compounds allows reaction with silanes to give the 1-silylalkyne.¹⁹⁰⁷ A Re catalyzed C–H insertion reaction is known using terminal alkynes and an active methylene compound.¹⁹⁰⁸ Alkynylzinc compounds undergo Pd catalyzed cross-coupling reactions.¹⁹⁰⁹

1-Haloalkynes react with various substrates in the presence of a metal catalyst. 1-Haloalkynes (e.g., $\text{R}-\text{C}\equiv\text{C}-\text{X}$ react with ArSnBu_3 and CuI to give $\text{R}-\text{C}\equiv\text{C}-\text{Ar}$.¹⁹¹⁰ Organozirconium compounds react in a similar manner.¹⁹¹¹ Acetylene reacts with 2 equiv of iodobenzene, in the presence of a Pd catalyst and CuI, to give 1,2-diphenylethyne.¹⁹¹²

10-75 Preparation of Nitriles

Cyano-de-halogenation

The reaction between cyanide ion and alkyl halides is a convenient method for the preparation of nitriles.¹⁹²⁹ The reaction proceeds by a $\text{S}_{\text{N}}2$ mechanism,¹⁹³⁰ so primary, benzylic, and allylic halides give good yields of nitriles; secondary halides give

¹⁹³⁰ For a discussion about the influence of solvent on this transition state, see Fang, Y.-r.; MacMillan, S.; Eriksson, J.; Kołodziejska-Huben, M.; Dybała-Defratyka, A.; Paneth, P.; Matsson, O.; Westaway, K.C. *J. Org. Chem.* **2006**, 71, 4742.

moderate yields. The reaction fails for tertiary halides, which give elimination under these conditions. Many other groups on the molecule do not interfere. A number of solvents have been used, but the high yields and short reaction times observed with DMSO make it a very good solvent for this reaction.¹⁹³¹ In general, polar aprotic solvents are the best choice. Other ways to obtain high yields under mild conditions are to use a phase-transfer catalyst,¹⁹³² in alternative solvents (e.g., PEG 400 (a polyethylene glycol)),¹⁹³³ or with ultrasound.¹⁹³⁴ This is an important way of increasing the length of a carbon chain by one carbon, since nitriles are easily hydrolyzed to carboxylic acids (Reaction 16-4).

The cyanide ion is an ambident nucleophile (it can react via N or via C) and isonitriles (also called isocyanides, $R-N\equiv C$) may be side products.¹⁹³⁵ If the preparation of isocyanides is desired (see Reaction 10-40), they can be made the main products by the use of reagents with more covalent metal-carbon bonds [e.g., silver or copper(I) cyanide,¹⁹³⁶ Sec. 10.G.vii, category 3]. However, the use of an excess of LiCN in acetone/THF gave the nitrile as the major product.¹⁹³⁷ Tosyl cyanide ($TOsO_2CN$) has been used in some cases.¹⁹³⁸ A radical cyanation of alkyl iodides has been reported using diethylphosphoryl cyanide¹⁹³⁹ (see Chap. 14).

Vinyl bromides can be converted to vinylic cyanides with $CuCN$,¹⁹⁴⁰ with KCN , a crown ether, and a Pd complex,¹⁹⁴¹ or with KCN and a $Ni(0)$ catalyst.¹⁹⁴² Halides can be converted to the corresponding nitriles by treatment with trimethylsilyl cyanide in the presence of catalytic amounts of $SnCl_4$: $R_3CCl + Me_3SiCN \rightarrow R_3CCN$.¹⁹⁴³ Primary, secondary, and tertiary alcohols are converted to nitriles in good yields by treatment with $NaCN$, Me_3SiCl , and a catalytic amount of NaI in $DMF-MeCN$.¹⁹⁴⁴ Lewis acids have been used in conjunction with $NaCN$ or KCN .¹⁹⁴⁵ α,β -Epoxy amides were opened to the β -cyano- α -hydroxyamide with Et_2AlCN .¹⁹⁴⁶ Cyanohydrins react with alkyl halides in some cases to give the nitrile.¹⁹⁴⁷

Substrates that react with cyanide may contain leaving groups other than halides (e.g., esters of sulfuric and sulfonic acids, sulfates and sulfonates, respectively). Vinylic triflates

10-76 Direct Conversion of Alkyl Halides to Aldehydes and Ketones

Formyl-de-halogenation

The direct conversion of alkyl bromides to aldehydes, with an increase in the chain length by one carbon, can be accomplished¹⁹⁵⁴ by treatment with sodium tetracarbonylferrate(-2)¹⁹⁵⁵ (*Collman's reagent*) in the presence of triphenylphosphine and subsequent quenching of **179** with acetic acid. The reagent Na₂Fe(CO)₄ can be prepared by treatment of iron pentacarbonyl [Fe(CO)₅] with sodium amalgam in THF. Good yields are obtained from primary alkyl bromides; secondary bromides give lower yields. The reaction is generally not satisfactory for benzylic bromides, but a good yield of the ketone was obtained using benzyl chloride and aryl iodides.¹⁹⁵⁶ The initial species produced from RX and Na₂Fe(CO)₄ is the ion RFe(CO)₄⁻, which can be isolated,¹⁹⁵⁷ it then reacts with Ph₃P to give **179**.¹⁹⁵⁸

The synthesis can be extended to the preparation of ketones in six distinct ways.¹⁹⁵⁹ These include quenching **179** with a second alkyl halide (R'X) rather than acetic acid; omitting PPh₃ with first RX and then adding the second, R'X; treatment with RX in the presence of CO,¹⁹⁵⁵ followed by treatment with R'X'; treatment with an acyl halide followed by treatment with an alkyl halide or an epoxide, gives an α,β -unsaturated

ketone.¹⁹⁶⁰ The final variations involve reaction of alkyl halides or tosylates with $\text{Na}_2\text{Fe}(\text{CO})_4$ in the presence of ethylene to give alkyl ethyl ketones,¹⁹⁶¹ when 1,4-dihalides are used, five-membered cyclic ketones are prepared.¹⁹⁶²

Yet another approach uses electrolysis conditions with the alkyl chloride, $\text{Fe}(\text{CO})_5$, and a Ni catalyst, which gives the ketone directly, in one step.¹⁹⁶³ In the first stage of methods 1, 2, and 3, primary bromides, iodides, and tosylates and secondary tosylates can be used. The second stage of the first-four methods requires more active substrates (e.g., primary iodides or tosylates or benzylic halides). Method 5 has been applied to primary and secondary substrates.

