When strain due to a ring fused on an aromatic ring deforms that ring out of planarity, the molecule is more reactive to electrophilic aromatic substitution.⁷⁹ This has been explained by the presence of a shortened bond for the sp^2 hybridized carbon, increasing the strain at that position. This finding is known as the *Mills–Nixon effect*.⁸⁰ There is EPR evidence (see Sec. 5.C.i) for 3,6-dimethyl-1,2,4,5-tetrahydrobenzo-bis-cyclobutene (**28**), which supports the *Mills–Nixon effect*,⁸¹ and a theoretical study, which supports this.⁸² However, *ab initio* studies of triannelated benzene rings shows *no evidence* for the *Mills–Nixon effect*, and a new motif for bond-alternating benzenes was proposed.⁸³ Indeed, it is argued that the *Mills–Nixon effect* is not real.⁸⁴

11.C. QUANTITATIVE TREATMENTS OF REACTIVITY IN THE SUBSTRATE

Quantitative rate studies of aromatic substitutions are complicated by the fact that there are usually several hydrogen atoms that can leave, so that measurements of overall rate ratios do not give a complete picture as they do in nucleophilic substitutions, where it is easy to compare substrates that have only one possible leaving group in a molecule. What is needed is not, say, the overall rate ratio for acetylation of toluene versus that for benzene, but the *rate ratio at each position*. These can be calculated from the overall rates and a careful determination of the proportion of isomers formed, provided that the products are kinetically controlled, as is usually the case. The *partial rate factor* may be defined for a given group and a given reaction as the rate of substitution at a single position relative to a single position in benzene. For example, for acetylation of toluene the partial rate factors follow: for the ortho position $o_f^{\text{Me}} = 4.5$, for the meta $m_f^{\text{Me}} = 4.8$, and for the para $p_f^{\text{Me}} = 749$.⁸⁵ This means that toluene is acetylated at the ortho position 4.5 times as fast as a single position in benzene, or 0.75 times as fast as the overall rate of acetylation of benzene. A partial rate factor >1 for a given position indicates that the group in question activates that position for the given reaction. Partial rate factors differ from one reaction to another and are even different, though less so, for the same reaction under different conditions.

Once the partial rate factors are known, the proportions of isomers to be obtained when two or more groups are present on a ring can be predicted, *if the assumption is made that the effect of substituents is independent*. For example, if the two methyl groups in *m*-xylene have the same effect as the methyl group in toluene, the theoretical partial rate factors at each position can be calculated by multiplying those from toluene, so they should be as indicated.

^aSee Ref. 86.

From this, it is possible to calculate the overall theoretical rate ratio for acetylation of *m*-xylene relative to benzene, since this is one-sixth the sum of the partial rate factors (in this case 1130), and the isomer distribution if the reaction is kinetically controlled. The overall rate ratio actually is 347⁸⁶ and the calculated and observed isomer distributions are listed in Table 11.2.⁸⁶ In this case, and in many others, agreement is fairly good, but many cases are known where the effects are not additive (as in Sec. 11.B.ii).⁸⁷ For example, this treatment predicts that for 1,2,3-trimethylbenzene there should be 35% 5 substitution and 65% 4 substitution, but acetylation gave 79% 5 substitution and 21% of the 4 isomer. The treatment is thrown off by steric effects (e.g., those mentioned earlier, Sec. 11.B.iv), by products arising from ipso attack (Sec. 11.B.ii) and by resonance interaction *between* groups (e.g., **29**), which must make the results deviate from simple additivity of the effects of the groups.

Another approach that avoids the problem created by having competing leaving groups present in the same substrate is the use of substrates that contain only one leaving group. This is most easily accomplished by the use of a leaving group other than hydrogen. By this means, overall rate ratios can be measured for specific positions.⁸⁸ Results obtained in this way⁸⁹ give a reactivity order quite consistent with that for hydrogen as leaving group.

A quantitative scale of reactivity for aromatic substrates (fused, heterocyclic, and substituted rings) has been devised, based on the HSAB concept (Sec. 8.E).⁹⁰ From MO theory, a quantity called *activation hardness* can be calculated for each position of an aromatic ring. The smaller the activation hardness, the faster the attachment at that position; hence the treatment predicts the most likely orientations for incoming groups.

11.D. A QUANTITATIVE TREATMENT OF REACTIVITY OF THE ELECTROPHILE: THE SELECTIVITY RELATIONSHIP

Not all electrophiles are equally reactive. The nitronium ion is attacked not only by benzene but also by aromatic rings that contain a strongly deactivating group. On the other hand, diazonium ions couple only with rings containing a powerful activating group. Attempts have been made to correlate the influence of substituents with the reactivity of the group being attacked. The most obvious way to do this is with the *Hammett equation* (Sec. 8.G):

$$\log(k, k_0) = \rho \sigma$$

For aromatic substitution,⁹¹ k_0 is divided by 6 and, for meta substitution, k is divided by 2, so that comparisons are made for only one position (consequently, k/k_0 for, say, the methyl group at a para position is identical to the partial rate factor p_f^{Me}). It was soon found that, while this approach worked fairly well for electron-withdrawing groups, it failed for those that are electron donating. However, if the equation is modified by the insertion of the Brown σ^+ values instead of the Hammett σ values (because a positive charge develops during the transition state), more satisfactory correlations can be made, even for electron-donating groups (see Table 9.4 for a list of σ^+ values).⁹² Groups with a negative value of σ_p^+ or σ_m^+ are activating for that position; groups with a positive value are deactivating. The ρ values correspond to the susceptibility of the reaction to stabilization or destabilization by the Z group and to the reactivity of the electrophile. The ρ values vary not only with the electrophile, but also with conditions. A large negative value of ρ means an electrophile of relatively low reactivity. Of course, this approach is completely useless for ortho substitution, since the Hammett equation does not apply there.

A modification of the Hammett approach, suggested by Brown, called the *selectivity relationship*,⁹³ is based on the principle that reactivity of a species varies inversely with selectivity. Table 11.3 shows how electrophiles can be arranged in order of selectivity as measured by two indexes: (1) their selectivity in attacking toluene rather than benzene, and (2) their selectivity between the meta and para positions in toluene.⁹³ As the table shows, an

TABLE 11.3 Relative Rates and Product Distributions in Some Electrophilic Substitutions on Toluene and Benzene^a

Reaction	Relative Rate	Product Distribution, (%)

electrophile more selective in one respect is also more selective in the other. In many cases, electrophiles known to be more stable (hence less reactive) than others show a higher selectivity, as would be expected. For example, the *tert*-butyl cation is more stable and more selective than the isopropyl (Sec. 5.A.ii), and Br₂ is more selective than Br⁺. However, deviations from the relationship are known.⁹⁴ Selectivity depends not only on the nature of the electrophile, but also on the temperature. As expected, it normally decreases with increasing temperature.

Brown assumed that a good measurement of selectivity was the ratio of the para and meta partial rate factors in toluene. He defined the selectivity S_f of a reaction as:

$$S_f = \log \left(\frac{p_f^{\text{Me}}}{m_f^{\text{Me}}} \right)$$

That is, the more reactive the reactive species, the less preference it has for the para position compared to the meta. If we combine the Hammett–Brown $\sigma^+ \rho$ relationship with the linearity between $\log S_f$ and $\log p_f^{\text{Me}}$ and between $\log S_f$ and $\log m_f^{\text{Me}}$, it is possible to derive the following expressions:

$$\begin{aligned} \log p_f^{\text{Me}} &= \left(\frac{\sigma_p^+}{\sigma_p^+ - \sigma_m^+} \right) S_f \\ \log m_f^{\text{Me}} &= \left(\frac{\sigma_m^+}{\sigma_p^+ - \sigma_m^+} \right) S_f \end{aligned}$$

S_f is related to ρ by $S_f = \rho(\sigma_p^+ - \sigma_m^+)$

The general validity of these equations is supported by a great deal of experimental data on aromatic substitution reactions of toluene. Examples of values for some reactions obtained from these equations are given in Table 11.4.⁹⁵ For other substituents, the treatment works well with groups that, like methyl, are not very polarizable. For more polarizable groups the correlations are sometimes satisfactory and sometimes not, probably because each electrophile in the transition state makes a different demand on the electrons of the substituent group.

Not only are there substrates for which the treatment is poor, but it also fails with very powerful electrophiles. This is the reason why it is necessary to postulate the encounter complex mentioned in Section 11.A.i. For example, relative rates of nitration of *p*-xylene,

TABLE 11.4 Values of m_f^{Me} , p_f^{Me} , S_f , and ρ for Three Reactions of Toluene^a

Reaction	m_f^{Me}	p_f^{Me}	S_f	ρ

⁹⁴ See Olah, G.A.; Olah, J.A.; Ohyama, T. *J. Am. Chem. Soc.* **1984**, *106*, 5284.

⁹⁵ Stock, L.M.; Brown, H.C. *Adv. Phys. Org. Chem.* **1963**, *1*, 35 presents many tables of these kinds of data. See also, DeHaan, F.P.; Chan, W.H.; Chang, J.; Ferrara, D.M.; Wainschel, L.A. *J. Org. Chem.* **1986**, *51*, 1591, and other papers in this series.

1,2,4-trimethylbenzene, and 1,2,3,5-tetramethylbenzene were 1.0, 3.7, and 6.4,⁹⁶ though the extra methyl groups should enhance the rates much more (*p*-xylene itself reacted 295 times faster than benzene). The explanation is that with powerful electrophiles the reaction rate is so rapid (reaction taking place at virtually every encounter⁹⁷ between an electrophile and substrate molecule)⁹⁸ that the presence of additional activating groups can no longer increase the rate.⁹⁹

Given this behavior (little selectivity in distinguishing between different substrate molecules), the selectivity relationship would predict that positional selectivity should also be very small. However, it is not. For example, under conditions where nitration of *p*-xylene and 1,2,4-trimethylbenzene takes place at about equal rates, there was no corresponding lack of selectivity at positions *within* the latter.¹⁰⁰ Although steric effects are about the same at both positions, >10 times as much 5-nitro product was formed as 6-nitro product. It is clear that the selectivity relationship has broken down and it becomes necessary to explain why such an extremely rapid reaction should occur with positional selectivity. The explanation offered is that the rate-determining step is formation of an encounter complex (**12**, Sec. 11.B.ii).¹⁰¹ Since the position of attachment is not determined in the rate-determining step, the 5:6 ratio is not related to the reaction rate. Essentially the same idea was suggested earlier¹⁰² and for the same reason (failure of the selectivity relationship in some cases), but the earlier explanation specifically pictured the complex as a π complex, and we have seen (Sec. 11.B.ii) that there is evidence against this.

One interesting proposal¹⁰³ is that the encounter pair is a radical pair $\text{NO}_2^\bullet \text{ArH}^{+\bullet}$ formed by an electron transfer (SET), which would explain why the electrophile, once in the encounter complex, can acquire the selectivity that the free NO_2^+ lacked (it is not proposed that a radical pair is present in all aromatic substitutions; only in those that do not obey the selectivity relationship). The radical pair subsequently collapses to the arenium ion. There is evidence¹⁰⁴ both for and against this proposal.¹⁰⁵

11.E. THE EFFECT OF THE LEAVING GROUP

In the vast majority of aromatic electrophilic substitutions, the leaving group is H^+ as indicated above, and very little work has been done on the relative electrofugal ability of other leaving groups. However, the following orders of leaving-group ability have been suggested¹⁰⁶: (1) for leaving groups that depart without assistance ($\text{S}_{\text{N}}1$ process with respect to the leaving group), $\text{NO}_2^+^{107} < i\text{Pr}^+ \sim \text{SO}_3 < t\text{-Bu}^+ \sim \text{ArN}_2^+ < \text{ArCHOH}^+ < \text{NO}^+ < \text{CO}_2$; (2) for leaving groups that depart with assistance from an outside nucleophile ($\text{S}_{\text{N}}2$ process), $\text{Me}^+ < \text{Cl}^+ < \text{Br}^+ < \text{D}^+ \sim \text{RCO}^+ < \text{H}^+ \sim \text{I}^+ < \text{Me}_3\text{Si}^+$. We can use this kind of list to help predict which group, X or Y, will cleave from an arenium ion **30** (see **1**, where $\text{Y} = \text{H}$) once it has been formed, and so obtain an idea of which electrophilic substitutions are feasible. However, a potential leaving group can also affect a reaction in another way: by influencing the rate at which attack of the original electrophile leads to attachment directly at the ipso position. Partial rate factors for electrophilic attack at a position substituted by a group other than hydrogen are called ipso partial rate factors (i_f^X).⁵⁷ Such factors for the nitration of *p*-haloanisoles are 0.18, 0.08, and 0.06, for *p*-iodo-, *p*-bromo-, and *p*-chloroanisole, respectively.¹⁰⁸ This means, for example, that attack at the electrophile in this case leads to attachment at the 4 position of 4-iodoanisole 0.18 times as fast as a single position of benzene. Note that this is far slower than attachment at the 4 position resulting from attack of anisole itself so that the presence of the iodo group greatly slows the reaction at that position. A similar experiment on *p*-cresol showed that ipso attack at the methyl position was 6.8 times slower than attack of phenol leading to attachment at the para position.¹⁰⁹ Thus, in these cases, both an iodo and a methyl group deactivate the ipso position.¹¹⁰

11.F. REACTIONS

The reactions in this chapter are classified according to leaving group. Hydrogen replacements are treated first, and then rearrangements in which the attacking entity is first cleaved from another part of the molecule (hydrogen is also the leaving group in these cases), and finally replacements of other leaving groups.

11.F.i. Hydrogen as the Leaving Group in Simple Substitution Reactions

A. Hydrogen as the Electrophile

11-1 Hydrogen Exchange

Deuterio-de-hydrogenation or Deuteration

Aromatic compounds can exchange hydrogen atoms when treated with acids. The reaction is used chiefly to study mechanistic questions¹¹¹ (including substituent effects), but can also be useful to deuterate (add ^2H) or tritiate (add ^3H) aromatic rings selectively. The usual directive effects apply and, for example, phenol treated with D_2O gives slow exchange on heating, with only ortho and para hydrogen atoms being exchanged.¹¹² Strong acids, of course, exchange faster with aromatic substrates, and this exchange must be taken into account when studying the mechanism of any aromatic substitution catalyzed by acids. There is a great deal of evidence that exchange takes place by the ordinary arenium ion mechanism. Among the evidence are the orientation effects noted above and the finding that the reaction is general acid catalyzed, which means that a proton is transferred in the slow step¹¹³ (Sec. 8.D). Furthermore, many examples have been reported of stable solutions of arenium ions formed by attack of a proton on an aromatic ring.⁵ Simple aromatic compounds can be extensively deuterated in a convenient fashion by treatment with D_2O and BF_3 .¹¹⁴ It has been shown that tritium exchange takes place readily at the 2 position of **31**, despite the fact that this position is hindered by the bridge. The rates were not very different from the comparison compound 1,3-dimethylnaphthalene.¹¹⁵

Hydrogen exchange can also be effected with strong bases¹¹⁶ (e.g., NH_2^-). In these cases, the slow step is the proton transfer:¹¹⁷

so the $\text{S}_{\text{E}}1$ mechanism and not the usual arenium ion mechanism is operating.¹¹⁸ Aromatic rings can also be deuterated by treatment with D_2O and a Rh(III) chloride¹¹⁹ or Pt¹²⁰ catalyst

or with C_6D_6 and an alkylaluminum dichloride catalyst,¹²¹ though rearrangements may take place during the latter procedure. Tritium (^3H , abbreviated T) can be introduced by treatment with T_2O and an alkylaluminum dichloride catalyst.¹²¹ Tritiation at specific sites (e.g., >90% para in toluene) has been achieved with T_2 gas and a microporous aluminophosphate catalyst.¹²²

B. Nitrogen Electrophiles

11-2 Nitration or Nitro-de-hydrogenation

Most aromatic compounds, whether of high or low reactivity, can be nitrated, because a wide variety of nitrating agents is available.¹²³ For benzene, the simple alkylbenzenes, and less reactive compounds, the most common reagent is a mixture of concentrated nitric and sulfuric acids,¹²⁴ but for active substrates, the reaction can be carried out with nitric acid alone,¹²⁵ or in water, acetic acid, acetic anhydride, or chloroform.¹²⁶ Milder conditions are necessary for active compounds (e.g., amines, phenols, and pyrroles), since reaction with mixed nitric and sulfuric acids would oxidize these substrates. With active substrates, (e.g., anilines¹²⁷ and phenols,¹²⁸ nitration can be accomplished by nitrosation under oxidizing conditions with a mixture of dilute nitrous and nitric acids.¹²⁹ Trimethoxybenzenes were nitrated easily with ceric ammonium nitrate on silica gel,¹³⁰ and mesitylene was nitrated in an ionic liquid using nitric acid–acetic anhydride.¹³¹ Phenol can also be nitrated in an ionic liquid.¹³² An alternative route for the nitration of activated aromatic compounds (e.g., anisole), used a nitrate ester (RONO_2) with triflic acid in an ionic liquid for ortho-selective nitration.¹³³

For nitration reactions of “normal” aromatic compounds, representative nitrating agents are NaNO_2 and trifluoroacetic acid,¹³⁴ $\text{N}_2\text{O}_4/\text{O}_2$ and a catalytic amount of zeolite H β ,¹³⁵ $\text{Yb}(\text{OTf})_3$,¹³⁶ $\text{Bi}(\text{NO}_3)_3 \cdot 5\text{H}_2\text{O}$,¹³⁷ ceric ammonium nitrate,¹³⁸ urea nitrate and nitrourea,¹³⁹ and nitronium salts.¹⁴⁰ A mixture of NO_2 and ozone has also been used.¹⁴¹ Nitric acid, in the presence of P_2O_5 supported on SiO_2 , is useful for the nitration of aromatic compounds under solvent-free conditions.¹⁴² Nitration of styrene poses a problem since addition occurs at the $\text{C}=\text{C}$ unit to give a 1-nitroethyl aryl.¹⁴³ Deactivated aromatic rings, as in acetophenone, were nitrated with N_2O_5 and $\text{Fe}(\text{acac})_2$ ($\text{acac}=\text{acetylacetone}$).¹⁴⁴ Heterocycles (e.g., pyridine) are nitrated with N_2O_5 and SO_2 .¹⁴⁵

When anilines are nitrated under strong acid conditions, meta orientation is generally observed, because the ammonium salt is the species undergoing nitration, which is the conjugate acid of the amine. If the conditions are less acidic, the free amine is nitrated and the orientation is ortho–para. Although the free base may be present in much smaller amounts than the conjugate acid, it is far more susceptible to aromatic substitution (see also, Sec. 11.B.i). Because of these factors and because they are vulnerable to oxidation by nitric acid, primary aromatic amines are often protected before nitration by treatment with acetyl chloride (Reaction 16-72) or acetic anhydride (Reaction 16-73). Nitration of the resulting acetanilide derivative avoids all these problems. There is evidence that when the reaction takes place on the free amine, it is the nitrogen that is attacked to give an *N*-nitro compound ($\text{Ar}-\text{NH}-\text{NO}_2$), which rapidly undergoes rearrangement (see Reaction 11-28) to give the product.¹⁴⁶

Since the nitro group is deactivating, it is usually easy to stop the reaction after one group has entered the ring, but a second and a third group can be introduced if desired, especially when an activating group is also present. Even *m*-dinitrobenzene can be nitrated if vigorous conditions are applied. This has been accomplished with $\text{NO}_2^+ \text{BF}_4^-$ in FSO_3H at 150 °C.¹⁴⁷

With most of the reagents mentioned, the attacking species is the nitronium ion (NO_2^+). Among the ways in which this ion is formed are

1. In concentrated sulfuric acid, by an acid–base reaction in which nitric acid is the base:

This ionization is essentially complete.

2. In concentrated nitric acid alone,¹⁴⁸ by a similar acid–base reaction in which one molecule of nitric acid is the acid and another the base:

This equilibrium lies to the left ($\sim 4\%$ ionization), but enough NO_2^+ is formed for nitration to occur.

3. The equilibrium just mentioned occurs to a small extent even in organic solvents.
4. With N_2O_5 in CCl_4 , there is spontaneous dissociation:

but in this case there is evidence that some nitration also takes place with undissociated N_2O_5 as the electrophile.

5. When nitronium salts are used, NO_2^+ is of course present to begin with. Esters and acyl halides of nitric acid ionize to form NO_2^+ .

There is a great deal of evidence that NO_2^+ is present in most nitration reactions and that it is the attacking entity,¹⁴⁹ for example,

1. Nitric acid has a peak in the Raman spectrum. When nitric acid is dissolved in concentrated sulfuric acid, the peak disappears and two new peaks appear, one at 1400 cm^{-1} attributable to NO_2^+ and one at 1050 cm^{-1} due to HSO_4^- .¹⁵⁰
2. On addition of nitric acid, the freezing point of sulfuric acid is lowered about four times the amount expected if no ionization has taken place.¹⁵¹ This means that the addition of one molecule of nitric acid results in the production of four particles, which is strong evidence for the ionization reaction between nitric and sulfuric acids given above.
3. The fact that nitronium salts in which nitronium ion is known to be present (by X-ray studies) nitrate aromatic compounds shows that this ion does attack the ring.
4. The rate of the reaction with most reagents is proportional to the concentration of NO_2^+ , not to that of other species.¹⁵² When the reagent produces this ion in small

amounts, the attack is slow and only active substrates can be nitrated. In concentrated and aqueous mineral acids, the kinetics are second order: first order each in aromatic substrate and in nitric acid (unless pure nitric acid is used in which case there are pseudo-first-order kinetics). But in organic solvents (e.g., nitromethane, acetic acid, and CCl_4), the kinetics are first order in nitric acid alone and zero order in aromatic substrate, because the rate-determining step is formation of NO_2^+ and the substrate does not take part in this.

In a few cases, depending on the substrate and solvent, there is evidence that the arenium ion is not formed directly, but via the intermediacy of a radical pair (see Sec. 11.D), such as **32**.¹⁵³

Arylboronic acids have been shown to react with ammonium nitrate and trifluoroacetic acid to give the corresponding nitrobenzene.¹⁵⁴

11-3 Nitrosation or Nitroso-de-hydrogenation

Ring nitrosation¹⁵⁵ with nitrous acid is normally carried out only with active substrates (e.g., amines and phenols). However, primary aromatic amines give diazonium ions (Reaction **13-19**) when treated with nitrous acid,¹⁵⁶ and secondary amines tend to give *N*-nitroso rather than *C*-nitroso compounds (Reaction **12-50**); hence this reaction is normally limited to phenols and tertiary aromatic amines. Nevertheless, secondary aromatic amines can be *C*-nitrosated in two ways. The *N*-nitroso compound first obtained can be isomerized to a *C*-nitroso compound (Reaction **11-29**), or it can be treated with another equivalent of nitrous acid to give an *N,C*-dinitroso compound. Also, a successful nitrosation of anisole has been reported, where the solvent was $\text{CF}_3\text{COOH}-\text{CH}_2\text{Cl}_2$.¹⁵⁷

Much less work has been done on the mechanism of this reaction than on Reaction **11-2**.¹⁵⁸ In some cases, the attacking entity is NO^+ , but in others it is apparently NOCl , NOBr , N_2O_3 , and so on, in each of which there is a carrier of NO^+ . Both NOCl and NOBr are formed during the normal process of making nitrous acid (the treatment of sodium nitrite with HCl or HBr). Nitrosation requires active substrates because NO^+ is much

less reactive than NO_2^+ . Kinetic studies have shown that NO^+ is at least 10^{14} times less reactive than NO_2^+ .¹⁵⁹ A consequence of the relatively high stability of NO^+ is that this species is easily cleaved from the arenium ion, so that k_{-1} competes with k_2 (Sec. 11.A.i) and isotope effects are found.¹⁶⁰ With phenols, there is evidence that nitrosation may first take place at the OH group, after which the nitrite ester thus formed rearranges to the C-nitroso product.¹⁶¹ Tertiary aromatic amines substituted in the ortho position generally do not react with HONO, probably because the ortho substituent prevents planarity of the dialkylamino group, without which the ring is no longer activated. This is an example of steric inhibition of resonance (Sec. 2.F).

OS I, 214, 411, 511; II, 223; IV, 247.

11-4 Diazonium Coupling

Arylazo-de-hydrogenation

Aromatic diazonium ions normally couple only with active substrates (e.g., amines and phenols).¹⁶² Many of the products of this reaction are used as dyes (*azo dyes*).¹⁶³ Presumably because of the size of the species attacked by the aromatic ring, substitution is mostly para to the activating group, unless that position is already occupied, in which case ortho substitution takes place. The pH of the solution is important both for phenols and amines. For amines, the solutions may be mildly acidic or neutral. The fact that amines give ortho and para products shows that even in mildly acidic solution they react in their un-ionized form. If the acidity is too high, the reaction does not occur, because the concentration of free amine becomes too small. Phenols must be coupled in slightly alkaline solution where they are converted to the more reactive phenoxide ions, because phenols themselves are not active enough for the reaction. However, neither phenols nor amines react in moderately alkaline solution, because the diazonium ion is converted to a diazo hydroxide ($\text{Ar}-\text{N}=\text{N}-\text{OH}$). Primary and secondary amines face competition from attack at the nitrogen.¹⁶⁴ However, the resulting *N*-azo compounds (aryl triazenes) can be isomerized to *C*-azo compounds (Reaction 11-30). In at least some cases, even when the *C*-azo compound is isolated, it is the result of initial *N*-azo compound formation followed by isomerization. It is therefore possible to synthesize the *C*-azo compound directly in one laboratory step.¹⁶⁵ Acylated amines and phenolic ethers and esters are ordinarily not active enough for this reaction, though it is sometimes possible to couple them (as well as such polyalkylated benzenes as mesitylene and pentamethylbenzene) to diazonium ions containing electron-withdrawing groups in the para position, since such groups increase the concentration of the positive charge and thus the electrophilicity of the ArN_2^+ . Some coupling reactions that are otherwise very slow

(in cases where the coupling site is crowded) are catalyzed by pyridine for reasons discussed in Section 11.A.i. Phase-transfer catalysis has also been used.¹⁶⁶

Coupling of a few aliphatic diazonium compounds to aromatic rings has been reported. All the examples reported so far involve cyclopropanediazonium ions and bridgehead diazonium ions, in which loss of N₂ would lead to very unstable carbocations.¹⁶⁷ Azobenzenes have been prepared by Pd catalyzed coupling of aryl hydrazides with aryl halides, followed by direct oxidation.¹⁶⁸

The mechanism of (*Z/E*) isomerization in Ar—N=NAr systems has been studied.¹⁶⁹ OS I, 49, 374; II, 35, 39, 145.

11-5 Direct Introduction of the Diazonium Group

Diazonation or Diazonio-de-hydrogenation

Diazonium salts can be prepared directly by replacement of an aromatic hydrogen without the necessity of going through the amino group.¹⁷⁰ The reaction is essentially limited to active substrates (amines and phenols), since otherwise poor yields are obtained. Since the reagents and the substrate are the same as in Reaction 11-3, the first species formed is the nitroso compound. In the presence of excess nitrous acid, this is converted to the diazonium ion.¹⁷¹ The reagent (azidochloromethylene)dimethylammonium chloride [Me₂N=C(Cl)N₃ Cl[−]] can also introduce the diazonium group directly into a phenol.¹⁷² A synthesis of solid aryldiazonium chlorides is now available.¹⁷³

11-6 Amination or Amino-de-hydrogenation¹⁷⁴

Aromatic compounds can be converted to primary aromatic amines in 10–65% yields, by treatment with hydrazoic acid (HN₃) in the presence of AlCl₃ or H₂SO₄.¹⁷⁵ Higher yields (>90%) have been reported with trimethylsilyl azide (Me₃SiN₃) and triflic acid (F₃CSO₂OH).¹⁷⁶ Treatment of an aromatic compound with tetramethylhydrazonium iodide and then ammonium also gives the aryl amine.¹⁷⁷ Tertiary amines have been prepared in ~50–90% yields by treatment of aromatic hydrocarbons with *N*-chlorodialkylamines; by heating in 96% sulfuric acid; or with AlCl₃ or FeCl₃ in nitroalkane solvents; or

by irradiation.¹⁷⁸ Treatment of an aryl halide with an amine and a Pd catalyst leads to the aniline derivative.¹⁷⁹

Tertiary (and to a lesser extent, secondary) aromatic amines can also be prepared in moderate-to-high yields by amination with an *N*-chlorodialkylamine (or an *N*-chloroalkylamine) and a metallic-ion catalyst (e.g., Fe²⁺, Ti³⁺, Cu⁺, Cr²⁺) in the presence of sulfuric acid.¹⁸⁰ The attacking species in this case is the aminium radical ion (R₂NH^{•+}) formed by¹⁸¹

Because attack is by a positive species (even though it is a free radical), orientation is similar to that in other electrophilic substitutions (e.g., phenol and acetanilide give ortho and para substitution, mostly para). When an alkyl group is present, attack at the benzylic position competes with ring substitution. Aromatic rings containing only meta-directing groups do not give the reaction at all. Fused-ring systems react well.¹⁸²

Unusual orientation has been reported for amination with haloamines and with NCl₃ in the presence of AlCl₃. For example, toluene gave predominately meta amination.¹⁸³ It has been suggested that initial attack in this case is by Cl⁺ and that a nitrogen nucleophile (whose structure is not known but is represented here as NH₂[−] for simplicity) adds to the resulting arenium ion, so that the initial reaction is addition to a carbon–carbon double bond followed by elimination of HCl from **33**.¹⁸⁴

According to this suggestion, the electrophilic attack is at the para position (or the ortho, which leads to the same product) and the meta orientation of the amino group arises indirectly. This mechanism is called the *σ*-substitution mechanism.

Diphenyliodonium salts react with amines in the presence of a Cu catalyst. Diphenyliodonium tetrafluoroborate, (Ph₂I⁺ BF₄[−]), reacts with indole in DMF at 150 °C with a Cu (OAc)₂ catalyst (e.g., to give *N*-phenylindole).¹⁸⁵

Aromatic compounds that do not contain meta-directing groups can be converted to diarylamines by treatment with aryl azides in the presence of phenol at −60 °C: ArH + Ar'N₃ → ArNHAr'.¹⁸⁶ Diarylamines are also obtained by the reaction of

C. Sulfur Electrophiles

11-7 Sulfonation or Sulfo-de-hydrogenation

The sulfonation reaction is very broad in scope and many aromatic hydrocarbons (including fused-ring systems), aryl halides, ethers, carboxylic acids, amines,¹⁹⁴ acylated amines, ketones, nitro compounds, and sulfonic acids have been sulfonated.¹⁹⁵ Phenols can also be successfully sulfonated, but attack at oxygen may compete.¹⁹⁶ Sulfonation is often accomplished with concentrated sulfuric acid, but it can also be done with fuming H_2SO_4 ,

SO_3 , ClSO_2OH , $\text{ClSO}_2\text{NMe}_2/\text{In}(\text{OTf})_3$,¹⁹⁷ or other reagents.¹⁹⁸ A FeCl_3 based ionic liquid has been used for the sulfonation of aromatic compounds.¹⁹⁹ As with nitration (Reaction 11-2), reagents of a wide variety of activity are available to suit both highly active and highly inactive substrates. Since this reaction is reversible (see Reaction 11-38), it may be necessary to drive the reaction to completion. However, at low temperatures the reverse reaction is very slow and the forward reaction is practically irreversible.²⁰⁰ Sulfur trioxide reacts much more rapidly than sulfuric acid with benzene (it is nearly instantaneous). Sulfones are often side products. When sulfonation is carried out on a benzene ring containing four or five alkyl and/or halogen groups, rearrangements usually occur (see Reaction 11-36).

A great deal of work has been done on the mechanism, chiefly by Cerfontain and co-workers.²⁰¹ Mechanistic study is made difficult by the complicated nature of the solutions. Indications are that the electrophile varies with the reagent, though SO_3 is involved in all cases, either free or combined with a carrier. In aq H_2SO_4 solutions, the electrophile is thought to be H_3SO_4^+ (or a combination of H_2SO_4 and H_3O^+) at concentrations below $\sim 80\text{--}85\%$ H_2SO_4 , and $\text{H}_2\text{S}_2\text{O}_7$ (or a combination of H_2SO_4 and SO_3) at concentrations higher than this²⁰² (the changeover point varies with the substrate²⁰³). Evidence for a change in electrophile is that in both the dilute and the concentrated solutions the rate of the reaction was proportional to the activity of H_3SO_4^+ and $\text{H}_2\text{S}_2\text{O}_7$, respectively. Further evidence is that with toluene as substrate the two types of solution gave very different ortho/para ratios. The mechanism is essentially the same for both electrophiles and may be shown as²⁰²:

The other product of the first step is HSO_4^- or H_2O from $\text{H}_2\text{S}_2\text{O}_7$ or H_3SO_4^+ , respectively. Path *a* is the principal route, except at very high H_2SO_4 concentrations, when path *b* becomes important. With H_3SO_4^+ the first step is rate determining under all conditions, but with $\text{H}_2\text{S}_2\text{O}_7$ the first step is the slow step only up to $\sim 96\%$ H_2SO_4 , when a subsequent proton transfer becomes partially rate determining.²⁰⁴ The $\text{H}_2\text{S}_2\text{O}_7$ is more reactive than H_3SO_4^+ . In fuming sulfuric acid (H_2SO_4 containing excess SO_3), the electrophile is

thought to be $\text{H}_3\text{S}_2\text{O}_7^+$ (protonated $\text{H}_2\text{S}_2\text{O}_7$) up to $\sim 104\%$ H_2SO_4 and $\text{H}_2\text{S}_4\text{O}_{13}$ ($\text{H}_2\text{SO}_4 + 3 \text{SO}_3$) beyond this concentration.²⁰⁵ Finally, when pure SO_3 is the reagent in aprotic solvents, SO_3 itself is the actual electrophile.²⁰⁶ Free SO_3 is the most reactive of all these species, so that attack here is generally fast and a subsequent step is usually rate determining, at least in some solvents.

11-8 Halosulfonation or Halosulfo-de-hydrogenation

Aromatic sulfonyl chlorides can be prepared directly, by treatment of aromatic rings with chlorosulfuric acid.²⁰⁷ Since sulfonic acids can also be prepared by the same reagent (Reaction 11-7), it is likely that they are intermediates, being converted to the halides by excess chlorosulfuric acid.²⁰⁸ The reaction has also been effected with bromo- and fluorosulfuric acids. Sulfinyl chlorides (ArSOCl) have been prepared by the reaction of thionyl chloride and an aromatic compound on Montmorillonite K-10 clay.²⁰⁹

OS I, 8, 85.

11-9 Sulfonylation

Alkylsulfonylation or Alkylsulfo-de-hydrogenation

Diaryl sulfoxides can be prepared by the reaction of aromatic compounds with thionyl chloride and triflic acid.²¹⁰ Diaryl sulfones have also been prepared using thionyl chloride with the ionic liquid $[\text{bmim}]\text{Cl} \cdot \text{AlCl}_3$.²¹¹ Diaryl sulfones can be formed by treatment of aromatic compounds with aryl sulfonyl chlorides and a *Friedel–Crafts catalyst*.²¹² This reaction is analogous to *Friedel–Crafts acylation* with carboxylic acid halides (Reaction 11-17). In a better procedure, the aromatic compound is treated with an aryl sulfonic acid and P_2O_5 in polyphosphoric acid.²¹³ Still another method uses an arylsulfonic trifluoromethanesulfonic anhydride ($\text{ArSO}_2\text{OSO}_2\text{CF}_3$) (generated *in situ* from ArSO_2Br and $\text{CF}_3\text{SO}_3\text{Ag}$) without a catalyst.²¹⁴ Indium tris(triflate)²¹⁵ and indium trichloride²¹⁶ leads to sulfonation of aromatic compounds with sulfonyl chlorides. Indium bromide was used

with indoles.²¹⁷ A ferric chloride catalyzed reaction with microwave irradiation has also been reported,²¹⁸ as has the use of zinc metal with microwave irradiation.²¹⁹ The reaction can be extended to the preparation of alkyl aryl sulfones by the use of a sulfonyl fluoride.²²⁰

Direct formation of diaryl sulfones from benzenesulfonic acid and benzene was accomplished using Nafion-H.²²¹ Aryl halides react with sulfinic acid salts, via a proline-promoted CuI catalyzed coupling reaction.²²² Arylboronic acids (see Reaction 10-73) are sulfonated in ionic liquids, using a Cu catalyst.²²³

OS X, 147.

D. Halogen Electrophiles

11-10 Halogenation²²⁴

Halo-de-hydrogenation

1. *Chlorine*²²⁵ and *Bromine*.²²⁶ Aromatic compounds can be brominated or chlorinated by treatment with bromine or chlorine in the presence of a catalyst.²²⁷ For amines and phenols the reaction is so rapid that it is carried out with a dilute solution of Br₂ or Cl₂ in water at room temperature, or with aqueous HBr in DMSO.²²⁸ Typically, it is not possible to stop the reaction with anilines before all the available ortho and para positions are substituted, because the initially formed haloamines are weaker bases than the original amines and are less likely to be protonated by the liberated HX.²²⁹ For this reason, the corresponding anilides are used if monosubstitution is desired. With phenols it is possible to stop after one group has entered.²³⁰ The rapid room temperature reaction with amines and phenols is often used as a test for these compounds. In general, for active substrates including anilines, phenols, naphthalene, and polyalkylbenzenes²³¹ (e.g., mesitylene and isodurene), no catalyst is needed. The overall effectiveness of reagents in aromatic substitution is Cl₂ >

$\text{BrCl} > \text{Br}_2 > \text{ICl} > \text{I}_2$. A mixture of ZnBr_2 /diazene has been suggested for the regioselective para-bromination of activated aromatic substrates.²³²

When chlorination or bromination is carried out at high temperatures (e.g., 300–400 °C), ortho–para directing groups direct meta and vice versa.²³³ A different mechanism operates here, which is not completely understood. It is also possible for bromination to take place by the $\text{S}_{\text{E}}1$ mechanism, for example, in the *t*-BuOK catalyzed bromination of 1,3,5-tribromobenzene.²³⁴

For less activated aromatic rings, iron was commonly used at one time for halogenation, but the real catalyst was shown not to be the iron itself, but rather the ferric bromide or chloride formed in small amounts from the reaction between iron and the reagent. Indeed, ferric chloride and other Lewis acids are typically directly used as catalysts, as is iodine. Many Lewis acids can be used, including thallium(III) acetate, which promotes bromination with high regioselectivity para to an ortho–para directing group.²³⁵ A mixture of $\text{Mn}(\text{OAc})_3$ and acetyl chloride, with ultrasound, chlorinates anisole with high selectivity.²³⁶

Other reagents can be used to promote chlorination or bromination. copper(II)-catalyzed chlorination has been reported using dioxygen as an oxidant.²³⁷ *N*-Bromosuccinimide under photochemical conditions²³⁸ brominates aromatic compounds, as does pyridinium bromide perbromide,²³⁹ and NBS in acetic acid with ultrasound is effective.²⁴⁰ Both NCS and NBS with aq BF_3 gave the respective chloride or bromide.²⁴¹ The NBS in an ionic liquid²⁴² gave the brominated aromatic, and para-bromination of aniline was reported by mixing aniline with the ionic liquid, bmim Br_2 .²⁴³ Similarly, hmim Br_3 ²⁴⁴ without another reagent is a brominating agent. Bromine on silica gel²⁴⁵ or with SO_2Cl_2 ²⁴⁶ gave good yields of the brominated aromatic compound. Majetich et al.²⁴⁷ reported the use of HBr/DMSO for the remarkably selective bromination of aniline. Highly para-selective bromination was accomplished using dioxane dibromide, under solvent free conditions.²⁴⁸

Other reagents have been used for chlorination and bromination. If the substrate contains alkyl groups, side-chain halogenation (Reaction **14-1**) is possible with most of the reagents mentioned, including chlorine and bromine. Since side-chain halogenation is catalyzed by light, the reactions should be run in the absence of light wherever possible. Sulfuryl chloride (SO_2Cl_2) in acetic acid chlorinates anisole derivatives,²⁴⁹ and acetyl chloride with a catalytic amount of ceric ammonium nitrate also converted aromatic compounds to the corresponding chlorinated derivative.²⁵⁰ A mixture of KCl and Oxone[®] chlorinated activated aromatic compounds.²⁵¹ Oxone and KBr gave good para-bromination of anisole,²⁵² as does NH_4Br /Oxone.²⁵³ Dibromoisocyanuric acid in H_2SO_4 is a very good brominating agent²⁵⁴ for substrates with strongly deactivating substituents.²⁵⁵ *N*-Chlorosuccinimide in isopropyl alcohol²⁵⁶ chlorinates aniline derivatives, and $\text{KBr}/\text{NaBO}_3 \cdot 4 \text{H}_2\text{O}$ has been used for the bromination of aniline derivatives.²⁵⁷ Conversion of aniline to the *N*- SnMe_3 derivative allowed *in situ* bromination with bromine, with high para selectivity after conversion to the free amine with aq KF.²⁵⁸ Pyridinium bromochromate converted phenolic derivatives to brominated phenols.²⁵⁹

Predominant ortho chlorination²⁶⁰ of phenols has been achieved with chlorinated cyclohexadienes,²⁶¹ while para chlorination of phenols, phenolic ethers, and amines can be accomplished with *N*-chloroamines²⁶² and with *N*-chlorodimethylsulfonium chloride ($\text{Me}_3\text{S}^+\text{Cl}^-$).²⁶³ The last method is also successful for bromination when *N*-bromodimethylsulfonium bromide is used. Highly selective ortho chlorination of acetanilides has been reported, using a combination of P and Cu catalysts.²⁶⁴ Iridium-catalyzed borylation of arenes leads to meta-halogenation.²⁶⁵ Certain alkylated phenols can be brominated in the meta positions with Br_2 in the superacid solution $\text{SbF}_5\text{—HF}$.²⁶⁶ It is likely that meta orientation is the result of conversion by the superacid of the OH group to the OH_2^+ group, which should be meta-directing because of its positive charge. Bromination and the *Sandmeyer reaction* (**14-20**) can be carried out in one laboratory step to give **37**

by treatment of an aromatic primary amine with CuBr_2 and *tert*-butyl nitrite, for example,²⁶⁷

With deactivated aromatic derivatives, NBS and H_2SO_4 is an effective reagent, giving the meta-brominated product.²⁶⁸ Bromination at C-6 of 2-aminopyridine was accomplished with NBS.²⁶⁹ An alternative route reacted pyridine *N*-oxide with POCl_3 and triethylamine to give 2-chloropyridine.²⁷⁰

For reactions in the absence of a catalyst, the attacking entity is simply Br_2 or Cl_2 that has been polarized by the ring.²⁷¹

Evidence for molecular chlorine or bromine as the attacking species in these cases is that acids, bases, and other ions, especially chloride ion, accelerate the rate about equally, though if chlorine dissociated into Cl^+ and Cl^- , the addition of chloride should decrease the rate and the addition of acids should increase it. Intermediate **38** has been detected spectrally in the aqueous bromination of phenol.²⁷²

When a Lewis acid catalyst²⁷³ is used with chlorine or bromine, the attacking entity may be Cl^+ or Br^+ , formed by $\text{FeCl}_3 + \text{Br}_2 \rightarrow \text{FeCl}_3\text{Br}^- + \text{Br}^+$, or it may be Cl_2 or Br_2 , polarized by the catalyst. With other reagents, the attacking entity in brominations may be Br^+ or a species (e.g., H_2OBr^+ , the conjugate acid of HOBr), in which H_2O is a carrier of Br^+ .²⁷⁴ With HOCl in water the electrophile may be Cl_2O , Cl_2 , or H_2OCl^+ ; in acetic acid it is generally AcOCl . All these species are more reactive than HOCl itself.²⁷⁵ It is extremely doubtful that Cl^+ is a significant electrophile in chlorinations by HOCl .²⁷⁵ It has been demonstrated in the reaction between *N*-methylaniline and calcium hypochlorite that the chlorine entity is

attacked by the *nitrogen* to give *N*-chloro-*N*-methylaniline, which rearranges (as in Reaction 11-31) to give a mixture of ring-chlorinated *N*-methylanilines in which the ortho isomer predominates.²⁷⁶ In addition to hypohalous acids and metal hypohalites, organic hypohalites are reactive. An example is *tert*-butylhypobromite (*t*-BuOBr), which brominated toluene in the presence of zeolite (HNaX).²⁷⁷

Furan and thiophene are known to polymerize in the presence of strong acid, both Brønsted–Lowry and Lewis. For such highly reactive heteroaromatic systems, alternative halogenating reagents are commonly used. Furan was converted to 2-bromofuran with a bromine•dioxane complex (e.g., at <0 °C.²⁷⁸ 3-Butylthiophene reacted with NBS/acetic acid to give 2-bromo-3-butylthiophene.²⁷⁹ *N*-Methylpyrrole reacted with NBS and a catalytic amount of PBr₃, at –78 °C → –10 °C, to give *N*-methyl-3-bromopyrrole.²⁸⁰

2. *Iodine*. Iodine is the least reactive of the halogens in aromatic substitution.²⁸¹ Except for active substrates, an oxidizing agent must normally be present to oxidize I₂ to a better electrophile.²⁸² Examples of such oxidizing agents used with I₂ are HNO₃, SO₃, hypervalent iodine compounds [e.g., PhI(OTf)₂,²⁸³ NaIO₄,²⁸⁴ ammonium iodide and H₂O₂,²⁸⁵ ceric ammonium nitrate,²⁸⁶ peroxydisulfates,²⁸⁷ and a mixture of NaIO₄/KI/NaCl].²⁸⁸ A solvent-free iodination used I₂ and AgNO₃.²⁸⁹ The reagent ICl is a better iodinating agent than iodine itself.²⁹⁰ A mixture of ICl/In(OTf)₃ has also been used.²⁹¹ Iodination can also be accomplished by treatment of the substrate with NCI and H₂SO₄,²⁹² *N*-Iodosuccinamide and trifluoroacetic acid,²⁹³ KI/KIO₃ in aq methanol,²⁹⁴ KI and H₂O₂,²⁹⁵ and NaI with an iron catalyst.²⁹⁶ Sodium periodate and iodine was used to iodinate β-carbolines.²⁹⁷ A solvent-free iodination was accomplished using NaICl₂ and

an *N*-bromoammonium salt.²⁹⁸ Another solvent-free iodination used I₂ with Bi(NO₃)₃ on silica gel.²⁹⁹ A mixture of iodine/pyridine/dioxane leads to selective para-iodination of aniline derivatives.³⁰⁰ Selective ortho cyanation allows the reaction with iodine to give the corresponding aryl iodide.³⁰¹ Iodination of activated aromatics has been reported using KI and ammonium peroxodisulfate.³⁰² *N*-Iodosuccinimide and *p*-toluenesulfonic acid give regioselective iodination of phenol and related compounds.³⁰³

The actual attacking species is less clear than with bromine or chlorine. Iodine itself is too unreactive, except for active species (e.g., phenols), where there is good evidence that I₂ is the attacking entity.³⁰⁴ There is evidence that AcOI may be the reactive entity when peroxyacetic acid is the oxidizing agent,³⁰⁵ and I₃⁺ when SO₃ or HIO₃ is the oxidizing agent.³⁰⁶ The I⁺ ion has been implicated in several procedures.³⁰⁷ For an indirect method for accomplishing aromatic iodination see (Reaction 12-31).

3. *Fluorine*. Direct fluorination of aromatic rings with F₂ is not feasible at room temperature, because of the extreme reactivity of F₂.³⁰⁸ It has been accomplished at low temperatures (e.g., -70 to -20 °C, depending on the substrate),³⁰⁹ but the reaction is not yet of preparative significance. Fluorination has also been reported with acetyl hypofluorite (CH₃CO₂F, generated from F₂ and sodium acetate),³¹⁰ and with an *N*-fluoroperfluoroalkyl sulfonamide [e.g., (CF₃SO₂)₂NF].³¹¹ Pyridine has been converted to 2-fluoropyridine with F₂/I₂/NEt₃ in 1,1,2-trichloro-1,2,2-trifluoroethane.³¹² However, none of these methods seems likely to displace the *Schiemann reaction* (13-23; heating diazonium tetrafluoroborates) as the most common method for introducing fluorine into aromatic rings.

E. Carbon Electrophiles

A new carbon–carbon bond is formed in the reactions in this section. With respect to the aromatic ring, they are electrophilic substitutions, because a positive species attacks the ring. We treat them in this manner because it is customary. However, with respect to the electrophile, most of these reactions are nucleophilic substitutions, and what was said in Chapter 10 is pertinent to them.

11-11 Friedel–Crafts Alkylation

Alkylation or Alkyl-de-hydrogenation

The alkylation of aromatic rings, called *Friedel–Crafts alkylation*, is a reaction of very broad scope.³¹³ Catalytic asymmetric Friedel–Crafts alkylation reactions are known.³¹⁴ The most important reagents are alkyl halides, alkenes, and alcohols, but other types of reagent have also been employed.³¹³ Tertiary halides are particularly good substrates since they form relatively stable tertiary carbocations. When alkyl halides are used, the reactivity order is $\text{F} > \text{Cl} > \text{Br} > \text{I}$.³¹⁵ This trend can be seen in reactions of dihalo compounds (e.g., $\text{FCH}_2\text{CH}_2\text{CH}_2\text{Cl}$), which react with benzene to give $\text{PhCH}_2\text{CH}_2\text{CH}_2\text{Cl}$ ³¹⁶ when the catalyst is BCl_3 . By the use of this catalyst, it is therefore possible to place a haloalkyl group on a ring (see also, Reaction 11-14).³¹⁷ Di- and trihalides, when all the halogens are the same, usually react with more than one molecule of an aromatic compound; it is usually not possible to stop the reaction earlier.³¹⁸ Thus, benzene with CH_2Cl_2 gives not PhCH_2Cl , but Ph_2CH_2 ; benzene with CHCl_3 gives Ph_3CH . With CCl_4 , however, the reaction stops when only three rings have been substituted to give Ph_3CCl . Functionalized alkyl halides [e.g., $\text{ClCH}(\text{SEt})\text{CO}_2\text{Et}$] undergo Friedel–Crafts alkylation.³¹⁹ Montmorillonite clay-(K10) is an effective medium for alkylation reactions.³²⁰

Alkenes are especially good alkylating agents, generally proceeding by formation of an intermediate carbocation that reacts with the electron-rich aromatic ring, and the final product (39) incorporates a H and Ar from ArH to a $\text{C}=\text{C}$ double bond. Many variations are possible. This reaction has been accomplished in an ionic liquid, using $\text{Sc}(\text{OTf})_3$ as the catalyst.³²¹ Other catalysts include $\text{Sm}(\text{OTf})_3$.³²² Intramolecular versions lead to

polycyclic aromatic compounds.³²³ Benzene reacted with 1,2,3,6-tetrahydropyridine in the presence of trifluoromethanesulfonic acid to give 4-phenylpiperidine.³²⁴

When 4-methoxyphenol reacted with isobutylene (electrolysis with 3 M LiClO₄ in nitromethane and acetic acid), initial reaction with the phenolic oxygen generated an ether moiety and the resulting carbocation was attacked by the aromatic ring to form a benzofuran.³²⁵ Enantioselective alkylations have been reported for pyrroles and indoles, using a chiral Pybox–Cu complex.³²⁶

Acetylene reacts with 2 mol of aromatic compound to give 1,1-diarylethanes, and phenylacetylene reacted to give 1,1-diarylethenes with a Sc(OTf)₃ catalyst.³²⁷ Variations are possible here as well. Phenol reacted with trimethylsilylethyne, in the presence of SnCl₄ and 50% BuLi, at 105 °C, to give the 2-vinyl phenolic derivative.³²⁸ A Ru catalyzed intramolecular reaction with a pendant alkyne unit led to a dihydronaphthalene derivative,³²⁹ and a Rh catalyzed reaction led to indanone derivatives.³³⁰ An acidic fluoroantimonate(V) ionic liquid has been used as a catalyst.³³¹

Alcohols are more active than alkyl halides, but if a Lewis acid catalyst is used more catalyst is required, since the catalyst complexes with the OH group. However, proton acids (e.g., H₂SO₄) are often used to catalyze alkylation with alcohols. An intramolecular cyclization was reported from an allylic alcohol, using P₂O₅, to give indene derivatives.³³² Secondary alcohols are coupled to aromatic compounds using a heterobimetallic Ir–Sn complex.³³³ Molecular iodine has been used to catalyze benzylation of arenes with benzylic alcohols.³³⁴ A “contra Friedel–Crafts” *tert*-butylation has been reported.³³⁵ Diastereoselective alkylation is possible from alcohol precursors. High facial diastereoselectivity was reported with “chiral benzylic cations”, for example.³³⁶

When carboxylic esters are the reagents, there is competition between alkylation and acylation (Reaction 11-17). This competition can often be controlled by choice of catalyst, and alkylation is usually favored, but carboxylic esters are not often employed in Friedel–Crafts reactions. Other alkylating agents are ethers,³³⁷ thiols, sulfates, sulfonates, alkyl nitro compounds,³³⁸ and even alkanes and cycloalkanes, under conditions where these are converted to carbocations. Notable here are ethylene oxide, which puts the CH₂CH₂OH group onto the ring,³³⁹ and cyclopropyl³⁴⁰ units. For all types of reagent, the reactivity order is allylic ~ benzylic > tertiary > secondary > primary. Alkyl mesylates undergo alkylation reaction with benzene rings in the presence of Sc(OTf)₃.³⁴¹ Allylic acetates undergo alkylation with Mo(CO)₆,³⁴² and allylic chlorides react in the presence of ZnCl₂/SiO₂.³⁴³

Naphthalene and other fused ring compounds are so reactive that they react with the catalyst, and therefore tend to give poor yields in Friedel–Crafts alkylation. Heterocyclic rings also tend to be poor substrates for the reaction. Although some furans and thiophenes have been alkylated, polymerization is quite common, and a true alkylation of a pyridine or a quinoline has never been described.³⁴⁴ *N*-Methylpyrrole reacted with the C=C unit of methacrolein in the presence of a chiral catalyst (a chiral Friedel–Crafts catalyst) to give the 2-alkylated pyrrole, with good enantioselectivity.³⁴⁵ Alkylation at C-5 of 2-trimethylsilylfuran was accomplished using the carbocation [(*p*-MeOC₆H₄)₂CH⁺ OTf] and Proton Sponge (see Sec. 8.F, category 6).³⁴⁶ The reaction of isoquinoline with ClCO₂Ph and AgOTf, followed by reaction with an allylic silane, led to a 2-allylic dihydroisoquinoline.³⁴⁷

Regardless of which reagent is used, a catalyst is nearly always required.³⁴⁸ Lewis acid catalysts (e.g., aluminum chloride and boron trifluoride) are the most common, but many other Lewis acids have been used,³⁴⁹ and also proton acids (e.g., HF and H₂SO₄).³⁵⁰ Calcium has been used to catalyze Friedel–Crafts alkylation reactions, at room temperature.³⁵¹ For active halides, a trace of a less active catalyst (e.g., ZnCl₂) may be enough. For an unreactive halide (e.g., chloromethane), a more powerful catalyst (e.g., AlCl₃) is needed, and in larger amounts. In some cases, especially with alkenes, a Lewis acid catalyst causes reaction only if a small amount of proton-donating cocatalyst is present. Catalysts have been arranged in the following order of overall reactivity: AlBr₃ > AlCl₃ > GaCl₃

$> \text{FeCl}_3 > \text{SbCl}_5^{352} > \text{ZrCl}_4, \text{SnCl}_4 > \text{BCl}_3, \text{BF}_3, \text{SbCl}_3^{353}$; but the reactivity order in each case depends on the substrate, reagent, and conditions. Other Lewis acids have been used, of course, including SeCl_2 ,³⁵⁴ InCl_3 ,³⁵⁵ and enantiopure cycloalkyldialkylsilyl triflimide catalysts.³⁵⁶

Friedel–Crafts alkylation is unusual among the principal aromatic substitutions in that the entering group is activating (the product is more reactive than the starting aromatic substrate), and di- and polyalkylation are frequently observed. However, the activating effect of simple alkyl groups (e.g., ethyl and isopropyl) is only ~ 1.5 –3 times as fast as benzene for *Friedel–Crafts alkylations*,³⁵⁷ so it is often possible to obtain high yields of monoalkyl product.³⁵⁸ Actually, the fact that di- and polyalkyl derivatives are frequently obtained is not due to the small difference in reactivity, but to the circumstance that alkylbenzenes are preferentially soluble in the catalyst layer, where the reaction actually takes place.³⁵⁹ This factor can be removed by the use of a suitable solvent, by high temperatures, or by high-speed stirring.

It is important to note that the OH, OR, NH_2 , and so on, groups do not facilitate the reaction, since most Lewis acid catalysts coordinate with these basic groups. Although phenols give the usual *Friedel–Crafts reactions*, orienting ortho and para, the reaction is very poor for aniline derivatives. However, amines can undergo the reaction if alkenes are used as reagents and aluminum anilides as catalysts.³⁶⁰ In this method, the catalyst is prepared by treating the amine to be alkylated with one-third equiv of AlCl_3 . A similar reaction can be performed with phenols, though here the catalyst is $\text{Al}(\text{OAr})_3$.³⁶¹ Primary aromatic amines (and phenols) can be methylated regioselectively in the ortho position by an indirect method (see Reaction 11-23). For an indirect method for regioselective ortho methylation of phenols, see Reaction 15-65.

In most cases, meta-directing groups make the ring too inactive for alkylation. Nitrobenzene cannot be alkylated, and there are only a few reports of successful *Friedel–Crafts alkylations* when electron-withdrawing groups are present.³⁶² This is not because the attacking species is not powerful enough; indeed we have seen (Sec. 11.D) that alkyl cations are among the most powerful of electrophiles. The difficulty is caused by the fact that, with inactive substrates, degradation and polymerization of the electrophile occurs before it can attack the ring. However, if an activating and a deactivating group are both present on a ring, *Friedel–Crafts alkylation* can be accomplished.³⁶³ Aromatic nitro compounds can be methylated by a nucleophilic mechanism (Reaction 13-17).

The intermediate for *Friedel–Crafts alkylation* is a carbocation, and rearrangement to a more stable cation can be quite facile. Therefore, rearrangement of the alkyl substrate occurs frequently and is an important synthetic limitation of *Friedel–Crafts alkylation*. For example, benzene treated with *n*-propyl bromide gives mostly isopropylbenzene (cumene) and much less *n*-propylbenzene. Rearrangement is usually in the order primary \rightarrow secondary \rightarrow tertiary and usually occurs by migration of the smaller group on the adjacent carbon. Therefore, in the absence of special electronic or resonance influences on the migrating group (e.g., phenyl), H migrates before methyl, which migrates before ethyl, and so on (see discussion of rearrangement mechanisms in Chap 18). It is therefore not usually possible to put a primary alkyl group (other than methyl³⁶⁴ and ethyl) onto an aromatic ring by *Friedel–Crafts alkylation*. Because of these rearrangements, *n*-alkylbenzenes are often prepared by *acylation* (Reaction 11-17), followed by reduction (Reaction 19-61).

An important use of the *Friedel–Crafts alkylation* reaction is to effect ring closure,³⁶⁵ via an intramolecular process.³⁶⁶ The most common method is to heat an aromatic compound with aluminum chloride having a halogen, hydroxy, or alkene group in the proper position, as, for example, in the preparation of tetralin (**40**).

Another way of effecting ring closure through *Friedel–Crafts alkylation* is to use a reagent containing two groups (e.g., **41**). These reactions are most successful for the preparation of six-membered rings,³⁶⁷ though five- and seven-membered rings have also been closed in this manner. For other *Friedel–Crafts* ring-closure reactions, see Reactions 11-15, 11-13, and 11-17. An interesting variation in this reaction showed that *N*-acyl aniline derivatives, upon treatment with $\text{Et}_2\text{P}(=\text{O})\text{H}$ in water and a water soluble initiator (V-501) led to an intramolecular alkylation reaction to give an amide.³⁶⁸

As mentioned above, the electrophile in *Friedel–Crafts alkylation* is a carbocation, at least in most cases.³⁶⁹ This is in accord with the knowledge that carbocations rearrange in the direction primary \rightarrow secondary \rightarrow tertiary (see Chap 18). In each case, the cation is

formed from the attacking reagent and the catalyst. For the three most important types of reagent these reactions are

From alkyl halides

From alcohols³⁷⁰ and Lewis acids

From alcohols and protonic acids

From alkenes (a supply of protons is usually required)

There is direct evidence, from IR and NMR spectra, that the *tert*-butyl cation is quantitatively formed when *tert*-butyl chloride reacts with AlCl_3 in anhydrous liquid HCl .³⁷¹ In the case of alkenes, *Markovnikov's rule* (Sec. 15.B.ii) is followed. Carbocation formation is particularly easy from some reagents, because of the stability of the cations. Triphenylmethyl chloride³⁷² and 1-chloroadamantane³⁷³ alkylate activated aromatic rings (e.g., phenols and amines) with no catalyst or solvent. Ions as stable as this are less reactive than other carbocations and often attack only active substrates. The tropylium ion, for example, alkylates anisole, but not benzene.³⁷⁴ Note in Section 10.F that relatively stable vinylic cations can be generated from certain vinylic compounds. These have been used to introduce vinylic groups into aryl substrates.³⁷⁵ Lewis acids (e.g., BF_3 ³⁷⁶ or AlEt_3 ³⁷⁷ can also be used for alkylation of aromatic rings with alkene units.

There is considerable evidence that many *Friedel–Crafts alkylations*, especially with primary reagents, do not go through a completely free carbocation. The ion may exist as a tight ion pair with, say, AlCl_4^- as the counterion or as a complex. Among the evidence is that methylation of toluene by methyl bromide and methyl iodide gave different ortho/para/meta ratios,³⁷⁸ although the same ratios are expected if the same species are attacked in each case. Other evidence is that, in some cases, the reaction kinetics are third order; first order each in aromatic substrate, attacking reagent, and catalyst.³⁷⁹ In these instances, a mechanism in which the carbocation is slowly formed and then rapidly attacked by the aromatic ring is ruled out since, in such a mechanism, the substrate would not appear in the rate expression. Since it is known that free carbocations, once formed, are rapidly attacked by the ring (acting as a nucleophile), there are no free carbocations here. Another possibility (with alkyl halides) is that some alkylations take place by an $\text{S}_{\text{N}}2$ mechanism (with respect to the halide), in which case no carbocations would be involved at all. However, a completely $\text{S}_{\text{N}}2$ mechanism requires inversion of configuration. Most investigations of *Friedel–Crafts stereochemistry*, even where an $\text{S}_{\text{N}}2$ mechanism might most be expected, have resulted in total racemization, or at best a few percent inversion.

A few exceptions have been found,³⁸⁰ most notably where the reagent was optically active propylene oxide, in which case 100% inversion was reported.³⁸¹

Rearrangement is possible even with a non-carbocation mechanism. The rearrangement could occur *before* the attack on the ring takes place. It has been shown that treatment of $\text{CH}_3^{14}\text{CH}_2\text{Br}$ with AlBr_3 in the absence of any aromatic compound gave a mixture of the starting material and $^{14}\text{CH}_3\text{CH}_2\text{Br}$.³⁸² Similar results were obtained with $\text{PhCH}_2^{14}\text{CH}_2\text{Br}$, in which case the rearrangement was so fast that the rate could be measured only below -7° .³⁸³ Rearrangement could also occur *after* formation of the product, since alkylation is reversible (see Reaction 11-33).³⁸⁴

11-12 Hydroxyalkylation or Hydroxyalkyl-de-hydrogenation

When an aldehyde, ketone, or other carbonyl-containing substrate is treated with a protonic or Lewis acid, an oxygen-stabilized cation is generated. In the presence of an aromatic ring, *Friedel–Crafts type alkylation* occurs. The condensation of aromatic rings with aldehydes or ketones is called *hydroxyalkylation*.³⁸⁵ The reaction can be used to prepare alcohols,³⁸⁶ though more often the alcohol initially produced reacts with another molecule of aromatic compound (Reaction 11-11) to give diarylation. For this the reaction is quite useful, an example being the preparation of 1,1,1-trichloro-2,2'-bis(*p*-chlorophenyl)ethane DDT, 44:

The diarylation reaction is especially common with phenols (the diaryl product here is called a bisphenol). The reaction is normally carried out in alkaline solution on the phenolate ion.³⁸⁷ Another variation involved *Friedel–Crafts coupling* of an aldehyde to an activated aromatic compound (an aniline derivative) to give diaryl carbinols that exhibited

³⁸⁰ Some instances of retention of configuration have been reported; a neighboring-group mechanism is likely in these cases: see Effenberger, F.; Weber, T. *Angew. Chem. Int. Ed.* **1987**, 26, 142.

atropisomerism (see Sec. 4.C, category 5).³⁸⁸ When the reaction was done with a chiral aluminum complex, modest enantioselectivity was observed.

The hydroxymethylation of phenols with formaldehyde is called the *Lederer–Manasse reaction*. This reaction must be carefully controlled,³⁸⁹ since it is possible for the para and both ortho positions to be substituted and for each of these to be rearylated, so that a polymeric structure (**45**) is produced. However, such polymers, which are of the Bakelite type (phenol–formaldehyde resins, **45**), are of considerable commercial importance.

The attacking species is the carbocation ($R_2(OH)C^+$) formed from the aldehyde or ketone and the acid catalyst, except when the reaction is carried out in basic solution.

When an aromatic ring is treated with diethyl oxomalonate $[(EtOOC)_2C=O]$, the product is an arylmalonic acid derivative $[ArC(OH)(COOEt)_2]$, which can be converted to an arylmalonic acid $[ArCH(COOEt)_2]$.³⁹⁰ This is therefore a way of applying the malonic ester synthesis (Reaction **10-67**) to an aryl group (see also, Reaction **13-14**). Of course, the opposite mechanism applies here: The aryl species is the nucleophile.

Two methods, both involving boron-containing reagents, have been devised for the regioselective ortho hydroxymethylation of phenols or aromatic amines.³⁹¹ Conjugated aldehydes undergo *Friedel–Crafts alkylation* with aryltrifluoroborate salts, in the presence of a catalytic amount of an imidazolidinone.³⁹²

11-13 Cyclodehydration of Carbonyl-Containing Compounds

As described in Reaction **11-12**, the reaction of carbonyl-containing functional groups with protonic or Lewis acids lead to oxygen-stabilized carbocations. When generated in the presence of an aromatic ring, *Friedel–Crafts alkylation* occurs to give an alcohol or an alkene, if dehydration occurs under the reaction conditions. When an

³⁹² Lee, S.; MacMillan, D.W.C. *J. Am. Chem. Soc.* **2007**, 129, 15438.

aromatic compound contains an aldehyde or ketone function in a position suitable for closing a suitably sized ring, treatment with acid results in cyclodehydration. The reaction is a special case of **11-12**, but in this case dehydration almost always takes place to give a double bond conjugated with the aromatic ring.³⁹³ The method is very general and is widely used to close both carbocyclic and heterocyclic rings.³⁹⁴ Polyphosphoric acid is a common reagent, but other acids have also been used. In a variation known as the *Bradsher reaction*,³⁹⁵ diarylmethanes, which contain a carbonyl group in the ortho position, can be cyclized to anthracene derivatives (**46**). In this case, 1,4-dehydration takes place, at least formally.

An intramolecular cyclization of an aryl ether to the carbonyl of a pendant aryl ketone, on clay with microwave irradiation, led to a benzofuran via *Friedel–Crafts cyclization* and elimination of water.³⁹⁶

A variation of this reaction involves acylation of a β -keto ester, followed by *Friedel–Crafts cyclization* of the ketone moiety. The product is a coumarin (**43**), in what is known as the *Pechmann condensation*.³⁹⁷ Isolation of esters (e.g., **42**) is not always necessary, and protonic acids can be used rather than Lewis acids. The *Pechmann condensation* is facilitated by the presence of hydroxyl (OH), dimethylamino (NMe₂), and alkyl groups meta to the hydroxyl of the phenol.³⁹⁸ The reaction has been accomplished using microwave irradiation on graphite/Montmorillonite K-10.³⁹⁹ *Pechmann condensation* in an ionic liquid using ethyl acetate has also been reported.⁴⁰⁰

The carbonyl unit involved in the cyclization process is not restricted to aldehydes and ketones. The carbonyl of acid derivatives (e.g., amides) also can be utilized. One of the more important cyclodehydration reactions is applied to the formation of heterocyclic systems via cyclization of β -aryl amides, in what is called the *Bischler–Napieralski reaction*.⁴⁰¹ In this reaction, amides of the type **47** are cyclized with phosphorous oxychloride or other reagents, including polyphosphoric acid, sulfuric acid, or phosphorus

pentoxide, to give a dihydroisoquinoline (**48**). The *Bischler–Napieralski reaction* has been done in ionic liquids using POCl_3 .⁴⁰² The reaction has also been done using solid-phase (see Sec. 9.D.iv) techniques.⁴⁰³

If the starting compound contains a hydroxyl group in the α position, an additional dehydration takes place and the product is an isoquinoline.⁴⁰⁴ Higher yields can be obtained if the amide is treated with PCl_3 to give an imino chloride ($\text{ArCH}_2\text{CH}_2\text{N}=\text{CR}-\text{Cl}$), which is isolated and then cyclized by heating.⁴⁰⁵ In this latter case, a nitrilium ion ($\text{ArCH}_2\text{CH}_2^+\text{N}\equiv\text{CR}$) is an intermediate.

Another useful variation is the *Pictet–Spengler isoquinoline synthesis*, also known as the *Pictet–Spengler reaction*.⁴⁰⁶ The reactive intermediate is an iminium ion (**49**) rather than an oxygen-stabilized cation, but attack at the electrophilic carbon of the $\text{C}=\text{N}$ unit (see Reaction **16-31**) leads to an isoquinoline derivative. When a β -arylamine reacts with an aldehyde, the product is an iminium salt, which cyclizes with an aromatic ring to complete the reaction and generate a tetrahydroisoquinoline.⁴⁰⁷ Metal-catalyzed reactions are known, including the use of $\text{AuCl}_3/\text{AgOTf}$.⁴⁰⁸ A variety of aldehydes can be used, and substitution on the aromatic ring leads to many derivatives. When the reaction is done in the presence of a chiral catalyst, good enantioselectivity was observed.⁴⁰⁹

Another variation in this basic procedure leads to tetrahydroisoquinolines. When phenethylamine was treated with *N*-hydroxymethylbenzotriazole and then AlCl_3 in chloroform, cyclization occurred, and reduction with sodium borohydride gave the 1,2,3,4-tetrahydro-*N*-methyloisoquinoline.⁴¹⁰

11-14 Haloalkylation or Haloalkyl-de-hydrogenation

When certain aromatic compounds are treated with formaldehyde and HCl, the CH_2Cl group is introduced into the ring in a reaction called *chloromethylation*. The reaction has also been carried out with other aldehydes and with HBr and HI. The more general term *haloalkylation* covers these cases.⁴¹¹ The reaction is successful for benzene, and alkyl-, alkoxy-, and halobenzenes. It is greatly hindered by meta-directing groups, which reduce yields or completely prevent the reactions. Amines and phenols are too reactive and usually give polymers unless deactivating groups are also present, but phenolic ethers and esters successfully undergo the reaction. Compounds of lesser reactivity can often be chloromethylated with chloromethyl methyl ether (ClCH_2OMe) or methoxyacetyl chloride ($\text{MeOCH}_2\text{COCl}$).⁴¹² Zinc chloride is the most common catalyst, but other Friedel–Crafts catalysts are also employed. As with Reaction 11-12 and for the same reason, an important side product is the diaryl compound Ar_2CH_2 (from formaldehyde).

Apparently, the initial step involves reaction of the aromatic compound with the aldehyde to form the hydroxyalkyl compound, exactly as in Reaction 11-12, and then the HCl converts this to the chloroalkyl compound.⁴¹³ The acceleration of the reaction by ZnCl_2 has been attributed⁴¹⁴ to the raising of the acidity of the medium, causing an increase in the concentration of HOCH_2^+ ions.

OS III, 195, 197, 468, 557; IV, 980.

11-15 Friedel–Crafts Arylation: The Scholl Reaction**De-hydrogen-coupling**

The coupling of two aromatic molecules by treatment with a Lewis and a proton acid is called the *Scholl reaction*.⁴¹⁵ Yields are low and the synthesis is seldom useful. High temperatures and strong-acid catalysts are required, and the reaction fails for substrates that are destroyed by these conditions. The reaction becomes important with large fused-ring systems, so ordinary *Friedel–Crafts reactions* (11-11) on these systems are rare. For example, naphthalene gives binaphthyl under *Friedel–Crafts conditions*. Yields can be

increased by the addition of a salt (e.g., CuCl_2 or FeCl_3), which acts as an oxidant.⁴¹⁶ Rhodium⁴¹⁷ and Ru catalysts⁴¹⁸ have also been used.

Intramolecular *Scholl reactions* (e.g., formation of **50** from triphenylmethane) are much more successful than the intermolecular reaction. The mechanism is not clear, but it may involve attack by a proton to give an arenium ion of type **12** (Sec. 11.A.i, category 2), which would be the electrophile that attacks the other ring.⁴¹⁹ Sometimes arylations have been accomplished by treating aromatic substrates with particularly active aryl halides, especially fluorides. For free radical arylations, see Reactions **12-15**, **13-26**, **13-27**, **13-10**, **14-17**, and **14-18**.

11-16 Arylation of Aromatic Compounds by Metalated Aryls

Many metalated aryl compounds are known to couple with aromatic compounds. Aniline derivatives react with $\text{ArPb}(\text{OAc})_3$, for example, to give the 2-arylaniline.⁴²⁰ Phenolic anions also react to form biaryls, with modest enantioselectivity in the presence of brucine.⁴²¹ A Mn(III) mediated synthesis of biaryls used microwave irradiation for the coupling reaction.⁴²² The homocoupling reaction of aryl *Grignard reagents* in the presence of TEMPO is known.⁴²³

Phenylboronates $[\text{ArB}(\text{OR})_2]$ react with electron-deficient aromatic compounds (e.g., acetophenone) to give the biaryl.⁴²⁴ Arylboronates also react with π -allyl Pd complexes to form the alkylated aromatic compound.⁴²⁵ Arylboronic acids are also coupled in the presence of metal catalysts.⁴²⁶ Organoborates can be coupled using an oxovanadium catalyst,⁴²⁷ and potassium phenyltrifluoroborates can be coupled to aromatics using a combination of Pd and Cu catalysts.⁴²⁸

11-17 Friedel–Crafts Acylation

Acylation or Acyl-de-hydrogenation

The most important method for the preparation of aryl ketones is known as *Friedel–Crafts acylation*.⁴³⁰ The reaction is of wide scope. Reagents other than acyl halides can be used,⁴³¹ including carboxylic acids,⁴³² anhydrides, and ketenes. Oxalyl chloride has been used to give diaryl 1,2-diketones.⁴³³ Carboxylic esters usually give alkylation as the predominant product (see Reaction **11-11**).⁴³⁴ *N*-Carbamoyl β -lactams reacted with naphthalene in the presence of trifluoromethanesulfonic acid to give the keto-amide.⁴³⁵

The alkyl group (R in RCOCl) may be aryl as well as alkyl.⁴³⁶ The major disadvantages of *Friedel–Crafts alkylation*, polyalkylation, and rearrangement of the intermediate carbocation, are not a problem in *Friedel–Crafts acylation*. Rearrangement of the alkyl group (R in RCOCl) is never found because the intermediate is an acylium ion (an acyl cation, $\text{RC}\equiv\text{O}^+$, see below), which is stabilized by resonance. Because the RCO group is deactivating, the reaction stops cleanly after one group is introduced. All four acyl halides can be used, though chlorides are most commonly employed. The order of activity is usually, but not always, $\text{I} > \text{Br} > \text{Cl} > \text{F}$.⁴³⁷ Catalysts are Lewis acids,⁴³⁸ similar to those in Reaction **11-11**, but in acylation a little >1 equiv of catalyst is required per mole of reagent, because the first mole coordinates with the oxygen of the reagent [as in $\text{R}(\text{Cl})\text{C}=\text{O}^{+-}\text{AlCl}_3$].⁴³⁹ A reusable catalyst $[\text{Ln}(\text{OTf})_3-\text{LiClO}_4]$ has been developed.⁴⁴⁰ Ferric chloride in an ionic liquid has

also been used.⁴⁴¹ The HY-Zeolite has also been used to facilitate the reaction with acetic anhydride.⁴⁴² Catalysts include a Pd catalyst, which was used with acetic anhydride,⁴⁴³ TiCl_4 ,⁴⁴⁴ SnI_2 ,⁴⁴⁵ In metal,⁴⁴⁶ acetyl chloride, and zinc powder with microwave irradiation.⁴⁴⁷ *Friedel–Crafts acylation* using a carboxylic acid with a catalyst called Envirocac-EPIC (an acid-treated clay-based material) was reported.⁴⁴⁸ *Friedel–Crafts acylation* was reported in an ionic liquid.⁴⁴⁹ An interesting acylation reaction was reported that coupled trichlorophenylmethane to benzene, giving benzophenone in the presence of the ionic liquid $\text{AlCl}_3\text{--BPC}$.⁴⁵⁰ (butylpyridiniumchloroaluminate = BPC). Acylation has been accomplished in carbon disulfide.⁴⁵¹ An interesting variation couples a conjugated acid chloride with benzene, in the presence of AlCl_3 and microwave irradiation, to give an indanone.⁴⁵²

Protonic acids can be used as catalysts when the reagent is a carboxylic acid.⁴⁵³ Triflic anhydride promotes dehydrative acylation of carboxylic acids,⁴⁵⁴ as does $\text{P}_2\text{O}_5/\text{SiO}_2$.⁴⁵⁵ An aryl carboxylic acid can be converted to the acid chloride *in situ* with cyanuric chloride and AlCl_3 , leading to *Friedel–Crafts acylation*.⁴⁵⁶ A solvent-free method is also available using tosic acid/graphite.⁴⁵⁷

The mixed carboxylic sulfonic anhydrides ($\text{RCOOSO}_2\text{CF}_3$) are extremely reactive acylating agents and can smoothly acylate benzene without a catalyst.⁴⁵⁸ With active substrates (e.g., aryl ethers, fused-ring systems, thiophenes), *Friedel–Crafts acylation* can be carried out with very small amounts of catalyst, often just a trace, or even sometimes with no catalyst at all.

The reaction is quite successful for many types of substrate, including fused ring systems, which give poor results in Reaction 11-11. Compounds containing ortho–para directing groups, including alkyl, hydroxy, alkoxy, halogen, and acetamido groups, are easily acylated and give mainly or exclusively the para products, because of the relatively large size of the acyl group. However, aromatic amines give poor results. With amines and phenols there may be competition from *N*- or *O*-acylation; however, *O*-acylated phenols can be converted to *C*-acylated phenols by the *Fries rearrangement* (Reaction 11-27). *Friedel–Crafts acylation* is usually prevented by meta-directing (deactivating) groups.

Indeed, nitrobenzene is often used as a solvent for the reaction. Many heterocyclic systems, including furans, thiophenes, pyrans, and pyrroles⁴⁵⁹ but not pyridines or quinolines, can be acylated in good yield. Initial reaction of indole with Et_2AlCl ⁴⁶⁰ or SnCl_4 ,⁴⁶¹ followed by acetyl chloride leads to 3-acetylindole. By comparison, the reaction of *N*-acetylindole with acetic anhydride and AlCl_3 gave *N*,6-diacetylindole.⁴⁶² Acetylation at C-3 was also accomplished with acetyl chloride in the ionic liquid $\text{emimcl}-\text{AlCl}_3$.⁴⁶³ Gore, in Ref. 430 (pp. 36–100; with tables, pp. 105–321), presents an extensive summary of the substrates to which this reaction has been applied.

Friedel–Crafts acylation can be carried out with cyclic anhydrides,⁴⁶⁴ in which case the product contains a carboxyl group in the side chain (**53**). When succinic anhydride is used, the product is $\text{ArCOCH}_2\text{CH}_2\text{CO}_2\text{H}$. This can be reduced (Reaction **19-61**) to $\text{ArCH}_2\text{CH}_2\text{CH}_2\text{CO}_2\text{H}$, and can then be cyclized by an internal *Friedel–Crafts acylation* to give **54**. The total process is called the *Haworth reaction*.⁴⁶⁵

When a mixed-anhydride ($\text{RCOOCOR}'$) is the reagent, two products are possible: ArCOR and ArCOR' . Which product predominates depends on two factors. If *R* contains electron-withdrawing groups, then ArCOR' is chiefly formed, but if this factor is approximately constant in *R* and *R'*, the ketone with the larger *R* group predominantly forms.⁴⁶⁶ This means that *formylations* of the ring do not occur with mixed anhydrides of formic acid (HCOOCOR).

An important use of the *Friedel–Crafts acylation* is to effect ring closure.⁴⁶⁷ This closure can be accomplished if an acyl halide, anhydride, or carboxylic acid⁴⁶⁸ group is in the proper position. An example is the conversion of **51** to **52**. The reaction is used mostly to close six-membered rings, but has also been done for five- and seven-membered rings, which close less readily. Even larger rings can be closed by high-dilution techniques.⁴⁶⁹ Tricyclic and larger systems are often made by using substrates containing one of the acyl groups on a ring. Many fused-ring systems are made in this manner. If the bridging group is CO, the product is a quinone.⁴⁷⁰ One of the most

common catalysts for intramolecular *Friedel–Crafts acylation* is polyphosphoric acid⁴⁷¹ (because of its high potency), but AlCl_3 , H_2SO_4 , and other Lewis and proton acids are also used, though acylations with acyl halides are not generally catalyzed by proton acids.