Other acyl organometallic reagents are known. An acyl zirconium reagent [e.g., $\text{RCOZr}(\text{Cl})\text{Cp}_2$] reacted with allylic bromide in the presence of CuI to give the corresponding ketone, but with allylic rearrangement.¹⁹⁶⁴

Symmetrical ketones (R_2CO) can be prepared by treatment of a primary alkyl or benzylic halide with $\text{Fe}(\text{CO})_5$ and a phase-transfer catalyst,¹⁹⁶⁵ or from a halide RX (R = primary alkyl, aryl, allylic, or benzylic) and CO by an electrochemical method involving a nickel complex.¹⁹⁶⁶ Aryl, benzylic, vinylic, and allylic halides have been converted to aldehydes by treatment with CO and Bu_3SnH , with a Pd catalyst.¹⁹⁶⁷ Various other groups do not interfere. Several procedures for the preparation of ketones are catalyzed by Pd complexes. Alkyl aryl ketones are formed in good yields by treatment of a mixture of an aryl iodide, an alkyl iodide, and a $\text{Zn}-\text{Cu}$ couple with CO ($\text{ArI} + \text{RI} + \text{CO} \rightarrow \text{RCOAr}$).¹⁹⁶⁸ Vinylic halides react with vinylic tin reagents in the presence of CO to give unsymmetrical divinyl ketones.¹⁹⁶⁹ Aryl, vinylic, and benzylic halides can be converted to methyl ketones ($\text{RX} \rightarrow \text{RCOMe}$) by reaction with (α -ethoxyvinyl)tributyltin [$\text{Bu}_3\text{SnC}(\text{OEt})=\text{CH}_2$].¹⁹⁷⁰ In addition, SmI_2 can be used to convert alkyl chlorides to ketones, in the presence of 50 atm of CO .¹⁹⁷¹

The conversion of alkyl halides to aldehydes and ketones can also be accomplished indirectly (Reaction 10-71). See also, Reaction 12-33.

A direct method for preparing a carboxylic acid treats an alkyl halide with NaNO_2 in acetic acid and DMSO.¹⁹⁷² Reaction of an alkyl halide with ClCOCO_2Me and $(\text{Bu}_3\text{Sn})_2$ under photochemical conditions leads to the corresponding methyl ester.¹⁹⁷³

Several methods, all based on carbon monoxide or metal carbonyls, have been developed for converting an alkyl halide to a carboxylic acid or an acid derivative with the chain extended by one carbon.¹⁹⁷⁴ When an alkyl halide is treated with $\text{SbCl}_5\text{—SO}_2$ at -70°C , it dissociates into the corresponding carbocation (Sec. 5.A.ii). If carbon monoxide and an alcohol are present, a carboxylic ester is formed by the following route:¹⁹⁷⁵

This has also been accomplished with concentrated H_2SO_4 saturated with CO .¹⁹⁷⁶ Not surprisingly, only tertiary halides perform satisfactorily; secondary halides give mostly rearrangement products. An analogous reaction takes place with alkanes possessing a tertiary hydrogen, using $\text{HF—SbF}_5\text{—CO}$.¹⁹⁷⁷

Carboxylic acids or esters are the products, depending on whether the reaction mixture is solvolyzed with water or an alcohol. Alcohols with more than seven carbons are cleaved into smaller fragments by this procedure.¹⁹⁷⁸ Similarly, tertiary alcohols¹⁹⁷⁹ react with H_2SO_4 and CO (which is often generated from HCOOH and the H_2SO_4 in the solution) to give trisubstituted acetic acids in a process called the *Koch–Haaf reaction* (see also, 15-35).¹⁹⁸⁰ If a primary or secondary alcohol is the substrate, the carbocation initially formed rearranges to a tertiary ion before reacting with the CO . Better results are obtained if trifluoromethanesulfonic acid ($\text{F}_3\text{CSO}_2\text{OH}$) is used instead of H_2SO_4 .¹⁹⁸¹ Iodo alcohols were transformed into lactones under radical conditions (AIBN , allylSnBu_3) and 45 atm of CO .¹⁹⁸²

Another method¹⁹⁸³ for the conversion of alkyl halides to carboxylic esters is treatment of a halide with nickel carbonyl $[\text{Ni}(\text{CO})_4]$ in the presence of an alcohol and its conjugate base.¹⁹⁸⁴ When R' is primary, RX may only be a vinylic or an aryl halide; retention of

configuration is observed at a vinylic R. Consequently, a carbocation intermediate is not involved here. When R' is tertiary, R may be primary alkyl as well as vinylic or aryl. This is thus one of the few methods for preparing esters of tertiary alcohols. Alkyl iodides give the best results, then bromides. In the presence of an amine, an amide can be isolated directly, at least in some instances.

Still another method for the conversion of halides to acid derivatives makes use of $\text{Na}_2\text{Fe}(\text{CO})_4$. As described in Reaction 10-76, primary and secondary alkyl halides and tosylates react with this reagent to give the ion $\text{RFe}(\text{CO})_4^-$ or, if CO is present, the ion $\text{RCOFe}(\text{CO})_4^-$. Treatment of $\text{RFe}(\text{CO})_4^-$ or $\text{RCOFe}(\text{CO})_4^-$ with oxygen or sodium hypochlorite gives, after hydrolysis, a carboxylic acid.¹⁹⁸⁵ Alternatively, $\text{RFe}(\text{CO})_4^-$ or $\text{RCOFe}(\text{CO})_4^-$ reacts with a halogen (e.g., I_2) in the presence of an alcohol to give a carboxylic ester,¹⁹⁸⁶ or in the presence of a secondary amine or water to give, respectively, the corresponding amide or free acid. Both $\text{RFe}(\text{CO})_4^-$ and $\text{RCOFe}(\text{CO})_4^-$, which are prepared from primary R, give high yields. With secondary R, the best results are obtained in the solvent THF by the use of $\text{RCOFe}(\text{CO})_4^-$ prepared from secondary tosylates. Ester and keto groups may be present in R without being affected. Carboxylic esters ($\text{RCO}_2\text{R'}$) have also been prepared by treating primary alkyl halides RX with alkoxides R'O^- in the presence of $\text{Fe}(\text{CO})_5$.¹⁹⁸⁷ Here $\text{RCOFe}(\text{CO})_4^-$ is presumably an intermediate.