Thioesters are coupled to arylboronic acids in the presence of a Pd catalyst, in a *Friedel–Crafts acylation*-type coupling.⁴⁷² Acyl halides are coupled to arylboronic acids under microwave irradiation.⁴⁷³

The mechanism of *Friedel–Crafts acylation* is not completely understood,⁴⁷⁴ but at least two mechanisms probably operate, depending on conditions.⁴⁷⁵ In most cases, the attacking species is the acyl cation, either free or as an ion pair, formed by⁴⁷⁶

If R is tertiary, RCO^+ may lose CO to give R^+ , so that the alkyl arene ArR is often a side product or even the main product. This kind of cleavage is much more likely with relatively unreactive substrates, where the acylium ion has time to break down. For example, pivaloyl chloride (Me_3CCOCl) gives the normal acyl product with anisole, but yields the alkyl product (Me_3CPh) with benzene. In the other mechanism, an acyl cation is not involved, but the 1:1 complex (**55**) attacks directly.⁴⁷⁷ Free-ion attack is more likely for sterically hindered R.⁴⁷⁸ The ion CH_3CO^+ has been detected (by IR spectroscopy) in the liquid complex between acetyl chloride and aluminum chloride, and in polar solvents (e.g., nitrobenzene); but in nonpolar solvents (e.g., as chloroform) only the complex and not the free ion is present.⁴⁷⁹ In any event, 1 molar equivalent of catalyst certainly remains complexed to the product at the end of the reaction. When the reaction is performed with $\text{RCO}^+ \text{SbF}_6^-$, no catalyst is required and the free ion⁴⁸⁰ (or ion pair) is undoubtedly the attacking entity.⁴⁸¹ The use of LiClO_4 on the metal triflate catalyzed *Friedel–Crafts acylation* of methoxynaphthalene derivatives has been examined. The presence of the lithium salt leads to acylation in the ring containing the methoxy unit, whereas reaction occurs in the other ring in the absence of lithium salts.⁴⁸² Note that lithium perchlorate

forms a complex with acetic anhydride, which can be used for the *Friedel–Crafts acetylation* of activated aromatic compounds.⁴⁸³

A related reaction couples an acid chloride with an aromatic compound in the presence of a Rh catalyst, but the coupling reaction involves a decarbonylation to give a biaryl.⁴⁸⁴

OS **I**, 109, 353, 476, 517; **II**, 3, 8, 15, 81, 156, 169, 304, 520, 569; **III**, 6, 14, 23, 53, 109, 183, 248, 272, 593, 637, 761, 798; **IV**, 8, 34, 88, 898, 900; **V**, 111; **VI**, 34, 618, 625 **X**, 125.

Reaction **11-18** is a direct formylation of the ring.⁴⁸⁵ Reaction **11-17** has not been used for formylation, since neither formic anhydride nor formyl chloride is stable at ordinary temperatures. Formyl chloride has been shown to be stable in chloroform solution for 1 h at -6° ,⁴⁸⁶ but it is not useful for formylating aromatic rings under these conditions. Formic anhydride has been prepared in solution, but has not been isolated.⁴⁸⁷ Mixed anhydrides of formic and other acids are known⁴⁸⁸ and can be used to formylate amines (see Reaction **16-73**) and alcohols, but no formylation takes place when they are applied to aromatic rings. See Reaction **13-17** for a nucleophilic method for the formylation of aromatic rings.

A related reaction involves a biaryl, where one ring is a phenol. Treatment with BCl_3 and an AlCl_3 catalyst, followed by reaction with CO and $\text{Pd}(\text{OAc})_2$, led to carbonylation and acylation to give the corresponding lactone.⁴⁸⁹ Carbonylation of aromatic compounds can lead to aryl ketones. Heating an aromatic compound with $\text{Ru}(\text{CO})_{12}$, ethylene and 20 atm. of CO gave the corresponding aryl ethyl ketone.⁴⁹⁰

11-18 Formylation

Formylation or Formyl-de-hydrogenation

The reaction with disubstituted formamides ($\text{R}_2\text{N-CHO}$) and phosphorus oxychloride, called the *Vilsmeier* or the *Vilsmeier–Haack reaction*,⁴⁹¹ is the most common method

for the formylation of aromatic rings.⁴⁹² However, it is applicable only to active substrates (e.g., amines and phenols). An intramolecular version is also known.⁴⁹³ Aromatic hydrocarbons and heterocycles can also be formylated, but only if they are much more active than benzene (e.g., azulenes and ferrocenes). Although *N*-phenyl-*N*-methylformamide is a common reagent, other arylalkyl amides and dialkyl amides are also used.⁴⁹⁴ Phosgene (COCl₂) has been used in place of POCl₃. The reaction has also been carried out with other amides to give ketones (actually an example of Reaction 11-17), but not often. The attacking species⁴⁹⁵ is **56**,⁴⁹⁶ and the mechanism is probably that shown to give **57**, which is unstable and easily hydrolyzes to the product. Either formation of **56** or the reaction of **56** with the substrate can be rate determining, depending on the reactivity of the substrate.⁴⁹⁷

When (CF₃SO₂)₂O was used instead of POCl₃, the reaction was extended to some less-active compounds, including naphthalene and phenanthrene.⁴⁹⁸

In a related reaction, paraformaldehyde can be used, with MgCl₂-NEt₃, to convert phenol to phenol 2-carbaldehyde.⁴⁹⁹ Another variation treated acetanilide with POCl₃—DMF and generated 2-chloroquinoline-3-carboxaldehyde.⁵⁰⁰ Used in conjunction with conjugated hydroxylamines, a tandem *Vilsmeier–Beckman reaction* (see Reaction 18-17 for the *Beckman rearrangement*) leads to pyridines (2-chloro-3-carboxaldehyde).⁵⁰¹ A chain-extension variation has been reported in which an aryl alkyl ketone is treated with POCl₃/DMF on silica with microwave irradiation to give a conjugated aldehyde [ArC(=O)R → ArC(Cl)=CHCHO].⁵⁰²

OS I, 217; **III**, 98, **IV**, 331, 539, 831, 915.

Formylation with Zn(CN)₂ and HCl is called the *Gatterman reaction*⁵⁰³ and can be applied to alkylbenzenes, phenols and their ethers, as well as many heterocyclic

compounds. However, it cannot be applied to aromatic amines. In the original version of this reaction, the substrate was treated with HCN, HCl, and ZnCl₂, but the use of Zn(CN)₂ and HCl (HCN and ZnCl₂ are generated *in situ*) makes the reaction more convenient to carry out and yields are not diminished. The mechanism of the *Gatterman reaction* has not been investigated very much, but it is known that an initially formed, but not isolated nitrogen-containing product, is hydrolyzed to aldehyde. This product is presumed to be ArCH=NH₂⁺Cl[−], as shown. When benzene was treated with NaCN under superacid conditions (F₃CSO₂OH–SbF₅, see Sec. 5.A.ii), a good yield of product was obtained, leading to the conclusion that the electrophile in this case was ⁺C(H)=N⁺H₂.⁵⁰⁴ The *Gatterman reaction* may be regarded as a special case of Reaction 11-24.

Another method, formylation with CO and HCl in the presence of AlCl₃ and CuCl⁵⁰⁵ (the *Gatterman–Koch reaction*), is limited to benzene and alkylbenzenes.⁵⁰⁶ Aryl halides are converted to aryl aldehydes with CO/H₂ in the presence of a Pd catalyst.⁵⁰⁷

OS II, 583; III, 549.

In the *Reimer–Tiemann reaction*, aromatic rings are formylated by reaction with chloroform and hydroxide ion.⁵⁰⁸ The method is useful only for phenols and certain heterocyclic compounds (e.g., pyrroles and indoles). Unlike the previous formylation methods (Reaction 11-18), this one is conducted in basic solution. Yields are generally low, seldom rising >50%.⁵⁰⁹ The incoming group is directed ortho, unless both ortho positions are filled, in which case the attack is para.⁵¹⁰ Certain substrates have been shown to give abnormal products instead of or in addition to the normal ones. For example, **58** and **60** gave, respectively, **59** and **61**, as well as the normal aldehyde products. From the nature of the reagents and

from the kind of abnormal products obtained, it is clear that the reactive entity in this reaction is dichlorocarbene (CCl₂).⁵¹¹ This product is known to be produced by treatment of chloroform with bases (see Reaction 10-3); it is an electrophilic reagent and is known to

give ring expansion of aromatic rings (see Reaction 15-64), accounting for products like 58. The mechanism of the normal reaction is thus something like⁵¹²:

The formation of 61 in the case of 60 can be explained by attack of some of the CCl_2 ipso to the CH_3 group. Since this position does not contain a hydrogen, normal proton loss cannot take place and the reaction ends when the CCl_2^- moiety acquires a proton.

A method closely related to the *Reimer-Tiemann reaction* is the *Duff reaction*, in which hexamethylenetetramine $[(\text{CH}_2)_6\text{N}_4]$ is used instead of chloroform. This reaction can be applied only to phenols and amines; ortho substitution is generally observed and yields are low. A mechanism⁵¹³ has been proposed that involves initial aminoalkylation (Reaction 11-22) to give ArCH_2NH_2 , followed by dehydrogenation to $\text{ArCH}=\text{NH}$ and hydrolysis of this to the aldehyde product. When $(\text{CH}_2)_6\text{N}_4$ is used in conjunction with $\text{F}_3\text{CCO}_2\text{H}$, the reaction can be applied to simple alkylbenzenes; yields are much higher and a high degree of regioselectively para substitution is found.⁵¹⁴ In this case too, an imine seems to be an intermediate.

OS III, 463; IV, 866

Besides Reaction 11-18, several other formylation methods are known.⁵¹⁵ In one of these, dichloromethyl methyl ether formylates aromatic rings with *Friedel-Crafts catalysts*.⁵¹⁶ The ArCHClOMe compound is probably an intermediate. Orthoformates have also been used.⁵¹⁷ In another method, aromatic rings are formylated with formyl fluoride (HCOF) and BF_3 .⁵¹⁸ Unlike formyl chloride, formyl fluoride is stable enough for this purpose. This reaction was successful for benzene, alkylbenzenes, PhCl , PhBr , and naphthalene. Phenols can be regioselectively formylated in the ortho position in high yields by treatment with 2 molar equivalents of paraformaldehyde in aprotic solvents in the presence of SnCl_4 and a tertiary amine.⁵¹⁹ Phenols have also been formylated indirectly by conversion to the aryllithium reagent followed by treatment with *N*-formyl piperidine.⁵²⁰ See also, the indirect method mentioned at Reaction 11-23. Aryl halides are converted to the corresponding aldehyde in a related reaction.⁵²¹

OS V, 49; VII, 162.

Reactions 11-19 and 11-20 are direct carboxylations⁵²² of aromatic rings.⁵²³

11-19 Carboxylation with Carbonyl Halides

Carboxylation or Carboxy-de-hydrogenation

Phosgene, in the presence of *Friedel–Crafts catalysts*, can carboxylate the ring. This process is analogous to Reaction **11-17**, but the ArCOCl initially produced hydrolyzes to the carboxylic acid. However, in most cases the reaction does not take this course, but instead the ArCOCl is attacked by another ring to give a ketone ArCOAr . A number of other reagents have been used to get around this difficulty, including oxalyl chloride, urea hydrochloride, chloral (Cl_3CCHO),⁵²⁴ carbamoyl chloride (H_2NCOCl), and *N,N*-diethylcarbamoyl chloride.⁵²⁵ With carbamoyl chloride the reaction is called the *Gatterman amide synthesis* and the product is an amide. Among compounds carboxylated by one or another of these reagents are benzene, alkylbenzenes, and fused ring systems.⁵²⁶

Although mechanistically different, other methods are available to convert aromatic compounds to aromatic carboxylic acids. The Pd catalyzed reaction of aromatic compounds and formic acid leads to benzoic acid derivatives.⁵²⁷ Diphenyliodonium tetrafluoroborate ($\text{Ph}_2\text{I}^+ \text{BF}_4^-$) reacts with CO and In in DMF, with a Pd catalyst, to give benzophenone.⁵²⁸

OS V, 706; VII, 420.

11-20 Carboxylation with Carbon Dioxide: The Kolbe–Schmitt Reaction

Carboxylation or Carboxy-de-hydrogenation

Sodium phenoxides can be carboxylated, mostly in the ortho position, by CO_2 (the *Kolbe–Schmitt reaction*). The mechanism is not clearly understood, but apparently some kind of a complex is formed between the reactants,⁵²⁹ making the carbon of the CO_2 more positive and putting it in a good position to attack the ring. Potassium phenoxide, which is less likely to form such a complex, is chiefly attacked in the para position. There is evidence that, in the complex formed from potassium salts, the bonding is between the aromatic compound and the carbon atom of CO_2 .⁵³⁰ At least part of the potassium *p*-hydroxybenzoate that forms comes from a rearrangement of initially formed potassium salicylate (sodium salicylate does not rearrange).⁵³¹ Carbon tetrachloride can be used instead of CO_2 under *Reimer–Tiemann* (Reaction **11-18**) conditions.

Sodium or potassium phenoxide can be carboxylated regioselectively in the para position in high yield by treatment with sodium or potassium carbonate and carbon monoxide.⁵³² The ¹⁴C labeling showed that it is the carbonate carbon that appears in the *p*-hydroxybenzoic acid product.⁵³³ The CO is converted to sodium or potassium formate. Carbon monoxide has also been used to carboxylate aromatic rings with Pd compounds as catalysts.⁵³⁴ In addition, a Pd catalyzed reaction has been used directly to prepare acyl fluorides $\text{ArH} \rightarrow \text{ArCOF}$.⁵³⁵ Molybdovanadophosphates have been used for anisole in the presence of CO and O₂.⁵³⁶ A Pd catalyzed carboxylation has been reported using Ag₂CO₃ and CO.⁵³⁷

An enzymatic carboxylation was reported, in supercritical CO₂ (see Sec. 9.D.ii), in which exposure of pyrrole to *Bacillus megaterium* PYR2910 and KHCO₃ gave the potassium salt of pyrrole 2-carboxylic acid.⁵³⁸

OS II, 557.

11-21 Amidation

N-Alkylcarbamoyl-de-hydrogenation

N-Substituted amides can be prepared by direct attack of isocyanates on aromatic rings.⁵³⁹ The R group may be alkyl or aryl, but if the latter, dimers and trimers are also obtained. Isothiocyanates similarly give thioamides.⁵⁴⁰ The reaction has been carried out intramolecularly both with aralkyl isothiocyanates and acyl isothiocyanates.⁵⁴¹ In the latter case, the product is easily hydrolyzable to a dicarboxylic acid; this is a way of putting a carboxyl group on a ring ortho to one already there (62 is prepared by treatment of the acyl halide with lead thiocyanate). The reaction gives better yields with substrates of the type $\text{ArCH}_2\text{CONCS}$, where six-membered rings are formed. An intramolecular reaction of 2-amido biaryls leads to carbazoles in the presence of Pd and Cu catalysts.⁵⁴²

There are interesting transition metal catalyzed reactions that lead to aryl amides. The use of POCl_3 and DMF, with a Pd catalyst, converts aryl iodides to benzamides.⁵⁴³ Carbonylation is another method that generates amides. When an aryl iodide was treated with a secondary amine and $\text{Mo}(\text{CO})_6$, in the presence of 3 equiv of DBU, 10% $\text{Pd}(\text{OAc})_2$, with microwave irradiation at 100°C , the corresponding benzamide was obtained.⁵⁴⁴ Aminocarbonylation is accomplished with microwave irradiation using hydroxylamine as an ammonia equivalent.⁵⁴⁵

OS V, 1051; VI, 465.

Reactions **11-12–11-23** involve the introduction of a CH_2Z group, where Z is halogen, hydroxyl, amino, or alkylthio. They are all *Friedel–Crafts reactions* of aldehydes and ketones and, with respect to the carbonyl compound, additions to the $\text{C}=\text{O}$ double bond. They follow mechanisms discussed in Chapter 16.

11-22 Aminoalkylation and Amidoalkylation

Dialkylaminoalkylation or Dialkylamino-de-hydrogenation

Phenols, secondary and tertiary aromatic amines,⁵⁴⁶ pyrroles, and indoles can be aminomethylated by treatment with formaldehyde and a secondary amine. Other aldehydes have sometimes been employed. Aminoalkylation is a special case of the *Mannich reaction* (**16-19**). When phenols and other activated aromatic compounds are treated with *N*-hydroxymethylchloroacetamide, *amidomethylation* takes place⁵⁴⁷ to give **63**, which is often hydrolyzed *in situ* to the aminoalkylated product. Other *N*-hydroxyalkyl and *N*-chlorinated compounds have also been used.³⁷⁹ Nitroethane in polyphosphoric acid can be used for the acetamidation of aromatic compounds.⁵⁴⁸

⁵⁴⁸ Aksenov, A.V.; Aksenov, N.A.; Nadein, O.N.; Aksenova, I.V. *Synlett* **2010**, 2628.

Aryl halides are aminomethylated with potassium organotrifluoroborates.⁵⁴⁹ OS I, 381; IV, 626; V, 434; VI, 965; VII, 162.

11-23 Thioalkylation

Alkylthioalkylation or Alkylthioalkyl-de-hydrogenation

A methylthiomethyl group can be inserted into the ortho position of phenols by heating with DMSO and 1,3-dicyclohexylcarbodiimide (DCC).⁵⁵⁰ Other reagents can be used instead of DCC, among them SOCl_2 ,⁵⁵¹ or acetic anhydride.⁵⁵² Alternatively, the phenol can be treated with DMS and NCS, followed by triethylamine.⁵⁵³ The reaction can be applied to amines (to give $o\text{-NH}_2\text{C}_6\text{H}_4\text{CH}_2\text{SMe}$) by treatment with *t*-BuOCl, Me_2S , and NaOMe in CH_2Cl_2 .⁵⁵⁴ Aromatic hydrocarbons have been thioalkylated with ethyl α -(chloromethylthio)acetate ($\text{ClCH}_2\text{SCH}_2\text{CO}_2\text{Et}$) to give $\text{ArCH}_2\text{SCH}_2\text{CO}_2\text{Et}$,⁵⁵⁵ and with methyl methylsulfinylmethyl sulfide ($\text{MeSCH}_2\text{SOMe}$) or methylthiomethyl *p*-tolyl sulfone ($\text{MeSCH}_2\text{SO}_2\text{C}_6\text{H}_4\text{Me}$) to give ArCH_2SMe ,⁵⁵⁶ in each case with a Lewis acid catalyst.

OS VI, 581, 601.

11-24 Acylation with Nitriles: The Hoesch Reaction

Acylation or Acyl-de-hydrogenation

Friedel–Crafts acylation with nitriles and HCl is called the *Hoesch* or the *Houben–Hoesch reaction*.⁵⁵⁷ In most cases, a Lewis acid is necessary; zinc chloride is the most common. The reaction is generally useful only with phenols, phenolic ethers, and some reactive heterocyclic compounds (e.g., pyrrole), but it can be extended to aromatic amines

by the use of BCl_3 .⁵⁵⁸ Acylation in the case of aniline derivatives is regioselectively ortho. Monohydric phenols, however, generally do not give ketones⁵⁵⁹ but are attacked at the oxygen to produce imino esters. Many nitriles have been used. Even aryl nitriles give good yields if they are first treated with HCl and ZnCl_2 , and then the substrate added at 0°C .⁵⁶⁰ In fact, this procedure increases yields with any nitrile. If thiocyanates (RSCN) are used, thiol esters (ArCOSR) can be obtained. The *Gatterman reaction* (Reaction 11-18) is a special case of the *Hoesch synthesis*.

The reaction mechanism is complex and not completely settled.⁵⁶¹ The first stage consists of an attack on the substrate by a species containing the nitrile and HCl (and the Lewis acid, if present) to give an imine salt (**66**). Among the possible reactive species are **64** and **65**. In the second stage, the salts are hydrolyzed to the products, first the iminium salt, and then the ketone. Ketones can also be obtained by treating phenols or phenolic ethers with a nitrile in the presence of $\text{F}_3\text{CSO}_2\text{OH}$.⁵⁶² The mechanism in this case is different.

OS II, 522.

11-25 Cyanation or Cyano-de-hydrogenation

Aromatic hydrocarbons (including benzene), phenols, and phenolic ethers can be cyanated with trichloroacetonitrile, BrCN , or mercury fulminate $[\text{Hg}(\text{ONC})_2]$.⁵⁶³ In the case of Cl_3CCN , the actual attacking entity is probably $\text{Cl}_3\text{C}-\text{C}^+=\text{NH}$, formed by addition of a proton to the cyano nitrogen. Secondary aromatic amines (ArNHR), as well as phenols, can be cyanated in the ortho position with Cl_3CCN and BCl_3 .⁵⁶⁴

Note that aryl triflates are converted to the aryl nitrile by treatment with $\text{Zn}(\text{CN})_2$ and a Pd catalyst.⁵⁶⁵

F. Oxygen Electrophiles

Oxygen electrophiles are very uncommon, since oxygen does not bear a positive charge very well. However, there is one reaction that can be mentioned.

11-26 Hydroxylation or Hydroxy-de-hydrogenation

There have been only a few reports of direct hydroxylation⁵⁶⁶ by an electrophilic process (see, however, **14-5**).⁵⁶⁷ In general, poor results are obtained, partly because the introduction of an OH group activates the ring, which suppresses further reaction. Quinone formation is common. However, alkyl-substituted benzenes (e.g., mesitylene or durene) can be hydroxylated in good yield with trifluoroperacetic acid and boron trifluoride.⁵⁶⁸ In the case of mesitylene, the product (**67**) is not subject to further attack.

In a related procedure, even benzene and substituted benzenes (e.g., PhMe, PhCl, and xylenes) can be converted to phenols in good yields with sodium perborate–F₃CSO₂OH.⁵⁶⁹ Aromatic amines, *N*-acyl amines, and phenols were hydroxylated with H₂O₂ in SbF₅–HF.⁵⁷⁰ Pyridine and quinoline were converted to their 2-acetoxy derivatives in high yields with acetyl hypofluorite (AcOF) at –75 °C.⁵⁷¹

Another hydroxylation reaction is the *Elbs reaction*.⁵⁷² In this method, phenols can be oxidized to *p*-diphenols with K₂S₂O₈ in alkaline solution.⁵⁷³ Primary, secondary, or tertiary aromatic amines give predominant or exclusive ortho substitution unless both ortho positions are blocked, in which case para substitution is found. The reaction with amines is called the *Boylan–Sims oxidation*. Yields are low with either phenols or amines, generally <50%. The mechanisms are not clear,⁵⁷⁴ but for the *Boylan–Sims oxidation* there is evidence that the S₂O₈^{2–} ion attacks at the ipso position, and then a migration follows.⁵⁷⁵

Electrolysis of benzene, in the presence of trifluoroacetic acid and triethylamine, leads to a 73% yield of phenol.⁵⁷⁶ Photolytic hydroxylation of benzene has been reported in the presence of mesoporous TiO₂.⁵⁷⁷ Deactivated rings (e.g., nitrobenzene) are selectively ortho hydroxylated by molecular oxygen in the presence of H₅PV₂Mo₁₀O₄₀ polyoxometalate.⁵⁷⁸ Nitrous oxide has been used as an oxidant, in the presence of FeAlPO catalysts.⁵⁷⁹

G. Metal Electrophiles

Reactions in which a metal replaces the hydrogen of an aromatic ring are considered along with their aliphatic counterparts in Chapter 12 (Reactions 12-22 and 12-23).

11.F.ii. Hydrogen as the Leaving Group in Rearrangement Reactions

In these reactions, a group is detached from a *side chain* and then reattached the ring, but in other aspects they resemble the reactions already treated in this chapter.⁵⁸⁰ Since a group moves from one position to another in a molecule, these are rearrangements (also see Chap 18). In all these reactions, the question arises as to whether the group that cleaves from a given molecule is attacked by the same molecule or another one; that is, Is the reaction intramolecular or intermolecular? For intermolecular reactions, the mechanism is the same as ordinary aromatic substitution, but for intramolecular cases the migrating group could never be completely free, or else it would be able to react with another molecule. Since the migrating species in intramolecular rearrangements is thus likely to remain near the atom from which it cleaved, it has been suggested that intramolecular reactions are more likely to lead to ortho products than are the intermolecular type. This characteristic has been used, among others, to help decide whether a given rearrangement is inter- or intramolecular, though there is evidence that at least in some cases, an intermolecular mechanism can still result in a high degree of ortho migration.⁵⁸¹

The *Claisen* (Reaction 18-33) and *benzidine* (Reaction 18-36) rearrangements, which superficially resemble those in this section, have different mechanisms and are treated in Chapter 18.

A. Groups Cleaving from Oxygen

11-27 The Fries Rearrangement

⁵⁸² This is the name for the para migration. For the ortho migration, the name is 1/C-hydro,3/O-acyl-interchange.

Phenolic esters can be rearranged by heating with *Friedel–Crafts catalysts* in a synthetically useful reaction known as the *Fries rearrangement*.⁵⁸³ Both *o*- and *p*-acylphenols can be produced, and it is often possible to select conditions so that either one predominates. The ortho/para ratio is dependent on the temperature, solvent, and amount of catalyst used. Exceptions are known, but low temperatures generally favor the para product and high temperatures favor the ortho product. The R group may be aliphatic or aromatic. Any meta-directing substituent on the ring interferes with the reactions, as might be expected for a *Friedel–Crafts* process. In the case of aryl benzoates treated with $\text{F}_3\text{CSO}_2\text{OH}$, the *Fries rearrangement* was shown to be reversible and an equilibrium was established.⁵⁸⁴ Transition metal catalyzed *Fries rearrangements* have been reported.⁵⁸⁵

Questions remain about the exact mechanism.⁵⁸⁶ Opinions have been expressed that it is completely intermolecular,⁵⁸⁷ completely intramolecular,⁵⁸⁸ and partially inter- and intramolecular.⁵⁸⁹ One way to decide between inter- and intramolecular processes is to run the reaction of the phenolic ester in the presence of another aromatic compound, say, toluene. If some of the toluene is acylated, the reaction must be, at least in part, intermolecular. If the toluene is not acylated, the presumption is that the reaction is intramolecular, though this is not certain, for it may be that the toluene is not attacked because it is less active than the other. A number of such experiments (called *crossover experiments*) have been carried out; sometimes crossover products have been found and sometimes not. As in Reaction 11-17, an initial complex (**68**) is formed between the substrate and the catalyst, so that a catalyst/substrate molar ratio of at least 1:1 is required. In the presence of aluminum chloride, the *Fries rearrangement* can be induced with microwave irradiation.⁵⁹⁰ Simply heating phenyl acetate with microwave irradiation gives the *Fries rearrangement*.⁵⁹¹ The *Fries rearrangement* has been carried out in ionic melts.⁵⁹²

The *Fries rearrangement* can also be carried out with UV light, in the absence of a catalyst.⁵⁹³ This reaction, called the *photo-Fries rearrangement*,⁵⁹⁴ is predominantly an intramolecular free radical process. Both ortho and para migration are observed.⁵⁹⁵ Unlike the Lewis acid catalyzed *Fries rearrangement*, the *photo-Fries reaction* can be accomplished, though often in low yields, when meta-directing groups are on the ring. The available evidence strongly suggests the following mechanism involving formation of the excited state⁵⁹⁷ followed by dissociation to a radical pair⁵⁹⁶ for the *photo-Fries rearrangement*⁵⁹⁷ (illustrated for para attack).

The phenol ArOH is always a side product, resulting from some ArO• that leaks from the solvent cage and abstracts a hydrogen atom from a neighboring molecule. When the reaction was performed on phenyl acetate in the gas phase, where there are no solvent molecules to form a cage (but in the presence of isobutane as a source of abstractable hydrogen atoms), phenol was the chief product and virtually no *o*- or *p*-hydroxyacetophenone was found.⁵⁹⁸ Other evidence⁵⁹⁹ for the mechanism is that CIDNP has been observed during the course of the reaction⁶⁰⁰ and that the ArO• radical has been detected by flash photolysis⁶⁰¹ and by nanosecond time-resolved Raman spectroscopy.⁶⁰²

A LDA-mediated *anionic Fries rearrangement* of aryl carbamates has been reported.⁶⁰³ The so-called *anionic Snieckus–Fries rearrangement* has also been discussed.⁶⁰⁴

Treatment of *O*-arylsulfonate esters with AlCl₃–ZnCl₂, on silica with microwave irradiation, leads to 2-sulfonyl phenols in a *thia-Fries rearrangement*.⁶⁰⁵ A similar reaction was reported with *O*-arylsulfonamides.⁶⁰⁶

B. Groups Cleaving from Nitrogen⁶⁰⁷

It has been shown that PhNH_2D rearranges to *o*- and *p*-deuterioaniline.⁶⁰⁸ The migration of OH, formally similar to Reactions **11-28**–**11-32**, is a nucleophilic substitution and is treated in Chapter 13 (**13-32**).

11-28 Migration of the Nitro Group

1/ *C*-Hydro,3/*N*-nitro-interchange

N-Nitro aromatic amines rearrange on treatment with acids to *o*- and *p*-nitroamines with the ortho compounds predominating.⁶⁰⁹ Aside from this indication of an intramolecular process, there is also the fact that virtually no meta isomer is produced in this reaction,⁶¹⁰ although direct nitration of an aromatic amine generally gives a fair amount of meta product. Thus a mechanism in which NO_2^+ is dissociated from the ring and then is attacked by another molecule must be ruled out. Further results indicating an intramolecular process include the observation that rearrangement of several substrates in the presence of K^{15}NO_3 gave products containing no ^{15}N ,⁶¹¹ and that rearrangement of a mixture of $\text{PhNH}^{15}\text{NO}_2$ and unlabeled *p*- $\text{MeC}_6\text{H}_4\text{NHNO}_2$ gave 2-nitro-4-methylaniline containing no ^{15}N .⁶¹² On the other hand, rearrangement of

69 in the presence of unlabeled PhNMeNO_2 gave labeled **70**, which did not arise by displacement of F.⁶¹³ The R group may be hydrogen or alkyl. Two principal mechanisms have been suggested, one involving cyclic attack by the oxygen of the nitro group at the ortho position before the group cleaves,⁶¹⁴ and the other involving a cleavage into a radical and a radical ion held together in a solvent cage.⁶¹⁵ Among the evidence

for the latter view⁶¹⁶ are the effects of substituents on the rate of the reaction,⁶¹⁷ ^{15}N and ^{14}C kinetic isotope effects that show nonconcertedness,⁶¹⁸ and the fact that both *N*-methylaniline and nitrous acid are produced in sizable and comparable amounts in addition to the normal products *o*- and *p*-nitro-*N*-methylaniline.⁶¹⁹ These side products are formed when the radicals escape from the solvent cage.

11-29 Migration of the Nitroso Group: The Fischer–Hepp Rearrangement

1/*C*-Hydro-5/*N*-nitroso-interchange

The migration of a nitroso group, formally similar to Reaction 11-28, is important because *p*-nitroso secondary aromatic amines cannot generally be prepared by direct *C*-nitrosation of secondary aromatic amines (see Reaction 12-50). The reaction, known as the *Fischer–Hepp rearrangement*,⁶²⁰ is brought about by treatment of *N*-nitroso secondary aromatic amines with HCl. Other acids give poor or no results. In benzene systems, the para product is usually formed exclusively.⁶²¹ The mechanism of the rearrangement is not completely understood. The fact that the reaction takes place in a large excess of urea⁶²² shows that it is intramolecular⁶²³ since, if NO^+ , NOCl , or some similar species were free in the solution, it would be captured by the urea, preventing the rearrangement.

11-30 Migration of an Arylazo Group

1/*C*-Hydro-5/*N*-arylazo-interchange

Rearrangement of aryl triazenes can be used to prepare azo derivatives of primary and secondary aromatic amines.⁶²⁴ These are first diazotized at the amino group (see Reaction 11-4) to give triazenes, which are then rearranged by treatment with acid. The rearrangement always gives the para isomer, unless that position is occupied.

11-31 Migration of Halogen: The Orton Rearrangement

1/C-Hydro-5/N-halo-interchange

Migration of a halogen from a nitrogen side chain to the ring by treatment with HCl is called the *Orton rearrangement*.⁶²⁵ The main product is the para isomer, though some ortho product may also be formed. The reaction has been carried out with *N*-chloro- and *N*-bromoamines and less often with *N*-iodo compounds. The amine must be acylated, except that PhNCl_2 gives 2,4-dichloroaniline. The reaction is usually performed in water or acetic acid. There is considerable evidence (cross-halogenation, labeling, etc.) that this is an intermolecular process.⁶²⁶ First, the HCl reacts with the starting material to give ArNHCOCH_3 and Cl_2 ; then the chlorine halogenates the ring as in Reaction 11-10. Among the evidence is that chlorine has been isolated from the reaction mixture. The *Orton rearrangement* can also be brought about photochemically⁶²⁷ and by heating in the presence of benzoyl peroxide.⁶²⁸ These are free radical processes.

11-32 Migration of an Alkyl Group⁶²⁹

1/C-Hydro-5/N-alkyl-interchange

When HCl salts of arylalkylamines are heated at $\sim 200\text{--}00^\circ\text{C}$, migration occurs in what is called the *Hofmann–Martius reaction*. It is an intermolecular reaction, since crossing is found. For example, methylanilinium bromide gave not only the normal products *o*- and *p*-toluidine, but also aniline and di- and trimethylanilines.⁶³⁰ As would be expected for an intermolecular process, there is isomerization when R is primary.

With primary R, the reaction probably goes through the alkyl halide formed initially in an $\text{S}_{\text{N}}2$ reaction:

Evidence for this view is that alkyl halides have been isolated from the reaction mixture and that Br^- , Cl^- , and I^- gave different ortho/para ratios, which indicates that the halogen is involved in the reaction.⁶³⁰ Further evidence is that the alkyl halides isolated are not rearranged (as would be expected if they are formed by an $\text{S}_{\text{N}}2$ mechanism), even though the alkyl groups in the ring are rearranged. Once the alkyl halide is formed, it reacts with the substrate by a normal *Friedel–Crafts alkylation* process (Reaction 11-11), accounting

⁶³⁰ Ogata, Y.; Tabuchi, H.; Yoshida, K. *Tetrahedron* **1964**, 20, 2717.

for the rearrangement. When R is secondary or tertiary, carbocations may be directly formed so that the reaction does not go through the alkyl halides.⁶³¹

It is also possible to carry out the reaction by heating the amine (not the salt) at a temperature between 200 and 350 °C with a metal halide (e.g., CoCl₂, CdCl₂, or ZnCl₂). When this is done, the reaction is called the *Reilly–Hickinbottom rearrangement*. Primary R groups larger than ethyl give both rearranged and unrearranged products.⁶³² The reaction is not generally useful for secondary and tertiary R groups, which are usually cleaved to alkenes under these conditions.

When acylated arylamines are photolyzed, migration of an acyl group takes place⁶³³ in a process that resembles the photo-Fries reaction (11-27).

11.F.iii. Other Leaving Groups

Three types of reactions are considered in this section.

1. Reactions in which hydrogen replaces another leaving group:

2. Reactions in which an electrophile other than hydrogen replaces another leaving group:

3. Reactions in which a group (other than hydrogen) migrates from one position in a ring to another. Such migrations can be either inter- or intramolecular:

The three types are not treated separately, but reactions are classified by leaving group.

A. Carbon Leaving Groups

11-3 Reversal of Friedel–Crafts Alkylation

Hydro-de-alkylation or Dealkylation

Alkyl groups can be cleaved from aromatic rings by treatment with proton and/or Lewis acids. Tertiary R groups are the most easily cleaved; because this is true, the *tert*-butyl group is occasionally introduced into a ring, used to direct another group, and then removed.⁶³⁴ For example, 4-*tert*-butyltoluene (**71**) reacted with benzoyl chloride and AlCl₃ to give the acylated product, and subsequent treatment with AlCl₃ led to loss of the *tert*-butyl group to give **72**.⁶³⁵

Secondary R groups are harder to cleave, and primary R harder still. Because of this reaction, care must be taken when using *Friedel–Crafts catalysts* (Lewis or proton acids)

on aromatic compounds containing alkyl groups. True cleavage, in which the R becomes an alkene, occurs only at high temperatures, $>400^\circ\text{C}$.⁶³⁶ At ordinary temperatures, the R group attacks another ring, so that the bulk of the product may be dealkylated, but there is a residue of heavily alkylated material. The isomerization reaction, in which a group migrates from one position in a ring to another or to a different ring, is therefore more important than true cleavage. In these reactions, the meta isomer is generally the most favored product among the dialkylbenzenes; and the 1,3,5-product the most favored among the trialkylbenzenes, because they have the highest thermodynamic stabilities. Alkyl migrations can be inter- or intramolecular, depending on the conditions and on the R group. The following experiments can be cited: Ethylbenzene treated with HF and BF_3 gave, almost completely, benzene and diethylbenzenes⁶³⁷ (entirely intermolecular); propylbenzene labeled in the β position gave benzene, propylbenzene, and di- and tripropylbenzenes, but the propylbenzene recovered was partly labeled in the α position and not at all in the γ position⁶³⁸ (both intra- and intermolecular); *o*-xylene treated with HBr and AlBr_3 gave a mixture of *o*- and *m*- but no *p*-xylene, while *p*-xylene gave *p*- and *m*- but no *o*-xylene, and no trimethyl compounds could be isolated in these experiments⁶³⁹ (exclusively intramolecular rearrangement). Apparently, methyl groups migrate only intramolecularly, while other groups may follow either path.⁶⁴⁰

The mechanism⁶⁴¹ of intermolecular rearrangement can involve free alkyl cations, but there is much evidence to show that this is not necessarily the case. For example, many of them occur without rearrangement within the alkyl group. The following mechanism has been proposed for intermolecular rearrangement without the involvement of carbocations that are separated from the ring.⁶⁴²

Evidence for this mechanism is that optically active PhCHDCH_3 labeled in the ring with ^{14}C and treated with GaBr_3 in the presence of benzene gave ethylbenzene containing no deuterium and two deuterium atoms and that the rate of loss of radioactivity was about equal

to the rate of loss of optical activity.⁶⁴² The mechanism of intramolecular rearrangement is not very clear. 1,2 shifts of this kind have been proposed:⁶⁴³

There is evidence from ¹⁴C labeling that intramolecular migration occurs only through 1,2-shifts.⁶⁴⁴ Any 1,3- or 1,4-migration takes place by a series of two or more 1,2-shifts.

Phenyl groups have also been found to migrate. Thus *o*-terphenyl, heated with AlCl₃—H₂O, gave a mixture containing 7% *o*-, 70% *m*-, and 23% *p*-terphenyl.⁶⁴⁵ Alkyl groups have also been replaced by groups other than hydrogen (nitro groups).

Unlike alkylation, *Friedel–Crafts acylation* has been generally considered to be irreversible, but a number of instances of electrofugal acyl groups have been reported,⁶⁴⁶ especially where there are two ortho substituents (e.g., the hydro-debenzoylation of **73**).⁶⁴⁷

11-34 Decarbonylation of Aromatic Aldehydes

Hydro-de-formylation or Deformylation

The decarbonylation of aromatic aldehydes with sulfuric acid⁶⁴⁸ is the reverse of the *Gatterman–Koch reaction* (**11-18**). It has been carried out with trialkyl- and trialkoxybenzaldehydes. The reaction takes place by the ordinary arenium ion mechanism: The attacking species is H⁺ and the leaving group is HCO⁺, which can lose a proton to give CO or combine with OH[−] from the water solvent to give formic acid.⁶⁴⁹ Aromatic aldehydes

have also been decarbonylated with basic catalysts.⁶⁵⁰ When basic catalysts are used, the mechanism is probably similar to the S_E1 process of Reaction **11-35** (see also, Reaction **14-32**).

11-35 Decarboxylation of Aromatic Acids

Hydro-de-carboxylation or Decarboxylation

The decarboxylation of aromatic acids is most often carried out by heating with copper and quinoline. However, two other methods can be used with certain substrates. In one method, the salt of the acid (ArCOO[−]) is heated, and in the other the carboxylic acid is heated with a strong acid, often sulfuric. The latter method is accelerated by the presence of electron-donating groups in ortho and para positions and by the steric effect of groups in the ortho positions; in benzene systems it is generally limited to substrates that contain such groups. In this method, decarboxylation takes place by the arenium ion mechanism,⁶⁵¹ with H⁺ as the electrophile and CO₂ as the leaving group.⁶⁵² Evidently, the order of electrofugal ability is CO₂ > H⁺ > COOH⁺, so that it is necessary, at least in most cases, for the COOH to lose a proton before it can cleave.

When carboxylate *ions* are decarboxylated, the mechanism is entirely different, being of the S_E1 type. Evidence for this mechanism is that the reaction is first order and that electron-withdrawing groups, which would stabilize a carbanion, facilitate the reaction.⁶⁵³

Despite its synthetic importance, the mechanism of the copper–quinoline method has been studied very little, but it has been shown that the actual catalyst is cuprous ion.⁶⁵⁴ In fact, the reaction proceeds much faster if the acid is heated in quinoline with cuprous oxide instead of copper, provided that atmospheric oxygen is rigorously excluded. A mechanism has been suggested in which it is the cuprous salt of the acid that actually undergoes the decarboxylation.⁶⁵⁴ It has been shown that cuprous salts of aromatic acids

are easily decarboxylated by heating in quinoline⁶⁵⁵ and that arylcopper compounds are intermediates that can be isolated in some cases.⁶⁵⁶ Metallic silver has been used in place of copper, with higher yields.⁶⁵⁷ Silver acetate has also been used to promote decarboxylation.⁶⁵⁸ A photolytic decarboxylation also has been reported, under a dioxygen atmosphere in the presence of HgF_2 .⁶⁵⁹

In certain cases, the carboxyl group can be replaced by electrophiles other than hydrogen (e.g., NO ,⁶⁵⁷ I ,⁶⁶⁰ Br ,⁶⁶¹ or Hg).⁶⁶² Although closely related to reactions in Chapter 13 (Reactions **13-9**, **13-11**, and **13-12**), a decarboxylative coupling reaction of aryl halides and arylcarboxylic acids has been reported, using Pd and Cu catalysts, to give the corresponding biaryl.⁶⁶³

Rearrangements are also known to take place. For example, when the phthalate ion is heated with a catalytic amount of cadmium, the terphthalate ion (**74**) is produced:⁶⁶⁴

In a similar process, potassium benzoate heated with Cd salts disproportionates to benzene and **74**. The term *Henkel reaction* (named for the company that patented the process) is used for these rearrangements.⁶⁶⁵ An $\text{S}_{\text{E}}1$ mechanism has been suggested.⁶⁶⁶ The terphthalate is the main product because it crystallizes from the reaction mixture, driving the equilibrium in that direction.⁶⁶⁷

For aliphatic decarboxylation, see Reaction **12-40**.

11-36 The Jacobsen Reaction

When polyalkyl- or polyhalobenzenes are treated with sulfuric acid, the ring is sulfonated, but rearrangement also takes place. The reaction, known as the *Jacobsen reaction*, is limited to benzene rings that have at least four substituents, which can be

any combination of alkyl and halogen groups, where the alkyl groups can be ethyl or methyl and the halogen iodo, chloro, or bromo. When isopropyl or *tert*-butyl groups are on the ring, these groups are cleaved to give alkenes. Since a sulfo group can later be removed (Reaction **11-38**), the Jacobsen reaction can be used as a means of rearranging polyalkylbenzenes. The rearrangement always brings the alkyl or halo groups closer together than they were originally. Side products in the case illustrated above are pentamethylbenzenesulfonic acid, 2,4,5-trimethylbenzenesulfonic acid, and so on, indicating an intermolecular process, at least partially.

The mechanism of the *Jacobsen reaction* is not established,⁶⁶⁸ but there is evidence, at least for polymethylbenzenes, that the rearrangement is intermolecular, and that the species to which the methyl group migrates is a polymethylbenzene, not a sulfonic acid. Sulfonation takes place after the migration.⁶⁶⁹ It has been shown by labeling that ethyl groups migrate without internal rearrangement.⁶⁷⁰

Isomerization of alkyl groups in substituted biphenyls has been observed⁶⁷¹ when the medium is a superacid (see Sec. 5.A.ii).

B. Oxygen Leaving Groups

11-37 Deoxygenation

In a few cases, it is possible to remove an oxygen substituent directly from the aromatic ring. Treatment of an aryl mesylate (ArOMs) with a Ni catalyst in DMF, for example, leads to the deoxygenated product, Ar-H.⁶⁷²

C. Sulfur Leaving Groups

11-38 Desulfonation or Hydro-de-sulfonation

The cleavage of sulfo groups from aromatic rings is the reverse of Reaction **11-7**.⁶⁷³ By the principle of microscopic reversibility, the mechanism is also the reverse.⁶⁷⁴ Dilution is generally used, as the reversibility of sulfonation decreases with increasing H₂SO₄ concentration. The reaction permits the sulfo group to be used as a blocking group to direct meta and then to be removed. The sulfo group has also been replaced by nitro and halogen groups. Sulfo groups have also been removed from the ring by heating with an alkaline solution of Raney nickel.⁶⁷⁵ In another catalytic process, aromatic

sulfonyl bromides or chlorides are converted to aryl bromides or chlorides, respectively, on heating with an Rh catalyst.⁶⁷⁶ This reaction is similar to the decarbonylation of aromatic acyl halides mentioned in Reaction 14-32.

OS I, 388; II, 97; III, 262; IV, 364. Also see, OS I, 519; II, 128; V, 1070.

D. Halogen Leaving groups

11-39 Dehalogenation or Hydro-de-halogenation

Aryl halides can be dehalogenated by *Friedel–Crafts catalysts*. Iodine is the most easily cleaved. Dechlorination is seldom performed and defluorination apparently never. The reaction is most successful when a reducing agent, say, Br^- or I^- is present to combine with the I^+ or Br^+ coming off.⁶⁷⁷ Except for deiodination, the reaction is seldom used for preparative purposes. Migration of halogen is also found,⁶⁷⁸ both intramolecular⁶⁷⁹ and intermolecular.⁶⁸⁰ The mechanism is probably the reverse of that of Reaction 11-10.⁶⁸¹ Debromination of aromatic rings having two attached amino groups was accomplished by refluxing in aniline containing acetic acid/HBr.⁶⁸²

Rearrangement of polyhalobenzenes can also be catalyzed by very strong bases (e.g., 1,2,4-tribromobenzene) is converted to 1,3,5-tribromobenzene by treatment with PhNHK.⁶⁸³ This reaction, which involves aryl carbanion intermediates ($\text{S}_{\text{E}}1$ mechanism), has been called the *halogen dance*.⁶⁸⁴

Removal of halogen from aromatic rings can also be accomplished by various reducing agents, among them Bu_3SnH ,⁶⁸⁵ catalytic-hydrogenolysis,⁶⁸⁶ catalytic-transfer hydrogenolysis,⁶⁸⁷ Na—Hg in liquid NH_3 ,⁶⁸⁸ LiAlH_4 ,⁶⁸⁹ NaBH_4 and a catalyst,⁶⁹⁰ NaH ,⁶⁹¹ HCO_2H ⁶⁹² or

aq HCO_2^- ⁶⁹³ with Pd/C,⁶⁹⁴ ammonium formate in aq isopropyl alcohol with a Pd catalyst,⁶⁹⁵ and Raney nickel in alkaline solution,⁶⁹⁶ the last method being effective for fluorine as well as for the other halogens. Aryl iodides are reduced with DMAP methiodide salt.⁶⁹⁷ Carbon monoxide, with potassium tetracarbonylhydridoferrate $[\text{KHF}(\text{CO})_4]$ as a catalyst, specifically reduces aryl iodides.⁶⁹⁸ Not all of these reagents operate by electrophilic substitution mechanisms. Some are nucleophilic substitutions and some are free radical processes. Photochemical⁶⁹⁹ and electrochemical⁷⁰⁰ reduction are also known. Halogen can also be removed from aromatic rings indirectly by conversion to *Grignard reagents* (Reaction 12-38) followed by hydrolysis (Reaction 11-41).

OS III, 132, 475, 519; V, 149, 346, 998; VI, 82, 821.

11-40 Formation of Organometallic Compounds

These reactions are considered along with their aliphatic counterparts at Reactions 12-38 and 12-39.

E. Metal Leaving Groups

11-41 Hydrolysis of Organometallic Compounds

Hydro-de-metalation or Demetalation

Organometallic compounds can be hydrolyzed by acid treatment. For active metals (e. g., Mg, Li, etc.), water is sufficiently acidic. The most important example of this reaction is hydrolysis of *Grignard reagents*, but M may be many other metals or metalloids. Examples are SiR_3 , HgR , Na, and $\text{B}(\text{OH})_2$. Since aryl *Grignard* and aryllithium compounds are fairly easy to prepare, they are often used to prepare salts of weak acids (e.g., alkynes).

Where the bond between the metal and the ring is covalent, the usual arenium ion mechanism operates.⁷⁰¹ Where the bonding is essentially ionic, this is a simple acid-base reaction. For the aliphatic counterpart of this reaction, see Reaction 12-24.

Other reactions of aryl organometallic compounds are treated with their aliphatic analogues: Reactions 12-25–12-27 and 12-30–12-37.

Aliphatic, Alkenyl, and Alkynyl Substitution, Electrophilic and Organometallic

Chapter 11 pointed out that the most important leaving groups in electrophilic substitution are those that can best exist with an outer shell that is deficient in a pair of electrons. For aromatic systems, the most common leaving group is the proton. The proton is also a leaving group in aliphatic systems, but the reactivity depends on the acidity. Protons in saturated alkanes are very unreactive, but electrophilic substitutions are often easily carried out at more acidic positions [e.g., α to a carbonyl group or at an alkynyl position ($\text{RC}\equiv\text{CH}$)]. Since metallic ions are easily able to bear positive charges, organometallic compounds should be especially susceptible to electrophilic substitution, and this is indeed the case.¹ Another important type of electrophilic substitution, known as *anionic cleavage*, involves the breaking of C—C bonds; in these reactions there are carbon leaving groups (Reactions 12-40–12-46). A number of electrophilic substitutions at a nitrogen atom are treated at the end of the chapter.

Since a carbanion is generated when an atom or group is removed as a positive species from a carbon atom, the subject of carbanion structure and stability (Chapter 5) is inevitably related to the material in this chapter. So is the subject of very weak acids and very strong bases (Chapter 8), because the weakest acids are those in which the hydrogen is bonded to carbon.

12.A. MECHANISMS

For aliphatic electrophilic substitution, at least four possible major mechanisms can be distinguished:² S_E1 , S_E2 (front), S_E2 (back), and S_Ei . The S_E1 is unimolecular; the other three are bimolecular. Note that the term " S_EAr " has been proposed to represent electrophilic aromatic substitution, so that the term " S_E2 " refers exclusively to electrophilic substitutions where a steric course is possible.³ To describe the steric course of an aliphatic substitution reaction, the suffixes "ret" and "inv" were proposed, referring to retention and inversion of configuration, respectively.

12.A.i. Bimolecular Mechanisms: S_E2 and S_Ei

The bimolecular mechanisms for electrophilic aliphatic substitution are analogous to the S_N2 mechanism in that the new bond forms as the old one breaks. However, in the S_N2 mechanism the incoming group brings with it a pair of electrons, and this orbital can overlap with the central carbon only to the extent that the leaving group takes away its electrons; otherwise the carbon would have more than eight electrons at once in its outer shell. Since electron clouds repel, this also means that the incoming group attacks backside, at a position 180° from the leaving group, resulting in inversion of configuration. When the nucleophilic species attacks (donates electrons to) an electrophile, it brings only a vacant orbital to the substrate. Predicting the direction of the attack is not as straightforward. Two main possibilities can be imagined: delivery of the electrophile to the front, which is S_E2 (front), or delivery of the electrophile to the rear, which is S_E2 (back). The possibilities can be pictured (charges not shown):

Both the S_E2 (front) and S_E2 (back) mechanisms are designated D_EA_E in the IUPAC system. With substrates in which these possibilities may be distinguished, the former mechanism should result in retention of configuration and the latter results in inversion. The reaction of allylsilanes with adamantyl chloride and $TiCl_4$, for example, gives primarily the antiprodukt via a S_E2' reaction.⁴ When the electrophile reacts from the front, there is a third possibility. A portion of the electrophile may assist in the removal of the leaving group, forming a bond with it at the same time that the new $C—Y$ bond is formed:

⁴ Buckle, M.J.C.; Fleming, I.; Gil, S. *Tetrahedron Lett.* **1992**, *33*, 4479.

This mechanism, which is called the S_{Ei} mechanism⁵ (IUPAC designation: *cyclo-D_EA_ED_nA_n*), also results in retention of configuration.⁶ Plainly, where a second-order mechanism involves this kind of internal assistance, backside attack is impossible.

It is evident that these three mechanisms are not easy to distinguish. All three mechanisms give second-order kinetics, and two mechanisms result in retention of configuration.⁷ In fact, although much work has been done on this question, there are few cases in which one of these three can be unequivocally established to demonstrate that another is not actually taking place. Clearly, a study of the stereochemistry can distinguish between S_{E2} (back) on the one hand and S_{E2} (front) or S_{Ei} on the other. Many such investigations have been made. In the overwhelming majority of second-order electrophilic substitutions, the result has been retention of configuration or some other indication of frontside attack, indicating an S_{E2} (front) or S_{Ei} mechanism. For example, when *cis*-**1** was treated with labeled mercuric chloride, the **2** produced was 100% *cis*. The bond between the mercury and the ring must have been broken (as well as the other Hg—C bond), since each of the products contained about one-half of the labeled mercury.⁸ Another indication of frontside attack is that second-order electrophilic substitutions proceed very easily at *bridgehead* carbons (see Sec. 10.A.i).⁹ Still another indication is the behavior of neopentyl as a substrate. The S_N2 reactions at neopentyl are extremely slow (Sec. 10.G.i), because attack from the rear is blocked and the transition state for the reaction lies very high in energy. The fact that neopentyl systems undergo electrophilic substitution only slightly more slowly than ethyl¹⁰ is further evidence for frontside attack. One final elegant experiment may be noted.

⁵ The names for these mechanisms vary throughout the literature. For example, the S_{Ei} mechanism has also been called the S_{E2} , the S_{E2} (closed), and the S_{E2} (cyclic) mechanism. The original designations, S_{E1} , S_{E2} , and so on, were devised by the Hughes–Ingold school.

⁶ It has been contended that the S_{Ei} mechanism violates the principle of conservation of orbital symmetry (see Reaction 15-60, A), and that the S_{E2} (back) mechanism partially violates it: Slack, D.A.; Baird, M.C. *J. Am. Chem. Soc.* **1976**, 98, 5539.

¹⁰ Hughes, E.D.; Volger, H.C. *J. Chem. Soc.* **1961**, 2359.

The compound di-*sec*-butylmercury was prepared with one *sec*-butyl group optically active and the other racemic.¹¹ This compound was prepared by treatment of optically active *sec*-butylmercuric bromide with racemic *sec*-butylmagnesium bromide. The di-*sec*-butyl compound was then treated with mercuric bromide to give 2 molar equivalents of *sec*-butylmercuric bromide. The steric course of the reaction could then be predicted by the following analysis, assuming that the bonds between the mercury and each carbon have a 50% chance of breaking. The original activity referred to is the activity of the optically active *sec*-butylmercuric bromide used to make the dialkyl compound. The actual result was that, under several different sets of conditions, the product had one-half of the original activity, demonstrating retention of configuration.

However, inversion of configuration has been found in certain cases, demonstrating that the S_E2 (back) mechanism can take place. For example, the reaction of optically active *sec*-butyltrineopentyltin with bromine (Reaction 12-40) gives inverted *sec*-butyl bromide.¹² A number of other organometallic compounds have also been shown to give inversion when treated with halogens,¹³ although others do not.¹⁴ So far, no inversion has been found with an organomercury substrate. It may be that still other examples of backside

attack exist¹⁵ but have escaped detection because of the difficulty in preparing compounds with a configurationally stable carbon–metal bond. Compounds that are chiral because of a stereogenic carbon at which a carbon–metal bond is located¹⁶ are often difficult to resolve and once resolved are often easily racemized. The resolution has been accomplished most often with organomercury compounds,¹⁷ and most stereochemical investigations have therefore been made with these substrates. Only a few optically active *Grignard reagents* (see Sec. 12-38) have been prepared¹⁸ (i.e., in which the only stereogenic center is the

¹⁸ This was done first by Walborsky, H.M.; Young, A.E. *J. Am. Chem. Soc.* **1964**, 86, 3288.

carbon bonded to the magnesium). Because of this, the steric course of electrophilic substitutions at the C—Mg bond has not often been determined. However, in one such case, the reaction of both the exo and endo isomers of the 2-norbornyl *Grignard reagent* with HgBr_2 (to give 2-norbornylmercuric bromide) has been shown to proceed with retention of configuration.¹⁹ It is likely that inversion takes place only when steric hindrance prevents reaction on the frontside and when the electrophile does not carry a Z group (see above).

The $\text{S}_{\text{E}2}$ (back) mechanism can be identified in certain cases (if inversion of configuration is found), but it is plain that stereochemical investigations cannot distinguish between the $\text{S}_{\text{E}2}$ (front) and the $\text{S}_{\text{E}i}$ mechanisms and that, in the many cases where configurationally stable substrates cannot be prepared, such investigations are of no help at all in distinguishing among all three of the second-order mechanisms. Unfortunately, there are not many other methods that lead to unequivocal conclusions. One method that has been used in an attempt to distinguish between the $\text{S}_{\text{E}i}$ mechanism on the one hand and the $\text{S}_{\text{E}2}$ pathways on the other, involves the study of salt effects on the rate. It may be recalled (Sec. 10.G.iv) that reactions in which neutral starting molecules acquire charges in the transition state are aided by an increasing concentration of added ions. Thus the $\text{S}_{\text{E}i}$ mechanism would be less influenced by salt effects than would either of the $\text{S}_{\text{E}2}$ mechanisms. On this basis, Abraham and Johnson²⁰ concluded that the reactions $\text{R}_4\text{Sn} + \text{HgX}_2 \rightarrow \text{RHgX} + \text{R}_3\text{SnX}$ ($\text{X} = \text{Cl}$ or I) take place by $\text{S}_{\text{E}2}$ and not by $\text{S}_{\text{E}i}$ mechanisms. Similar investigations involve changes in solvent polarity²¹ (see also, Sec. 12.C.i). In the case of the reaction (where $\text{R} = \text{R}' = i\text{Pr}$ and $\text{R} = i\text{Pr}$, $\text{R}' = \text{neopentyl}$), the use of polar solvents gave predominant inversion, while nonpolar solvents gave predominant retention.²²

On the basis of evidence from reactivity studies, it has been suggested²³ that a variation of the $\text{S}_{\text{E}i}$ mechanism is possible in which the group Z becomes attached to X before the latter becomes detached:

This process has been called the $\text{S}_{\text{E}}\text{C}^{22}$ or $\text{S}_{\text{E}2}$ (co-ord)²⁴ mechanism (IUPAC designation $\text{A}_n + \text{cyclo-D}_\text{E}\text{A}_\text{E}\text{D}_\text{n}$).

It has been shown that in certain cases (e.g., $\text{Me}_4\text{Sn} + \text{I}_2$) the reactants in an $\text{S}_{\text{E}2}$ reaction, when mixed, give rise to an immediate charge-transfer spectrum (Sec. 3.C.i), showing that an EDA complex has been formed.²⁵ In these cases, it is likely that the EDA complex is an intermediate in the reaction.

12.A.ii. The S_E1 Mechanism

The S_E1 mechanism is analogous to the S_N1. It involves two steps: A slow ionization and a fast combination.

The IUPAC designation is D_E + A_E. First-order kinetics are predicted and many such examples have been found. Other evidence for the S_E1 mechanism was obtained in a study of base-catalyzed tautomerization. In the reaction, the rate of deuterium exchange was the same as the rate of racemization²⁶ and there was an isotope effect.²⁷

It is known that S_N1 reactions do not proceed at strained bridgehead carbons (e.g., in [2.2.1]bicyclic systems, Sec. 10.A.ii) because planar carbocations cannot form at these carbons. However, carbanions not stabilized by resonance are probably not planar, and S_E1 reactions readily occur with this type of substrate. Indeed, the question of carbanion structure is intimately tied into the problem of the stereochemistry of the S_E1 reaction. If a carbanion is planar, racemization should occur. If it is pyramidal and *can hold its structure*, the result should be retention of configuration, or at least partial retention. On the other hand, even a pyramidal carbanion will give racemization if it cannot hold its structure (this means that there is pyramidal inversion as with amines, Sec. 4.C, category 3). Unfortunately, the only carbanions that can be studied easily are those stabilized by resonance, which makes them planar, as expected (Sec. 5.B.i). For simple alkyl carbanions, the main approach to deduce the structure has been to study the stereochemistry of S_E1 reactions rather than the other way around. Racemization is almost always observed, but whether this is caused by planar carbanions or by oscillating pyramidal carbanions is not known. In either case, racemization occurs whenever a carbanion is completely free or is symmetrically solvated.

However, even planar carbanions need not give racemization. Cram found that retention and even inversion can occur in an alkoxide (see **3**) cleavage Reaction (12-41):

which is a first-order S_E1 reaction involving resonance-stabilized planar carbanions (here designated R⁻).²⁸ By changing the solvent, Cram was able to produce products ranging from 99% retention to 60% inversion and including complete racemization. These results are explained by a carbanion that is not completely free, but is solvated. In nondissociating,

²⁶ Hsu, S.K.; Ingold, C.K.; Wilson, C.L. *J. Chem. Soc.* **1938**, 78.

²⁷ Wilson, C.L. *J. Chem. Soc.* **1936**, 1550.

²⁸ See Hoffman, T.D.; Cram, D.J. *J. Am. Chem. Soc.* **1969**, *91*, 1009. For a discussion, see Cram, D.J. *Fundamentals of Carbanion Chemistry*, Academic Press, NY, **1965**, pp. 138–158.

nonpolar solvents (e.g., benzene or dioxane), the alkoxide ion exists as an ion pair, solvated by the solvent BH:

In the course of the cleavage, the proton of the solvent moves in to solvate the newly forming carbanion. This solvation is asymmetrical since the solvent molecule is already on the front side of the carbanion. When the carbanion actually bonds with the proton, the result is retention of the original configuration. In protic solvents (e.g., diethylene glycol), a good deal of inversion is found. In these solvents, the *leaving group* solvates the carbanion, so the solvent can solvate it only from the opposite side:

When C—H bond formation occurs, the result is inversion. Racemization occurs in polar aprotic solvents (e.g., DMSO). In these solvents, the carbanions are relatively long lived (because the solvent has no proton to donate) and is solvated symmetrically.

Similar behavior was found for carbanions generated by base-catalyzed hydrogen-exchange (Reaction 12-1).²⁹ In this case, information was obtained from measurement of the ratio of k_e (rate constant for isotopic exchange) to k_a (rate constant for racemization). A k_e/k_a ratio substantially >1 means retention of configuration, since many individual isotopic exchanges are not producing a change in configuration. A k_e/k_a ratio of ~ 1 indicates racemization and a ratio of $\frac{1}{2}$ corresponds to inversion (see Sec. 10.A.i). All three types of steric behavior were found, depending on R, the base, and the solvent. As with the alkoxide cleavage reaction, retention was generally found in solvents of low dielectric constant, racemization in polar aprotic solvents, and inversion in protic solvents. However, in the proton-exchange reactions, a fourth type of behavior was encountered. In aprotic solvents, with aprotic bases like tertiary amines, the k_e/k_a ratio was found to be <0.5 , indicating that racemization took place *faster* than isotopic exchange (this process is known as *isoracemization*). Under these conditions, the conjugate acid of the amine remains associated with the carbanion as an ion pair. Occasionally, the ion pair dissociates long enough for the carbanion to turn over and recapture the proton:

²⁹ See Roitman, J.N.; Cram, D.J. *J. Am. Chem. Soc.* **1971**, 93, 2225, 2231 and references cited therein; Cram, J.M.; Cram, D.J. *Intra-Sci. Chem. Rep.* **1973**, 7(3), 1; Cram, D.J. *Fundamentals of Carbanion Chemistry*, Academic Press, NY, **1965**, pp. 85–105.

Thus, inversion (and hence racemization, which is produced by repeated acts of inversion) occurs without exchange. A single act of inversion without exchange is called *isoinversion*.

The isoinversion process can take place by a pathway in which a positive species migrates in a stepwise fashion around a molecule from one nucleophilic position to another. For example, in the exchange reaction of 3-carboxamido-9-methylfluorene (**4**) with Pr₃N in *t*-BuOH, it has been proposed that the amine removes a proton from the 9 position of **4** and conducts the proton out to the C=O oxygen (**6**), around the molecule, and back to C-9 on the opposite face of the anion. Collapse of **7** gives the inverted product **8**. Of course, **6** could also go back to **4**, but a molecule that undergoes the total process **4** → **5** → **6** → **7** → **8** has experienced an inversion without an exchange. Evidence for this pathway, called the *conducted tour mechanism*,³⁰ is that the 12-carboxamido isomer of **4** does not give isoracemization. In this case, the negative charge on the oxygen atom in the anion corresponding to **6** is less, because a canonical form in which oxygen acquires a full negative charge (**9**) results in disruption of the aromatic sextet in both benzene rings (cf. **10** where one benzene ring is intact). Whether the isoracemization process takes place by the conducted tour mechanism or a simple nonstructured contact ion-pair mechanism depends on the nature of the substrate (e.g., a proper functional group is necessary for the conducted tour mechanism) and of the base.³¹

It is known that vinylic carbanions *can* maintain configuration, so that S_E1 mechanisms should produce retention, which is the case. For example, *trans*-2-bromo-2-butene was converted to 64–74% angelic acid:³²

³⁰ Cram, D.J.; Ford, W.T.; Gosser, L. *J. Am. Chem. Soc.* **1968**, *90*, 2598; Ford, W.T.; Cram, D.J. *J. Am. Chem. Soc.* **1968**, *90*, 2606, 2612. See also, Buchholz, S.; Harms, K.; Massa, W.; Boche, G. *Angew. Chem. Int. Ed.* **1989**, *28*, 73.

³¹ Almy, J.; Hoffman, D.H.; Chu, K.C.; Cram, D.J. *J. Am. Chem. Soc.* **1973**, *95*, 1185.

³² Dreiding, A.S.; Pratt, R.J. *J. Am. Chem. Soc.* **1954**, *76*, 1902. See also, Walborsky, H.M.; Turner, L.M. *J. Am. Chem. Soc.* **1972**, *94*, 2273.

Only ~5% of the cis isomer (tiglic acid) was produced. In addition, certain carbanions in which the negative charge is stabilized by *d*-orbital overlap can maintain configuration (Sec. 5.B.ii) and S_E1 reactions involving them proceed with retention of configuration.

12.A.iii. Electrophilic Substitution Accompanied by Double-Bond Shifts

When electrophilic substitution is carried out at an allylic substrate, the product may be rearranged (**11** \rightarrow **12**). This type of process is analogous to the nucleophilic allylic rearrangements discussed in Section 10.D. There are two principal pathways. The first of these is analogous to the S_E1 mechanism in that the leaving group is first removed, giving a resonance-stabilized allylic carbanion, which then attacks the electrophile Y.

In the other pathway, the Y group is first attacked by the π -bond, giving a carbocation, which then loses X with formation of the alkene unit.

These mechanisms are more fully discussed under Reaction **12-2**.

Most electrophilic allylic rearrangements involve loss of hydrogen, but they have also been observed with metallic leaving groups.³³ Sleezer et al.³⁴ found that crotylmercuric bromide reacted with HCl $\sim 10^7$ times faster than *n*-butylmercuric bromide and the product was >99% 1-butene. These facts point to an $S_{Ei'}$ mechanism (IUPAC designation *cyclo*-1/3/ $D_EA_E D_n A_n$):

The reaction of the same compound with acetic acid–perchloric acid seems to proceed by an $S_{E2'}$ mechanism (IUPAC designation 1/3/ D_EA_E)³⁴:

³³ See Courtois, G.; Miginiac, L. *J. Organomet. Chem.* **1974**, 69, 1.

³⁴ Sleezer, P.D.; Winstein, S.; Young, W.G. *J. Am. Chem. Soc.* **1963**, 85, 1890. See also, Kashin, A.N.; Bakunin, V.N.; Khutoryanskii, V.A.; Beletskaya, I.P.; Reutov, O.A. *J. Organomet. Chem.* **1979**, 171, 309.

The geometry of electrophilic allylic rearrangement has not been studied very much (cf. the nucleophilic case, Sec. 10.E), but in most cases the rearrangement takes place with antistereoselectivity,³⁵ although syn stereoselectivity has also been demonstrated.³⁶ In one case, use of the electrophile H^+ and the leaving group $SnMe_3$ gave both syn and anti stereoselectivity, depending on whether the substrate was cis or trans.³⁷

12.A.iv. Other Mechanisms

Addition–elimination (Reaction 12-16) and cyclic mechanisms (Reaction 12-40) are also known.

Much less work has been done on electrophilic aliphatic substitution mechanisms than on nucleophilic substitutions. The exact mechanisms of many of the reactions in this chapter are in doubt. For many of them, not enough work has been done to permit us to decide which of the mechanisms described in this chapter is operating, if indeed any is. There may be other electrophilic substitution mechanisms, and some of the reactions in this chapter may not even be electrophilic substitutions at all.

12.B. REACTIVITY

Only a small amount of work has been done in this area, compared to the vast amount done for aliphatic nucleophilic substitution and aromatic electrophilic substitution. Therefore, only a few conclusions can be drawn, most of them sketchy or tentative.³⁸

1. *Effect of Substrate.* For S_E1 reactions, electron-donating groups decrease rates and electron-withdrawing groups increase them. This is expected for a reaction in which the rate-determining step is analogous to the cleavage of a proton from an acid. For the S_E2 (back) mechanism, Jensen and Davis¹² showed that the reactivity of alkyl groups is similar to that for the S_N2 mechanism (i.e., $Me > Et > Pr > iPr > neopentyl$), as is expected, since both involve backside attack and both are equally affected by steric hindrance. In fact, this pattern of reactivity can be regarded as evidence for the occurrence of the S_E2 (back) mechanism in cases where stereochemical investigation is not feasible.³⁹ For S_E2 reactions that proceed with retention, several studies have been made with varying results, depending on the reaction.⁴⁰ One such study, which examined the reaction $RHgBr + Br_2 \rightarrow RBr$ catalyzed by Br^- , gave the results shown in Table 12.1.⁴¹ This data shows that branching increased the rates, while β branching decreased them. Sayre and Jensen⁴¹

attributed the decreased rates to steric hindrance, although attack here was definitely frontside, and the increased rates to the electron-donating effect of the alkyl groups, which stabilized the electron-deficient transition state.⁴² Of course, steric hindrance should also be present with the a branched groups, so these workers concluded that if it were not, the rates would be even greater. The Br electrophile is a rather large one and it is likely that smaller steric effects are present with smaller electrophiles. The rates of certain second-order substitutions of organotin compounds have been found to increase with increasing electron withdrawal by substituents. This behavior has been ascribed⁴³ to an S_E2 mechanism involving ion pairs, analogous to S_N2's ion-pair mechanism for nucleophilic substitution (Sec. 10.A.iv). Solvolysis of 2-bromo-1,1,1-trifluoro-2-(*p*-methoxyphenyl)ethane in water proceeds via a free carbocation intermediate, but ion pairing influences the reaction in the presence of bromide ion.⁴⁴

2. *Effect of Leaving Group.* For both S_E1 and second-order mechanisms, the more polar the C—X bond, the easier it is for the electrofuge to cleave. For metallic leaving groups in which the metal has a valence >1, the nature of the other group or groups attached to the metal thus has an effect on the reaction. For example, consider a series of organomercurials (RHgW). Because a more electronegative W decreases the polarity of the C—Hg bond and furthermore results in a less stable HgW⁺, the electrofugal ability of HgW decreases with increasing electronegativity of W. Thus, HgR' (from RHgR') is a better leaving group than HgCl (from RHgCl). Also in accord with this is the leaving-group order Hg—*t*-Bu > Hg—*i*Pr > HgEt > HgMe, reported for acetolysis of R₂Hg,⁴² since the more highly branched alkyl groups better help to spread the positive charge. It might be expected that, when metals are the leaving groups, S_E1 mechanisms would be favored, while with carbon leaving groups, second-order mechanisms would be found. However, the reported results have been just about the reverse of this. For carbon leaving groups the mechanism is usually S_E1, while for metallic leaving groups the mechanism is almost always S_E2 or S_Ei. A number of reports of S_E1 reactions with metallic leaving groups have appeared,⁴⁵ but the mechanism is not easy to prove and many of

these reports have been challenged.⁴⁶ Reutov and co-workers⁴⁵ expressed the view that in such reactions a nucleophile (which may be the solvent) must assist in the removal of the electrofuge and refer to such processes as $S_E1(N)$ reactions.

3. *Effect of Solvent.*⁴⁷ In addition to the solvent effects on certain S_E1 reactions mentioned earlier (Sec. 12.A.ii), solvents can influence the mechanism that is preferred. As with nucleophilic substitution (Sec. 10.G.iv), an increase in solvent polarity increases the possibility of an ionizing mechanism, in this case S_E1 , in comparison with the second-order mechanisms, which do not involve ions. As previously mentioned (Sec. 12.A.ii), the solvent can also exert an influence between the S_E2 (front or back) and S_{Ei} mechanisms in that the rates of S_E2 mechanisms should be increased by an increase in solvent polarity, while S_{Ei} mechanisms are much less affected.

12.C. REACTIONS

The reactions in this chapter are arranged in order of leaving group: hydrogen, metals, halogen, and carbon. Electrophilic substitutions at a nitrogen atom are treated last.

12.C.i. Hydrogen as Leaving Group

A. Hydrogen as the Electrophile

12-1 Hydrogen Exchange

Deuterio-de-hydrogenation or Deuteriation

Hydrogen exchange can be accomplished by treatment with acids or bases. As with Reaction 11-1, the exchange reaction is mostly used to study mechanistic questions (e.g., relative acidities), but it can be used synthetically to prepare deuterated or tritiated molecules. When ordinary strong acids (e.g., H_2SO_4) are used, only fairly acidic protons on carbon can exchange (e.g., acetylenic and allylic). However, primary, secondary, and tertiary hydrogen atoms of alkanes can be exchanged by treatment with superacids (Sec. 5.A.ii).⁴⁸ The order of hydrogen reactivity is tertiary > secondary > primary. Where C—C bonds are present, they may be cleaved also (Reaction 12-47). The mechanism of the exchange (illustrated for methane) has been formulated as involving attack of H^+ on the C—H bond to give the pentavalent methanonium ion, which loses

⁴⁶ See Kitching, W. *Rev. Pure Appl. Chem.* **1969**, 19, 1.

⁴⁷ See Petrosyan, V.S. *J. Organomet. Chem.* **1983**, 250, 157.

⁴⁸ See Olah, G.A.; Prakash, G.K.S.; Sommer, J. *Superacids*, Wiley, NY, **1985**, pp. 244–249; Olah, G.A. *Angew. Chem. Int. Ed.* **1973**, 12, 173.

H₂ to give a tervalent carbocation.⁴⁹ The methanonium ion (CH₅⁺) has a three-center, two-electron bond.⁵⁰ It is not known whether the methanonium ion is a transition state or a true intermediate, but an ion (CH₅⁺) has been detected in the mass spectrum.⁵¹ The IR spectrum of the ethanonium ion (C₂H₇⁺) has been measured in the gas phase.⁵² Note that the two electrons in the three-center, two-electron bond can move in three directions, in accord with the threefold symmetry of such a structure. The electrons can move to unite the two hydrogen atoms, leaving the CH₃⁺ free (the forward reaction), or they can unite the CH₃ with either of the two hydrogen atoms, leaving the other hydrogen as a free H⁺ ion (the reverse reaction). Actually, the methyl cation is not stable under these conditions. It can go back to CH₄ by the route shown (leading to H⁺ exchange), or it can react with additional CH₄ molecules (Reaction 12-20) to eventually yield the *tert*-butyl cation, which is stable in these superacid solutions. Hydride ion can also be removed from alkanes (producing tervalent carbocations) by treatment with pure SbF₅ in the absence of any source of H⁺.⁵³ Complete or almost complete perdeuteration of cyclic alkenes has been achieved by treatment with dilute DCl/D₂O in sealed Pyrex tubes at 165–280 °C.⁵⁴

Exchange with bases involves an S_E1 mechanism.

Of course, such exchange is most successful for relatively acidic protons (e.g., those α to a carbonyl group), but even weakly acidic protons can exchange with bases if the bases are strong enough (see Sec. 5.B.i).

Alkanes and cycloalkanes, of both low and high molecular weight, can be fully perdeuterated treatment with D₂ gas and a catalyst (e.g., Rh, Pt, or Pd).⁵⁵

Chem. Res.* **1968**, *1*, 231.

thermodynamically most stable isomer predominates.⁵⁸ If the new double bond can be in conjugation with one already present or with an aromatic ring, the conjugated compound is favored.⁵⁹ If the choice is between an exocyclic and an endocyclic double bond (particularly with six-membered rings), endocyclic is usually preferred. In the absence of such considerations, *Zaitsev's rule* (Sec. 17.B) applies and the double bond goes to the carbon with the fewest hydrogen atoms. All these considerations lead to predictions that terminal alkenes can be isomerized to internal ones, nonconjugated alkenes to conjugated, exo six-membered ring alkenes to endo, and so on, and not the other way around.

The term *prototropic rearrangement* is sometimes used as an example of electrophilic substitution with accompanying allylic rearrangement. The mechanism involves abstraction by a base to give a resonance-stabilized carbanion, and reaction with a proton is at the position that will give the more stable alkene.⁶⁰

This mechanism is exactly analogous to the allylic-rearrangement mechanism for nucleophilic substitution (Sec. 10.D). Ultraviolet spectra of allylbenzene and 1-propenylbenzene in solutions containing NH_2^+ are identical, showing that the same carbanion is present in both cases, as required by this mechanism.⁶¹ The acid BH^+ protonates the position that will give the more stable product, although the ratio of the two possible products can vary with the identity of BH^+ .⁶² It has been shown that base-catalyzed double-bond shifts are partially intramolecular, at least in some cases.⁶³ The intramolecular nature has been ascribed to a *conducted tour mechanism* (Sec. 12.A.iii) in which the base leads the proton from one carbanionic site to the other (**13** \rightarrow **14**).⁶⁴

Double-bond rearrangements can also take place on treatment with acids. Both proton and Lewis⁶⁵ acids can be used. The mechanism in the case of proton acids is the reverse of the previous one; first a proton is gained, giving a carbocation and then another is lost:

As in the case of the base-catalyzed reaction, the thermodynamically most stable alkene is the one predominantly formed. However, the acid-catalyzed reaction is much less synthetically useful because carbocations give rise to many side products. If the substrate has several possible locations for a double bond, mixtures of all possible isomers are usually obtained. Isomerization of 1-decene, for example, gives a mixture that contains not only 1-decene and *cis*- and *trans*-2-decene, but also the *cis* and *trans* isomers of 3-, 4-, and 5-decene as well as branched alkenes resulting from rearrangement of carbocations. It is true that the most stable alkenes predominate, but many of them have stabilities that are close together.

Double-bond isomerization can take place in other ways. Nucleophilic allylic rearrangements were discussed in Chapter 10 (Sec. 10.E). Electrocyclic and sigmatropic rearrangements are treated at Reactions **18-27** to **18-35**. Double-bond migrations have also been accomplished photochemically,⁶⁶ and by means of metallic ion (most often complex ions containing Pt, Rh, or Ru) or metal carbonyl catalysts.⁶⁷ With metal compounds there are at least two possible mechanisms. One of these, which requires external hydrogen, is called the *metal hydride addition-elimination mechanism*:

The other mechanism, called the *π -allyl complex mechanism*, does not require external hydrogen and proceeds by hydrogen abstraction to form the η^3 - π -allyl complex **15** (see Sec. 3.C.i, category 1 and Reaction **10-60**). Another difference between the two mechanisms is that the former involves 1,2- and the latter 1,3-shifts. The isomerization of 1-butene Rh catalyzed reaction is an example that takes place by the metal hydride mechanism,⁶⁸ while an example of the π -allyl complex mechanism is found in the $\text{Fe}_3(\text{CO})_{12}$ catalyzed isomerization of 3-ethyl-1-pentene.⁶⁹ A Pd catalyst was used to convert alkynones ($\text{RCOC}\equiv\text{CCH}_2\text{CH}_2\text{R}'$) to 2,4-alkadien-1-ones ($\text{RCOCH}=\text{CHCH}=\text{CHCHR}'$).⁷⁰ The reaction of an en-yne with HSiCl_3 and a Pd catalyst generated an allene with moderate enantioselectivity (see Sec. 4.C, category 5 for chiral allenes).⁷¹

The metal-catalysis method has been used for the preparation of simple enols, by isomerization of allylic alcohols, for example.⁷² Some enols are stable enough for isolation

(see Sec. 4.Q.iv), but slowly tautomerize to the aldehyde or ketone, with half-lives ranging from 40 to 50 min to several days.⁷²

No matter which of the electrophilic methods of double-bond shifting is employed, the thermodynamically most stable alkene is usually formed in the largest amount, although a few anomalies are known. An indirect method of double-bond isomerization is known, leading to migration in the other direction. This involves conversion of the alkene to a borane (Reaction **15-16**), rearrangement of the borane (Reaction **18-11**), oxidation and hydrolysis of the newly formed borane to the alcohol (**17**) (see Reaction **12-31**), and dehydration of the alcohol (Reaction **17-1**) to the alkene. The reaction is driven by the fact that with heating the addition of borane is reversible, and the equilibrium favors formation of the less sterically hindered borane, **16** in this case.

Since the migration reaction is always toward the end of a chain, terminal alkenes can be produced from internal ones, so the migration is often opposite to that with the other methods. Alternatively, the rearranged borane can be converted directly to the alkene by heating with an alkene of molecular weight higher than that of the product (Reaction **17-15**). Photochemical isomerization can also lead to the thermodynamically less stable isomer.⁷³

See Reaction **15-1** for related reactions in which double bonds migrate or isomerize.

Triple bonds can also migrate in the presence of bases,⁷⁴ but through an allene intermediate:⁷⁵ In general, strong bases (e.g., NaNH_2) convert internal alkynes to terminal alkynes (a particularly good base for this purpose is potassium 3-aminopropylamide, $\text{NH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{NHHK}$ ⁷⁶), because the equilibrium is shifted by formation of the acetylide ion. With weaker bases (e.g., NaOH), which are not strong enough to remove the acetylenic proton, the internal alkynes are favored because of their greater thermodynamic stability. In some cases, the reaction can be stopped at the allene stage.⁷⁷ The reaction then becomes a method for the preparation of allenes.⁷⁸ The reaction of propargylic alcohols with tosylhydrazine (PPh_3) and DEAD also generates allenes.⁷⁹ In a related reaction, base

induced isomerization of propargylic alcohols leads to conjugated ketones in some cases.⁸⁰ Acid-catalyzed migration of triple bonds (with allene intermediates) can be accomplished if very strong acids (e.g., $\text{HF}-\text{PF}_5$) are used.⁸¹ If the mechanism is the same as that for double bonds, vinyl cations are intermediates.

12-3 Keto–Enol Tautomerization

3/O-Hydro-de-hydrogenation

The tautomeric equilibrium between enols and ketones or aldehydes (keto–enol tautomerism) is a form of prototropy,⁸² but is not normally a preparative reaction. For some ketones, however, both forms can be prepared (see Sec. 2.N.i, category 3 for a discussion of this and other types of tautomerism). Keto–enol tautomerism occurs in systems containing one or more carbonyl groups linked to sp^3 carbons bearing one or more hydrogen atoms. *The keto is generally more stable than the enol tautomer for neutral systems*, and for most ketones and aldehydes only the keto form is detectable under ordinary conditions. The availability of additional intramolecular stabilization through hydrogen bonding or complete electron delocalization (as in phenol), may cause the enol tautomer to be favored.

Keto–enol tautomerism is usually a slow process, but it can be catalyzed by a trace of acid or base.⁸³ In this equilibrium, the heteroatom is the basic site and the proton is the acidic site. For tautomerism in general (see Sec. 2.N.i),⁸⁴ the presence of an acid or a base is not necessary to initiate the isomerization since each tautomeric substance possesses amphotropic properties.⁸⁴ Polar protic solvents (e.g., water or alcohol) may participate in the proton transfer by forming a cyclic or a linear complex with the tautomers.⁸⁵ Whether the complex formed is cyclic or linear depends on the conformation and configuration of the tautomers. In a strongly polar aprotic solvent and in the presence of an acid or a base,

the tautomeric molecule may lose or gain a proton and form the corresponding mesomeric anion or cation, which, in turn, may gain or lose a proton, respectively, and yield a new tautomeric form.⁸⁶ The structural features of the carbonyl compound influences the equilibrium.⁸⁷ Differing conjugative stabilization by CH- π orbital overlap does not directly influence stereoselectivity, and steric effects are generally not large enough to cause the several kilocalorie per mole (kcal mol^{-1}) energy difference seen between transition structures unless there is exceptional crowding.⁸⁸ Note that sterically stabilized enols are known,⁸⁹ including arylacetaldehydes.⁹⁰ Torsional strain involving vicinal bonds does contribute significantly to stereoselectivity in enolate formation.⁸⁸

The acid base catalyzed mechanisms are identical to those in Reaction 12-2.⁹¹

Acid catalyzed

Base catalyzed⁹²

For each catalyst, the mechanism for one direction is the exact reverse of the other, by the principle of *microscopic reversibility*.⁹³ As expected from mechanisms in which the C—H bond is broken in the rate-determining step, substrates of the type RCD_2COR show deuterium isotope effects (of ~ 5) in both the basic-⁹⁴ and the acid-⁹⁵-catalyzed processes. The keto-enol/enolate anion equilibrium has been studied in terms of the influence of β -oxygen⁹⁶ or β -nitrogen⁹⁷ substituents. The stereochemistry of enol protonation can be controlled by varying the proximal group and by changing the acidity of the medium.⁹⁸

The base induced reaction generates an enolate anion rather than an enol, and the formation of and reactions of enolate anions are discussed further in Reactions **10-60**, **10-67**, **16-24**, and **16-34**. Note that ring strain plays no significant role on the rate of base-catalyzed enolization.⁹⁹ In certain cases (e.g., benzofuranones), base-induced enolate anion formation may give a transition state in which aromaticity can play a role. One study showed that aromatic stabilization of the transition state is ahead of proton transfer, and aromaticity appears to lower the intrinsic barrier to this reaction.¹⁰⁰ Enolizable hydrogen atoms can be replaced by deuterium (and ¹⁶O by ¹⁸O) by passage of a sample through a deuterated (or ¹⁸O containing) gas-chromatography column.¹⁰¹

Although the conversion of an aldehyde or a ketone to its enol tautomer is not generally a preparative procedure, the reactions do have their preparative aspects. When enol ethers or esters are hydrolyzed, the initially formed enols immediately tautomerize to the aldehydes or ketones. In addition, the overall processes (forward plus reverse reactions) are often used for equilibration purposes. When an optically active compound in which the chirality is due to a stereogenic carbon α to a carbonyl group (as in **19**) is treated with acid or base, racemization results.¹⁰² If there is another stereogenic center in the molecule, the less stable diastereomer can be converted to the more stable one in this manner. For example, *cis*-decalone can be equilibrated to the *trans* isomer. Isotopic exchange can similarly be accomplished at the α position of an aldehyde or ketone. In cyclic compounds, *cis*- to *trans*- isomerization can occur via the enol.¹⁰³ The role of additives (e.g., ZnCl_2) on the stereogenic enolization reactions using chiral cases has been discussed.¹⁰⁴

If a full equivalent of base per equivalent of ketone is used, the enolate ion (**18**) is formed and can be isolated¹⁰⁵ (see, e.g., the alkylation reaction in Reaction **10-68**).¹⁰⁶

Enantioselective enolate anion protonation reactions have been studied.¹⁰⁷ Enolate protonation is discussed in section Reaction 16-34. For the acid-catalyzed process, exchange or equilibration is accomplished only if the carbonyl compound is completely converted to the enol and then back, but in the base-catalyzed process exchange or equilibration can take place if only the first step (conversion to the enolate ion) takes place. The difference is usually academic. Aggregation behavior of stereoselective enolizations mediated by Mg and Ca bis(amides) have been studied.¹⁰⁸

In the case of the ketone (**20**), a racemic mixture was converted to an optically active mixture (optical yield 46%) by treatment with the chiral base (**21**).¹⁰⁹ This happened because **21** reacted with one enantiomer of **20** faster than with the other (an example of *kinetic resolution*). The enolate (**22**) must remain coordinated with the chiral amine, and it is the amine that reprotonate **22**, not an added proton donor.

There are many enol–keto interconversions and acidification reactions of enolate ions to the keto forms listed in *Organic Syntheses*. No attempt is made to list them here.

B. Halogen Electrophiles

Halogenation of unactivated hydrocarbons is discussed in Reaction 14-1.

12-4 Halogenation of Aldehydes and Ketones

Halogenation or Halo-de-hydrogenation

Aldehydes and ketones can be halogenated in the α position with bromine, chlorine, or iodine,¹¹⁰ although the reaction is less successful with fluorine.¹¹¹ Sulfuryl chloride,¹¹² $Me_3SiCl-Me_2SO$,¹¹³ and NCS ¹¹⁴ have been used as reagents for chlorination.

α -Chloroaldehydes are formed with Cl_2 and a catalytic amount of tetraethylammonium chloride.¹¹⁵ Bromination methods include NBS (see Reaction 14-3),¹¹⁶ Me_3SiBr —DMSO,¹¹⁷ tetrabutylammonium tribromide,¹¹⁸ *in situ* generated ZnBr_2 in water,¹¹⁹ and bromine•dioxane on silica with microwave irradiation.¹²⁰ α -Chlorination¹²¹ and also bromination¹²² have been reported in ionic liquids. Enantioselective chlorination¹²³ and bromination¹²⁴ methods are known, including methods that use enolate anions as intermediates.¹²⁵ Organocatalyzed asymmetric α -halogenation methods are known that can be applied to incorporation of virtually any halogen.¹²⁶ β -Keto esters and 1,3-diketones are α -brominated using bromodimethylsulfonium bromide.¹²⁷ 1,3-Diketones, β -ketoesters, and malonates are chlorinated using sodium hypochlorite or brominated using sodium hypobromite.¹²⁸

Iodination has been accomplished by the direct reaction of ketones with molecular iodine,¹²⁹ with I_2 -cerium(IV) ammonium nitrate,¹³⁰ NCS/NaI ,¹³¹ $\text{ICl}/\text{NaI}/\text{FeCl}_3$,¹³² and with iodine using 1-chloromethyl-4-fluoro-1,4-diazoniabicyclo[2.2.2]octane bis(tetrafluoroborate) in methanol.¹³³ Methyl ketones react with NIS and tosic acid with microwave irradiation without solvent to give the α -iodoketone.¹³⁴ An asymmetric iodination of aldehydes used NIS, with a catalytic amount of benzoic acid and a chiral biaryl amine.¹³⁵

Although less prevalent than those noted above, several methods have been reported for the preparation of α -fluoro aldehydes and ketones,¹³⁶ including enantioselective fluorination protocols.¹³⁷ Organocatalytic α -fluorination is known for aldehydes and ketones.¹³⁸

Selectfluor, [F–TEDA–BF₄. 1-Fluoro-4-hydroxy-1,4-diazoniabicyclo[2.2.2]octane bis(tetrafluoroborate)] has been used for the monofluorination of ketones,¹³⁹ as has a mixture of KI–KIO₃–H₂SO₄.¹⁴⁰ Active compounds (e.g., β -keto esters and β -diketones) have been fluorinated with an *N*-fluoro-*N*-alkylsulfonamide¹⁴¹ (this can result in enantioselective fluorination, if an optically active *N*-fluorosulfonamide is used¹⁴²), with F₂/N₂–HCO₂H,¹⁴³ and with NF₃O/Bu₄NOH.¹⁴⁴ Acetyl hypofluorite fluorinates simple ketones in the form of their lithium enolate anions.¹⁴⁵ Aldehydes have been α -fluorinated using *N*-fluorobenzenesulfonimide as an electrophilic source of fluorine and an imidazolidinone as an organocatalyst.¹⁴⁶ The enantioselective α -fluorination of oxindoles has been reported using *N*-fluorobenzenesulfonimide, a Pd catalyst, and a chiral ligand,¹⁴⁷ and also with an organocatalyst.¹⁴⁸

For unsymmetrical ketones, the preferred position of halogenation is usually the more substituted: a CH group, then a CH₂ group, and then CH₃.¹⁴⁹ However, mixtures are frequent. With aldehydes the aldehydic hydrogen is sometimes replaced, but only when there is no α -hydrogen and the reaction is generally not very useful (see Reaction 14-4). It is also possible to prepare di- and polyhalides. When basic catalysts are used, one α position of a ketone is completely halogenated before the other is attacked, and the reaction cannot be stopped until all the hydrogen atoms of the first carbon have been replaced (see below). If one of the groups is methyl, the haloform reaction (12-44) takes place. With acid catalysts, it is usually possible to stop the reaction after only one halogen has been incorporated, although a second halogen can be introduced by the use of excess reagent. In chlorination, the second halogen generally appears on the same side as the first,¹⁵⁰ while in bromination the α,α' -dibromo product is found.¹⁵¹ Actually, with both halogens it is the α,α -dihalo ketone that is formed first, but in the case of bromination this compound isomerizes under the reaction conditions to the α,α' -isomer.¹⁵⁰ α,α' -Dichloro ketones are formed by reaction of a methyl ketone with an excess of CuCl₂ and LiCl in DMF¹⁵² or with HCl and H₂O₂ in methanol.¹⁵³ Aryl methyl ketones can be dibrominated in high yields with benzyltrimethylammonium tribromide.¹⁵⁴ Active methylene compounds are chlorinated

with NCS and $\text{Mg}(\text{ClO}_4)_2$.¹⁵⁵ Similar chlorination in the presence of a chiral copper catalyst led to α -chlorination with modest enantioselectivity.¹⁵⁶

It is not the aldehyde or ketone itself that is halogenated, but the corresponding enol or enolate ion. The purpose of the catalyst is to provide a small amount of enol or enolate (Reaction 12-3). The reaction is often done without addition of acid or base, but traces of acid or base are always present, and these are enough to catalyze formation of the enol or enolate. With acid catalysis the mechanism is

The first step, as seen in Reaction 12-3, actually consists of two steps. The second step is very similar to the first step in electrophilic addition to double bonds (Sec. 15.A.i). There is a great deal of evidence for this mechanism: (1) the rate is first order in substrate; (2) bromine does not appear in the rate expression at all,¹⁵⁷ a fact consistent with a rate-determining first step;¹⁵⁸ (3) the reaction rate is the same for bromination, chlorination, and iodination under the same conditions;¹⁵⁹ (4) the reaction shows an isotope effect; and (5) the rate of the step 2–step 3 sequence has been independently measured (by starting with the enol) and found to be very fast.¹⁶⁰

With basic catalysts the mechanism may be the same as that given above (since bases also catalyze formation of the enol), or the reaction may go directly through the enolate ion without formation of the enol:

It is difficult to distinguish the two possibilities. It was mentioned above that in the base-catalyzed reaction, if the substrate has two or three α halogens on the same side of

the C=O group, it is not possible to stop the reaction after just one halogen atom has entered. The reason is that the electron-withdrawing field effect of the first halogen increases the acidity of the remaining hydrogen atoms; that is, a CHX group is more acidic than a CH₂ group, so that the initially formed halo ketone is converted to enolate ion (and hence halogenated) more rapidly than the original substrate. Other halogenating agents can be used in this reaction.

Regioselectivity in the halogenation of unsymmetrical ketones can be attained by treatment of the appropriate enol borinate of the ketone with NBS or NCS.¹⁶¹ The desired halo ketone is formed in high yield. The appropriate lithium enolate can be brominated at a low temperature¹⁶² (see Reaction 10-68, category 4 for the regioselective formation of enolate ions). α -Halo aldehydes have been prepared in good yield by treatment of silyl enol ethers (R₂C=CHOSiMe₃) with Br₂ or Cl₂,¹⁶³ with sulfonyl chloride (SO₂Cl₂),¹⁶⁴ or with I₂ and silver acetate.¹⁶⁵ Silyl enol ethers generate α -chloroketones with good enantioselectivity using ZrCl₄ in conjunction with an α,α -dichloromalonate ester.¹⁶⁶ Silyl enol ethers can also be fluorinated, with XeF₂¹⁶⁷ or with 5% F₂ in N₂ at -78 °C in FCCL₃.¹⁶⁸ Enol acetates have been regioselectively iodinated with I₂ and either Th(I) acetate¹⁶⁹ or Cu(II) acetate.¹⁷⁰

α,β -Unsaturated ketones can be converted to α -halo- α,β -unsaturated ketones by treatment with phenylselenium bromide or chloride,¹⁷¹ and to α -halo- β,γ -unsaturated ketones by two-phase treatment with HOCl.¹⁷² Conjugated ketones were converted to the α -bromo conjugated ketone (a vinyl bromide) using the *Dess-Martin periodinane* (see Reaction 19-3, category 5) and tetraethylammonium bromide.¹⁷³

The α hydrogen atoms of carboxylic acids are replaced by bromine or chlorine using a phosphorus halide as catalyst.¹⁷⁴ The reaction, known as the *Hell–Volhard–Zelinskii reaction*, is not applicable to iodine or fluorine. When there are two α hydrogen atoms, one or both may be replaced, although it is often hard to stop with just one. The reaction actually takes place on the acyl halide formed initially from the carboxylic acid and the halogenating reagent. This means that each molecule of acid is α halogenated while it is in the acyl halide stage. The acids alone are inactive, except for those with relatively high enol content (e.g., malonic acid). Less than one full molar equivalent of catalyst (per molar equivalent of substrate) is required, because of the exchange reaction between carboxylic acids and acyl halides (see Reaction 16-79). The halogen from the catalyst is *not* transferred to the α position. For example, the use of Cl_2 and PBr_3 results in α -chlorination, not bromination. As expected from the foregoing, acyl halides undergo a halogenation without a catalyst. An enantioselective α -halogenation was reported to give chiral α -haloesters via an alkaloid-catalyzed reaction of acyl halides with perhaloquinone-derived reagents.¹⁷⁵ So do anhydrides and many compounds that enolize easily (e.g., malonic ester and aliphatic nitro compounds). The mechanism is usually regarded as proceeding through the enol as in Reaction 12-4.¹⁷⁶ If chlorosulfuric acid (ClSO_2OH) is used as a catalyst, carboxylic acids can be α -iodinated,¹⁷⁷ as well as chlorinated or brominated.¹⁷⁸ *N*-Bromosuccinimide in a mixture of sulfuric acid–trifluoroacetic acid can monobrominate simple carboxylic acids.¹⁷⁹

A number of other methods exist for the α halogenation of carboxylic acids or their derivatives.¹⁸⁰ Under electrolytic conditions with NaCl , malonates are converted to 2-chloro malonates.¹⁸¹ Acyl halides can be α brominated or chlorinated by use of NBS or NCS and HBr or HCl .¹⁸² The latter is an ionic, not a free radical halogenation (see Reaction 14-3). Direct iodination of carboxylic acids has been achieved with I_2 – Cu(II) acetate in HOAc .¹⁸³ Acyl chlorides can be α iodinated with I_2 and a trace of HI .¹⁸⁴ Carboxylic acids, esters, and amides have been α -fluorinated at -78°C with F_2 diluted in N_2 .¹⁸⁵ Amides have been α -iodinated using iodine and *s*-collidine.¹⁸⁶

12-6 Halogenation of Sulfoxides and Sulfones

Halogenation or Halo-de-hydrogenation

Sulfoxides can be chlorinated in the α position¹⁸⁷ by treatment with Cl_2 ¹⁸⁸ or NCS ,¹⁸⁹ in the presence of pyridine. These methods involve basic conditions. The reaction can also be accomplished in the absence of base with SO_2Cl_2 in CH_2Cl_2 ,¹⁹⁰ or with TsNCl_2 .¹⁹¹ The bromination of sulfoxides with bromine¹⁹² and with NBS -bromine¹⁹³ have also been reported. Sulfones have been chlorinated by treatment of their conjugate bases ($\text{RSO}_2\text{C}^-\text{HR}'$) with various reagents, among them SO_2Cl_2 , CCl_4 ,¹⁹⁴ or NCS .¹⁹⁵ The α -fluorination of sulfoxides was reported via treatment with diethylaminosulfur trifluoride (Et_2NSF_3 , DAST) to give an α -fluoro thioether, usually in high yield. Oxidation of this compound with *m*-chloroperoxybenzoic acid gave the sulfoxide.¹⁹⁶

C. Nitrogen Electrophiles

12-7 Aliphatic Diazonium Coupling

Arylhydrazono-de-dihydro-bisubstitution

If a $\text{C}-\text{H}$ unit is acidic enough, that carbon couples with diazonium salts in the presence of a base (via the enolate anion), most often aq sodium acetate.¹⁹⁷ The reaction is commonly carried out on compounds of the form $\text{Z}-\text{CH}_2-\text{Z}'$, where Z and Z' are as defined in Section 16-38 (e.g., β -keto esters, β -keto amides, malonic ester).

The mechanism is probably of the simple $\text{S}_{\text{E}}1$ type:

Aliphatic azo compounds in which the carbon containing the azo group is attached to a hydrogen are unstable and tautomerize to the isomeric hydrazones (**23**), which are the products of the reaction.

When the reaction is carried out on a compound of the form $Z-CHR-Z'$, the azo compound does not have a hydrogen that can lead to tautomerism, and at least one Z is acyl or carboxyl, this group usually cleaves:

so the product in this case is also the hydrazone, and not the azo compound. In fact, compounds of the type **24** are seldom isolable from the reaction, although this has been accomplished.¹⁹⁸ The cleavage step shown is an example of Reaction **12-43** and, when a carboxyl group cleaves, of Reaction **12-40**. The overall process in this case is called the *Japp-Klingemann reaction*¹⁹⁹ and involves conversion of a ketone (**25**) or a carboxylic acid (**26**)

to a hydrazone (**27**). When an acyl and a carboxyl group are both present, the leaving group order has been reported to be $\text{MeCO} > \text{COOH} > \text{PhCO}$.²⁰⁰ When there is no acyl or carboxyl group present, the aliphatic azo compound is stable.

OS **III**, 660; **IV**, 633.

12-8 Nitrosation at a Carbon Bearing an Active Hydrogen

Hydroxyimino-de-dihydro-bisubstitution

Nitrosation or Nitroso-de-hydrogenation

Carbons adjacent to a Z group (as defined in Reaction **10-67**) can be nitrosated with nitrous acid or alkyl nitrites.²⁰¹ The initial product is the C-nitroso compound, but these are stable only when there is no hydrogen that can undergo tautomerism. When there is, the product is the more stable oxime. The situation is analogous to that with azo compounds

²⁰¹ For a review, see Williams, D.L.H. *Nitrosation*, Cambridge Univ. Press, Cambridge, **1988**, pp. 1–45.

and hydrazones (Reaction 12-7). The mechanism is similar to that in Reaction 12-7:²⁰² $R-H \rightarrow R^- + {}^+N=O \rightarrow R-N=O$. The reactive species is either NO^+ or a carrier of it. When the substrate is a simple ketone, the mechanism goes through the enol (as in halogenation Reaction 12-4):

Evidence is that the reaction, in the presence of X^- (Br^- , Cl^- , or SCN^-) was first order in ketone and in H^+ , but zero order in HNO_2 and X^- .²⁰³ Furthermore, the rate of the nitrosation was about the same as that for enolization of the same ketones. The species NOX is formed by $HONO + X^- + H^+ \rightarrow HOX + H_2O$. In the cases of $F_3CCOCH_2COCF_3$ and malononitrile, the nitrosation went entirely through the enolate ion rather than the enol.²⁰⁴

As in the *Japp-Klingemann reaction*, when Z is an acyl or carboxyl group (in the case of R_2CH-Z), it can be cleaved. Since oximes and nitroso compounds can be reduced to primary amines, this reaction often provides a route to amino acids. As in the case of Reaction 12-4, the silyl enol ether of a ketone can be used instead of the ketone itself.²⁰⁵ Good yields of α -oximinoketones (**28**) can be obtained by treating ketones with *tert*-butyl thionitrate.²⁰⁶

Imines can be prepared in a similar manner by treatment of an active hydrogen compound with a nitroso compound:

Alkanes can be nitrosated photochemically, by treatment with $NOCl$ and UV light.²⁰⁷ For nitration at an activated carbon, see Reaction 12-9. Trialkyltin enol ethers ($C=C-O-SnR_3$) react with $PhNO$ to give α -(*N*-hydroxylamino)ketones.²⁰⁸

Nitration of alkanes²⁰⁹ can be carried out in the gas phase at $\sim 400^\circ\text{C}$ or in the liquid phase. The reaction is not practical for the production of pure products for any alkane except methane. For other alkanes, not only does the reaction produce mixtures of the mono-, di-, and polynitrated alkanes at every combination of positions, but extensive chain cleavage occurs.²¹⁰ A free radical mechanism is involved.²¹¹

Activated positions (e.g., $\text{ZCH}_2\text{Z}'$ compounds) can be nitrated by fuming nitric acid in acetic acid, by acetyl nitrate and an acid catalyst,²¹² or by alkyl nitrates under alkaline conditions.²¹³ In the latter case, it is the carbanionic form of the substrate that is actually nitrated. The conjugate base of the nitro compound is isolated under these alkaline conditions, but yields are not high. Of course, the mechanism in this case is not of the free radical type, but is electrophilic substitution with respect to the carbon (similar to the mechanisms of Reactions 12-7 and 12-8). Positions activated by only one electron-withdrawing group (e.g., α positions of simple ketones, nitriles, sulfones, or *N,N*-dialkyl amides) can be nitrated with alkyl nitrates if a very strong base (e.g., *t*-BuOK or NaNH_2) is present to convert the substrate to the carbanionic form.²¹⁴

Electrophilic nitration of alkanes has been performed with nitronium salts (e.g., $\text{NO}_2^+ \text{PF}_6^-$ and with $\text{HNO}_3\text{--H}_2\text{SO}_4$ mixtures), but mixtures of nitration and cleavage products are obtained and yields are generally low.²¹⁵ The reaction of alkanes with nitric acid and *N*-hydroxysuccinimide (NHS), however, gave moderate-to-good yields of the corresponding nitroalkane.²¹⁶ Similar nitration was accomplished with NO_2 , NHS and air.²¹⁷ Aliphatic nitro compounds can be nitrated [$\text{R}_2\text{C--NO}_2 \rightarrow \text{R}_2\text{C(NO}_2)_2$] by treatment of their conjugate bases RCNO_2 with NO_2^- and $\text{K}_3\text{Fe(CN)}_6$.²¹⁸

Compounds containing a CH_2 bonded to two Z groups (active methylene compounds, with Z as defined in Reaction 10-67) can be converted to diazo compounds on treatment with tosyl azide in the presence of a base.²¹⁹ The use of phase-transfer catalysis increases the convenience of the method.²²⁰ Sulfonyl azides also give the reaction.²²¹ The *diazo-transfer reaction* can also be applied to other reactive positions (e.g., the 5 position of cyclopentadiene).²²² The mechanism is probably as follows:

A diazo group can be introduced adjacent to a single carbonyl group indirectly by first converting the ketone to an α -formyl ketone (Reaction 16-85) and then treating it with tosyl azide. As in the similar cases of Reactions 12-7 and 12-8, the formyl group is cleaved during the reaction.²²³

OS V, 179; VI, 389, 414.

12-11 Conversion of Amides to α -Azido Amides

Azidation or Azido-de-hydrogenation

In Reaction 12-10, treatment of $\text{Z}-\text{CH}_2-\text{Z}'$ with tosyl azide gave the α -diazo compound via diazo transfer. When this reaction is performed on a compound with a single Z group (e.g., an amide), formation of the azide becomes a competing process via the enolate anion.²²⁴ Factors favoring azide formation rather than diazo transfer include K^+ as the enolate counterion rather than Na^+ or Li^+ and the use of 2,4,6-triisopropylbenzenesulfonyl azide rather than TsN_3 . When the reaction was applied to amides with a chiral R' (e.g., the oxazolidinone derivative 29), it was highly stereoselective, and the product could be converted to an optically active amino acid.²²⁴

12-12 Direct Amination at an Activated Position

Alkyamino-de-hydrogenation, and so on

Alkenes can be aminated²²⁵ in the allylic position by treatment with solutions of imido selenium compounds ($\text{R}-\text{N}=\text{Se}=\text{N}-\text{R}$).²²⁶ The reaction, which is similar to the allylic oxidation of alkenes with SeO_2 (see Reaction 19-14), has been performed with $\text{R} = t\text{-Bu}$ and $\text{R} = \text{Ts}$. The imido sulfur compound $\text{TsN}=\text{S}=\text{NTs}$ has also been used,²²⁷ as well as $\text{PhNHOH}-\text{FeCl}_2/\text{FeCl}_3$.²²⁸ Benzylic positions can be aminated with $t\text{-BuOOCONHTs}$ in the presence of a catalytic amount of $\text{Cu}(\text{OTf})_2$.²²⁹ Enantioselective allylic amination has been reported using organocatalysts.²³⁰ A Rh catalyzed amination of benzylic positions has also been reported.²³¹

Tertiary alkyl hydrogen can be replaced in some cases via $\text{C}-\text{H}$ nitrogen insertion. The reaction of sulfamate ester (**30**) with $\text{PhI}(\text{OAc})_2$, MgO , and a dinuclear Rh carboxylate catalyst, for example, generated oxathiazinane (**31**).²³² This transformation is a formal oxidation, and primary carbamates have been similarly converted to oxazolidin-2-ones.²³³

Amination of 1,3-dicarbonyl compounds can be done using functionalized dimides and an appropriate catalyst, generating the corresponding hydrazone. Enantioselective amination using this method has been reported, using a chiral guanidine catalyst.²³⁴

Carbonylnitrenes (:NCOW, W = R', Ar, or OR') are very reactive species (Sec. 5.E) and insert into the C—H bonds of alkanes to give amides (W = R' or Ar) or carbamates (W = OR').²³⁵ The nitrenes are generated as discussed in Section 5.E. The order of reactivity among alkane C—H bonds is tertiary > secondary > primary.²³⁶ Nitrenes are much more selective (and less reactive) in this reaction than carbenes (Reaction 12-17).²³⁷ It is likely that only singlet and not triplet nitrenes insert.²³⁸ Retention of configuration is found at a stereogenic carbon.²³⁹ The mechanism is presumably similar to the simple one-step mechanism for insertion of carbenes (Reaction 12-21). Other nitrenes [e.g., cyanonitrene (NCN)²⁴⁰ and aryl nitrenes (NAr)²⁴¹] can also insert into C—H bonds, but alkyl nitrenes usually undergo rearrangement before they can react with the alkane. The Au(III) catalyzed insertion of nitrenes into aromatic and benzylic C—H groups has been reported.²⁴² *N*-Carbamoyl nitrenes undergo insertion reactions that often lead to mixtures of products, but exceptions are known,²⁴³ chiefly in cyclizations.²⁴⁴ For example, heating of 2-(2-methylbutyl)phenyl azide gave ~60% 2-ethyl-2-methylindoline (32).²³⁹ Enantioselective nitrene insertion reactions are known.²⁴⁵

Ketones, carboxylic esters (including lactones),²⁴⁶ and amides (including lactams)²⁴⁷ can be sulfonylated²⁴⁸ in the α position by conversion to the enolate anion (see Sec. 8.F, part 7), and subsequent treatment with a disulfide.²⁴⁹ The reaction, shown above for ketones, involves nucleophilic substitution at sulfur. α -Phenylseleno ketones [RCH(SePh)COR'] and α -phenylseleno esters [RCH(SePh)COOR'] can be similarly prepared²⁵⁰ by treatment of the corresponding enolate anions with PhSeBr,²⁵¹ PhSeSePh,²⁵² or benzeneseleninic anhydride [PhSe(O)OSe(O)Ph].²⁵³ Another method for the introduction of a phenylseleno group into the α position of a ketone involves simple treatment of an ethyl acetate solution of the ketone with PhSeCl (but not PhSeBr) at room temperature.²⁵⁴ This procedure is also successful for aldehydes but not for carboxylic esters. *N*-Phenylselenophthalimide has been used to convert ketones²⁵⁵ and aldehydes²⁵⁶ to the α -PhSe derivative. Silyl enol ethers are converted to α -alkylthio and α -arylthio ketones via a sulfonylation method, driven by aromatization of an added quinone mono-*O,S*-acetal in the presence of Me₃SiOTf.²⁵⁷

The α -seleno and α -sulfonyl carbonyl compounds prepared by this reaction can be converted to α,β -unsaturated carbonyl compounds (Reaction 17-12). The sulfonylation reaction has also been used²⁵⁸ as a key step in a sequence for moving the position of a carbonyl group to an adjacent carbon.²⁵⁹

Aldehydes, ketones, and carboxylic acids containing α hydrogen atoms can be sulfonated with sulfur trioxide.²⁶⁰ The mechanism is presumably similar to that of Reaction 12-4. Sulfonation has also been accomplished at vinylic hydrogen.

E. Carbon Reagents

12-15 Alkylation and Alkenylation of Alkenes

Alkylation or Alkyl-de-oxy-sulfonation (de-halogenation), Arylation or Aryl-de-oxy-sulfonation (de-halogenation), and so on

Vinyl triflates ($\text{C}=\text{C}-\text{OSO}_2\text{CF}_3$) react with vinyl tin derivatives in the presence of Pd catalysts to form dienes, in what is known as *Stille coupling*.²⁶¹ Phosphine or bis (phosphine) ligands are most commonly used with the Pd catalyst,²⁶² but other ligands have been used,²⁶³ including triphenylarsine.²⁶⁴ Vinyl triflates can be prepared from the enolate anion by reaction with *N*-phenyl triflimide.²⁶⁵ Vinyltin compounds are generally prepared by the reaction of an alkyne with an trialkyltin halide (see Reactions **15-17** and **15-21**).²⁶⁶ *Stille cross-coupling* reactions are an important variation of the basic reaction,²⁶⁷ including cross-coupling reactions of unactivated secondary halides and monoorganotin reagents.²⁶⁸ Stille reactions are compatible with many functional groups. Vinyl halides can be used,²⁶⁹ and allenic tin compounds have been used.²⁷⁰ Intramolecular reactions are possible.²⁷¹ *Stille coupling* has been done using microwave irradiation,²⁷² in fluorous solvents,²⁷³ and in supercritical carbon dioxide (see Sec. 9.D.ii).²⁷⁴ *Stille coupling* using alkynes as a substrate are known.²⁷⁵

This reaction is highly stereoselective, and proceeds with a retention of geometry of the $\text{C}=\text{C}$ units, and are usually regiospecific with respect to the newly formed $\text{C}-\text{C}$ σ -bond. Cine substitution is known with this reaction, and its mechanism has been studied.²⁷⁶ Using ArSnCl_3 derivatives, Stille coupling can be done in aq. KOH.²⁷⁷

Aryl halides,²⁷⁸ heteroaryl halides,²⁷⁹ and heteroaryl triflates²⁸⁰ can be coupled to vinyltin reagents²⁸¹ using a Pd catalyst. A Mo catalyzed variation is known.²⁸² A Cu catalyzed cross coupling variation²⁸³ has been reported in ionic liquids.²⁸⁴ Vinyl halides can be coupled to alkenes to form dienes.²⁸⁵ The reaction of dihydrofurans with vinyl triflates and a Pd catalyst leads to a nonconjugated diene,²⁸⁶ illustrating that the product is formed by an elimination step, as with the *Heck reaction* (**13-10**), and double-bond migration can occur resulting in allylic rearrangement.

The accepted mechanism for the *Stille reaction* involves a catalytic cycle²⁸⁷ in which an oxidative addition²⁸⁸ and a reductive elimination step²⁸⁹ are fast, relative to Sn/Pd transmetalation (the rate-determining step).²⁹⁰ It appears that the greater the coordinating ability of the unsaturated species is important, and a coordinated solvent molecule is likely involved in the electrophilic substitution at tin. Another mechanism has been proposed, in which oxidative addition of the vinyl triflate to the ligated Pd gives a *cis*-Pd complex that isomerizes rapidly to a *trans*-Pd complex, which then reacts with the organotin compound following an S_E2 (cyclic) mechanism, with release of a ligand.²⁹¹ This pathway gives a bridged intermediate, and subsequent elimination of XSnBu₃ yields a three-coordinate species *cis*-Pd complex, which readily gives the coupling product.²⁹¹ Most of the major intermediates have been intercepted, isolated, and characterized using electrospray ionization mass spectrometry.²⁹²

Cyclopropylboronic acids (Reaction **12-28**) couple with vinylic halides²⁹³ or vinyl triflates²⁹⁴ to give vinylcyclopropanes, using a Pd catalyst. Vinyl borates (Reaction **12-28**) were coupled to vinyl triflates using a Pd catalyst.²⁹⁵ Vinyltrifluoroborates can be coupled to allylic chlorides using microwave irradiation²⁹⁶ and vinyl halides react with vinyltrifluoroborates to give dienes with high stereoselectivity.²⁹⁷ Stille coupling to enols has

been reported.²⁹⁸ The coupling of vinyl silanes to give the symmetrically conjugated diene using CuCl and air has also been reported.²⁹⁹

Other methods are available to give Stille-like products. 1-Lithioalkynes were coupled to vinyl tellurium compounds ($\text{C}=\text{C}-\text{TeBu}$) using a Ni³⁰⁰ or a Pd catalyst³⁰¹ to give a conjugated en-yne. 2-Alkynes ($\text{R}-\text{C}\equiv\text{C}-\text{Me}$) react with HgCl_2 , *n*-butyllithium, and ZnBr_2 , sequentially, and then with vinyl iodides and a Pd catalyst to give the nonconjugated en-yne.³⁰² Alkynyl groups can be coupled to vinyl groups to give ene-yne, via reaction of silver alkynes ($\text{Ag}-\text{C}\equiv\text{C}-\text{R}$) with vinyl triflates and a Pd catalyst.³⁰³ In the presence of CuI and a Pd catalyst, vinyl triflates³⁰⁴ or vinyl halides³⁰⁵ couple to terminal alkynes. Alkynyl zinc reagents ($\text{R}-\text{C}\equiv\text{C}-\text{ZnBr}$) can be coupled to vinyl halides with a Pd catalyst to give the conjugated en-yne.³⁰⁶

Alkyl groups can be coupled to a vinyl unit to give substituted alkenes. The reaction of vinyl iodides and EtZnBr , with a Pd catalyst, gave the ethylated alkene ($\text{C}=\text{C}-\text{Et}$).³⁰⁷ Aliphatic alkyl bromides reacted with vinyltin compounds to give the alkylated alkene using a Pd catalyst.³⁰⁸ Allylic tosylates were coupled to conjugated alkenes to give a non-conjugated diene using a Pd catalyst.³⁰⁹ An internal coupling reaction was reported in which an alkenyl enamide (**33**) reacted with Ag_3PO_4 and a chiral palladium catalyst to give **34** enantioselectively.³¹⁰

For the related coupling reaction of alkenes and aryl compounds (arylation of alkenes), see Reaction 13-10.

12-16 Acylation at an Aliphatic Carbon

Alkenes can be acylated with an acyl halide and a Lewis acid catalyst in what is essentially a *Friedel–Crafts Reaction* (**11-17**) at an aliphatic carbon.³¹¹ The product can arise by two paths. The initial attack is by the π bond of the alkene unit on the acyl cation (RCO^+ ; or on the acyl halide free or complexed; see Reaction **11-17**) to give a carbocation, (**35**).

Ion **35** can either lose a proton or combine with chloride ion. If it loses a proton, the product is an unsaturated ketone. The mechanism is similar to the *tetrahedral mechanism* in Section 16.A.i, but with the charges reversed. If it combines with chloride, the product is a β -halo ketone, which can be isolated, so that the result is addition to the double bond (see Reaction **15-47**). On the other hand, the β -halo ketone may, under the conditions of the reaction, lose HCl to give the unsaturated ketone, this time by an addition–elimination mechanism. In the case of unsymmetrical alkenes, the more stable alkene is formed (the more highly substituted and/or conjugated alkene, following *Markovnikov's rule*, see Sec. 15.B.ii). Anhydrides and carboxylic acids (the latter with a proton acid e.g., anhydrous HF , H_2SO_4 , or polyphosphoric acid as a catalyst) are sometimes used instead of acyl halides. With some substrates and catalysts, double-bond migrations are occasionally encountered so that, for example, when 1-methylcyclohexene was acylated with acetic anhydride and zinc chloride, the major product was 6-acetyl-1-methylcyclohexene.³¹²

Conjugated dienes can be acylated by treatment with acyl- or alkylcobalt tetracarbonyls, followed by base-catalyzed cleavage of the resulting π -allyl carbonyl derivatives³¹³ (π -allyl metal complexes were discussed in Sec. 3.C.i. The reaction is very general. With unsymmetrical dienes, the acyl group generally substitutes most readily at a *cis* double bond, next at a terminal alkenyl group, and least readily at a *trans* double bond. The most useful bases are strongly basic, hindered amines (e.g., dicyclohexylethylamine). Acylation of vinylic ethers has been accomplished with aromatic acyl chlorides, a base, and a Pd catalyst: $\text{ROCH}=\text{CH}_2 \rightarrow \text{ROCH}=\text{CHCOAr}$.³¹⁴

Formylation of alkenes can be accomplished with *N*-disubstituted formamides and POCl_3 .³¹⁵ This is an aliphatic *Vilsmeier reaction* (see Reaction **11-18**). Vilsmeier formylation can also be performed on the α position of acetals and ketals, so that hydrolysis of the products gives keto aldehydes or dialdehydes:³¹⁶ A variation

heated a 1,1-dibromoalkene with a secondary amine in aq DMF to give the corresponding amide.³¹⁷

Acetylation of acetals or ketals can be accomplished with acetic anhydride and BF_3 -etherate.³¹⁸ The mechanism with acetals or ketals also involves attack at an alkenyl carbon, since enol ethers are intermediates.³¹⁸ Ketones can be formylated in the α position by treatment with CO and a strong base.³¹⁹

12-17 Conversion of Enolates to Silyl Enol Ethers, Silyl Enol Esters, and Silyl Enol Sulfonate Esters

3/O-Trimethylsilyl-de-hydrogenation

Silyl enol ethers,³²⁰ important reagents with a number of synthetic uses (see, e.g., Reactions **10-68**, **12-4**, **15-24**, **15-64**, and **16-36**), can be prepared by base treatment of a ketone (converting it to its enolate anion) followed by addition of a trialkylchlorosilane. Other silylating agents have also been used.³²¹ Both strong bases (e.g., LDA), and weaker bases (Et_3N) have been used for this purpose.³²² In some cases, the base and the silylating agent can be present at the same time.³²³ Enolate anions prepared in other ways (e.g., as shown in Reaction **10-58**) also give the reaction.³²⁴ The reaction can be applied to aldehydes by the use of the base KH in 1,2-dimethoxyethane.³²⁵ A particularly mild method for conversion of ketones or aldehydes to silyl enol ethers uses Me_3SiI and the base hexamethyldisilazane [$(\text{Me}_3\text{Si})_2\text{NH}$].³²⁶ Cyclic ketones can be converted to silyl enol ethers in the presence of acyclic ketones, by treatment with Me_3SiBr , tetraphenylstibonium

bromide (Ph_4SbBr), and an aziridine.³²⁷ bis(Trimethylsilyl)acetamide is an effective reagent for the conversion of ketones to the silyl enol ether, typically giving the thermodynamic product (see below).³²⁸ Silyl enol ethers have also been prepared by the direct reaction of a ketone and a silane (R_3SiH) with a Pt catalyst.³²⁹

For substituted ketones, (*E*) and (*Z*) isomers are usually formed. For **36**, the enol is (*Z*) when R^1 is the priority group, but (*E*) when R^2 is the priority group. In some cases, it is possible to control the selectivity to favor more of one isomer than the other. Treatment of 2-methyl-3-pentanone with LDA (THF, -78°C), for example, gave a 60:40 mixture of the (*Z*) and (*E*) enolates.³³⁰ The base used to generate an enolate anion, the solvent and temperature, the conjugate acid of the base used, and the nature of the carbonyl substrate will all play a role in the selectivity. In general, equilibrating (thermodynamic) conditions [protic solvents (e.g., ethanol, water, or ammonia), a base generating a conjugate acid stronger than the starting ketone, more ionic counterions (e.g., K or Na), higher temperatures and longer reaction times] are expected to give more of the (*E*)-isomer. Conversely, kinetic conditions [aprotic solvents (e.g., ether or THF), a base generating a conjugate acid weaker than the starting ketone, more covalent counterions (e.g., Li, lower temperatures), and relatively short reaction times] usually give more of the (*Z*)-isomer. It is not always easy to predict the ratio, however. Either isomer is possible from aldehydes using the proper Rh catalyst.³³¹

Magnesium diisopropylamide has been used to prepare kinetic silyl enol ethers in virtual quantitative yield.³³² Reaction with $\text{Me}_3\text{SiCl/KI}$ in DMF gives primarily the thermodynamic silyl enol ether.³³³

An interesting synthesis of silyl enol ethers involves chain extension of an aldehyde. Aldehydes are converted to the silyl enol ether of a ketone upon reaction with lithium (trimethylsilyl)diazomethane and then a dirhodium catalyst.³³⁴ For example, initial reaction of lithium(trimethylsilyl)diazomethane [LTMSD, prepared *in situ* by reaction of butyllithium with (trimethylsilyl)diazomethane] to the aldehyde (e.g., **37**) gave the alkoxide addition product. Protonation and then capture by a transition metal catalyst, and a 1,2-hydride migration gave the silyl enol ether, (**38**). Silyl enol ethers can be prepared from acyloin derivatives (see Reaction **19-78**).³³⁵

Enol acetates are generally prepared by the reaction of an enolate anion with a suitable acylating reagent.³³⁶ Enolate anions react with acyl halides and with anhydrides to give the acylated product. Both C- and O-acylation are possible, but in general O-acylation predominates.³³⁷ Note that the extent of O- versus C-acylation is very dependent on the local environment and electronic effects within the enolate anion.³³⁸ O-Benzoate enols are formed in good yield from aldehydes or 1,3-diketones in the presence of CuBr and *tert*-butylhydroperoxide.³³⁹ Silyl sulfonate esters can be prepared by similar methods, using sulfonic acid anhydrides rather than carboxylic anhydrides. A polymer-supported triflating agent was used to prepare silyl enol triflate from ketones, in the presence of diisopropylethylamine.³⁴⁰

When a silyl enol ether is the trimethylsilyl derivative ($\text{Me}_3\text{Si}-\text{O}-\text{C}=\text{C}$), treatment with methylolithium will regenerate the lithium enolate anion and the volatile trimethylsilane (Me_3SiH).³⁴¹

12-18 Conversion of Aldehydes to β -Keto Esters or Ketones

Alkoxyacylalkylation or Alkoxyacylalkyl-de-hydrogenation

β -Keto esters have been prepared in moderate to high yields by treatment of aldehydes with diethyl diazoacetate in the presence of a catalytic amount of a Lewis acid (e.g., SnCl_2 , BF_3 , or GeCl_2).³⁴³ The reaction was successful for both aliphatic and aromatic aldehydes, but the former react more rapidly than the latter, and the difference is great enough to allow selective reactivity. In a similar process, aldehydes react with certain carbanions stabilized by boron, in the presence of $(\text{F}_3\text{CCO})_2\text{O}$ or NCS, to give ketones.³⁴⁴

Ketones can be prepared from aryl aldehydes (ArCHO) by treatment with a Rh complex $[(\text{Ph}_3\text{P})_2\text{Rh}(\text{CO})\text{Ar}']$, whereby the Ar group is transferred to the aldehyde, producing the ketone (Ar—CO—Ar').³⁴⁵ In another Rh catalyzed reaction, aryl aldehydes (ArCHO) react with $\text{Me}_3\text{SnAr}'$ to give the diaryl ketone (Ar—CO—Ar').³⁴⁶

Acylation of aryl halides with aldehydes gives arylketones in the presence of a Pd catalyst.³⁴⁷

12-19 Cyanation or Cyano-de-hydrogenation

There are several reactions in which a C—H unit is replaced by C—CN. In virtually all cases, the hydrogen being replaced is on a carbon α to a heteroatom or functional group. There are several examples.

Introduction of a cyano group α to the carbonyl group of a ketone can be accomplished by prior formation of the enolate anion with LDA in THF and addition of this solution to *p*-TsCN at -78°C .³⁴⁸ The products are formed in moderate to high yields but the reaction is not applicable to methyl ketones. Treatment of $\text{TMSCH}_2\text{N}(\text{Me})\text{C}=\text{N}t\text{-Bu}$ with *sec*-butyllithium and $\text{R}_2\text{C}=\text{O}$, followed by iodomethane and NaOMe leads to the nitrile ($\text{R}_2\text{CH}-\text{CN}$).³⁴⁹

Cyanation has been shown to occur α to a nitrogen, specifically in *N,N*-dimethylaniline derivatives. Treatment with a catalytic amount of RuCl_3 in the presence of oxygen and NaCN leads to the corresponding cyanomethylamine.³⁵⁰ Conversion of tertiary amines to the α -cyanoamine has been reported in the presence of FeCl_2 and *t*-BuOOH.³⁵¹

In a different kind of reaction, nitro compounds are α -cyanated by treatment with CN^- and $\text{K}_3\text{Fe}(\text{CN})_6$.³⁵² The mechanism probably involves ion radicals. In still another reaction, secondary amines are converted to α -cyanoamines by treatment with phenylseleninic anhydride and NaCN or Me_3SiCN .^{353,354}

Another specialized reaction converts the methyl group of arenes (e.g., toluene) into a cyano group: toluene \rightarrow benzonitrile, for example.³⁵⁵

12-20 Alkylation of Alkanes

Alkylation or Alkyl-de-hydrogenation

Alkanes can be alkylated by treatment with solutions of stable carbocations³⁵⁶ (Sec. 5.A.ii), but the availability of such carbocations is limited and mixtures are usually obtained. In a typical experiment, the treatment of propane with isopropyl fluoroantimonate ($\text{Me}_2\text{HC}^+ \text{SbF}_6^-$) gave 26% 2,3-dimethylbutane, 28% 2-methylpentane, 14% 3-methylpentane, and 32% *n*-hexane, as well as some butanes, pentanes (formed by Reaction 12-47), and higher alkanes. Mixtures arise in part because intermolecular hydrogen exchange ($\text{RH} + \text{R}'^+ \rightarrow \text{R}^+ + \text{R}'\text{H}$) is much faster than alkylation, so that alkylation products are also derived from the new alkanes and carbocations formed in the exchange reaction. Furthermore, the carbocations present are subject to rearrangement (Chapter 18), giving rise to new carbocations. Products result from all the hydrocarbons and carbocations present in the system. As expected from their relative stabilities, secondary alkyl cations alkylate alkanes more readily than tertiary alkyl cations (the *tert*-butyl cation does not alkylate methane or ethane). Stable primary alkyl cations are not available, but alkylation has been achieved with complexes formed between CH_3F or $\text{C}_2\text{H}_5\text{F}$ and SbF_5 .³⁵⁷ The mechanism of alkylation can be formulated (similar to that shown in hydrogen exchange with superacids, Reaction 12-1) as

It is by means of successive reactions of this sort that simple alkanes like methane and ethane give *tert*-butyl cations in superacid solutions (Sec. 5.A.ii).³⁵⁸

Intramolecular insertion has been reported. The positively charged carbon of the carbocation (**40**), generated from the diazonium salt of the triptycene compound (**39**), reacted with the CH_3 group in close proximity with it.³⁵⁹

12-21 Insertion by Carbenes

CH-Methylene-insertion

The highly reactive species methylene (:CH_2) inserts into C—H bonds,³⁶⁰ both aliphatic and aromatic,³⁶¹ although with aromatic compounds subsequent ring expansion is also possible (see Reaction 15-64). This is effectively a homologation reaction.³⁶² The methylene insertion reaction has limited utility because of its nonselectivity (see Sec. 5.D.i). The insertion reaction of carbenes has been used for synthetic purposes.³⁶³

The carbenes can be generated in any of the ways mentioned in Chapter 5 (Sec. 5.D.ii). Alkylcarbenes usually rearrange rather than give insertion (Sec. 5.D.ii, category 4), but, when this is impossible, *intramolecular* insertion³⁶⁴ is found rather than intermolecular.³⁶⁵ Methylene (:CH_2) generated by photolysis of diazomethane (CH_2N_2) in the liquid phase is indiscriminate (totally nonselective) in its reactivity (Sec. 5.D.ii, category 2). Methylene (:CH_2) generated in other ways and monoalkyl and dialkyl carbenes are less reactive and insert in the order tertiary > secondary > primary.³⁶⁶ Carbene insertion with certain allylic systems can proceed with rearrangement of the double bond.³⁶⁷ Carbenes have been generated using ultrasound.³⁶⁸ Halocarbenes (:CCl_2 , :CBr_2 , etc.) insert much less readily, although a number of instances have been reported.³⁶⁹

Insertion at an allylic carbon of alkenes has been reported.³⁷⁰ Dirhodium catalyzed insertion into H—C^{sp^2} bonds is known,³⁷¹ and also H—C^{sp} bonds.³⁷² Note that

cyclopropanation may compete with C—H insertion with electron-rich highly substituted alkenes.³⁷³ Palladacycles formed by C—H insertion reactions with biphenylene have been intercepted.³⁷⁴ Such species have been implicated in the *Heck reaction* (Reaction **13-10**). Insertion of diazoalkane and diazocarbonyl compounds can be catalyzed by copper compounds³⁷⁵ and silver compounds³⁷⁶ as well. Insertion into the α -C—H bond of an aldehyde gives an α -substituted aldehyde.³⁷⁷ Intramolecular insertion at the α carbon of a ketone by a diazoketone, using TiCl_4 , gives a bicyclic 1,3-diketone.³⁷⁸ The reaction in which aldehydes are converted to methyl ketones, $\text{RCHO} + \text{CH}_2\text{N}_2 \rightarrow \text{RCOCH}_3$, while apparently similar, does not involve a free carbene intermediate and is considered in Reaction **18-9**. Note that aryl ketenes react with $\text{Me}_3\text{SiCHN}_2$ and then silica to give 2-indanone derivatives.³⁷⁹ A three component coupling reaction of vinyl iodides, secondary amines, and diazo(trimethylsilyl)methane gives allylic amines.³⁸⁰ A gold-catalyzed reaction is known that uses alkynes as an α -diazo ketone equivalent.³⁸¹

Insertion into the O—H bond of alcohols, to produce ethers, has been reported using a diazocarbonyl compound and an $\text{In}(\text{OTf})_3$ catalyst.³⁸² The Cu catalyzed insertion of a diazo ester into an oxetane gives the ring-expanded THF derivative.³⁸³ Insertion is also possible with other ethers, including silyl ethers.³⁸⁴ Metal-catalyzed silylene insertion into allylic ethers leads to allylic silanes.³⁸⁵ Similar insertion at the α carbon of an ether leads to cyclic ethers, with high enantioselectivity when a chiral ligand is used with a Rh catalyst.³⁸⁶

The insertion of the diazocarbonyl unit into the C—H bond of an α -diazo amide gives the lactam shown in the reaction.³⁸⁷ Insertion into a 2-pyrrolidinone derivative using $\text{Me}_3\text{SiCH}_2\text{N}_2$ followed by AgCO_2Ph with ultrasound gave the ring-expanded 2-piperidone derivative.³⁸⁸ Intramolecular insertion reactions are well known,³⁸⁹ and tolerate a variety of functional groups.³⁹⁰

The metal carbene insertion reaction, in contrast to the methylene insertion reaction can be highly selective³⁹¹ and useful in synthesis.³⁹² There are numerous examples, usually requiring a transition metal catalyst.³⁹³ The catalyst typically converts a diazoalkane or diazocarbonyl compound to the metal carbene *in situ*, allowing the subsequent insertion reaction. Intermolecular reactions are known, including diazoalkane insertion reaction with a dirhodium catalyst.³⁹⁴ When chiral ligands are present good enantioselectivity is observed in the insertion product.³⁹⁵

The mechanism³⁹⁶ of the insertion reaction is not known with certainty, but there seem to be at least two possible pathways.

1. A simple one-step process involving a three-center cyclic transition state:

The most convincing evidence for this mechanism is that in the reaction between isobutene-1—¹⁴C and carbene the product 2-methyl-1-butene was labeled only in the 1 position.³⁹⁷ This rules out a free radical or a carbocation or carbanion intermediate. If **41** (or a corresponding ion) were an intermediate, resonance would ensure that some carbene attacked at the 1 position:

Other evidence is that retention of configuration, which is predicted by this mechanism, has been found in a number of instances.³⁹⁸ An ylid intermediate was trapped in the reaction of :CH_2 with allyl alcohol.³⁹⁹

2. A free radical process in which the carbene directly abstracts a hydrogen from the substrate to generate a pair of free radicals:

One fact supporting this mechanism is that among the products obtained (beside butane and isobutane) on treatment of propane with CH_2 (generated by photolysis of diazomethane and ketene) were propene and ethane,⁴⁰⁰ which could arise, respectively, by

and

That this mechanism can take place under suitable conditions has been demonstrated by isotopic labeling⁴⁰¹ and by other means.⁴⁰² However, the formation of disproportionation and dimerization products does not always mean that the free radical abstraction process takes place. In some cases, these products arise in a different manner.⁴⁰³ The product of the reaction between a carbene and a molecule may have excess energy (see Sec. 5.D.ii). Therefore it is possible for the substrate and the carbene to react by mechanism 1 (the direct-insertion process) and for the excess energy to cause the compound thus formed to cleave to free radicals. When this pathway is in operation, the free radicals are formed *after* the actual insertion reaction.

The mechanism of cyclopropylcarbene reactions has also been discussed.⁴⁰⁴

It has been suggested⁴⁰⁵ that singlet carbenes insert by the one-step direct-insertion process and triplets (which, being free radicals, are more likely to abstract hydrogen) by the free radical process. In support of this suggestion, CIDNP signals⁴⁰⁶ (Sec. 5.C.i) were observed in the ethylbenzene produced from toluene and triplet CH_2 , but not from the same reaction with singlet CH_2 .⁴⁰⁷ Carbenoids (e.g., compounds of the form R_2CMCl , see Reaction 12-39) can insert into a C—H bond by a different mechanism, similar to pathway 2, but involving abstraction of a hydride ion rather than a hydrogen atom.⁴⁰⁸

For the similar insertion reaction of nitrenes, see Reaction 12-13.

Many organic compounds can be metalated by treatment with an organometallic compound.⁴⁰⁹ Since the reaction involves a proton transfer, the equilibrium lies on the side of the weaker acid.⁴¹⁰ For example, fluorene reacts with *n*-butyllithium to give butane and 9-fluorenyllithium. Since aromatic hydrocarbons are usually stronger acids than aliphatic ones, R is most often aryl. The most common reagent is probably butyllithium.⁴¹¹ Reductive lithiation is an important method for the preparation of organolithium reagents.⁴¹² Normally, only active aromatic rings react with butyllithium. Benzene itself reacts very slowly and in low yield, although benzene can be metalated by butyllithium either in the presence of *tert*-BuOK⁴¹³ or by *n*-butyllithium that is coordinated with various diamines.⁴¹⁴ Metalation of aliphatic RH is most successful when the carbanions are stabilized by resonance (allylic, benzylic, propargylic,⁴¹⁵ etc.) or when the negative charge is at an *sp* carbon (at triple bonds). Trimethylsilylmethyl potassium (Me₃SiCH₂K)⁴¹⁶ and also a combination of an organolithium compound with a bulky alkoxide (LICKOR superbases)⁴¹⁷ are very good reagents for allylic metalation. The former is also useful for benzylic positions. A combination of BuLi, *t*-BuOK, and tetramethylethylenediamine has been used to convert ethylene to vinylpotassium.⁴¹⁸ The reaction can be used to determine relative acidities of very weak acids by allowing two R—H compounds to compete for the same R'M and to determine which proton in a molecule is the most acidic.⁴¹⁹

Note that organolithium compounds are aggregated species and can form hetero-aggregates containing different organic groups.⁴²⁰ *N*-Lithio-*N*-(trialkylsilyl)allylamines are deprotonated in ether solvents at the *cis*-vinyl position to give 3,*N*-dilithio-*N*-(trialkylsilyl)allylamines.⁴²¹

In general, the reaction can be performed only with organometallics of active metals (e.g., Li, Na, and K), but *Grignard reagents* abstract protons from a sufficiently acidic C—H bond, as in $R-C\equiv C-H \rightarrow R-C\equiv C-MgX$. This is the best method for the

preparation of alkynyl *Grignard reagents*.⁴²² Lewis acids have been used to promote α -lithiation of amines.⁴²³ Triethylgallium has been used to generate enolate anions from ketones.⁴²⁴

When a heteroatom (e.g., N, O, S,⁴²⁵ or a halogen),⁴²⁶ is present in a molecule containing an aromatic ring or a double bond, lithiation is usually quite regioselective.⁴²⁷ It has been shown that fluorine is more effective for stabilization of carbanions when compared to the heavier halogens.⁴²⁸ In such compounds, the lithium usually bonds with the sp^2 carbon closest to the heteroatom, probably because the attacking species coordinates with the heteroatom.⁴²⁹ This type of reaction with compounds such as anisole are often called directed metalations.⁴³⁰ In the case of aromatic rings, this means attack at the ortho position,⁴³¹ but this is considered in Reaction 13-17.

In the case of γ,δ -unsaturated disubstituted amides (**42**), the lithium does not go to the closest position, but in this case too the regiochemistry is controlled by coordination to the oxygen.⁴³³ Cyclopropyllithium reagents are rather stable.⁴³⁴

The mechanism involves an attack by R'^- (or a polar R') on the *hydrogen*⁴³⁵ (an acid–base reaction) Evidence is that resonance effects of substituents in R seem to make little difference. When R is aryl, OMe and CF_3 *both* direct ortho, while isopropyl directs meta

and para (mostly meta).⁴³⁶ These results are exactly what would be expected from pure field effects, with no contribution from resonance effects, which implies that attack occurs at the hydrogen and not at R. Other evidence for the involvement of H in the rate-determining step is that there are large isotope effects.⁴³⁷ The nature of R' also has an effect on the rate. In the reaction between triphenylmethane and R'Li, the rate decreased in the order R' = allyl > Bu > Ph > vinyl > Me, although this order changed with changing concentration of R'Li, because of varying degrees of aggregation of the R'Li.⁴³⁸ With respect to the reagent, this reaction is a special case of Reaction 12-24.

Enantioselective reactions are known. The preparation of chlorodeuteriomethylithium proceeds with inversion from the corresponding enantiopure stannyl derivative.⁴³⁹ Although highly reactive chemically, it is configurationally stable at temperatures up to -78°C . Enantioselective catalytic deprotonation with chiral ligands has been used for the deprotonation of *N*-Boc amines to give chiral α -trimethylsilyl derivatives.⁴⁴⁰ A barrier to enantiomerization has been observed for unstabilized, chelated, and dipole-stabilized organolithium compounds. Studies of lithiopyrrolidines show free energies for enantiomerization in the range of $19\text{--}22\text{ kcal mol}^{-1}$ ($79.5\text{--}92.1\text{ kJ mol}^{-1}$) at 0°C .⁴⁴¹

A closely related reaction is formation of nitrogen ylids⁴⁴² from quaternary ammonium salts (see Reaction 17-8):

Phosphonium salts undergo a similar reaction (see Reaction 16-44).

application.⁴⁴⁴ A gold-catalyst conversion of trimethylsilyl substituted esters and carbonates to the corresponding enolate anion has been reported⁴⁴⁵. Synthetically, an important use of the method is to convert aldehydes and ketones,⁴⁴⁶ carboxylic esters, and similar compounds to their enolate forms,⁴⁴⁷ for example,

for use in nucleophilic substitutions (Reactions **10-67**, **10-68**, and **13-14**) and in additions to multiple bonds (Reactions **15-24** and **16-53**). Note that the reaction of carbonyl compounds with lithium dialkylamides leads to the corresponding enolate anion. This reaction was discussed in Reaction **10-68**, in connection with the alkylation reaction of enolate anions.

OS I, 70, 161, 490; IV, 473; VI, 468, 542, 611, 683, 709; VII, 229, 339. Conversions of ketones or esters to enolates are not listed.

12.C.ii. Metals as Leaving Groups

A. Hydrogen as the Electrophile

12-24 Replacement of Metals by Hydrogen

Hydro-de-metalation or Demetalation

Organometallic compounds, including enolate anions, react with acids in reactions that replace the metal with hydrogen.⁴⁴⁸ The R group may be aryl (see Reaction **11-41**). The reaction is often used to introduce deuterium or tritium into susceptible positions. For *Grignard reagents*, water is usually a strong enough acid, but stronger acids are also used. An important method for the reduction of alkyl halides consists of the process $\text{RX} \rightarrow \text{RMgX} \rightarrow \text{RH}$.

The organometallic compounds that are hydrolyzed by water are the ones high in the electromotive series: Na, K, Li, Zn, and so on. Enantioselective protonation of lithium enolates⁴⁴⁹ and cyclopropyllithium compounds⁴⁵⁰ have been reported. When the metal is less active, stronger acids are required. For example, R_2Zn compounds react explosively with water, R_2Cd slowly, and R_2Hg not at all, although the latter can be cleaved with

concentrated HCl. However, this general statement has many exceptions, some hard to explain. For example, BR_3 compounds are completely inert to water, and GaR_3 at room temperature cleave just one R group, but AlR_3 reacts violently with water. However, BR_3 can be converted to RH with carboxylic acids.⁴⁵¹ For less active metals, it is often possible to cleave just one R group from a multivalent metal. For example,

Organometallic compounds of less active metals and metalloids (e.g., Si,⁴⁵² Sb, and Bi), are quite inert to water. Organomercury compounds (RHgX or R_2Hg) can be reduced to RH by H_2 , NaBH_4 , or other reducing agents.⁴⁵³ The reduction with NaBH_4 takes place by a free radical mechanism.⁴⁵⁴ Alkyl-Si bonds are cleaved by H_2SO_4 [e.g., $\text{HOOCCH}_2\text{CH}_2\text{SiMe}_3 \rightarrow 2\text{CH}_2 + (\text{HOOCCH}_2\text{CH}_2\text{SiMe}_3)_2\text{O}$].⁴⁵⁵

When the hydrogen of the HA is attached to carbon, this reaction is the same as **12-22**.

This section does not list the many hydrolyses of Na or K enolates, and so on found in *Organic Syntheses*. The hydrolysis of a *Grignard reagent* to give an alkane is found at **OS II**, 478; the reduction of a vinylic tin compound at **OS VIII**, 381; and the reduction of an alkynylsilane at **OS VIII**, 281.

B. Oxygen Electrophiles

12-25 The Reaction between Organometallic Reagents and Oxygen⁴⁵⁶

Hydroperoxy-de-metalation; Hydroxy-de-metalation

Oxygen reacts with *Grignard reagents* to give either hydroperoxides⁴⁵⁷ or alcohols. The reaction can be used to convert alkyl halides to alcohols without side reactions. With aryl *Grignard reagents*, yields are lower and only phenols are obtained, not hydroperoxides. Because of this reaction, oxygen should be excluded when *Grignard reagents* are prepared and used in various reactions.

Most other organometallic compounds also react with oxygen. Trialkylboranes and alkylchloroboranes (RBCl_2) can be conveniently converted to hydroperoxides by treatment with oxygen followed by hydrolysis.⁴⁵⁸ Dilithiated carboxylic acids (see Reaction **10-70**) react with oxygen to give (after hydrolysis) α -hydroxy carboxylic

acids.⁴⁵⁹ There is evidence that the reaction between *Grignard reagents* and oxygen involves a free radical mechanism.⁴⁶⁰

OS V, 918. See also, OS VIII, 315.

12-26 Reaction between Organometallic Reagents and Peroxides

tert-Butoxy-de-metalation

A convenient method of preparation of *tert*-butyl ethers consists of treating *Grignard reagents* with *tert*-butyl acyl peroxides.⁴⁶¹ Both alkyl and aryl *Grignard reagents* can be used. The application of this reaction to *Grignard reagents* prepared from cyclopropyl halides permits cyclopropyl halides to be converted to *tert*-butyl ethers of cyclopropanols,⁴⁶² which can then be easily hydrolyzed to the cyclopropanols. The direct conversion of cyclopropyl halides to cyclopropanols by Reaction 10-1 is not generally feasible, because cyclopropyl halides do not generally undergo nucleophilic substitutions without ring opening.

Vinyl lithium reagents (**43**) react with silyl peroxides to give high yields of silyl enol ethers with retention of configuration.⁴⁶³ Since the preparation of **43** from vinylic halides (Reaction 12-39) also proceeds with retention, the overall procedure is a method for the stereospecific conversion of a vinylic halide to a silyl enol ether. Dialky ethers have been prepared from organotrifluoroborates and acetals.⁴⁶⁴

OS V, 642, 924.

12-27 Oxidation of Trialkylboranes to Borates

The reaction of alkenes with borane, monoalkyl, and dialkylboranes leads to a new organoborane (see Reaction 15-16). Treatment of organoboranes with alkaline H₂O₂ oxidizes trialkylboranes to esters of boric acid.⁴⁶⁵ This reaction does not affect double

or triple bonds, aldehydes, ketones, halides, or nitriles that may be present elsewhere in the molecule. There is no rearrangement of the R group itself, and this reaction is a step in the hydroboration method of converting alkenes to alcohols (Reaction 15-16). The mechanism has been formulated as involving initial formation of an ate complex when the hydroperoxide anion attacks the electrophilic boron atom. Subsequent rearrangement from boron to oxygen,⁴⁶⁵ as shown, leads to the B—O—R unit.

Similar migration of the other two R groups and hydrolysis of the B—O bonds leads to the alcohol and boric acid. Retention of configuration is observed in R. Boranes can also be oxidized to borates in good yields with oxygen,⁴⁶⁶ with sodium perborate (NaBO_3)⁴⁶⁷ and with trimethylamine oxide, either anhydrous⁴⁶⁸ or in the form of the dihydrate.⁴⁶⁹ The reaction with oxygen is free radical in nature.⁴⁷⁰

OS V, 918; VI, 719, 852, 919.

12-28 Preparation of Borates and Boronic Acids

Alkylboronic and arylboronic acids [RB(OH)_2 , and ArB(OH)_2], respectively, are increasingly important in organic chemistry. The Pd catalyzed coupling reaction of aryl halides and aryl triflates with arylboronic acids (the *Suzuki–Miyaura reaction*, 13-12) is probably the most notable example. A simple synthesis involves the reaction of a *Grignard reagent* (e.g., phenylmagnesium bromide) with an alkyl borate to give phenylboronic acid.⁴⁷¹ Alkylboronic acids are similarly prepared.⁴⁷² Note that boronic acids are subject to cyclic trimerization with loss of water to form boroxines. Tetrahydroxydiboron has been used to prepare allylboronic acids, as well as potassium trifluoro(allyl)borates.⁴⁷³

Trimethylborate [B(OMe)_3] can be used in place of tri-*n*-butyl borate.⁴⁷⁴ Newer methods involve the Pd mediated borylation of alcohols with bis(pinacolato)diboron⁴⁷⁵ or pinacolborane,⁴⁷⁶ but deprotection of the boronate esters can be a problem. Diolboranes (e.g., catecholborane 44)⁴⁷⁷ are prepared by the reaction of a diol with borane.

Cedranediolborane (**45**, prepared from the cedrane-8,9-diol⁴⁷⁸ by treatment with borane•dimethyl sulfide) can be coupled to aryl iodides with a palladium catalyst, and generates the free boronic acid by treatment with diethanolamine and then aq acid.⁴⁷⁹ Boronate esters are often prepared as a means to purify the organoboron species, but some of these esters are hydrolytically unstable and difficult to deal with upon completion of the reaction.⁴⁸⁰

Alkeneboronic esters and acids are also readily available, as in the addition of vinylmagnesium chloride⁴⁸¹ to trimethyl borate below -50°C , followed by hydrolysis.⁴⁸² A nonaqueous workup procedure has been reported for the preparation of arylboronic esters $[\text{ArB}(\text{OR}')_2]$.⁴⁸³ Uncontrollable polymerization or oxidation of much of the boronic acid occurred during the final stages of the isolation procedure, but could be avoided by *in situ* conversion to the dibutyl ester by adding the crude product to 1-butanol. The Sm(III) catalyzed hydroboration of olefins with catecholborane is a good synthesis of boronate esters.⁴⁸⁴

Trialkyl borates (sometimes called orthoborates) can be prepared by heating the appropriate alcohol with boron trichloride in a sealed tube, but the procedure works well only for relatively simple alkyl groups.⁴⁸⁵ Heating alcohols with boron trioxide (B_2O_3) in an autoclave at $110\text{--}170^{\circ}\text{C}$ give the trialkyl borate.⁴⁸⁶ Boric acid can be used for the preparation of orthoborates⁴⁸⁷ by heating with alcohols in the presence of either hydrogen chloride or concentrated sulfuric acid. Removal of water as an azeotrope with excess alcohol improves the yield,⁴⁸⁸ and good yields can be obtained for trialkyl borates⁴⁸⁹ and even for triphenyl borate.⁴⁹⁰ This method is unsuccessful for those borates whose parent alcohols do not form azeotropes with water and for the tertiary alkyl borates,⁴⁸⁹ impure samples are usually obtained.⁴⁹¹

Potassium organotrifluoroborates (RBF_3K) are readily prepared by the addition of inexpensive KHF_2 to a variety of organoboron intermediates.⁴⁹² They are monomeric, crystalline solids that are readily isolated and indefinitely stable in the air. These reagents can be used in several of the applications where boronic acids or esters are used (Reactions 13-10–13-13).⁴⁹³ Note that vinylboronic acid and even vinylboronate esters are unstable to polymerization,⁴⁹⁴ whereas the analogous vinyltrifluoroborate is readily synthesized and completely stable.⁴⁹⁵

OS 13, 16; 81, 134.

12-29 Oxygenation of Organometallic Reagents and Other Substrates to O-Esters and Related Compounds

In some cases, it is possible to oxygenate a nonaromatic carbon atom using various reagents, where the product is an *O*- ester rather than an alcohol. In one example, a vinyl iodonium salt was heated with DMF to produce the corresponding formate ester.⁴⁹⁶

organometallic compounds⁴⁹⁸ react with sulfonyl chloride to give sulfonyl chlorides,⁴⁹⁹ with esters of sulfinic acids to give (stereospecifically) sulfoxides,⁵⁰⁰ with disulfides to give sulfides,⁵⁰¹ and with SO₂ to give sulfinic acid salts,⁵⁰² which can be hydrolyzed to sulfinic acids or treated with halogens to give sulfonyl halides.⁵⁰³

OS **III**, 771; **IV**, 667; **VI**, 533, 979.

D. Halogen Electrophiles

12-31 Halo-de-metalation

Grignard reagents react with halogens to give alkyl halides. The reaction is useful for the preparation of iodo compounds from the corresponding chloro or bromo compounds. The reaction is not useful for preparing chlorides, since the reagents RMgBr and RMgI react with Cl₂ to give mostly RBr and RI, respectively.⁵⁰⁴

Most organometallic compounds, both alkyl and aryl, also react with halogens to give alkyl or aryl halides.⁵⁰⁵ The reaction can be used to convert acetylide ions to 1-haloalkynes.⁵⁰⁶ Vinylodonium tetrafluoroborates were converted to vinyl fluorides by heating.⁵⁰⁷ Similarly, vinyl trifluoroborates were converted to the vinyl iodide with NaI and chloramine-T in aq THF.⁵⁰⁸ The reaction of an alkene with CuO·BF₄, iodine and triethylsilane gave the 2-iodoalkane.⁵⁰⁹ Vinylzirconate reagents react with I₂ to give the corresponding vinyl iodide.⁵¹⁰

Enolate anions can be converted to the corresponding vinyl phosphate, and subsequent reaction with triphenylphosphine dihalide leads to the vinyl halide.⁵¹¹

Trialkylboranes react rapidly with I₂⁵¹² or Br₂⁵¹³ in the presence of NaOMe in methanol, or with FeCl₃ or other reagents⁵¹⁴ to give alkyl iodides, bromides, or chlorides,

respectively. Combined with the hydroboration reaction (Reaction **15-16**), this is an indirect way of adding HBr, HI, or HCl to a double bond to give products with an *anti-Markovnikov* orientation (see Reaction **15-1**). Trialkylboranes can also be converted to alkyl iodides by treatment with allyl iodide and air in a free radical process.⁵¹⁵ *trans*-1-Alkenylboronic acids (**47**), prepared by hydroboration of terminal alkynes with catecholborane to give **46**⁵¹⁶ (Reaction **15-16**), followed by hydrolysis, react with I₂ in the presence of NaOH at 0 °C in ethereal solvents to give *trans*-vinylic iodides.⁵¹⁷

Treatment with ICl also gives the vinyl iodide.⁵¹⁸ This is an indirect way of accomplishing the *anti-Markovnikov* addition of HI to a terminal triple bond. The reaction cannot be applied to alkenylboronic acids prepared from internal alkynes. However, alkenylboronic acids prepared from both internal and terminal alkynes react with Br₂ (2 molar equivalents of Br₂ must be used) followed by base to give the corresponding vinylic bromide, but in this case with *inversion* of configuration; so the product is the *cis*-vinylic bromide.⁵¹⁹ Alkenylboronic acids also give vinylic bromides and iodides when treated with a mild oxidizing agent and NaBr or NaI, respectively.⁵²⁰ Treatment of **47** (prepared from terminal alkynes) with Cl₂ gave vinylic chlorides with inversion.⁵²¹ Vinylic boranes can be converted to the corresponding vinylic halide by treatment with NCS or NBS.⁵²² Vinylic halides can also be prepared from vinylic silanes⁵²³ and from vinylic copper reagents. The latter react with I₂ to give iodides,⁵²⁴ and with NCS or NBS at -45 °C to give chlorides or bromides.⁵²⁵ The reaction of an aryl alkyne with HInCl₂/BEt₃ and then iodine leads to a (*Z*)-vinyl iodide with respect to the aryl group and the iodine atom.⁵²⁶ Boronic acids can be fluorinated in a reaction mediated by Ag(I) triflate.⁵²⁷

For the reaction of lithium enolate anions of esters with I_2 or CX_4 , see Reaction **12-5**.

The conversion of terminal alkynes to 1-iodo-1-alkynes was reported using NaI under electrochemical conditions.⁵²⁸ 1-Bromo-1-alkynes were converted to the 1-iodo-1-alkyne

with CuI.⁵²⁹ 1-Trialkyldisilylalkynes were converted to the corresponding 1-bromoalkyne via reaction with NBS and AgF.⁵³⁰ Terminal alkynes react with (diacetoxyiodo)benzene, KI, and CuI to give 1-iodo-alkynes.⁵³¹ Trichloroisocyanuric acid has been used to convert terminal alkynes to 1-chloroalkynes.⁵³²

It is unlikely that a single mechanism suffices to cover all conversions of organometallic compounds to alkyl halides.⁵³³ In a number of cases, the reaction has been shown to involve inversion of configuration (see Sec. 12.A.i), indicating an S_E2 (back) mechanism, while in other cases retention of configuration has been shown,⁵³⁴ implicating an S_E2 (front) or S_Ei mechanism. In still other cases, complete loss of configuration as well as other evidence demonstrated the presence of a free radical mechanism.^{534,535}

E. Nitrogen Electrophiles

12-32 The Conversion of Organometallic Compounds to Amines

Amino-de-metalation

There are several methods for conversion of alkyl- or aryllithium compounds to primary amines.⁵³⁶ The two most important are treatment with hydroxylamine derivatives and with certain azides.⁵³⁷ In the first of these methods, treatment of RLi with methoxyamine and MeLi in ether at -78°C gives RNH₂.⁵³⁸ Grignard reagents from aliphatic halides give lower yields. The reaction can be extended to give secondary amines by the use of *N*-substituted methoxyamines (CH₃ONHR').⁵³⁹ There is evidence⁵⁴⁰ that the mechanism involves the direct displacement of OCH₃ by R on an intermediate CH₂ONR' (CH₂ONR' Li⁺ + RLi → CH₃OLi + RNR' Li⁺). Tosyl azide (TsN₃) is a highly useful azide.⁵⁴¹ The initial product is usually RN₃, but this is easily reduced to the amine (Reaction 19-51). With some azides (e.g., azidomethyl phenyl sulfide, PhSCH₂N₃), the group attached to the N₃ is a poor leaving group, so the initial

product is a triazene (in this case $\text{ArNHN}=\text{NCH}_2\text{SPh}$ from ArMgX), which can be hydrolyzed to the amine.⁵⁴²

Organoboranes react with a mixture of aq NH_3 and NaOCl to produce primary amines.⁵⁴³ It is likely that the actual reagent is chloramine (NH_2Cl). Chloramine itself,⁵⁴⁴ hydroxylamine-*O*-sulfonic acid in diglyme,⁵⁴⁵ and trimethylsilyl azide⁵⁴⁶ also give the reaction. Since the boranes can be prepared by the hydroboration of alkenes (Reaction 15-16), this is an indirect method for the addition of NH_3 to a double bond with *anti*-Markovnikov orientation. Secondary amines can be prepared⁵⁴⁷ by the treatment of alkyl- or aryl dichloroboranes or dialkylchloroboranes with alkyl or aryl azides.

The use of an optically active R^*BCl_2 gave secondary amines of essentially 100% optical purity.⁵⁴⁸ Aryllead triacetates $[\text{ArPb}(\text{OAc})_3]$ give secondary amines (ArNHR') when treated with primary aromatic amines $\text{Ar}'\text{NH}_2$ and $\text{Cu}(\text{OAc})_2$.⁵⁴⁹

Secondary amines have been converted to tertiary amines by treatment with lithium dialkylcuprate reagents: $\text{R}_2\text{CuLi} + \text{NHR} \rightarrow \text{RNR}'_2$.⁵⁵⁰ The reaction was also used to convert primary amines to secondary, but yields were lower.⁵⁵¹

Terminal alkynes reacted with chlorodiphenylphosphine (Ph_3PCl) and a Ni catalyst to give the 1-diphenylphosphino alkyne ($\text{R}-\text{C}\equiv\text{C}-\text{PPh}_2$).⁵⁵² Alkynyl halides can be used for a similar reaction. Treatment of methyl carbamates with KHMDS and CuI , followed by 2 equiv of 1-bromophenylacetylene gave the *N*-substituted alkyne, $\text{Ph}-\text{C}\equiv\text{C}-\text{N}(\text{CO}_2\text{Me})\text{R}$.⁵⁵³

Metal-catalyzed amination reactions are increasingly important in organic methodology. In a typical reaction, an amine is coupled to an alkyl, vinyl, or aryl halide (or with a different leaving group) in the presence of a transition metal, usually Pd. Presumably, the amination occurs via reaction with a transient organometallic species. Amination of aromatic compounds via this approach is discussed in section Reaction 13-5. Aliphatic

and vinyl substrates are treated here. In one example, a vinyl triflate is converted to an enamine via reaction with pyrrole in the presence of a Pd catalyst.⁵⁵⁴

OS VI, 943.