Palladium complexes also catalyze the carbonylation of halides.¹⁹⁸⁸ Aryl (see Reaction 13-15),¹⁹⁸⁹ vinylic,¹⁹⁹⁰ benzylic, and allylic halides (especially iodides) can be converted to carboxylic esters with CO, an alcohol or alkoxide, and a Pd complex.¹⁹⁹¹ The Pd catalyzed carbonylation of organoindium compounds in the presence of methanol gives methyl esters.¹⁹⁹² Similar reactivity was reported with vinyl triflates.¹⁹⁹³ α -Halo ketones are converted to β -keto esters with CO, an alcohol, NBu_3 and a palladium catalyst at

110 °C.¹⁹⁹⁴ Use of an amine instead of the alcohol or alkoxide leads to an amide.¹⁹⁹⁵ Reaction with an amine, AIBN, CO, and a tetraalkyltin catalyst also leads to an amide.¹⁹⁹⁶ Benzylic and allylic halides were converted to carboxylic acids electrocatalytically, with CO and a Co-imine complex.¹⁹⁹⁷ Vinylic halides were similarly converted with CO and nickel cyanide, under phase-transfer conditions.¹⁹⁹⁸ Allylic *O*-phosphates were converted to allylic amides with CO and ClTi=NTMS, in the presence of a Pd catalyst.¹⁹⁹⁹ Terminal alkynes were converted to the alkynyl ester using CO, PdBr₂, CuBr₂ in methanol, and sodium bicarbonate.²⁰⁰⁰

Other organometallic reagents can be used to convert alkyl halides to carboxylic acid derivatives. Benzylic halides were converted to carboxylic esters with CO in the presence of a rhodium complex.²⁰⁰¹ Variations introduce the R' group via an ether (R'₂O),²⁰⁰² or an Al, Ti, or Zr alkoxide.²⁰⁰³ The reaction of an alkene, a primary alcohol, and CO, in the presence of a Rh catalyst, led to carbonylation of the alkene and formation of the corresponding ester.²⁰⁰⁴ Vinyl triflates were converted to the conjugated carboxylic acid with CO₂ and a Ni catalyst.²⁰⁰⁵ Reaction with an α,ω-diiodide, Bu₄NF, and Mo(CO)₆ gave the corresponding lactone.²⁰⁰⁶

A number of double carbonylations have been reported. In these reactions, two molecules of CO are incorporated in the product, leading to α-keto acids or their derivatives.²⁰⁰⁷ When the catalyst is a Pd complex, best results are obtained in the formation of α-keto amides.²⁰⁰⁸ The R group is usually aryl or vinylic.²⁰⁰⁹ The formation of α-keto acids²⁰¹⁰ or esters²⁰¹¹ requires more severe conditions. α-Hydroxy acids were obtained from aryl iodides when the reaction was carried out in the presence of an alcohol, which functioned as a reducing agent.²⁰¹² Cobalt catalysts have also been used and require lower CO pressures.²⁰⁰⁷

Aromatic Substitution, Electrophilic

Most substitutions at an aliphatic carbon are by nucleophiles. In aromatic systems the situation is reversed, because the high electron density at the aromatic ring leads to its reactivity as a Lewis base or a Brønsted–Lowry base, depending on the positive species. In electrophilic substitutions, a positive ion or the positive end of a dipole or induced dipole is attacked by the aromatic ring. The leaving group (the electrofuge) must necessarily depart without its electron pair. In nucleophilic substitution reactions, the chief leaving groups are those best able to carry the unshared pair: Br^- , H_2O , OTs^- , and so on (i.e., the weakest bases). In electrophilic substitution reactions, the most important leaving groups are those that can best exist without the pair of electrons necessary to fill the outer shell; that is, the weakest Lewis acids. The influence of solvents will vary with the reaction in many cases, and such details are discussed where appropriate in the reactions section (Sec. 11.F).¹

11.A. MECHANISMS

Electrophilic aromatic substitutions are unlike nucleophilic substitutions in that the large majority proceeds by just one mechanism with respect to the substrate.² In this mechanism, called the *arenium ion mechanism*, the electrophile, which can be viewed as a Lewis acid, is attacked by the π electrons of the aromatic ring, which can be viewed as a Lewis base, in the first step. This reaction leads to formation of a new C—X bond and a new sp^3 carbon in a positively charged intermediate called an arenium ion, where X is the electrophile. The positively charged intermediate (the arenium ion) is resonance stabilized, but not aromatic. Loss of a proton from the sp^3 carbon that is “adjacent” to the positive carbon in the arenium ion, in what is effectively an E1 process (see Sec. 17.A.ii) is driven by rearomatization of the ring from the arenium ion to give the aromatic substitution product. A proton therefore becomes the leaving group in this overall transformation, where X replaces H. The IUPAC designation for this mechanism is $\text{A}_\text{E} + \text{D}_\text{E}$. Another mechanism, much less common, consists of the opposite behavior: a leaving group departs *before* the electrophile arrives.

¹ For a review of electrophilic aromatic reactions in ionic liquids, see Borodkin, G.I.; Shubin, V.G. *Russ. J. Org. Chem.* **2006**, *42*, 1745.

² See Taylor, R. *Electrophilic Aromatic Substitution*, Wiley, NY, **1990**; Katritzky, A.R.; Taylor, R. *Electrophilic Substitution of Heterocycles: Quantitative Aspects* (Vol. 47 of *Adv. Heterocycl. Chem.*), Academic Press, NY, **1990**; Taylor, R. in Bamford, C.H.; Tipper, C.F.H. *Comprehensive Chemical Kinetics*, Vol. 13, Elsevier, NY, **1972**, pp. 1–406.

In this case, a substituent (*not* H) is attached to the aromatic ring, and the substituent is lost prior to incorporation of the electrophile. This mechanism, the S_E1 mechanism, corresponds to the S_N1 mechanism of nucleophilic substitution. Simultaneous attack and departure mechanisms (corresponding to S_N2) are not found at all. An addition–elimination mechanism has been postulated in one case (see Reaction 11-6).

11.A.i. The Arenium Ion Mechanism³

In the arenium ion mechanism, the electrophilic species may be produced in various ways, but when H is replaced by X conversion of the aromatic ring to an arenium ion it is basically the same in all cases. For this reason, most attention in the study of this mechanism centers on the identity of the electrophilic entity and how it is produced.

The electrophile may be a positive ion (X^+) or be a molecule that has a positive dipole. If it is a positive ion, it is attacked by the ring (a pair of electrons from the aromatic sextet is donated to the electrophile) and the product is a carbocation. This intermediate is a resonance hybrid, as shown in **1**, but is often represented as in **2**. The H atom to be replaced by X is shown in **1** for convenience. Ions of this type have been called⁴ *Wheland intermediates*, σ *complexes*, but nowadays they are called *arenium ions*.⁵ The inherent stability associated with aromaticity is no longer present in **1**, but the ion is stabilized by resonance. For this reason, the arenium ion is generally a highly reactive intermediate, although there are cases in which it has been isolated (see below).

Carbocations can react in various ways (see Sec. 5.A.iii), but for this type of ion the most likely pathway⁶ is loss of either X^+ or H^+ . In the second step of the mechanism, the reaction proceeds with loss of the proton and the aromatic sextet is restored in the final product (**3**). The second step is nearly always faster than the first, making the first rate determining, and the reaction is second order. If formation of the attacking species is slower still, the aromatic compound does not take part in the rate expression at all. If X^+ is lost, there is no net reaction, but if H^+ is lost, an aromatic substitution has taken place and a base (generally the counterion of the electrophilic species although solvents can also serve this purpose) is necessary to help remove it.