F. Carbon Electrophiles

12-33 The Conversion of Organometallic Compounds to Ketones, Aldehydes, Carboxylic Esters, or Amides

Acyl-de-metalation, and so on

Symmetrical ketones⁵⁵⁵ can be prepared in good yields by the reaction of organomercuric halides⁵⁵⁶ with dicobalt octacarbonyl in THF,⁵⁵⁷ or with nickel carbonyl in DMF or certain other solvents.⁵⁵⁸ The R group may be aryl or alkyl. However, when R is alkyl, rearrangements may intervene in the $\text{Co}_2(\text{CO})_8$ reaction, although the $\text{Ni}(\text{CO})_4$ reaction seems to be free from such rearrangements.⁵⁵⁹ Divinylic ketones (useful in the *Nazarov cyclization*, **15-20**) have been prepared in high yields by treatment of vinylic mercuric halides with CO and a Rh catalyst.⁵⁵⁹ In a more general synthesis of unsymmetrical ketones, tetraalkyltin compounds (R_4Sn) are treated with a halide $\text{R}'\text{X}$ ($\text{R}' = \text{aryl, vinylic, benzylic}$), CO, and a Pd complex catalyst.⁵⁶⁰ Similar reactions use *Grignard reagents*, $\text{Fe}(\text{CO})_5$, and an alkyl halide.⁵⁶¹

Grignard reagents react with formic acid to give good yields of aldehydes. Two molar equivalents of RMgX are used; the first converts HCO_2H to HCOO^- , which reacts with the second equivalent to give RCHO .⁵⁶² Alkyl lithium reagents and Grignard reagents react with CO to give symmetrical ketones.⁵⁶³ An interesting variation reacts CO_2 with an organolithium, which is then treated with a different organolithium reagent to give the unsymmetrical ketone.⁵⁶⁴ α,β -Unsaturated aldehydes can be prepared by treatment of vinylic silanes with dichloromethyl methyl ether and TiCl_4 at -90°C .⁵⁶⁵

α,β -Unsaturated esters can be prepared by treating boronic esters (**27**) with CO, PdCl_2 , and NaOAc in MeOH.⁵⁶⁶ The synthesis of α,β -unsaturated esters has also been

G. Metal Electrophiles

12-35 Transmetalation with a Metal

Metallo-de-metalation

Many organometallic compounds are best prepared by this reaction, which involves replacement of a metal in an organometallic compound by another metal. The RM' compound can be successfully prepared only when M' is above M in the electromotive series, unless some other way is found to shift the equilibrium. That is, RM is usually an unreactive compound and M' is a metal more active than M . Most often, RM is R_2Hg , since mercury alkyls⁵⁷⁶ are easy to prepare and mercury is far down in the electromotive series.⁵⁷⁷ Alkyls of Li, Na, K, Be, Mg, Al, Ga, Zn, Cd, Te, Sn, and so on, have been prepared this way. An important advantage of this method over Reaction **12-38** is that it ensures that the organometallic compound will be prepared free of any possible halide. This method can be used for the isolation of solid sodium and potassium alkyls.⁵⁷⁸ If the metals lie too close together in the series, it may not be possible to shift the equilibrium. For example, alkylbismuth compounds cannot be prepared in this way from alkylmercury compounds.

OS V, 1116.

12-36 Transmetalation with a Metal Halide

Metallo-de-metalation

In contrast to Reaction **12-35**, the reaction between an organometallic compound and a metal *halide* is successful only when M' is *below* M in the electromotive series.⁵⁷⁹ The two reactions considered together therefore constitute a powerful tool for preparing all kinds of organometallic compounds. In this reaction, the most common substrates are *Grignard reagents* and organolithium compounds.⁵⁸⁰

The MgX of *Grignard reagents*⁵⁸¹ can migrate to terminal positions in the presence of small amounts of TiCl_4 .⁵⁸² The proposed mechanism consists of metal exchange (Reaction 12-36), elimination–addition, and metal exchange:

The addition step is similar to Reactions 15-16 or 15-17 and follows *Markovnikov's* rule, so the positive titanium goes to the terminal carbon.

Among others, alkyls of Be, Zn,⁵⁸³ Cd, Hg, Al, Sn, Pb, Co, Pt, and Au have been prepared by treatment of *Grignard reagents* with the appropriate halide.⁵⁸⁴ The reaction has been used to prepare alkyls of almost all nontransition metals and even of some transition metals. Alkyls of metalloids and of nonmetals, including Si, B,⁵⁸⁵ Ge, P, As, Sb, and Bi, can also be prepared in this manner.⁵⁸⁶ Except for alkali-metal alkyls and *Grignard reagents*, the reaction between RM and M'X is the most common method for the preparation of organometallic compounds.⁵⁸⁷ In the presence of Ir,⁵⁸⁸ or Pd catalysts,⁵⁸⁹ aromatic compounds react with boranes to give the corresponding arylborane.

Lithium dialkylcopper reagents are prepared from 2 molar equivalents of RLi with 1 molar equivalent of a cuprous halide in ether at low temperatures:⁵⁹⁰ The formation of organocuprates of this type are discussed in more detail in Reaction 10-58, in connection with the coupling reaction of organocuprates with alkyl halides.

Another way is to dissolve an alkylcopper compound in an alkyllithium solution. Higher order cuprates can also be prepared, as well as “non-ate” copper reagents.⁵⁹¹

Metallocenes (48, see Sec. 2.I.ii) are usually made by this method. Among others, metallocenes of Sc, Ti, V, Cr, Mn, Fe, Co, and Ni have been prepared in this manner.⁵⁹²

12-37 Transmetalation with an Organometallic Compound

Metallo-de-metalation

This type of metallic exchange is used much less often than Reactions **12-35** and **12-36**. It is an equilibrium reaction and is useful only if the equilibrium lies in the desired direction. Usually the goal is to prepare a lithium compound that is not prepared easily in other ways,⁵⁹⁴ for example, a vinylic or an allylic lithium, most commonly from an organotin substrate. Examples are the preparation of vinyl lithium from phenyllithium and tetravinyltin and the formation of α -dialkylamino organolithium compounds from the corresponding organotin compounds⁵⁹⁵

The reaction has also been used to prepare 1,3-dilithiopropanes⁵⁹⁶ and 1,1-dilithiomethylenecyclohexane⁵⁹⁷ from the corresponding mercury compounds. In general, the equilibrium lies in the direction in which the more electropositive metal is bonded to that alkyl or aryl group that is the more stable carbanion (Sec. 5.B.i). The reaction proceeds with retention of configuration,⁵⁹⁸ an S_{Ei} mechanism is likely.⁵⁹⁹

“Higher order” cuprates⁶⁰⁰ (see Reaction **10-58**) have been produced by this reaction starting with a vinylic tin compound:⁶⁰¹

These compounds are not isolated, but used directly *in situ* for conjugate addition reactions (Reaction 15-25). Another method for the preparation of such reagents (but with Zn instead of Li) allows them to be made from α -acetoxy halides:⁶⁰²

OS V, 452; VI, 815; VIII, 97.

12.C.iii. Halogen as Leaving Group

The reduction of alkyl halides can proceed by an electrophilic substitution mechanism, but it is considered in Chapter 19 (Reaction 19-53).

12-38 Metallo-de-halogenation

Alkyl halides react directly with certain metals to give organometallic compounds.⁶⁰³ The most common metal is Mg, and of course this is by far the most common method for the preparation of *Grignard reagents*.⁶⁰⁴ The *Grignard reaction* with aldehydes or ketones is discussed in Reaction 16-24. The order of halide activity is $\text{I} > \text{Br} > \text{Cl}$. This reaction can be applied to many alkyl halides primary, secondary, and tertiary and to aryl halides, although aryl *chlorides* require the use of THF or another higher-boiling solvent instead of the usual ether, or special entrainment methods.⁶⁰⁵ Aryl iodides and bromides can be treated in the usual manner. Allylic *Grignard reagents* can also be prepared in the usual manner (or in THF),⁶⁰⁶ although in the presence of excess halide these may give *Wurtz-type coupling* products (see Reaction 10-56).⁶⁰⁷ Like aryl chlorides, vinylic halides require higher-boiling solvents (see OS IV, 258). A good procedure for benzylic and allylic halides is to use magnesium anthracene (prepared from Mg and anthracene in THF)⁶⁰⁸ instead of ordinary magnesium,⁶⁰⁹ although activated magnesium turnings have also been used.⁶¹⁰ Alkynyl *Grignard reagents* are generally prepared by the method in Reaction 12-22.

Dihalides⁶¹¹ can be converted to *Grignard reagents* if the halogens are different and are at least three carbons apart. If the halogens are the same, it is possible to obtain

dimagnesium compounds [e.g., $\text{BrMg}(\text{CH}_2)_4\text{MgBr}$].⁶¹² 1,2-Dihalides give elimination⁶¹³ rather than *Grignard reagent* formation (Reaction 17-22), and the reaction is seldom successful with 1,1-dihalides, although the preparation of *gem*-disubstituted compounds [e.g., $\text{CH}_2(\text{MgBr})_2$], has been accomplished with these substrates.⁶¹⁴ α -Halo Grignard reagents and α -halolithium reagents can be prepared by the method given in Reaction 12-39.⁶¹⁵ Alkylmagnesium fluorides can be prepared by refluxing alkyl fluorides with Mg in the presence of appropriate catalysts (e.g., I_2 or EtBr) in THF for several days.⁶¹⁶ Nitrogen-containing *Grignard reagents* have been prepared.⁶¹⁷

The presence of other functional groups in the halide usually affects the preparation of the *Grignard reagent*. Groups that contain active hydrogen (defined as any hydrogen that will react with a *Grignard reagent*, e.g., OH, NH_2 , and CO_2H), can be present in the molecule, but only if they are converted to the salt form (O^- , NH^- , COO^- , respectively). Groups that react with *Grignard reagents* (e.g., $\text{C}=\text{O}$, $\text{C}\equiv\text{N}$, NO_2 , CO_2R) inhibit *Grignard* formation entirely. In general, the only functional groups that may be present in the halide molecule without any interference at all are double and triple bonds (except terminal triple bonds) and OR and NR_2 groups. However, β -halo ethers generally give β elimination when treated with Mg (see Reaction 17-24), and *Grignard reagents* from α -halo ethers⁶¹⁸ can only be formed in THF or dimethoxymethane at a low temperature, for example,⁶¹⁹

because such reagents immediately undergo α elimination (see Reaction 12-39) at room temperature in ether solution.

Because *Grignard reagents* react with water (Reaction 12-24) and with oxygen (Reaction 12-25), it is generally best to prepare them in an anhydrous nitrogen atmosphere. *Grignard reagents* are generally neither isolated nor stored; solutions of *Grignard reagents* are used directly for the required synthesis. *Grignard reagents* can also be prepared in benzene or toluene, if a tertiary amine is added to complex with the RMgX .⁶²⁰ This method eliminates the need for an ether solvent. With certain primary alkyl halides it is even possible to prepare alkylmagnesium compounds in hydrocarbon solvents in the absence of an organic base.⁶²¹ It is also possible to obtain *Grignard reagents* in powdered form, by complexing them with the chelating agent tris(3,6-dioxaheptyl)amine [$\text{N}(\text{CH}_2\text{CH}_2\text{OCH}_2\text{CH}_2\text{OCH}_3)_3$].⁶²²

Next to the formation of *Grignard reagents*, the most important application of this reaction is the conversion of alkyl and aryl halides to organolithium compounds,⁶²³ but it has also been carried out with many other metals (e.g., Na, Be, Zn, Hg, As, Sb, and Sn). With Na, the *Wurtz Reaction* (**10-56**) is an important side reaction. In some cases, where the reaction between a halide and a metal is too slow, an alloy of the metal with K or Na can be used instead. The most important example is the preparation of tetraethyl-lead from ethyl bromide and a Pb—Na alloy.

The efficiency of the reaction can often be improved by use of the metal in its powdered⁶²⁴ or vapor⁶²⁵ form. These techniques have permitted the preparation of some organometallic compounds that cannot be prepared by the standard procedures. Among the metals produced in an activated form are Mg,⁶²⁶ Ca,⁶²⁷ Zn,⁶²⁸ Al, Sn, Cd,⁶²⁹ Ni, Fe, Ti, Cu,⁶³⁰ Pd, and Pt.⁶³¹

The mechanism of *Grignard reagent* formation involves free radicals,⁶³² and there is much evidence for this, from CIDNP⁶³³ (Sec. 5.C.i) and from stereochemical, rate, and product studies.⁶³⁴ Further evidence is that free radicals have been trapped,⁶³⁵ and that experiments that studied the intrinsic reactivity of MeBr on a magnesium single-crystal surface showed that *Grignard reagent* formation does not take place by a single-step insertion mechanism.⁶³⁶ The following SET mechanism has been proposed:⁶³³

Other evidence has been offered to support a SET initiated radical process for the second step of this mechanism.⁶³⁷ The species $R-X^{\bullet-}$ and $Mg^{\bullet+}$ are radical ions.⁶³⁸ The subscript “s” is meant to indicate that the species so marked are bound to the surface of the magnesium. It is known that this is a surface reaction.⁶³⁹ It has been suggested that some of the R^{\bullet} radicals diffuse from the magnesium surface into the solution and then return to the surface to react with the XMg^{\bullet} . There is evidence both for⁶⁴⁰ and against⁶⁴¹ this suggestion. Another proposal is that the fourth step is not the one shown here, but that the R^{\bullet} is reduced by Mg^+ to the carbanion R^- , which combines with MgX^+ to give $RMgX$.⁶⁴²

There are too many preparations of *Grignard reagents* in *Organic Syntheses* for us to list here. Chiral *Grignard reagents* are rare, since they are configurationally unstable in most cases. However, a few chiral *Grignard reagents* are known.⁶⁴³ Use of the reaction to prepare other organometallic compounds can be found in OS **I**, 228; **II**, 184, 517, 607; **III**, 413, 757; **VI**, 240; **VII**, 346; **VIII**, 505. The preparation of unsolvated butylmagnesium bromide is described at OS **V**, 1141. The preparation of highly reactive (powdered) magnesium is given at OS **VI**, 845.

12-39 Replacement of a Halogen by a Metal from an Organometallic Compound

Metallo-de-halogenation

The exchange reaction between halides and organometallic compounds occurs most readily when M is Li and X is Br or I,⁶⁴⁴ although it has been shown to occur with Mg.⁶⁴⁵ The R' group is usually, although not always, alkyl, and often butyl; R is usually aromatic.⁶⁴⁶ Alkyl halides are generally not reactive enough, while allylic and benzylic halides usually give *Wurtz coupling*. Of course, the R that becomes bonded to the halogen is the one for which RH is the weaker acid. Despite the preponderance of reactions with bromides and iodides, it is noted that the reaction of 1-fluorooctane with 4–10 equiv of Li powder and 2–4 equiv of DTBB (4,4'-di-*tert*-butylbiphenyl) in THP (THP=tetrahydropyran) at 0 °C for 5 min, was shown to give a solution of the corresponding 1-octyllithium.⁶⁴⁷ Vinylic halides

react with retention of configuration.⁶⁴⁸ The reaction can be used to prepare α -halo organolithium and α -halo organomagnesium compounds.⁶⁴⁹ Carbon tetrachloride reacts with butyllithium to give lithiotrichloromethane ($\text{Cl}_3\text{C}-\text{Li}$), for example.⁶⁵⁰ Such compounds can also be prepared by hydrogen-metal exchange, for example,⁶⁵¹

This is an example of Reaction 12-22. However, these α -halo organometallic compounds are stable (and configurationally stable as well⁶⁵²) only at low temperatures (ca. $-100\text{ }^\circ\text{C}$) and only in THF or mixtures of THF and other solvents (e.g., HMPA). At ordinary temperatures, they lose MX (α elimination) to give carbenes, which then react further, or carbenoid reactions. The α -chloro- α -magnesium sulfones $[\text{ArSO}_2\text{CH}(\text{Cl})\text{MgBr}]$ are exceptions, being stable in solution at room temperature and even under reflux.⁶⁵³ Compounds in which a halogen and a transition metal are on the same carbon can be more stable than the ones with lithium.⁶⁵⁴

There is evidence that the mechanism⁶⁵⁵ of the reaction of alkyllithium compounds with alkyl and aryl iodides involves free radicals.⁶⁵⁶

Among the evidence is the fact that coupling and disproportionation products are obtained from R^\bullet and R'^\bullet and the observation of CIDNP.^{656,657} However, in the degenerate exchange between PhI and PhLi the ate complex $\text{Ph}_2\text{I}^- \text{Li}^+$ has been shown to be an intermediate,⁶⁵⁸ and there is other evidence that radicals are not involved in all instances of this reaction.⁶⁵⁹

In a completely different kind of process, alkyl halides can be converted to certain organometallic compounds by treatment with organometalate ions, for example,

⁶⁴⁸ For examples of exchange, R = vinylic, see Miller, R.B.; McGarvey, G. *Synth. Commun.* **1979**, 9, 831; Sugita, T.; Sakabe, Y.; Sasahara, T.; Tsukuda, M.; Ichikawa, K. *Bull. Chem. Soc. Jpn.* **1984**, 57, 2319.

Most of the evidence is in accord with a free radical mechanism involving electron transfer, although an S_N2 mechanism can compete under some conditions.⁶⁶⁰ Electrochemically generated zinc has been used to prepare organozinc bomide from the corresponding alkyl halide.⁶⁶¹

12.C.iv. Carbon Leaving Groups

In these reactions (12-40–12-48), a carbon–carbon bond cleaves. The substrate is the side that retains the electron pair; hence the reactions are considered electrophilic substitutions. The incoming group is hydrogen in all but one (Reaction 12-42) of the cases. The reactions in groups A and B are sometimes called *anionic cleavages*,⁶⁶² although they do not always occur by mechanisms involving free carbanions (S_E1). When they do, the reactions are facilitated by increasing stability of the carbanion.

A. Carbonyl-Forming Cleavages These reactions follow the pattern:

The leaving group is stabilized because the electron deficiency at its carbon is satisfied by a pair of electrons from the oxygen. With respect to the leaving group the reaction is elimination to form a C=O bond. Retrograde aldol reactions (16-34) and cleavage of cyanohydrins (16-52) belong to this classification but are treated in Chapter 16 under their more important reverse reactions. Other eliminations to form C=O bonds are discussed in Reaction 17-32.

12-40 Decarboxylation of Aliphatic Acids

Hydro-de-carboxylation

Many carboxylic acids can be successfully decarboxylated, either as the free acid or in the salt form, but not simple aliphatic acids.⁶⁶³ An exception is acetic acid, which as the acetate, heated with base, gives good yields of methane. Malonic acid derivatives are the most common substrates for decarboxylation, giving the corresponding mono-carboxylic acid. Decarboxylation of 2-substituted malonic acids has been reported using microwave irradiation.⁶⁶⁴ Aliphatic acids that do undergo successful decarboxylation have certain functional groups or double or triple bonds in the α or β position. Some of these are shown in Table 12.2.

TABLE 12.2 Some Acids That Undergo Decarboxylation Fairly Readily^a

Acid Type	Decarboxylation Product
	
	
	
	
$X_3C-COOH$	X_3C-H
	
	

^aOthers are described in the text.

For decarboxylation of aromatic acids, see Reaction 11-35. Decarboxylation of an α -cyano acid can give a nitrile or a carboxylic acid, since the cyano group may or may not be hydrolyzed in the course of the reaction. In addition to the compounds listed in Table 12.2, decarboxylation can be carried out on α,β -unsaturated⁶⁶⁵ and α,β -acetylenic acids. Glycidic acids give aldehydes on decarboxylation. The following mechanism has been suggested:⁶⁶⁶

The direct product is an enol that tautomerizes to the aldehyde.⁶⁶⁷ This is the usual last step in the *Darzens Reaction* (16-40).

Decarboxylations can be regarded as reversal of the addition of carbanions to carbon dioxide (Reaction 16-82), but free carbanions are not always involved.⁶⁶⁸ When the carboxylate *ion* is decarboxylated, the mechanism can be either S_E1 or S_E2 . In the case of the S_E1 mechanism, the reaction is of course aided by the presence of electron-withdrawing

⁶⁶⁵ See Roy, S.C.; Guin, C.; Maiti, G. *Tetrahedron Lett.* **2001**, 42, 9253.⁶⁶⁶ Singh, S.P.; Kagan, J. J. *Org. Chem.* **1970**, 35, 2203.⁶⁶⁷ Shiner, Jr., V.J.; Martin, B. *J. Am. Chem. See Dunn, G.E. *Isot. Org. Chem.* **1977**, 3, 1.

groups, which stabilize the carbanion.⁶⁶⁹ Decarboxylation of carboxylate ions can be accelerated by the addition of a suitable crown ether, which in effect removes the metallic ion.⁶⁷⁰ The reaction without the metallic ion has also been performed in the gas phase.⁶⁷¹ Some acids can also be decarboxylated directly and, in most of these cases, there is a cyclic, six-center mechanism:

Here too there is an enol that tautomerizes to the product. The mechanism is illustrated for the case of β -keto acids,⁶⁷² but it is likely that malonic, α -cyano, α -nitro, and β,γ -unsaturated acids⁶⁷³ behave similarly, since similar six-membered transition states can be written for them. Some α,β -unsaturated acids

are also decarboxylated by this mechanism by isomerizing to the β,γ -isomers before they actually decarboxylate.⁶⁷⁴ Evidence is that **49** and similar bicyclic β -keto acids resist decarboxylation.⁶⁷⁵ In such compounds, the six-membered cyclic transition state cannot form for steric reasons,⁶⁷⁶ and if it could, formation of the intermediate enol would violate *Bredt's rule* (Sec. 4.Q.iii).

Some carboxylic acids that cannot form a six-membered transition state can still be decarboxylated, and these presumably react through an S_E1 or S_E2 mechanism.⁶⁷⁷ Further evidence for the cyclic mechanism is that the reaction rate varies very little with a change from a nonpolar to a polar solvent (even from benzene to water⁶⁷⁸), and is not subject to acid catalysis.⁶⁷⁹ The rate of decarboxylation of a β,γ -unsaturated acid was increased $\sim 10^5$ – 10^6 times by introduction of a β -methoxy group, indicating that the cyclic transition state has dipolar character.⁶⁸⁰ Rate constants for decarboxylation reactions have been calculated using no barrier theory.⁶⁸¹

β -Keto acids⁶⁸² are easily decarboxylated, but such acids are usually prepared from β -keto esters, and the esters are easily decarboxylated themselves on hydrolysis without isolation of the acids.⁶⁸³ This decarboxylation of β -keto esters involving cleavage on the carboxyl side of the substituted methylene group (arrow) is carried out under acidic, neutral, or slightly basic conditions to yield a ketone. When strongly basic conditions are used, cleavage occurs on the other side of the CR_2 group (Reaction **12-43**). β -Keto esters can be decarbalkoxylated without passing through the free-acid stage by treatment with boric anhydride (B_2O_3) at 150°C .⁶⁸⁴ The alkyl portion of the ester (R') is converted to an alkene or, if it lacks a β hydrogen, to an ether ($\text{R}'\text{OR}'$). Another method for the decarbalkoxylation of β -keto esters, malonic esters, and α -cyano esters consists of heating the substrate in wet DMSO containing NaCl , Na_3PO_4 , or some other simple salt.⁶⁸⁵ In this method too, the free acid is probably not an intermediate, but here the alkyl portion of the substrate is converted to the corresponding alcohol. α -Amino acids have been decarboxylated by treatment with a catalytic amount of 2-cyclohexenone.⁶⁸⁶ Amino acids are decarboxylated by sequential treatment with NBS at pH 5 followed by NaBH_4 and NiCl_2 .⁶⁸⁷ Certain decarboxylations can also be accomplished photochemically.⁶⁸⁸ See also, the decarbonylation of acyl halides, mentioned in Reaction **14-32**. In some cases, decarboxylations can give organometallic compounds: $\text{RCOOM} \rightarrow \text{RM} + \text{CO}_2$.⁶⁸⁹ The Cu catalyzed decarboxylation of 2-alkynoic acids to terminal alkynes has been reported.⁶⁹⁰

Decarboxylative alkylation and arylation reactions are known. In the presence of a Ru catalyst and a B-phenyl borinate, decarboxylation of proline esters leads to 2-phenylpyrrolidine derivatives.⁶⁹¹ In the presence of a Pd catalyst, esters undergo decarboxylation with coupling between the alkyl groups on the carbonyl and the ester oxygen to give the corresponding hydrocarbon fragment.⁶⁹²

Some of the decarboxylations listed in *Organic Syntheses* are performed with concomitant ester or nitrile hydrolysis and others are simple decarboxylations.

12-41 Cleavage of Alkoxides

Hydro-de-(α -oxidoalkyl)-substitution

Alkoxides of tertiary alcohols can be cleaved in a reaction that is essentially the reverse of addition of carbanions to ketones (Reaction **16-24**).⁶⁹³ The reaction is unsuccessful when the R groups are simple unbranched alkyl groups (e.g., the alkoxide of triethylcarbinol). Cleavage is accomplished with branched alkoxides (e.g., the alkoxides of diisopropylneopentylcarbinol or tri-*tert*-butylcarbinol).⁶⁹⁴ Allylic,⁶⁹⁵ benzylic,⁶⁹⁶ and aryl groups also cleave (e.g., the alkoxide of triphenylcarbinol gives benzene and benzophenone). Studies in the gas phase show that the cleavage is a simple one, giving the carbanion and ketone directly in one step.⁶⁹⁷ However, with some substrates in solution, substantial amounts of dimer R—R have been found, indicating a radical pathway.⁶⁹⁸ Hindered alcohols (not the alkoxides) also lose one R group by cleavage, also by a radical pathway.⁶⁹⁹ The so-called retro-aldol (see Reaction **16-34**) is another example.

The reaction has been used for extensive mechanistic studies (see Sec. 12.A.ii).

OS **VI**, 268.

12-42 Replacement of a Carboxyl Group by an Acyl Group

Acyl-de-carboxylation

When an α -amino acid is treated with an anhydride in the presence of pyridine, the carboxyl group is replaced by an acyl group and the NH_2 becomes acylated. This is called the *Dakin–West reaction*.⁷⁰⁰ The mechanism involves formation of an oxazolone.⁷⁰¹ The reaction sometimes takes place on carboxylic acids even when an amino group is not present. A number of *N*-substituted amino acids [$\text{RCH}(\text{NHR}')\text{COOH}$] give the corresponding *N*-alkylated products.

B. Acyl Cleavages

In these reactions (**12-43–2-46**), a carbonyl group is attacked by a hydroxide ion (or an amide ion), giving an intermediate that undergoes cleavage to a carboxylic acid (or an amide). With respect to the leaving group, this is nucleophilic substitution at a carbonyl group and the mechanism is the tetrahedral one discussed in Section 16.A.i.

With respect to R this is of course electrophilic substitution. The mechanism is usually $\text{S}_{\text{E}}1$.

12-43 Basic Cleavage of β -Keto Esters and β -Diketones

Hydro-de-acylation

When β -keto esters are treated with concentrated base, cleavage occurs, but on the keto side of the CR_2 group (arrow) in contrast to the acid cleavage mentioned in Reaction **12-40**. The products are a carboxylic ester and the salt of an acid. However, the utility of the reaction is somewhat limited by the fact that decarboxylation is a side reaction, even under basic conditions. β -Diketones behave similarly to give a ketone and the salt of a carboxylic acid. With both β -keto esters and β -diketones, OEt^- can be used instead of OH^- , in which case the ethyl esters of the corresponding acids are obtained instead of the salts. In the case of β -keto esters, this is the reverse of *Claisen condensation* (Reaction **16-85**). The related cleavage of cyclic α -cyano ketones, in an intramolecular fashion, has been used in a synthesis of macrocyclic lactones (e.g., **50**).⁷⁰²

Activated F^- (from KF and a crown ether) has been used as the base to cleave an α -cyano ketone.⁷⁰³ Treatment with ceric ammonium nitrate led to cleavage of β -diketones to give a carboxylic acid.⁷⁰⁴

OS II, 266, 531; III, 379; IV, 415, 957; V, 179, 187, 277, 533, 747, 767.

12-44 Haloform Reaction

⁷⁰² Milenkov, B.; Hesse, M. *Helv. Chim. Acta* **1987**, 70, 308. For a similar preparation of lactams, see Wälichli, R.; Bienz, S.; Hesse, M. *Helv. Chim. Acta* **1985**, 68, 484.

⁷⁰⁴ Zhang, Y.; Jiao, J.; Flowers II, R.A. *J. Org. Chem.* **2006**, 71, 4516.

In the *haloform reaction*, methyl ketones (and the only methyl aldehyde, acetaldehyde) are cleaved with halogen and a base.⁷⁰⁵ The halogen can be bromine, chlorine, or iodine. What takes place is actually a combination of two reactions. The first is an example of Reaction 12-4, in which, under the basic conditions employed, the methyl group is trihalogenated. Then the resulting trihalo ketone is attacked by hydroxide ion to give tetrahedral intermediate (51).⁷⁰⁶ The X_3C^- group is a sufficiently good leaving group (not HX_2C^- or H_2XC^-) that a carboxylic acid is formed, which quickly reacts with the carbanion to give the final products. Primary or secondary methylcarbinols also give the reaction, because they are oxidized to the carbonyl compounds under the conditions employed.

As with Reaction 12-4, the rate-determining step is the preliminary enolization of the methyl ketone.⁷⁰⁷ A side reaction is α halogenation of the non-methyl R group. Sometimes these groups are also cleaved.⁷⁰⁸ The reaction cannot be applied to F_2 , but ketones of the form RCOCF_3 (R = alkyl or aryl) give fluoroform and RCOO^- when treated with base.⁷⁰⁹ Rate constants for cleavage of X_3CCOPh (X = F, Cl, Br) were found to be in the ratio $1 : 5.3 \times 10^{10} : 2.2 \times 10^{13}$, showing that an F_3C^- group cleaves much more slowly than the others.⁷¹⁰ In the past, the haloform reaction was used as a test for methylcarbinols and methyl ketones. Iodine was most often used as the test reagent, since iodoform (HClI_3) is an easily identifiable yellow solid. The reaction can be used for synthetic purposes. Methyl ketones (RCOCH_3) can be converted directly to methyl esters (RCO_2CH_3) by an electrochemical reaction.⁷¹¹ Trifluoromethyl ketones have been converted to ethyl esters via treatment with NaH in aq DMF followed by reaction with bromoethane.⁷¹²

12-45 Cleavage of Nonenolizable Ketones

Hydro-de-acylation

Ordinary ketones are generally much more difficult to cleave than trihalo ketones or β -diketones. However, nonenolizable ketones can be cleaved by treatment with a 10:3 mixture of $t\text{-BuOK-H}_2\text{O}$ in an aprotic solvent [e.g., ether, DMSO, 1,2-dimethoxyethane

(glyme),⁷¹³ or with solid *t*-BuOK in the absence of a solvent].⁷¹⁴ When the reaction is applied to monosubstituted diaryl ketones, that aryl group preferentially cleaves that comes off as the more stable carbanion, except that aryl groups substituted in the ortho position are more readily cleaved than otherwise because of the steric effect (relief of strain).^{714,715} In certain cases, cyclic ketones can be cleaved by base treatment, even if they are enolizable.⁷¹⁶

OS VI, 625. See also, OS VII, 297.

12-46 The Haller–Bauer Reaction

Hydro-de-acylation

Cleavage of ketones with sodium amide is called the *Haller–Bauer reaction*.⁷¹⁷ As with Reaction 12-45, which is exactly analogous, the reaction is usually applied only to non-enolizable ketones, most often to ketones of the form ArCOCR₃, where the products R₃CCONH₂ (after hydrolysis) are not easily attainable by other methods. However, many other ketones have been used, although benzophenone is virtually unaffected. It has been shown that the configuration of optically active alkyl groups (R) is retained.⁷¹⁸ The NH₂ loses its proton from the tetrahedral intermediate (**52**) before the R group is cleaved.⁷¹⁹

An extension of this cleavage process involves the reaction of α-nitro ketones (O=C—CHRNO₂) with a primary amine, neat, to give the corresponding amide, O=C—NHR'.⁷²⁰

OS V, 384, 1074.

C. Other Cleavages

12-47 The Cleavage of Alkanes

Hydro-de- *tert*- butylation, and so on

The C—C bonds of alkanes can be cleaved by treatment with superacids (Sec. 5.A.ii). For example, neopentane in FSO₃H—SbF₅ can cleave to give methane and the *tert*-butyl cation. The C—H cleavage (see Reaction 12-1) is a competing reaction and, for example,

⁷¹⁸ Paquette, L.A.; Gilday, J.P. *J. Org. Chem.* **1988**, 53, 4972; Paquette, L.A.; Ra, C.S. *J. Org. Chem.* **1988**, 53, 4978.

⁷¹⁹ Bunnett, J.F.; Hrutfiord, B.F. *J. Org. Chem.* **1962**, 27, 4152.

⁷²⁰ Ballini, R.; Bosica, G.; Fiorini, D. *Tetrahedron* **2003**, 59, 1143.

neopentane can give H_2 and the *tert*-pentyl carbocation (formed by rearrangement of the initially formed neopentyl cation) by this pathway. In general, the order of reactivity is tertiary $C-H > C-C > \text{secondary } C-H \gg \text{primary } C-H$, although steric factors cause a shift in favor of $C-C$ cleavage in such a hindered compound as tri-*tert*-butylmethane. The mechanism is similar to that shown in Reactions 12-1 and 12-20 and involves attack by H^+ on the $C-C$ bond to give a pentavalent cation.

Catalytic hydrogenation seldom breaks unactivated $C-C$ bonds (i.e., $R-R' + H_2 \rightarrow RH + R'H$), but methyl and ethyl groups have been cleaved from substituted adamantanes by hydrogenation with a $Ni-Al_2O_3$ catalyst at $\sim 250^\circ C$.⁷²¹ Certain $C-C$ bonds have been cleaved by alkali metals.⁷²²

The $C-C$ bond of 2-allyl-2-arylmalonate derivatives was cleaved, with loss of the allylic group to give the 2-arylmalonate, by treatment with a Ni catalyst.⁷²³

12-48 Decyanation or Hydro-de-cyanation

The cyano group of alkyl nitriles can be removed⁷²⁴ by treatment with metallic Na , either in liquid ammonia,⁷²⁵ or together with tris(acetylacetonato)iron(III) $[Fe(acac)_3]$ ⁷²⁶ or, with lower yields, titanocene. The two procedures are complementary. Although both can be used to decyanate many kinds of nitriles, the $Na-NH_3$ method gives high yields with R groups (e.g., trityl, benzyl, phenyl, and tertiary alkyl), but lower yields ($\sim 35-50\%$) when R = primary or secondary alkyl. On the other hand, primary and secondary alkyl nitriles are decyanated in high yields by the $Na-Fe(acac)_3$ procedure. Sodium in liquid ammonia is known to be a source of solvated electrons, and the reaction may proceed through the free radical R^\bullet that would then be reduced to the carbanion R^- , which by abstraction of a proton from the solvent, would give RH . The mechanism with $Fe(acac)_3$ is presumably different. Another procedure,⁷²⁷ which is successful for R = primary, secondary, or tertiary, involves the use of potassium metal and the crown ether dicyclohexano-18-crown-6 in toluene.⁷²⁸

α -Amino and α -amido nitriles $RCH(CN)NR'_2$ and $RCH(CN)NHCOR'$ can be decyanated in high yield by treatment with $NaBH_4$.⁷²⁹

12.C.v. Electrophilic Substitution at Nitrogen

In most of the reactions in this section, an electrophile bonds with the unshared pair of a nitrogen atom. The electrophile may be a free positive ion or a positive species attached to a carrier that breaks off in the course of the attack or shortly after:

Further reaction of **53** depends on the nature of Y and of the other groups attached to the nitrogen.

12-49 The Conversion of Hydrazines to Azides

Hydrazine-azide transformation

Monosubstituted hydrazines treated with nitrous acid give azides in a reaction exactly analogous to the formation of aliphatic diazo compounds mentioned in Reaction **13-19**. Among other reagents used for this conversion have been N_2O_4 ⁷³⁰ and nitrosyl tetrafluoroborate (NOBF_4).⁷³¹

OS **III**, 710; **IV**, 819; **V**, 157.

12-50 N-Nitrosation

N-Nitroso-de-hydrogenation

When secondary amines are treated with nitrous acid (typically formed from sodium nitrite and a mineral acid),⁷³² *N*-nitroso compounds (also called nitrosamines) are formed.⁷³³ The reaction can be accomplished with dialkyl-, diaryl-, or alkylarylamines, and even with mono-*N*-substituted amides: $\text{RCONHR}' + \text{HONO} \rightarrow \text{RCON}(\text{NO})\text{R}'$.⁷³⁴ Tertiary amines have also been *N*-nitrosated, but in these cases one group cleaves, so that the product is the nitroso derivative of a secondary amine.⁷³⁵ The group that cleaves appears as an aldehyde or ketone product. Other reagents have also been used (e.g., NOCl), which is useful for amines or amides that are not soluble in an acidic aqueous solution or where the *N*-nitroso compounds are highly reactive. *N*-Nitroso compounds can be prepared in basic solution by treatment of secondary amines with gaseous N_2O_3 , N_2O_4 ,⁷³⁶ or alkyl

nitrites,⁷³⁷ and, in aqueous or organic solvents, by treatment with BrCH_2NO_2 .⁷³⁸ Secondary amines are converted to the *N*-nitroso compound with H_5IO_6 on wet silica.⁷³⁹

The mechanism of nitrosation is essentially the same as in Reaction **13-19** up to the point where **54** is formed. Since this species cannot lose a proton, it is stable and the reaction ends there. The attacking entity can be any of those mentioned in Reaction **13-19**. The following has been suggested as the mechanism for the reaction with tertiary amines:⁷⁴⁰

The evidence for this mechanism includes the facts that nitrous oxide is a product (formed by $2\text{HNO} \rightarrow \text{H}_2\text{O} + \text{N}_2\text{O}$) and that quinuclidine, where the nitrogen is at a bridgehead and cannot give elimination, does not react. Tertiary amines have also been converted to nitrosamines with nitric acid in Ac_2O ⁷⁴¹ and with N_2O_4 .⁷⁴²

Amines and amides can be *N*-nitrated⁷⁴³ with nitric acid,⁷⁴⁴ or NO_2^+ ,⁷⁴⁵ and aromatic amines can be converted to triazenes with diazonium salts. Aliphatic primary amines can also be converted to triazenes if the diazonium salts contain electron-withdrawing groups.⁷⁴⁶ *C*-Nitrosation is discussed at Reactions **11-3** and **12-8**.

determined by the nature of the R groups, not by which R groups came from which starting compound. Both R and R' can be alkyl or aryl, but when two different aryl groups are involved, mixtures of azoxy compounds (ArNONAr, ArNONAr', and Ar'NONAr') are obtained⁷⁴⁸ and the unsymmetrical product (ArNONAr') is likely to be formed in the smallest amount. This behavior is probably caused by an equilibration between the starting compounds prior to the actual reaction ($\text{ArNO} + \text{Ar}'\text{NHOH} \rightarrow \text{Ar}'\text{NO} + \text{ArNHOH}$).⁷⁴⁹ The mechanism⁷⁵⁰ has been investigated in the presence of base. Under these conditions both reactants are converted to radical anions, which couple:

These radical anions have been detected by ESR.⁷⁵¹ This mechanism is consistent with the following result: When nitrosobenzene and phenylhydroxylamine are coupled, ¹⁸O and ¹⁵N labeling show that the two nitrogen atoms and the two oxygen atoms become equivalent.⁷⁵² Unsymmetrical azoxy compounds can be prepared⁷⁵³ by combination of a nitroso compound with an *N,N*-dibromoamine. Symmetrical and unsymmetrical azo and azoxy compounds are produced when aromatic nitro compounds react with aryliminodimagnesium reagents $[\text{ArN}(\text{MgBr})_2]$.⁷⁵⁴

12-52 N-Halogenation

N-Halo-de-hydrogenation

Treatment with sodium hypochlorite or hypobromite converts primary amines into *N*-halo- or *N,N*-dihaloamines. Secondary amines can be converted to *N*-halo secondary amines. Similar reactions can be carried out on unsubstituted and *N*-substituted amides and on sulfonamides. With unsubstituted amides the *N*-halogen product is seldom isolated but usually rearranges (see Reaction 18-13); however, *N*-halo-*N*-alkyl amides and *N*-halo imides are quite stable. The important reagents NBS and NCS are made in this manner. *N*-Halogenation has also been accomplished with other reagents (e.g., sodium bromite, NaBrO_2),⁷⁵⁵ benzyltrimethylammonium tribromide ($\text{PhCH}_2\text{NMe}_3^+\text{Br}_3^-$),⁷⁵⁶ NaCl with Oxone,⁷⁵⁷ and NCS.⁷⁵⁸ Sodium hypohalite in the presence of *tert*-butanol and acetic acid is

12-53 The Reaction of Amines With Carbon Monoxide or Carbon Dioxide

***N*-Formylation** or ***N*-Formyl-de-hydrogenation**, and so on

Three types of product can be obtained from the reaction of amines with CO, depending on the catalyst. (1) Both primary and secondary amines react with CO in the presence of various catalysts [e.g., Cu(CN)₂, Me₃N-H₂Se, and Rh or Ru complexes] to give *N*-substituted and *N,N*-disubstituted formamides, respectively.⁷⁶⁷ Primary aromatic amines react with ammonium formate to give the formamide.⁷⁶⁸ Tertiary amines react with CO and a Pd catalyst to give an amide.⁷⁶⁹ (2) Symmetrically substituted ureas can be prepared by treatment of a primary amine (or ammonia) with CO⁷⁷⁰ in the presence of Se⁷⁷¹ or S.⁷⁷² The R source can be alkyl or aryl. The same thing can be done with secondary amines, using Pd(OAc)₂—I₂—K₂CO₃.⁷⁷³ Primary aromatic amines react with β-keto esters and a Mo—ZrO₂ catalyst to give the symmetrical urea.⁷⁷⁴ Treatment of a secondary amine with nitrobenzene, selenium and carbon monoxide leads to the unsymmetrical urea.⁷⁷⁵ (3) When PdCl₂ is the catalyst, primary amines yield isocyanates.⁷⁷⁶ Isocyanates can also be obtained by treatment of CO with azides: RN₃ + CO → RNCO,⁷⁷⁷ or with an aromatic

nitroso or nitro compound and a Rh complex catalyst.⁷⁷⁸ Primary amines react with di-*tert*-butyltricarboxylate to give the isocyanate.⁷⁷⁹

Lactams are converted to the corresponding *N*-chloro lactam with $\text{Ca}(\text{OCl})_2$ with moist alumina in dichloromethane.⁷⁸⁰ Ring-expanded lactams are obtained from cyclic amines via a similar reaction⁷⁸¹ (see also, Reaction 16-22). Intramolecular carbonylation of amines also leads to lactams.⁷⁸²

A fourth type of product, a carbamate ($\text{RNHCOOR}'$), can be obtained from primary or secondary amines, if these are treated with CO , O_2 , and an alcohol ($\text{R}'\text{OH}$) in the presence of a catalyst.⁷⁸³ Primary amines react with dimethyl carbonate in supercritical CO_2 (see Sec. 9.D.ii) to give a carbamate.⁷⁸⁴ Carbamates can also be obtained from nitroso compounds, by treatment with CO , $\text{R}'\text{OH}$, $\text{Pd}(\text{OAc})_2$, and $\text{Cu}(\text{OAc})_2$,⁷⁸⁵ and from nitro compounds.⁷⁸⁶ When allylic amines ($\text{R}_2\text{C}=\text{CHRCHNR}'_2$) are treated with CO and a Pd-phosphine catalyst, the CO inserts to produce the β,γ -unsaturated amides ($\text{R}_2\text{C}=\text{CHRCHRCONR}'_2$) in good yields.⁷⁸⁷ Silyloxy carbamates ($\text{RNHCO}_2\text{SiR}'_3$) can be prepared by the reaction of a primary amine with carbon dioxide and triethylamine, followed by reaction with triisopropylsilyl triflate and tetrabutylammonium fluoride.⁷⁸⁸

Carbon dioxide reacts with amines (ArNH_2) and alkyl halides, under electrolysis conditions, to give the corresponding carbamate (ArNHCO_2Et).⁷⁸⁹ Secondary amines react with all halides and an onium salt in supercritical CO_2 (see Sec. 9.D.ii) to give the carbamate.⁷⁹⁰ *N*-Phenylthioamines react with CO and a palladium catalyst to give a thiocarbamate ($\text{ArSCO}_2\text{NR}'_2$).⁷⁹¹ Urea derivatives were obtained from amines, CO_2 , and an antimony catalyst.⁷⁹²

Aziridines can be converted to cyclic carbamates (oxazolidinones) by heating with carbon dioxide and a chromium–salen catalyst.⁷⁹³ The reaction of aziridines with LiI , and then CO_2 also generates oxazolidinones.⁷⁹⁴

Aromatic Substitution: Nucleophilic and Organometallic

In Section 10.G, category 2, it was pointed out that nucleophilic substitutions proceed so slowly at an aromatic carbon that the reactions of Chapter 10 are not feasible for aromatic substrates. There are, however, exceptions to this statement, and these exceptions form the subject of this chapter.¹ Reactions that *are* successful at an aromatic substrate are largely of five kinds: (1) reactions activated by electron-withdrawing groups ortho and para to the leaving group; (2) reactions catalyzed by very strong bases and proceeding through aryne intermediates; (3) reactions initiated by electron donors; (4) reactions in which the nitrogen of a diazonium salt is replaced by a nucleophile; and (5) coupling reactions catalyzed by transition metals, primarily Pd,² Cu, Ni, and so on. Note that solvent effects can be important.³ The transition metal catalyzed coupling reactions are included because they involve replacement of a leaving group on an aromatic ring.

13.A. MECHANISMS

There are four principal mechanisms for aromatic nucleophilic substitution.⁴ Each of the four is similar to one of the aliphatic nucleophilic substitution mechanisms discussed in Chapter 10.

13.A.i. The S_NAr Mechanism⁵

By far the most important mechanism for nucleophilic aromatic substitution consists of two steps, attack of the nucleophilic species at the ipso carbon of the aromatic ring

¹ See Zoltewicz, J.A. *Top. Curr. Chem.* **1975**, 59, 33.

(the carbon bearing the leaving group in this case), followed by elimination of the leaving group and regeneration of the aromatic ring.

The first step is usually, but not always, rate determining. It can be seen that this mechanism greatly resembles the tetrahedral mechanism discussed in Chapter 16 and, in another way, the arenium ion mechanism of electrophilic aromatic substitution discussed in Chapter 11. In all three cases, the attacking species forms a bond with the substrate, giving an intermediate (e.g., **1**) and then the leaving group departs. This mechanism is the S_NAr mechanism.⁶ The IUPAC designation is $A_N + D_N$ (the same as for the tetrahedral mechanism; cf. the designation $A_E + D_E$ for the arenium ion mechanism). This mechanism is generally found where activating groups are present on the ring (see Sec. 13.B.i).

There is a great deal of evidence for the mechanism.⁴ Probably the most convincing evidence was the isolation, as long ago as 1902, of the intermediate **2** in the reaction between 2,4,6-trinitrophenetole and methoxide ion.⁷ Intermediates of this type are stable salts, called *Meisenheimer* or *Meisenheimer–Jackson salts*,⁸ and many more have been isolated.⁹ The structures of several of these intermediates have been proved by NMR¹⁰ and by X-ray crystallography.¹¹ Further evidence comes from studies of the effect of the leaving group on the reaction. If the mechanism were similar to either the S_N1 or S_N2 mechanisms described in Chapter 10, the Ar–X bond would be broken in the rate-determining step. In the S_NAr mechanism, this bond is not broken until after the rate-determining step (i.e., if step 1 is rate

determining). There is some evidence that electron transfer may be operative during this process.¹² If the S_NAr mechanism is operating, a change in leaving group should not have much effect on the reaction rate. In the reaction of dinitro compound **3** with piperidine, when X was Cl, Br, I, SPh, SO₂Ph, or *p*-nitrophenoxy, the rates differed only by a factor of ~ 5 .¹³ This behavior would not be expected in a reaction in which the Ar—X bond is broken in the rate-determining step. The rates are not expected to be *identical*, because the nature of X affects the rate at which Y attacks.¹⁴ An increase in the electronegativity of X causes a decrease in the electron density at the site of attack, resulting in a faster attack by a nucleophile. Thus, in the reaction just mentioned, when X = F, the relative rate was 3300 (compared with I = 1). The very fact that fluoro is the best leaving group among the halogens in most aromatic nucleophilic substitutions is good evidence that the mechanism is different from the S_N1 and the S_N2 mechanisms, where fluoro is by far the poorest leaving group of the halogens. This is an example of the element effect (Sec. 10.F).

The pattern of base catalysis of reactions with amine nucleophiles provides additional evidence. Bases only catalyze these reactions when a relatively poor leaving group (e.g., OR) is present (not Cl or Br) and only when relatively bulky amines are nucleophiles.¹⁵ Bases could not catalyze step 1, but if amines are nucleophiles, bases can catalyze step 2. Base catalysis is found precisely in those cases where the amine moiety cleaves easily, but X does not, so that k_1 is large and step 2 is rate determining. This is evidence for the S_NAr mechanism because it implies two steps. Furthermore, in cases where bases *are* catalysts, they catalyze only at low-base concentrations: A plot of the rate against the base concentration shows that small increments of base rapidly increase the rate until a certain concentration of base is reached, after which further base addition no longer greatly affects the rate. This behavior, based on a partitioning effect (see Sec. 11.A.i), is also evidence for the S_NAr mechanism. At low-base concentration, each increment of base, by increasing the rate of step 2, increases the fraction of intermediate that goes to product rather than reverting to reactants. At high-base concentration, the process is virtually complete: There is very little reversion to reactants and the rate becomes dependent on step 1. Just how bases catalyze step 2 has been investigated. For protic solvents, two proposals have been presented. One is that step 2 consists of two steps: rate-determining deprotonation of **4** followed by

rapid loss of X, and that bases catalyze the reaction by increasing the rate of the deprotonation step.¹⁶ According to the other proposal, loss of X assisted by BH^+ is rate determining.¹⁷ Two mechanisms, both based on kinetic evidence, have been proposed for aprotic solvents (e.g., benzene). In both proposals, the ordinary $\text{S}_{\text{N}}\text{Ar}$ mechanism operates, but in one the attacking species involves two molecules of the amine (the *dimer mechanism*),¹⁸ while in the other there is a cyclic transition state.¹⁹ Further evidence for the $\text{S}_{\text{N}}\text{Ar}$ mechanism has been obtained from $^{18}\text{O}/^{16}\text{O}$ and $^{15}\text{N}/^{14}\text{N}$ isotope effects.²⁰

Step 1 of the $\text{S}_{\text{N}}\text{Ar}$ mechanism has been studied for the reaction between picryl chloride (as well as other substrates) and OH^- ions (Reaction **13-1**), and spectral evidence has been reported²¹ for two intermediates, one a π complex (Sec. 11.A.i), and the other a radical ion–radical pair.

As with the tetrahedral mechanism at an acyl carbon, nucleophilic catalysis (Sec. 16.A.i) has been demonstrated with an aryl substrate, in certain cases.²² There is also evidence of an interaction of anions with the π -cloud of aromatic compounds.²³

13.A.ii. The $\text{S}_{\text{N}}1$ Mechanism

For aryl halides and sulfonates, even active ones, a unimolecular $\text{S}_{\text{N}}1$ mechanism (IUPAC: $\text{D}_{\text{N}} + \text{A}_{\text{N}}$) is very rare; it has only been observed for aryl triflates in which both ortho positions contain bulky groups (*tert*-butyl or SiR_3).²⁴ It is in reactions with diazonium salts²⁵ that this mechanism is important²⁶:

²⁶ Aryl iodonium salts Ar_2I^+ also undergo substitutions by this mechanism (and by a free radical mechanism).

Among the evidence for the S_N1 mechanism²⁷ with aryl cations as intermediates,^{28,29} is the following:³⁰

1. The reaction rate is first order in diazonium salt and independent of the concentration of Y.
2. When high concentrations of halide salts are added, the product is an aryl halide, but the rate is independent of the concentration of the added salts.
3. The effects of ring substituents on the rate are consistent with a unimolecular rate-determining cleavage.³¹
4. When reactions were run with substrate deuterated in the ortho position, isotope effects of ~ 1.22 were obtained.³² It is difficult to account for such high secondary isotope effects in any other way except that an incipient phenyl cation is stabilized by hyperconjugation (see Sec. 2.M),³³ which is diminished when hydrogen is replaced by deuterium.

5. That the first step is reversible cleavage³⁴ was demonstrated by the observation that when $\text{Ar}^{15}\text{N}^+ \equiv \text{N}$ was the reaction species, recovered starting material contained not only $\text{Ar}^{15}\text{N}^+ \equiv \text{N}$, but also $\text{Ar}^{15}\text{N}^+ \equiv \text{N}$.^{35,36} This could arise only if the nitrogen breaks away from the ring and then returns. Additional evidence was obtained by treating $\text{PhN}^+ \equiv \text{N}^{15}\text{N}$ with unlabeled N_2 at various pressures. At 300 atm, the recovered product had lost $\sim 3\%$ of the labeled nitrogen, indicating that PhN_2^+ was exchanging with atmospheric N_2 .³⁶

There is kinetic and other evidence³⁷ that step 1 is more complicated and involves two steps, both reversible:

Intermediate **5**, which is probably some kind of a tight ion–molecule pair, has been trapped with carbon monoxide.³⁸

13.A.iii. The Benzyne Mechanism³⁹

Some aromatic nucleophilic substitutions are clearly different in character from those that occur by the S_NAr mechanism (or the S_N1 mechanism). These substitutions occur with aryl halides that have no activating groups; stronger bases are required than those normally used; and the incoming group does not always take the position vacated by the leaving group. The validity of the latter statement was elegantly demonstrated by the reaction of 1-¹⁴C-chlorobenzene with potassium amide:

The product consisted of almost equal amounts of aniline labeled in the 1 and 2 positions.⁴⁰

A mechanism that can explain all these facts involves elimination followed by addition. In step 1, a suitable base removes the ortho hydrogen, with subsequent (or concomitant) loss of the chlorine (leaving group) to

generate symmetrical intermediate **6**⁴¹ called benzyne⁴² (see below).⁴³ In step 2, benzyne is attacked by the NH_3 at either of two positions, which explains why about one-half of the aniline produced from the radioactive chlorobenzene was labeled at the 2 position. The fact that the 1 and 2 positions were not labeled equally is the result of a small isotope effect. Other evidence for this mechanism follows:

1. If the aryl halide contains two ortho substituents, the reaction should not be able to occur. This is indeed the case.³⁸

2. It had been known many years earlier that aromatic nucleophilic substitution occasionally results in substitution at a different position. This is called *cine substitution*⁴⁴ and can be illustrated by the conversion of *o*-bromoanisole to *m*-aminoanisole.⁴⁵ In this particular case, only the meta isomer is formed. The reason a 1:1 mixture is not formed is that the intermediate **7** is not symmetrical and the methoxy group directs the incoming group meta, but not ortho (see Sec. 13.B.i). However, not all cine substitutions proceed by this kind of mechanism (see Reaction **13-30**). A study of the influence of structure on the formation of substituted benzyne, along with rate studies, has been reported.⁴⁶

3. The fact that the order of halide reactivity is Br > I > Cl > F (when the reaction is performed with KNH₂ in liquid NH₃) shows that the S_NAr mechanism is not operating here.⁴⁰

In the conversion of the substrate to **7**, either proton removal or subsequent loss of halide ion can be rate determining. In fact, the unusual leaving-group order just mentioned (Br > I > Cl) stems from a change in the rate-determining step. When the leaving group is Br or I, proton removal is rate determining and the rate order for this step is F > Cl > Br > I. When Cl or F is the leaving group, cleavage of the C—X bond is rate determining and the order for this step is I > Br > Cl > F. Confirmation of the latter order was found in a direct competitive study. *meta*-Dihalobenzenes in which the two halogens are different were treated with ⁻NH₂.⁴⁷ In such compounds, the most acidic hydrogen is the one between the two halogens; when it leaves, the remaining anion can lose either halogen. Therefore a study of which halogen is preferentially lost provides a direct measure of leaving-group ability. The order was found to be I > Br > Cl.^{47,48}

Species, such as **6** and **7**, are called *benzyne*s (sometimes *dehydrobenzenes*), or more generally, *arynes*.⁴⁹ The mechanism in which such species are intermediates is known as the *benzyne mechanism*. Benzyne are very reactive, and neither benzyne nor any other arynes has yet been isolated under ordinary conditions,⁵⁰ but benzyne has been isolated in an Ar matrix at 8 K,⁵¹ and its IR spectrum is observed. In addition, benzyne can be trapped (e.g., they undergo the *Diels–Alder reaction*, See Reaction **15-60**). Note that the extra pair of electrons does not affect the aromaticity. However, evaluation by a series of aromaticity indicators, including magnetic susceptibility anisotropies and exaltations,

nucleus-independent chemical shifts (NICS), aromatic stabilization energies, and valence bond Pauling resonance energies point to the *o*-benzyne > *m*-benzyne > *p*-benzyne aromaticity order.⁵² The relative order with respect to benzene depends on the aromaticity criterion.⁴⁸ Note that tunable reactivity for *m*-benzynes has been demonstrated.⁵³ The aromatic sextet from the aromatic precursor functions as a closed ring, and the two additional electrons are merely located in a π orbital that covers only two carbons. Benzyne does not have a formal triple bond, since two canonical forms (**A** and **B**) contribute to the hybrid. The Ir spectrum, mentioned above, indicates that **A** contributes more than **B**. Not only benzene rings, but also other aromatic rings⁵⁴ and even non-aromatic rings (Sec. 10.F) can react through this kind of intermediate. Of course, the non-aromatic rings do have a formal triple bond. When a benzyne unit is fused to a small ring, strain induced regioselectivity was observed in its reactions.⁵⁵

13.A.iv. The $S_{RN}1$ Mechanism

When 5-iodo-1,2,4-trimethylbenzene (**8**) was treated with KNH_2 in NH_3 , **9** and **10** were formed in the ratio 0.63:1. The presence of an unactivated substrate, a strong base, and the occurrence of cine substitution along with normal substitution are strong indications of a benzyne mechanism. Yet if that were so, the 6-iodo isomer of **8** should have given **9** and **10** in the same ratio (because the same aryne intermediate would be formed in both cases), but in this case the ratio of **9** to **10** was 5.9:1 (the chloro and bromo analogues did give the same ratio (1.46:1), showing that the benzyne mechanism may be taking place there).

To explain the iodo result, it has been proposed⁵⁶ that in addition to the benzyne mechanism, a free radical mechanism is also operating here:

Heterocycl. Chem.* **1971**, 40, 121; Kauffmann, T.; Wirthwein, R. *Angew. Chem, Int. Ed.* **1971**, 10, 20.

⁵⁵ Hamura, T.; Ibusuki, Y.; Sato, K.; Matsumoto, T.; Osamura, Y.; Suzuki, K. *Org. Lett.* **2003**, 5, 3551.

⁵⁶ Kim, J.K.; Bunnett, J.F. *J. Am. Chem. Soc.* **1970**, 92, 7463, 7464.

This is called the $S_{RN}1$ mechanism,⁵⁷ and many other examples are known (see Reactions **13-3**, **13-4**, **13-6**, and **13-14**). The IUPAC designation is $T + D_N + A_N$.⁵⁸ Note that the last step of the mechanism produces $ArI^{\bullet-}$ radical ions, so the process is a chain mechanism⁵⁹ (see Sec. 14.A.i). An electron donor is required to initiate the reaction. In the case above, it was solvated electrons from KNH_2 in NH_3 . Evidence was that the addition of potassium metal (a good producer of solvated electrons in ammonia) completely suppressed the cine substitution. Further evidence for the $S_{RN}1$ mechanism was that addition of radical scavengers, which would suppress a free radical mechanism, led to **9:10** ratios much closer to 1.46:1. Numerous other observations of $S_{RN}1$ mechanisms that were stimulated by solvated electrons and inhibited by radical scavengers have also been recorded.⁶⁰ Further evidence for the $S_{RN}1$ mechanism in the case above was that some 1,2,4-trimethylbenzene was found among the products. This could easily be formed by abstraction by Ar^{\bullet} of H from the solvent NH_3 . Besides initiation by solvated electrons,⁶¹ $S_{RN}1$ reactions have been initiated photochemically,⁶² electrochemically,⁶³ and even thermally.⁶⁴

The $S_{RN}1$ reactions have a fairly wide scope. The efficiency of the reaction has been traced to the energy level of the radical anion of the substitution product.⁶⁵ There is no requirement for activating groups or strong bases, but in DMSO haloarenes are less reactive as the stability of the anion increases.⁶⁶ The reaction has also been done in liquid ammonia, promoted by ultrasound (Sec. 7.B),⁶⁷ and ferrous ion has been used as a catalyst.⁶⁸ Alkyl, alkoxy, aryl, and COO^- groups do not interfere, although Me_2N , O^- , and NO_2 groups do interfere. Cine substitution is not found.

13.A.v. Other Mechanisms

There is no clear-cut proof that a one-step S_N2 mechanism, so important at a saturated carbon, ever actually occurs with an aromatic substrate. The hypothetical aromatic S_N2 process is sometimes called the *one-stage* mechanism to distinguish it from the *two-stage* S_NAr mechanism. A "clean" example of a $S_{RN}2$ reaction has been reported, the

conversion of **11** to **12** in methanol.⁶⁹ Both $S_{RN}1$ and $S_{RN}2$ reactions have been reviewed.⁷⁰

Some of the reactions in this chapter operate by still other mechanisms, among them an addition–elimination mechanism (see Reaction **13-17**). A new mechanism has been reported in aromatic chemistry, a reductively activated “polar” nucleophilic aromatic substitution.⁷¹ The reaction of phenoxide with *p*-dinitrobenzene in DMF shows radical features that cannot be attributed to a radical anion, and it is not $S_{RN}2$. The new designation was proposed to account for these results.

13.B. REACTIVITY

13.B.i. The Effect of Substrate Structure

In the discussion of electrophilic aromatic substitution (Chapter 11), equal attention was paid to the effect of substrate structure on reactivity (activation or deactivation) and on orientation. The question of orientation was important because in a typical substitution there are four or five hydrogen atoms that could serve as leaving groups. This type of question is much less important for aromatic nucleophilic substitution, since in most cases there is only one potential leaving group in a molecule. Therefore attention is largely focused on the reactivity of one molecule compared with another and not on the comparison of the reactivity of different positions within the same molecule.

S_NAr Mechanism. These substitutions are accelerated by electron-withdrawing groups, especially in positions ortho and para to the leaving group⁷² and hindered by electron-attracting groups. This is, of course, opposite to the effects of these groups on electrophilic substitutions, and the reasons are similar to those discussed in Section 11.A.i. When attached to a benzene ring, the rate of reaction depends on the substituent.⁷³ Activating groups include 2-nitro,^{74,75} N_2^+ , NO, or C=N units with strong nucleophiles and when a nitro group is attached to SO_2Me , NMe_3 , CF_3 , CN, CHO, COR, CO_2H , SO_3 , halogen, H, Me, or OMe activate.⁷³ Table 13.1 contains a list of groups arranged approximately in order of activating or deactivating ability.^{73–76} Nitrogen

atoms are also strongly activating (especially to the α and γ positions) and are even more so when quaternized.⁷⁷ Both 2- and 4-chloropyridine, for example, are often used as substrates. Heteroaromatic amine *N*-oxides are readily attacked by nucleophiles in the 2 and 4 positions, but the oxygen is generally lost in these reactions.⁷⁸ The most highly activating group (N_2^+) is seldom deliberately used to activate a reaction, but it sometimes happens that in the diazotization of a compound (e.g., *p*-nitroaniline or *p*-chloroaniline), the group para to the diazonium group is replaced by OH from the solvent or by X from $\text{ArN}_2^+ \text{X}^-$ untouched. By far, the most common activating group is the nitro group and the most common substrates are 2,4-dinitrophenyl halides and 2,4,6-trinitrophenyl halides (also called picryl halides).⁷⁹ Polyfluorobenzenes⁸⁰ (see **11**) also undergo aromatic nucleophilic substitution quite well.⁸¹ Benzene rings that lack activating substituents are generally not useful substrates for the $\text{S}_{\text{N}}\text{Ar}$ mechanism, because the two extra electrons in **1** are in an antibonding orbital (Sec. 2.A). Activating groups, by withdrawing electron density, are able to stabilize the intermediates and the transition states leading to them. Reactions taking place by the $\text{S}_{\text{N}}\text{Ar}$ mechanism are also accelerated when the aromatic ring is coordinated with a transition metal.⁸²

Just as electrophilic aromatic substitutions were found more or less to follow the *Hammett relationship* (with σ^+ instead of σ ; see Sec. 9.C) so do nucleophilic substitutions, with σ^- instead of σ for electron-withdrawing groups.⁸³

Benzynes Mechanism. Two factors affect the position of the incoming group, the first being the direction in which the aryne forms.⁸⁴ When there are groups ortho or para to the leaving group, there is no choice:

but when a meta group is present, the aryne can form in two different ways:

⁷⁷ Miller, J.; Parker, A.J. *Aust. J. Chem.* **1958**, *11*, 302.

⁷⁸ Berliner, E.; Monack, L.C. *J. Am. Chem. Soc.* **1952**, *74*, 1574.

⁷⁹ See de Boer, T.J.; Dirkx, I.P. in Feuer, H. *The Chemistry of the Nitro and Nitroso Groups*, pt. 1, Wiley, NY, **1970**, pp. 487–612.

⁸⁰ Fluorine significantly activates ortho and meta positions, and slightly deactivates para positions (see Table 13.1): See Chambers, R.D.; Seabury, N.J.; Williams, D.L.H.; Hughes, N. *J. Chem. Soc. Perkin Trans. 1* **1988**, 255.

⁸² See Balas, L.; Jhurry, D.; Latxague, L.; Grelrier, S.; Morel, Y.; Hamdani, M.; Ardoin, N.; Astruc, D. *Bull. Soc. Chim. Fr.* **1990**, 401.

⁸³ See Bartoli, G.; Todesco, P.E. *Acc. Chem. Res.* **1977**, *10*, 125; a list of σ^- values in Table 9.4.

⁸⁴ From Roberts, J.D.; Vaughan, C.W.; Carlsmith, L.A.; Semenow, D.A. *J. Am. Chem. Soc.* **1956**, *78*, 611. See Hoffmann, R.W. *Dehydrobenzene and Cycloalkynes*, Academic Press, NY, **1973**, pp. 134–150.

In such cases, the more acidic hydrogen is removed. Since acidity is related to the field effect of Z, it can be stated that an electron-attracting Z favors removal of the ortho hydrogen while an electron-donating Z favors removal of the para hydrogen. The second factor is that the aryne, once formed, can be attacked at two positions. The favored position for nucleophilic attack is the one that leads to the more stable carbanion intermediate. This in turn also depends on the field effect of Z. For *-I* groups, the more stable carbanion is the one in which the negative charge is closer to the substituent. These principles are illustrated by the reaction of the three dichlorobenzenes (**13-15**) with alkali metal amides to give the predicted products shown. In each case, the predicted product was the one chiefly formed.⁸⁵ The observation that *m*-aminoanisole is obtained, mentioned in Section 13.A.iii, is also in accord with these predictions.

13.B.ii. The Effect of the Leaving Group⁸⁶

The common leaving groups in aliphatic nucleophilic substitution (halide, sulfate, sulfonate, NR_3^+ , etc.) are also common leaving groups in aromatic nucleophilic substitutions, but the groups NO_2 , OR, OAr, SO_2R ⁸⁷, and SR, which are not generally lost in aliphatic systems, *are* leaving groups when attached to aromatic rings. Surprisingly, NO_2 is a particularly good leaving group.⁸⁸ An approximate order of leaving-group ability is⁸⁹ $\text{F} > \text{NO}_2 > \text{OTs} > \text{SOPh} > \text{Cl}, \text{Br}, \text{I} > \text{N}_3 > \text{NR}_3^+ > \text{OAr}, \text{OR}, \text{SR}, \text{NH}_2$. However, this depends greatly on the nature of the nucleophile, as illustrated by the fact that $\text{C}_6\text{Cl}_5\text{OCH}_3$ treated with NH_2^- gives mostly $\text{C}_6\text{Cl}_5\text{NH}_2$; that is, one methoxy group is replaced in preference to five chlorines.⁹⁰ As usual, OH can be a leaving group if it is converted to an

inorganic ester. Among the halogens, fluoro is generally a much better leaving group than the other halogens, which have reactivities fairly close together. The order is usually $\text{Cl} > \text{Br} > \text{I}$, but not always.⁹¹ The leaving-group order is quite different from that for the $\text{S}_{\text{N}}1$ or $\text{S}_{\text{N}}2$ mechanisms. The most likely explanation is that the first step of the $\text{S}_{\text{N}}\text{Ar}$ mechanism is usually rate determining, and this step is promoted by groups with strong $-I$ effects. This would explain why fluoro and nitro are such good leaving groups when this mechanism is operating. Fluoro is the poorest leaving group of the halogens when the second step of the $\text{S}_{\text{N}}\text{Ar}$ mechanism is rate determining or when the benzyne mechanism is operating. The four halogens, as well as SPh , NMe_3^+ , and $\text{OPO}(\text{OEt})_2$, have been shown to be leaving groups in the $\text{S}_{\text{RN}}1$ mechanism.⁶⁰ The only important leaving group in the $\text{S}_{\text{N}}1$ mechanism is N_2^+ .

13.B.iii. The Effect of the Attacking Nucleophile⁹²

It is not possible to construct an invariant nucleophilicity order because different substrates and different conditions lead to different orders of nucleophilicity, but an overall approximate order is $^-\text{NH}_2 > \text{Ph}_3\text{C}^- > \text{PhNH}^-$ (aryne mechanism) $> \text{ArS}^- > \text{RO}^- > \text{R}_2\text{NH} > \text{ArO}^- > ^-\text{OH} > \text{ArNH}_2 > \text{NH}_3 > \text{I}^- > \text{Br}^- > \text{Cl}^- > \text{H}_2\text{O} > \text{ROH}$.⁹³ As with aliphatic nucleophilic substitution, nucleophilicity is generally dependent on base strength and nucleophilicity increases as the attacking atom moves down a column of the periodic table, but there are some surprising exceptions (e.g., ^-OH), a stronger base than ArO^- , is a poorer nucleophile.⁹⁴ In a series of similar nucleophiles (e.g., substituted anilines), nucleophilicity *is* correlated with base strength. Oddly, the cyanide ion is not a nucleophile for aromatic systems, except for sulfonic acid salts and in the *von Richter* (13-30) and *Rosenmund-von Braun* (13-8) reactions, which are special cases. Studies on the nature of the nucleophile continue. Indeed, the second-order rate constants for vicarious nucleophilic substitution reactions of some carbanions were measured to define electrophilicity parameters for electron-deficient heteroarenes.⁹⁵

13.C. REACTIONS

In the first part of this section, reactions are classified according to attacking species, with all leaving groups considered together, except for hydrogen and N_2^+ , which are treated subsequently. Finally, a few rearrangement reactions are discussed.

13.C.i. All Leaving Groups Except Hydrogen and N₂⁺

A. Oxygen Nucleophiles

13-1 Hydroxylation of Aromatic Compounds

Hydroxy-de-halogenation

Direct hydroxylation of aryl halides to give phenols generally requires the presence of activating groups or exceedingly strenuous reaction conditions.⁹⁶ When the reaction is carried out at high temperatures, cine substitution is observed, indicating a benzyne mechanism.⁹⁷ However, phenols are prepared from aryl halides using KOH and a Pd catalyst at 100 °C.⁹⁸ Formation of phenols is possible using AgNO₃ with microwave irradiation,⁹⁹ or CuI.¹⁰⁰ There is a hydrogen peroxide promoted hydroxylation of aryl halides with metal hydroxide salts.¹⁰¹ Other microwave-promoted phenol-forming reactions are known.¹⁰²

A slightly related reaction involves the amino group of naphthylamines where can be replaced by a hydroxyl group after treatment with aq bisulfite.¹⁰³ The scope is greatly limited; the amino group, with very few exceptions may be NH₂ or NHR and must be on a naphthalene ring. The reaction is reversible (see **13-6**), and both the forward and reverse reactions are called the *Bucherer reaction*.

An indirect method for conversion of an aryl halide to a phenol involves initial conversion to an organometallic, followed by oxidation to the phenol. For the conversion of aryl *Grignard reagents* to phenols, a good procedure is the use of trimethyl borate followed by oxidation with H₂O₂ in acetic acid¹⁰⁴ (see Reaction **12-31**). Phenols have been obtained from unactivated aryl halides by treatment with borane and a metal (e.g., lithium), followed by oxidation with alkaline H₂O₂.¹⁰⁵ Arylboronic acids [ArB(OH)₂] are oxidized by aq H₂O₂ to give the corresponding phenol.¹⁰⁶ The reaction of an aromatic compound

with a borane in the presence of an Ir catalyst, followed by oxidation with aq Oxone, gave the corresponding phenol.¹⁰⁷ Aryllithium reagents have been converted to phenols by treatment with oxygen.¹⁰⁸ In a related indirect method, arylthallium bis(trifluoroacetates) (prepared by Reaction 12-23) can be converted to phenols by treatment with lead tetraacetate followed by triphenylphosphine, and then dilute NaOH.¹⁰⁹ Diarylthallium trifluoroacetates undergo the same reaction.¹¹⁰

OS I, 455; II, 451; V, 632. Also see, OS V, 918.

13-2 Alkali Fusion of Sulfonate Salts

Oxido-de-sulfonato-substitution

Aryl sulfonic acids can be converted, through their salts, to phenols, by alkali fusion. In spite of the extreme conditions, the reaction gives fairly good yields, except when the substrate contains other groups that are attacked by alkali at the fusion temperatures. Milder conditions can be used when the substrate contains activating groups, but the presence of deactivating groups hinders the reaction. The mechanism is not clear, but a benzyne intermediate has been ruled out by the finding that cine substitution does not occur.¹¹¹

OS I, 175; III, 288.

13-3 Replacement by OR or OAr

Alkoxy-de-halogenation

This reaction is similar to 13-1 and, like that one, generally requires activated substrates.^{96,112} With unactivated substrates, side reactions predominate, although aryl methyl ethers have been prepared from unactivated chlorides by treatment with MeO^- in HMPA.¹¹³ This reaction gives better yields than 13-1 and is used more often. A good solvent is liquid ammonia. Aryl chlorides react with phenol and KOH with microwave irradiation to give the diaryl ether.¹¹⁴ Potassium phenoxide reacts with iodobenzene in an ionic solvent at 100 °C with CuCl .¹¹⁵ Sodium methoxide reacted with *o*- and *p*-fluoronitrobenzenes $\sim 10^9$ times faster in NH_3 at $-70\text{ }^\circ\text{C}$ than in MeOH .¹¹⁶ Phase-transfer catalysis

has also been used.¹¹⁷ Phenols reacted with aryl fluorides¹¹⁸ or aryl chlorides¹¹⁹ to give the diaryl ether. Intramolecular versions are known that produce benzofurans.¹²⁰ Heating aryl iodides and phenols in an ionic liquid forms ethers.¹²¹ In addition to halides, leaving groups can be other OR, or even OH.¹²²

For aroxide nucleophiles, the reaction is promoted by Cu salts,¹²³ and activating groups need not be present. This method of preparation of diaryl ethers is called the *Ullmann ether synthesis*¹²⁴ and should not be confused with the *Ullmann biaryl synthesis* (13-11). The reactivity order is typical of nucleophilic substitutions, despite the presence of the Cu salts.¹²⁵ Copper-catalyzed coupling is known using ligand and additive-free conditions.¹²⁶ Because aryloxycopper(I) reagents (ArOCu) react with aryl halides to give ethers, it has been suggested that they are intermediates in the Ullmann ether synthesis.¹²⁷ Indeed, high yields of ethers can be obtained by reaction of ROCu or ArOCu with aryl halides.¹²⁸ Aryl halides are converted to aryl ethers with aliphatic alcohols in the presence of suitable Cu salts.¹²⁹

An increasingly important variation of this reaction couples an alkoxide and an aryl halide to give aryl ethers in the presence of a Pd catalyst and a suitable ligand.¹³⁰ Ligand effects are important in such reactions.¹³¹ A Pd catalyzed, intramolecular displacement of an aryl halide with a pendant alkoxide unit leads to dihydrobenzofurans.¹³² Nickel catalysts have also been used.¹³³ Aryl iodides react with phenols in the presence of K₂CO₃, CuI, and Raney nickel alloy.¹³⁴ An Fe catalyzed etherification reaction is known.¹³⁵

In a related reaction, acid salts (RCOO^-) are sometimes used as nucleophiles.¹³⁶ Unactivated substrates have been converted to carboxylic esters in low-to-moderate yields under oxidizing conditions.¹³⁷ The following chain mechanism, called the $\text{S}_{\text{ON}}2$ mechanism,¹³⁸ has been suggested¹³⁸:

OS I, 219; II, 445; III, 293, 566; V, 926; VI, 150; X, 418.

B. Sulfur Nucleophiles

13-4 Replacement by SH or SR

Aryl thiols and thioethers can be prepared by reactions that are similar to **13-1** and **13-3**.¹³⁹ Activated aryl halides generally give good results, but side reactions are occasionally important. Some reagents give the thiol directly. 4-Bromonitrobenzene reacts with Na_3SPO_3 , in refluxing methanol, to give 4-nitrothiophenol, for example.¹⁴⁰

Diaryl sulfides can be prepared by the use of ^-SAr .¹⁴¹ Even unactivated aryl halides react with ^-SAr if polar aprotic solvents (e.g., DMF,¹⁴² DMSO¹⁴³ 1-methyl-2-pyrrolidinone,¹⁴⁴ or HMPA)¹⁴⁵ are used, though the mechanisms are still mostly or entirely nucleophilic substitution. 2-Iodothiophene reacts directly with thiophenol to give 2-(phenylthio)thiophene.¹⁴⁶

Metal-catalyzed reactions of aryl halides and thiols lead to thioethers. Perhaps the most common metal used nowadays is Pd.¹⁴⁷ Copper catalysts have been used,¹⁴⁸ including

catalysis in aqueous media,¹⁴⁹ and also Ni¹⁵⁰ or In¹⁵¹ catalysts. Copper-catalyzed coupling is known using ligand- and additive-free conditions.¹⁵² Aryl iodides react with dialkyl disulfides and a nickel catalyst to give aryl alkyl sulfides.¹⁵³ Diaryl sulfides can also be prepared (in high yields) by treatment of unactivated aryl iodides with ArS[−] in liquid ammonia under irradiation.¹⁵⁴ The mechanism in this case is probably S_{RN}1. The reaction (with unactivated halides) has also been carried out electrolytically, with a Ni catalyst.¹⁵⁵ In the presence of a Pd catalyst, thiophenols react with diaryliodonium salts (Ar₂I⁺BF₄[−]) to give the unsymmetrical diaryl sulfide.¹⁵⁶

Other sulfur nucleophiles also react with activated aryl halides:

Arylboronic acids [ArB(OH)₂] react with thiols and copper(II) acetate to give the corresponding alkyl aryl sulfide.¹⁵⁷ Arylboronic acids also react with *N*-methylthiosuccinimide, with a Cu catalyst, to give the aryl methyl sulfide.¹⁵⁸

Aryl sulfones have been prepared from sulfinic acid salts, aryl iodides, and CuI.¹⁵⁹ A Pd catalyzed arylation of sulfenate anions leads to aryl sulfoxides.¹⁶⁰ The copper-catalyzed reaction of NaO₂SMe and aryl iodides give the aryl methyl sulfone,¹⁶¹ and aryl sulfones have been prepared from arylboronic acids using a Cu catalyst.¹⁶² A similar synthesis of diaryl sulfones has been reported using a Pd catalyst.¹⁶³

Aryl selenides (ArSeAr and ArSeAr') can be prepared by similar methodology. Symmetrical diaryl selenides were prepared by the reaction of iodobenzene with diphenyl diselenide (PhSeSePh), in the presence of Mg and a Cu catalyst.¹⁶⁴ Aryl halides react with tin selenides (ArSeSnR₃), with a Cu catalyst, to give the diaryl selenide,¹⁶⁵ and a CuS—Fe catalyst was also used.¹⁶⁶

Thiocyanates have been generated from unactivated aryl halides using charcoal supported copper(I) thiocyanate.¹⁶⁷

C. Nitrogen Nucleophiles

13-5 Replacement of Halogen by NH₂, NHR, or NR₂

Amino-de-halogenation

Amido-de-halogenation

Activated aryl halides react with ammonia and primary and secondary amines to give the corresponding arylamines. Primary and secondary amines usually give better results than ammonia, with piperidine especially reactive. Picryl chloride (2,4,6-trinitrochlorobenzene) is often used to form amine derivatives. 2-Chloronitrobenzene also reacts with aniline derivatives directly with microwave irradiation.¹⁶⁸ Other leaving groups in this reaction may be NO₂,¹⁶⁹ N₃, OSO₂R, OR, SR, N=NAr (where Ar contains electron-withdrawing groups)¹⁷⁰ and even NR₂.¹⁷¹ Aryl triflates react directly with secondary amines in *N*-methylpyrrolidine solvent using microwave irradiation.¹⁷² Aniline derivatives react with activated aromatic rings, in the presence of tetrabutylammonium fluoride and under photolysis conditions, to give a *N,N*-diarylamine.¹⁷³ Arylation of amines with aryl halides has also been done in ionic liquids¹⁷⁴ and in supercritical CO₂.¹⁷⁵ Flow reactor technology has been used for the direct, uncatalyzed amination of 2-chloropyridine.¹⁷⁶

Aryl halides can be converted to amines by the use of NaNH₂, NaNHR, or NaNR₂.¹⁷⁷ Lithium dialkylamides also react with aryl halides to give the *N*-arylamine.¹⁷⁸ With amide base reagents, the benzyne mechanism generally operates, so *cine* substitution (Sec. 13.A.iii, category 2) is often found. The amide base is usually generated by reaction of the amine with an organolithium reagent, but other bases may be used. The reaction of an amine, an aryl halide, and potassium *tert*-butoxide generates the *N*-aryl amine.¹⁷⁹ Triarylamines have been prepared in a similar manner from ArI and Ar'₂NLi, even with unactivated ArI.¹⁸⁰

Aryl fluorides react in the presence of KF–alumina and 18-crown-6 in DMSO.¹⁸¹ Aryl fluorides react with amines in the presence of potassium carbonate/DMSO and ultrasound,¹⁸² and aryl chlorides react on basic alumina with microwave irradiation.¹⁸³

2-Fluoropyridine reacts with R_2NBH_3Li to give the 2-aminoalkylpyridine.¹⁸⁴ 2,4-Dinitrofluorobenzene, known as *Sanger's reagent*, is used to tag the amino end of a peptide or protein chain.¹⁸⁵

The reaction of amines with aryl halides can be done under milder conditions using a catalyst to initiate or mediate the reaction. Both amines (aliphatic and aniline derivatives)¹⁸⁶ and amide bases¹⁸⁷ have been coupled to aryl halides using Pd catalysts and an appropriate ligand.¹⁸⁸ A considerable amount of work¹⁸⁹ has been done to vary the nature of the ligand and the Pd catalyst, as well as the base.¹⁹⁰ Work to discern the mechanism of this reaction has also received considerable attention.¹⁹¹ This amination has come to be called the *Buchwald–Hartwig Cross-Coupling Reaction*.

Polymer-supported Pd catalysts,¹⁹² polymer-bound phosphine ligands used in conjunction with a Pd catalyst,¹⁹³ and polymer-bound amines¹⁹⁴ have been used for *N*-arylation. These reactions have been done in ionic liquids using a Pd catalyst.¹⁹⁵ Palladium-catalyzed amination of aryl halides has been reported using microwave irradiation.¹⁹⁶ Catalysts are available for the amination of aryl halides in aqueous media.¹⁹⁷ The Pd-catalyzed amination of aryl substrates is not limited to halides, and the reaction with mesylates lead to arylamines.¹⁹⁸ Arylamines with chiral substituents on nitrogen can be prepared using a Pd-catalyst with optically active ligands.¹⁹⁹

Aniline derivatives have been prepared by the reaction of aryl chlorides with silylamines (Ph_3SiNH_2) using lithium hexamethyldisilazide and a Pd catalyst.²⁰⁰ Amines react with

$\text{Ph}_2\text{I}^+\text{BF}_4^-$, in the presence of Pd catalysts,²⁰¹ or a CuI catalyst²⁰² to give the *N*-phenyl amine. Aminoalkylation of heteroaromatic rings is possible, as in the reaction of 3-bromothiophene with a primary amine and a Pd catalyst.²⁰³ 2-Halopyridines react to give the 2-aminoalkyl pyridine.²⁰⁴

Copper catalysts have been used for the reaction of amines or aniline derivatives with aryl halides.²⁰⁵ The selectivity of *O*- versus *N*-arylation for reactions of amino alcohols has been discussed.²⁰⁶ Copper-catalyzed amination reactions can be done in aqueous media using 2-dimethylaminoethanol as a ligand.²⁰⁷ Ammonium salts serve as a nitrogen source in some cases.²⁰⁸ In the *Goldberg reaction*, an aryl bromide reacts with an acetanilide in the presence of K_2CO_3 and CuI to give an *N*-acetyldiarylamine, which can be hydrolyzed to a diarylamine: $\text{ArBr} + \text{Ar}'\text{NHAc} \rightarrow \text{ArAr}'\text{NAc}$.²⁰⁹

Nickel catalysts have been used in the reaction of aryl halides with *N*-alkyl aniline derivatives²¹⁰ and also with aliphatic amines.²¹¹ *N*-Arylation was also accomplished with butyllithium and a secondary amine using Ni/C-diphenylphosphinoferrocene (dppf).²¹² An intramolecular reaction of a pendant aminoalkyl unit with an aryl chloride moiety, catalyzed by Ni(0) gave a dihydroindole.²¹³ An arylbismuth reagent reacts with aliphatic amines, in the presence of copper(II) acetate, to give an *N*-arylamine.²¹⁴ Diarylzinc reagents give the *N*-aryl amine in the presence of a Cu^{215} or a Ni catalyst²¹⁶. Aryl halides also react with $\text{Zn}(\text{NTMS}_2)_2$ in the presence of a Pd catalyst to give arylamines.²¹⁷ Iron-catalyzed arylation reactions are known.²¹⁸ A $\text{Mo}(\text{CO})_6$ mediated, Pd catalyzed reaction is known for allylamines and aryl halides.²¹⁹

²¹⁹ Appukkuttan, P.; Axelsson, L.; Van der Eycken, E.; Larhed, M. *Tetrahedron Lett.* **2008**, 49, 5625.

Intramolecular versions of this reaction generate bicyclic or polycyclic amines.²²⁰ An example is the conversion of **16** to the tetrahydroquinoline.²²¹ Larger ring amines can be prepared using this approach: 8- and even 12-membered.

Arylboronic acids react with aliphatic amines²²² or aq ammonia²²³ in the presence of a Cu catalyst. *N*-Aryl imides have been prepared by similar methodology, from arylboronic acids.²²⁴ Trifluoroarylboronates react with copper(II) acetate and then an aliphatic amine to give the *N*-phenylamine.²²⁵ Primary aromatic amines (ArNH₂) were converted to diaryl amines (ArNHPh) by treatment with Ph₃Bi(OAc)₂²²⁶ and a Cu powder catalyst.²²⁷

The metal-catalyzed reaction with ammonia or amines likely proceeds by the S_NAr mechanism.²²⁸ This reaction, with phase-transfer catalysis, has been used to synthesize triarylamines.²²⁹ In certain cases, the S_{RN}1 mechanism has been found (Reaction 10-26). When the substrate is a heterocyclic aromatic nitrogen compound, still a different mechanism [the S_N(ANRORC) mechanism], involving opening and reclosing of the aromatic ring, has been shown to take place.²³⁰

There are a number of indirect approaches for the preparation of aryl amines. Activated aromatic compounds can be directly converted to the *N*-aryl amine in high yield with hydroxylamine in the presence of strong bases.²³¹ Aryl halides can be converted to the corresponding *Grignard reagent* (Reaction 12-38). Subsequent reaction with allyl azide followed by hydrolysis leads to the corresponding aniline derivative.²³² Aryl *Grignard reagents* react with nitroaryl compounds to give, after reduction with FeCl₃/NaBH₄, a diaryl amine.²³³ Aryl halides can be converted to the aryllithium via halogen–lithium exchange or hydrogen–lithium exchange (Reactions 12-38 and 12-39).

The use of transition metal catalysts allows aryl halides to react with the nitrogen of amides or carbamates to give the corresponding *N*-aryl amide or *N*-aryl carbamate.

Amides react with aryl halides in the presence of a Pd²³⁴ or a Cu catalyst.²³⁵ *N*-Aryl lactams are prepared by the reaction of a lactam with an aryl halide in the presence of a Pd catalyst.²³⁶ β -Lactams also react.²³⁷ The reaction of 2-oxazolidinones with aryl halides in the presence of a Pd catalyst gave the *N*-aryl-2-oxazolidinone.²³⁸ *N*-Aryl amides are prepared from amides using PhSi(OMe)₃/Cu(OAc)₂/Bu₄NF.²³⁹ *N*-Boc hydrazine derivatives (BocNHNH₂) gave the *N*-phenyl derivative [BocN(Ph)NH₂] when reacted with iodobenzene and a catalytic amount of CuI and 10% of 1,10-phenanthroline.²⁴⁰ 3-Bromothiophene was converted to the 3-amido derivative with an amide and CuI-dimethylethylenediamine.²⁴¹ *N*-(2-Thiophene)-2-pyrrolidinone was similarly prepared from 2-iodothiophene, the lactam, and a copper catalyst.²⁴² *N*-Arylation of urea is possible using a Cu catalyst.²⁴³

The transition metal catalyzed couplings of primary or secondary phosphines with aryl halides or sulfonate esters to give arylphosphines is known.²⁴⁴ The Pd catalyzed conversion of aryl halides to aryl phosphines using (trimethylsilyl)diphenylphosphine tolerates many functional groups (not those that are easily reducible, e.g., aldehydes, because Zn metal²⁴⁵ is often used as a coreagent), but it is mainly limited to aryl iodides.²⁴⁶ Diphenylphosphine reacts with aryl iodides and a copper catalyst to give the triarylphosphine.²⁴⁷ Aryl iodides also react with a secondary phosphine and 5% Pd/C to give the *P*-arylphosphine.²⁴⁸ Tertiary phosphines can be used via aryl-aryl exchange, as in the reaction of an aryl triflate and triphenylphosphine and a Pd catalyst, for example, gave the arylphosphonium salt (ArPPh₃).²⁴⁹ Aryl iodides can also be used.²⁵⁰

13-6 Replacement of a Hydroxy Group by an Amino Group

Amino-de-hydroxylation

The reaction of naphthols with ammonia and sodium bisulfite is called the *Bucherer reaction*. Primary amines can be used instead of ammonia, in which case *N*-substituted naphthylamines are obtained. In addition, primary naphthylamines can be converted to secondary ($\text{ArNH}_2 + \text{RNH}_2 + \text{NaSO}_3 \rightarrow \text{ArNHR}$), by a transamination reaction. The mechanism of the *Bucherer reaction* amounts to a kind of overall addition–elimination, via **18** and **19**.²⁵¹

The first step in either direction consists of addition of NaHSO₃ to one of the double bonds of the ring, which gives an enol from **17** (or enamine from **20**) that tautomerizes to the keto form **18** (or imine form, **19**). The conversion of **18** to **19** (or vice versa) is an example of Reaction 16-13 (or 16-2). Evidence for this mechanism was the isolation of **18**²⁵² and the demonstration that for β-naphthol treated with ammonia and HSO₃[−], the rate of the reaction depends only on the substrate and on HSO₃[−], indicating that ammonia is not involved in the rate-determining step.²⁵³ If the starting compound is a β-naphthol, the intermediate is a 2-keto-4-sulfonic acid compound, so the sulfur of the bisulfite in either case attacks meta to the OH or NH₂.²⁵⁴

Hydroxy groups on benzene rings can be replaced by NH₂ groups if they are first converted to aryl diethyl phosphates. Treatment of these with KNH₂ and potassium metal in liquid ammonia gives the corresponding primary aromatic amines.²⁵⁵ The mechanism of the second step is S_{RN}1.²⁵⁶

It is possible to replace a halogen on an aromatic ring by another halogen²⁵⁷ if the ring is activated. In such cases, there is equilibrium, which is usually shifted in the desired direction by the use of an excess of added halide ion.²⁵⁸ A phenolic hydroxy group can be replaced by chloro with PCl_5 or POCl_3 , but only if the ring is activated. Unactivated phenols give phosphates when treated with POCl_3 : $3 \text{ ArOH} + \text{POCl}_3 \rightarrow (\text{ArO})_3\text{PO}$. Phenols, even unactivated ones, can be converted to aryl bromides by treatment with Ph_3PBr_2 ²⁵⁹ (see Reaction 10-47) and to aryl chlorides by treatment with PhPCl_4 .²⁶⁰

Halide exchange is particularly useful for putting fluorine into a ring, since there are fewer alternate ways of doing this than for the other halogens. Activated aryl chlorides give fluorides when treated with KF in DMF , DMSO , or dimethyl sulfone.²⁶¹ Reaction of aryl halides with $\text{Bu}_4\text{PF}/\text{HF}$ is also effective for exchanging a halogen with fluorine.²⁶²

Halide exchange can also be accomplished with copper halides. Since the leaving-group order in this case is $\text{I} > \text{Br} > \text{Cl} \gg \text{F}$, which means that iodides cannot normally be made by this method, the $\text{S}_{\text{N}}\text{Ar}$ mechanism is probably not operating.²⁶³ However, aryl iodides have been prepared from bromides, by the use of Cu supported on charcoal or Al_2O_3 ,²⁶⁴ with an excess of NaI and a Cu catalyst,²⁶⁵ and by treatment with excess KI and a Ni catalyst.²⁶⁶ Interestingly, aryl chlorides have been prepared from aryl iodides using 2 molar equivalents of NiCl_2 in DMF , with microwave irradiation.²⁶⁷ Aryl and vinyl triflates can be converted to the corresponding bromide or chloride using a Pd catalyst.²⁶⁸

Aryl iodides²⁶⁹ and fluorides can be prepared from arylthallium bis(trifluoroacetates) (see Reaction 12-23), indirectly achieving the $\text{ArH} \rightarrow \text{ArI}$ and $\text{ArH} \rightarrow \text{ArF}$ conversions. The bis(trifluoroacetates) react with KI to give ArI in high yields.²⁷⁰ Aryllead triacetates [$\text{ArPb}(\text{OAc})_3$] can be converted to aryl fluorides by treatment with BF_3 -etherate.²⁷¹ Treatment of $\text{PhB}(\text{OH})_2$ with NIS gives iodobenzene.²⁷² Arylboronic acids (Reaction 12-28) can be converted to the corresponding aryl bromides by reaction with

The reduction of phenols and phenolic esters and ethers is discussed in Reactions **19-38** and **19-35**. The reaction $\text{ArX} \rightarrow \text{ArH}$ is treated in **11-39**, although, depending on reagent and conditions, it can be nucleophilic or free radical substitution, as well as electrophilic.

E. Carbon Nucleophiles²⁷⁴

Some formations of new aryl-carbon bonds formed from aryl substrates have been considered in Reactions **10-57**, **10-68**, **10-76**, and **10-77**.

13-8 Cyanation of Aromatic Rings

Cyano-de-halogenation

Cyano-de-metalation

The reaction between aryl halides and cuprous cyanide is called the *Rosenmund-von Braun reaction*.²⁷⁵ Reactivity of the aryl halide is in the order $\text{I} > \text{Br} > \text{Cl} > \text{F}$, indicating that the $\text{S}_{\text{N}}\text{Ar}$ mechanism does not apply.²⁷⁶ Cyanides (e.g., KCN and NaCN) do not react with aryl halides, even activated ones, but this reaction has been done in ionic liquids using CuCN.²⁷⁷ The reaction has also been done in water using CuCN, a phase-transfer catalyst, and microwave irradiation.²⁷⁸ L-Proline has been used to promote the reaction.²⁷⁹

Aryl halides react with metal cyanides, often with another transition metal catalyst, to give aryl nitriles (aryl cyanides). Alkali cyanides convert aryl halides to nitriles²⁸⁰ in dipolar aprotic solvents in the presence of Pd(II) salts²⁸¹ or Cu²⁸² or Ni²⁸³ complexes. In the presence of a Pd- catalyst,²⁸⁴ several cyanide-containing compounds react with aryl halides. Several different sources of cyanide may be used with the Pd catalyzed reaction, including: $\text{Zn}(\text{CN})_2$,²⁸⁵ CuCN,²⁸⁶ sodium cyanoborohydride/catechol,²⁸⁷

potassium ferricyanide,²⁸⁸ and KCN.²⁸⁹ Microwave irradiation has been used to facilitate Pd catalyzed cyanation.²⁹⁰ Aryl triflates may be used in aryl cyanation reactions, as well as aryl halides.²⁹¹ Benzylthiocyanate reacts with boronic acids to give aryl cyanides in a “cyanide-free” reaction, catalyzed by a Pd complex and mediated by Cu(I).²⁹² Cyanation reactions catalyzed by copper salts are common.²⁹³ Aryl bromides react with Ni(CN)₂ with microwave irradiation to give ArCN.²⁹⁴ A nickel complex also catalyzes the reaction between aryl triflates and KCN to give aryl nitriles.²⁹⁵ Iridium-catalyzed borylation of arenes also leads to aryl nitriles.²⁹⁶

Alternative procedures are available. One uses excess aq KCN followed by photolysis of the resulting complex ion [ArTi(CN)₃][−] in the presence of excess KCN.²⁹⁷ Alternatively, arylthallium acetates react with Cu(CN)₂ or CuCN to give aryl nitriles.²⁹⁸ Yields from this procedure are variable, ranging from almost nothing to 90 or 100%.

Metal-free methods have been reported. For example, conversion of an aromatic compound to the corresponding iminium salt used POCl₃ and DMF, and subsequent reaction with molecular iodine in aq ammonia gave the nitrile.²⁹⁹ An indirect method involves the reaction of an aromatic ring with *tert*-butyllithium, particularly when there is a directing group (see Reaction 13-17), followed by reaction with PhOCN (phenyl cyanate) to give the aryl nitrile.³⁰⁰ Aromatic ethers (ArOR)³⁰¹ have been photochemically converted to ArCN.

OS III, 212, 631.

13-9 Coupling of Aryl and Alkyl Organometallic Compounds with Functionalized Aryl Compounds

Aryl-de-halogenation, and so on

A number of methods involving transition metals have been used to prepare unsymmetrical biaryls³⁰² (see also, Reaction 13-11). The uncatalyzed coupling of aryl halides and metalated aryls (particularly aryllithium reagents) is also known, including

cyclization of organolithium reagents to aromatic rings.³⁰³ Noncatalyzed coupling reactions of aryllithium reagents and haloarenes can proceed via the well-known aryne route, but a novel addition–elimination pathway is possible when substituents facilitate a chelation-driven nucleophilic substitution pathway.³⁰⁴ Such noncatalyzed coupling reactions often proceed with high regioselectivity and high yield.³⁰⁴ 2-Bromopyridine reacts with pyrrolidine, at 130 °C with microwave irradiation, to give 2-(2-pyrrolidino)pyridine.³⁰⁵ Aryl iodides undergo homocoupling to give the biaryl by heating with triethylamine in an ionic liquid.³⁰⁶ Note that alkyl bromides are coupled to pyrrolidine by heating in an ionic liquid.³⁰⁷

Palladium-catalyzed coupling reactions that generate biaryls are increasingly important in synthesis. Aryl halides undergo homocoupling to give the biaryl with a Pd³⁰⁸ or a Ni catalyst.³⁰⁹ Aryl iodides have been coupled to form symmetric biphenyls with a Pd catalyst,³¹⁰ and homocoupling occurs with aryl triflates under electrolysis conditions with a Pd catalyst.³¹¹ A recyclable Pd catalyst for use in ionic liquids has been developed.³¹² Other alternative solvents include PEG.³¹³

Thiophene derivatives,³¹⁴ pyrrole,³¹⁵ azoles,³¹⁶ quinoline,³¹⁷ and indolizine³¹⁸ have been coupled to aryl halides using a Pd catalyst. Fused polycyclic aromatic compounds can also be prepared from halobiaryls.³¹⁹ Trimethylsilylpyridine derivatives are coupled to aryl halides in the presence of a Pd catalyst.³²⁰ A related reaction is the Pd catalyzed decarboxylative coupling of arylcarboxylic acids with aryl iodides.³²¹

Palladium catalysts are often used in conjunction with another metal compound or complex. Arylgermanium compounds are coupled with aryl iodides using tetrabutylammonium fluoride and a Pd catalyst.³²² Homocoupling of triphenylbismuth is known,³²³ as well as the coupling of arylbismuth reagents to arylodonium salts³²⁴ and to aryltin compounds³²⁵ with Pd compounds or complexes. Aryl triflates were coupled to triphenylbismuth using a Pd catalyst.³²⁶ Specialized arylbismuth compounds

have been used with a Pd catalyst to convert aryl chlorides to biaryls.³²⁷ An aryltin–aryl halide coupling has been done in ionic liquids.³²⁸ Aryl halides react with cyclopentadiene and Cp_2ZrCl_2 and a Pd catalyst to give pentaphenylcyclopentadiene.³²⁹ The homocoupling of arylzinc iodides with a Pd catalyst has been reported.³³⁰ In a related reaction, arylsulfonyl chlorides also react with ArSnBu_3 with Pd and Cu catalysts to give the biaryl.³³¹

Aryl triflates (halides) couple with $\text{ArZn}(\text{halide})$ reagents in the presence of a Ni catalyst.³³² A homocoupling-type reaction was reported in which PhSnBu_3 was treated with 10% CuCl_2 , 0.5 equiv of iodine, and heated in DMF to give biphenyl.³³³ Similar coupling was accomplished with aryltellurium compounds.³³⁴ A Co(II) catalyzed cross-coupling of arylcopper compounds with aryl halides gives the corresponding biaryl.³³⁵ Another homocoupling reaction of pyridyl bromides was reported using NiBr_2 under electrolytic conditions. Both alkylmanganese compounds (RMnCl)³³⁶ and Ph_3In ³³⁷ react with aryl halides or aryl triflates to give the arene. Aryl halides also react with phenols to form biaryls using a Rh catalyst.³³⁸ Diaryliodonium salts react with $\text{PhPb}(\text{OAc})_3$ and a Pd catalyst to give the biaryl.³³⁹ Coupling of trialkylbismuth compounds with aryl halides leads to the arene in the presence of a Pd catalyst.³⁴⁰ A cross-coupling reaction of benzylium compounds and aryl halides in the presence of a Pd catalyst has been reported.³⁴¹

Grignard reagents couple with aryl halides without a Pd catalyst, by the benzyne mechanism,³⁴² but metal-catalyzed reactions are known. Typical catalysts include Fe,³⁴³ Ni,³⁴⁴ Co,³⁴⁵ or Ti,³⁴⁶ and Pd-catalyzed reactions are important.³⁴⁷ Aryl *Grignard reagents* react with aryltrimethylammonium triflates in the presence of a Pd catalyst to give the corresponding biaryl.³⁴⁸ Arylmagnesium halides couple with aryl tosylates in the presence

of a Pd catalyst to give unsymmetrical biaryls,³⁴⁹ and to halopyridines to give the arylated pyridine.³⁵⁰ Aryl *Grignard reagents* are coupled to arylodonium salts, with ZnCl₂ and a Pd catalyst, to give the biaryl.³⁵¹

The coupling reaction of an excess of a *Grignard reagent* (RMgX) with methoxy aromatic compounds, when the aromatic ring contains multiple alkoxy groups, proceeds with replacement of the OMe group by R.³⁵² Aryl sulfones were coupled with aryl *Grignard reagents* in the presence of a Ni catalyst.³⁵³

Unsymmetrical binaphthyls were synthesized by photochemically stimulated reaction of naphthyl iodides with naphthoxide ions in an S_{RN}1 reaction.³⁵⁴ Methyl chloroacetate coupled with aryl iodides under electrolysis conditions, using a Ni catalyst.³⁵⁵ Unsymmetrical biaryls were prepared from two aryl iodides using a CuI catalyst and microwave irradiation.³⁵⁶

It is possible to couple metalated alkyl compounds to aryl compounds. Alkyl halides³⁵⁷ are coupled to aryl halide using a Ni catalyzed reductive cross coupling.³⁵⁸ Organozinc compounds, available by reaction of an alkyl halide and zinc metal, are coupled to aryl halides using a Pd- catalyst.³⁵⁹ Specialized alkyl indium complexes have been used with a Pd catalyst to give arenes.³⁶⁰ Iron complexes have been used for coupling reactions.³⁶¹ Triarylbiomuth compounds are coupled with aryl bromides in the presence of a Pd catalyst.³⁶² Organolithium reagents are coupled to aryl bromides in the presence of a Ni catalyst,³⁶³ as are arylzinc compounds.³⁶⁴ The lithium enolate anion of an ester was coupled to an aryl halide using a Pd catalyst.³⁶⁵ Other ketones can be coupled to aryl triflates, in the presence of a Pd catalyst, and with good enantioselectivity.³⁶⁶

Arylation of alkenes³⁶⁷ is an important reaction using an “arylpalladium” reagent, typically generated *in situ* from an aryl halide or other suitably functionalized aromatic compound and a Pd catalyst.³⁶⁸ The Pd catalyzed aryl–alkene coupling reaction is known as *the Heck reaction*.³⁶⁹ Mizoroki³⁷⁰ had earlier described the coupling between iodobenzene and styrene to form stilbene in methanol at 120 °C in the presence of potassium acetate and a palladium chloride catalyst leading some to call this the *Mizoroki–Heck reaction*. The reaction works best with aryl iodides, but conditions are available for aryl bromides and aryl chlorides.³⁷¹ Aryldiazonium salts (see Reactions **13-25** and **13-26**) have also been used.³⁷² Activated aromatic compounds couple readily,³⁷³ but unactivated aromatic compounds often require special reaction conditions. The *Heck reaction* can be done with heterocyclic compounds,³⁷⁴ and heteroaryl halides can be used in the coupling reaction.³⁷⁵ Intramolecular *Heck reactions* are increasingly important.³⁷⁶ A silane-tethered, intramolecular *Heck reaction* is known.³⁷⁷ Other nucleophiles can be coupled to aryl halides.³⁷⁸

Phosphine-free catalysts,³⁷⁹ halogen-free reactions,³⁸⁰ and base-free reactions³⁸¹ have been developed for the *Heck reaction*. Improvements to the Pd catalyst system are constantly being reported,³⁸² including polymer-supported³⁸³ silica-supported,³⁸⁴ and

recoverable catalysts.³⁸⁵ Considerable work has been done to study and improve the ligand.³⁸⁶ Efforts have been made to produce a homogeneous catalyst for the Heck reaction.³⁸⁷ The *Heck reaction* can be done in aq media,³⁸⁸ in perfluorinated solvents,³⁸⁹ in polyethylene glycol,³⁹⁰ in neat tricaprylmethylammonium chloride,³⁹¹ and in supercritical CO₂ (See Sec. 9.D.ii).³⁹² The reaction has been done on solid support,³⁹³ including Montmorillonite clay,³⁹⁴ glass beads,³⁹⁵ on a reverse-phase silica support,³⁹⁶ and using microwave irradiation.³⁹⁷ A microwave irradiated *Heck coupling* was done in water using a Pd catalyst.³⁹⁸ A noncatalytic reaction was reported using supercritical water.³⁹⁹ The effects of high pressure have been studied.⁴⁰⁰ The *Heck reaction* has also been done in ionic liquids,⁴⁰¹ and it is known that the nature of the halide is important in such reactions.⁴⁰² Ionic liquids have been shown to actually promote the *Heck reaction*.⁴⁰³

Ethylene is the most reactive alkene, and increasing substitution lowers the reactivity. Coupling generally takes place at the less highly substituted side of the double bond.⁴⁰⁴ Unlike the diazonium coupling reaction in Reaction 13-26, the *Heck reaction* is not limited

to activated substrates. Both electron-deficient alkenes (e.g., acrylates),⁴⁰⁵ and electron-rich alkenes⁴⁰⁶ undergo the *Heck reaction*. The substrate can be an unactivated alkene,⁴⁰⁷ and the alkene can contain a variety of functional groups (e.g., esters, ether,⁴⁰⁸ enol ethers,⁴⁰⁹ enamides,⁴¹⁰ carboxyl, phenolic, or cyano groups).⁴¹¹ The aryl halide or aryl triflate can be coupled to dienes,⁴¹² allenes,⁴¹³ allylic acetates,⁴¹⁴ allylic silanes,⁴¹⁵ allylic amines,⁴¹⁶ vinyl phosphonate esters,⁴¹⁷ and with terminal alkynes.⁴¹⁸ Aryliodonium salts can be coupled to conjugated alkenes in a *Heck-like* manner using a Pd catalyst.⁴¹⁹ Double-coupling reactions have been reported, generating diaryl aromatic compounds.⁴²⁰ *Heck-type reactions* have been reported with imines.⁴²¹

Control of regiochemistry is a serious problem in the coupling to unsymmetrical alkenes. Some regioselectivity can be obtained by the use of alkenes attached to an auxiliary coordinating group,⁴²² or by using special ligands and acrylate or styrene as substrates.⁴²³ Neighboring-group effects play a role in the *Heck reaction*.⁴²⁴ Steric effects are thought to control regioselectivity,⁴²⁵ but electronic influences have also been proposed.⁴²⁶ It has been shown that the presence of steric effects generally improves 1,2-selectivity, and that electronic effects can be used to favor 1,2- or 2,1-selectivity.⁴²⁷ A 1,4-Pd migration between the *o*- and *o'*-positions of biaryls has been observed in organopalladium intermediates derived from *o*-halobiaryls.⁴²⁸ Migration of the double bond is a problem in some cases, and reaction conditions play a significant role in such migrations.⁴²⁹ It has been

reported that double-bond isomerization can be suppressed in intramolecular *Heck reactions* done in supercritical CO₂ (see Sec. 9.D.ii).⁴³⁰

The Pd catalyzed reactions are usually stereospecific,⁴³¹ yielding products expected from syn addition followed by syn elimination.⁴³² Because the product is formed by an elimination step, with suitable substrates, double-bond migration can occur, resulting in allylic rearrangement (as in the reaction of cyclopentene and iodobenzene to give **21**).⁴³³ Asymmetric *Heck reactions* are known,⁴³⁴ including asymmetric intramolecular *Heck reactions*.⁴³⁵ Dihydrofurans react with aryl triflates and a Pd catalyst that includes a chiral ligand, to give the 5-phenyl-3,4-dihydrofuran with good enantioselectivity.⁴³⁶ A similar reaction was reported for an *N*-carbamoyl dihydropyrrole.⁴³⁷

An addition–elimination mechanism (addition of ArPdX followed by elimination of HPdX) operates in most cases.⁴³⁸ In the conventionally accepted reaction mechanism,⁴³⁹ which is shown,⁴⁴⁰ a four-coordinate arylPd(II) intermediate (a palladacycle)⁴⁴¹ is formed by oxidative addition of the aryl halide to a Pd(0) complex prior to olefin addition.⁴⁴² This description suggests that cleavage of the dimeric precursor complex, reduction

of Pd²⁺, and ligand dissociation combine to give a viable catalytic species.⁴⁴³ σ -Alkyl Pd(II) intermediates are thought to be involved.⁴⁴⁴ An analysis of reaction kinetics under dry conditions was reported.⁴³⁵ In this study, the mechanism requires a first-order dependence on olefin concentration, and anomalous kinetics may be observed when the rate-limiting step is not directly on the catalytic cycle.⁴³⁵ The mechanism requires a proton abstraction step, and there are substituent effects for this step.⁴⁴⁵ A mechanistic study has been reported for the Pd catalyzed decarboxylative reaction of alkenes and arylcarboxylic acids.⁴⁴⁶ The kinetics and mechanism of the *Heck reaction* promoted by a C—N palladacycle has been studied.⁴⁴⁷ The mechanistic implications of asymmetric Heck reactions have been examined.⁴⁴⁸

There are a number of variations of this reaction, including the use of transition metal catalysts other than Pd. Rhodium-catalyzed *Heck reactions* are known,⁴⁴⁹ and there are Co-,⁴⁵⁰ Ru-,⁴⁵¹ and Ni catalyzed variations.⁴⁵² Iron-mediated arylation of alkenes has been reported,⁴⁵³ and vinylgermanes are coupled to aryl halides with a Pd catalyst.⁴⁵⁴ Aryl chlorides were coupled to conjugated esters using a RuCl₃·3 H₂O, in an atmosphere of O₂ and CO.⁴⁵⁵ Aryl halides have been coupled to allenyltin compounds (C=C=C-SnR₃).⁴⁵⁶ Divinylindium chloride [(CH₂=CH)₂InCl] reacted with an aryl iodide in aq THF with a Pd catalyst to give the styrene derivative.⁴⁵⁷ Trialkenylindium reagents reacted similarly with

aryl halides in the presence of a Pd catalyst.⁴⁵⁸ Arylzinc chlorides (ArZnCl) were coupled to vinyl chlorides using a Pd catalyst,⁴⁵⁹ and vinyl zinc compounds were coupled to aryl iodides.⁴⁶⁰ In the presence of trimethylsilylmagnesium chloride, primary alkyl halides coupled to aryl alkenes to give the substituted alkene (R'—CH=CHAr), using a Co catalyst.⁴⁶¹

Potassium vinyltrifluoroborates can be coupled to aryl halides in *Heck-like* coupling reactions.⁴⁶² Likewise, the reaction of aryltrifluoroborates with vinyl halides, in the presence of a Pd catalyst, leads to the aryl alkene.⁴⁶³ In a related reaction, alkyltrifluoroborates react with aryl halides in the presence of a Pd and a Rh catalyst.⁴⁶⁴

Although related to chemistry found in Reaction 10-57, metal-catalyzed alkylation reactions are easily viewed as *Heck-like* reactions. For that reason, they are discussed here. Alkyl halides are coupled to alkenes to form substituted alkenes using a Co catalyst, promoted by Me₃SiCH₂MgCl.⁴⁶⁵ Alkylation requires that the alkyl group lacks a β-hydrogen, and the reaction is successful for the introduction of methyl, benzyl, and neopentyl groups.⁴⁶⁶ However, vinylic groups, even those possessing β-hydrogen atoms, have been successfully introduced (to give 1,3-dienes) by the reaction of the alkene with a vinylic halide in the presence of a trialkylamine and a Pd(0) catalyst.⁴⁶⁷

13-11 Homo-Coupling of Aryl Halides: The Ullmann Reaction

de-halogen-coupling

The coupling of aryl halides with copper is called the *Ullmann reaction*.⁴⁶⁸ The reaction is clearly related to Reaction 13-9, but involves aryl copper intermediates. The reaction is of broad scope and has been used to prepare many symmetrical and unsymmetrical biaryls.⁴⁶⁹ When a mixture of two different aryl halides is used, there are three possible products, but often only one is obtained. The best leaving group is iodo, and the reaction is most often done on aryl iodides, but bromides, chlorides, and even thiocyanates have been used. New ligands have been developed to promote the reaction, including an air-stable

diazaphospholane ligand.⁴⁷⁰ The Cu catalyst has been immobilized.⁴⁷¹ Intramolecular reactions are known.⁴⁷² The coupling reaction can be applied to heterocyclic compounds.⁴⁷³

The effects of other groups on the ring are not easily predicted. The nitro group is strongly activating, but only in the ortho (not meta or para) position.⁴⁷⁴ Both R and OR groups activate in all positions. Not only do OH, NH₂, NHR, and NHCOR inhibit the reaction, as would be expected for aromatic nucleophilic substitution, but so do CO₂H (but not CO₂R), SO₂NH₂, and similar groups for which the reaction fails completely. These groups inhibit the coupling reaction by causing side reactions.

The mechanism is not known with certainty. It seems likely that it is basically a two-step process, similar to that of the *Wurtz reaction* (**10-56**), which can be represented schematically by

Organocopper compounds have been trapped by coordination with organic bases.⁴⁷⁵ In addition, aryl copper compounds (ArCu) have been independently prepared and shown to give biaryls (Ar—Ar') when treated with aryl iodides (Ar'I).⁴⁷⁶ A similar reaction has been used for ring closure⁴⁷⁷: Copper-catalyzed coupling of aryl halides and heterocycles has been reported.⁴⁷⁸

An important alternative to the *Ullmann method* is the use of certain Ni complexes.⁴⁷⁹ Aryl halides (ArX) can also be converted to Ar—Ar⁴⁸⁰ by treatment with activated Ni metal,⁴⁸¹ with Zn and Ni complexes,⁴⁸² with aq alkaline sodium formate, Pd—C and a phase-transfer catalyst,⁴⁸³ and in an electrochemical process catalyzed by a Ni complex.⁴⁸⁴

An asymmetric *Ullmann reaction* has been reported.⁴⁸⁵

13-12 Coupling of Aryl Compounds with Arylboronic Acid Derivatives

Aryl-de-halogenation, and so on

Aryl-de-boronylation, and so on

Arylboronic acids are coupled to aryl halides using a Pd catalyst to give the arene in what is called *Suzuki coupling* (or *Suzuki–Miyaura coupling*).⁴⁸⁶ Aryl triflates react with arylboronic acids [ArB(OH)₂, Reaction 12-28],⁴⁸⁷ or with organoboranes,⁴⁸⁸ in the presence of a Pd catalyst.⁴⁸⁹ Even hindered boronic acids give good yields of the coupled product.⁴⁹⁰ Homocoupling of arylboronic acids has been reported.⁴⁹¹ Some aromatic compounds are so reactive that a catalyst may not be required. Using tetrabutylammonium bromide, phenylboronic acid was coupled to 2-bromofuran without a catalyst.⁴⁹²

Different conditions (including additives and solvent) for the reaction have been reported,⁴⁹³ often focusing on the Pd catalyst⁴⁹⁴ or the ligand.⁴⁹⁵ Phosphine-⁴⁹⁶ and

ligand-free conditions⁴⁹⁷ have been developed. Recyclable catalysts have been developed.⁴⁹⁸ Catalysts have been developed for deactivated aryl chlorides.⁴⁹⁹ *Suzuki coupling* has also been done in ionic liquids,⁵⁰⁰ in supercritical CO₂⁵⁰¹ (see Sec. 9.D.ii), and there are solvent-free procedures.⁵⁰² Several procedures for coupling in aqueous media have been reported.⁵⁰³ The reaction has been done neat on alumina,⁵⁰⁴ and on alumina with microwave irradiation.⁵⁰⁵ Several procedures have been reported using microwave irradiation.⁵⁰⁶ Modifications to the basic procedure include tethering the aryl triflate⁵⁰⁷ or the boronic acid⁵⁰⁸ to a polymer, allowing a polymer-supported *Suzuki reaction*. Polymer-bound Pd complexes have been used.⁵⁰⁹ There is even a Pd free cross-coupling.⁵¹⁰

Arylboronic acids have been coupled to vinyl halides⁵¹¹ or vinyl tosylates⁵¹² using a Pd catalyst. Halogenated heteroaromatic compounds react, as do aryl carbamates, carbonates and sulfamates,⁵¹³ and aryl phosphoramides.⁵¹⁴ Aryl sulfonates have been used.⁵¹⁵

Arylboronic acids couple with aryl sulfonate esters.⁵¹⁶ Many different heterocycles have been arylated.⁵¹⁷ 4-Pyridylboronic acids have been used.⁵¹⁸ 3-Iodopyridine reacted with NaBPh and palladium acetate, with microwave irradiation, to give 3-phenylpyridine.⁵¹⁹

A variety of functional groups are compatible with Suzuki coupling, including $\text{Ar}_2\text{P}=\text{O}$,⁵²⁰ CHO ,⁵²¹ $\text{C}=\text{O}$ of a ketone,⁵²² CO_2R ,⁵²³ cyclopropyl,⁵²⁴ NO_2 ,⁵²⁵ CN , and halogen substituents.⁵²⁶ Vinyl halides react with arylboronic acids to give alkenyl derivatives (vinyl arenes, $\text{C}=\text{C}-\text{Ar}$),⁵²⁷ in what is clearly a *Heck-like* reaction. In a variation, vinylboronic acids coupled to aryl halides to give the vinyl-coupling product.⁵²⁸ Vinylboronic acids have been coupled to aryldiazonium salts (see Reaction 13-25) without added base, using a Pd catalyst with an imidazolium ligand.⁵²⁹

Alkylation can accompany arylation if alkyl halides are added, as in the conversion of iodobenzene to 2,6-dibutylbiphenyl.⁵³⁰ Alkyl groups may be coupled to aryls, as in the Pd catalyzed reaction of arylboronic acids with benzylic carbonates.⁵³¹ Arylboronic acids also couple with alkyl halides using either a palladium(II) acetate⁵³² or a Ni catalyst.⁵³³ Conversely, arylboronic acids can be coupled to aliphatic halides.⁵³⁴ Arylboronic acids can be coupled to allylic alcohols as well.⁵³⁵ Benzylic phosphonates have also been used.⁵³⁶ Double *Suzuki coupling* reactions are known.⁵³⁷ An alkyl-alkyl coupling reaction has been classified as a *Suzuki cross-coupling* reaction.⁵³⁸ The reaction of an arylboronic acid and 1,2-dibromoethane, with KOH and a Pd catalyst, leads to the styrene derivative.⁵³⁹

Since many biaryls are chiral due to atropisomerism (see Sec. 4.C, category 5), the use of a chiral catalyst, and/or a chiral ligand can lead to enantioselectivity in the *Suzuki coupling*.⁵⁴⁰

For a mechanistic viewpoint,⁵⁴¹ the *Suzuki coupling* proceeds via oxidative addition of areneboronic acids to give a Pd species, followed by 1,2-arene migration to an electron-deficient Pd atom, eventually leading to very fast reductive elimination to afford biaryls.⁵⁴² This mechanism is illustrated.⁵⁴³ Several intermediates of the oxidative coupling process have been identified by electrospray ionization mass spectrometry.⁵⁴⁴ Palladium peroxo complexes have been shown to be key intermediates.⁵⁴⁵

Other transition metals have been employed in these coupling reactions, sometimes as cocatalysts. Arylboronic acids have been coupled to conjugated alkenes to give the aryl-alkene coupling product using a Pd catalyst,⁵⁴⁶ a Ru catalyst with copper(II) acetate,⁵⁴⁷ a Ni catalyst,⁵⁴⁸ or a Rh catalyst.⁵⁴⁹ Aryl boronic acids are coupled with aryl ammonium salts to give the biaryl, with a Ni catalyst.⁵⁵⁰ Allylic acetates have been coupled to arylboronic acids using nickel bis(acetylacetonate) and diisobutylaluminum hydride.⁵⁵¹ Arylboronic acids (Reaction 12-28) were shown to react directly with benzene in the presence of Mn(OAc)_3 .⁵⁵² Aryl halides couple with ArB(OR')_2 species with a Pd catalyst.⁵⁵³ Iron catalysts have been developed for coupling with alkyl halides.⁵⁵⁴ Arylboronic

acids couple with the phenyl group of Ph_2TeCl_2 with a Pd catalyst.⁵⁵⁵ Tributyltin aryl compounds were coupled to the aryl group of $\text{Ar}_2\text{I}^+\text{BF}_4^-$ with a Ni catalyst.⁵⁵⁶

Suzuki-type coupling reactions have been reported involving acyl halides. When arylboronic acids were reacted with benzoyl chloride and PdCl_2 , the product was the diaryl ketone.⁵⁵⁷ This coupling reaction was also accomplished using a $\text{Pd}(0)$ catalyst.⁵⁵⁸ Cyclopropylboronic acids couple with benzoyl chloride, in the presence of Ag_2O and a Pd catalyst, to give the cyclopropyl ketone.⁵⁵⁹ A Ni catalyst has been used,⁵⁶⁰ and $\text{Ph}_3\text{P}/\text{Ni}/\text{C}-\text{BuLi}$ has also been used.⁵⁶¹ Arylboronic acids have also been coupled to anhydrides,⁵⁶² and the methoxy group of anisole derivatives has been replaced with phenyl using phenylboronic acid and a Ru catalyst.⁵⁶³

Arylborates (see Reaction **12-28**), $\text{ArB}(\text{OR})_2$, can be used in place of the boronic acid.⁵⁶⁴ The coupling reaction of aryl iodide (**22**) with boronate (**23**), for example, gave biaryl **24**.⁵⁶⁵ Base-free conditions, using nitrogen ligands, have been reported.⁵⁶⁶ Aryl and heteroarylboroxines (**25**) can be coupled to aryl halides using a Pd catalyst.⁵⁶⁷ Vinylboranes have been coupled to aryl iodides to give the aryl alkene, in the presence of a Pd catalyst.⁵⁶⁸ Organoboranes are coupled to aryl halides with a Pd catalyst.⁵⁶⁹

In a useful variation, aryltrifluoroborates ($\text{ArBF}_3^+ \text{X}^-$) (Reaction **12-28**), are coupled to aryl halides with a Pd catalyst to give the biaryl.⁵⁷⁰ Alkyltrifluoroborates⁵⁷¹ (RBF_3K , see Reaction **12-28**) react with aryl triflates⁵⁷² aryl halides,⁵⁷³ or arylodonium salts⁵⁷⁴ with a Pd catalyst, to give the arene. In a related reaction, vinyltrifluoroborates ($\text{C}=\text{C}-\text{BF}_3^+ \text{X}^-$ see Reaction **12-28**), are coupled to aryl halides with a Pd catalyst to give the styrene derivative.⁵⁷⁵ *Suzuki coupling* with trifluoroborates has also been done using microwave irradiation.⁵⁷⁶ Aryltellurides have been used in this reaction.⁵⁷⁷ A Pd catalyzed reaction with enamino ketones, mediated by Cu(II) salts, led to coupling to give the aryl derivative.⁵⁷⁸ Ruthenium catalysts have also been used.⁵⁷⁹

OS 75, 53, 61

The coupling reactions of alkylboronic acids are covered in Reaction **13-17**.

OS CV, 102, 467; OS 81, 89.

13-13 Aryl-Alkyne Coupling Reactions

Alkynyl-de-halogenation, and so on

When aryl halides react with copper acetylides to give 1-aryl alkynes, the reaction is known as *Stephens–Castro coupling*.⁵⁸⁰ Both aliphatic and aromatic substituents can be attached to the alkyne unit, and a variety of aryl iodides have been used. Benzonitrile was shown to react with alkynyl zinc bromides, with a Ni catalyst and after electrolysis to give the diarylalkyne, where the cyano unit was replaced with an alkyne unit.⁵⁸¹

A Pd catalyzed variation is known in which an aryl halide reacts with a terminal alkyne to give 1-aryl alkynes is called *Sonogashira coupling*.⁵⁸² Terminal aryl alkynes react with aryl iodides and Pd(0)⁵⁸³ to give the corresponding diaryl alkyne,⁵⁸⁴ but monoalkynes are easily prepared.⁵⁸⁵ Aryl iodides are more reactive than aryl fluorides.⁵⁸⁶ Alkynes can be coupled to heteroaromatic compounds.⁵⁸⁷ As with all of the metal-catalyzed reactions in this chapter, work has been done to vary reaction conditions, including the catalyst,⁵⁸⁸ the ligand,⁵⁸⁹ the solvent, and additives.⁵⁹⁰ There are copper-⁵⁹¹ and ligand-free variations.⁵⁹² Transition metal free coupling has been reported using a 2,2,6,6-tetramethylpiperidine-*N*-oxyl radical as an oxidant.⁵⁹³ Variations include *Sonogashira coupling* in water, without Cu,⁵⁹⁴ and other reactions are done in aqueous media.⁵⁹⁵ The coupling has been done in aq polyethylene glycol,⁵⁹⁶ and in ionic liquids.⁵⁹⁷ Microwave irradiation is an important tool in this reaction.⁵⁹⁸ *Sonogashira coupling* was reported on microbeads,⁵⁹⁹ with

nanoparticulate nickel powder,⁶⁰⁰ and the aryl iodide was tethered to a polymer for a solid-state reaction.⁶⁰¹ Polymer-supported catalysts are known.⁶⁰² A variation scavenged the triphenylphosphine byproduct by addition of *Merrifield* resin.⁶⁰³

Coupling of the alkynes to form a diyne (see Reaction **14-16**) can be a problem in some cases, although the aryl–alkyne coupling usually predominates.⁶⁰⁴ There are many variations. Alkyl groups are coupled to alkynes under *Sonogashira conditions*, including unactivated secondary alkyl halides.⁶⁰⁵ Coupling propargyl bromide and an aryl iodide, in the presence of an amine, gives the aryl aminomethylalkyne.⁶⁰⁶ 4-Chloroacetophenone reacts with 1-phenylethyne, showing that the carbonyl group is compatible with this reaction.⁶⁰⁷ Arenediazonium salts can be used for the coupling reaction.⁶⁰⁸ Similar Pd catalyzed coupling of bromoalkynes with heterocycles also leads to the alkynyl derivative.⁶⁰⁹ Ynamides are coupled using copper-free conditions.⁶¹⁰

There are variations of the *Sonogashira reaction* that use other metals as catalysts or cocatalysts. A Pd free reaction is known, using Cu complexes as the catalyst.⁶¹¹ An In catalyzed reaction is known that does not use Cu, Pd, or phosphine ligands.⁶¹² Gold(I) has been used to catalyze *Sonogashira reactions*,⁶¹³ and there are Ni⁶¹⁴ and Fe catalyzed⁶¹⁵ reactions. Silver iodide has been used to catalyze the reaction.⁶¹⁶ Conversion of 1-lithioalkynes to the corresponding alkynyl zinc reagent allows coupling with aryl iodides when a Pd catalyst is used.⁶¹⁷ A 1-lithioalkyne was directly coupled to aryl bromides in the presence of B(OiPr)₃ and a Pd catalyst,⁶¹⁸ where an alkynylboronic acid was generated *in situ*. Lithium alkynyltrimethylborates are coupled to aryl chlorides as well.⁶¹⁹ Terminal alkynes are coupled to acylpyridinium salts in the presence of a Cu catalyst, giving a product with high enantioselectivity when a chiral ligand is used.⁶²⁰ Coupling with alkynyl tin compounds is known.⁶²¹ A triphenylstibine [Ph₃Sb(OAc)₂] was used to transfer a phenyl group to the alkyne carbon of PhC≡CSiMe₃, using Pd and CuI catalysts.⁶²²

A variation of this aryl–alkyne coupling reaction reacted methylthioalkynes ($R-C\equiv C-SMe$) with arylboronic acids and a Pd catalyst to give the aryl alkyne ($R-C\equiv C-Ar$).⁶²³ The boron trifluoride induced Pd catalyzed cross-coupling reaction of 1-aryltriazenes with areneboronic acids has been reported.⁶²⁴ Aryl halides are coupled to alkynyltrifluoroboronates ($R-C\equiv C-BF_3K$, Reaction **12-28**) using a Pd catalyst.⁶²⁵ Aryl iodides were also coupled to lithium alkynyl borate complexes, $Li[R-C\equiv C-B(OR')_3]$, to give the aryl alkyne.⁶²⁶

Diaryliodonium salts react with terminal alkynes to give the phenyl alkyne.⁶²⁷ A variation couples the phenyl group of $Ph_2I^+OTf^-$ with an en-yne using a Pd catalyst.⁶²⁸ Aryl sulfonate esters can be coupled to terminal alkynes using a Pd catalyst in polymethylhydrosiloxane.⁶²⁹

OS 11, 2009, 234.

13-14 Arylation at a Carbon Containing an Active Hydrogen

Bis(ethoxycarbonyl)methyl-de-halogenation, and so on

The arylation of compounds of the form ZCH_2Z' is analogous to Reaction **10-67**, where Z is defined as an electron-withdrawing group (ester, cyano, sulfonyl, etc.). Activated aryl halides generally give good results.⁶³⁰ Treatment with an aryl halide in liquid ammonia containing Na or K, for example, leads in the formation of **26** and **27**.⁶³¹ When the solution is irradiated with near-UV light, but Na or K is omitted, the same products are

obtained (though in different proportions).⁶³² In either case, other leaving groups can be used instead of halogens (e.g., NR_3^+ , SAr) and the mechanism is the $S_{RN}1$ mechanism. *N*-Heterocyclic carbene ligands in the presence of alkoxide bases lead to coupling of ketones and aryl halides, at the α -position of the ketone.⁶³³ The reaction can also take place without an added initiator. The reaction of 2-fluoroanisole and KHMDS, and 4 equiv

of 2-cyanopropane, leads to substitution of the fluorine atom by CMe_2CN .⁶³⁴ β -Keto esters were coupled to aryl fluorides using CsOH and a chiral quaternary ammonium salt, leading to the aryl substitution product with good enantioselectivity.⁶³⁵

Even unactivated aryl halides can be employed if the reaction is carried out in the presence of a strong base (e.g., NaNH_2 ⁶³⁶ or LDA). Compounds of the form $\text{ZCH}_2\text{Z}'$, and even simple ketones⁶³⁷ or carboxylic esters have been arylated in this manner. The reaction with unactivated halides proceeds by the benzyne mechanism and represents a method for extending the malonic ester (and similar) syntheses to aromatic compounds. The base performs two functions: It removes a proton from $\text{ZCH}_2\text{Z}'$ and catalyzes the benzyne mechanism. The reaction has been used for ring closure, as in the formation of indole **28**.⁶³⁸

A similar reaction was reported using a Pd catalyst.⁶³⁹ Nitroethane was converted to 2-phenylnitroethane using bromobenzene and a Pd catalyst.⁶⁴⁰ Palladium catalysts have been developed for the α -arylation of ketones.⁶⁴¹ α -Arylation of esters has been accomplished using Pd catalysts.⁶⁴² Malonate esters are coupled unactivated aryl halides using a Pd catalyst.⁶⁴³ Bis-(sulfones) $[\text{CH}_2(\text{SO}_2\text{Ar})_2]$, react with aryl halides in the presence of a Pd catalyst.⁶⁴⁴ Iron(II) salts have also been used to initiate this reaction.⁶⁴⁵ The coupling of active methylene compounds and unactivated aryl halides can also be done with copper halide catalysts¹⁰³ (the *Hurtley reaction*).⁶⁴⁶ Similar coupling was accomplished with $\text{CH}_2(\text{CN})_2$ and a Ni catalyst.⁶⁴⁷ A variation of α -arylation reacts α -halocarbonyl compounds with arylboronic acids, in the presence of a Ni catalyst.⁶⁴⁸ Malonic and β -keto esters can be arylated at the α -carbon in high yields by treatment

with aryllead tricarboxylates $[\text{ArPb}(\text{OAc})_3]$,⁶⁴⁹ with triphenylbismuth carbonate $(\text{Ph}_2\text{BiCO}_3)$,⁶⁵⁰ and other Bi reagents.⁶⁵¹ In a related process, manganese(III) acetate was used to convert a mixture of ArH and $\text{ZCH}_2\text{Z}'$ to ArCHZZ' .⁶⁵² Arylzinc reagents have also been used.⁶⁵³

Enolate ions of ketones react with PhI in the dark.⁶⁵⁴ In this case, it has been suggested⁶⁵⁵ that initiation takes place by formation of a radical (e.g., **29**).

This is a SET mechanism (see Sec. 10.B). The photostimulated reaction has also been used for ring closure.⁶⁵⁶ In certain instances of the intermolecular reaction, there is evidence that the leaving group exerts an influence on the product ratios, even when it has already departed at the time that product selection takes place.⁶⁵⁷

The reaction of the enolate anions of ketones and aldehydes, generated *in situ* by addition of a suitable base, with aryl halides can be accomplished by treatment with a Pd catalyst.⁶⁵⁸ Formation of an enolate anion of a conjugated ketone (cyclohexenone) via reaction with LDA (see Sec. 8.F, category 7), in the presence of Ph_3BiCl_2 , leads to the α -phenyl conjugated ketone (6-phenylcyclohex-2-enone).⁶⁵⁹ An ester reacted with TiCl_4 and *N,N*-dimethylaniline to give the para-substitution product ($\text{Me}_2\text{N}-\text{Ar}-2\text{Et}$).⁶⁶⁰ Nickel-catalyzed α -arylation of ketone enolate anions is also known.⁶⁶¹ The enolate anion of lactams will react with aryl halides in the presence of a Pd catalyst via the 3-aryl lactam.⁶⁶² When the enolate anion of a ketone is generated in the presence of a Pd catalyst and a chiral phosphine ligand, the α -aryl ketone is formed with good enantioselectivity.⁶⁶³

13-15 Conversion of Aryl Substrates to Carboxylic Acids, Their Derivatives, Aldehydes, and Ketones⁶⁶⁴

Alkoxycarbonyl-de-halogenation, and so on

Carbonylation of aryl halides⁶⁶⁵ and aryl triflates⁶⁶⁶ with CO, an alcohol and a base (which gives an alkoxide), and a Pd catalyst, gives carboxylic esters. Similar carbonylation reactions are possible with alkyl halides. Aryl carboxylic acids were also prepared from aryl iodides by heating in DMF with lithium formate, LiCl, acetic anhydride, and a Pd catalyst.⁶⁶⁷ Even very sterically hindered alkoxides can be used to produce the corresponding ester.⁶⁶⁸ The use of H₂O, RNH₂, or an alkali metal or calcium carboxylate⁶⁶⁹ instead of ROH, gives the carboxylic acid,⁶⁷⁰ amide,⁶⁷¹ or mixed anhydride, respectively.⁶⁷² Ester formation via carbonylation was done in supercritical CO₂ (see Sec. 9.D.ii).⁶⁷³ Microwave promoted carbonylation reactions have been reported.⁶⁷⁴

Variations including a silica-supported Pd reagent have been used to convert iodobenzene to butyl benzoate, in the presence of CO and butanol.⁶⁷⁵ 2-Chloropyridine was converted to the butyl pyridine 2-carboxylate with this procedure.⁶⁷⁶ Dicobalt octacarbonyl [Co₂(CO)₈] may be used as a surrogate reagent for CO.⁶⁷⁷ Heating an aryl iodide, CO in ethanol and DBU, with a Pd catalyst, gave the ethyl ester of the aryl carboxylic acid.⁶⁷⁸ A similar result was obtained when an aryl iodide was heated in ethanol with triethylamine, CO, and Pd/C.⁶⁷⁹ Phenols and aryl halides react with a Pd catalyst, and carbonylation leads to the phenyl ester.⁶⁸⁰ Arylthallium bis(trifluoroacetates) [ArTl(O₂CCF₃)₂], (see Reaction 12-23), can be carbonylated with CO, an alcohol, and a PdCl₂ catalyst to give esters.⁶⁸¹ Note that seleno esters (ArCOSeAr) were prepared

from aryl iodides, CO, PhSeSnBu₃, and a Pd catalyst.⁶⁸² Aminocarbonylation reactions are known.⁶⁸³

Modification of this approach allows the synthesis of ketones, and aryl iodides can be converted to aldehydes.⁶⁸⁴ Aryl ketones can be prepared from aryltrimethylsilanes (ArSiMe₃) and acyl chlorides in the presence of AlCl₃.⁶⁸⁵ Aryllithium and *Grignard reagents* react with iron pentacarbonyl to give aldehydes ArCHO.⁶⁸⁶ The reaction of CO with aryllithium may occur by electron transfer.⁶⁸⁷ Aryl iodides are converted to unsymmetrical diaryl ketones on treatment with arylmercury halides and nickel carbonyl: ArI + Ar'HgX + Ni(CO)₄ → ArCOAr'.⁶⁸⁸ Aryl iodides are carbonylated to give the aryl alkyl ketone with CO and R₃In.⁶⁸⁹ Aryl iodides are coupled with aryl acid chlorides in the presence of an In complex to form a diaryl ketone.⁶⁹⁰ Organomercury compounds undergo a similar reaction.⁶⁹¹ The aryllead reagent [PhPb(OAc)₂] was converted to benzophenone using NaOMe, CO, and a Pd catalyst.⁶⁹² Aryl iodides containing an ortho substituent with a β-cyano group that served as the source of a carbonyl group, was converted to a bicyclic ketone with a Pd catalyst at 130 °C in aq DMF.⁶⁹³

Diaryl ketones can also be prepared by coupling aryl iodides with phenylboronic acid (Reaction 12-28), in the presence of CO and a Pd catalyst.⁶⁹⁴ This reaction has been extended to heteroaromatic systems, with the preparation of phenyl 4-pyridyl ketone from phenylboronic acid and 4-iodopyridine.⁶⁹⁵ 2-Bromopyridine as coupled with phenylboronic acid, CO, and a Pd catalyst to give phenyl 2-pyridyl ketone.⁶⁹⁶ Carbonylation of an alkyne and an aryl halide, with CO and Pd and Cu catalysts, gave the alkynyl ketone RC≡C(C=O)Ar.⁶⁹⁷

In the presence of transition metal catalysts (e.g., Pd), trialkoxysilanes [$\text{HSi}(\text{OR})_3$] react with aryl halides to give the corresponding arylsilane.⁶⁹⁸ This transformation is an alternative to the *Suzuki coupling* (Reaction 13-12).⁶⁹⁹ The influence of silicon substituents on the cross-coupling reaction has been studied.⁷⁰⁰ A similar reaction was reported using a Rh catalyst.⁷⁰¹ Similar coupling of aryl halides with trialkylsilanes (HSiR_3) in the presence of a Pd,⁷⁰² or Rh catalyst,⁷⁰³ or PtO_2 ⁷⁰⁴ gives the arylsilane. Cyclic alkoxy silanes are prepared using Pd catalyzed cross-coupling reactions.⁷⁰⁵ Vinylsilanes are coupled to aryl halides to give the aryl alkene.⁷⁰⁶ Disilanes have also been employed, using a Pd catalyst.⁷⁰⁷ Arylsilanes can be coupled to aryl iodides using a Pd catalyst⁷⁰⁸ and in aqueous media.⁷⁰⁹ Arylsilanes react with alkyl halides to give the corresponding arene, in the presence of a Pd catalyst.⁷¹⁰

Other variations include the conversion of vinyl silanes to styrene derivatives upon treatment with Bu_4NF (TBAF), an aryl iodide and a Pd catalyst.⁷¹¹ Arylsilanes were coupled to alkenes to give the styrene derivative using palladium acetate in an oxygen atmosphere,⁷¹² or TBAF and an Ir catalyst.⁷¹³ Aryl iodides can be coupled to 1-methyl-1-vinyl- and 1-methyl-1-(prop-2-enyl)silacyclobutane with desilylation, using a Pd catalyst and TBAF, to give the corresponding styrene derivative.⁷¹⁴ Aryl silanes can be coupled to aryl iodides using Ag_2O and a Pd catalyst,⁷¹⁵ and arylsiloxanes [$\text{ArSi}(\text{OR})_3$] are coupled to aryl halides with TBAF and a Pd catalyst.⁷¹⁶ 1-Trialkylsilylalkynes ($\text{R}_3\text{Si}-\text{C}\equiv\text{C}-\text{R}'$) were coupled to aryl iodides using a Pd catalyst.⁷¹⁷

An alternative approach reacts aryllithium reagents with siloxanes [$\text{Si}(\text{OR})_4$], to give the aryl derivative $\text{ArSi}(\text{OR})_3$.⁷¹⁸ Biaryl derivatives are similarly prepared from

aryl halides.⁷¹⁹ Arylsiloxanes are similarly coupled at the ortho position of anilide derivatives.⁷²⁰

The reaction of NaBPh₄ (sodium tetraphenylborate) and a silyl dichloride (Ph₂SiCl₂) gives biphenyl.⁷²¹

13.C.ii. Hydrogen as Leaving Group⁷²²

13-17 Alkylation and Arylation

Alkylation or Alkyl-de-hydrogenation, and so on

The alkylation of aromatic rings was introduced, in part, in Reaction **10-57**. The reaction of an aromatic ring with an organolithium reagent can give H–Li exchange to form an aryllithium. This reaction tends to be slow if there are activating substituents on the aryl halide, or in the absence of diamine additives.⁷²³ When heteroatom substituents are present as in **30**, however, the reaction is facile and the Li goes into the 2 position (as in **31**).⁷²⁴ This regioselectivity can be quite valuable synthetically, and is now known as *directed ortho metalation*⁷²⁵ (see Reaction **10-57**). Subsequent reaction with a suitable electrophilic agent (e.g., D₂O) leads to **32** in this case. Aryllithium reagents give arylation. The reaction occurs by an addition–elimination mechanism and the adduct can be isolated.⁷²⁶ Upon heating of the adduct, elimination of LiH occurs and an alkylated product is obtained. With respect to C-2, the first step is the same as that of the S_NAr mechanism. The difference is that the unshared pair of electrons on the nitrogen combines with the lithium, so the extra pair of ring electrons has a place to go: It becomes the new unshared pair on the nitrogen.

With TMEDA/*n*-butyllithium mediated arene lithiation reactions, the viability of directive effects (complex-induced proximate effects) has been questioned,⁷²⁷ although it is not clear if this extends to other systems (particularly when there is a strong coordinating group (e.g., carbamate)).⁷²⁸ The 2 position is much more acidic than the 3 position (see Table 8.1), but a negative charge at C-3 is in a more favorable position to be

stabilized by the Li^+ . Lithiation reactions do not necessarily rely on a complex-induced proximity effect.⁷²⁹ *N,N*-Dialkyl aryl-*O*-sulfamates are substrates for ortho metalation.⁷³⁰ Phenylaziridines also undergo this reaction.⁷³¹ Formation of the ortho arylmagnesium compound has been accomplished with bases of the form $(\text{R}_2\text{N})_2\text{Mg}$.⁷³² A directed meta metalation has been reported, using alkali metal mediated zincation.⁷³³ Note that the substrate-dependent mechanism of the ortho lithiation of aryloxazolines using butyllithium has been studied.⁷³⁴

Benzene, naphthalene, and phenanthrene have been alkylated with alkyllithium reagents, although the usual reaction with these reagents is Reaction **12-22**,⁷³⁵ and *Grignard reagents* have been used to alkylate naphthalene.⁷³⁶ The addition–elimination mechanism apparently applies in these cases too. A protected form of benzaldehyde (protected as the benzyl imine) has been similarly alkylated at the ortho- position with butyllithium.⁷³⁷ The alkylation of heterocyclic nitrogen compounds⁷³⁸ with alkyllithium reagents is called *Ziegler alkylation*. The reaction of 2-chloropyridine with 3 equiv of butyllithium– $\text{Me}_2\text{NCH}_2\text{CH}_2\text{OLi}$ and then iodomethane gave 2-chloro-6-methylpyridine.⁷³⁹ Note that H–Li exchange can be faster than Cl–Li exchange. Treatment of 2-chloro-5-phenylpyridine with *tert*-butyllithium leads to lithiation on the phenyl ring rather than Li–Cl exchange, and subsequent treatment with dimethyl sulfate gave 2-chloro-5-(2-methylphenyl)pyridine.⁷⁴⁰ The reaction of *N*-triisopropylsilyl indole with *tert*-butyllithium and then iodomethane gave the 3-methyl derivative.⁷⁴¹ Heteroaromatic compounds can be alkylated. Pyrrole, for example, reacts with an allylic halide and zinc to give primarily the 3-substituted pyrrole.⁷⁴²

Mercuration of aromatic compounds⁷⁴³ can be accomplished with mercuric salts, most often $\text{Hg}(\text{OAc})_2$,⁷⁴⁴ to give ArHgOAc . This is ordinary electrophilic aromatic substitution and takes place by the arenium ion mechanism (Sec. 11.A.i).⁷⁴⁵ Aromatic compounds can also be converted to arylthallium bis(trifluoroacetates) $[\text{ArTl}(\text{OOCF}_3)_2]$ by treatment

with thallium(III) trifluoroacetate⁷⁴⁶ in trifluoroacetic acid.⁷⁴⁷ These arylthallium compounds can be converted to phenols, aryl iodides or fluorides (Reaction 12-31), aryl cyanides (Reaction 12-34), aryl nitro compounds,⁷⁴⁸ or aryl esters (Reaction 12-33). The mechanism of thallation appears to be complex, with electrophilic and electron-transfer mechanisms both taking place.⁷⁴⁹ Transient metalated aryl complexes can be formed that react with another aromatic compound. Aryl iodides reacted with benzene to form a biaryl in the presence of an Ir catalyst.⁷⁵⁰ Aniline derivatives reacted with TiCl_4 to give the para-homo coupling product ($\text{R}_2\text{N}-\text{Ar}-\text{Ar}-\text{NR}_2$).⁷⁵¹

Aromatic nitro compounds can be methylated with dimethyloxosulfonium methylid⁷⁵² or the methylsulfinyl carbanion (obtained by treatment of DMSO with a strong base)⁷⁵³:

The reactions with the sulfur carbanions are especially useful, since none of these substrates can be methylated by the *Friedel-Crafts* procedure (Reaction 11-10).

A different kind of alkylation of nitro compounds uses carbanion nucleophiles that have a chlorine at the carbanionic carbon. The following process takes place:⁷⁵⁴

This type of process is called *vicarious nucleophilic substitution of hydrogen*.⁷⁵⁵ The Z group is electron withdrawing (e.g., SO_2R , SO_2OR , SO_2NR_2 , COOR , or CN); it stabilizes the negative charge. The carbanion attacks the activated ring ortho or para to the nitro group.⁷⁵⁶ Hydride ion (H^-) is not normally a leaving group, but in this case the presence of the adjacent Cl allows the hydrogen to be replaced. Hence, Cl is a “vicarious” leaving group. Other leaving groups have been used (e.g., OMe and SPh), but Cl is generally the best. Many W groups in the ortho, meta, or para positions do not interfere. The reaction is

also successful for di- and trinitro compounds, for nitronaphthalenes,⁷⁵⁷ and for many nitro heterocycles, $^-Z-CR-Cl$ may also be used.⁷⁵⁸ When the nucleophile is Br_3C^- or Cl_3C^- , the product is $ArCHX_2$, which can easily be hydrolyzed to $ArCHO$.⁷⁵⁹ This is therefore an indirect way of formylating an aromatic ring containing one or more NO_2 groups, which cannot be done by any of the formylations mentioned in Reaction 11-1-11-18.

Replacement of an amino group is possible. When aniline derivatives were treated with allyl bromide and *tert*-butyl nitrite (*t*-BuONO), the aryl-allyl coupling product was formed ($Ar-NH_2 \rightarrow Ar-CH_2CH=CH_2$).⁷⁶⁰

For the introduction of CH_2SR groups into phenols, see Reaction 11-23. See also, Reaction 14-19.

OS II, 517.

13-18 Amination of Nitrogen Heterocycles

Amination or Amino-de-hydrogenation

Pyridine and other heterocyclic nitrogen compounds can be aminated with alkali metal amides in a process called the *Chichibabin reaction*.⁷⁶¹ The attack is always in the 2 position unless both such positions are filled, in which case the 4 position is attacked. Substituted alkali metal amides (e.g., RNH^- and R_2N^-), have also been used. The mechanism is probably similar to that of Reaction 13-17. The existence of intermediate ions (e.g., 33)

(from quinoline) has been demonstrated by NMR spectra.⁷⁶² A pyridyne type of intermediate was ruled out by several observations including the facts that 3-ethylpyridine gave 2-amino-3-ethylpyridine⁷⁶³ and that certain heterocycles that cannot form an aryne could nevertheless be successfully aminated. Nitro compounds do not give this reaction,⁷⁶⁴ but they have been aminated ($ArH \rightarrow ArNH_2$ or $ArNHR$) via the vicarious substitution principle (see Reaction 13-17), using 4-amino- or 4-alkylamino-1,2,4-triazoles as nucleophiles.⁷⁶⁵ The vicarious leaving group in this case is the triazole ring. Note, however, that 3-nitropyridine was converted to 6-amino-3-nitropyridine by reaction with KOH, hydroxylamine, and $ZnCl_2$.⁷⁶⁶

Analogous reactions have been carried out with hydrazide ions (R_2NNH^-).⁷⁶⁷ A mixture of NO_2 and O_3 , with excess $NaHSO_3$, converted pyridine to 3-aminopyridine.⁷⁶⁸ For other methods of aminating aromatic rings, see Reaction 11-6.

There are no *Organic Syntheses* references, but see OS V, 977, for a related reaction.

13.C.iii. Nitrogen as Leaving Group

The diazonium group can be replaced by a number of groups.⁷⁶⁹ Some of these are nucleophilic substitutions, with S_N1 mechanisms (Sec. 10.A.ii), but others are free radical reactions and are treated in Chapter 14. The solvent in diazonium group reactions is usually water. With other solvents it has been shown that the S_N1 mechanism is favored by solvents of low nucleophilicity, while those of high nucleophilicity favor free radical mechanisms.⁷⁷⁰ The N_2^+ group⁷⁷¹ can be replaced by Cl^- , Br^- , and CN^- , by a nucleophilic mechanism (see OS IV, 182), but the *Sandmeyer reaction* is much more useful (Reaction 14-20). Transition metal catalyzed reactions are known involving aryldiazonium salts, and diazonium variants of the *Heck reaction* (13-10) and *Suzuki coupling* (13-12) were mentioned previously. As mentioned in Section 13.B.i, it must be kept in mind that the N_2^+ group can activate the removal of another group on the ring. In a few cases, nitrogen groups (e.g., nitro or ammonium) can be replaced.

13-19 Diazotization

When primary aromatic amines are treated with nitrous acid, diazonium salts are formed.⁷⁷² The reaction also occurs with aliphatic primary amines, but aliphatic diazonium ions are extremely unstable, even in solution (see Sec. 10.G.iii). Aromatic diazonium ions are more stable, because of the resonance interaction between the nitrogen atoms and the ring:

⁷⁷² See in Patai, S. *The Chemistry of Diazonium and Diazo Groups*, Wiley, NY, **1978**, the articles by Hegarty, A.F. pt. 2, pp. 511–591, and Schank, K. pt. 2, pp. 645–657; Godovikova, T.I.; Rakitin, O.A.; Khmel'nitskii, L.I. *Russ. Chem. Rev.* **1983**, 52, 440; Challis, B.C.; Butler, A.R. in Patai, S. *The Chemistry of the Amino Group*, Wiley, NY, **1968**, pp. 305–320. See Butler, A.R. *Chem. Rev.* **1975**, 75, 241.

Incidentally, **34** contributes more than **35**, as shown by bond-distance measurements.⁷⁷³ In benzenediazonium chloride, the C—N distance is $\sim 1.42 \text{ \AA}$, and the N—N distance $\sim 1.08 \text{ \AA}$,⁷⁷⁴ and these values fit more closely to a single and a triple bond than to two double bonds (see Table 1.5). Even aromatic diazonium salts are unstable at temperatures other than about $<5^\circ\text{C}$. A few are more stable (e.g., the diazonium salt obtained from sulfanilic acid), which is stable up to 10 or 15°C . Diazonium salts are usually prepared in aqueous solution and *used without isolation*.⁷⁷⁵ While it is possible to prepare solid diazonium salts (see Reaction **13-23**), many dry diazonium salts are explosive if not handled with great care and extreme caution should be exercised. The stability of aryl diazonium salts can be increased by crown ether complexion.⁷⁷⁶

For aromatic amines, the reaction is very general. Halogen, nitro, alkyl, aldehyde, sulfonic acid, and so on, groups do not interfere. Since aliphatic amines do not react with nitrous acid below a pH of ~ 3 , it is even possible, by working at a pH ~ 1 , to diazotize an aromatic amine without disturbing an aliphatic amino group in the same molecule.⁷⁷⁷

If an aliphatic amino group is α to a COOR, CN, CHO, COR, and so on, and has a hydrogen, treatment with nitrous acid gives not a diazonium salt, but a *diazo compound*.⁷⁷⁸ Such diazo compounds can also be prepared, often more conveniently, by treatment of the substrate with isoamyl nitrite ($\text{Me}_2\text{CHCH}_2\text{CH}_2\text{ONO}$) and a small amount of acid.⁷⁷⁹ Certain heterocyclic amines also give diazo compounds rather than diazonium salts.⁷⁸⁰

Despite the fact that diazotization takes place in acid solution, the actual reactive species is not the salt of the amine, but is the small amount of free amine present.⁷⁸¹ Because aliphatic amines are stronger bases than aromatic ones that at pH values <3 there is not enough free amine present for the former to be diazotized, while the latter still undergo the reaction. In dilute acid, the actual attacking species is N_2O_3 , which acts as a carrier of NO^+ . Evidence is that the reaction is second order in nitrous acid and, at sufficiently low acidities, the amine does not appear in the rate expression.⁷⁸² Under these conditions the mechanism is

Other evidence exists for this mechanism.⁷⁸³ Other attacking species can be NOCl, H_2NO_2^+ , and at high acidities even NO^+ . Nucleophiles (e.g., Cl^- , SCN^- , and thiourea) catalyze the reaction by converting the HONO to a better electrophile (e.g., $\text{HNO}_2 + \text{Cl}^- + \text{H}^+ \rightarrow \text{NOCl} + \text{H}_2\text{O}$).⁷⁸⁴

N-Aryl ureas are converted to the aryldiazonium nitrate upon treatment with NaNO_2 and H_2SO_4 in dioxane⁷⁸⁵ or with $\text{DMF}-\text{NO}_2$ in DMF.⁷⁸⁶

There are many preparations of diazonium salts listed in *Organic Syntheses*, but they are always prepared for use in other reactions. They are listed under reactions in which they are used. The preparation of aliphatic diazo compounds can be found in OS **III**, 392; **IV**, 424. See also, OS **VI**, 840.

13-20 Hydroxylation of Aryldiazonium Salts

Hydroxy-de-diazoniatio

This reaction is formally analogous to **13-1**, but with a N_2^+ leaving group rather than a halide. Water is usually present whenever diazonium salts are made, but at these temperatures (0–5 °C) the reaction proceeds very slowly. When it is *desired* to have OH replace the diazonium group, the excess nitrous acid is destroyed and the solution is usually boiled. Some diazonium salts require even more vigorous treatment, for example, boiling with aq H_2SO_4 or with trifluoroacetic acid containing potassium trifluoroacetate.⁷⁸⁷ The reaction can be performed on solutions of any diazonium salts, but hydrogen sulfates are preferred to chlorides or nitrates, since in these cases there is competition from the nucleophiles Cl^- or NO_3^- .

A better method, which is faster, avoids side reactions, takes place at room temperature, and gives higher yields consists of adding Cu_2O to a dilute solution of the diazonium salt dissolved in a solution containing a large excess of $\text{Cu}(\text{NO}_3)_2$.⁷⁸⁸ Aryl radicals are intermediates when this method is used. It has been shown that aryl radicals are at least

partly involved when ordinary hydroxy-de-diazonation is carried out in weakly alkaline aqueous solution.⁷⁸⁹ Decomposition of arenediazonium tetrafluoroborates in F_3CSO_2OH gives aryl triflates directly, in high yields.⁷⁹⁰

OS I, 404; **III**, 130, 453, 564; **V**, 1130.

13-21 Replacement by Sulfur-Containing Groups

Mercapto-de-diazonation, and so on

These reactions are convenient methods for incorporating a sulfur-containing group onto an aromatic ring. With Ar'S^- , diazosulfides (Ar-N=N-S-Ar') are intermediates,⁷⁹¹ which can in some cases be isolated.⁷⁹² Thiophenols can be made as shown above, but more often the diazonium ion is treated with EtO-CSS^- or S_2^{2-} , which give the expected products, and these are easily convertible to thiophenols. Aryldiazonium salts are prepared by the reaction of an aniline derivative with an alkyl nitrite (RONO), and when formed in the presence of dimethyl disulfide (MeS-SMe), the product is the thioether (Ar-S-Me).⁷⁹³ Aryl triflates have been converted to the aryl thiol using NaST(P5) and a Pd catalyst, followed by treatment with tetrabutylammonium fluoride⁷⁹⁴ (see also, Reaction **14-22**).

OS **II**, 580; **III**, 809 (but see OS **V**, 1050). Also see, OS **II**, 238.

13-22 Replacement by Iodine

Iodo-de-diazonation

One of the best methods for the introduction of iodine into aromatic rings (see Reaction **13-7**) is the reaction of diazonium salts with iodide ions.⁷⁹⁵ Analogous reactions with chloride, bromide, and fluoride ions give poorer results, and Reactions **14-20** and **13-23** are preferred for the preparation of aryl chlorides, bromides, and fluorides. However, when other diazonium reactions are carried out in the presence of these ions, halides are usually side products. Aniline has also been converted to fluorobenzene by treatment with *t*-BuONO and SiF_4 followed by heating.⁷⁹⁶ A related reaction between PhN=N-NR_2 and iodine gave iodobenzene.⁷⁹⁷

⁷⁹⁷ Wu, Z.; Moore, J.S. *Tetrahedron Lett.* **1994**, 35, 5539.

The actual attacking species is probably not only I^- if it is I^- at all. The iodide ion is oxidized (by the diazonium ion, nitrous acid, or some other oxidizing agent) to iodine, which in a solution containing iodide ions is converted to I_3^- ; this is the actual attacking species, at least partly. This was shown by isolation of $\text{ArN}_2^+ \text{I}_3^-$ salts, which, on standing, gave ArI .⁷⁹⁸ From this, it can be inferred that the reason the other halide ions give poor results is *not* that they are poor nucleophiles but *rather* they are poor reducing agents (compared with iodide). There is also evidence for a free radical mechanism.⁷⁹⁹

The hydroxyl group of a phenol can be replaced with iodine. The reaction of phenol with a boronic ester and a Pd catalyst, followed by reaction with NaI and chloramine-T (see Reaction 15-52) converts phenol to iodobenzene.⁸⁰⁰ Arylboronic acids are converted to the aryl fluoride with Selectfluor, in the presence of a Pd catalyst.⁸⁰¹

OS II, 351, 355, 604; V, 1120.

13-23 The Schiemann Reaction

Fluoro-de-diazonation (overall transformation)

Heating diazonium fluoroborates (the *Schiemann* or *Balz–Schiemann reaction*) is by far the best way to introduce fluorine into an aromatic ring.⁸⁰² In the most common procedure, the tetrafluoroborate salts are prepared by diazotizing as usual with nitrous acid and HCl and then adding a cold aqueous solution of NaBF_4 , HBF_4 , or NH_4BF_4 . A precipitate forms, which is dried, and the salt is heated in the dry state. These salts are unusually stable for diazonium salts, and the reaction is usually successful (since diazonium salts are generally unstable, care should be exercised any time a diazonium salt is dried). In general, any aromatic amine that can be diazotized will form a BF_4^- salt, usually with high yields. The diazonium fluoroborates can be formed directly from primary aromatic amines with *tert*-butyl nitrite and BF_3 -etherate.⁸⁰³ The reaction has also been carried out on $\text{ArN}_2^+ \text{PF}_6^-$, $\text{ArN}_2^+ \text{SbF}_6^-$, and $\text{ArN}_2^+ \text{AsF}_6^-$ salts, in many cases with better yields.⁸⁰⁴ Aryl chlorides and bromides are commonly prepared by the *Sandmeyer reaction* (14-20). In an alternative procedure, aryl fluorides are prepared by treatment of aryltriazenes $\text{Ar}-\text{N}=\text{N}-\text{NR}_2$ with 70% HF in pyridine.⁸⁰⁵

The mechanism is of the $\text{S}_{\text{N}}1$ type. That aryl cations are intermediates was shown by the following experiments⁸⁰⁶: Aryl diazonium chlorides are known to arylate other aromatic rings by a free radical mechanism (see Reaction 13-27). In radical arylation it does not matter whether the other ring contains electron-withdrawing or electron-donating groups; in either case a mixture of isomers is obtained, since the attack is not by a charged species.