³ This mechanism is sometimes called the S_E2 mechanism because it is bimolecular, but in this book we reserve that name for aliphatic substrates (see Chap 12).

⁴ See Olah, G.A. *J. Am. Chem. Soc.* **1971**, 94, 808.

⁵ See Brouwer, D.M.; Mackor, E.L.; MacLean, C. in Olah, G.A.; Schleyer, P.v.R. *Carbonium Ions*, Vol. 2, Wiley, NY, **1970**, pp. 837–897; Perkampus, H. *Adv. Phys. Org. Chem.* **1966**, 4, 195.

⁶ Also see de la Mare, P.B.D. *Acc. Chem. Res.* **1974**, 7, 361.

If the electrophilic species is not an ion but a molecule with a polarized covalent bond, the product must have a negative charge unless part of the dipole, with its pair of electrons, is broken off somewhere in the process, as in the conversion of **4** to **5**. Note that when the aromatic ring attacks X, Z may be lost directly to give **5**.

The electrophilic entities and how they are formed are discussed for each reaction in the reactions section of this chapter.

The evidence for the arenium ion mechanism is mainly of two kinds:

1. *Isotope Effects.* If the hydrogen ion departs before the arrival of the electrophile (S_E1 mechanism) or if the arrival and departure are simultaneous, there should be a substantial isotope effect (i.e., deuterated substrates should undergo substitution more slowly than non-deuterated compounds) because, in each case, the C—H bond is broken in the rate-determining step. However, in the arenium ion mechanism, the C—H bond is not broken in the rate-determining step, so no isotope effect should be found. Many such studies have been carried out and, in most cases, especially in the case of nitrations, there is no isotope effect.⁷ This result is incompatible with either the S_E1 or the simultaneous mechanism.

However, in many instances, isotope effects have been found. Since the values are generally much lower than expected for either the S_E1 or the simultaneous mechanisms (e.g., 1–3 for k_H/k_D instead of 6–7), there must be another explanation. For the case where hydrogen is the leaving group, the arenium ion mechanism can be summarized:

The small isotope effects found most likely arise from the reversibility of step 1 by a *partitioning effect*.⁸ The rate at which ArHY^+ reverts to ArH should be essentially the same as that at which ArDY^+ (or ArTY^+) reverts to ArD (or ArT), since the Ar—H bond is not cleaving. However, ArHY^+ should go to ArY faster than either ArDY^+ or ArTY^+ , since the Ar—H bond is broken in this step. If $k_2 \gg k_{-1}$, this does not matter; since a large majority of the intermediates go to product, the rate is determined only by the slow step ($k_2[\text{ArH}][\text{Y}^+]$) and no isotope effect is predicted. However, if $k_2 \leq k_{-1}$, reversion to starting materials is important. If k_2 for ArDY^+ (or ArTY^+) is $< k_2$ for ArHY^+ , but k_{-1} is the same, then a larger proportion of ArDY^+ reverts to starting compounds. That is, k_2/k_{-1} (the *partition factor*) for

⁷ Berglund-Larsson, U.; Melander, L. *Ark. Kemi* **1953**, 6, 219. See also, Zollinger, H. *Adv. Phys. Org. Chem.* **1964**, 2, 163.

⁸ See Hammett, L.P. *Physical Organic Chemistry*, 2nd ed.; McGraw-Hill, NY, **1970**, pp. 172–182.

ArDY^+ is less than that for ArHY^+ . Consequently, the reaction is slower for ArD than for ArH and an isotope effect is observed.

One circumstance that could affect the k_2/k_{-1} ratio is steric hindrance. Thus, diazonium coupling of **6** gave no isotope effect, while coupling of **8** gave a k_H/k_D ratio of 6.55.⁹ For steric reasons, it is much more difficult for **9** to lose a proton (it is harder for a base to approach) than it is for **7**, so k_2 is greater for the latter. Since no base is necessary to remove ArN_2^+ , k_{-1} does not depend on steric factors¹⁰ and is about the same for each. Thus the partition factor k_2/k_{-1} is sufficiently different for **7** and **9** that **8** exhibits a large isotope effect and **6** exhibits none.¹¹ Base catalysis can also affect the partition factor, since an increase in base concentration increases the rate at which the intermediate goes to product without affecting the rate at which it reverts to starting materials. In some cases, isotope effects can be diminished or eliminated by a sufficiently high concentration of base.

Evidence for the arenium ion mechanism has also been obtained from other kinds of isotope-effect experiments, involving substitutions of the type

where M is Si, Ge, Sn, or Pb, and R is methyl or ethyl. In these reactions, the proton is the electrophile. If the arenium ion mechanism is operating, then the use of D_3O^+ should give rise to an isotope effect, since the D—O bond would be broken in the rate-determining step. Isotope effects of 1.55–0.05 were obtained,¹² in accord with the arenium ion mechanism.

2. *Isolation of Arenium Ion Intermediates.* Very strong evidence for the arenium ion mechanism comes from the isolation of arenium ions in a number of instances.¹³ For example, **7** was isolated as a solid with a

¹³ See Koptug, V.A. *Top. Curr. Chem.* **1984**, 122, 1; *Bull. Acad. Sci. USSR Div. Chem. Sci.* **1974**, 23, 1031; Shteingarts, V.D. *Russ. Chem. Rev.* **1981**, 50, 735; Farcasiu, D. *Acc. Chem. Res.* **1982**, 15, 46.

melting point of -15°C from treatment of mesitylene with ethyl fluoride and the catalyst BF_3 at -80°C . When **10** was heated, the normal substitution product (**11**) was obtained.¹⁴ Even the simplest such ion, the benzenonium ion (**12**) has been prepared in $\text{HF}-\text{SbF}_5-\text{SO}_2\text{ClF}-\text{SO}_2\text{F}_2$ at -134°C , where it could be studied

spectrally.¹⁵ The ^{13}C NMR spectra of the benzenonium ion¹⁶ and the pentamethylbenzenonium ion¹⁷ give graphic evidence for the charge distribution shown in **12** (see the electron density map for the arenium ion, **13**). According to this, the 1, 3, and 5 carbons, each of which bears a positive charge of about $+1/3$ [note that C-1,-3,-5 (numbering from **12**) are lighter, indicating less electron density in **13**, whereas C-2,-4 are darker for higher electron density], should have a greater chemical shift in the NMR than the 2 and 4 carbon atoms, which are uncharged. The spectra bear this out. For example, ^{13}C NMR chemical shifts for **12** are C-3: 178.1; C-1 and C-5: 186.6; C-2 and C-4: 136.9, and C-6: 52.2.¹⁶