⁸⁰⁶ See also, Swain, C.G.; Sheats, J.E.; Harbison, K.G. *J. Am. Chem. Soc.* **1975**, 97, 783, 796; Becker, H.G.O.; Israel, G. *J. Prakt. Chem.* **1979**, 321, 579.

If an aryl radical were an intermediate in the *Schiemann reaction* and the reaction were run in the presence of other rings, it should not matter what kinds of groups were on these other rings: Mixtures of biaryls should be obtained in all cases. But if an aryl cation is an intermediate in the *Schiemann reaction*, compounds containing meta-directing groups (i.e., meta-directing for *electrophilic* substitutions), should be meta arylated and those containing ortho–para directing groups should be ortho and para arylated, since an aryl cation should behave in this respect like any electrophile (see Chapter 11). Experiments have shown⁸⁰⁷ that such orientation is observed, demonstrating that the *Schiemann reaction* has a positively charged intermediate. The attacking species, in at least some instances, is not F^- but BF_4^- .⁸⁰⁸

OS II, 188, 295, 299; V, 133.

13-24 Conversion of Amines to Azo Compounds

N-Arylimino-de-dihydro-bisubstitution

Aromatic nitroso compounds combine with primary arylamines in glacial acetic acid to give symmetrical or unsymmetrical azo compounds (the *Mills reaction*).⁸⁰⁹ A wide variety of substituents may be present in both aryl groups. Unsymmetrical azo compounds have also been prepared by the reaction between aromatic nitro compounds ($ArNO_2$) and *N*-acyl aromatic amines ($Ar'NHAc$).⁸¹⁰ The use of phase-transfer catalysis increased the yields.

13-25 Methylation, Vinylation, and Arylation of Diazonium Salts

Methyl-de-diazonation, and so on

A methyl group can be introduced into an aromatic ring by treatment of diazonium salts with tetramethyltin and a Pd catalyst.⁸¹¹ The reaction has been performed with Me, Cl, Br, and NO_2 groups on the ring. A vinylic group can be introduced with $CH_2=CHSnBu_3$. When an aryl amine is treated with *tert*-butyl hyponitrite (*t*-BuONO) and allyl bromide, the nitrogen is displaced to give the allyl–aryl compound.⁸¹²

Aryl diazonium salts can be used coupled with alkenes in a *Heck-like reaction* (Reaction 13-10).⁸¹³ Other reactive aryl species also couple with aryldiazonium salts in the presence of a Pd catalyst.⁸¹⁴ A *Suzuki-type* coupling (Reaction 13-12) has also been reported using arylboronic acids, aryldiazonium salts, and a Pd catalyst.⁸¹⁵

Aryltrifluoroborates (Reaction **12-28**) react with aryldiazonium salts in the presence of a Pd catalyst to give the corresponding biaryl.⁸¹⁶ See Reaction **13-12**. Arylborate esters also react using a Pd catalyst, and the aryl diazonium unit reacts faster than an aryl halide.⁸¹⁷

13-26 Arylation of Activated Alkenes by Diazonium Salts: Meerwein Arylation

Arylation or Aryl-de-hydrogenation

Alkenes activated by an electron-withdrawing group (Z may be C=C, halogen, C=O, Ar, CN, etc.) can be arylated by treatment with a diazonium salt and a cupric chloride⁸¹⁸ catalyst. This is called the *Meerwein arylation reaction*.⁸¹⁹ Addition of ArCl to the double bond (to give Z(Cl)C—CHAr) is a side reaction (**15-46**). In an improved procedure, an arylamine is treated with an alkyl nitrite (generating ArN₂⁺ *in situ*) and a copper(II) halide in the presence of the alkene.⁸²⁰

The mechanism is probably of the free radical type, with Ar• (**36**) forming as in Reaction **14-20**, and then halogen transfer to give **37** or elimination to give **38**.⁸²¹

The radical **36** can react with cupric chloride by two pathways, one of which leads to addition and the other to substitution. Even when the addition pathway is taken, however, the substitution product may still be formed by subsequent elimination of HCl. Note that radical reactions are presented in Chapter 14, but the coupling of an alkene with an aromatic compound containing a leaving group prompted its placement here. Note the similarity to the *Heck reaction* in Reaction **13-10**.

OS IV, 15.

13-27 Arylation of Aromatic Compounds by Diazonium Salts

Arylation or Aryl-de-hydrogenation

When the normally acidic solution of a diazonium salt is made alkaline, the aryl portion of the diazonium salt can couple with another aromatic ring. Known as the *Gomberg* or *Gomberg–Bachmann reaction*,⁸²² it has been performed on several types of aromatic rings and on quinones. Yields are not high (usually <40%) because of the many side reactions undergone by diazonium salts, although higher yields have been obtained under phase-transfer conditions.⁸²³ The conditions of the *Meerwein reaction* (**13-26**), treatment of the solution with a copper-ion catalyst, have also been used, as has the addition of sodium nitrite in DMSO (to benzenediazonium tetrafluoroborate).⁸²⁴ When the *Gomberg–Bachmann reaction* is performed intramolecularly as in the formation of **39**, either by the alkaline solution or by the copper-ion procedure, it is called the *Pschorr reaction*⁸²⁵ and yields are usually somewhat higher. Still higher yields have been obtained by carrying out the *Pschorr reaction* electrochemically.⁸²⁶ The *Pschorr reaction* has been carried out for $Z = \text{CH}=\text{CH}$, CH_2CH_2 , NH , $\text{C}=\text{O}$, CH_2 , and quite a few others. A rapid and convenient way to diazotize the amine substrate uses isopropyl nitrite in the presence of sodium iodide, in which case the ring-closed product is formed in one step.⁸²⁷ Palladium-catalyzed arylation of arenediazonium salts are known.⁸²⁸

Other compounds with nitrogen–nitrogen bonds have been used instead of diazonium salts. Among these are *N*-nitroso amides [$\text{ArN}(\text{NO})\text{COR}$], triazenes,⁸²⁹ and azo compounds. Still another method involves treatment of an aromatic primary amine directly with an alkyl nitrite in an aromatic substrate as solvent.⁸³⁰

In each case, the mechanism involves generation of an aryl radical from a covalent azo compound. In acid solution, diazonium salts are ionic and their reactions are polar. When they cleave, the product is an aryl cation (see Sec. 13.A.i). However, in neutral or basic solution, diazonium ions are converted to covalent compounds, and these cleave to give free radicals (Ar^\bullet and Z^\bullet). Note that radical reactions are presented in Chapter 14, but the coupling of an aromatic ring with an aromatic compound containing a leaving group prompted its placement here. Note the similarity to the *Suzuki Reaction* in **13-12**.

⁸³⁰ Fillipi, G.; Verrin, G.; Dou, H.J.; Metzger, J.; Perkins, M.J. *Bull. Soc. Chim. Fr.* **1974**, 1075.

Under *Gomberg–Bachmann* conditions, the species that cleaves is the anhydride (**40**).⁸³¹

The aryl radical thus formed attacks the substrate to give the aryl cation⁸³² intermediate **42** (see Sec. 14.A.iii), from which the radical **41** abstracts hydrogen to give the product (**43**). *N*-Nitroso amides probably rearrange to *N*-acyloxy compounds (**44**), which cleave to give aryl radicals.⁸³³ There is evidence that the reaction with alkyl nitrites also involves attack by aryl radicals.⁸³⁴

The *Pschorr reaction* can take place by two different mechanisms, depending on conditions: (1) attack by an aryl radical (as in the *Gomberg–Bachmann reaction*) or (2) attack by an aryl cation (similar to the $\text{S}_{\text{N}}1$ mechanism discussed in Sec. 13.A.ii).⁸³⁵ Under certain conditions the ordinary *Gomberg–Bachmann reaction* can also involve attack by aryl cations.⁸³⁶

OS **I**, 113; **IV**, 718.

13-28 Aryl Dimerization with Diazonium Salts

De-diazonio-coupling; Arylazo-de-diazonio-substitution

When diazonium salts are treated with cuprous ion (or with Cu and acid, in which case it is called the *Gatterman method*), two products are possible. If the ring contains electron-withdrawing groups, the main product is the biaryl, but the presence of electron-donating groups leads mainly to the azo compound. This reaction is different from Reaction **13-27** (and from **19-14**) in that *both* aryl groups in the product originate from ArN_2^+ , that is, hydrogen is not a leaving group in this reaction. The mechanism probably involves free radicals.⁸³⁷

13-29 Replacement of Nitro

Alkyl-de-nitration, Hydroxy and alkoxy-de-nitration, Halo-de-nitration

In some cases, the nitrogen group of an aromatic nitro compound can be replaced with an alkyl group. The reaction of 1,4-dinitrobenzene with potassium *tert*-butoxide in the presence of BEt_3 , for example, gave 4-ethylnitrobenzene.⁸³⁸

Other nucleophiles can replace a nitrogen-containing group. The reaction of hydroxide with $\text{Ar}-\text{Y}$, where $\text{Y} = \text{nitro},^{839} \text{ azide}, \text{NR}_3^+$, and so on gives the corresponding phenol. This latter reaction works with alkoxide nucleophiles to give the corresponding aryl ether. The nitro can be replaced with chloro by use of NH_4Cl , PCl_5 , SOCl_2 , HCl , Cl_2 , or CCl_4 . Some of these reagents operate only at high temperatures and the mechanism is not always nucleophilic substitution. Activated aromatic nitro compounds can be converted to fluorides with fluoride ion.⁸⁴⁰

The reaction of vinyl nitro compounds ($\text{C}=\text{C}-\text{NO}_2$) and aryl iodide to give the styrene compound ($\text{C}=\text{C}-\text{Ar}$) was reported using BEt_3 and exposure to air.⁸⁴¹

13.C.iv. REARRANGEMENTS

13-30 The von Richter Rearrangement

Hydro-de-nitro-cine-substitution

When aromatic nitro compounds are treated with cyanide ion, the nitro group is displaced and a carboxyl group enters with cine substitution (Sec. 13.A.iii), always ortho to the displaced group, never meta or para. The scope of this reaction, called the *von Richter rearrangement*, is variable.⁸⁴² As with other nucleophilic aromatic substitutions, the reaction gives best results when electron-withdrawing groups are in ortho and para positions, but yields are low, usually <20% and never >50%.

At one time, it was believed that a nitrile (ArCN) was an intermediate, since cyanide is the reagent and nitriles are hydrolyzable to carboxylic acids under the reaction conditions (16-4). However, a remarkable series of results proved this belief to be in error. Bunnett and Rauhut⁸⁴³ demonstrated that α -naphthyl cyanide is *not* hydrolyzable to α -naphthoic acid under conditions at which β -nitronaphthalene undergoes the *von Richter rearrangement* to give α -naphthoic acid. This proved that the nitrile could not be an intermediate. It was subsequently demonstrated that N_2 is a major product of the reaction.⁸⁴⁴ It had

previously been assumed that all the nitrogen in the reaction was converted to ammonia, which would be compatible with a nitrile intermediate, since ammonia is a hydrolysis product of nitriles. At the same time it was shown that NO_2^+ is not a major product. The discovery of nitrogen indicated that a nitrogen–nitrogen bond must be formed during the course of the reaction. Rosenblum proposed a mechanism in accord with all the facts⁸⁴³:

Note that **46** is a stable compound: Hence, it should be possible to prepare it independently and to subject it to the conditions of the *von Richter rearrangement*. This was done and the correct products are obtained.⁸⁴⁵ Further evidence is that when **45** ($Z = \text{Cl}$ or Br) was treated with cyanide in H_2^{18}O , half the oxygen in the product was labeled, showing that one of the oxygen atoms of the carboxyl group came from the nitro group and one from the solvent, as required by this mechanism.⁸⁴⁶

13-31 The Sommelet–Hauser Rearrangement

Benzylic quaternary ammonium salts, when treated with alkali metal amides, undergo a rearrangement called the *Sommelet–Hauser rearrangement*.⁸⁴⁷ Since the product is a benzylic tertiary amine, it can be further alkylated and the product again subjected to the rearrangement. This process can be continued around the ring until an ortho position is blocked.⁸⁴⁸

The rearrangement occurs with high yields and can be performed with various groups present in the ring.⁸⁴⁹ The reaction is most often carried out with three methyl groups on the

nitrogen, but other groups can also be used, though if a β -hydrogen is present, *Hofmann elimination* (Reaction 17-7) often competes. The *Stevens rearrangement* (Reaction 18-21) is also a competing process.⁸⁵⁰ When both rearrangements are possible, the *Stevens rearrangement* is favored at high temperatures and the *Sommelet–Hauser* at low temperatures.⁸⁵¹ The mechanism is:

The benzylic hydrogen is most acidic and is the one that first loses a proton to give the ylide (47). However, 48, which is present in a smaller amount, is the species that undergoes the rearrangement, shifting the equilibrium in its favor. This mechanism is an example of a [2,3]-sigmatropic rearrangement (see Reaction 18-35). Another mechanism that might be proposed is one in which a methyl group actually breaks away (in some form) from the nitrogen and then attaches itself to the ring. That this is not so was shown by a product study.⁸⁵² If the second mechanism were true, 49 should give 50, but the first mechanism predicts the formation of 51, which is what was actually obtained.⁸⁵³

The mechanism as shown can lead only to an ortho product. However, a small amount of para product has been obtained in some cases.⁸⁵⁴ A mechanism⁸⁵⁵ in which there is a dissociation of the $\text{ArC}-\text{N}$ bond (similar to the ion-pair mechanism of the *Stevens rearrangement*, Reaction 18-21) has been invoked to explain the para products that are observed.

Sulfur ylids containing a benzylic group (analogous to 48) undergo an analogous rearrangement.⁸⁵⁶

13-32 Rearrangement of Aryl Hydroxylamines

1/C-Hydro-5/N-hydroxy-interchange

Aryl hydroxylamines treated with acids rearrange to aminophenols.⁸⁵⁷ Although this reaction (known as the *Bamberger rearrangement*) is similar in appearance to Reactions **11-28–11-32**, the attack on the ring is not electrophilic but nucleophilic. The rearrangement is intermolecular, with the following mechanism:

Among the evidence⁸⁵⁸ for this mechanism are the facts that other products are obtained when the reaction is run in the presence of competing nucleophiles (e.g., *p*-ethoxyaniline) when ethanol is present, and that when the para position is blocked, compounds similar to **53** are isolated. In the case of 2,6-dimethylphenylhydroxylamine, the intermediate nitrenium ion (**52**) was trapped, and its lifetime in solution was measured.⁸⁵⁹ The reaction of **52** with water was found to be diffusion controlled.⁸⁶⁰

There is a base-mediated rearrangement of aromatic hydroxamic acids to anilines.⁸⁶¹ OS IV, 148.

13-33 The Smiles Rearrangement

The *Smiles rearrangement* actually comprises a group of rearrangements that follow the pattern given above.⁸⁶² A specific example is the reaction of **54** with hydroxide to give **55**.

Smiles rearrangements are simply intramolecular nucleophilic substitutions. In the example given, SO_2Ar is the leaving group and ArO^- is the nucleophile. The nitro group serves to activate its ortho position. Halogens also serve as activating groups.⁸⁶³ The ring at which the substitution takes place is nearly always activated, usually by ortho or para nitro groups. Here X is usually S, SO, SO_2 ,⁸⁶⁴ O, or CO_2 , and Y is usually the conjugate base of OH, NH_2 , NHR , or SH. The reaction has even been carried out with $\text{Y} = \text{CH}_2^-$ (phenyllithium was the base here).⁸⁶⁵

The reaction rate is greatly enhanced by substitution in the 6 position of the attacking ring, for steric reasons. For example, a methyl, chloro, or bromo group in the 6 position of **54** caused the rate to be $\sim 10^5$ times faster than when the same groups were in the 4 position,⁸⁶⁶ although electrical effects should be similar at these positions. The enhanced rate comes about because the most favorable conformation of the molecule can adapt to suit the bulk of the 6-substituent is also the conformation required for the rearrangement. Thus, less entropy of activation is required.

Although the *Smiles rearrangement* is usually carried out on compounds containing two rings, this need not be the case, as in the formation of **56**.⁸⁶⁷

In this case the, sulfenic acid (**56**) is unstable⁸⁶⁸ and the actual products isolated were the corresponding sulfinic acid (RSO_2H) and disulfide (R_2S_2).

In the *Smiles rearrangement*, the nucleophile Y is most often the conjugate base of SH, SO_2NHR , SO_2NH_2 , NH_2 , NHR , OH, and OR. There are few examples where Y is a

carbanion, and the most common example is probably the *Truce–Smiles rearrangement*, where L—YH is an *o*-tolyl group.⁸⁶⁹ The prototypical *Truce–Smiles rearrangement* requires use of a strong base to form the benzylic carbanion that undergoes the rearrangement. When sulfone (**57**) was treated with butyllithium, for example, deprotonation led to the benzylic lithium compound (**58**). *Truce–Smiles rearrangement* led to **59**, and hydrolysis gave the sulfinic acid (**60**).⁸⁷⁰ *Truce–Smiles rearrangements* with stabilized benzylic carbanions are known,⁸⁷⁰ and rearrangements of carbanions in general fall under this category.⁸⁷¹ Relatively few examples have been reported, however.⁸⁷² *Truce–Smiles rearrangements* of sulfones that proceed through a six-membered transition state have been reported.⁸⁷³ In another example, displacement of an activated aryl fluoride with *o*-hydroxyacetophenone gave a product that was C-arylated adjacent to the ketone.⁸⁷⁴

Substitution Reactions: Radical

This chapter discusses many types of radical reactions, including reactions in which radicals may be intermediates. Radicals are increasingly important in organic synthesis.¹ The formation, fate, and properties of radicals were introduced in Section 5.C. Additional information concerning radicals may be found in Section 7.A, in the discussion of photochemical processes.

For the most part, this chapter discusses radical substitution reactions. Free radical additions to unsaturated compounds and rearrangements are discussed in Chapters 15 and 18, respectively. Fragmentation reactions are covered, in part, in Chapter 17. In addition, many of the oxidation–reduction reactions considered in Chapter 19 involve free radical mechanisms. Several important types of free radical reactions do not usually lead to reasonable yields of pure products and are not generally treated in this book.

14.A. MECHANISMS

14.A.i. Radical Mechanisms in General²

A free radical process (or just a radical process) consists of at least two steps. Any radical reaction first step involve the *formation* of free radicals, usually by homolytic cleavage of a bond; that is, a cleavage in which each fragment retains one electron:

This is called an *initiation* step. It may happen spontaneously or may be induced by heat³ or light (see the discussion in Sec. 5.C.ii), depending on the type of bond.⁴ Peroxides,

including hydrogen peroxide, dialkyl, diacyl, alkyl acyl peroxides, and peroxyacids are the most common source of free radicals. However, other organic compounds with low-energy bonds (e.g., azo compounds) are also used. Chlorine, bromine, and various ketones (see Chapter 7) are most commonly cleaved by light. Radicals can also be formed by a one-electron transfer (loss or gain) (e.g., $A^+ + e^- \rightarrow A^\bullet$). One-electron transfers usually involve inorganic ions or electrochemical processes.⁵

Dialkyl peroxides (ROOR) or alkyl hydroperoxides (ROOH) decompose to hydroxy radicals (HO^\bullet) or alkoxy radicals (RO^\bullet) when heated.⁶ Cumene hydroperoxide ($PhCMe_2OOH$), bi-*tert*-butylperoxide ($Me_3COOCMe_3$),⁷ and benzoyl peroxide [$(PhCO)O_2$] undergo homolytic cleavage at temperatures compatible with many organic reactions. They are also reasonably soluble in organic solvents.⁸ In general, when a peroxide decomposes, the oxygen radical remains in a “cage” for $\sim 10^{-11}$ s before diffusing away. The radical can

recombine (dimerize), or react with other molecules. Azo compounds, characterized by a $-\text{N}=\text{N}-$ bond, are free radical precursors that liberate nitrogen gas (N_2) upon decomposition. Azo bisisobutyronitrile (AIBN, **1**) is a well-known example, which decomposes to give nitrogen gas and the cyano stabilized radical (**2**).⁹ Homolytic dissociation of symmetrical diazo compounds may be stepwise.¹⁰ A derivative has been developed that decomposes at room temperature: 2,2'-azobis(2,4-dimethyl-4-methoxyvaleronitrile), **3**.¹¹ Water soluble azo compounds are known, and can be used as radical initiators.¹²

Alkyl hypochlorites ($\text{R}-\text{O}-\text{Cl}$) generate chlorine radicals (Cl^\bullet) and alkoxy radicals (RO^\bullet) when heated.¹³ Heating *N*-alkoxydithiocarbamates is another useful source of alkoxy radicals (RO^\bullet).¹⁴ Alkoxy radicals, particularly those derived from cyclic compounds, may undergo β -scission reactions to give carbonyl derivatives.¹⁵

It has been known for many years that boron compounds participate in radical reactions.¹⁶ Trialkylboranes (R_3B ; see Reactions **15-27** and **12-27**), such as triethylborane (Et_3B), can be used to initiate radical reactions. Indeed, Et_3B is widely used.¹⁷ In radical reactions, Et_3B functions as both a radical initiator and also as a chain-propagation agent.¹⁸ Reactions are usually run in open vessels exposed to oxygen or under an oxygen atmosphere. It is known that O_2 is involved in the initiation step, as shown, in this case using an atom-transfer reaction with an alkyl iodide to give the alkyl radical, (R^\bullet). Trialkylborane/water-mediated radical reactions are also known.¹⁹

In general, the order of reactivity is $R_3B > R_2BOR > RB(OR)_2$ where $R = \text{alkyl}$.²⁰ Boronic acids are less reactive, presumably due to π -bonding between B and O.¹⁷ However, B-alkylcatecholboranes are very reactive, and highly useful for initiating radical reactions.²¹ Reaction conditions usually involve addition of catecholborane (**4**, abbreviated CatBH), and the B-alkyl derivative is presumably generated *in situ* by reaction with an alkene.²² Note that borole derivatives (the B analogue of pyrrole, **5**) have been used to initiate radical reactions.²³

Aldehydes can be a source of acyl radicals ($^\bullet C=O$) via reaction with transition metal salts (e.g., Mn(III) acetate or Fe(II) compounds).²⁴ α,β -Unsaturated acyl radicals are subject to an isomerization that generates α -ketenyl radicals.²⁵ Another useful variation employs imidoyl radicals as synthons for unstable aryl radicals.²⁶

An important step in radical reactions involves the *destruction* of free radicals. This usually happens by a process opposite to the first, namely, a combination of two like or unlike radicals to form a new bond:²⁷

This type of step is called *termination* because the product of the reaction is a neutral compound and not a radical.²⁸ Note that this reaction constitutes a radical coupling process. The termination step rarely follows initiation because most radicals are very reactive, and there are several radical processes that occur faster than the termination step. In the usual situation, in which the concentration of radicals is low, a radical is more likely to react with a molecule rather than another radical (i.e., the radical coupling reaction is usually slower). When a radical, which has an odd number of electrons, reacts with a molecule, which has an even number, the total number of electrons in the products must be odd. In other words, the product is another radical. When a radical

reacts with a π bond, for example, the product is free radical (**6**). This reaction is called a *radical addition*. Another reaction constitutes an *atom-transfer reaction*. The abstraction of an atom (e.g., hydrogen atom) from an alkyl fragment gives two particles: $R-H$ and the new radical (R'^{\bullet}), as shown. This type of atom-transfer reaction is called a *hydrogen-transfer reaction*.

Once again, the product is a free radical. This type of step is called *propagation*, since the newly formed radical can now react with another molecule and produce another radical, and so on, until two radicals undergo coupling and terminate the sequence. The process of initiation, propagation, and then termination constitutes what is called a *chain reaction*,²⁹ and there may be hundreds or thousands of propagation steps between an initiation and a termination. Two other types of propagation reactions do not involve a molecule at all. These are (1) cleavage of a radical into, necessarily, a radical and a molecule and (2) rearrangement of one radical to another (see Chapter 18). When radicals are highly reactive (e.g., alkyl radicals), chains are long, since reactions occur with many molecules; but with radicals of low reactivity (e.g., aryl radicals), the radical may be unable to react with anything until it meets another radical, so that chains are short. Alternatively, the reaction may be a nonchain process. In any particular chain process, there is usually a wide variety of propagation and termination steps so there may be many products. Such reaction are often difficult to treat kinetically.³⁰

²⁷ For a review of stereochemistry, see Porter, N.A.; Krebs, P.J. *Top. Stereochem.* **1988**, 18, 97.

²⁸ Another type of termination step is *disproportionation* (see Sec. 5.C.ii).

²⁹ See Walling, C. *Tetrahedron* **1985**, 41, 3887.

³⁰ See Huyser, E.S. *Free-Radical Chain Reactions*, Wiley, NY, **1970**, pp. 39–65.

Is it possible to terminate a radical reaction under controlled conditions? The answer is yes, using an atom-transfer reaction. When a carbon radical (R^\bullet) is generated in the presence of tributyltin hydride ($n\text{-Bu}_3\text{SnH}$), a hydrogen atom is transferred to the radical to give $R\text{—H}$ and a new radical ($n\text{-Bu}_3\text{Sn}^\bullet$). The tin radical usually undergoes rapid coupling to another tin radical to give $n\text{-Bu}_3\text{Sn—Sn—}n\text{-Bu}_3$, which effectively terminates the chain-radical process. The carbon radical is *reduced* ($R^\bullet \rightarrow R\text{—H}$) as a result of the hydrogen-atom transfer, and the tin dimer can be removed from the reaction. Again, hydrogen-atom transfer³¹ is simply a variation of the radical reaction known as atom transfer. Silanes (e.g., triethylsilane, Et_3SiH), have also been used as an effective radical reducing agent.³² The rate constants for the reaction of both tributyltin hydride and $(\text{Me}_3\text{Si})_3\text{Si—H}$ with acyl radical have been measured and the silane quenches the radical faster than the tin hydride.³³ Thermolysis of bis(tri-*n*-butylstannyl)benzopinacolate has also been used as a source of $n\text{-Bu}_3\text{Sn}^\bullet$, used to mediate radical reactions.³⁴

The following are some general characteristics of free radical reactions³⁵:

1. Reactions are fairly similar whether they are occurring in the vapor or liquid phase, but solvation of free radicals in solution does cause some differences.³⁶
2. They are largely unaffected by the presence of acids or bases or by changes in the polarity of solvents, except that nonpolar solvents may suppress competing ionic reactions.
3. They are initiated or accelerated by typical free radical sources (e.g., the peroxides or diazo compounds) noted above, or by light. In the latter case, the concept of quantum yield applies (Sec. 7.A.viii). Quantum yields can be quite high (e.g., 1000), if each quantum generates a long chain, or low, in the case of nonchain processes.
4. Their rates are decreased or the reactions are suppressed entirely by substances that scavenge free radicals (e.g., nitric oxide, molecular oxygen, or benzoquinone). These substances are called *inhibitors*.³⁷ Note that there are C-centered radicals in thermal equilibrium with their dimers that show poor reactivity with molecular oxygen, but good reactivity with peroxy radicals.³⁸

14.A.ii. Free Radical Substitution Mechanisms³⁹

In a free radical substitution reaction

there must first be a cleavage of the substrate RX so that R^\bullet radicals are produced. This can happen by a spontaneous cleavage,

³⁹ See Poutsma, M.L. in Kochi, J.K. *Free Radicals*, Vol. 2, Wiley, NY, **1973**, pp. 113–158.

or it can be caused by light or heat, or, more often, there is no actual cleavage, but R^\bullet is produced by an *abstraction* of another atom, X by the radical W^\bullet .

The radical W^\bullet is produced by adding a compound (e.g., peroxide) that spontaneously forms free radicals. Such a compound is called an *initiator* (see above). Once R^\bullet is formed, it can go to product in this system, by another atom abstraction, such as the reaction with $\text{A}-\text{B}$ to form $\text{R}-\text{A}$ and a new radical B^\bullet (atom transfer).

Another reaction is coupling with another radical to form the neutral product $\text{R}-\text{Y}$.

In a reaction with a moderately long chain, much more of the product will be produced by abstraction (4) than by coupling (5). Cleavage steps like (2) have been called $\text{S}_{\text{H}}1$ (H for homolytic), and abstraction steps like (3) and (4) have been called $\text{S}_{\text{H}}2$; reactions can be classified as $\text{S}_{\text{H}}1$ or $\text{S}_{\text{H}}2$ on the basis of whether RX is converted to R by (2) or (3).⁴⁰ Most chain substitution mechanisms follow the pattern (3), (4), (3), (4) ... Chains are long and reactions go well where both (3) and (4) are energetically favored (no worse than slightly endothermic, see Sec. 14.B.i and 14.C.i). The IUPAC designation of a chain reaction that follows the pattern (3),(4) ... is $\text{A}_\text{r}\text{D}_\text{R} + \text{A}_\text{r}\text{D}_\text{r}$ (R stands for radical).

With certain radicals the transition state in an abstraction reaction has some polar character. Consider the abstraction of hydrogen from the methyl group of toluene by a bromine atom. Since bromine is more electronegative than carbon, it is reasonable to assume that there is a separation of charge in the transition state, with a partial negative charge on the halogen and a partial positive charge on the carbon:

Evidence for the polar character of the transition state is that electron-withdrawing groups in the para position of toluene, which would destabilize a positive charge, decrease the rate of hydrogen abstraction by bromine while electron-donating groups increase it.⁴¹ However, substituents have a smaller effect here ($\rho \approx -1.4$) than they do in reactions where a completely ionic intermediate is involved (e.g., the $\text{S}_{\text{N}}1$ mechanism, Sec. 10.A.ii). Other evidence for polar transition states in radical abstraction reactions is mentioned in Section 14.B.i, category 4. For abstraction by radicals such as methyl or phenyl, polar effects are very small or completely absent. For example, rates of hydrogen-atom abstraction from ring-substituted toluenes by methyl radical were relatively unaffected by the presence of electron-donating or electron-withdrawing substituents.⁴² Those radicals (e.g., Br^\bullet) that have a tendency to abstract electron-rich hydrogen atoms are called *electrophilic radicals*.

When the reaction step $\text{R}-\text{X} \rightarrow \text{R}^\bullet$ takes place at a stereogenic carbon, *racemization is almost always observed because free radicals do not retain configuration*. Exceptions

to this rule are found with cyclopropyl substrates, where both inversion⁴³ and retention⁴⁴ of configuration have been reported, and in the reactions mentioned in Section 14.A.iv. Enantioselective radical processes have been reviewed.⁴⁵

14.A.iii. Mechanisms at an Aromatic Substrate⁴⁶

When R in reaction (1) is aromatic, the simple abstraction mechanism just discussed may be operating, especially in gas-phase reactions. However, mechanisms of this type cannot account for all reactions of aromatic substrates. In processes such as Reactions 13-27, 14-17, and 14-18:

which occur in solution, the simple coupling of two rings by abstraction of an entire group (e.g., phenyl) to generate H^\bullet by the free radical mechanism shown here is very unlikely (see Sec. 14.B.i).

The products can be explained by a mechanism similar to that of electrophilic and nucleophilic aromatic substitution. In the first step, the radical attacks the ring in much the same way as would an electrophile or a

nucleophile to generate 7. The intermediate radical (7) is relatively stable because of the resonance. The reaction can terminate in three ways: by simple coupling to give 8, by disproportionation to give 9,

or, if a species (R'^{\bullet}) is present that abstracts hydrogen, by abstraction to give **10**.⁴⁷

Coupling product **8** is a partially hydrogenated *o*-quaterphenyl (an *o,o'*-diphenylbiphenyl). Of course, the coupling need not be ortho–ortho, and other isomers can also be formed. Among the evidence (9) and (10) was isolation of compounds of types **8** and **9**.⁴⁸ However, under the reaction conditions dihydrobiphenyls like **9** are normally oxidized to the corresponding biphenyls. Other evidence for this mechanism is the detection of the intermediate **7** by CIDNP⁴⁹ and the absence of isotope effects, expected if the rate-determining step were (7), which involves cleavage of the Ar—H bond. In the mechanism just given, the rate-determining step (8) does not involve loss of hydrogen. The reaction between aromatic rings and the HO^{\bullet} radical takes place by the same mechanism. Intramolecular hydrogen-transfer reactions of aryl radicals are known.⁵⁰ A similar mechanism has been shown for substitution at some vinylic⁵¹ and acetylenic substrates, giving the substituted alkene (**11**).⁵² The kinetics of radical heterolysis reactions that form alkene radical cations has been studied.⁵³

This is reminiscent of the nucleophilic tetrahedral mechanism at a vinylic carbon (Sec. 10.F).

There are many transition metal mediated coupling reactions of aromatic substrates that probably proceed by radical coupling. It is likely that many of these reactions do *not* proceed by free radicals, but rather by metal-mediated radicals or by ligand transfer at the metal. Reactions in these categories were presented in Chapter 13 for convenient correlation with other displacement reactions of aryl halides, aryl diazonium salts, and so on.

14.A.iv. Neighboring-Group Assistance in Free Radical Reactions

In a few cases, it has been shown that cleavage steps (2) and abstraction steps (3) were accelerated by the presence of neighboring groups. Photolytic halogenation (Reaction **14-1**) is a process that normally leads to mixtures of many products. However, bromination of carbon chains containing a bromine atom occurs with high regioselectivity. Bromination of

alkyl bromides gave 84–94% substitution at the carbon adjacent to the bromine already in the molecule.⁵⁴ This result may seem surprising because, as will be seen (Sec. 14.B.i, category 3), positions close to a polar group (e.g., bromine) should actually be *deactivated* by the electron-withdrawing field effect of the bromine. However, the unusual regioselectivity is explained by a mechanism in which abstraction (3) is assisted by a neighboring bromine atom, as in **12**.⁵⁵ In the normal mechanism, Br^\bullet abstracts a hydrogen atom from RH , leaving R^\bullet . When a bromine is present in the proper position, it assists this process, giving a cyclic intermediate (a *bridged free radical*, **13**).⁵⁶ In the final step (very similar to $\text{R}^\bullet + \text{Br}_2 \rightarrow \text{RBr} + \text{Br}^\bullet$) the ring is broken. If this mechanism is correct, the configuration at the substituted carbon (marked *) should be retained. This has been shown to be the case: Optically active 1-bromo-2-methylbutane gave 1,2-dibromo-2-methylbutane with retention of configuration.⁵⁵ Furthermore, when this reaction was carried out in

the presence of DBr , the “recovered” 1-bromo-2-methylbutane was found to be deuterated in the 2 position, and its configuration was retained.⁵⁷ This is just what would be predicted if some of the **11** present abstracted D from DBr . There is evidence that Cl can form bridged radicals,⁵⁸ though ESR spectra show that the bridging is not necessarily symmetrical.⁵⁹ Still more evidence for bridging by Br has been found in isotope effects and other studies.⁶⁰ However, evidence from CIDNP shows that the methylene protons of the β -bromoethyl radical are not equivalent, at least while the radical is present in the radical pair $[\text{PhCOO}^\bullet \cdot \text{CH}_2\text{CH}_2\text{Br}]$ within a solvent cage.⁶¹ This evidence indicates that under these conditions $\text{BrCH}_2\text{CH}_2^\bullet$ is not a symmetrically bridged radical, but it could be unsymmetrically bridged. A bridged intermediate has also been invoked, when a bromo group is in the proper position, in the *Hunsdiecker reaction*⁶² (**14-30**), and in abstraction of iodine atoms by the phenyl radical.⁶³ Participation by other neighboring groups (e.g. SR, SiR_3 , SnR_3) has also been reported.⁶⁴

Note that a traditional explanation for the selectivity of bromine relative to chlorine is that abstraction of hydrogen by a bromine radical has a later transition state relative to abstraction of hydrogen by a chlorine radical. In a later transition state, the relative stability of the radical plays a greater role than the strength of the C—H bond. Since a tertiary radical is more stable than a secondary, which is more stable than a primary radical, bromination favors formation of the secondary radical over the primary, and a tertiary over secondary. This analysis is supported by the relative rates of hydrogen-atom abstraction by Br^\bullet when compared to Cl^\bullet , where there is a large difference between 1° , 2° , and 3° for Br^\bullet and a small difference for Cl^\bullet . This effect is discussed in more detail in Section 14.B.i, categories 1–5.

14.B. REACTIVITY

14.B.i. Reactivity for Aliphatic Substrates⁶⁵

In a chain reaction, the step that determines what the product will be is most often an abstraction (atom-transfer) step. The atom abstracted by a free radical is almost never a tetra-⁶⁶ or trivalent atom⁶⁷ (except in strained systems, see Sec. 15.B.iv)⁶⁸ and seldom a divalent one.⁶⁹ Nearly always it is univalent, and for organic compounds, it is commonly hydrogen or halogen. Further, in a reaction between a chlorine radical and ethane, formation of an ethyl radical is preferred (H atom transfer) to formation of a hydrogen-atom radical (Cl atom transfer):

The principal reason for this preference is steric. A univalent atom is much more exposed to attack by the incoming radical than an atom with a higher valence. Also, in many cases abstraction of a univalent atom is energetically more favored. For example, in the reaction given above, a $\text{C}_2\text{H}_5\text{—H}$ bond is broken ($D = 100 \text{ kcal mol}^{-1}$, 419 kJ mol^{-1} , from Table 5.3) whichever pathway is taken, but in the former case an H—Cl bond is formed ($D = 103 \text{ kcal mol}^{-1}$, 432 kJ mol^{-1}) while in the latter case it is a $\text{C}_2\text{H}_5\text{—Cl}$ bond ($D = 82 \text{ kcal mol}^{-1}$, 343 kJ mol^{-1}). Thus the first reaction is favored because it is exothermic by 3 kcal mol^{-1} ($100-103$) [13 kJ mol^{-1} ($419-432$)], while the latter is endothermic by 18 kcal mol^{-1} ($100-82$) [76 kJ mol^{-1} ($419-343$)].⁷⁰ However, the steric reason is more important, because even in cases where ΔH is not very different for the two possibilities, the univalent atom is chosen.⁷¹ *Ab initio* studies have probed the transition structures for radical hydrogen abstractions.⁷²

Most studies of aliphatic reactivity have been made with hydrogen as the leaving atom and chlorine atoms as the abstracting species.⁷³ In these reactions, every hydrogen atom in the substrate is potentially replaceable and mixtures of several products may be obtained. However, the abstracting radical is not totally unselective, and some positions on a molecule lose hydrogen more easily than others. *Ab initio* studies have studied the factors controlling hydrogen abstraction by radicals.⁷⁴ For hydrogen abstraction by the *tert*-butoxy radical (*t*-Bu—O[•]) the factors that influence rate in their order of importance are structure of the radical > substituent effects⁷⁵ > solvent effects.⁷⁶ The position of attack will be discussed under several headings⁷⁷:

1. *Alkanes*. If a tertiary hydrogen atoms is present in an alkane, it is preferentially abstracted by almost any radical, with secondary hydrogen atoms being next preferred. This is in the same order as *D* values for these types of C—H bonds (Table 5.3). The extent of the preference depends on the selectivity of the abstracting radical and on the temperature. Table 14.1 shows⁷⁸ that at high temperatures selectivity decreases, as might be expected.⁷⁹ An example of the effect of radical selectivity is the comparison of fluorine atoms with bromine atoms. For the former, the ratio of primary to tertiary abstraction (of hydrogen) is 1:1.4, while for the less reactive bromine atom this ratio is 1:1600. With certain large radicals there is a steric factor that may change the selectivity pattern. For example, in the photochemical chlorination of isopentane in H₂SO₄ with *N*-chloro-di-*tert*-butylamine and *N*-chloro-*tert*-butyl-*tert*-pentylamine, the primary hydrogen atoms are abstracted 1.7 times *faster* than the tertiary hydrogen.⁸⁰ In this case, the attacking

radicals (the radical ions $R_2NH^{\bullet+}$, see Reaction 14-1) are bulky enough for steric hindrance to become a major factor.

Cyclopropylcarbinyl radicals (**14**) are alkyl radicals, but because of the cyclopropane ring with its relatively weak bonds, they undergo rapid ring opening to give butenyl radicals.⁸¹ The rate constant for this process has been measured by picosecond radical kinetic techniques to be in the range of $10^7 \text{ M}^{-1} \text{ s}^{-1}$ for the parent⁸² to $10^{10} \text{ M}^{-1} \text{ s}^{-1}$ for substituted derivatives.⁸³ Cyclobutylcarbinyl radicals undergo the cyclobutylcarbinyl to 4-pentenyl radical process,⁸⁴ but examples are generally limited to the parent system and phenyl-substituted derivatives.⁸⁵ Cyclization of the 4-pentenyl radical is usually limited to systems where a stabilized radical can be formed.⁸⁶ The effect of substituents has been studied.⁸⁷ Note that 2-aziridinylmethyl radicals also undergo ring opening via C—N or C—C cleavage to give a nitrogen or carbon radical, respectively, and the ring opening is strongly influenced by substituents at C-1 rather than those on nitrogen.⁸⁸ An alkyl substituent at the C-1 substituent generally leads to C—N cleavage, whereas a carbonyl substituent at C-1 usually favors C—C cleavage.⁸⁸

The rate of the ring-opening reaction of **5**,⁸⁹ and other substrates have been determined using an indirect method for the calibration⁹⁰ of fast radical reactions, applicable for radicals with lifetimes as short as 1 ps.⁹¹ This 'radical clock'⁹² method is based on the use of pyridine-2-thione-*N*-oxycarbonyl esters as radical precursors and radical trapping by the highly reactive thiophenol and benzeneselenenol.⁹³ A number of radical clock substrates are known.⁹⁴ Other radical clock processes include: racemization of radicals with chiral conformations,⁹⁵ one-carbon

ring expansion in cyclopentanones,⁹⁶ norcarane and spiro[2,5]octane,⁹⁷ α - and β -thujone radical rearrangements,⁹⁸ and cyclopropylcarbinyl radicals or alkoxy-carbonyl radicals containing stabilizing substituents,⁹⁹ and cyclobutylcarbinyl radicals.¹⁰⁰ *Ab initio* and density functional theory have been used to study radical clock reactions.¹⁰¹

2. *Alkenes*. When the substrate molecule contains a double bond, treatment with chlorine or bromine usually leads to addition rather than substitution, as described in Reaction 15-39. However, for other radicals (and even for chlorine or bromine atoms when they react by hydrogen transfer) the position of attack is at the allylic carbon. Vinylic hydrogen atoms are practically never abstracted, and allylic hydrogen atoms are greatly preferred to other positions of the molecule. Allylic hydrogen abstraction from a cyclic alkene is usually faster than abstraction from an acyclic alkene.¹⁰² This is generally attributed¹⁰³ to resonance stabilization of the allylic radical (15). As might be expected, allylic rearrangements (see Reaction 14-7) are common in these cases.¹⁰⁴

3. *Alkyl Side Chains of Aromatic Rings*. The preferential position of attack on a side chain is usually the one directly attached to the ring (the benzylic position). Both for active radicals (e.g., chlorine and phenyl) and for more selective ones (e.g., bromine), hydrogen exchange is faster than that at a primary carbon. For active radicals, hydrogen exchange at the benzylic position is slower than for tertiary positions, while for the selective ones it is faster. Two or three aryl groups on a carbon activate its hydrogen atoms even more, as would be expected from the resonance involved. These statements can be illustrated by the following abstraction ratios:¹⁰⁵

	Me—H	MeCH ₂ —H	Me ₂ CH—H	Me ₃ C—H	PhCH ₂ —H	Ph ₂ CH—H	Ph ₃ C—H
Br	0.0007	1	220	19,400	64,000	1.1×10^6	6.4×10^6
Cl	0.004	1	4.3	6.0	1.3	2.6	9.5

However, many anomalous results have been reported for these substrates. The benzylic position is not always the most favored. One thing certain is that *aromatic* hydrogen atoms are seldom abstracted if there are aliphatic ones to compete (note from Table 5.3, that *D* for Ph—H is higher than that for any alkyl H bond). Several

σ^\bullet scales (similar to the σ , σ^+ , and σ^- scales discussed in Chapter 9) have been developed for benzylic radicals.¹⁰⁶

4. *Compounds Containing Electron-Withdrawing Substituents.* In halogenations, electron-withdrawing groups greatly deactivate adjacent positions. Compounds of the type $Z-CH_2-CH_3$ are attacked predominantly or exclusively at the β position when Z is CO_2H , $COCl$, $COOR$, SO_2Cl , or CX_3 . Compounds, such as acetic acid and acetyl chloride, are not attacked at all, in sharp contrast to electrophilic halogenations (Reactions 12-4–12-6), where *only* the α position is substituted. This deactivation of α positions is also at variance with the expected stability of the resulting radicals, since they would be expected to be stabilized by resonance similar to that for allylic and benzylic radicals. This behavior is a result of the polar transition states discussed in Section 14.A.ii. Halogen atoms are electrophilic radicals and look for positions of high electron density. Hydrogen atoms on carbon atoms next to electron-withdrawing groups have low-electron densities (because of the field effect of Z) and are therefore shunned. Radicals that are not electrophilic do not display this behavior. For example, the methyl radical is essentially nonpolar and does not avoid positions next to electron-withdrawing groups; relative rates of abstraction at the α and β carbons of propionic acid are¹⁰⁷

CH ₃ —CH ₂ —COOH		
Me [•]	1	7.8
Cl [•]	1	0.02

It is possible to generate radicals adjacent to electron-withdrawing groups. Radical **16** can be generated and undergoes coupling reactions with little selectivity. When **17** is generated, it rapidly disproportionates rather than couples, giving the corresponding alkene and alkane.¹⁰⁸ Such radicals have also been shown to have a conformational preference for orientation of the orbital containing the single electron. In such cases, hydrogen abstraction proceeds with good stereoselectivity.¹⁰⁹

Some radicals (e.g., *tert*-butyl,¹¹⁰ benzyl,¹¹¹ and cyclopropyl)¹¹² are *nucleophilic* (they tend to abstract electron-poor hydrogen atoms).¹¹³ The phenyl radical appears to have a very small degree of nucleophilic character.¹¹⁴ For longer chains, the field effect

continues, and the β position is also deactivated to attack by halogen, though much less so than the α position. Note that in Section 14.A.ii the abstraction of an α hydrogen atom from ring-substituted toluenes can be correlated by the *Hammett equation*.

5. *Stereoelectronic Effects*. In Section 16.A.i, category 4, there is an example of a stereoelectronic effect. It has been shown that such effects are important where a hydrogen is abstracted from a carbon adjacent to a C—O or C—N bond. In such cases, hydrogen is abstracted from C—H bonds that have a relatively small dihedral angle ($\approx 30^\circ$) with the unshared orbitals of the O or N much more easily than from those with a large angle ($\sim 90^\circ$). For example, the starred hydrogen of **18** was abstracted about eight times faster than the starred hydrogen of **19**.¹¹⁵

The presence of an OR or SiR₃ substituent β - to the carbon bearing the radical accelerates the rate of halogen abstraction.¹¹⁶ Tertiary arylcarbinyloxy radicals undergo β -scission to give a ketone:¹¹⁷

Abstraction of a halogen has been studied much less,¹¹⁸ but the order of reactivity is RI > RBr > RCl \gg RF.

There are now many cases where free radical reactions are promoted by transition metals.¹¹⁹

14.B.ii. Reactivity at a Bridgehead¹²⁰

Many free radical reactions have been observed at bridgehead carbons, as in formation of bromide **20** (see Reaction 14-30),¹²¹ demonstrating that the free radical need not be planar. However, treatment of norbornane with sulfuryl chloride and benzoyl peroxide gave mostly 2-chloronorbornane, although the bridgehead position is tertiary.¹²² So, while bridgehead free radical substitution is possible, it is not preferred, presumably because of the strain involved.¹²³

14.B.iii. Reactivity in Aromatic Substrates

Free radical substitution at an aromatic carbon seldom takes place by a mechanism in which a hydrogen atom is abstracted to give an aryl radical. Reactivity considerations here are similar to those in Chapters 11 and 13; that is, which position on the ring will be attacked to give the intermediate **21**.

The obvious way to obtain this information is to carry out reactions with various Z groups and to analyze the products for percent ortho, meta, and para isomers, as has so often been done for electrophilic substitution. However, this procedure is much less accurate in the case of free radical substitutions because of the many side reactions. It may be, for example, that in a given case the ortho position is more reactive than the para, but the intermediate from the para attack may go on to product while that from the ortho attack gives a side reaction. In such a case, analysis of the three products does not give a true picture of which position is most susceptible to attack. The following generalizations can nevertheless be drawn, though there has been much controversy over just how meaningful such conclusions are¹²⁴

1. All substituents increase reactivity at ortho and para positions over that of benzene. There is no great difference between electron-donating and electron-withdrawing groups.
2. Reactivity at meta positions is usually similar to that of benzene, perhaps slightly higher or lower. This fact, coupled with the preceding one, means that all substituents are activating and ortho–para directing; none are deactivating or (chiefly) meta directing.
3. Reactivity at ortho positions is usually somewhat greater than at para positions, except where a large group decreases ortho reactivity for steric reasons.
4. In direct competition, electron-withdrawing groups exert a somewhat greater influence than electron-donating groups. Arylation of para-disubstituted compounds ($\text{XC}_6\text{H}_4\text{Y}$) showed that substitution ortho to the group X became increasingly preferred as the electron-withdrawing character of X increases (with Y held constant).¹²⁵ The increase could be correlated with the Hammett σ_p values for X.
5. Substituents have a much smaller effect than in electrophilic or nucleophilic substitution; hence the partial rate factors (see Sec. 11.C) are not great.¹²⁶ Partial rate factors for a few groups are given in Table 14.2.¹²⁷
6. Although hydrogen is the leaving group in most free radical aromatic substitutions, ipso attack (Sec. 11.B.iii) and ipso substitution (e.g., with Br, NO_2 , or CH_3CO as the leaving group) have been found in certain cases.¹²⁸

Note that interconvertible 1,4-hydrogen atom shifts are possible in radicals derived from biaryls.¹²⁹

14.B.iv. Reactivity in the Attacking Radical¹³⁰

As seen above, some radicals are much more selective than others (Sec. 14.B.i). The bromine atom is so selective that when only primary hydrogen atoms are available, as in neopentane or *tert*-butylbenzene, the reaction is slow; and isobutane can be selectively brominated to give *tert*-butyl bromide in high yields. However, toluene reacts with bromine atoms instantly. Bromination of other alkylbenzenes (e.g., ethylbenzene and cumene) takes place exclusively at the α position,¹³¹ emphasizing the selectivity of Br \cdot . The dissociation energy (*D*) of the C—H bond is more important for radicals of low reactivity than for highly reactive radicals, since bond breaking in the transition state is greater. Thus, bromine shows a greater tendency than chlorine to attack α to an electron-withdrawing group because the energy of the C—H bond there is lower than in other places in the molecule.

Some radicals (e.g., triphenylmethyl) are so unreactive that they abstract hydrogen atoms very poorly if at all. Table 14.3 lists some common free radicals in approximate order of reactivity.¹³²

iPr \cdot is < Me \cdot and *t-Bu* \cdot is still less¹³³

As mentioned earlier, some free radicals (e.g., chloro) are electrophilic and some (e.g., *tert*-butyl) are nucleophilic. Bear in mind that these tendencies are relatively slight compared with the electrophilicity of a positive ion or the nucleophilicity of a negative ion. The predominant character of a free radical is neutral, whether it has slight electrophilic or nucleophilic tendencies.

14.B.v. The Effect of Solvent on Reactivity¹³⁴

As noted earlier, the solvent usually has little effect on free radical substitutions in contrast to ionic substitution reactions: Indeed, reactions in solution are often quite similar in character to those in the gas phase, where there is no solvent at all. However, in certain cases the solvent *can* make an appreciable difference. Chlorination of 2,3-dimethylbutane in aliphatic solvents gave ~60% (CH₃)₂CHCH(CH₃)CH₂Cl and 40% (CH₃)₂CHCCl(CH₃)₂, while in aromatic solvents the ratio became 10:90.¹³⁵ This result is attributed to

complex formation between the aromatic solvent and the chlorine atom that makes the chlorine more selective.¹³⁶ This type of effect is not found in cases where the differences in ability to abstract the atom are caused by field effects of electron-withdrawing groups (Sec 14.B.i). In such cases, aromatic solvents make little difference.¹³⁷ Complex **22** has been detected¹³⁸ as a very short-lived species by observation of its visible spectrum in the pulse radiolysis of a solution of benzene in CCl₄.¹³⁹ Differences caused by solvents have also been reported in reactions of other radicals.¹⁴⁰ Some of the anomalous results obtained in the chlorination of aromatic side chains (Sec 14.B.i) can also be explained by this type of complexing, in this case not with the solvent but with the reacting species.¹⁴¹ Much smaller, though real, differences in selectivity have been found when the solvent in the chlorination of 2,3-dimethylbutane is changed from an alkane to CCl₄.¹⁴² However,

these differences are not caused by formation of a complex between Cl^\bullet and the solvent. There are cases, however, where the rate of reaction for trapping a radical depends on the polarity of the solvent, particularly in water.¹⁴³

14.C. REACTIONS

The reactions in this chapter are classified according to leaving group. The most common leaving groups are hydrogen and nitrogen (generally the diazonium ion); these are considered first.

14.C.i. Hydrogen as a Leaving Group

A. Substitution by Halogen

14-1 Halogenation at an Alkyl Carbon¹⁴⁴

Halogenation or Halo-de-hydrogenation

Alkanes can be chlorinated or brominated by treatment with chlorine or bromine in the presence of visible or UV light, or with heat.¹⁴⁵ These reactions require an added chemical reagent as the radical chain initiator, or exposure to light, or higher temperatures.¹⁴⁶ The reaction can also be applied to alkyl chains containing many functional groups. The chlorination reaction is usually not useful for preparative purposes precisely because it is so general: Not only does substitution take place at virtually every alkyl carbon in the molecule, but di- and polychloro substitution almost invariably occur even if there is a large molar ratio of substrate to halogen. Note that benzylic halogenation (e.g., the *Wohl-Ziegler bromination*) is discussed in Reaction 14-3.

When functional groups are present, the principles are those outlined in Section 14.B.i. Tertiary carbons are most likely to be functionalized and primary are least likely. Favored positions are those α to aromatic rings, while positions α to electron-withdrawing groups are least likely to be substituted. Hydrogen atoms α to an OR group are very readily replaced. Nevertheless, mixtures are nearly always obtained. This can be contrasted to the regioselectivity of electrophilic halogenation (Reactions 12-4–12-6), which always takes place α to a carbonyl group (except when the reaction is catalyzed by AgSbF_6). Of course, if a *mixture* of chlorides is wanted, the reaction is usually quite satisfactory. For obtaining pure compounds, the chlorination reaction is essentially limited to substrates with only one type of replaceable hydrogen (e.g., ethane, cyclohexane, and neopentane). The most common are methylbenzenes and other substrates with methyl groups on aromatic rings,

¹⁴⁶ Hill, C.L. *Activation and Functionalization of Alkanes*, Wiley, NY, **1989**.

since few cases are known where halogen atoms substitute at an aromatic position.¹⁴⁷ Of course, ring substitution *does* take place in the presence of a positive-ion-forming catalyst (Reaction 11-10). In addition to mixtures of various alkyl halides, traces of other products are obtained. These include H₂, alkenes, higher alkanes, lower alkanes, and halogen derivatives of these compounds. Solvent plays an important role in this process.¹⁴⁸

The bromine atom is much more selective than the chlorine atom. As indicated in Section 14.B.iv, it is often possible to brominate tertiary and benzylic positions selectively. High regioselectivity can also be obtained where the neighboring-group mechanism (Sec 14.A.iv) can operate.

As already mentioned, halogenation can be performed with chlorine or bromine. Fluorine has also been used,¹⁴⁹ but seldom, because it is too reactive and hard to control.¹⁵⁰ It often breaks carbon chains down into smaller units, a side reaction that sometimes becomes troublesome in chlorinations as well. Fluorination¹⁵¹ has been achieved by the use of chlorine trifluoride (ClF₃) at -75°C.¹⁵² For example, cyclohexane gave 41% fluorocyclohexane and methylcyclohexane gave 47% 1-fluoro-1-methylcyclohexane. Fluorox-ytrifluoromethane (CF₃OF) fluorinates tertiary positions of certain molecules in good yields with high regioselectivity.¹⁵³ For example, adamantane gave 75% 1-fluoroadamantane. Fluorine at -70 °C, diluted with N₂,¹⁵⁴ and bromine trifluoride at 25–35 °C¹⁵⁵ are also highly regioselective for tertiary positions. These reactions probably have electrophilic,¹⁵⁶ not free radical mechanisms. In fact, the success of the F₂ reactions depends on the suppression of free radical pathways, by dilution with an inert gas, by working at low temperatures, and/or by the use of radical scavengers. Fluorination of 1,3-dicarbonyl compounds and activated aromatic compounds was achieved under solvent-free conditions using SelectfluorTM F–TEDA–BF₄.¹⁵⁷

Iodine can be used if the activating light has a wavelength of 184.9 nm,¹⁵⁸ but iodinations using I₂ alone are seldom attempted, largely because the HI formed reduces the alkyl iodide. The direct free radical halogenation of aliphatic hydrocarbons with iodine is significantly endothermic relative to the other halogens, and the requisite chain reaction does not occur.¹⁵⁹ On the other hand, when iodine (CCl₄ • 2 AlI₃) reacts with an alkane in

dibromomethane at -20°C , good yields of the iodoalkane are obtained.¹⁶⁰ The reaction of an alkane with *tert*-butylhypoiodite (*t*-BuOI) at 40°C gave the iodoalkane in good yield.¹⁶¹ The reaction of alkanes with iodine and $\text{PhI}(\text{OAc})_2$ generates the iodoalkane.¹⁶² A radical protocol was developed using Cl_4 with base. Cyclohexane could be iodinated, for example, with Cl_4 in the presence of powdered NaOH .¹⁶³ The reaction led to the use of iodoform on solid NaOH as the iodination reagent of choice. A base-induced bromination has been reported. 2-Methyl butane reacts with 50% aq NaOH and CBr_4 , in a phase-transfer catalyst, to give a modest yields of 2-bromo-2-methylbutane. α -Iodo ethers and α -iodolactones have been prepared from the parent ether or lactone via treatment with $\text{Et}_4\text{N}^+\text{HF}$ under electrolytic conditions.¹⁶⁴

Many other halogenation agents have been employed, and a common reagent is sulfuryl chloride (SO_2Cl_2).¹⁶⁵ Among other agents used have been NBS (see Reaction 14-3), CCl_4 ,¹⁶⁶ PCl_5 ,¹⁶⁷ *N*-haloamines, and sulfuric acid.¹⁶⁸ In all these cases, an initiator is required, usually peroxides or UV light.¹⁶⁹

When chlorination is carried out with *N*-haloamines and sulfuric acid (catalyzed by either UV light or metal ions), selectivity is much greater than with other reagents.¹⁶⁸ In particular, alkyl chains are chlorinated with high regioselectivity at the position next to the end of the chain (the $\omega - 1$ position).¹⁷⁰ Some typical selectivity values are¹⁷¹

Furthermore, di- and polychlorination are much less prevalent. Dicarboxylic acids are predominantly chlorinated in the middle of the chain,¹⁷⁵ and adamantane and bicyclo [2.2.2]octane at the bridgeheads¹⁷⁶ by this procedure. The reasons for the high $\omega - 1$

specificity are not clearly understood.¹⁷⁷ Alkyl chlorides can be converted to *vic*-dichlorides by treatment with MoCl_5 .¹⁷⁸ Enhanced selectivity at a terminal position of *n*-alkanes has been achieved by absorbing the substrate onto a pentasil zeolite.¹⁷⁹ For regioselective chlorination at certain positions of the steroid nucleus, see Reaction 19-2.

In almost all cases, the mechanism involves a free radical chain:

When the reagent is halogen, initiation occurs as shown above.¹⁸⁰ When it is another reagent, a similar cleavage occurs (catalyzed by light or, more commonly, peroxides), followed by propagation steps that do not necessarily involve abstraction by halogen. For example, the propagation steps for chlorination by *tert*-butyl hypochlorite (*t*-BuOCl) have been formulated as:¹⁸¹

and the abstracting radicals in the case of *N*-haloamines are the aminium radical cations ($\text{R}_2\text{NH}^{\bullet+}$, Reaction 11-5), with the following mechanism (in the case of initiation by Fe^{2+}):¹⁶⁸

This mechanism is similar to that of the *Hofmann–Löffler Reaction* (18-40).

The two propagation steps shown above for X_2 are those that lead directly to the principal products (RX and HX), but many other propagation steps are possible and many occur. Similarly, the only termination step shown is the one that leads to RX, but any two radicals may combine (H^\bullet , CH_3^\bullet , Cl^\bullet , $\text{CH}_2\text{CH}_3^\bullet$ in all combinations). Thus, products like H_2 , higher alkanes, and higher alkyl halides can be accounted for. When methane is the substrate, the rate-determining step is

since an isotope effect of 12.1 was observed at 0 °C.¹⁸² For chlorinations, chains are very long, typically 10^4 – 10^6 propagations before a termination step takes place.

^aSee Ref. 183.

The order of reactivity of the halogens can be explained by energy considerations. For the substrate methane, ΔH values for the two principal propagation steps follow:

	F ₂	Cl ₂	Br ₂	I ₂	F ₂	Cl ₂	Br ₂	I ₂
	(kcal mol ⁻¹)				(kJ mol ⁻¹)			
CH ₄ + X [•] → CH ₃ [•] + HX	-31	+2	+17	+34	-132	+6	+72	+140
CH ₄ + X ₂ → CH ₃ X + X [•]	-70	-26	-24	-21	-293	-113	-100	-87

In each case, D for CH₃—H is 105 kcal mol⁻¹ (438 kJ mol⁻¹), while D values for the other bonds involved are given in Table 14.4.¹⁸³ Fluorine (F₂) is so reactive¹⁸⁴ that neither UV light nor any other initiation is needed (total $\Delta H = -101$ kcal mol⁻¹, -425 kJ mol⁻¹)¹⁸⁵; while Br₂ and I₂ essentially do not react with methane. The second step is exothermic in all four cases, but it cannot take place before the first, and it is this step that is very unfavorable for Br₂ and I₂. It is apparent that the most important single factor causing the order of halogen reactivity to be F₂ > Cl₂ > Br₂ > I₂ is the decreasing strength of the HX bond in the order HF > HCl > HBr > HI. The increased reactivity of secondary and tertiary positions is in accord with the decrease in D values for R—H in the order primary > secondary > tertiary (Table 5.3). (Note that for chlorination, step 1 is exothermic for practically all substrates other than CH₄, since most other aliphatic C—H bonds are weaker than those in CH₄.)

¹⁸⁴ See Johnson, G.L.; Andrews, L. *J. Am. Chem. Soc.* **1980**, 102, 5736.

¹⁸⁵ For F₂ the following initiation step is possible: F₂ + RH → R[•] + F[•] + HF (first demonstrated by Miller, Jr., W.T.; Koch, Jr., S.D.; McLafferty, F.W. *J. Am. Chem. Soc.* **1956**, 78, 4992).

Metal mediated halogenation reactions are known. Heating alkenes with bromine in the presence of MnO_2 leads to monobromination.¹⁸⁶ Hydrogen peroxide–HBr in water has been used for radical bromination.¹⁸⁷ Bromination and chlorination of alkanes and cycloalkanes can also take place by an electrophilic mechanism if the reaction is catalyzed by AgSbF_6 .¹⁸⁸ Direct chlorination at a vinylic position by an electrophilic mechanism has been achieved with benzeneselenenyl chloride [PhSe(O)Cl] and AlCl_3 or AlBr_3 .¹⁸⁹ However, while some substituted alkenes give high yields of chloro-substitution products, others (e.g., styrene) undergo addition of Cl_2 to the double bond (Reaction 15-39).¹⁵¹ Electrophilic fluorination has already been mentioned (Sec. 14.C.i).

14-2 Halogenation at Silicon

Halogenation or Halo-de-hydrogenation

Just as free radical halogenation occurs at the carbon of an alkane, via hydrogen abstraction to form the radical, a similar reaction occurs at silicon. When triisopropylsilane ($i\text{Pr}_3\text{Si}-\text{H}$) reacts with *tert*-butyl hypochlorite at -10°C , the product is triisopropylchlorosilane ($i\text{Pr}_3\text{Si}-\text{Cl}$).¹⁹⁰

14-3 Allylic and Benzylic Halogenation

Halogenation or Halo-de-hydrogenation

This reaction is a special case of Reaction 14-1, but is important enough to be treated separately.¹⁹¹ Alkenes can be brominated in the allylic position and also a benzylic position by a number of reagents, of which NBS¹⁹² is by far the most common. When this reagent is used, the reaction is known as *Wohl–Ziegler bromination*. A nonpolar solvent is used, most often CCl_4 , but the reaction has been done in an ionic liquid.¹⁹³ A variation in the reaction used NBS with 5% Yb(OTf)_3 and 5% ClSiMe_3 .¹⁹⁴ Other *N*-bromo amides have also been used. With any reagent an initiator is needed; this is usually AIBN (**1**), a peroxide (e.g., di-*tert*-butyl peroxide) or benzoyl peroxide or, less often, UV light. Boron trifluoride has been used for benzylic bromination.¹⁹⁵

¹⁹⁵ Chen, H.; Shen, L.; Lin, Y. *Synth. Commun.* **2010**, 40, 998.

1,3-Dibromo-5,5-dimethylhydantoin (DBDMH) has been used for benzylic bromination in the presence of a Lewis acid (e.g., ZrCl_4).¹⁹⁶ Similarly, *N*-fluoro-2,4,6-trimethylpyridinium tetrafluoroborate, in the presence of a Pd catalyst and microwave irradiation, led to benzylic fluorides.¹⁹⁷

Allylic chlorination has also been carried out¹⁹⁸ with NCS and either arylselenenyl chlorides (ArSeCl), aryl diselenides (ArSeSeAr), or TsNSO as catalysts. Allylic chlorination has been carried out with *tert*-butyl hypochlorite¹⁹⁹ or $\text{NaClO/CeCl}_3 \cdot 7\text{H}_2\text{O}$.²⁰⁰

The reaction is usually quite specific at an allylic or benzylic position and good yields are obtained. However, when the allylic radical intermediate is unsymmetrical, allylic rearrangements can take place, so that mixtures of both possible products are obtained (**23** and **24**). Use of the selenium catalysts produces almost entirely the allylically rearranged chlorides in high yields. With TsNSO the products are the unrearranged chlorides in lower yields. Dichlorine monoxide (Cl_2O), with no catalyst, also leads to allylically rearranged chlorides in high yields.²⁰¹ A free radical mechanism is unlikely in these latter reactions.

When a double bond has two different allylic positions (e.g., $\text{CH}_3\text{CH}=\text{CHCH}_2\text{CH}_3$), a secondary position is substituted more readily than a primary. The relative reactivity of tertiary hydrogen is not clear, though many substitutions at allylic tertiary positions have been performed.²⁰² It is possible to brominate both sides of the double bond.²⁰³ Because of the electron-withdrawing nature of bromine, the second bromine substitutes on the other side of the double bond rather than α to the first bromine. Molecules with a benzylic hydrogen (e.g., toluene) react rapidly to give α -bromomethyl benzene (e.g., $\text{PhCH}_3 \rightarrow \text{PhCH}_2\text{Br}$).

N-Bromosuccinimide is a highly regioselective brominating agent at other positions, including positions α to a carbonyl group, to a $\text{C}\equiv\text{C}$ triple bond, and to an aromatic ring (benzylic position). When both a double and a triple bond are in the same molecule, the preferred position is α to the triple bond.²⁰⁴

Dauben and McCoy²⁰⁵ demonstrated that the mechanism of allylic bromination is of the free radical type, showing that the reaction is very sensitive to free radical initiators and inhibitors and indeed does not proceed at all unless at least a trace of initiator is present. Subsequent work indicated that the species that actually abstracts hydrogen from the

substrate is the bromine atom. The reaction is initiated by small amounts of Br^\bullet . Once it is formed, the main propagation steps are

The source of the Br_2 is a fast ionic reaction between NBS and the HBr liberated in step 1:

The function of the NBS is therefore to provide a source of Br_2 , as shown in the reaction, in a low, steady-state concentration, which effectively uses up the HBr liberated in step 1.²⁰⁶ The main evidence for this mechanism is that NBS and Br_2 show similar selectivity²⁰⁷ and that the various *N*-bromo amides also show similar selectivity,²⁰⁸ which is consistent with the hypothesis that the same species is abstracting in each case.²⁰⁹

It may be asked why, if Br_2 is the reacting species, it does not add to the double bond, either by an ionic or by a free radical mechanism (see Reaction 15-39). Apparently, the concentration is too low. In bromination of a double bond, only one atom of an attacking bromine molecule becomes attached to the substrate, whether the addition is electrophilic or free radical:

The other bromine atom comes from another bromine-containing molecule or ion. This result is clearly not a problem in reactions with benzylic species since the benzene ring is not prone to such addition reactions. If the concentration is sufficiently low, there is a low probability that the proper species will be in the vicinity once the intermediate forms. The intermediate in either case reverts to the initial species and the allylic substitution competes successfully. If this is true, it should be possible to brominate an alkene in the allylic position without competition from addition, even in the absence of NBS or a similar compound, if a very low concentration of bromine is used and if the HBr is

²⁰⁶ See Adam, J.; Gosselain, P.A.; Goldfinger, P. *Nature (London)* **1953**, 171, 704; *Bull. Soc. Chim. Belg.* **1956**, 65, 533.

removed as it is formed so that it is not available to complete the addition step. This has indeed been demonstrated.²¹⁰

When NBS is used to brominate non-alkenyl substrates (e.g., alkanes) another mechanism, involving abstraction of the hydrogen of the substrate by the succinimidyl radical²¹¹ **25** can operate.²¹² This mechanism is facilitated by certain solvents (e.g., CH_2Cl_2 , CHCl_3 , or MeCN) in which NBS is more soluble, and by the presence of small amounts of an alkene that lacks an allylic hydrogen (e.g., ethene). The alkene serves to scavenge any Br^\bullet that forms from the reagent. Among the evidence for the mechanism involving **25** are abstraction selectivities similar to those of Cl^\bullet atoms and the isolation of β -bromopropionyl isocyanate ($\text{BrCH}_2\text{CH}_2\text{CONCO}$), which is formed by ring opening of **25**.

Allyl silanes react with transition metals bearing chlorine ligands to give allyl chlorides, where a chlorine replaces a Me_3Si unit.²¹³

OS IV, 108; V, 825; VI, 462; IX, 191.

14-4 Halogenation of Aldehydes

Halogenation or Halo-de-hydrogenation

The α -halogenation reaction of carbonyl compounds was mentioned in Reaction **14-2**. A different halogenation reaction is possible in which aldehydes can be directly converted to acyl chlorides by treatment with chlorine, but the reaction operates only when the aldehyde does not contain an α hydrogen and even then it is not very useful. When there is an α hydrogen, α halogenation (Reactions **14-2** and **12-4**) occurs instead. Other sources of chlorine have also been used, among them SO_2Cl_2 ²¹⁴ and t -BuOCl.²¹⁵ The mechanisms are probably of the free radical type. *N*-Bromosuccinimide, with AIBN (Sec. 14.A.i) as a catalyst, has been used to convert aldehydes to acyl bromides.²¹⁶ In the presence of benzoyl peroxide as an initiator, $\text{Br}_3\text{CCO}_2\text{Et}$ converts aldehydes to acyl bromides under radical conditions.²¹⁷

B. Substitution by Oxygen

14-5 Hydroxylation at an Aromatic Carbon²¹⁸

Hydroxylation or Hydroxy-de-hydrogenation

A mixture of hydrogen peroxide and ferrous sulfate,²¹⁹ called *Fenton's reagent*,²²⁰ can be used to hydroxylate aromatic rings, although yields are usually not high.²²¹ Biaryls are typical side products.²²² Among other reagents used H_2O_2 and titanous ion; O_2 and Cu(I) ²²³ or Fe(III) ,²²⁴ a mixture of ferrous ion, oxygen, ascorbic acid, and ethylenetetraaminetetraacetic acid (*Udenfriend's reagent*)²²⁵; O_2 and KOH in liquid NH_3 ²²⁶; and peroxyacids (e.g., peroxyntrous and trifluoroperoxyacetic acids).

Much work has been done on the mechanism of the reaction with *Fenton's reagent*, and it is known that free aryl radicals (formed by a process, e.g., $\text{HO}^\bullet + \text{ArH} \rightarrow \text{AR}^\bullet + \text{H}_2\text{O}$) are *not* intermediates. The mechanism is essentially that outlined in Section 14.A.iii, with HO^\bullet as the attacking species,²²⁷ formed by

The rate-determining step is formation of HO^\bullet and not its reaction with the aromatic substrate.

An alternative oxidation of arene to phenol was reported using $\text{Cu(NO}_3)_3 \cdot 3 \text{H}_2\text{O}$, 30% hydrogen peroxide and a phosphate buffer.²²⁸

Alcohols with hydrogen in the δ position can be cyclized with lead tetraacetate.²²⁹ The reaction is usually carried out at $\sim 80^\circ\text{C}$ (most often in refluxing benzene), but can also be done at room temperature if the reaction mixture is irradiated with UV light. Tetrahydrofurans are formed in high yields. Little or no four- and six-membered cyclic ethers (oxetanes and tetrahydropyrans, respectively) are obtained even when γ and ϵ hydrogen atoms are present. The reaction has also been carried out with a mixture of halogen (Br_2 or I_2) and a salt or oxide of silver or mercury (especially HgO or AgOAc),²³⁰ with iodosobenzene diacetate and I_2 ,²³¹ and with ceric ammonium nitrate (CAN).²³² The following mechanism is likely for the lead tetraacetate reaction²³³:

although **26** has never been isolated. The step marked **A** is a 1,5-internal hydrogen abstraction. Such abstractions are well known (see Reaction **18-40**) and are greatly favored over 1,4 or 1,6 abstractions (the small amounts of tetrahydropyran formed result from 1,6-abstractions).²³⁴

Oxidation to the aldehyde or acid (Reactions **19-3** and **19-22**) and fragmentation of the substrate sometimes compete. When the OH group is on a ring of at least seven members, a transannular product can be formed, as in the cyclization reaction of 1-octanol to **27**.²³⁵ β -Hydroxy ethers can give cyclic acetals (e.g., **28**).²³⁶

14-7 Formation of Hydroperoxides

Hydroperoxy-dehydrogenation

The slow atmospheric oxidation (*slow* meaning without combustion) of C—H to C—O—O—H is called *autoxidation*.²³⁷ The reaction occurs when compounds are allowed to stand in air and is catalyzed by light, so unwanted autoxidations can be greatly slowed by keeping the compounds in dark places. Most autoxidations proceed by free radical chain processes that involve peroxy radicals.²³⁸ To suppress autoxidation, an antioxidant can be added that will prevent or retard the reaction with atmospheric oxygen.²³⁹ Although some lactone compounds are sold as antioxidants, many radicals derived from lactones show poor or no reactivity toward oxygen.²³⁹ The hydroperoxides produced often react further to give alcohols, ketones, and more complicated products, so the reaction is not often used for preparative purposes, although in some cases hydroperoxides have been prepared in good yield.²⁴⁰ It is because of autoxidation that foods, rubber, paint, lubricating oils, and so on deteriorate on exposure to the atmosphere over periods of time. On the other hand, a useful application of autoxidation is the atmospheric drying of paints and varnishes. As with other free radical reactions of C—H bonds, some bonds are attacked more readily than others,²⁴¹ and these are the ones seen before (Sec. 14.B.i), although the selectivity is very low at high temperatures and in the gas phase. The reaction can be carried out successfully at tertiary (to a lesser extent, secondary), benzylic,²⁴² and allylic (though allylic rearrangements are common) R.²⁴³ 2-Phenylpropane reacted with oxygen to give PhMe₂C—OOH, for example. Another susceptible position is aldehydic C—H, but the peroxyacids so produced are not easily isolated²⁴⁴ since they are converted to the corresponding carboxylic acids (Reaction 19-23). The α positions of ethers are also easily attacked by oxygen [RO—C—H \rightarrow RO—C—OOH], but the resulting hydroperoxides are seldom isolated. However, this reaction constitutes a hazard in the storage of ethers since solutions of these hydroperoxides and their rearrangement products in ethers are potential spontaneous explosives.²⁴⁵

Oxygen itself (a diradical) is not reactive enough to be the species that actually abstracts the hydrogen. But if a trace of free radical (say R') is produced by some initiating process, it reacts with oxygen²⁴⁶ to give R'—O—O'; since this type of radical *does* abstract

²³⁷ The term autoxidation actually applies to any slow oxidation with atmospheric oxygen. See Goosen, A.; Morgan, D.H. *J. Chem. Soc. Perkin Trans. 2* **1994**, 557. hydrogen, the chain is

In at least some cases (in alkaline media),²⁴⁷ the radical R^\bullet can be produced by formation of a carbanion and its oxidation (by O_2) to a radical, such as allylic radical **29**.²⁴⁸ Autoxidations in alkaline media can also proceed by a different mechanism: $\text{R}-\text{H} + \text{base} \rightarrow \text{R}^- + \text{O}_2 \rightarrow \text{ROO}^-$.²⁴⁹

When alkenes are treated with oxygen that has been photosensitized (Sec. 7.A.vi, category 6), they are substituted by OOH in the allylic position in a synthetically useful reaction.²⁵⁰ Although superficially similar to autoxidation, this reaction is clearly different because 100% allylic rearrangement always takes place. The reagent here is not the ground-state oxygen (a triplet), but an excited singlet state²⁵¹ (in which all electrons are paired), and the function of the photosensitization is to promote the oxygen to this singlet state. Singlet oxygen can also be produced by nonphotochemical means,²⁵² for example, by the reaction between H_2O_2 and NaOCl ²⁵³ or between ozone and triphenyl phosphite.²⁵⁴ Calcium peroxide diperoxohydrate ($\text{CaO}_2 \cdot 2\text{H}_2\text{O}_2$) has been reported as a storable compound used for the chemical generation of singlet oxygen.²⁵⁵ The oxygen generated by either photochemical or nonphotochemical methods reacts with alkenes in the same way;²⁵⁶ this is evidence that singlet oxygen is the reacting species in the photochemical reaction and not some hypothetical

complex between triplet oxygen and the photosensitizer, as had previously been suggested. The fact that 100% allylic rearrangement always takes place is incompatible with a free radical mechanism. Further evidence that free radicals are not involved comes from the treatment of optically active limonene (**30**) with singlet oxygen. Among other products is the optically active hydroperoxide **31**, though if **32** were an intermediate, it could not give an optically active product since it possesses a plane of symmetry.²⁵⁷ In contrast, autoxidation of **30** gave optically inactive **31** (a mixture of four diastereomers in which the two pairs of enantiomers are present as racemic mixtures). As this example shows, singlet oxygen reacts faster with more highly substituted than with less highly substituted alkenes. The order of alkene reactivity is tetrasubstituted > trisubstituted > disubstituted. Electron-withdrawing substituents deactivate the alkene.²⁵⁸ In simple trisubstituted alkenes, there is a general preference for the hydrogen to be removed from the more highly congested side of the double bond.²⁵⁹ With *cis*-alkenes of the form RCH=CHR', the hydrogen is removed from the larger R group.²⁶⁰ Many functional groups in an allylic position cause the hydrogen to be removed from that side rather than the other (geminal selectivity).²⁶¹ Also, in alkyl-substituted alkenes, the hydrogen that is preferentially removed is the one geminal to the larger substituent on the double bond.²⁶²

Several mechanisms have been proposed for the reaction with singlet oxygen.²⁶³ One of these is a pericyclic mechanism, similar to that of the ene synthesis (Reaction **15-23**) and to the first step of the reaction between alkenes and SeO₂ (Reaction **19-14**). However, there is strong evidence against this mechanism,²⁶⁴ and a more likely mechanism involves addition of singlet oxygen to the double bond to give a perepoxide (**33**),²⁶⁵ followed by internal proton transfer.²⁶⁶

Still other proposed mechanisms involve diradicals or dipolar intermediates.²⁶⁷

14-8 Formation of Peroxides

Alkyldioxy-de-hydrogenation

Peroxy groups (ROO) can be introduced into susceptible organic molecules by treatment with a hydroperoxide in the presence of cuprous chloride or other catalysts (e.g., cobalt and manganese salts).²⁶⁸ Very high yields can be obtained. The type of hydrogen replaced is similar to that with NBS (Reaction 14-3); that is, mainly benzylic, allylic, and tertiary. The mechanism is therefore of the free radical type, involving ROO^\bullet formed from ROOH and the metal ion. The reaction can be used to demethylate tertiary amines of the form R_2NCH_3 , since the product $\text{R}_2\text{NHCH}_2\text{OOR}'$ can easily be hydrolyzed by acid (Reaction 10-6) to give R_2NH .²⁶⁹

14-9 Acyloxylation

Acyloxylation or Acyloxy-de-hydrogenation

Susceptible positions of organic compounds can be directly acyloxylated²⁷⁰ by *tert*-butyl peroxyesters, the most frequently used being acetic and benzoic ($\text{R}' = \text{Me}$ or Ph).²⁷¹ The reaction requires a catalyst (cuprous ion is the actual catalyst, but a trace is all that is necessary, and such traces are usually present in cupric compounds, so that these are often used) and without it is not selective. Susceptible positions are similar to those in Reaction 14-6: benzylic, allylic, and the α position of ethers and sulfides. Terminal alkenes are substituted almost entirely in the 3 position; that is, with only a small amount of allylic rearrangement, but internal alkenes generally give mixtures containing a large amount of allylic-shift product. If the reaction with alkenes is carried out in an excess of another acid ($\text{R}''\text{CO}_2\text{H}$), the ester produced is of *that* acid ROCOR'' . Aldehydes give anhydrides:

Acyloxylation has also been achieved with metallic acetates (e.g., lead tetraacetate,²⁷² mercuric acetate,²⁷³ and palladium(II) acetate).²⁷⁴ In the case of the lead and mercuric acetates, not only does the reaction take place at allylic and benzylic positions and at those α

to an OR or SR group, but also at positions α to the carbonyl groups of aldehydes, ketones, or esters and at those α to two carbonyl groups (ZCH_2Z'). It is likely that in the latter cases it is the enol forms that react. Ketones can be α -acyloxyated indirectly by treatment of various enol derivatives with metallic acetates (e.g., silyl enol ethers with silver carboxylates-iodine,²⁷⁵ enol thioethers with lead tetraacetate,²⁷⁶ and enamines²⁷⁷ with lead tetraacetate).²⁷⁸ Lead tetraacetate even acyloxyates alkanes, in a slow reaction (10 days–2 weeks), with tertiary and secondary positions greatly favored over primary ones.²⁷⁹ α,β -Unsaturated ketones can be acyloxyated in good yields in the α' position with manganese triacetate.²⁸⁰ Palladium acetate converts alkenes to vinylic and/or allylic acetates.²⁸¹ Acyloxylation of certain alkanes has also been reported with palladium(II) acetate.²⁸²

Studies of the mechanism of the cuprous-catalyzed reaction show that the most common mechanism is the following²⁸³:

This mechanism, involving a free radical R^\bullet , is compatible with the allylic rearrangements found.²⁸⁴ The fact that *tert*-butyl peroxyesters labeled with ^{18}O in the carbonyl oxygen gave an ester with 50% of the label in each oxygen²⁸⁵ is in accord with coupling of R^\bullet with intermediate **34**, in which the Cu is ionically bound, so that the oxygen atoms are essentially equivalent. Other evidence is that *tert*-butoxy radicals have been trapped with dienes.²⁸⁶ Much less is known about the mechanisms of the reactions with other metal acetates.²⁸⁷

Free radical acyloxylation of aromatic substrates²⁸⁸ has been accomplished with a number of reagents, including copper(II) acetate,²⁸⁹ silver(II) complexes,²⁹⁰ and cobalt(III) trifluoroacetate.²⁹¹

C. Substitution by Sulfur

14-10 Chlorosulfonation or Chlorosulfo-de-hydrogenation

The chlorosulfonation of organic molecules with chlorine and sulfur dioxide is called the *Reed reaction*.²⁹² In scope and range of products obtained, the reaction is similar to 14-1. The mechanism is also similar, except that there are two additional main propagation steps:

*Chlorosulfenation*²⁹³ can be accomplished by treatment with SCl_2 and UV light:

D. Substitution by Nitrogen

14-11 The Direct Conversion of Aldehydes to Amides

Amination or Amino-de-hydrogenation

Aliphatic and aromatic aldehydes have been converted to the corresponding amides with ammonia or a primary or secondary amine, NBS, and a catalytic amount of AIBN (Sec. 14.A.i).²⁹⁴ In a reaction of more limited scope, amides are obtained from aromatic and α,β -unsaturated aldehydes by treatment with dry ammonia gas and nickel peroxide.²⁹⁵ Best yields (80–90%) are obtained at -25 to -20 °C. In the nickel peroxide reaction, the corresponding alcohols (ArCH_2OH) have also been used as substrates.

Oxidative amidation of aldehydes has been done using AgIO_3 in the presence of a CuI catalyst.²⁹⁶ Similar oxidative amidation was accomplished using H_2O_2 and a Pd-catalyst.²⁹⁷ Amides were prepared from aldehydes using NBS with a Cu catalyst.²⁹⁸ Hypervalent iodine with a Fe catalyst has also been used.²⁹⁹ Oxidative amidation of aromatic aldehydes using Oxone and ball milling without solvent gave the corresponding amide.³⁰⁰ Amidation using nucleophilic *N*-heterocyclic carbenes leads to amidation

accompanied by ring opening of proximal epoxides³⁰¹ or cyclopropane moieties.³⁰² Aromatic aldehydes are converted to the corresponding amide by treatment with LiN(TMS)₂ in the presence of LnCl₃, and a stoichiometric reaction was reported using (Me₃Si)₂N]₃Ln(*i*-Cl)Li(THF)₃.³⁰³

The reaction has been performed with MnO₂ and NaCN along with ammonia or an amine at 0 °C in isopropyl alcohol.³⁰⁴ Treatment of an aldehyde with iodine in aq ammonia, followed by oxidation with aq H₂O₂ generates a primary amide.³⁰⁵ Secondary amines react with aldehydes to give an amide using a Pd³⁰⁶ or a Rh catalyst.³⁰⁷ For an indirect way of converting aldehydes to amides, see Reaction 12-32. Thioamides (RCSNR'₂) have been prepared in good yield from thioaldehydes (produced *in situ* from phosphoranes and sulfur) and secondary amines.³⁰⁸

14-12 Amidation and Amination at an Alkyl Carbon

Acylamino-de-hydrogenation

When alkanes bearing a tertiary hydrogen are exposed to UV light in acetonitrile containing a heteropolytungstic acid, they are amidated.³⁰⁹ The oxygen in the product comes from the tungstic acid. When the substrate bears two adjacent tertiary hydrogen atoms, alkenes are formed (by loss of two hydrogen atoms), rather than amides (Reaction 19-2). Amidyl radicals can be generated by other means.³¹⁰

14-13 Substitution by Nitro

Nitro-de-carboxylation

In a reaction termed a “nitro-Hunsdiecker” (see Reaction 14-30), vinyl carboxylic acids (conjugated acids) are treated with nitric acid and a catalytic amount of AIBN (Sec. 14.A.i). The product is the vinyl nitro compound, generated via decarboxylation of a radical intermediate.³¹¹

Aryl halides are converted to aromatic nitro compounds via a Cu catalyzed reaction with nitrite salts (Ar—X → Ar—NO₂).³¹² Ceric ammonium nitrate in acetonitrile also facilitates this reaction.³¹³

Conjugated amides were coupled via the γ -carbon to give good yields of the dimeric diamide, with an excess of samarium(II) iodide, and with modest enantioselectivity using a chiral additive.³¹⁴

E. Substitution by Carbon

In these reactions, a new carbon–carbon bond is formed, and they may be given the collective title *coupling reactions*. In each case, an alkyl or aryl radical is generated and then combines with another radical (a termination process) or attacks an aromatic ring or alkene to give the coupling product.³¹⁵

14-14 Simple Coupling at a Susceptible Position

De-hydrogen-coupling

Alkane and alkyl substrates RH are treated with peroxides, which decompose to give a radical that abstracts a hydrogen from RH to give R^\cdot , which dimerizes. Dialkyl and diacyl peroxides have been used, as well as *Fenton's reagent* (Reaction 14-5). This reaction is far from general, although in certain cases respectable yields have been obtained. Among susceptible positions are those at a tertiary carbon,³¹⁶ as well as those α to a phenyl group (especially if there is also an α -alkyl or α -chloro group),³¹⁷ an ether group,³¹⁸ a carbonyl group,³¹⁹ a cyano group,³²⁰ a dialkylamino group,³²¹ or a carboxylic ester group (either the acid or alcohol side).³²² Cross-coupling is possible in some cases. When toluene was heated with allyl bromide, in the presence of di-*tert*-butyl peroxide, 4-phenyl-1-butene was formed quantitatively.³²³

Alkanes can be dimerized by vapor-phase mercury photosensitization³²⁴ in a synthetically useful process. Best results are obtained for coupling at tertiary positions, but compounds lacking tertiary hydrogen atoms (e.g., cyclohexane) also give good yields. Dimerization of *n*-alkanes gives secondary–secondary coupling in a nearly statistical distribution, with primary positions essentially unaffected. Alcohols and ethers dimerize at the position α to the oxygen [e.g., $2 \text{ EtOH} \rightarrow \text{MeCH(OH)CH(OH)Me}$].

When a mixture of compounds is treated, cross-dimerization (to give **35**) and homo-dimerization take place statistically. Even with the limitation on yield implied by the statistical process, cross-dimerization is still useful when one of the reactants is an alkane, because the products are easy to separate, and because of the few other ways to functionalize an alkane. The cross-coupling of an alkane with trioxane is especially valuable, because hydrolysis of the product (Reaction **10-6**) gives an aldehyde, thus achieving the conversion $\text{RH} \rightarrow \text{RCHO}$. The mechanism probably involves abstraction of H by the excited Hg atom, and coupling of the resulting radicals.

The reaction has been extended to ketones, carboxylic acids and esters (all of which couple α to the C=O group), and amides (which couple α to the nitrogen) by running it in the presence of H_2 .³²⁵ Under these conditions it is likely that the excited Hg abstracts H^\bullet from H_2 , and that the remaining H^\bullet abstracts H from the substrate. Radicals have also been generated at benzylic positions and shown to couple with epoxides, forming an alcohol.³²⁶

OS IV, 367; V, 1026; VII, 482.

14-15 Coupling at a Susceptible Position via Silanes

De-silyl-coupling

Under electrochemical conditions it is possible to couple two silanes. The reaction of **36** and allyltrimethylsilane, for example, gave the corresponding homoallylic ether.³²⁷

14-16 Coupling of Alkynes³²⁸

De-hydrogen-coupling

Terminal alkynes can be coupled by heating with stoichiometric amounts of cupric salts in pyridine or a similar base. This reaction, which produces symmetrical diynes in high yields, is called the *Eglinton reaction*.³²⁹ The large-ring annulenes (see Sec. 2.K) were prepared by rearrangement and hydrogenation of cyclic polyynes,³³⁰ prepared by the *Eglinton reaction* with terminal diynes to give **37**, a cyclic trimer of 1,5-hexadiyne.³³¹ The corresponding tetramers (C_{24}), pentamers (C_{30}), and hexamers

(C₃₆) were also formed. The *Eglinton reaction* is of wide scope and many functional groups can be present on the alkyne. The oxidation is usually quite specific for triple-bond hydrogen.

Another common procedure is the use of catalytic amounts of cuprous salts in the presence of ammonia or ammonium chloride (this method is called the *Glaser reaction*). Atmospheric oxygen or some other oxidizing agent (e.g., permanganate or hydrogen peroxide) is required in the latter procedure. This method is not satisfactory for cyclic coupling. Hydrogen peroxide, potassium permanganate, potassium ferricyanide, iodine, or Cu(II) can be used instead of oxygen as oxidants.³³² Isolation of copper acetylide during the reaction can be avoided by doing the reaction in pyridine or cyclohexylamine, in the presence of a catalytic amount of CuCl₂.³³³ If the *Glaser reaction* is done with a *N,N,N',N'*-tetramethylethylenediamine–CuCl complex, the reaction proceeds in good yield in virtually any organic solvent.³³⁴ When molecular oxygen is the oxidant, this modification of the *Glaser reaction* is known as the *Hay reaction*.

A variation couples terminal alkynes using CuCl₂ in supercritical CO₂ (see Sec. 9.D.ii),³³⁵ and in ionic liquids.³³⁶ Coupling was also achieved using CuCl₂ on KF–Al₂O₃ with microwave irradiation.³³⁷ A Co catalyzed *Glaser coupling* has been reported³³⁸ and also a transition metal free coupling.³³⁹ A modified *Glaser coupling* has been reported using KF/Alumina.³⁴⁰ Coupling has been achieved under ambient conditions using cupric acetate.³⁴¹ Copper(II) promoted homocoupling of terminal alkynes has been done in supercritical CO₂.³⁴² Another variation is a Ni catalyzed cross-coupling.³⁴³ Terminal alkynes give 1,3-diynes upon treatment with Cu–iodine.³⁴⁴

Unsymmetrical diynes can be prepared by *Cadiot–Chodkiewicz coupling*³⁴⁵:

This may be regarded as a variation of Reaction 10-74, but it must have a different mechanism since acetylenic halides give the reaction but ordinary alkyl halides do not,

which is hardly compatible with a nucleophilic mechanism. However, the mechanism is not fully understood. One version of this reaction binds the alkynyl bromide unit to a polymer, and the di-yne is released from the polymer after the solid-state transformation.³⁴⁶ Alkynes have also been coupled using CuI and a Pd catalyst.³⁴⁷ A variation of the *Cadiot–Chodkiewicz method* consists of treating a haloalkyne ($R'C\equiv CX$) with a copper acetylide ($RC\equiv CCu$).³⁴⁸ The *Cadiot–Chodkiewicz procedure* can be adapted to the preparation of diynes in which $R'=H$ by the use of $BrC\equiv CSiEt_3$ and subsequent cleavage of the $SiEt_3$ group.³⁴⁹ This protecting group can also be used in the *Eglinton* or *Glaser* methods.³⁵⁰

The mechanism of the *Eglinton* and *Glaser reactions* probably begins with loss of a proton

since there is a base present and acetylenic protons are acidic. It is known, of course, that cuprous ion can form complexes with triple bonds. The last step is probably the coupling of two radicals:

but just how the carbanion becomes oxidized to the radical and what part the cuprous ion plays (other than forming the acetylide salt) are matters of considerable speculation,³⁵¹ and depend on the oxidizing agent. One proposed mechanism postulated Cu(II) as the oxidant.³⁵² It has been shown that molecular oxygen forms adducts with Cu(I) supported by tertiary amines, which might be the intermediates in the *Glaser reaction* where molecular oxygen is the oxidant.³⁵³ For the *Hay reaction*, the mechanism involves a Cu(I)/Cu(III)/Cu(II)/Cu(I) catalytic cycle, and the key step for this reaction is the dioxygen activation during complexation of two molecules of acetylide with molecular oxygen, giving a Cu(III) complex.³⁵⁴ This mechanism is supported by isolation and characterization of Cu(III) complexes formed under the conditions of the *Glaser coupling*.

Sonogashira coupling, which involves aryl halides and terminal alkynes in the presence of a Pd catalyst, has been extended to the coupling of two alkynes.³⁵⁵ Indeed, the Pd catalyzed coupling of two alkynes to form a diyne³⁵⁶ is often referred to as *Sonogashira cross-coupling*, or *Sonogashira-like coupling*. An example is the

conversion of **38** to **39**.³⁵⁷ Here rt = room temperature and DABCO = 1,4-diazabicyclo [2.2.2]octane.

Terminal alkynes are not the only reaction partners. 1-Trimethylsilyl alkynes ($\text{R}-\text{C}\equiv\text{C}-\text{SiMe}_3$) give the diyne $\text{R}-\text{C}\equiv\text{C}-\text{C}\equiv\text{C}-\text{R}$ upon reaction with CuCl ³⁵⁸ or $\text{Cu(OAc)}_2/\text{Bu}_4\text{NF}$.³⁵⁹

Alkynylboronates undergo homocoupling to give symmetrical 1,3-diynes in the presence of a Cu salt.³⁶⁰ The Cu-catalyzed homocoupling of alkynyltrifluoroborates leads to 1,3-diynes.³⁶¹

In related reactions, alkynyltrifluoroborates react with vinylic tellurides to give 1,3-enynes.³⁶² The Pd catalyzed reaction of vinyl bromides and terminal alkynes gives enynes.³⁶³ 1,3-Dienes are prepared by the Pd catalyzed homocoupling of alkenyltrifluoroborates.³⁶⁴

OS V, 517; VI, 68, 925; VIII, 63.

14-17 Alkylation and Arylation of Aromatic Compounds by Peroxides

Alkylation or Alkyl-de-hydrogenation

This reaction is most often carried out with $\text{R} = \text{aryl}$, so the net result is the same as in Reaction 13-27, though the reagent is different.³⁶⁵ It is used less often than Reaction 13-27, but the scope is similar. When $\text{R} = \text{alkyl}$, the scope is more limited.³⁶⁶ Only certain aromatic compounds, particularly benzene rings with two or more nitro groups, and fused ring systems, can be alkylated by this procedure. 1,4-Quinones can be alkylated with diacyl peroxides or with lead tetraacetate (methylation occurs with this reagent).

The mechanism is as shown in Section 14.A.iii (CIDNP has been observed³⁶⁷); the radicals are produced by

Since no relatively stable free radical is present (e.g., $^\bullet\text{O}-\text{N}=\text{N}-\text{Ar}$ in Reaction **13-27**), most of the product arises from dimerization and disproportionation.³⁶⁸ The addition of a small amount of nitrobenzene increases the yield of arylation product because the nitrobenzene is converted to diphenyl nitroxide, which abstracts a hydrogen atom and diminishes the extent of side reactions.³⁶⁹ The Pd catalyzed methylation of aromatic rings in the presence of dicumyl peroxide is another variation.³⁷⁰

Aromatic compounds can also be arylated by aryllead tricarboxylates.³⁷¹ Best yields (~ 70 – 85%) are obtained when the substrate contains alkyl groups; an electrophilic mechanism is likely. Phenols are phenylated ortho to the OH group (and enols are a phenylated) by triphenylbismuth dichloride or by certain other Bi(V) reagents.³⁷² *O*-Phenylation is a possible side reaction. As with the aryllead tricarboxylate reactions, a free radical mechanism is unlikely.³⁷³

OS V, 51. See also, OS V, 952; VI, 890.

14-18 Photochemical Arylation of Aromatic Compounds

Arylation or Aryl-de-hydrogenation

Another free radical arylation method consists of the photolysis of aryl iodides in an aromatic solvent.³⁷⁴ Yields are generally higher than in Reactions **13-27** or **14-17**. The aryl iodide may contain OH or COOH groups. The coupling reaction of iodobenzene and azulene to give a phenylazulene was reported (41% conversion and 85% yield).³⁷⁵ The mechanism is similar to that of Reaction **13-27**. The aryl radicals are generated by the photolytic cleavage $\text{ArI} \rightarrow \text{AR}^\bullet + \text{I}^\bullet$. The reaction has been applied to intramolecular arylation (analogous to the *Pschorr reaction*).³⁷⁶ A similar reaction is photolysis of an

³⁶⁷ Kaptein, R.; Freeman, R.; Hill, H.D.W.; Bargon, J. *J. Chem. Soc., Chem. Commun.* **1973**, 953.

³⁶⁸ The mechanism is actually more complicated. See DeTar, D.F.; Long, R.A.J.; Rendleman, J.; Bradley, J.; Duncan, P. *J. Am. Chem. Soc.* **1967**, 89, 4051; DeTar, D.F. *J. Am. Chem. Soc.* **1967**, 89, 4058. See also, Jandu, K.S.; Nicolopoulou, M.; Perkins, M.J. *J. Chem. Res. (S)* **1985**, 88.

arylthallium bis(trifluoroacetate) (**12-23**) in an aromatic solvent. Here too, an unsymmetrical biaryl is produced in good yields.³⁷⁷ In this case, it is the C—Tl bond that is cleaved to give aryl radicals.

14-19 Alkylation, Acylation, and Carbalkoxylation of Nitrogen Heterocycles³⁷⁸

Alkylation or **Alkyl-de-hydrogenation**, and so on

Alkylation of protonated nitrogen heterocycles (e.g., pyridines, quinolines) can be accomplished by treatment with a carboxylic acid, silver nitrate, sulfuric acid, and ammonium peroxydisulfate.³⁷⁹ The R group can be primary, secondary, or tertiary. The attacking species is R^\bullet , formed by³⁸⁰

A hydroxymethyl group can be introduced ($\text{ArH} \rightarrow \text{ArCH}_2\text{OH}$) by several variations of this method.³⁸¹ Alkylation of these substrates can also be accomplished by generating the alkyl radicals in other ways: from hydroperoxides and FeSO_4 ,³⁸² from alkyl iodides and H_2O_2 — Fe(II) ,³⁸³ from carboxylic acids and lead tetraacetate, or from the photochemically induced decarboxylation of carboxylic acids by iodosobenzene diacetate.³⁸⁴

Protonated nitrogen heterocycles (e.g., quinoxaline, **40**) can be acylated by treatment with an aldehyde, *tert*-butyl hydroperoxide, sulfuric acid, and ferrous sulfate, in this case giving **41**.³⁸⁵

Photochemical alkylation of protonated quinoline occurred with $\text{Ph}_2\text{Se}(\text{O}_2\text{Cc-C}_6\text{H}_{11})_2$.³⁸⁶

³⁸⁶ Togo, H.; Miyagawa, N.; Yokoyama, M. *Chem. Lett.* **1992**, 1677.

Other positively charged heterocycles react as well. When *N*-fluoropyridinium triflate was treated with the enolate anion of acetone, 2-(2-oxopropyl)pyridine was formed in modest yield.³⁸⁷

These alkylation and acylation reactions are important because *Friedel–Crafts* alkylation and acylation (Reactions **11-11** and **11-17**) cannot be applied to most nitrogen heterocycles (see also, Reaction **13-17**).

Protonated nitrogen heterocycles can be carbalkoxylated³⁸⁸ by treatment with esters of α -keto acids and *Fenton's reagent*. Pyridine is carbalkoxylated at C-2 and C-4, for example. The attack is by $\cdot\text{COOR}$ radicals generated from the esters via a hydroperoxide (**42**).

Similarly, a carbamoyl group can be introduced³⁸⁹ by the use of the radicals $\text{H}_2\text{N}-\dot{\text{C}}=\text{O}$ or $\text{Me}_2\text{N}-\dot{\text{C}}=\text{O}$ generated from formamide or DMF and H_2SO_4 , H_2O_2 , and FeSO_4 or other oxidants.

14.C.ii. N_2 as Leaving Group³⁹⁰

In these reactions, diazonium salts are cleaved to aryl radicals,³⁹¹ in most cases with the assistance of copper salts. Reactions **13-27** and **13-26** may also be regarded as belonging to this category with respect to the attacking compound. For nucleophilic substitutions of diazonium salts (see Reactions **13-20–13-23**). Removal of nitrogen and replacement with a hydrogen atom is a reduction, found in Chapter 19.

14-20 Replacement of the Diazonium Group by Chlorine or Bromine

Chloro-de-diazonation, and so on

Treatment of diazonium salts with cuprous chloride or bromide leads to aryl chlorides or bromides, respectively. In either case, the reaction is called the *Sandmeyer Reaction*.³⁹² The reaction can also be carried out with copper and HBr or HCl, in which case it is called the *Gatterman Reaction* (not to be confused with **11-18**). However, a Cu catalyzed *Sandmeyer bromination* reaction is known.³⁹³ The *Sandmeyer reaction* is not useful for the preparation of fluorides or iodides, but for bromides and chlorides it is

³⁹² Rate constants for this reaction have been determined. See Hanson, P.; Hammond, R.C.; Goodacre, P.R.; Purcell, J.; Timms, A.W. *J. Chem. Soc. Perkin Trans. 2* **1994**, 691.

³⁹³ Beletskaya, I.P.; Sigeev, A.S.; Peregudov, A.S.; Petrovskii, P.V. *Synthesis* **2007**, 2534.

of wide scope and is probably the best way of introducing bromine or chlorine into an aromatic ring. The yields are usually high.

The mechanism is not known with certainty, but is believed to take the following course³⁹⁴:

The first step involves a reduction of the diazonium ion by the cuprous ion, which results in the formation of an aryl radical. In the second step, the aryl radical abstracts halogen from cupric chloride, reducing it. CuX is regenerated and is thus a true catalyst.

Aryl bromides and chlorides can be prepared from primary aromatic amines in one step by several procedures,³⁹⁵ including treatment of the amine (1) with *tert*-butyl nitrite and anhydrous CuCl₂ or CuBr₂ at 65 °C,³⁹⁶ and (2) with *tert*-butyl thionitrite or *tert*-butyl thionitrate and CuCl₂ or CuBr₂ at room temperature.³⁹⁷ These procedures are, in effect, a combination of Reaction **13-19** and the *Sandmeyer Reaction*. A further advantage is that cooling to 0 °C is not needed. A mixture of Me₃SiCl and NaNO₂ was used to convert aniline to chlorobenzene in a related reaction.³⁹⁸

For the preparation of fluorides and iodides from diazonium salts, see Reactions **13-32** and **13-31**.

Note that the reaction of aryl diazonium salts with CuCN to give benzonitrile derivatives is also called the *Sandmeyer Reaction*. It is usually conducted in neutral solution to avoid liberation of HCN.

OS **I**, 135, 136, 162, 170; **II**, 130; **III**, 185; **IV**, 160. Also see, OS **III**, 136; **IV**, 182. For the reaction with CuCN see OS **I**, 514.

14-21 Replacement of the Diazonium Group by Nitro

Nitro-de-diazoniatio

Nitro compounds can be formed in good yields by treatment of diazonium salts with sodium nitrite in the presence of cuprous ion. The reaction occurs only in neutral or alkaline solution. This is not usually called the *Sandmeyer Reaction*, although, like Reaction **14-20**, it was discovered by Sandmeyer. Tetrafluoroborate (BF₄[−]) is often used as the negative ion, since the diminished nucleophilicity avoids competition from the chloride ion. The mechanism is probably like that of Reaction **14-20**.³⁹⁹ If electron-withdrawing groups

are present, the catalyst is not needed; NaNO_2 alone gives nitro compounds in high yields.⁴⁰⁰

An alternative procedure used electrolysis, in 60% HNO_3 to convert 1-aminonaphthalene to naphthalene.⁴⁰¹

OS II, 225; III, 341.

14-22 Replacement of the Diazonium Group by Sulfur-Containing Groups

Chlorosulfo-de-diazoniatio

Diazonium salts can be converted to sulfonyl chlorides by treatment with sulfur dioxide in the presence of cupric chloride.⁴⁰² The use of FeSO_4 and copper metal instead of CuCl_2 gives sulfinic acids (ArSO_2H)⁴⁰³ (see also, Reaction 13-21).

OS V, 60; VII, 508.

14-23 Conversion of Diazonium Salts to Aldehydes, Ketones, or Carboxylic Acids

Acyl-de-diazoniatio

Diazonium salts react with oximes to give aryl oximes, which are easily hydrolyzed to aldehydes ($\text{R} = \text{H}$) or ketones.⁴⁰⁴ A copper sulfate–sodium sulfite catalyst is essential. In most cases, higher yields (40–60%) are obtained when the reaction is used for aldehydes rather than for ketones. In another method⁴⁰⁵ for achieving the conversion $\text{ArN}_2^+ \rightarrow \text{ArCOR}$, diazonium salts are treated with R_4Sn and CO with palladium acetate as catalyst.⁴⁰⁶ In a different kind of reaction, silyl enol ethers of aryl ketones ($\text{Ar}'\text{C}(\text{OSiMe}_3)=\text{CHR}$) react with solid diazonium fluoroborates ($\text{ArN}_2^+ \text{BF}_4^-$) to give ketones ($\text{ArCHRCOAr}'$).⁴⁰⁷ This is, in effect, an arylation of the aryl ketone.

Carboxylic acids can be prepared in moderate-to-high yields by treatment of diazonium fluoroborates with carbon monoxide and palladium acetate⁴⁰⁸ or copper(II) chloride.⁴⁰⁹ The mixed anhydride (ArCOOCOMe) is an intermediate that can be isolated. Other mixed anhydrides can be prepared by the use of other salts instead of sodium acetate.⁴¹⁰ An arylpalladium compound is probably an intermediate.³⁶⁸

14.C.iii. Metals as Leaving Groups

14-24 Coupling of Grignard Reagents

De-metallo-coupling

This organometallic coupling reaction is clearly related to the *Wurtz coupling*, discussed in Reaction **10-56**, and the coupling of other organometallic compounds is discussed in Reaction **14-25**. *Grignard reagents* can be coupled to give symmetrical dimers⁴¹¹ by treatment with either thallium(I) bromide⁴¹² or with a transition metal halide (e.g., Fe compounds,⁴¹³ CrCl₂, CrCl₃, CoCl₂, CoBr₂, or CuCl₂).⁴¹⁴ The metallic halide is an oxidizing agent and becomes reduced. Both aryl and alkyl *Grignard reagents* can be dimerized by either procedure, though the TlBr method cannot be applied to R = primary alkyl or to aryl groups with ortho substituents. Aryl *Grignard reagents* can also be dimerized by treatment with 1,4-dichloro-2-butene, 1,4-dichloro-2-butyne, or 2,3-dichloropropene.⁴¹⁵ Vinylic and alkynyl *Grignard reagents* can be coupled (to give 1,3-dienes and 1,3-diynes, respectively) by treatment with thionyl chloride.⁴¹⁶ Primary alkyl, vinylic, aryl, and benzylic *Grignard reagents* give symmetrical dimers in high yield (~90%) when treated with a silver(I) salt in the presence of a nitrogen-containing oxidizing agent (e.g., lithium nitrate, methyl nitrate, or NO₂).⁴¹⁷ This method has been used to close rings of four, five, and six members.⁴¹⁸

The mechanisms of the reactions with metal halides, at least in some cases, probably begin with conversion of RMgX to the corresponding RM (Reaction **12-36**), followed by its decomposition to free radicals.⁴¹⁹

OS VI, 488.

14-25 Coupling of Other Organometallic Reagents³³²

De-metallo-coupling

Lithium dialkylcopper reagents can be oxidized to symmetrical dimers by O₂ at -78 °C in THF.⁴²⁰ The reaction is successful for R = primary and secondary alkyl, vinylic, or aryl. Other oxidizing agents (e.g., nitrobenzene) can be used instead of O₂. Vinylic

copper reagents dimerize on treatment with oxygen, or simply on standing at 0 °C for several days or at 25 °C for several hours, to yield 1,3-dienes.⁴²¹ The finding of retention of configuration for this reaction demonstrates that free radical intermediates are not involved.

The coupling reaction of *Grignard reagents* was discussed in Reaction **14-24**. There are iron-catalyzed cross-coupling reactions.⁴²² Lithium organoaluminates (LiAlR_4) are dimerized to $\text{R}-\text{R}$ by treatment with $\text{Cu}(\text{OAc})_2$.⁴²³ Terminal vinylic alanes (prepared by Reaction **15-17**) can be dimerized to 1,3-dienes with CuCl in THF.⁴²⁴ Symmetrical 1,3-dienes can also be prepared in high benzylic bromides to give the coupling product.⁴²⁵ Coupling products are obtained by treatment of vinylic mercury chlorides⁴²⁶ with LiCl and a Rh catalyst⁴²⁷ and by treatment of vinylic tin compounds with a Pd catalyst.⁴²⁸ Vinylic, alkynyl, and aryl tin compounds were dimerized with $\text{Cu}(\text{NO}_3)_2$.⁴²⁹ Allylindium reagents were coupled to alkyl- and aryllithium compounds can be dimerized by transition metal halides in a reaction similar to Reaction **14-24**.⁴³⁰

Unsymmetrical coupling of vinylic, alkynyl, and arylmercury compounds was achieved in moderate-to-good yields by treatment with alkyl and vinylic dialkylcopper reagents (e.g., $\text{PhCH}=\text{CHHgCl} + \text{Me}_2\text{CuLi} \rightarrow \text{PhCH}=\text{CHMe}$).⁴³¹ A radical coupling reaction has been reported, in which an aryl halide reacted with Bu_3SnH , AIBN, and benzene, followed by treatment with methyllithium to give the biaryl.⁴³²

14-26 Coupling of Boranes

Alkyl-de-dialkylboration

Alkylboranes can be coupled by treatment with silver nitrate and base.⁴³³ Since alkylboranes are easily prepared from alkenes (Reaction **15-16**), this is essentially a way of coupling and reducing alkenes; in fact, alkenes can be hydroborated and coupled in the same flask. For symmetrical coupling ($\text{R} = \text{R}'$) yields range from 60 to 80% for terminal alkenes and from 35 to 50% for internal ones. Unsymmetrical coupling has also been

carried out,⁴³⁴ but with lower yields. Arylboranes react similarly, yielding biaryls.⁴³⁵ The mechanism is probably of the free radical type.

Dimerization of two vinylborane units to give a conjugated diene can be achieved by treatment of divinylchloroboranes (prepared by addition of BH_2Cl to alkynes; see Reaction 15-16) with methylcopper. (*E,E*)-1,3-Dienes are prepared in high yields.⁴³⁶

In a similar reaction, symmetrical conjugated diynes $\text{RC}\equiv\text{C}-\text{C}\equiv\text{CR}$ can be prepared by reaction of lithium dialkyldialkynylborates, $\text{Li}^+ [\text{R}'_2\text{B}(\text{C}\equiv\text{CR})_2]^-$, with iodine.⁴³⁷

14.C.iv. Halogen as Leaving Group

The conversion of RX to RH can occur by a free radical mechanism, but is treated at Reaction 19-53.

14.C.v. Sulfur as Leaving Group

14-27 Desulfurization

Hydro-de-thio-substitution, and so on

Thiols and thioethers,⁴³⁸ both alkyl and aryl, can be desulfurized by hydrogenolysis with Raney nickel.⁴³⁹ The hydrogen is usually not applied externally, since Raney nickel already contains enough hydrogen for the reaction. Other sulfur compounds can be similarly desulfurized, among them disulfides (RSSR), thiono esters (RCSOR'),⁴⁴⁰ thioamides (RCDNHR'), sulfoxides, and dithioacetals. The last reaction, which is an indirect way of accomplishing reduction of a carbonyl to a methylene group (see

⁴³⁹ See Belen'kii, L.I. in Belen'kii, L.I. *Chemistry of Organosulfur Compounds*, Ellis Horwood, Chichester, **1990**, pp. 193–228; Pettit, G.R.; van Tamelen, E.E. *Org. React.* **1962**, 12, 356; Hauptmann, H.; Walter, W.F. *Chem. Rev.* **1962**, 62, 347.

⁴⁴⁰ See Baxter, S.L.; Bradshaw, J.S. *J. Org. Chem.* **1981**, 46, 831.

Reaction **19-61**), can also give the alkene if a hydrogen atom is present.⁴⁴¹ In most of the examples given, R can also be aryl. Other reagents⁴⁴² have also been used,⁴⁴³ including Sm in acetic acid for desulfurization of vinyl sulfones.⁴⁴⁴

An important special case of RSR reduction is desulfurization of thiophene derivatives. This proceeds with concomitant reduction of the double bonds. Many compounds have been made by alkylation of thiophene (see **39**), followed by reduction to the corresponding alkane.

Thiophenes can also be desulfurized to alkenes ($\text{RCH}_2\text{CH}=\text{CHCH}_2\text{R}'$ from **43**) with a nickel boride catalyst prepared from nickel(II) chloride and NaBH_4 in methanol.⁴⁴⁵ It is possible to reduce just one SR group of a dithioacetal by treatment with borane–pyridine in trifluoroacetic acid or in CH_2Cl_2 in the presence of AlCl_3 .⁴⁴⁶ Phenyl selenides (RSePh) can be reduced to RH with Ph_3SnH ⁴⁴⁷ and with nickel boride.⁴⁴⁸

The exact mechanisms of the Raney nickel reactions are still in doubt, though they are probably of the free radical type.⁴⁴⁹ It has been shown that reduction of thiophene proceeds through butadiene and butene, not through 1-butanethiol or other sulfur compounds; that is, the sulfur is removed before the double bonds are reduced. This was demonstrated by isolation of the olefins and the failure to isolate any potential sulfur-containing intermediates.⁴⁵⁰

See Chapter 19 for other reduction reactions involving sulfur compounds.

with R = primary, secondary, or tertiary alkyl, or allylic,⁴⁵³ and containing groups, such as double bonds or halogens. Dilithio compounds can be made from compounds containing two separated SPh groups, but it is also possible to replace just one SPh from a compound with two such groups on a single carbon, to give an α -lithio sulfide.⁴⁵⁴ The reaction has also been used to prepare α -lithio ethers and α -lithio organosilanes.⁴⁵¹ For some of these compounds, lithium 1-(dimethylamino)naphthalenide is a better reagent than either Li or lithium naphthalenide.⁴⁵⁵ The mechanism is presumably of the free radical type.

14.C.vi. Carbon as Leaving Group

14-29 Decarboxylative Dimerization: The Kolbe Reaction

De-carboxylic-coupling

Electrolysis of carboxylate ions, results in decarboxylation and combination of the resulting radicals to give the coupling product R—R. This coupling reaction is called the *Kolbe Reaction* or the *Kolbe electrosynthesis*.⁴⁵⁶ It is used to prepare symmetrical R—R, where R is straight chained, since little or no yield is obtained when there is a branching. The reaction is not successful for R = aryl. Many functional groups may be present, though many others inhibit the reaction.⁴⁵⁶ Unsymmetrical R—R' have been made by coupling mixtures of acid salts. The *Kolbe reaction* has been done using solid-supported bases.⁴⁵⁷

A free radical mechanism is involved

There is much evidence⁴⁵⁸ for this mechanism, including side products (RH, alkenes) characteristic of free radical intermediates and the fact that electrolysis of acetate ion in the presence of styrene caused some of the styrene to polymerize to polystyrene (such polymerizations can be initiated by free radicals, see Sec. 15.B.i). Other side products (ROH, RCO₂R) are sometimes found, stemming from further oxidation of the radical R[•] to a carbocation R⁺.⁴⁵⁹

When the reaction is conducted in the presence of 1,3-dienes, additive dimerization can occur.⁴⁶⁰

The radical R^\bullet adds to the conjugated system to give $\text{RCH}_2\text{CH}=\text{CHCH}_2^\bullet$, which dimerizes. Another possible product is $\text{RCH}_2\text{CH}=\text{CHCH}_2\text{R}$, from coupling of the two kinds of radicals.⁴⁶¹

In a nonelectrolytic reaction, which is limited to R = primary alkyl, the thiohydroxamic esters (**44**) give dimers when irradiated at -64°C in an Ar atmosphere.⁴⁶²

In another nonelectrolytic process, aryl acetic acids are converted to *vic*-diaryl compounds ($2\text{ArCR}_2\text{COOH} \rightarrow \text{ArCR}_2\text{CR}_2\text{Ar}$) by treatment with sodium persulfate ($\text{Na}_2\text{S}_2\text{O}_8$) and a catalytic amount of AgNO_3 .⁴⁶³ Photolysis of carboxylic acids in the presence of Hg_2F_2 leads to the dimeric alkane via decarboxylation.⁴⁶⁴ Both of these reactions involve dimerization of free radicals. In still another process, electron-deficient aromatic acyl chlorides are dimerized to biaryls ($\text{Ar}-\text{Ar}$) by treatment with a disilane R_3SiSiR_3 and a Pd catalyst.⁴⁶⁵

14-30 The Hunsdiecker Reaction

Bromo-de-carboxylation

Reaction of a silver salt of a carboxylic acid with bromine is called the *Hunsdiecker reaction*⁴⁶⁶ and is a method of decreasing the length of a carbon chain by one unit.⁴⁶⁷ The reaction is of wide scope, giving good results for *n*-alkyl R from 2 to 18 carbons and for many branched R too, producing primary, secondary, and tertiary bromides. Many functional groups may be present as long as they are not a substituted. The R group may also be aryl. However, if R contains unsaturation, the reaction seldom gives good results. Although bromine is the most often used halogen, chlorine, and iodine have also

been used. Catalytic Hunsdiecker reactions are known,⁴⁶⁸ and microwave enhancement has been employed.⁴⁶⁹

When iodine is the reagent, the ratio between the reactants is very important and determines the products. A 1:1 ratio of salt/iodine gives the alkyl halide, as above. A 2:1 ratio, however, gives the ester RCOOR. This is called the *Simonini Reaction* and is sometimes used to prepare carboxylic esters. The *Simonini reaction* can also be carried out with lead salts of acids.⁴⁷⁰ A more convenient way to perform the *Hunsdiecker Reaction* is by use of a mixture of the acid and mercuric oxide instead of the salt, since the silver salt must be very pure and dry and such pure silver salts are often not easy to prepare.⁴⁷¹

Other methods for accomplishing the conversion $\text{RCOOH} \rightarrow \text{RX}$ are⁴⁷² (1) treatment of thallium(I) carboxylates with bromine;⁴⁷³ (2) treatment of carboxylic acids with lead tetraacetate and halide ions (Cl^- , Br^- , or I^-);⁴⁷⁴ (3) reaction of the acids with lead tetraacetate and NCS, which gives tertiary and secondary chlorides in good yields, but is not good for R = primary alkyl or phenyl;⁴⁷⁵ (4) treatment of thiohydroxamic esters with CCl_4 , BrCCl_3 (which gives bromination), CHI_3 , or CH_2I_2 in the presence of a radical initiator;⁴⁷⁶ (5) photolysis of benzophenone oxime esters of carboxylic acids in CCl_4 ($\text{RCON}=\text{CPh}_2 \rightarrow \text{RCl}$).⁴⁷⁷ Alkyl fluorides can be prepared in moderate-to-good yields by treating carboxylic acids (RCOOH) with XeF_2 .⁴⁷⁸ This method works best for R = primary and tertiary alkyl, and benzylic. Aromatic and vinylic acids do not react.

The mechanism of the *Hunsdiecker reaction* is believed to be as follows:

The first step is not a free radical process, and its actual mechanism is not known.⁴⁷⁹ Compound **45** is an acyl hypohalite and is presumed to be an intermediate, though it has never been isolated from the reaction mixture. Among the evidence for the mechanism is that optical activity at R is lost (except when a neighboring bromine atom is present, see Sec. 14.A.iv); if R is neopentyl, there is no rearrangement, which would certainly happen with a carbocation; and the side products, notably R-R, are consistent with a free radical mechanism. There is evidence that the *Simonini reaction* involves the same mechanism as the *Hunsdiecker reaction*, but that the alkyl halide formed then reacts with excess RCOOAg (Reaction **10-17**) to give the ester⁴⁸⁰ (see also, Reaction **19-12**).

Vinyl carboxylic acids (conjugated acids) were shown to react with NBS and lithium acetate in aq acetonitrile, to give the corresponding vinyl bromide ($\text{C}=\text{C}-\text{CO}_2\text{H} \rightarrow \text{C}=\text{C}-\text{Br}$), using microwave irradiation.⁴⁸¹ A similar reaction was reported using Na_2MoO_4 , KBr and aq H_2O_2 .⁴⁸²

A related reaction reacts the sodium salt of an alkylsulfonic acid with thionyl chloride at 100 °C, to give the alkyl chloride.⁴⁸³

14-31 Decarboxylative Allylation

Allyl-de-carboxylation

The COOH group of a β -keto acid is replaced by an allylic group when the acid is treated with an allylic acetate and a Pd catalyst at room temperature.⁴⁸⁴ The reaction is successful for various substituted allylic groups. The less highly substituted end of the allylic group forms the new bond. Thus, both $\text{CH}_2=\text{CHCHMeOAc}$ and $\text{MeCH}=\text{CH}-\text{CH}_2\text{OAc}$ gave $\text{O}=\text{C}(\text{R})-\text{C}-\text{CH}_2\text{CH}-\text{CHMe}$ as the product.

14-32 Decarbonylation of Aldehydes and Acyl Halides

Carbonyl-extrusion

Aldehydes, both aliphatic and aromatic, can be decarbonylated⁴⁸⁵ by heating with a Rh catalyst⁴⁸⁶ or other catalysts (e.g., Pd).⁴⁸⁷ The compound $\text{RhCl}(\text{Ph}_3\text{P})_3$ is often called

⁴⁷⁹ When Br_2 reacts with aryl R, at low temperature in inert solvents, it is possible to isolate a complex containing both Br_2 and the silver carboxylate: see Bryce-Smith, D.; Isaacs, N.S.; Tumi, S.O. *Chem. Lett.* **1984**, 1471.

Wilkinson's catalyst.⁴⁸⁸ In an older reaction aliphatic (but not aromatic) aldehydes are decarbonylated by heating with di-*tert*-butyl peroxide or other peroxides,⁴⁸⁹ usually in a solution containing a hydrogen donor, such as a thiol. The reaction has also been initiated with light, and thermally (without an initiator) by heating at $\sim 500^\circ\text{C}$.

Wilkinson's catalyst has also been reported to decarbonylate aromatic acyl halides at 180°C ($\text{ArCOX} \rightarrow \text{ArX}$).⁴⁹⁰ This reaction has been carried out with acyl iodides,⁴⁹¹ bromides, and chlorides. Aliphatic acyl halides that lack a hydrogen also give this reaction,⁴⁹² but if an α hydrogen is present, elimination takes place instead (Reaction 17-17). Aromatic acyl cyanides give aryl cyanides ($\text{ArCOCN} \rightarrow \text{ArCN}$).⁴⁹³ Aromatic acyl chlorides and cyanides can also be decarbonylated with Pd catalysts.⁴⁹⁴

It is possible to decarbonylate acyl halides in another way, to give alkanes ($\text{RCOCl} \rightarrow \text{RH}$). This is done by heating the substrate with tripropylsilane (Pr_3SiH) in the presence of *tert*-butyl peroxide.⁴⁹⁵ Yields are good for R = primary or secondary alkyl and poor for R = tertiary alkyl or benzylic. There is no reaction when R = aryl. (See also, the decarbonylation $\text{ArCOCl} \rightarrow \text{Ar}-\text{Ar}$ mentioned in Reaction 14-29.)

The mechanism of the peroxide- or light-induced reaction seems to be as follows (in the presence of thiols).⁴⁹⁶

The reaction of aldehydes with *Wilkinson's catalyst* goes through complexes of the form 46 and 47, which have been trapped.⁴⁹⁷ The reaction has been shown to give retention of configuration at a chiral R ,⁴⁹⁸ and deuterium labeling demonstrates that the reaction is

Addition to Carbon–Carbon Multiple Bonds

There are four fundamental ways in which addition to a double or triple bond can take place. Three of these are two-step processes, with initial attack by a nucleophile, or attack upon an electrophile or a free radical. The second step consists of combination of the resulting intermediate with, respectively, a positive species, a negative species, or a neutral entity. In the fourth type of mechanism, attack at the two carbon atoms of the double or triple bond is simultaneous (concerted). Which of the four mechanisms is operating in any given case is determined by the nature of the substrate, the reagent, and the reaction conditions. Some of the reactions in this chapter can take place by all four mechanistic types.

15.A. MECHANISMS

15.A.i. Electrophilic Addition¹

In this mechanism, a positive species approaches the double or triple bond and in the first step forms a bond by donation of the π pair of electrons² to the electrophilic species to form a σ bond:

The IUPAC designation for this mechanism is $A_E + A_N$ (or $A_H + A_N$ if $Y^+ = H^+$). As in electrophilic substitution (Sec. 11.A.i), Y need not actually be a positive ion, but can be the

¹ See de la Mare, P.B.D.; Bolton, R. *Electrophilic Additions to Unsaturated Systems*, 2nd ed., Elsevier, NY, **1982**. For reviews, see Schmid, G.H. in Patai, S. *Supplement A: The Chemistry of Double-bonded Functional Groups*, Vol. 2, pt. 1, Wiley, NY, **1989**, pp. 679–731; Schmid, G.H.; Garratt, D.G. in Patai, S. *Supplement A: The Chemistry of Double-bonded Functional Groups*, Vol. 1, pt. 2, Wiley, NY, **1977**, pp. 725–912; Freeman, F. *Chem. Rev.* **1975**, 75, 439.

² See Mayr, H.; Kempf, B.; Ofial, A.R. *Acc. Chem. Res.* **2003**, 36, 66.

positive end of a dipole or an induced dipole, with the negative part breaking off either during the first step or shortly after. The second step is a combination of **1** with a species carrying an electron pair and often bearing a negative charge. This step is the same as the second step of the S_N1 mechanism. Not all electrophilic additions follow the simple mechanism given above. In many bromination reactions it is fairly certain that **1**, if formed at all, very rapidly cyclizes to a bromonium ion (**2**):

This intermediate is similar to those encountered in the neighboring-group mechanism of nucleophilic substitution (see Sec. 10.C). The attack of W: on an intermediate like **2** is an S_N2 step. Whether the intermediate is **1** or **2**, the mechanism is called Ad_E2 (electrophilic addition, bimolecular).

The most useful type of information for investigating the mechanism of addition to a double bond, is perhaps, the stereochemistry of the reaction.³ The two carbons of the double bond and the four atoms immediately attached to them are all in a plane (Sec. 1.D); there are thus three possibilities. Both Y and W may enter from the same side of the plane, in which case the addition is stereospecific and syn; they may enter from opposite sides for stereospecific anti addition; or the reaction may be nonstereospecific. In order to determine which of these possibilities is occurring in a given reaction, the following type of experiment is often done: YW is added to the *cis* and *trans* isomers of an alkene of the form $ABC=CBA$. Using the *cis*-alkene as an example, if the addition is syn, the product will be the erythro *dl* pair, because each carbon has a 50% chance of being attacked by Y:

On the other hand, if the addition is anti, the threo *dl* pair will be formed:

Of course, the *trans* isomer will give the opposite results: the threo pair if the addition is syn and the erythro pair if it is anti. These diastereomers have different physical properties. In the special case, where $Y = W$ (as in the addition of Br_2), the “erythro pair” is a meso

³ See Fahey, R.C. *Top. Stereochem.* **1968**, 3, 237; Bartlett, P.A. *Tetrahedron* **1980**, 36, 2, pp. 3–15.

compound. In addition to triple-bond compounds of the type $AC\equiv CA$, syn addition results in a *cis*-alkene and anti addition in a *trans*-alkene. By the definition given in Section 4.N, addition to triple bonds cannot be stereospecific, although it can be, and often is, stereoselective.

It is easily seen that in reactions involving cyclic intermediates like **2**, addition must be anti, since the second step is an S_N2 step and must occur from the rear. It is not so easy to predict the stereochemistry for reactions involving **1**. If **1** has a relatively long life, the addition should be nonstereospecific, since there will be free rotation about the single bond. In addition, the carbocation is planar, so there is no facial bias for nucleophilic attack. On the other hand, if there is some factor that maintains the configuration, the group W may come in from the same *or* the opposite side, depending on the circumstances. For example, the positive charge might be stabilized by an attraction for Y that does not involve a full bond (see **3**). In such a case, Y is said to stabilize the positive center via back-donation.

Such stabilization usually leads to anti attack of the second group. This contrasts with a circumstance that would favor syn addition: Formation of an ion pair (**4**) after the addition of Y^4 :

Since W is already on the same side of the plane as Y, collapse of the ion pair leads to syn addition.

Another possibility is that anti addition might, at least in some cases, be caused by the operation of a mechanism in which attack by W and Y are essentially *simultaneous*, but from opposite sides:

This mechanism, called the Ad_E3 mechanism (*termolecular addition*, IUPAC A_NA_E),⁵ has the disadvantage that three molecules must come together in the transition state. Note that it is the reverse of the $E2$ mechanism for elimination, for which the transition state is known to possess this geometry (Sec. 17.A.i).

⁴ Heasley, G.E.; Bower, T.R.; Dougherty, K.W.; Easdon, J.C.; Heasley, V.L.; Arnold, S.; Carter, T.L.; Yaeger, D.B.; Gipe, B.T.; Shellhamer, D.F. *J. Org. Chem.* **1980**, *45*, 5150.

⁵ See Roberts, R.M.G. *J. Chem. Soc. Perkin Trans. 2*, **1976**, 1374; Pasto, D.J.; Gadberry, J.F. *J. Am. Chem. Soc.* **1978**, *100*, 1469; Naab, P.; Staab, H.A. *Chem. Ber.* **1978**, *111*, 2982.

There is much evidence that when an alkene attacks Br^+ (or a carrier of it), bromonium ion **2** is usually the intermediate and the addition is anti, so the reaction is diastereospecific. Such ions have also been isolated in reactions involving addition of a Br^+ species to a double bond.⁶ Treatment of maleic acid with bromine gave the *dl* pair of 2,3-dibromosuccinic acid, for example, while fumaric acid (the *trans* isomer) gave the meso compound.⁷ Many similar experiments have been performed with similar results. Bromination of dicarboxyacetylene gave 70% of the *trans* isomer.⁸

There is other evidence for mechanisms involving **2**. As seen in Section 10.C, bromonium ions have been isolated in stable solutions in nucleophilic substitution reactions involving bromine as a neighboring group. The following is further evidence. If the two bromines approach the double bond from opposite sides, it is very unlikely that they could come from the same bromine molecule. This means that if the reaction is performed in the presence of nucleophiles, some of these will compete in the second step with the bromide liberated from the bromine. It has been found, indeed, that treatment of ethylene with bromine in the presence of chloride ions gives some 1-chloro-2-bromoethane along with the dibromoethane.⁹ Similar results are found when the reaction is carried out in the presence of water (Reaction **15-40**) or of other nucleophiles.¹⁰ *Ab initio* MO studies show that **2** is more stable than its open isomer **1** ($\text{Y} = \text{Br}$).¹¹ There is evidence that formation of **2** is reversible.¹²

However, a number of examples have been found where addition of bromine is not stereospecifically anti. For example, the addition of Br_2 to *cis*- and *trans*-1-phenylpropenes in CCl_4 was nonstereospecific.¹³ Furthermore, the stereospecificity of bromine addition to stilbene depends on the dielectric constant of the solvent. In solvents of low dielectric constant, the addition was 90–100% anti, but with an increase in dielectric constant, the reaction became less stereospecific, until at a dielectric constant of ~ 35 , the addition was completely nonstereospecific.¹⁴ Likewise in the case of triple bonds, stereoselective anti addition was found in bromination of 3-hexyne, but both *cis* and *trans* products were obtained in bromination of phenylacetylene.¹⁵ These results indicate that a bromonium ion

is not formed where the open cation can be stabilized in other ways (e.g., addition of Br^+ to 1-phenylpropene gives the ion $\text{PhC}^+\text{HCHBrCH}_3$, which is a relatively stable benzylic cation). In addition, there is probably a spectrum of mechanisms between complete bromonium ion (**2**, no rotation) formation and completely open-cation (**1**, free rotation) formation, with partially bridged bromonium ions (**3**, restricted rotation) in between.¹⁶ Previously seen cases (Sec. 10.C.i, category 4) showed that cations require more stabilization from outside sources as they become intrinsically less stable themselves.¹⁷ Further evidence for the open cation mechanism where aryl stabilization is present was reported in an isotope effect study of Br_2 addition to $\text{ArCH}=\text{CHCHAr}'$ ($\text{Ar} = p$ -nitrophenyl, $\text{Ar}' = p$ -tolyl). The ^{14}C isotope effect for one of the double-bond carbons (the one closer to the NO_2 group) was considerably larger than for the other one.¹⁸

When the π bond of an alkene attacks Cl^+ ,¹⁹ I^+ ,²⁰ or RS^+ ,²¹ the result is similar to that when the electrophile is Br^+ ; there is a spectrum of mechanisms between cyclic intermediates and open cations. As might be expected from the discussion in Section 10.C, iodonium ions compete with open carbocations more effectively than bromonium ions, while chloronium ions compete less effectively. There is kinetic and spectral evidence that at least in some cases (e.g., in the addition of Br_2 or ICl), the electrophile forms a π complex with the alkene before a covalent bond is formed.²² There is evidence for β -chloro and β -bromocarbenium ions in some reactions.²³

When the electrophile is a proton,²⁴ a cyclic intermediate is not possible, and the mechanism is the simple $\text{A}_\text{H} + \text{A}_\text{N}$ process shown before

This is an $\text{A-S}_\text{E}2$ mechanism (see Reaction 10-6). There is a great deal of evidence²⁵ for it, including:

1. The reaction is general acid, not specific acid catalyzed, implying rate-determining proton transfer from the acid to the double bond.²⁶

2. The existence of open carbocation intermediates is supported by the contrast in the pattern of alkyl substituent effects²⁷ with that found in brominations, where cyclic intermediates are involved. In the latter case, substitution of alkyl groups on $\text{H}_2\text{C}=\text{CH}_2$ causes a cumulative rate acceleration

until all four hydrogen atoms have been replaced by alkyl groups, because each group helps to stabilize the positive charge.²⁸ In addition of HX, the effect is not cumulative. Replacement of the two hydrogen atoms on one carbon causes great rate increases (primary \rightarrow secondary \rightarrow tertiary carbocation), but additional substitution on the other carbon produces little or no acceleration.²⁹ This is evidence for open cations when a proton is the electrophile.³⁰

3. Open carbocations are prone to rearrange (Chapter 18). Many rearrangements have been found to accompany additions of HX and H_2O .³¹

It may also be recalled that vinylic ethers react with proton donors in a similar manner (see Reaction 10-6).

The stereochemistry of HX addition is varied. Examples are known of predominant syn, anti, and nonstereoselective addition. It was found that treatment of 1,2-dimethylcyclohexene (**5**) with HBr gave predominant anti addition,³² while addition of water to **5** gave equal amounts of the cis and trans alcohols:³³

On the other hand, addition of DBr to acenaphthylene and to indene and 1-phenylpropene gave predominant syn addition, as shown:³⁴

In fact, it has been shown that changing the reaction conditions can control the stereoselectivity of HCl addition. Addition of HCl to **5** in CH_2Cl_2 at -98°C

gave predominantly syn addition, while in ethyl ether at 0°C, the addition was mostly anti.³⁵

Addition of HX to triple bonds has the same mechanism, although the intermediate in this case is a vinylic cation (**6**).³⁶

In all these cases (except for the Ad_E3 mechanism), it was assumed that formation of the intermediate (**1**, **2**, or **3**) is the slow step and attack by the nucleophile on the intermediate is rapid. This finding is probably true in most cases. However, some additions have been found in which the second step is rate determining.³⁷

15.A.ii. Nucleophilic Addition³⁸

In the first step of nucleophilic addition, a nucleophile donates a pair of electrons to one carbon atom of the double or triple bond, creating a carbanion, which reacts with a positive species in the second step:

This mechanism is the same as the simple electrophilic one shown in Section 15.A.i except that the charges are reversed (IUPAC A_N + A_E or A_N + A_H). When the alkene contains a good leaving group (as defined for nucleophilic substitution), substitution is a side reaction (this is nucleophilic substitution at a vinylic substrate, see Sec. 10.F).

In the special case of addition of HY to a substrate of the form —C=C—Z, where Z = CHO, COR³⁹ (including quinones⁴⁰), CO₂R, CONH₂, CN, NO₂, SOR, 2R,⁴¹ and so on, addition nearly always follows a nucleophilic mechanism,⁴² with Y[−] bonding with the carbon *away* from the Z group, for example,

After the reaction with HY, the product is a resonance-stabilized enolate anion. Subsequent protonation of the enolate ion is probably at the oxygen to give an enol, which tautomerizes to the ketone (Sec. 2.N.i). Although the net result of the reaction is addition to a carbon-carbon double bond, the *mechanism* is 1,4-nucleophilic addition to the $\text{C}=\text{C}-\text{C}=\text{O}$ (or similar) system and is thus very similar to the mechanism of addition to carbon-oxygen double and similar bonds (see Chapter 16). This mechanism is essentially that of the *Michael reaction* discussed in Reaction 15-24, and such reactions are often called *Michael reactions* or *Michael-type reactions*. When Z is CN or a $\text{C}=\text{O}$ group, it is also possible for Y^- to attack C of the cyano or carbonyl, which sometimes competes. When it happens, it is called 1,2-addition (see nucleophilic acyl addition in Chapter 16). 1,4-Addition to these substrates is also known as *conjugate addition*. Attack of the Y^- ion at the 3 position is very difficult, since the resulting carbanion would have no resonance stabilization.⁴³ Systems of the type $\text{C}=\text{C}-\text{C}=\text{C}-\text{Z}$ can give 1,2-, 1,4-, or 1,6-addition.⁴⁴ *Michael-type reactions* are reversible, and compounds of the type $\text{YCH}_2\text{CH}_2\text{Z}$ can often be decomposed to YH and $\text{CH}_2=\text{CHZ}$ by heating, either with or without alkali.

If the mechanism for nucleophilic addition is the simple carbanion mechanism outlined above for an alkene, the addition should be nonstereospecific, although it might well be stereoselective (see Sec. 4.N for the distinction). For example, the (*E*) and (*Z*) forms of an alkene $\text{ABC}=\text{CDE}$ would give **7** and **8**. If the carbanion has

even a short lifetime, **7** and **8** will assume the most favorable conformation before the reaction with W. This is of course the same for both, and reaction with W will give the same product. This will be one of two possible diastereomers, so the reaction will be diastereoselective; but since the *cis* and *trans* isomers do not give rise to different isomers, it will not be diastereospecific. Unfortunately, this prediction has not been tested on open-chain alkenes. Except for *Michael-type substrates*, the stereochemistry of nucleophilic addition to double bonds has been studied only in cyclic systems, where only the *cis* isomer exists. In these cases, the reaction has been shown to be stereoselective, with *syn* addition reported in some cases⁴⁵ and *anti* addition in others.⁴⁶ When the reaction is performed on a *Michael-type substrate* ($\text{C}=\text{C}-\text{Z}$) the hydrogen does not arrive at the carbon directly, but only

through a tautomeric equilibrium. The product naturally assumes the most thermodynamically stable configuration, without relation to the direction of original attack of Y. In one such case (the addition of EtOD and of Me₃CSD to *trans*-MeCH=CHCOOEt), predominant anti addition was found. There is evidence that the stereoselectivity here results from the final protonation of the enolate, and not from the initial attack.⁴⁷ For obvious reasons, additions to triple bonds cannot be stereospecific. As with electrophilic additions, nucleophilic additions to triple bonds are usually stereoselective and anti,⁴⁸ although syn addition⁴⁹ and nonstereoselective addition⁵⁰ have also been reported.

15.A.iii. Free Radical Addition

The mechanism of free radical addition⁵¹ follows the pattern discussed in Section 14.A.i. The method of principal component analysis has been used to analyze polar and enthalpic effects in radical addition reactions.⁵² A radical is generated by

or

For subsequent reaction with an alkene, propagation occurs by

Step 2 is an abstraction (an atom transfer), so W is nearly always univalent, either hydrogen or halogen (Sec. 14.B.i). Termination of the chain can occur in any of the ways discussed in Section 14.A.i. If **9** adds to another alkene molecule, a dimer is formed. This can add to still another alkene unit, and chains, long or short, may be built up. This is the mechanism of free radical polymerization. Short polymeric molecules (called *telomers*), formed in this manner, are often troublesome side products in free radical addition reactions.

⁵² Héberger, K.; Lopata, A. *J. Chem. Soc. Perkin Trans. 2*, **1995**, 91.

When free radicals are added to 1,5- or 1,6-dienes, the initially formed radical (**10**) can add intramolecularly to the other bond, leading to a cyclic product (**11**).⁵³ When the radical is generated from a precursor that gives vinyl radical **12**, however, cyclization leads to **13**, which is in equilibrium with cyclopropylcarbinyl radical **14** via a 5-exo-trig reaction.⁵⁴ A 6-endo-trig reaction (Sec. 6.E) leads to **15**, but unless there are perturbing substituent effects, cyclopropanation should be the major process. Radicals of type **10**, generated in other ways, also undergo these cyclizations. Both five- and six-membered rings can be formed (Sec. 15.B.i).

The free radical addition mechanism just outlined predicts that the addition should be nonstereospecific, at least if **9** has any, but an extremely short lifetime. However, the reactions may be stereoselective, for reasons similar to those discussed above for nucleophilic addition to alkenes. A few free radical additions are selective. For example, addition of HBr to 1-bromocyclohexene is regioselective in that it gave only *cis*-1,2-dibromocyclohexane and none of the *trans* isomer (anti addition),⁵⁵ and propyne (at -78 to -60°C) gave only *cis*-1-bromopropene (anti addition), making it stereoselective.⁵⁶ Selectivity was observed in radical cyclization reactions of functionalized alkenes, which proceeded via a *trans*-ring closure.⁵⁷ The most important case is probably addition of HBr to 2-bromo-2-butene under free radical conditions at -80°C . Under these conditions, the *cis* isomer gave 92% of the *meso* product, while the *trans* isomer gave mostly the *dl* pair.⁵⁸ This stereospecificity disappeared at room temperature, where both alkenes gave the same mixture of products ($\sim 78\%$ of the *dl* pair and 22% of the *meso* compound), so the addition was still stereoselective, but no longer stereospecific. The stereospecificity at low temperatures is probably caused by a stabilization of the intermediate radical through the formation of a bridged bromine radical, of the type mentioned in Section 14.A.iv:

This species is similar to the bromonium ion (**2**) that is responsible for stereospecific anti addition in the electrophilic mechanism. Further evidence for the existence of such bridged

radicals was obtained by addition of Br^\bullet to alkenes at 77 K. The ESR spectra of the resulting species were consistent with bridged structures.⁵⁹

For many radicals, step 1 ($\text{C}=\text{C} + \text{Y}^\bullet \rightarrow \bullet\text{C}-\text{C}-\text{Y}$) is reversible. In such cases free radicals can cause *cis* \rightarrow *trans* isomerization of a double bond by the pathway⁶⁰

15.A.iv. Cyclic Mechanisms

There are some addition reactions where the initial reaction is not at one carbon of the double bond, but both carbons react simultaneously. Some of these are four-center mechanisms, which follow the following pattern:

In others, there is a five- or a six-membered transition state. In these cases the addition to the double or triple bond must be *syn*. The most important reaction of this type is the *Diels-Alder reaction* (15-60).

15.A.v. Addition to Conjugated Systems

When electrophilic addition is carried out on a compound with two double bonds in conjugation, a 1,2-addition product (16) is often obtained, but in most cases there is also a 1,4-addition product (17), often in larger yield:⁶¹

If the diene is unsymmetrical, there may be two 1,2-addition products. The competition between two types of addition product comes about because the carbocation resulting from attack on Y^+ is a resonance hybrid, with partial positive charges at the 2 and 4 positions:

W^- may then be attacked by either position. The original reaction with Y^+ is always at the end of the conjugated system because reaction at a middle carbon would give a cation unstabilized by resonance. In the case of electrophiles like Br^+ , which can form cyclic intermediates, both 1,2- and 1,4-addition products can be rationalized as stemming from an

⁶⁰ Golden, D.M.; Furuyama, S.; Benson, S.W. *Int. J. Chem. Kinet.* **1969**, 1, 57.

⁶¹ Khristov, V.Kh.; Angelov, Kh.M.; Petrov, A.A. *Russ. Chem. Rev.* **1991**, 60, 39.

intermediate like **18**. Direct nucleophilic attack by W^- would give the 1,2-product, while the 1,4-product could be formed by attack at the 4 position, by an S_N2' -type mechanism (see Sec. 10.E). Intermediates like **19** have been postulated, but ruled out for Br and Cl by the observation that chlorination or bromination of butadiene gives trans 1,4-products.⁶² If an ion like **19** were the intermediate, the 1,4-products would have to have the cis configuration.

In most cases, more 1,4- than 1,2-addition product is obtained. This may be a consequence of thermodynamic control of products, as against kinetic, and usually temperature dependent. In most cases, under the reaction conditions, **16** is converted to a mixture of **16** and **17** that is richer in **17**. That is, either isomer gives the same mixture of both, which contains more **17**. It was found that at low temperatures, butadiene and HCl gave only 20–25% 1,4-adduct, while at high temperatures, where attainment of equilibrium is more likely, the mixture contained 75% 1,4-product.⁶³ 1,2-Addition predominated over 1,4- in the reaction between DCl and 1,3-pentadiene, where the intermediate was symmetrical (except for the D label).⁶⁴ Ion pairs were invoked to explain this result, since Cl^- would attack a free ion equally well at both positions, except for the very small isotope effect.

Addition to conjugated systems can also be accomplished by any of the other three mechanisms. In each case, there is competition between 1,2- and 1,4-addition. In the case of nucleophilic or free radical attack,⁶⁵ the intermediates are resonance hybrids and behave like the intermediate from electrophilic attack. Dienes can similarly give 1,4-addition by a cyclic mechanism:

Other conjugated systems, including trienes, enynes, diynes, and so on, have been studied much less but behave similarly. 1,4-Addition to enynes is an important way of making allenes:

Radical addition to conjugated systems is an important part of chain-propagation reactions. The rate constants for addition of cyclohexyl radical to conjugated amides

have been measured, and shown to be faster than addition to styrene.⁶⁶ In additions to $\text{RCH}=\text{C}(\text{CN})_2$ systems, where the R group has a stereogenic center, the *Felkin-Anh model* (Sec. 4.H, category 1) applies and the reaction proceeds with high selectivity.⁶⁷ Addition of some radicals [e.g., $(\text{Me}_3\text{Si})_3\text{Si}^\bullet$], is reversible and this can lead to poor selectivity or isomerization.⁶⁸

15.B. ORIENTATION AND REACTIVITY

15.B.i. Reactivity

As with electrophilic aromatic substitution (Chapter 11), electron-donating groups increase the reactivity of a double bond toward electrophilic addition and electron-withdrawing groups decrease it. This is illustrated in Tables 15.1 and 15.2.⁶⁹ As a further illustration, the reactivity toward electrophilic addition of a group of alkenes increased in the order $\text{CCl}_3\text{CH}=\text{CH}_2 < \text{Cl}_2\text{CHCH}=\text{CH}_2 < \text{ClCH}_2\text{CH}=\text{CH}_2 < \text{CH}_3\text{CH}_2=\text{CH}_2$.⁷⁰ For nucleophilic addition, the situation is reversed. These reactions are best carried out on substrates containing three or four electron-withdrawing groups, two of the most common being $\text{F}_2\text{C}=\text{CF}_2$ ⁷¹ and $(\text{NC})_2\text{C}=\text{C}(\text{CN})_2$.⁷² The effect of substituents is so great that it is possible to make the statement that *simple alkenes do not react by the nucleophilic mechanism, and polyhalo or polycyano alkenes do not generally react by the electrophilic mechanism*.⁷³ There are some reagents that attack only as nucleophiles (e.g., ammonia) and these add only to substrates susceptible to nucleophilic attack. Other reagents attack only as electrophiles, and, for example, $\text{F}_2\text{C}=\text{CF}_2$ does not react with these. In still other cases, the same reagent reacts with a simple alkene by the electrophilic mechanism and with a polyhalo alkene by a nucleophilic mechanism. For example, Cl_2 and HF are normally electrophilic reagents, but it has been shown that Cl_2 adds to $(\text{N}\equiv\text{C})_2\text{C}=\text{CHC}\equiv\text{N}$ with initial attack by Cl^- ⁷⁴ and that HF adds to $\text{F}_2\text{C}=\text{CClF}$ with initial attack by F^- .⁷⁵ Compounds that have a double bond conjugated with a Z group (as defined in Sec. 15.A.ii) nearly always react by a nucleophilic mechanism.⁷⁶ These are actually 1,4-additions, also discussed in Section 15.A.ii. A number of studies have been made of the relative activating abilities of various Z groups.⁷⁷ On the basis of these studies,

the following order of decreasing activating ability has been suggested: Z = NO₂, COAr, CHO, COR, SO₂Ar, CN, CO₂R, SOAr, CONH₂, and CONHR.⁷⁸

It seems obvious that electron-withdrawing groups enhance nucleophilic addition and inhibit electrophilic addition because they lower the electron density of the double bond. Addition of electrophilic radicals to electron-rich alkenes has been reported,⁷⁹ so the reaction is possible in some cases. This is probably true, and yet similar reasoning does not always apply to a comparison between double and triple bonds.⁸⁰ There is a higher concentration of electrons between the carbons of a triple bond than in a double bond, and

For comparisons of double and triple bond reactivity, see Melloni, G.; Modena, G.; Tonellato, U. *Acc. Chem. Res.* **1981**, 14, 227; Allen, A.D.; Chiang, Y.; Kresge, A.J.; Tidwell, T.T. *J. Org. Chem.* **1982**, 47, 775.

yet triple bonds are *less* subject to attack at an electrophilic site and *more* subject to nucleophilic attack than double bonds.⁸¹ This statement is not universally true, but it does hold in most cases. In compounds containing both double and triple bonds (nonconjugated), bromine, an electrophilic reagent, always adds to the double bond.⁸² In fact, all reagents that form bridged intermediates like **2** react faster with double than with triple bonds. On the other hand, addition of electrophilic H^+ (acid-catalyzed hydration, Reaction **15-3**; addition of hydrogen halides, Reaction **15-2**) takes place at about the same rates for alkenes as for corresponding alkynes.⁸³ Furthermore, the presence of electron-withdrawing groups lowers the alkene/alkyne rate ratio. For example, while styrene ($PhCH=CH_2$) was brominated 3000 times faster than $PhC\equiv CH$, the addition of a second phenyl group ($PhCH=CHPh$ versus $PhC\equiv CPh$) lowered the rate ratio to ~ 250 .⁸⁴ In the case of *trans*- $MeOOCCH=CHCOOMe$ versus $MeOOC\equiv CCOOMe$, the triple-bond compound was actually brominated faster.⁸⁵

As mentioned earlier, it is true that in general triple bonds are more susceptible to nucleophilic and less prone to reaction at an electrophilic site than double bonds, in spite of their higher electron density. One explanation is that the electrons in the triple bond are held more tightly because of the smaller carbon-carbon distance. Thus it is harder to donate an electron pair to an electrophile. There is evidence from far-UV spectra to support this conclusion.⁸⁶ Another possible explanation has to do with the availability of the unfilled orbital in the alkyne. It has been shown that a π^* orbital of bent alkynes (e.g., cyclooctyne) has a lower energy than the π^* orbital of alkenes, and it has been suggested⁸⁷ that linear alkynes can achieve a bent structure in their transition states when reacting with an electrophile. Where electrophilic addition involves bridged-ion intermediates, those arising from triple bonds (**20**) are more strained than the corresponding **21**. This may be a reason why electrophilic addition by such electrophiles as Br, I, SR, and so on, is slower for triple than for double bonds.⁸⁸ As might be expected, triple bonds connected to a Z group ($C\equiv C-Z$) undergo nucleophilic addition especially well.⁸⁹

Although alkyl groups in general increase the rates of electrophilic addition, as mentioned in Section 15.A.i, category 1, there is a different pattern depending on whether the intermediate is a bridged ion or an open carbocation. For brominations and other electrophilic additions in which the first step of the mechanism is rate determining, the rates for substituted alkenes correlate well with the ionization potentials of the alkenes, which means that steric effects are not important.⁹⁰ Where the second step is rate

determining [e.g., oxymercuration Reaction (15-3), hydroboration Reaction (15-17)], steric effects are important.⁸⁹

Free radical additions can occur with any type of substrate. The determining factor is the presence of a reactive free radical species. Some reagents (e.g., HBr, RSH) attack by ionic mechanisms if no initiator is present, but in the presence of a free radical initiator, the mechanism changes and the addition is of the free radical type. Nucleophilic radicals (Sec. 14.A.ii) behave like nucleophiles in that the rate is increased by the presence of electron-withdrawing groups in the substrate. The reverse is true for electrophilic radicals.⁹¹ However, nucleophilic radicals react with alkynes more slowly than with the corresponding alkenes,⁹² which is contrary to what might have been expected.⁹³

Steric influences are important in some cases. In catalytic hydrogenation, where the substrate must be adsorbed onto the catalyst surface, the reaction becomes more difficult with increasing substitution. The hydrocarbon (22), in which the double bond is entombed between the benzene rings, does not react with Br₂, H₂SO₄, O₃, BH₃, :CBr₂, or other reagents that react with most double bonds.⁹⁴ A similarly inactive compound is tetra-*tert*-butyllallene (*t*-Bu)₂C=C=C(*t*-Bu)₂, which is inert to Br₂, Cl₂, O₃, and catalytic hydrogenation.⁹⁵

15.B.ii. Orientation

When an unsymmetrical reagent is added to an unsymmetrical substrate, the question arises: Which side of the reagent goes to which side of the double or triple bond? In other words, what is the *regioselectivity* of the reaction? *Regioselectivity is defined as one direction of bond making or breaking that occurs preferentially over all other possible directions.* The terms side and face are arbitrary, and a simple guide is shown to help understand

the arguments used here. For reaction with an electrophile, the traditional answer is given by *Markovnikov's rule*: *The positive portion of the reagent goes to the side of the double or triple bond that has more hydrogen atoms.*⁹⁶ Mechanistically, regioselectivity is predicted by attack of the π bond on Y^+ , forming a bond to the carbon that will give the

more stable carbocation. For example, secondary carbocations are more stable than primary:

This mechanism is supported by evidence from core electron spectroscopy and by theoretical analysis.⁹⁷ The *Hammond postulate* is invoked to say that the lower energy carbocation is preceded by the lower energy transition state. *Markovnikov's rule* also applies for halogen substituents, and the mechanistic rationale is that the halogen stabilizes the carbocation by resonance, so the intermediate with the positive charge on the Cl bearing carbon is more stable.

Markovnikov's rule is also followed where bromonium ions or other three-membered rings are intermediates formed in protic solvents (e.g., methanol).⁹⁸ In such a medium, attack by the nucleophile W on the three-membered ring must resemble the S_N1 (see Sec. 10.A.ii) rather than the S_N2 mechanism (and see Sec. 10.G.viii), although the overall stereospecific anti addition in these reactions means that the nucleophilic substitution step is taking place with inversion of configuration. This result suggests a tight ion pair rather than a free carbocation.

Alkenes containing strong electron-withdrawing groups may violate *Markovnikov's rule*, but formation of the more stable carbocation still controls the reaction. For example, attack at the *Markovnikov* position of Me₃N⁺—CH=CH₂ would give an ion with positive charges on adjacent atoms. The compound CF₃CH=CH₂ has been reported to give electrophilic addition with acids in an *anti-Markovnikov* direction, but it has been shown⁹⁹ that, when treated with acids, this compound does not give simple electrophilic addition at all; the apparently *anti-Markovnikov* products are formed by other pathways. Molecular electrostatic potentials for the π-region of substituted alkenes were studied, with electron donating and withdrawing substituents (based on the increase or decrease in the negative character of V_{min} - most negative-valued point), and plots of V_{min} shows a good linear correlation with the *Hammett* σ_ρ constants, suggesting similar substituent electronic effects for substituted ethylenes and substituted benzenes.¹⁰⁰

In free radical addition¹⁰¹ the main effect seems to be steric.¹⁰² All substrates CH₂=CHX preferentially react at the CH₂, regardless of the identity of X or of the radical. With a reagent, such as HBr, which generates Br• *in situ* via hydrogen-atom exchange, this means that the addition is *anti-Markovnikov*:

¹⁰⁰ Suresh, C.H.; Koga, N.; Gadre, S.R. *J. Org. Chem.* **2001**, *66*, 6883.

¹⁰¹ Tedder, J.M.; Walton, J.C. *Tetrahedron* **1980**, *36*, 701; *Acc. Chem. Res.* **1976**, *9*, 183. See also, Giese, B. *Rev. Chem. Intermed.* **1986**, *7*, 3; Tedder, J.M. *J. Chem. Educ.* **1984**, *61*, 237.

¹⁰² See, however, Gleicher, G.J.; Mahiou, B.; Aretakis, A.J. *J. Org. Chem.* **1989**, *54*, 308.

Thus the observed orientation in both kinds of HBr addition (*Markovnikov* electrophilic and *anti-Markovnikov* free radical) is caused by formation of the more stable secondary intermediate.

In *intramolecular* additions (radical cyclization, see Reaction **15-30**) of radicals containing a 5,6 double bond,⁵³ both five- and six-membered rings can be formed, but in most cases¹⁰³ the five-membered rings are greatly preferred kinetically, even (as in the case shown) where five-membered ring closure means generating a primary radical and six-membered ring closure a secondary radical. This phenomenon may be caused by more favorable entropy factors leading to a five-membered ring, as well as by stereoelectronic factors, but other explanations have also been offered.¹⁰⁴ Similar behavior is found when the double bond is in other positions (from the 3,4 to the 7,8 position). In each case, the smaller ring (*exo-trig* addition) is preferred to the larger (*endo-trig* addition)¹⁰⁵ (see *Baldwin rules*, Sec. 6.E). However, when a radical that is unsaturated in the 5,6 position contains an alkyl group in the 5 position, formation of the six-membered ring is generally favored, presumably due to unfavorable steric interactions.¹⁰⁶

For conjugated dienes, attack at a positive ion, by a negative ion, or reaction with a free radical is almost always at the *end* of the conjugated system, since in each case this gives an intermediate stabilized by resonance. In the case of an unsymmetrical diene, the more stable ion is formed. For example, isoprene ($\text{CH}_2=\text{CMeCH}=\text{CH}_2$) treated with HCl gives only $\text{Me}_2\text{CClCH}=\text{CH}_2$ and $\text{Me}_2\text{C}=\text{CHCH}_2\text{Cl}$, with none of the product arising from attack at the other end. The compound $\text{PhCH}=\text{CHCH}=\text{CH}_2$ gives only $\text{PhCH}=\text{CHCHClCH}_3$ since it is the only one of the eight possible products that has a double bond in conjugation with the ring and that results from attack that places the proton at an end of the conjugated system.