In Chapter 3, it was mentioned that positive ions can form addition complexes with π systems. Since the initial step of electrophilic substitution involves attack of a positive ion by an aromatic ring, it has been suggested¹⁸ that such a complex, called a π -complex (represented as **14**), is formed first, and then is converted to the arenium ion (**15**).¹⁹ Stable solutions of arenium ions or π complexes (e.g., with Br_2 , I_2 , picric acid, Ag^+ , or HCl) can be formed.²⁰ For example, π -complexes are formed when aromatic hydrocarbons are treated with HCl alone, but the use of HCl plus a Lewis acid (e.g., AlCl_3) gives arenium ions. The two types of solution have very different properties. For example, a solution of an arenium ion is colored and conducts electricity, which shows that positive and negative ions are present, while a π complex formed from HCl and benzene is colorless and does not conduct a current. Furthermore, when DCl is used to form a π complex, no deuterium exchange takes place (because there is no covalent bond between the electrophile and the ring), while formation of an arenium ion with DCl and AlCl_3 gives deuterium exchange. The relative stabilities of some methylated arenium ions and π complexes are shown in Table 11.1. The arenium ion stabilities listed were

determined by the relative basicity of the substrate toward HF.²¹ The π -complex stabilities are relative equilibrium constants for the reaction²² between the aromatic hydrocarbon and HCl. As shown in Table 11.1, the relative stabilities of the two types of species are very different: The π complex stability changes very little with methyl substitution, but the arenium ion stability changes a great deal. Note that stable arenium ions have been obtained from large methylene-bridged polycyclic aromatic hydrocarbons.²³

How can we tell if **14** is present on the reaction path? If it is present, there are two possibilities: (1) The formation of **14** is rate determining (the conversion of **14** to **15** is much faster), or (2) the formation of **14** is rapid, and the conversion **14** to **15** is rate determining. One way to ascertain which species is formed in the rate-determining step in a given reaction is to use the stability information given in Table 11.1. We measure the relative rates of reaction of a given electrophile with the series of compounds listed in Table 11.1. If the relative rates resemble the arenium ion stabilities, we conclude that the arenium ion is formed in the slow step; but if they resemble the stabilities of the π

²¹ Kilpatrick, M.; Luborsky, F.E. *J. Am. Chem. Soc.* **1953**, 75, 577.

²³ Laali, K.K.; Okazaki, T.; Harvey, R.G. *J. Org. Chem.* **2001**, 66, 3977.

complexes, the latter are formed in the slow step.²⁴ When such experiments are carried out, it is found in most cases that the relative rates are similar to the arenium ion and not to the π complex stabilities. For example, Table 11.1 lists chlorination rates.²² Similar results were obtained in room temperature bromination with Br_2 in acetic acid²⁵ and in acetylation with $\text{CH}_3\text{CO}^+ \text{SbF}_6^-$.²⁶ It is clear that in these cases the π complex either does not form at all, or if it does, its formation is not rate determining (unfortunately, it is very difficult to distinguish between these two possibilities).

On the other hand, in nitration with the powerful electrophile NO_2^+ (in the form of $\text{NO}_2^+ \text{BF}_4^-$), the relative rates resembled π complex stabilities much more than arenium ion stabilities (Table 11.1).²⁷ Similar results were obtained for bromination with Br_2 and FeCl_3 in nitromethane. These results were taken to mean²⁸ that in these cases π complex formation is rate determining. However, graphical analysis of the NO_2^+ data showed that a straight line could not be drawn when the nitration rate was plotted against π -complex stability,²⁹ which casts doubt on the rate-determining formation of a π complex in this case.³⁰ There is other evidence, from positional selectivities (discussed in Sec. 11.D), that *some* intermediate is present before the arenium ion is formed, whose formation can be rate determining with powerful electrophiles. Not much is known about this intermediate, which is given the nondescriptive name *encounter complex* and generally depicted as **16**. The arenium complex mechanism is therefore written as:³¹

For the reason given above and for other reasons, it is unlikely that the encounter complex is a π complex, but just what kind of attraction exists between Y^+ and ArH is not known, other than the presumption that they are together within a solvent cage (see also, Sec. 11.D). There is evidence (from isomerizations occurring in the alkyl group, as well as other observations) that π complexes are present on the pathway from substrate to arenium ion in the gas-phase protonation of alkylbenzenes.³²

11.A.ii. The S_E1 Mechanism

The S_E1 mechanism (*substitution electrophilic unimolecular*) is rare, being found only in certain cases in which carbon is the leaving atom (see Reactions **11-33** and **11-35**) or when a very strong base is present (see Reactions **11-1**, **11-10**, and **11-39**).³³ It consists of two steps with an intermediate carbanion. The IUPAC designation is D_E + A_E.

Reactions **12-41**, **12-45**, and **12-46** also take place by this mechanism when applied to aryl substrates.

11.B. ORIENTATION AND REACTIVITY

11.B.i. Orientation and Reactivity in Monosubstituted Benzene Rings³⁴

When an electrophilic substitution reaction is performed on a monosubstituted benzene, the new group may be directed primarily to the ortho, meta, or para position and the substitution may be slower or faster than with benzene itself.³⁵ The group already on the ring determines which position the new group will take and whether the reaction will be slower or faster than with benzene. Groups that increase the reaction rate are called *activating* and those that slow it are *deactivating*. Some groups are predominantly meta directing; all of these are deactivating. Others are mostly ortho–para directing; while some of these (e.g., halogens) are deactivating too, most are activating. Groups direct *predominantly*, but usually not *exclusively*. For example, nitration of nitrobenzene gave 93% *m*-dinitrobenzene, 6% of the ortho, and 1% of the para isomer.

The orientation and reactivity effects are explained on the basis of resonance and field effects of each group on the stability of the intermediate arenium ion. To understand why we can use this approach, it is necessary to know that in these reactions the product is usually kinetically and not thermodynamically controlled (see Sec. 6.F). Some of the reactions are irreversible and the others are usually stopped well before equilibrium is reached. *Therefore, which of the three possible intermediates is formed is dependent not on the thermodynamic stability of the products, but on the activation energy necessary to form each of the three intermediates.* It is not easy to predict which of the three activation energies is lowest, but it is necessary to make the assumption that the free energy profile resembles either Fig. 6.2a or b. In either case, the transition state is closer in energy to the arenium ion intermediate than to the starting compounds. Invoking the *Hammond postulate* (Sec. 6.G), assume that the geometry of the transition state also resembles that of the intermediate and that anything that increases the stability of the intermediate will

³³ Also see Eaborn, C.; Hornfeld, H.L.; Walton, D.R.M. *ccqBunnett, J.F.; Miles J.H.; Nahabedian, K* **1967**, 1036.

³⁴ See Hoggett, J.G.; Moodie, R.B.; Penton, J.R.; Schofield, K. *Nitration and Aromatic Reactivity*, Cambridge University Press, Cambridge, **1971**, pp. 122–145, 163–220.

³⁵ For a computational approach to evaluate substituent constants, see Galabov, B.; Ilieva, S.; Schaefer III, H.F. *J. Org. Chem.* **2006**, 71, 6382.

also lower the activation energy necessary to attain it. Since the intermediate, once formed, is rapidly converted to products, the relative stabilities of the three intermediates can be used as guides to predict which products will predominantly form. Of course, if reversible reactions are allowed to proceed to equilibrium, product ratios that are quite different may be obtained. For example, the sulfonation of naphthalene at 80 °C, where the reaction does not reach equilibrium, gives mostly α -naphthalenesulfonic acid,³⁶ while at 160 °C, where equilibrium is attained, the β isomer predominates³⁷ (the α isomer is thermodynamically less stable because of steric interaction between the SO_3H group and the hydrogen at the 8 position).

The three possible ions from incorporation of Y at the ortho, meta, and para positions are shown below, and each arenium ion obviously has a positive charge in the ring. It is therefore possible to predict that any group Z that has an electron-donating field effect ($+I$, Z will have a δ^- charge or a δ^- dipole in most cases) should stabilize all three ions (relative to **1**), since electron donation to a positive center is stabilizing. On the other hand, electron-withdrawing groups ($-I$, Z will have a δ^+ charge or a δ^+ dipole in most cases) will increase the positive charge on the ring (like charges repel), and destabilize the arenium ion. Formation of a stabilized ion should be faster than benzene, which generates **1**, or activating, but formation of a destabilized ion should be slower, or deactivating. Such field effects should taper off with distance and are thus strongest at the carbon connected to the group Z (known as the ipso carbon). Of the three arenium ions, only the ortho and para have any positive charge at this carbon. None of the canonical forms of the meta ion has a positive charge at the ipso carbon. Therefore, $+I$ groups should stabilize all three ions, but mostly the ortho and para, so they should be not only activating but ortho-para-directing as well. On the other hand, $-I$ groups, by removing electron density, should destabilize all three ions, but mostly the ortho and para, and should be not only deactivating but also meta directing.

These conclusions are correct as far as they go, but they do not lead to the proper results in all cases. In many cases, there is *resonance interaction* between Z and the ring; this also

³⁶ Fierz, H.E.; Weissenbach, P. *Helv. Chim. Acta* **1920**, 3, 312.

³⁷ Witt, O.N. *Ber.* **1915**, 48, 743.

affects the relative stability, in some cases in the same direction as the field effect, in others differently.

Some substituents have a pair of electrons (usually unshared) that may be contributed *toward* the ring. Two of the three (ortho and para) arenium ions would then have a fourth resonance contributor as shown. For each ion, the same three canonical forms can be drawn as before, but now we can draw an extra form for the ortho and para ions. The stability of these two ions is increased by the extra form not only because it is another canonical form, but also because it is more stable than the others and makes a greater contribution to the hybrid. Every atom (except, of course, hydrogen) in these forms (**C** and **D**) has a complete octet, while all the other forms have one carbon atom with a sextet. No corresponding form can be drawn for the meta isomer. The inclusion of this form in the hybrid lowers the energy not only because of rule 6 (Sec. 2.E), but also because it spreads the positive charge over a larger area, out onto group Z. Groups with a pair of electrons (e.g., the halogens) to contribute would be expected, then, in the absence of field effects, not only to direct ortho and para, but also to activate these positions for electrophilic attack.

On the basis of these discussions, we can distinguish three types of groups.

1. *Groups that Contain an Unshared Pair of Electrons on the Atom Connected to the Ring.* In this category are O^- , NR_2 , NHR , NH_2 ,³⁸ OH , OR , $NHCOR$, $OCOR$, SR , and the four halogens.³⁹ The halogens deactivate the aromatic ring to substitution (the rate of reaction is slower than that of benzene), and this effect may arise from the unique energy level of the halogen lone-pair orbital, which is higher than the

³⁸ It must be remembered that in acid solution amines are converted to their conjugate acids, which for the most part are meta directing (type 2). However, unless the solution is highly acidic, there will be a small amount of free amine present, and since amino groups are activating and the conjugate acids deactivating, ortho-para direction is often found even under acidic conditions.

³⁹ See Chuchani, G. in Patai, S. *The Chemistry of the Amino Group*, Wiley, NY, **1968**, pp. 250–265; for ether groups see Kohnstam, G.; Williams, D.L.H. in Patai, S. *The Chemistry of the Ether Linkage*, Wiley, NY, **1967**, pp. 132–150.

adjacent π molecular orbital of benzene (π_1).⁴⁰ The widely held explanation for this, however, is that the halogens have a $-I$ effect. The SH group would probably belong here too, except that in the case of thiophenols, electrophiles usually attack the sulfur rather than the ring, and ring substitution is not feasible with these substrates.⁴¹ The resonance explanation predicts that all these groups should be ortho-para directing, and they are, though all except O^- are electron withdrawing by the field effect (Sec. 11.I). Therefore, for these groups, resonance is more important than the field effect. This result is especially true for NR_2 , NHR , NH_2 , and OH , which are *strongly* activating, as is O^- . The other groups are mildly activating, except for the halogens, which are deactivating. Fluorine⁴² is the least deactivating, and fluorobenzenes usually show a reactivity approximating that of benzene itself. The other three halogens deactivate about equally. In order to explain why chlorine, bromine, and iodine deactivate the ring, even though they direct ortho-para, assume that the canonical forms **C** and **D** make such great contributions to the respective hybrids that they make the ortho and para arenium ions more stable than the meta, even though the $-I$ effect of the halogen is withdrawing sufficient electron density from the ring to deactivate it. The three halogens make the ortho and para ions more stable than the meta, but less stable than the unsubstituted arenium ion (**1**). For the other groups that contain an unshared pair, the ortho and para ions are more stable than either the meta or the unsubstituted ion. For most of the groups in this category, the meta ion is more stable than **1**, so that groups, such as NH_2 and OH , activate the meta positions too, but not as much as the ortho and para positions (see also, the discussion in Sec. 11.C).

2. *Groups that Lack an Unshared Pair on the Atom Connected to the Ring and that Are $-I$.* In this category are, in approximate order of decreasing deactivating ability, NR_3^+ , NO_2 , CF_3 ,⁴³ CN , SO_3H , CHO , COR , CO_2H , CO_2R , $CONH_2$, CCl_3 , and NH_3^+ . Also in this category are all other groups with a positive charge on the atom directly connected to the ring⁴⁴ (SR_2^+ , PR_3^+ , etc.) and many groups with positive charges on atoms farther away, since often these are still powerful $-I$ groups. The field-effect explanation predicts that these should all be meta directing and deactivating, and (except for NH_3^+) this is the case. The NH_3^+ group is an anomaly, since this group directs para about as much as or a little more than it directs meta.⁴⁵ The NH_2Me^+ , $NHMe_2^+$, and NMe_3^+ groups all give more meta than para substitution, the percentage of para product decreasing with the increasing number of methyl groups.⁴⁶

3. *Groups that Lack an Unshared pair on the Atom connected to the Ring and that Are ortho–para Directing.* In this category are alkyl groups,⁴⁷ aryl groups, and the COO^- group,⁴⁸ all of which activate the ring. Since aryl groups are $-I$ groups, they might seem to belong to category 2. They are nevertheless ortho–para directing and activating. This can be explained in a similar manner as in category 1, with a pair of electrons from the aromatic sextet playing the part played by the unshared pair, so that forms like **E** are generated. The effect of negatively charged groups like CO_2^- is easily explained by the field effect (negatively charged groups are of course electron donating), since there is no resonance interaction between the group and the ring. The effect of alkyl groups can be explained in the same way, but, in addition, canonical forms can be drawn, even though there is no unshared pair. These, of course, are hyperconjugation forms like **F** (see above). This effect, like the field effect, predicts activation and ortho–para direction, so that it is not possible to say how much each effect contributes to the result. Another way of looking at the effect of alkyl groups, which sums up both field and hyperconjugation effects, is that (for $Z = R$) the ortho and para arenium ions are more stable because each contains a form (**A** and **B**) that is a tertiary carbocation, while all the canonical forms for the meta ion and for **1** are secondary carbocations. In activating ability, alkyl groups usually follow the *Baker–Nathan order* (Sec. 2.M), but not always.⁴⁹

11.B.ii. The Ortho/Para Ratio⁵⁰

When an ortho–para directing group is on a ring, it is usually difficult to predict how much of the product will be the ortho isomer and how much is the para isomer. Indeed, these proportions can depend greatly on the reaction conditions. For example, chlorination of toluene gives an ortho/para ratio anywhere from 62:38 to 34:66.⁵¹ Nevertheless, certain points can be made. On a purely statistical basis there would be 67% ortho and 33% para, since there are two ortho positions and only one para. However, the phenonium ion (**12**), which arises from protonation of benzene, has the approximate charge distribution shown⁵² (see **13** as well). If this model were accepted for the arenium ion in aromatic substitution, a para substituent would have a greater stabilizing effect on the adjacent carbon than an ortho substituent. If other effects are absent, this would mean that >33% para and <67% ortho substitution would be found. In hydrogen exchange (Reaction 11-1), where other effects are absent, it has been found for a number of

⁴⁷ For a discussion of the substituents effect of the methyl group, see Myrseth, V.; Sæthre, L.J.; Børve, K.J.; Thomas, T.D. *J. Org. Chem.* **2007**, 72, 5715.

⁴⁸ Spryskov, A.A.; Golubkin, L.N. *J. Gen. Chem. USSR* **1961**, 31, 833. Since the CO_2^- group is present only in alkaline solution, where electrophilic substitution is not often done, it is seldom encountered.

⁴⁹ See, however, Schubert, W.M.; Gurka, D.F. *J. Am. Chem. Soc.* **1969**, 91, 1443; Himoe, A.; Stock, L.M. *J. Am. Chem. Soc.* **1969**, 91, 1452.

⁵⁰ See Effenberger, F.; Maier, A.J. *J. Am. Chem. Soc.* **2001**, 123, 3429.

⁵² Olah, G.A. *Acc. Chem. Res.* **1970**, 4, 240, p. 248.

substituents that the average ratio of the logarithms of the partial rate factors for these positions (see Sec. 11.C for a definition of partial rate factor) was close to 0.865,⁵³ which is not far from the value predicted from the ratio of charge densities in **12**. This picture is further supported by the fact that meta-directing groups, which destabilize a positive charge, give ortho/para ratios $>67:33$ ⁵⁴ (of course, the total amount of ortho and para substitution with these groups is small, but the *ratios* are generally $>67:33$). Another important factor is the steric effect. If either the group on the attacking ring or the group on the electrophile is large, steric hindrance inhibits formation of the ortho product and increases the amount of the para isomer. An example may be seen in the nitration, under the same conditions, of toluene and *tert*-butylbenzene. The former gave 58% of the ortho compound and 37% of the para, while the more bulky *tert*-butyl group gave 16% of the ortho product and 73% of the para.⁵⁵ Some groups are so large that they direct almost entirely para.

When the ortho–para directing group is one with an unshared pair (this of course applies to most of them), there is another effect that increases the amount of para product at the expense of the ortho. A comparison of the intermediates involved (see above) shows that **C** is a canonical form with an *ortho*-quinoid structure, while **D** has a *para*-quinoid structure. *para*-Quinones are more stable than the ortho isomers, so it seems reasonable to assume that **D** is more stable than **C**, and therefore contributes more to the hybrid and increases its stability compared to the ortho intermediate.

It has been shown that it is possible to compel regiospecific para substitution by enclosing the substrate molecules in a cavity from which only the para position projects. Anisole was chlorinated in solutions containing a cyclodextrin, a molecule in which the anisole is almost entirely enclosed (see Fig. 3.4). With a high enough concentration of cyclodextrin, it was possible to achieve a para/ortho ratio of 21.6⁵⁶ (in the absence of the cyclodextrin the ratio was only 1.48). This behavior is a model for the regioselectivity found in the action of enzymes.

11.B.iii. Ipso Attack

Orientation has been discussed previously in the case of monosubstituted benzenes entirely in terms of attachment at the ortho, meta, and para positions, but attachment at

the position bearing the substituent (called the *ipso position*⁵⁷) can also be important. Ipso attack has mostly been studied for nitration.⁵⁸ When attack of NO_2^+ leads to incorporation at the ipso position there are at least five possible fates for the resulting arenium ion (**17**).

Path a. The arenium ion can lose NO_2^+ and revert to the starting compounds. This results in no net reaction and is often undetectable.

Path b. The arenium ion can lose Z^+ , in which case this is simply aromatic substitution with a leaving group other than H (see Reactions **11-33–11-41**).

Path c. The electrophilic group (in this case NO_2^+) can undergo a 1,2-migration, followed by loss of the proton. The product in this case is the same as that obtained by direct attachment of NO_2^+ at the ortho position of PhZ . It is not always easy to tell how much of the ortho product in any individual case arises from this pathway,⁵⁹ though there is evidence that it can be a considerable proportion. Because of this possibility, many of the reported conclusions about the relative reactivity of the ortho, meta, and para positions are cast into doubt, since some of the product may have arisen not from direct attachment at the ortho position, but from attachment at the ipso position followed by rearrangement.⁶⁰

Path d. The ipso substituent (Z) can undergo 1,2-migration, which also produces the ortho product (although the rearrangement would become apparent if there were other substituents present). The evidence is that this pathway is very minor, at least when the electrophile is NO_2^+ .⁶¹

Path e. Attack of a nucleophile on **17**. In some cases, the products of such an attack (cyclohexadienes) have been isolated⁶² (this is 1,4-addition to the aromatic ring), but further reactions are also possible.

11.B.iv. Orientation in Benzene Rings with More Than One Substituent⁶³

It is often possible in these cases to predict the correct isomer. In many cases, the groups already on the ring reinforce each other. Thus, 1,3-dimethylbenzene is substituted at the 4 position (ortho to one group and para to the other), but not at the 5 position (meta to both). Likewise, the incoming group in *p*-chlorobenzoic acid goes to the position ortho to the chloro and meta to the carboxyl group.

When the groups oppose each other, predictions may be more difficult, as in *N*-acetyl-2-methoxyaniline. In a case such as where two groups of about equal directing ability are in competing positions, all four products can be expected, and it is not easy to predict the proportions, except that steric hindrance should probably reduce the yield of substitution ortho to the acetamido group, especially for large electrophiles. Mixtures of about equal proportions are frequent in such cases. Nevertheless, even when groups on a ring oppose each other, there are some regularities.

1. If a strong activating group competes with a weaker one or with a deactivating group, the former controls. Thus *o*-cresol gives substitution mainly ortho and para to the *hydroxyl* group and not to the methyl. For this purpose, we can arrange the groups in the following order: NH_2 , OH , NR_2 , $\text{O}^- > \text{OR}$, OCOR , $\text{NHCOR} > \text{R}$, $\text{Ar} > \text{halogen} > \text{meta-directing groups}$.
2. All other things being equal, a third group is least likely to enter between two groups in the meta relationship. This is the result of steric hindrance and increases in importance with the size of the groups on the ring and with the size of the attacking species.⁶⁴
3. When a meta-directing group is meta to an ortho-para directing group, the incoming group primarily goes ortho to the meta-directing group rather than para. For example, chlorination of **18** gives mostly **19**. The importance of this effect is underscored by the fact that **20**, which is in violation of the preceding rule, is formed in smaller amounts, but **21** is not formed at all. This is called the *ortho effect*,⁶⁵ and many such examples are known.⁶⁶ Another is the nitration of *p*-bromotoluene, which gives 2,3-dinitro-4-bromotoluene. In this case, once the first nitro group came in, the second was directed ortho to it rather than para, even though this means that the group has to come in between two groups in the meta position. There is no good explanation yet for the ortho effect, though possibly there is intramolecular assistance from the meta-directing group.

⁶³ For a quantitative discussion, see Section 11.C.

⁶⁴ See Kruse, L.I.; Cha, J.K. *J. Chem. Soc., Chem. Commun.* **1982**, 1333.

⁶⁵ This is not the same as the ortho effect mentioned at the end of Section 9.C.

⁶⁶ See Hammond, G.S.; Hawthorne, M.F. in Newman, M.S. *Steric Effects in Organic Chemistry*, Wiley, NY, **1956**, pp. 164–200, 178–182.

It is interesting that chlorination of **18** illustrates all three rules. Of the four positions open to the electrophile, the 5 position violates rule 1, the 2 position rule 2, and the 4 position rule 3. The principal attachment is therefore at position 6.

11.B.v. Orientation in Other Ring Systems⁶⁷

In fused ring systems, the positions are not equivalent and there is usually a preferred orientation, even in the unsubstituted hydrocarbon. The preferred positions may often be predicted as for benzene rings. Thus it is possible to draw more canonical forms for the arenium ion when attack by naphthalene leads to attachment of the electrophile at the α position than when attack by naphthalene leads to attachment of the electrophile at the β position. Therefore, the α position is the preferred site of attachment,⁶⁸ although, as previously mentioned (Sec. 11.B.i), the isomer formed by substitution at the β -position is thermodynamically more stable and is the product if the reaction is reversible and equilibrium is reached. Because of the more extensive delocalization of charges in the corresponding arenium ions, naphthalene is more reactive than benzene and substitution is faster at both positions. Similarly, anthracene, phenanthrene, and other fused polycyclic aromatic hydrocarbons are also substituted faster than benzene.

Heterocyclic compounds, too, have nonequivalent positions, and the principles are similar,⁶⁹ in terms of mechanism, and rate data is available.⁷⁰ Furan, thiophene, and pyrrole are chiefly substituted at the 2 position, and all are substituted faster than benzene.⁷¹ Pyrrole is particularly reactive, with a reactivity approximating that of aniline or the phenoxide ion. For pyridine,⁷² it is not the free base that must attack the electrophile but the conjugate acid (the pyridinium ion),⁷³ making the reactivity much less than that of benzene, being similar to that of nitrobenzene. The 3 position is most reactive in electrophilic substitution reactions of pyridine. However, groups can be introduced into the 4 position of a pyridine ring indirectly, by performing the reaction on the corresponding pyridine *N*-oxide.⁷⁴ Note that calculations show that the 2-pyridyl and 2-pyrimidyl cations are best represented as *ortho*-hetaryonium ions, being more stable than their positional, nonconjugated isomers by as much as 18–28 kcal mol⁻¹ (75–117 kJ mol⁻¹).⁷⁵

When fused ring systems contain substituents, successful predictions can often be made by using a combination of the above principles. Thus, ring A of 2-methylnaphthalene (**22**) is activated by the methyl group; ring B is not (although the presence of a substituent in a fused ring system affects all the rings,⁷⁶ the effect is generally greatest on the ring to which it is attached). Substitution is therefore expected in ring A. The methyl group activates positions 1 and 3, which are ortho to itself, but not position 4, which is meta to it. However, substitution at the 3 position gives rise to an arenium ion for which it is impossible to write a low-energy canonical form in which ring B has a complete sextet. Only forms like **23** are possible, in which the sextet is no longer intact. In contrast, substitution at the 1 position gives rise to a more stable arenium ion, for which two canonical forms (one of them is **24**) can be written in which ring B is benzenoid. We thus predict predominant substitution at C-1, and that is what is generally found.⁷⁷ However, in some cases predictions are much harder to make. For example, chlorination or nitration of **25** gives mainly the 4 derivative, but bromination yields chiefly the 6 compound.⁷⁸

For fused heterocyclic systems too, predictions can be made based on the above principles, although many exceptions are known. Thus, indole is chiefly substituted in the pyrrole ring (at position 3) and reacts faster than benzene, while quinoline generally reacts in the benzene ring, at the 5 and 8 positions, and slower than benzene, though faster than pyridine.

In alternant hydrocarbons (Sec. 2.J), the reactivity at a given position is similar for electrophilic, nucleophilic, and free radical substitution, because the same kind of resonance can be shown in all three types of intermediate (cf. **24**, **26**, and **27**). Attachment of the electrophile at the position that will best delocalize a positive charge will also best delocalize a negative charge or an unpaired electron. Most results are in accord with these predictions. For example, naphthalene is attacked primarily at the 1 position by NO_2^+ , NH_2^- , and Ph^\cdot , and always more readily than benzene.