When allenes attack electrophilic reagents,¹⁰⁷ *Markovnikov's rule* would predict that formation of the new bond should be at the end of the system, since there are no hydrogen

atoms in the middle. Reaction at the center gives a carbocation stabilized by resonance, but not immediately. In order for such stabilization to be in effect, the three p orbitals must be parallel, and it requires a rotation about the C—C bond.¹⁰⁸ Therefore, the stability of the allylic cation has no effect on the transition state, which still has a geometry similar to that of the original allene (Sec. 4.C, category 5). Probably because of this, reaction of the unsubstituted $\text{CH}_2=\text{C}=\text{CH}_2$ is most often at the end carbon, to give a vinylic cation, although reaction at the center carbon has also been reported. However, as alkyl or aryl groups are substituted on the allene carbons, reaction at the middle carbon becomes more favorable because the resulting cation is stabilized by the alkyl or aryl groups (it is now a secondary, tertiary, or benzylic cation). For example, allenes of the form $\text{RCH}=\text{C}=\text{CH}_2$ react most often at the end, but $\text{RCH}=\text{C}=\text{CHR}'$ usually gives reaction at the center carbon.¹⁰⁹ Free radicals¹¹⁰ react with allenes most often at the end,¹¹¹ although reaction at the middle carbon has also been reported.¹¹² As with reactions that proceed via electrophilic intermediates and for the same reason, the stability of the allylic radical has no effect on the transition state of the reaction between a free radical and an allene. Again, the presence of alkyl groups increases the extent of reaction by a radical at the middle carbon.¹¹³

15.B.iii. Stereochemical Orientation

It has already been pointed out that some additions are syn, with both groups approaching from the same side, and that others are anti, with the groups approaching from opposite sides of the double or triple bond. For cyclic compounds steric orientation must be considered. In syn addition to an unsymmetrical cyclic alkene, the two groups can come in from the more- or from the less-hindered face of the double bond. The rule is that syn addition is usually, although not always, from the less-hindered face. For example, epoxidation of 4-methylcyclopentene gave 76% addition from the less-hindered and 24% from the more-hindered face.¹¹⁴

In anti addition to a cyclic substrate, the initial reaction with the electrophile is also from the less-hindered face. However, many (although not all) electrophilic additions to norbornene and similar strained bicycloalkenes are syn additions.¹¹⁵ In these cases reaction

is always from the exo side, as in formation of **23**,¹¹⁶ unless the exo

side is blocked by substituents in the 7 position, in which case endo attack may predominate [e.g., 7,7-dimethylnorbornene undergoes syn–endo epoxidation (Reaction **15-50**) and hydroboration¹¹⁷ (Reaction **15-16**)]. However, addition of DCl and F₃CCO₂D to, and oxymercuration (Reaction **15-2**) of, 7,7-dimethylnorbornene proceeds syn–exo in spite of the methyl groups in the 7 position.¹¹⁸ Similarly, free radical additions to norbornene and similar molecules are often syn–exo, although anti additions and endo attacks are also known.¹¹⁹

Electronic effects can also play a part in determining which face reacts preferentially with the electrophilic species. In the adamantane derivative (**24**), steric effects are about the same for each face of the double bond. Yet epoxidation, dibromocarbene reactions (**15-64**), and hydroboration (**15-16**) all take place predominantly from the face that is syn to the electron-withdrawing fluorine.¹²⁰ In the case shown, about twice as much **25** was formed, compared to **26**. Similar results have been obtained on other substrates:¹²¹ groups that are electron withdrawing by the field effect ($-I$) direct attack from the syn face; $+I$ groups from the anti face, for both electrophilic and nucleophilic attack. These results are attributed¹²² to hyperconjugation (Sec. 2.M): For the adamantane case, there is overlap between the σ^* orbital of the newly forming bond (between the attacking species and C-2 in **24**) and the filled σ orbitals of the C $_{\alpha}$ –C $_{\beta}$ bonds on the opposite side. This is called the *Cieplak effect*. The LiAlH₄ reduction of 2-axial methyl or methoxy cyclohexanones supports Cieplak's proposal.¹²³ In addition reactions of methanol to norbornanones, however, little evidence was found to support the Cieplak effect.¹²⁴ The four possible bonds are C-3–C-4 and C-1–C-9 on the syn side and C-3–C-10 and C-1–C-8 on the anti side. The preferred pathway is the one where the incoming group has the more electron-rich bonds on the side *opposite* to it (these are the ones it overlaps with). Since the electron-withdrawing F has its greatest effect on the bonds closest to it, the C-1–C-8 and C-3–C-10 bonds are more electron rich, and the group comes in on the face syn to the F.

It has been mentioned that additions of Br_2 and HOBr are often anti because of formation of bromonium ions and that free radical addition of HBr is also anti. When the substrate in any of these additions is a cyclohexene, the addition is not only anti but the initially formed product is conformationally specific too, being mostly diaxial.¹²⁵ This is so because diaxial opening of the three-membered ring preserves a maximum coplanarity of the participating centers in the transition state; indeed, on opening, epoxides also give diaxial products.¹²⁶ However, the initial diaxial product may then pass over to the diequatorial conformer unless other groups on the ring render the latter less stable than the former. In free radical additions to cyclohexenes in which cyclic intermediates are not involved, the initial reaction with the radical is also usually from the axial direction,¹²⁷ resulting in a diaxial initial product if the overall addition is anti. The direction from which unsymmetrical radicals react has also been studied.¹²⁸ For example, when the radical (**27**) adds to a double bond it preferentially does so anti to the OH group, leading to a diaxial trans product.¹²⁶

15.B.iv. Addition to Cyclopropane Rings¹²⁹

Section 4.Q.iv showed that cyclopropane rings resemble double bonds in some aspects of their reactivity.¹³⁰ It is not surprising, therefore, that cyclopropanes undergo addition reactions analogous to those undergone by double-bond compounds, resulting in the opening of the three-membered rings, as in the two examples shown, where Reactions **15-2** and **15-47** describe the reaction to alkene chemistry.

Reaction **15-2**

Ref. 131

Reaction **15-47**

Other examples are discussed at Reaction **15-3**, **15-15**, and **15-63**.

Additions to cyclopropanes can take place by any of the four mechanisms already discussed in this chapter, but the most important type involves attack on an electrophile.¹³²

For substituted cyclopropanes, these reactions usually follow *Markovnikov's rule*, although exceptions are known and the degree of regioselectivity is often small. The application of *Markovnikov's rule* to these substrates can be illustrated by the reaction of 1,1,2-trimethylcyclopropane with HX.¹³³ The rule predicts that the electrophile (in this case H⁺) goes to the

carbon with the most hydrogen atoms and the nucleophile goes to the carbon that can best stabilize a positive charge (in this case the tertiary rather than the secondary carbon). The stereochemistry of the reaction can be investigated at two positions: the one that becomes connected to the electrophile and the one that becomes connected to the nucleophile. The results at the former position are mixed. Additions have been found to take place with 100% retention,¹³⁴ 100% inversion,¹³⁵ and with mixtures of retention and inversion.¹³⁶ At the carbon that becomes connected to the nucleophile, the result is usually inversion, although retention has also been found,¹³⁷ and elimination, rearrangement, and racemization processes often compete, indicating that in many cases a positively charged carbon is generated at this position.

At least three mechanisms have been proposed for electrophilic addition (these mechanisms are shown for reaction with HX, but analogous mechanisms can be written for other electrophiles).

Mechanism *a* involves a corner-protonated cyclopropane¹³⁸ (**28**). Examples of such ions were seen in the 2-norbornyl and 7-norbornenyl cations (Sec. 10.C.i). Mechanism *b* involves an edge-protonated cyclopropane (**29**). Mechanism *c* consists of a one-step S_E2 type attack on H⁺ to give the classical cation **30**, which then reacts with the nucleophile. Although the three mechanisms as drawn show retention of configuration at the carbon that

becomes attached to the proton, mechanisms *a* and *c* at least can also result in inversion at this carbon. Unfortunately, the evidence on hand at present does not allow us unequivocally to select any of these as the exclusive mechanism in all cases. Matters are complicated by the possibility that more than one edge-protonated cyclopropane is involved, at least in some cases. There is strong evidence for mechanism *b* with the electrophiles Br^+ and Cl^+ ¹³⁹; and for mechanism *a* with D^+ and Hg^{2+} .¹⁴⁰ *Ab initio* studies show that the corner-protonated **28** is slightly more stable ($\sim 1.4 \text{ kcal mol}^{-1}$, 6 kJ mol^{-1}) than the edge-protonated **29**.¹⁴¹ There is some evidence against mechanism *c*.¹⁴²

Free radical additions to cyclopropanes have been studied much less, but it is known that Br_2 and Cl_2 add to cyclopropanes by a free radical mechanism in the presence of UV light. The addition follows *Markovnikov's rule*, with the initial radical reacting at the least-substituted carbon and the second group going to the most-substituted position. Several investigations have shown that the reaction is stereospecific at one carbon, taking place with inversion there, but nonstereospecific at the other carbon.¹⁴³ A mechanism that accounts for this behavior is¹⁴⁴

In some cases, conjugate addition has been performed on systems where a double bond is “conjugated” with a cyclopropyl ring. An example is the formation of **31**.¹⁴⁵

isomerization of an alkene from (*E*) to (*Z*) or (*Z*) to (*E*) is a well-studied reaction.¹⁴⁷ Among the metals used, Pt is widely used, and rather selective.¹⁴⁸ The Pd catalyzed isomerization of (*Z*)-alkenes to (*E*)-alkenes required the presence of Bu₃SnH.¹⁴⁹ However, a 1:1 mixture of *cis*/*trans*-styrene derivatives was isomerized to a 90% yield of the *trans*-styrene derivatives reported using a Pd catalyst.¹⁵⁰ Isomerization of cyclic alkenes is difficult for rings of seven members and less, but *cis*/*trans* isomerization of cyclooctene is induced photochemically.¹⁵¹ Radical-induced (*E*/*Z*) isomerization is known.¹⁵² Isomerization of the C=C units in dienes is also induced photochemically.¹⁵³

In a different type of reaction, isomerization of alkynes to 1,3-dienes is possible using Rh or Pd catalysts.¹⁵⁴

There are several reagents that lead to isomerization of a double bond to form a new alkene. In general, there is an energetic preference of an α,β - versus β,γ -double bond.¹⁵⁵ Allylic arenes (Ar—CH₂CH=CH₂) have been converted to the corresponding (*Z*)-1-propenyl arene (Ar—CH=CHMe) using an Ru catalyst¹⁵⁶ or a polymer-supported Ir catalyst.¹⁵⁷ In the presence of a Rh catalyst, certain allylic amines are converted to an enamine with high selectivity for the (*Z*) isomer.¹⁵⁸ Double-bond migration has been observed in sulfide photoirradiation, induced by singlet oxygen.¹⁵⁹ Many of these reactions were discussed in Reaction 12-2.

For conjugated carbonyl compounds that have a hydrogen atom at the γ -position (C-4), it is possible to move a double bond *out* of conjugation. Photolysis of conjugated esters, at -40 °C in the presence of *N,N*-dimethylaminoethanol, gave the nonconjugated ester.¹⁶⁰ Heating an *N*-allylic amide (N—C—C=C) with Fe(CO)₅, neat, gave the enamide (N—C=C—C).¹⁶¹ Conjugated aldehydes have been isomerized using thiourea in DMF.¹⁶²

Double bonds of atoms other than carbon are subject to isomerization. Azobenzenes (Ar—N=N—Ar) exist as (*E*) and (*Z*) isomers, and photochemical isomerization is possible.¹⁶³

15.C.ii. Reactions in Which Hydrogen Adds to One Side

A. Halogen on the Other Side

15-2 Addition of Hydrogen Halides

Hydro-halo-addition

Any of the four hydrogen halides can be added to double bonds.¹⁶⁴ Alkenes react as Brønsted–Lowry bases with HI, HBr, and HF¹⁶⁵ at room temperature, but reaction with HCl is more difficult and usually requires heat.²⁴ Hydrogen Chloride adds easily in the presence of silica gel. However,¹⁶⁶ HF is difficult to handle, but a convenient method for the addition of HF involves the use of a polyhydrogen fluoride–pyridine solution in THF.¹⁶⁷

The addition of hydrogen halides to simple alkenes, in the absence of peroxides, takes place by an electrophilic mechanism, and the orientation is in accord with *Markovnikov's rule*.¹⁶⁸ In other words, the π bond of the alkenes donates two electrons to the acidic proton of H—X. The addition follows second-order kinetics.¹⁶⁹ When peroxides are added, the addition of HBr occurs by a free-radical mechanism and the orientation is *anti-Markovnikov* (Sec. 15.B.i).¹⁷⁰ It must be emphasized that this is true *only* for HBr. Free radical addition of HF and HI has never been observed, even in the presence of peroxides; free radical addition of HCl has been observed only rarely. In the rare cases where free radical addition of HCl was noted, the orientation was still *Markovnikov*, presumably because the more stable product was formed.¹⁷¹ Free radical addition of HF, HI, and HCl is energetically unfavorable (see the discussions in Sec. 14.B.i and 14.C.i). It is known that under some conditions *anti-Markovnikov addition* of HBr takes place even when peroxides have not been added. This happens because the substrate alkenes absorb oxygen from the air, forming small amounts of peroxides (Reaction 14-7). *Markovnikov addition* can be ensured by rigorous purification of the substrate, but in practice this is not easy to achieve. It is more common to add inhibitors (e.g., phenols or quinones), which suppress the free radical pathway. The presence of free radical precursors (e.g., peroxides) does not inhibit the ionic mechanism, but does inhibit the more rapid radical reaction, which is a chain process. In most cases, it is possible to control the mechanism (and hence the orientation) by adding peroxides to achieve complete free radical addition, or inhibitors to achieve complete electrophilic addition, although there are some cases where the ionic mechanism is fast enough to compete with the free radical

mechanism and complete control cannot be attained. *Markovnikov addition* of HBr, HCl, and HI has also been accomplished, in high yields, by the use of phase transfer catalysis.¹⁷² For alternative methods of adding HBr (or HI) with *anti-Markovnikov orientation*, see Reaction **12-31**.

Alkynes also react as bases with acids (e.g., HX). It is possible to add 1¹⁷³ or 2 equiv of any of the four hydrogen halides to triple bonds. *Markovnikov's rule* ensures that *gem*-dihalides and not *vic*-dihalides are the products of the addition of 2 equiv.

Chlorotrimethylsilane can be added to alkenes to give alkyl chlorides. 1-Hexene reacts with Me₃SiCl in water, for example, to give 2-chlorohexane.¹⁷⁴ Treatment of an alkene with KHF₂ and SiF₄ leads to the alkyl fluoride,¹⁷⁵ and bromotrimethylsilane adds to alkynes to give the vinyl bromide.¹⁷⁶

Brønsted–Lowry acids (e.g., HX) are electrophilic reagents, and many polyhalo or polycyano alkenes do not react with them in the absence of free radical conditions. Vinylcyclopropanes, however, react with opening of the cyclopropane ring to give a homoallylic chloride.¹⁷⁷ When such reactions do occur, however, they take place by a nucleophilic addition mechanism, that is, initial attack is by X[−]. This type of mechanism also occurs with *Michael-type substrates* (C=C—Z),¹⁷⁸ where the orientation is always such that the halogen goes to the carbon that does not bear the Z, so the product is of the form X—C—CH—Z, even in the presence of free radical initiators.

The reaction has been carried out with conjugated dienes, where both 1,2- and 1,4-addition are possible. Hydrogen iodide adds 1,4 to conjugated dienes in the gas phase by a pericyclic mechanism:¹⁷⁹

In a related reaction, HX can be added to ketenes¹⁸⁰ to give acyl halides:

B. Oxygen on the Other Side

15-3 Hydration of Double bonds

Hydro-hydroxy-addition

Double bonds can be hydrated by treatment with water and an acid catalyst. Sulfuric acid is a common catalyst, but other acids that have relatively non-nucleophilic counterions, such as nitric, perchloric, or more commonly sulfonic acids (*p*-toluenesulfonic acid, methanesulfonic acid, etc.) can also be used. The mechanism is electrophilic and begins with attack of the π bond on an acidic proton (Sec. 15.A.i). The resulting carbocation is then attacked by negative species (e.g., HSO_4^- , or a similar counterion in the case of other acids), to give the initial product (**32**), which can be isolated in some cases. However, such compounds are rather unstable, and

under the conditions of the reaction are usually hydrolyzed to the alcohol (Reaction 10-4). Under some reaction conditions, other nucleophiles are present in the reaction, either from the solvent or from added compounds. In an aqueous medium, water is a competitive nucleophile, and attack by water forms oxonium ion **33**. Products, such as **32**, are not involved when other nucleophiles react with the carbocation, and the mechanism is exactly (by the principle of microscopic reversibility) the reverse of *E1* elimination of alcohols (Reaction 17-1).¹⁸¹ The initial carbocation occasionally rearranges to a more stable one. For example, hydration of $\text{CH}_2=\text{CHCH}(\text{CH}_3)_2$ gives $\text{CH}_3\text{CH}_2\text{COH}(\text{CH}_3)_2$. Hydration of simple alkenes leads to alcohols predicted by *Markovnikov's rule*.

*Oxymercuration*¹⁸² (addition of oxygen and mercury) of alkenes followed by *in situ* treatment with sodium borohydride¹⁸³ (Reaction 12-24), gives an alcohol (see example) under mild conditions, in high yields, and without rearrangement products. For example, treatment of 2-methyl-1-butene with mercuric acetate,¹⁸⁴ followed by NaBH_4 , gave 2-methyl-2-butanol. *Oxymercuration* of alkenes has been reported in water, using cyclodextrins as phase-transfer catalysts.¹⁸⁵

¹⁸⁵ Abreu, A.R.; Costa, I.; Rosa, C.; Ferreira, L.M.; Lourenço, A.; Santos, P.P. *Tetrahedron* **2005**, 61, 11986.

This method, which is applicable to mono-, di-, tri-, and tetraalkyl, as well as phenyl-substituted alkenes, gives almost complete *Markovnikov addition*. Hydroxy, methoxy, acetoxy, halo, and other groups may be present in the substrate, and generally do not cause difficulties.¹⁸⁶ When two double bonds are present in the same molecule, changing the carboxylic acid ligand of the mercuric salt allows oxymercuration of the less-substituted one without affecting the other, with ultrasound.¹⁸⁷ A related reaction treats an alkene with zinc borohydride on silica gel to give a 35:65 mixture of secondary/primary alcohols.¹⁸⁸

With substrates of the type $\text{C}=\text{C}-\text{Z}$ (Z is as defined in Sec.15.A.ii) the product is almost always $\text{HO}-\text{C}-\text{CH}-\text{Z}$ and the mechanism is usually nucleophilic,¹⁸⁹ although electrophilic addition gives the same product¹⁹⁰ since a cation $\text{CH}-\text{C}-\text{Z}$ would be destabilized by the positive charges (full or partial) on two adjacent atoms. However, the α -hydroxy compound $\text{HC}-\text{CH}(\text{OH})\text{Z}$, was obtained by treatment of the substrate with O_2 , PhSiH_3 , and a manganese-complex catalyst.¹⁹¹ Addition of water to $\text{RCH}=\text{CZZ}'$ substrates may result in cleavage of the adduct to give an aldehyde and $\text{CH}_2\text{ZZ}'$ (**34**).¹⁹² The cleavage step is an example of Reaction **12-41**.

For another method of *anti-Markovnikov* hydration, see hydroboration (Reaction **15-16**).

Indirect hydration, with *anti-Markovnikov* orientation, was achieved by treatment of the alkene with a 1:1 mixture of $\text{PhCH}_2\text{NEt}_3^+ \text{BH}_4^-$ and Me_3SiCl , followed by addition of an aqueous solution of K_2CO_3 .¹⁹³ Reaction of alkenes with $\text{Ti}(\text{BH}_4)_3$, and then aq K_2CO_3 also leads to the *anti-Markovnikov* alcohol.¹⁹⁴ Alkenes react with PhO_2BH and a Nb catalyst, followed by oxidation with NaOO^- , to give the alcohol,¹⁹⁵ and Cp_2TiCl_4 can also be used.¹⁹⁶ Conjugated alkenes also react with PhSiH_2 and oxygen, with a Mn catalyst, to give an α -hydroxy ketone.¹⁹⁷ Alkenes react with molecular oxygen in the presence of a Co porphyrin catalyst, and reduction with $\text{P}(\text{OMe})_3$ leads to the secondary alcohol.¹⁹⁸ This procedure has also been used to hydrate conjugated dienes,¹⁹⁹ although conjugated dienes are seldom hydrated.

The addition of water to enol ethers causes hydrolysis to aldehydes or ketones (Reaction 10-6). Ketenes add water to give carboxylic acids ($R_2C=C=O \rightarrow R_2CO_2H$) in a reaction catalyzed by acids²⁰⁰:

OS IV, 555, 560; VI, 766. Also see, OS V, 818.

15-4 Hydration of Triple Bonds

Dihydro-oxo-biaddition

The hydration of triple bonds is generally carried out with mercuric ion salts (often the sulfate or acetate or even mercuric oxide) as catalysts.²⁰¹ In contrast to oxymercuration of alkenes, the organomercury intermediate from this reaction is unstable and loss of mercury *in situ* leads to an enol product. The enol tautomerizes to the ketone (see Sec. 2.N.i), so the isolated product is the ketone from either an internal or terminal alkyne (the OH unit will always be on the more substituted carbon via the more stable secondary vinyl carbocation). Only acetylene gives an aldehyde. With alkynes of the form $RC\equiv CR'$ both possible ketone products are usually obtained. The reaction can be conveniently carried out with a catalyst prepared by impregnating mercuric oxide onto Nafion-H (a superacidic perfluorinated resinsulfonic acid; see Sec. 5.A.ii).²⁰² Gold,²⁰³ In,²⁰⁴ and Ru²⁰⁵ catalysts have been used to convert alkynes to the ketone. Gold(I) catalysts have also been used in the hydration of allenes.²⁰⁶ Internal alkynes were treated with 2-aminophenol in refluxing dioxane using a Pd catalyst to produce the corresponding ketone.²⁰⁷ Lactones have been prepared from trimethylsilyl alkenes containing a hydroxyl unit elsewhere in the molecule, when reacted with molecular oxygen, $CuCl_2$, and a Pd catalyst.²⁰⁸ When a carboxylic acid that contains a double bond in the chain is treated with a strong acid, the intramolecular hydration reaction gives a γ - and/or a δ -lactone, regardless of the original position of the double bond in the chain, since strong acids catalyze double-bond shifts (Reaction 15-1; and see 12-2).²⁰⁹ The double bond always migrates to a position favorable for the reaction, whether this has to be toward or away from the carboxyl group. The use of a chiral *Cinchonidine*

alkaloid additive leads to lactone formation with modest enantioselectivity.²¹⁰

The first step of the mercury-mediated mechanism is formation of a complex (**35**). It is known that ions like Hg^{2+} form complexes with alkynes (Sec. 3.C.i). Water then attacks in an $\text{S}_{\text{N}}2$ type process to give the intermediate **36**, which loses a proton to give **37**. Hydrolysis of **37** (an example of Reaction **12-34**) gives the enol, which tautomerizes to the product. A spectrum of the enol was detected by flash photolysis when phenylacetylene was hydrated photolytically.²¹¹ Note that another possibility for **35** is a mercury-stabilized carbocation rather than a formal three-membered ring complex. In such a carbocation, the carbocation is stabilized by back-donation from the metal, and nucleophilic attack is more like a $\text{S}_{\text{N}}1$ type process.

Metal-free reactions are known, often using strong acids. Phenyl acetylene was converted to acetophenone [e.g., in water at 100°C with a catalytic amount of Tf_2NH (trifluoromethanesulfonimide)], which is a very powerful acid.²¹² Simple alkynes can also be converted to ketones by heating with formic acid, without a catalyst.²¹³ Metal-free hydration of terminal alkynes occurs by reacting water, heated with microwave irradiation, to give the corresponding methyl ketone.²¹⁴ 1-Selenoalkynes (e.g., $\text{PhSe-C}\equiv\text{C-Ph}$) react with tosic acid in dichloromethane to give a seleno ester [$\text{PhSeC(=O)SH}_2\text{Ph}$] after treatment with water.²¹⁵ Allenes can be hydrolyzed to ketones using an acid catalyst.²¹⁶

Carboxylic esters, thiol esters, and amides can be made, respectively, by acid-catalyzed hydration of acetylenic ethers, thioethers,²¹⁷ and ynamines, without a mercuric catalyst.²¹⁸

This is ordinary electrophilic addition, with rate-determining protonation as the first step.²¹⁹ Certain other alkynes have also been hydrated to ketones with strong acids in the absence of mercuric salts.²²⁰

Catalysts have been developed for the *anti-Markovnikov* hydration of alkynes.²²¹ When 1-octyne was heated with water, isopropyl alcohol and a Ru catalyst, for example, the product was octanal.²²² The presence of certain functionality can influence the regioselectivity of hydration.

A Ni catalyzed reaction has been reported between alkynes and allyl phenyl sulfides to give thioallylation.²²³

15-5 Addition of Alcohols and Phenols

Hydro-alkoxy-addition

Just as water adds to an alkene via hydration to form an alcohol, alcohols can also add to form an ether. Addition of alcohols and phenols to double bonds is catalyzed by acids or bases. When the reactions are acid catalyzed, the mechanism is electrophilic, where H^+ of the acid catalyst, is attacked by the π bond. The more stable carbocation is formed and subsequently attacked by a molecule of alcohol to give an oxonium ion (**38**).

The addition, therefore, follows *Markovnikov's rule*. Primary alcohols give better results than secondary, and tertiary alcohols are relatively inactive. This method is convenient for the preparation of tertiary ethers by the use of a suitable alkene (e.g., $\text{Me}_2\text{C}=\text{CH}_2$). Addition of alcohols to allylic systems can proceed with rearrangement, and the use of chiral additive can lead to asymmetric induction.²²⁴ The uncatalyzed addition of alcohols occurs in supercritical alcohols.²²⁵

Metal-catalyzed addition to alkenes is a useful variation. The Pd catalyzed addition of alcohols to aryl alkenes gives the ether.²²⁶ The Au(III)— CuCl_2 catalyzed reaction of alcohols and alkenes gives the ether.²²⁷ Gold(I) catalyzed intermolecular addition of phenols leads to aryl ethers.²²⁸

Alcohols add intramolecularly to alkenes to generate cyclic ethers, and the product often bears a hydroxyl unit,²²⁹ but not always.²³⁰ Cyclization is facilitated by Re,²³¹ Ti,²³² or Pt compounds,²³³ forming functionalized tetrahydrofurans or tetrahydropyans. Intramolecular addition of alcohols to alkenes can be promoted by a Pd catalyst, but migration of the double bond in the final product is sometimes a problem.²³⁴ Furan derivatives are available from alkene–ketones using CuCl₂ and a Pd²³⁵ Cr,²³⁶ Ag(I),²³⁷ or lanthanide catalyst.²³⁸ A gold catalyst was used with conjugated ketones bearing an alkyne substituent to give fused-ring furans.²³⁹ Note that the reaction of an alkene–alcohol and NIS with a chiral Ti catalyst leads to a THF with a pendant iodoalkyl group, with modest enantioselectivity.²⁴⁰

Alcohols add to alkynes under certain conditions to give vinyl ethers. In an excess of alcohol, and in the presence of a Pt²⁴¹ or a Au catalyst,²⁴² internal alkynes are converted to ketals. The alcohol to alkyne addition reaction is quite useful for the preparation of heterocycles. Dihydrofurans,²⁴³ furans,²⁴⁴ benzofurans,²⁴⁵ and pyran derivatives²⁴⁶ have been prepared using this approach. Tetrahydrofurans bearing an exocyclic double bond (vinylidene tetrahydrofurans) were prepared from alkynyl alcohols and a silver carbonate catalyst.²⁴⁷

Allenes that react with alcohols and allenic alcohols have been converted to THF derivatives bearing a vinyl group at the α -position, using diphenyliodonium salts.²⁴⁸ In the presence of allylic bromide and a Pd catalyst, allenic alcohols lead to allylically substituted dihydrofurans.²⁴⁹ The intramolecular Au(I) catalyzed reaction of alcohols and allenes has been reported.²⁵⁰ Intramolecular addition of alcohols to allenes leads to cyclic vinyl ethers.²⁵¹

Functionalized ethers can be formed in the presence of other reagents. In methanol with a $R-Se-Br$ reagent, alkenes are converted to selenoalkyl ethers ($MeO-C-C-SeR$).²⁵²

Base-catalyzed reactions are known. For those substrates more susceptible to nucleophilic attack, for example, polyhalo alkenes and alkenes of the type $C=C-Z$, it is better to carry out the reaction in basic solution, where the attacking species is RO^- .²⁵³ The reactions with $C=C-Z$ are of the *Michael type*, and OR goes to the side away from the Z .²⁵⁴

Since triple bonds are more susceptible to nucleophilic attack than double bonds, it might be expected that bases would catalyze addition to triple bonds particularly well. This is the case, and enol ethers and acetals can be produced by this reaction.²⁵⁵ Because enol ethers are more susceptible than triple bonds to electrophilic attack, the addition of alcohols to enol ethers can also be catalyzed by acids.²⁵⁶ One utilization of this reaction

involves the compound dihydropyran (**39**), which is often used to protect the OH groups of primary and secondary alcohols²⁵⁷ and phenols.²⁵⁸ When the desired reactions are completed, **40** is easily cleaved by treatment with dilute acids (Reaction 10-6). In base-catalyzed addition to triple bonds, the rate falls in going from a primary to a tertiary alcohol, and phenols require more severe conditions.

Photochemical addition of alcohols to certain double-bond compounds (cyclohexenes, cycloheptenes) is possible²⁵⁹ in the presence of a photosensitizer (e.g., benzene). The mechanism is electrophilic and *Markovnikov* orientation is found. The alkenes react in their first excited triplet states.²⁶⁰

The oxymercuration–demercuration procedure mentioned in Reaction 15-3 can be adapted to the preparation of ethers in what is known as *alkoxymercuration–demercuration* (*Markovnikov* orientation), if the reaction is carried out in an alcohol (ROH) solvent.²⁶¹ For example, oxymercuration of 2-methyl-1-butene in ethanol gives $EtMe_2COEt$.²⁶² Primary alcohols give good yields when mercuric acetate is used, but for secondary and tertiary alcohols, it is necessary to use mercuric trifluoroacetate.²⁶³ However, even this reagent fails where the product would be a ditertiary ether. It is possible to combine the alcohol reactant with another reagent. The reaction of an alkene with iodine and allyl alcohol, in the presence of HgO , gave the *vic*-iodo ether.²⁶⁴ Alkene-alcohols react with mercuric trifluoroacetate and the aq KBr (with $LiBH_4/BEt_3$) to

give a THF derivative bearing an iodoalkyl substituent [—O—C—CH(I)R].²⁶⁵ Alkynes generally react under the same conditions to give acetals. If the oxymercuration is carried out in the presence of a hydroperoxide instead of an alcohol, the product (after demercuration with NaBH_4) is an alkyl peroxide (*peroxy-mercuration*).²⁶⁶ This can be done intramolecularly.²⁶⁷

Both alcohols and phenols add to ketenes to give carboxylic esters [$\text{R}_2\text{C}=\text{C}=\text{O} + \text{ROH} \rightarrow \text{R}_2\text{CHCO}_2\text{R}$].²⁶⁸ This has been done intramolecularly (with the ketene end of the molecule generated and used *in situ*) to form medium- and large-ring lactones.²⁶⁹ In the presence of a strong acid, ketene reacts with aldehydes or ketones (in their enol forms) to give enol acetates. 1,4-Asymmetric induction is possible when chiral alcohols add to ketenes.²⁷⁰

15-6 Addition of Carboxylic Acids to Form Esters

Hydro-acyloxy-addition

Carboxylic esters are produced by the addition of carboxylic acids to alkenes, a reaction that is usually acid catalyzed (by Brønsted–Lowry or Lewis acids²⁷¹) and similar in mechanism to Reaction **15-5**. Since *Markovnikov's rule* is followed, hard-to-get esters of tertiary alcohols can be prepared from alkenes of the form $\text{R}_2\text{C}=\text{CHR}$.²⁷² Carboxylic esters have also been prepared by the acyloxymercuration–demercuration of alkenes (similar to the procedures mentioned in Reactions **15-3** and **15-4**).²⁷³ Addition of carboxylic acids to alkenes to form esters or lactones is catalyzed by Pd compounds.²⁷⁴ Thallium acetate also promotes this cyclization reaction.²⁷⁵ Diene carboxylic acids have been cyclized using acetic acid and a Pd catalyst to form lactones that have an allylic acetate moiety elsewhere in the molecule.²⁷⁶

Triple bonds can give enol esters²⁷⁷ or acylals when treated with carboxylic acids. Mercuric salts are usually catalysts,²⁷⁸ and vinylmercury compounds ($\text{RO}_2\text{C}-\text{C}=\text{C}-\text{HgX}$) are intermediates,²⁷⁹ but Ru complexes have also been used.²⁸⁰ Terminal alkynes ($\text{RC}\equiv\text{CH}$) react with CO_2 , a secondary amine ($\text{R}'_2\text{NH}$), and a Ru complex catalyst, to give enol carbamates $[\text{RCH}=\text{CHOC}(=\text{O})\text{NR}]$.²⁸¹ This reaction has also been performed intramolecularly, to produce unsaturated lactones.²⁸² Cyclic unsaturated lactones (internal vinyl esters) have been generated from alkyne-carboxylic acids using a Pd²⁸³ or a Ru catalyst.²⁸⁴ Carboxylic esters can also be obtained by the addition to alkenes of diacyl peroxides.²⁸⁵ These reactions are catalyzed by Cu and are free radical processes.

Allene carboxylic acids have been cyclized to butenolides with copper(II) chloride.²⁸⁶ Allene esters were converted to butenolides by treatment with acetic acid and LiBr.²⁸⁷ Cyclic carbonates can be prepared from allene alcohols using carbon dioxide and a Pd catalyst.²⁸⁸ Carboxylic acids react with ketenes to give anhydrides²⁸⁹ and acetic anhydride is prepared industrially in this manner $[\text{CH}_2=\text{C}=\text{O} + \text{MeCO}_2\text{H} \rightarrow (\text{MeC}=\text{O})_2\text{O}]$.

Sulfonic acids add to alkenes and alkynes. The reaction of an alkyne with *p*-toluenesulfonic acid and treatment with silica gives the vinyl sulfonate ($\text{C}=\text{C}-\text{OSO}_2\text{ToI}$).²⁹⁰ Cyclic sulfonates can be generated by the reaction of an allylic sulfonate salt ($\text{C}=\text{C}-\text{C}-\text{OSO}_3^-$) with silver nitrate in acetonitrile containing an excess of bromine and a catalytic amount of water.²⁹¹ Sultones are formed when alkenes react with PhIO and 2 equiv of $\text{Me}_2\text{SiSO}_3\text{Cl}$.²⁹²

Hydrogen sulfide (H_2S) and thiols add to alkenes to give alkyl thiols or sulfides by electrophilic, nucleophilic, or free radical mechanisms.²⁹³ In the absence of initiators, the addition to simple alkenes is by an electrophilic mechanism, similar to that in Reaction 15-5, and *Markovnikov's rule* is followed. However, this reaction is usually very slow and often cannot be done or requires very severe conditions unless a Brønsted–Lowry or Lewis acid catalyst is used. For example, the reaction can be performed in concentrated H_2SO_4 ²⁹⁴ or with the addition of AlCl_3 .²⁹⁵ In the presence of free radical initiators, H_2S and thiols add to double and triple bonds by a free radical mechanism and the orientation is *anti-Markovnikov*.²⁹⁶ *Anti-Markovnikov* addition of thiols to vinyl ethers occurs under solvent- and catalyst-free conditions,²⁹⁷ and is promoted by water.²⁹⁸

Additives can influence the regioselectivity. Styrene reacts with thiophenol to give primarily the *anti-Markovnikov* product, whereas addition of thiophenol in the presence of Montmorillonite K-10 clay gives primarily the *Markovnikov addition* product.²⁹⁹ The addition of thiophenol to an alkene with a zeolite, however, leads to the *anti-Markovnikov* sulfide.³⁰⁰ In fact, the orientation can be used as a diagnostic tool to indicate which mechanism is operating. Free radical addition can be done with H_2S , RSH (R may be primary, secondary, or tertiary), ArSH , or RCOSH .³⁰¹ The R group may contain various functional groups. The alkenes may be terminal, internal, contain branching, be cyclic, and have various functional groups including OH, CO_2H , CO_2R , NO_2 , RSO_2 , and so on. Addition of Ph_3SiSH to terminal alkenes under radical conditions also leads to the primary thiol.³⁰²

Alkynes react with thiols to give vinyl sulfides. With alkynes it is possible to add 1 or 2 molar equivalents of RSH , giving a vinyl sulfide³⁰³ or a dithioacetal, respectively. Thiols also add to alkynes with a Pd catalyst to give vinyl sulfides.³⁰⁴ Thiols add to alkenes under photochemical conditions to form thioethers, and the reaction can be done intramolecularly to give cyclic thioethers.³⁰⁵ Thiocarbonates function as thiol surrogates, converting alkenes to alkyl thiols in the presence of TiCl_4 and CuO .³⁰⁶ Sulfonic acids add to alkynes to give vinyl sulfonates in the presence of a Au catalyst.³⁰⁷ A cesium carbonate catalyzed reaction

gives the vinyl sulfide with good (*Z*)-selectivity.³⁰⁸ The $\text{Rh}^{-309}\text{In}^{-}$,³¹⁰ organoactinide³¹¹, organozirconium-,³¹² or Pt catalyzed³¹³ reaction of alkynes with thiols gives the corresponding vinyl sulfide. Similar results were obtained under solvent-free conditions using an alumina-KF system.³¹⁴ Alternative preparations are available, as in the reaction of a terminal alkyne with $\text{Cp}_2\text{Zr}(\text{H})\text{Cl}$ followed by PhSCl to give the vinyl sulfide with the SPh unit at the less substituted position ($\text{PhCH}=\text{CHSPh}$).³¹⁵ The intramolecular addition of a thiol to an ene-yne, with a Pd catalyst, leads to substituted thiophene derivatives.³¹⁶ Alkenes react with diphenyl disulfide in the presence of GaCl_3 to give the product with two phenylthio units ($\text{PhS}-\text{C}-\text{C}-\text{SPh}$).³¹⁷ The reaction of an alkyne with diphenyl disulfide and a Pd catalyst leads to the bis(vinyl) sulfide ($\text{PhS}-\text{C}=\text{C}-\text{SPh}$).³¹⁸

When thiols are added to substrates susceptible to nucleophilic attack, bases catalyze the reaction and the mechanism is nucleophilic. These substrates may be of the *Michael type*³¹⁹ or may be polyhalo alkenes or alkynes.²⁵⁵ As with the free-radical mechanism, alkynes can give either vinylic thioethers or dithioacetals:

By any mechanism, the initial product of addition of H_2S to a double bond is a thiol, which is capable of adding to a second molecule of alkene, so that sulfides are often produced: $\text{C}=\text{C} \rightarrow \text{H}-\text{C}-\text{C}-\text{S}-\text{C}-\text{C}-\text{H}$. As with alcohols, ketenes add thiols to give thiol esters $[\text{R}_2\text{C}=\text{C}=\text{O} + \text{RSH} \rightarrow \text{R}_2\text{CHCOSR}]$.³²⁰

Selenium compounds (RSeH) add in a similar manner to thiols.³²¹ Vinyl selenides can be prepared from alkynes using diphenyl diselenide and sodium borohydride.³²² A Pd(II) catalyzed reaction of PhSeH with alkynes, in pyridine, also gives the corresponding vinyl selenide.³²³

The conjugate addition of thiols to α,β -unsaturated carbonyl derivatives is discussed in Reaction 15-31.

D. Nitrogen or Phosphorus on the Other Side

15-8 Addition of Ammonia and Amines, Phosphines, and Related Compounds³²⁴

Hydro-amino-addition

Hydro-phosphino-addition

Ammonia and primary and secondary amines add to alkenes *in some cases*.³²⁵ Ammonia and amines are much weaker acids than water, alcohols, and thiols (see Reactions **15-3**, **15-5**, and **15-7**) and since acids turn NH_3 into the weak acid, the ammonium ion (NH_4^+), this reaction does not occur by an electrophilic mechanism. The reaction tends to give very low yields, if any, with ordinary alkenes, unless extreme conditions are used (e.g., 178–200 °C, 800–1000 atm, and the presence of metallic Na, for the reaction between NH_3 and ethylene³²⁶). There is, however, a proton-catalyzed hydroamination reaction in which aniline derivatives add to alkenes in the presence of anilinium salts, in 20–90% yield depending on the alkene.³²⁷

There are many examples of transition-catalyzed addition of nitrogen compounds to alkenes, alkynes,³²⁸ and so on. Amines can be added to certain nonactivated alkenes using Pd,³²⁹ Rh,³³⁰ In,³³¹ Ti,³³² Fe,³³³ Ta,³³⁴ Au,³³⁵ Y,³³⁶ Mo,³³⁷ and various lanthanide catalysts.³³⁸ 1,3-Dienes,³³⁹ and also allenes,³⁴⁰ undergo hydroamination in the presence

of an Au catalyst. Complexation with the metal lowers the electron density of the double bond, facilitating nucleophilic attack.³⁴¹ *Markovnikov* orientation is observed and the addition is anti.³⁴² Aniline reacts with dienes and a Pd catalyst to give allylic amines.³⁴³ Diene amines react with Sm catalysts to give 2-alkenyl pyrrolidines.³⁴⁴ The mechanism of the Au(I) catalyzed hydroamination reaction of alkenes has been studied.³⁴⁵ It is believed to involve a ligand substitution reaction in the active Au species followed by nucleophile attack of the N-nucleophile on the activated double bond, which is followed by proton transfer from the NH₂ group to the unsaturated carbon atom.

Cyclization reactions are useful variations of this reaction. An intramolecular addition of an amine unit to an alkene to form a pyrrolidine was reported using a Pd³⁴⁶ Rh,³⁴⁷ Sc,³⁴⁸ Sm,³⁴⁹ Ti,³⁵⁰ Zr,³⁵¹ or a Lu catalyst.³⁵² as well as a lanthanide reagent,³⁵³ or a Y reagent.³⁵⁴ An intramolecular Ca mediated reaction of amino alkenes leads to cyclic amines.³⁵⁵ Alkenyl amines give cyclic amines as the major product, in good yield, when treated with *n*-butyllithium.³⁵⁶ Reaction of a secondary amine with butyllithium generates an amide base, which reacts with alkenes to give alkyl amines,³⁵⁷ and can add intramolecularly to an alkene to form a pyrrolidine.³⁵⁸ Pyrroles can be generated in this manner.³⁵⁹

Other nitrogen compounds, among them hydroxylamine and hydroxylamines,³⁶⁰ hydrazines, and amides (Reaction 15-9), also add to alkenes. Tertiary amines (except those that are too bulky) add to *Michael-type* substrates (C=C—Z) in a reaction that is catalyzed by acids like HCl or HNO₃ to give the corresponding quaternary ammonium salts (R₃N⁺—C—C—Z).³⁶¹ The tertiary amine can be aliphatic, cycloalkyl, or heterocyclic (including pyridine). The reaction of NaOH with an amine containing two distal alkene units, followed by addition of a neodymium catalyst, leads to a bicyclic amine.³⁶²

Primary amines add to triple bonds³⁶³ to give enamines that have a hydrogen on the nitrogen and (analogously to enols) tautomerize (Sec. 2.N.ii, category 4) to the more stable imines (**41**).³⁶⁴ The reaction has been done with a Pd,³⁶⁵ a Ti,³⁶⁶ a Ta,³⁶⁷ a Cu,³⁶⁸ or an Au catalyst.³⁶⁹ An intramolecular addition of amines to an alkyne unit in the presence of a Pd catalyst generated heterocyclic or cyclic amine compounds.³⁷⁰ A variation treats an alkynyl imine with CuI to form pyrroles.³⁷¹ *N,N*-Diphenylhydrazine reacts with diphenyl acetylene and a Ti catalyst to give indole derivatives.³⁷² Treatment of an imine of 2-alkynyl benzaldehyde with iodide gave a functionalized isoquinoline.³⁷³ When ammonia is used instead of a primary amine, the corresponding $\text{R}_2\text{C}=\text{NH}$ imine product is not stable enough for isolation, but polymerizes. Ammonia and primary amines (aliphatic and aromatic) add to conjugated diynes to give pyrroles (**42**).³⁷⁴ *Anti-Markovnikov* addition of alkynes is possible using a Cu catalyst.³⁷⁵

A related reaction of amines and alkynes, in supercritical CO_2 , leads to amides.³⁷⁶

Allenes are reaction partners,³⁷⁷ and amines add to allenes in the presence of a catalytic amount of CuBr,³⁷⁸ Au,³⁷⁹ or Pd compounds.³⁸⁰ Intramolecular reaction of allene amines leads to dihydropyrroles, using a Au catalyst.³⁸¹ Cyclic imines can be prepared from allene amines using a Ti catalyst.³⁸²

A NH_2 or NR_2 unit can be added to double bonds (even ordinary double bonds) in an indirect manner by the use of hydroboration (Reaction 15-16) followed by treatment with NH_2Cl or $\text{NH}_2\text{OSO}_2\text{OH}$ (Reaction 12-32). This produces a primary amine with *anti-Markovnikov* orientation. An indirect way of adding a primary or secondary amine to a double bond consists of aminomercuration to give **43**, followed by reduction (see Reaction 15-3 for the analogous *oxymmercuration-demercuration* procedure) to give amine **44**.³⁸³ The addition of a secondary amine produces a tertiary amine, while addition of a primary amine gives a secondary amine. The overall orientation follows *Markovnikov's rule*. For conversion of **43** to other products, see Reaction 15-53.

Phosphines add to alkenes to give alkyl phosphines (**45**) and to alkynes to give vinyl phosphines. A Pd catalyzed reaction of alkenes and triarylphosphines gives alkyltrialkylphosphonium salts.³⁸⁴ Alkenes also react with diarylphosphines and a Ni catalyst to give the alkyl phosphine.³⁸⁵ Silylphosphines ($\text{R}_3\text{Si}-\text{PAR}_2$) react with alkenes and Bu_4NF to give the *anti-Markovnikov* allyl phosphine.³⁸⁶ Phosphine oxides can be prepared by the reaction of an aryl substituted alkene and diphenylphosphine oxide, $\text{Ph}_2\text{P}(=\text{O})\text{H}$.³⁸⁷ Phosphonate esters were similarly prepared from alkenes and diethyl phosphite $[(\text{EtO})_2\text{P}(=\text{O})\text{H}]$ and an Mn catalyst in a reaction exposed to oxygen.³⁸⁸ Similar addition was observed in the reaction of an alkene with NaH_2PO_2 to give the phosphinate $[\text{RCH}=\text{CH}_2 \rightarrow \text{RCH}_2\text{CH}_2\text{P}(=\text{O})\text{ONa}]$.³⁸⁹ Palladium catalysts were used for the preparation of similar compounds from alkenes³⁹⁰ and the reaction of terminal alkynes with dimethyl phosphite and a Ni catalyst gave the *Markovnikov* vinyl phosphonate ester.³⁹¹

In the presence of an Yb catalyst, diphenylphosphine added to diphenyl acetylene to give the corresponding vinyl phosphine.³⁹² A Pd catalyst was used for the addition of diphenylphosphine to terminal alkynes, giving the *anti-Markovnikov* vinyl phosphine, but a Ni catalyst led to the *Markovnikov* vinyl phosphine.³⁹³ A Co catalyst has also been used.³⁹⁴ Diphenylphosphine oxide also reacted with terminal alkynes to give the

15-9 Addition of Amides

Hydro-amido-addition

Under certain conditions, primary and secondary amides can add directly to alkenes to form *N*-alkylated amides. Sulfonamides react in a similar manner. Alkenes react with amides and related compounds in the presence of certain transition metals. The Ti catalyzed reaction of alkenyl *N*-tosylamines gives *N*-tosyl cyclic amines.³⁹⁸

The reaction can be done intramolecularly. 3-Pentenamide cyclized to 5-methyl-2-pyrrolidinone by treatment with trifluorosulfonic acid.³⁹⁹ *N*-Benzyl pent-4-ynamide reacted with tetrabutylammonium fluoride to an alkylidene lactam.⁴⁰⁰ Acyl hydrazine derivatives also cyclize in the presence of hypervalent iodine reagents to give lactams.⁴⁰¹ Treatment of triflamide alkenes with triflic acid gives the corresponding *N*-triflyl cyclic amine.⁴⁰² Intramolecular cyclization of sulfamate esters, catalyzed by a Rh complex, leads to cyclic sulfamates.⁴⁰³

Alkynes and allenes also react with amides. A Ru/In catalyzed addition of sulfonamides to alkynes leads to cyclic *N*-sulfonyl derivatives.⁴⁰⁴ Palladium-catalyzed reactions give similar results,⁴⁰⁵ and Bi and Hf have been used as catalysts.⁴⁰⁶ Phenylthiomethyl alkynes were converted to *N*-Boc-*N*-phenylthio allenes with Boc azide and an iron catalyst.⁴⁰⁷ Enamides are prepared by the Re⁴⁰⁸ or Ru catalyzed⁴⁰⁹ hydroamidation of terminal alkynes with amides. The Pd catalyzed reaction of an allene amide, with iodobenzene, leads to *N*-sulfonyl aziridines having an allylic group at C-1.⁴¹⁰ Other allene *N*-tosylamines similarly give *N*-tosyl tetrahydropyridines.⁴¹¹

N-Bromocarbamates also add to alkenes, in the presence of $\text{BF}_3 \cdot \text{OEt}_2$ to give a *vic*-bromo *N*-Boc amine.⁴¹² When a carbamate was treated with Bu_3SnH , and AIBN, addition to an alkene led to a bicyclic lactam.⁴¹³ Alkenyl amides and carbamates react with transition metal catalysts to form lactams or cyclic carbamates. Similar addition of a tosylamide–alkene, with a Pd catalyst, led to a vinyl *N*-tosyl pyrrolidine.⁴¹⁴ Both Pd⁴¹⁵ and Au⁴¹⁶ catalyzed cyclization reactions of carbamates are known, and Os compounds have been used.⁴¹⁷ Ionic liquids have been used to catalyze these reactions.⁴¹⁸

Imides can also add to alkenes or alkynes. Phthalimide reacts with an alkene in the presence of a Pd catalyst.⁴¹⁹ Ethyl 2-propynoate reacted with phthalimide, in the presence of a Pd catalyst, to give ethyl 2-phthalimido-2-propenoate.⁴²⁰

Nickel-catalyzed hydrophosphinylation reactions are known, such as the reaction of an alkyne with an alkyl phosphinate to give a vinyl phosphinate ester.⁴²¹ Both H-phosphinates and secondary phosphine oxides add to alkenes in an *anti*-Markovnikov manner, induced by air in what is likely a radical reaction.⁴²²

15-10 Addition of Hydrazoic Acid

Hydro-azido-addition

Hydrazoic acid (HN_3) can be added to certain Michael-type substrates (Z is as defined in Sec. 15.A.ii) to give β -azido compounds.⁴²³ The reaction apparently fails if R is phenyl. Hydrazoic acid also adds to enol ethers $\text{CH}_2=\text{CHOR}$ to give $\text{CH}_3-\text{CH}(\text{OR})\text{N}_3$, and to silyl enol ethers,⁴²⁴ but it does not add to ordinary alkenes unless a Lewis acid catalyst (e.g., TiCl_4) is used, in which case good yields of azide can be obtained.⁴²⁴

Hydrazoic acid can also be added indirectly to ordinary alkenes by azidomercuration, followed by demercuration,⁴²⁵ analogous to the

similar procedures mentioned in Reactions **15-3**, **15-5**, **15-6**, and **15-8**. The method can be applied to terminal alkenes or strained cycloalkenes (e.g., norbornene), but fails for unstrained internal alkenes. A variation is the hydroazidation reaction of alkenes using a Co catalyst and *tert*-BuOOH to give the alkyl azide.⁴²⁶

E. Hydrogen on Both Sides

15-11 Hydrogenation of Double and Triple Bonds⁴²⁷

Dihydro-addition

Most carbon–carbon double bonds, whether substituted by electron-donating or electron-withdrawing substituents, can be catalytically hydrogenated, usually in quantitative or near-quantitative yields.⁴²⁸ However, a transition metal catalyst is required to break apart H₂ into metal-bound hydrogen atoms before reaction can occur with the alkene. Almost all known alkenes added hydrogen at temperatures between 0 and 275 °C. The catalysts used can be divided into two broad classes, both of which mainly consist of transition metals and their compounds: (1) Catalysts insoluble in the reaction medium (*heterogeneous catalysts*). Among the most effective are Raney nickel,⁴²⁹ Pd-on-charcoal (perhaps the most common),⁴³⁰ NaBH₄ reduced nickel⁴³¹ (also called nickel boride), Pt metal or its oxide, Rh, Ru, and zinc oxide,⁴³² (2) Catalysts soluble in the reaction medium

(homogeneous catalysts).⁴³³ An important example is chlorotris(triphenylphosphine)rhodium [RhCl(Ph₃P)₃],⁴³⁴ **46**, *Wilkinson's catalyst*,⁴³⁵ which catalyzes the hydrogenation of many alkenyl compounds without disturbing such groups as CO₂R, NO₂, CN, or COR present in the same molecule.⁴³⁶ Even unsaturated aldehydes can be reduced to saturated aldehydes,⁴³⁷ although in this case decarbonylation (Reaction **14-32**) may be a side reaction. In general, for catalytic hydrogenation many functional groups may be present in the molecule, for example, OH, COOH, NR₂ (including NH₂), and N(R)COR' (including carbamates),⁴³⁸ CHO, COR, CO₂R, or CN. Vinyl esters can be hydrogenated using homogeneous Rh catalyst.⁴³⁹ Some of these groups are also susceptible to catalytic reduction, but it is usually possible to find conditions under which double bonds can be reduced selectively⁴⁴⁰ (see Table 19.2). Controlling the solvent allows catalytic hydrogenation of an alkene in the presence of an aromatic nitro group.⁴⁴¹

Modification of the catalyst includes a polymer bound Ru catalyst,⁴⁴² and a polymer incarcerated Pd catalyst.⁴⁴³ A nanoparticulate Pd catalyst in an ionic liquid has been used for the hydrogenation of alkenes.⁴⁴⁴

Homogeneous catalysts have the advantages of better catalyst reproducibility and better selectivity. Apart from *Wilkinson's catalyst* (**46**), chlorotris(triphenylphosphine)hydridoruthenium(II) [(Ph₃P)₃RuClH]⁴⁴⁵ is an important homogeneous catalyst that is specific for terminal double bonds (other double bonds are hydrogenated slowly or not at all). Homogeneous catalysts are also less susceptible to catalyst poisoning.⁴⁴⁶ Heterogeneous catalysts are usually poisoned by small amounts of sulfur, often found in rubber stoppers, or by thiols and sulfides.⁴⁴⁷ Note that heterogeneous catalysts are usually easier to separate from a reaction mixture.

Using soluble, homogeneous catalysts, unfunctionalized alkenes are hydrogenated with good diastereoselectivity and enantioselectivity⁴⁴⁸ using various metal catalysts

(e.g., Ir,⁴⁴⁹ Pd,⁴⁵⁰ or Zr,⁴⁵¹ and chiral ligands).⁴⁵² The chiral transition metal catalyst (Rh and Ru are probably the most common) is usually prepared with suitable chiral ligands prior to addition to the reaction. Alternatively, an achiral catalyst (e.g., *Wilkinson's catalyst*, **46**), is simply added along with a chiral ligand. With monophosphine chiral ligands,⁴⁵³ the phosphorous may be chiral, as in **47** (called R-camp)⁴⁵⁴ or bis(phosphine) **48** (called dipamp),⁴⁵⁵ but pyramidal inversion at elevated temperatures (see Sec. 4.C) limits the utility of such ligands. The alternative is to prepare phosphines that contain a chiral carbon, as in **49** (known as Chiraphos),⁴⁵⁶ but there are many variations of chiral bis(phosphine) ligands.⁴⁵⁷ Chiral poisoning has been used as a strategy for asymmetric catalysis.⁴⁵⁸

Hydrogenations are carried out at room temperature and just above atmospheric pressure, in most cases, but some double bonds are more resistant and require higher temperatures and pressures. The poor reactivity is usually a function of increasing substitution and is presumably caused by steric factors. Trisubstituted double bonds require, say, 25 °C and 100 atm, while tetrasubstituted double bonds may require 275 °C and 1000 atm. Among the double bonds most difficult to hydrogenate or which cannot be hydrogenated at all are those common to two rings, as in steroid **49**. Hydrogenations, even at about atmospheric pressure, are often performed in a special hydrogenator, but this is not always necessary. Indeed, placing a hydrogen-filled balloon over the reaction flask is common for small-scale hydrogenations that do not require heat or

pressure. The great variety of catalysts available often allows an investigator to find one that is highly selective. For example, the catalyst Pd(salen) encapsulated in zeolites permitted the catalytic hydrogenation of 1-hexene in the presence of cyclohexene.⁴⁵⁹ It has been shown that the pressure of the reaction can influence enantioselectivity in asymmetric catalytic hydrogenations.⁴⁶⁰

Triple bonds can be reduced, either by catalytic hydrogenation or by the other methods mentioned in the following two sections. The comparative reactivity of triple and double bonds depends on the catalyst. *With most catalysts (e.g., Pd), triple bonds are hydrogenated more easily*, and therefore it is usually possible to add just 1 equiv of hydrogen and reduce a triple to a double bond or to reduce a triple bond without affecting a double bond present in the same molecule.⁴⁶¹ A particularly good catalyst for this purpose is the *Lindlar catalyst* (Pd—CaCO₂—PbO),⁴⁶² which gives rather lean syn addition, and a (Z)-alkene. An alternative catalyst used for selective hydrogenation to *cis*-alkenes is the Pd on a barium sulfate (BaSO₄) catalyst, poisoned with quinoline⁴⁶³ (sometimes called the *Rosenmund catalyst*). Palladium on calcium carbonate in PEG has also been used as a recyclable catalyst system.⁴⁶⁴ Catalytic hydrogenation of alkynes leads to *cis*-alkenes with a Pd catalyst and DMF/KOH was found to be an efficient transfer-hydrogen source.⁴⁶⁵ Hydrogenation of a C≡C unit occurs in the presence of other functional groups, including NR₂ including NH₂,⁴⁶⁶ and sulfonyl.⁴⁶⁷

Conjugated dienes can add hydrogen by 1,2- or 1,4-addition. Selective 1,4-addition can be achieved by hydrogenation in the presence of CO, with bis(cyclopentadienyl)chromium as catalyst.⁴⁶⁸ With allenes,⁴⁶⁹ catalytic hydrogenation usually reduces both double bonds. Hydrogenation of functionalized alkenes is possible. The Rh catalyzed hydrogenation of enamines leads to amines,⁴⁷⁰ for example. Hydrogenation of fluorinated alkenes has been reported using an Ir catalyst.⁴⁷¹ The hydrogenation of conjugated alkenes is discussed in Reaction 15-14.

Most catalytic reductions of double or triple bonds, whether heterogeneous or homogeneous, have been shown to be mostly *syn*, with the hydrogen atoms incorporated from the less-hindered side of the molecule.⁴⁷² This selectivity depends in large part of how well the reactive intermediates are bound to the metal, and isomerization of the double bond is possible. Stereospecificity can be investigated only for tetrasubstituted alkenes (except when the reagent is D₂), which are the hardest to hydrogenate, but the results of these investigations show that the addition is usually 80–100% *syn*, although some of the anti-addition product is normally also found and in some cases predominates. Catalytic hydrogenation of alkynes is nearly always stereoselective, giving the *cis*-alkene (usually at least 80%), even when it is thermodynamically less stable. For example, **50** gave **51**, even though the steric hindrance is such that a planar molecule is impossible.⁴⁷³ This is

thus a useful method for preparing *cis*-alkenes.⁴⁷⁴ However, when steric hindrance is too great, the *trans*-alkene may be formed. One factor that complicates the study of the stereochemistry of heterogeneous catalytic hydrogenation is that exchange of hydrogen atoms takes place, as can be shown by hydrogenation with deuterium.⁴⁷⁵ Thus deuteration of ethylene produced all the possible deuterated ethylenes and ethanes (even C₂H₆), as well as HD.⁴⁷⁶ With 2-butene, it was found that double-bond migration, *cis*–*trans* isomerization, and even exchange of hydrogen with groups not on the double bond could occur (e.g., C₄H₂D₈ and C₄HD₉ were detected on treatment of *cis*-2-butene with deuterium and a catalyst).⁴⁷⁷ Indeed, *alkanes* have been found to exchange with deuterium over a catalyst,⁴⁷⁸ and even without deuterium (e.g., CH₄ + CD₄ → CHD₃ + CH₃D in the gas phase), with a catalyst. All this makes it difficult to investigate the stereochemistry of heterogeneous catalytic hydrogenation.

The mechanism of the heterogeneous catalytic hydrogenation of double bonds is not thoroughly understood because it is a very difficult reaction to study.⁴⁷⁹ Because the reaction is heterogeneous, kinetic data, although easy to obtain (measurement of decreasing hydrogen pressure), are difficult to interpret. Furthermore, there are the difficulties

caused by the aforementioned hydrogen exchange. The currently accepted mechanism for the common two-phase reaction was originally proposed in 1934.⁴⁸⁰ According to this, the alkene is adsorbed onto the surface of the metal, although the nature of the actual bonding is unknown,⁴⁸¹ despite many attempts to elucidate it.⁴⁸² In the 1934 work, the metallic site was indicated by an asterisk, but here  is used. For steric reasons it is apparent that adsorption of the alkene takes place with its less-hindered side attached to the catalyst surface, probably as an η^2 complex (Sec. 3.C.i). The fact that addition of hydrogen is generally also from the less-hindered side indicates that the hydrogen too is probably adsorbed on the catalyst surface before it reacts with the alkene. It is likely that as the H_2 molecule is adsorbed on (coordinated to) the metal catalyst, cleavage occurs to give η^1 -coordinated hydrogen atoms (Sec. 3.C.i). Note that this model suggests a single metal particle for coordination of the alkene and the hydrogen atoms, but the hydrogen atoms and the alkene could be coordinated to different metal particles. It has been shown that Pt catalyzes homolytic cleavage of hydrogen molecules.⁴⁸³ In the second step, one of the adsorbed (η^1 -coordinated) hydrogen atoms becomes attached to a carbon atom, creating in effect, an alkyl radical, which is still bound to the catalyst although only by one bond, probably η^1 -coordination. Transfer of a hydrogen atom to carbon opens a site on the metal catalyst for coordination to additional hydrogen atoms. Finally, another hydrogen atom (not necessarily the one originally connected to the first hydrogen) combines with the radical to give the reaction product, freed from the catalyst surface, and the metal catalyst that is now available for coordination of additional hydrogen atoms and/or alkenes. All the various side reactions, including hydrogen exchange and isomerism, can be explained by this type of process.⁴⁸⁴ Although this mechanism is satisfactory as far as it goes,⁴⁸⁵ there are still questions it does not answer, among them questions⁴⁸⁶ that involve the nature of the asterisk, the nature of the bonding, and the differences caused by the differing nature of each catalyst.⁴⁸⁷

Another problem with any study of heterogeneous catalysis is that it occurs at the surface, and different types of metal particles are exposed to the medium and reactants. Maier⁴⁸⁸ suggested the presence of **terrace**-, **step**-, and **kink**-type atoms (in Fig. 15.1)⁴⁸⁸ on the surface of a heterogeneous catalyst. These terms refer to different atom types, characterized by the number of nearest neighbors, which correspond to different transition metal fragments, as well as to different coordination states of that metal.⁴⁸⁹ A terrace-type atom (A in Fig. 15.1) typically has eight or nine neighbors and corresponds to a geometry shown for the ML_5 particle. The step type of atom (B) usually has seven neighbors and can

be correlated with the geometry shown for the ML_4 particle. Finally, the kink-type atom (C) has six neighbors and corresponds to geometry shown for the ML_3 particle. In general, as the particle size increases, the relative concentration of terrace atoms will increase, whereas small particle size favors the kink type of surface atoms.

The mechanism of homogeneous hydrogenation⁴⁹⁰ catalyzed by $RhCl(Ph_3P)_3$ (**46**, *Wilkinson's catalyst*)⁴⁹¹ involves reaction of the catalyst with hydrogen to form a metal hydride $(PPh_3)_2RhH_2Cl$ (**52**).⁴⁹² Replacement of a triphenylphosphine ligand with two atoms of hydrogen constitutes an oxidative addition. After coordination of the alkene to form **53**, transfer of hydrogen to carbon is an insertion process, presumably generating **55**, and a second insertion liberates the hydrogenated compound, and Rh species **54**, which adds hydrogen by oxidative addition to give **55**. In a different study of Pd catalyzed hydrogenations, a palladium hydride species was detected.⁴⁹³ Alternatively, replacement of triphenylphosphine can lead to **53**, with two hydrogen atoms and a η^2 alkene complex. If a mixture of H_2 and D_2 is used, the product contains only dideuterated and nondeuterated

compounds; no monodeuterated products are found, indicating that (unlike the case of heterogeneous catalysis) H_2 or D_2 has been added to one alkene molecule and that no exchange takes place.⁴⁹¹ Although conversion of **53** to the products takes place in two steps,⁴⁹⁴ the addition of H_2 to the double bond is syn, although bond rotation in **55** can lead to stereochemical mixtures.

The occurrence of hydrogen exchange and double-bond migration in heterogeneous catalytic hydrogenation means that the hydrogenation does not necessarily take place by straightforward addition of two hydrogen atoms at the site of the original double bond. Consequently, this method is not synthetically useful for adding D_2 to a double or triple bond in a regioselective or stereospecific manner. However, this objective can be achieved (with syn addition) by a homogeneous catalytic hydrogenation, which usually adds D_2 without scrambling⁴⁹⁵ or by the use of one of the diimide methods (Reaction **15-12**). Deuterium can also be regioselectively added by the hydroboration–reduction procedure previously mentioned.

Reductions of double and triple bonds are found at OS **I**, 101, 311; **II**, 191, 491; **III**, 385, 794; **IV**, 298, 304, 408; **V**, 16, 96, 277; **VI**, 68, 459; **VII**, 226, 287; **VIII**, 420, 609; **IX**, 169, 533.

Catalysts and apparatus for hydrogenation are found at OS **I**, 61, 463; **II**, 142; **III**, 176, 181, 685; **V**, 880; **VI**, 1007.

15-12 Other Reductions of Double and Triple Bonds

Although catalytic hydrogenation is the method most often used, double or triple bonds can be reduced by other reagents as well. These include sodium in ethanol, sodium and *tert*-butyl alcohol in HMPA,⁴⁹⁶ lithium in aliphatic amines⁴⁹⁷ (see also, Reaction **15-13**), zinc and acids, and $(\text{EtO})_3\text{SiH}-\text{Pd}(\text{OAc})_2$.⁴⁹⁸ Trialkylsilanes (R_3SiH) in conjunction with an acid will reduce double bonds.⁴⁹⁹ When double bonds are reduced by lithium in ammonia or amines, the mechanism is similar to that of the *Birch reduction* (Reaction **15-13**).⁵⁰⁰ The reduction with trifluoroacetic acid and Et_3SiH has an ionic mechanism, with H^+ coming in from the acid and H^- from the silane.²⁸⁹ In accord with this mechanism, the reaction can be applied only to those alkenes that when protonated can form a tertiary carbocation or one stabilized in some other way (e.g., by a OR substitution).⁵⁰¹ It has been

shown, by the detection of CIDNP, that reduction of α -methylstyrene by hydridopentacarbonylmanganese(I), $[\text{HMn}(\text{CO})_5]$, involves free radical addition.⁵⁰²

Triethylamine reduces alkynes in the presence of a Pd catalyst.⁵⁰³ Samarium iodide in water and a triamine additive led to reduction of alkenes.⁵⁰⁴ Similar reduction was reported using $\text{Co}_2(\text{CO})_8$ and an excess of water in dimethoxyethane.⁵⁰⁵

Another hydrogenation method is called *transfer hydrogenation*.⁵⁰⁶ In this method, the hydrogen atom comes from another organic molecule, and that molecule is oxidized. A transition metal catalyst, heterogeneous or homogeneous, is frequently employed. A common reducing agent is cyclohexene, which, when a Pd catalyst is used, is oxidized to benzene, losing 2 molar equivalents of hydrogen. Nickel nanoparticles reduce alkenes by transfer hydrogenation using 2-propanol.⁵⁰⁷

Diimide ($\text{NH}=\text{NH}$) is a reducing agent for simple alkenes, formed *in situ* from N_2H_4 from the reaction of a mixture of hydrazine and hydroxylamine.⁵⁰⁸ The rate of this reaction has been studied.⁵⁰⁹ Diimide is also generated from hydrazine using a flavin catalyst in an oxygen atmosphere.⁵¹⁰ Although both the syn and anti forms of diimide are produced, only the syn form reduces the double bond,⁵¹¹ at least in part by a cyclic mechanism.⁵¹²

The addition is stereospecifically syn⁵¹³ and, like catalytic hydrogenation, generally takes place from the less-hindered side of a double bond, although not much discrimination in this respect is observed where the difference in bulk effects is small.⁵¹⁴ Diimide reductions are most successful with symmetrical multiple bonds ($\text{C}=\text{C}$, $\text{C}\equiv\text{C}$, $\text{N}=\text{N}$) and are not useful for those inherently polar ($\text{C}\equiv\text{N}$, $\text{C}=\text{N}$, $\text{C}=\text{O}$, etc.). Diimide is not stable enough for isolation at ordinary temperatures, although it has been prepared⁵¹⁵ as a yellow solid at -196°C .

An indirect method⁵¹⁶ of double-bond reduction involves formation of an alkylborane from an alkene, followed by hydrolysis of the borane (prepared by Reaction **15-16**).

Trialkylboranes can be hydrolyzed by heating to reflux with carboxylic acids,⁵¹⁷ while monoalkylboranes (RBH₂) can be hydrolyzed with base.⁵¹⁸ A mild procedure involves treatment of the alkene with 2 molar equivalents of catecholborane, a catalytic amount of MeCONMe₂, followed by reduction of the organoborane with 4 molar equivalents of MeOH and then treatment with air.⁵¹⁹ Triple bonds can be similarly reduced to *cis*-alkenes.⁵²⁰ Further reduction is also possible. When an alkyne was treated with decaborane and Pd/C in methanol, 2 equiv of hydrogen are transferred to give the alkane.⁵²¹ Reduction of alkenes occurs with *tert*-butylamine•borane complex in methanol with 10% Pd/C.⁵²² In a related reaction, reduction occurs *in situ* when an alkene is treated with NaBH₄, NiCl₂•6 H₂O with moist alumina.⁵²³ Hydrogenation with Ni₂B on borohydride-exchange resin (BER) has also been used.⁵²⁴

Metallic hydrides (e.g., lithium aluminum hydride and sodium borohydride) do not typically reduce carbon–carbon double bonds, although in special cases where the double bond is polar, as in 1,1-diarylethenes⁵²⁵ and in enamines,⁵²⁶ reduction can occur. Note that both LiAlH₄ and NaBH₄, as well as NaH, reduce ordinary alkenes and alkynes when complexed with transition metal salts (e.g., FeCl₂ or CoBr₂).⁵²⁷ Lithium aluminum hydride reduces cyclopropenes with a pendant alcohol in the allylic position to the corresponding cyclopropane.⁵²⁸ Transition metals catalyze the reduction of alkenes using NaBH₄. Among the metals used for this purpose are Pd,⁵²⁹ and Ru.⁵³⁰ A mixture of NaBH₄ and BiCl₃ also reduced certain alkenes.⁵³¹ Zinc metal catalyzes the reduction of alkenes in water in the presence of a Rh complex.⁵³²

The fact that ordinary double bonds are inert toward metallic hydrides is quite useful, since it permits reduction of, say, a carbonyl or nitro group, without disturbing a double bond in the same molecule (see Chap 19 for a discussion of selectivity in reduction reactions). Sodium in liquid ammonia also does not reduce ordinary double bonds,⁵³³ although it does reduce alkynes, allenes, conjugated dienes,⁵³⁴ and aromatic rings (Reaction 15-13).

Enantioselective reduction of certain alkenes has also been achieved by reducing with baker's yeast.⁵³⁵

Catalytic hydrogenation of triple bonds and the reaction with Dibal-H (diisobutylaluminum hydride) usually give the *cis*-alkene (Reaction 15-11). Most of the other methods of triple-bond reduction lead to the more thermodynamically stable *trans*-alkene. However, this is not the case with the method involving hydrolysis of boranes or with the reductions with activated zinc, hydrazine, or $\text{NH}_2\text{OSO}_3\text{H}$, which also give the *cis* products.

Triple bonds can also be selectively reduced to double bonds with Dibal-H,⁵³⁶ with activated zinc (see Reaction 12-38),⁵³⁷ or (internal triple bonds only) with alkali metals (Na, Li) in liquid ammonia or a low-molecular-weight amine.⁵³⁸ Terminal alkynes are not reduced by the $\text{Na}-\text{NH}_3$ procedure because they are converted to acetylide ions under these conditions. However, terminal triple bonds can be reduced to double bonds by the addition to the $\text{Na}-\text{NH}_2$ solution of $(\text{NH}_4)_2\text{SO}_4$, which liberates the free ethynyl group.⁵³⁹ The reaction of a terminal alkyne with lithium naphthalenide and NiCl_2 effectively reduced the alkyne unit.⁵⁴⁰ This reagent is also effective for the reduction of simple alkenes.⁵⁴¹

Alkynes are converted to *trans*-alkenes with siloxanes $[(\text{RO})_3\text{SiH}]$ ⁵⁴² and a Ru catalyst, followed by treatment with AgF , or silanes⁵⁴³ and a Ru catalyst, followed by treatment with CuI and Bu_4NF . Reduction of an alkyne to an alkene can be done via an organometallic, by heating the alkyne with In metal in aq ethanol.⁵⁴⁴ Alkynes are reduced with palladium acetate and sodium ethoxide. In methanol, the product is the alkane, whereas in THF the product is the *cis*-alkene.⁵⁴⁵

Reduction of just one double bond of an allene, to give an alkene, has been accomplished by treatment with $\text{Na}-\text{NH}_3$ ⁵⁴⁶ or with Dibal-H,⁵⁴⁷ and by hydrogenation with $\text{RhCl}(\text{PPh}_3)_3$ as catalyst.⁵⁴⁸

Aromatic rings can be reduced by catalytic hydrogenation,⁵⁴⁹ but higher temperatures (100–200 °C) are required than for double bonds in alkenes.⁵⁵⁰ Although the reaction is usually carried out with heterogeneous catalysts, homogeneous catalysts have also been used; conditions are much milder with these.⁵⁵¹ Hydrogenations using phase transfer catalysts often proceed under mild conditions.⁵⁵² Hydrogenation in ionic liquids is known,⁵⁵³ and also hydrogenation in supercritical ethane containing water.⁵⁵⁴ Many functional groups (e.g., OH, O[−], CO₂H, CO₂R, NH₂) do not interfere with the reaction, but some groups may be preferentially reduced. Among these are CH₂OH groups, which undergo hydrogenolysis to CH₃ (Reaction 19-54). Phenols may be reduced to cyclohexanones, presumably through the enol. A computational study of the mechanism of hydrogenation of aromatic compounds has been reported, and it was shown that the barrier for uncatalyzed 1,4-hydrogenation is substantially lower than that for 1,2-hydrogenation, despite similar reaction enthalpies.⁵⁵⁵

It is usually impossible to stop the reduction of benzene rings after only one or two bonds have been reduced, since alkenes are more easily reduced than aromatic rings.⁵⁵⁶ Thus, 1 molar equivalent of benzene, treated with 1 molar equivalent of hydrogen, gives no cyclohexadiene or cyclohexene, but one-third equivalent of cyclohexane and two-thirds equivalent of recovered benzene. This is not true for all aromatic systems. With anthracene, for example, it is easy to stop after only the 9,10-bond has been reduced (Sec. 2.I.i). Hydrogenation of phenol derivatives can lead to conjugated cyclohexenones.⁵⁵⁷ Hydrogenation of toluene in an ionic liquid using a Ru catalyst gave methylcyclohexane.⁵⁵⁸

Heterocyclic compounds are often reduced by hydrogenation.⁵⁵⁹ Furan gives THF, pyrroles⁵⁶⁰ give pyrrolidines, and pyridines⁵⁶¹ give piperidines. The nitrogen-containing ring of quinolines is reduced by hydrogenation using iodine and an Ir catalyst.⁵⁶² Catalytic hydrogenation of the five-membered ring in indole derivatives using a chiral Rh catalyst gave hydroindoles with excellent enantioselectivity.⁵⁶³

When aromatic rings are reduced by Li (or K or Na) in liquid ammonia (such reductions are known as *dissolving metal reductions*), usually in the presence of an alcohol (often ethyl, isopropyl, or *tert*-butyl alcohol), 1,4-addition of hydrogen takes place and

nonconjugated cyclohexadienes are produced.⁵⁶⁴ This reaction is called the *Birch reduction*.⁵⁶⁵ Heterocycles (e.g., pyrroles,⁵⁶⁶ furans,⁵⁶⁷ pyridines,⁵⁶⁸ and indolones⁵⁶⁹) can be reduced using *Birch reduction*. Ammonia obtained commercially often has iron salts as impurities that lower the yield in the *Birch reduction*. Therefore it is often necessary to distill the ammonia. When substituted aromatic compounds are subjected to the *Birch reduction*, electron-donating groups (e.g., alkyl or alkoxy) decrease the rate of the reaction and are generally found on the nonreduced positions of the product. For example, anisole gives 1-methoxy-1,4-cyclohexadiene, not 3-methoxy-1,4-cyclohexadiene. On the other hand, electron-withdrawing groups (e.g., COOH or CONH₂) increase the reaction rate and are found on the reduced positions of the product.⁵⁷⁰ The regioselectivity of the reaction has been examined.⁵⁷¹ The mechanism involves solvated electrons,⁵⁷² which are transferred from the metal to the solvent, and hence to the ring.⁵⁷³

The sodium becomes oxidized to Na⁺ and creates a radical ion (**56**).⁵⁷⁴ There is a great deal of evidence from ESR spectra for these species.⁵⁷⁵ The radical ion accepts a proton from the alcohol to give a radical, which is reduced to a carbanion by another sodium atom. Finally, **57** accepts another proton. Thus the function of the alcohol is to supply protons, since with most substrates ammonia is not acidic enough for this purpose. In the absence of the alcohol, products arising from dimerization of **56** are frequently obtained. There is evidence⁵⁷⁶ at least with some substrates (e.g., biphenyl) that the radical ion corresponding to **56** is converted to the carbanion corresponding to **56** by a different pathway, in which the order of the steps is reversed: First a second electron is gained to give a dianion,⁵⁷³ which then acquires a proton, producing the intermediate (e.g., **56**).

Ordinary alkenes are usually unaffected by *Birch-reduction* conditions, and double bonds may be present in the molecule if they are not conjugated with the ring. However,

phenylated alkenes, internal alkynes (Reaction 15-12),⁵⁷⁷ and conjugated alkenes (with C=C or C=O) are reduced under these conditions.

Note that **56** is a resonance hybrid; that is, two additional canonical forms can be written. The question therefore arises: Why does the carbanion pick up a proton at the 6 position to give the 1,4-diene? Why not at the 2 position to give the 1,3-diene?⁵⁷⁸ An answer to this question has been proposed by Hine,⁵⁷⁹ who suggested that this case is an illustration of the operation of the *principle of least motion*. According to this principle, “those elementary reactions will be favored that involve the least change in atomic position and electronic configuration.”⁵⁷⁸ The principle can be applied to the case at hand in the following manner (simplified): The valence bond bond orders (Sec. 2.A) for the six carbon–carbon bonds (on the assumption that each of the three forms contributes equally) are (going around the ring) $1\frac{2}{3}$, 1, 1, $1\frac{2}{3}$, $1\frac{1}{3}$, and $1\frac{1}{3}$. When the carbanion is converted to the diene, these bond orders change as follows:

It can be seen that the two bonds whose bond order is 1 are unchanged in the two products, but for the other four bonds there is a change. If the 1,4-diene is formed, the change is $\frac{1}{3} + \frac{1}{3} + \frac{1}{3} + \frac{1}{3}$, while formation of the 1,3-diene requires a change of $\frac{1}{3} + \frac{2}{3} + \frac{2}{3} + \frac{1}{3}$. Since a greater change is required to form the 1,3-diene, the principle of least motion predicts formation of the 1,4-diene. This may not be the only factor, because the ^{13}C NMR spectrum of **111** shows that the 6 position has a somewhat greater electron density than the 2 position, which presumably would make the former more attractive to a proton.⁵⁸⁰

Reduction of aromatic rings with Li ⁵⁸¹ or Ca ⁵⁸² in amines (instead of ammonia: called *Benkeser reduction*) proceeds further and cyclohexenes are obtained. It is thus possible to reduce a benzene ring, by proper choice of reagent, so that one, two, or all three double bonds are reduced.⁵⁸³ Lithium triethylborohydride (LiBET_3H) has also been used, to reduce pyridine derivatives to piperidine derivatives.⁵⁸⁴

Transition metals and metal compounds can reduce aromatic rings in the proper medium. Indium metal reduces the pyridine ring in quinoline in aq ethanol solution,⁵⁸⁵ as well as the C=C unit in the five-membered ring of indole derivatives.⁵⁸⁶ Samarium

15-14 Reduction of the Double or Triple Bonds Conjugated to Carbonyls, Cyano, Nitro, and so on

Reduction of only the C=C bond of conjugated $\text{C}=\text{C}-\text{C}=\text{O}$ and $\text{C}=\text{C}-\text{C}\equiv\text{N}$ systems⁵⁹¹ has been achieved by many reducing agents,⁵⁹² including catalytic hydrogenation with a Rh,⁵⁹³ a Ru,⁵⁹⁴ a Pd,⁵⁹⁵ or an Ir catalyst,⁵⁹⁶ and with Raney nickel alone.⁵⁹⁷ Reagents, such as SmI_2 ⁵⁹⁸ and catecholborane,⁵⁹⁹ are effective. Conjugated ketones react with 2 equiv of Cp_2TiCl in THF/MeOH to give the corresponding saturated ketone.⁶⁰⁰ Zinc and acetic acid has been used for the conjugate reduction of dihydropyridin-4-ones.⁶⁰¹ Formic acid with a Pd catalyst reduced conjugated carboxylic acids.⁶⁰² A zinc–titanocene protocol has been developed for conjugate reductions.⁶⁰³ Both NaBH_4 in MeOH—THF⁶⁰⁴ and NaCNBH_3 on a zeolite⁶⁰⁵ reduce α,β -unsaturated nitro compounds to nitroalkanes.

In certain cases,⁶⁰⁶ metallic hydride reagents may selectively reduce double bonds that are in conjugation with C=O bonds,⁶⁰⁷ although the C=O bonds are also reduced in many

⁶⁰⁷ For a discussion of hydride affinity with respect to hydride reducing agents, see Zhu, X.-Q.; Zhang, M.; Liu, Q.-Y.; Wang, X.-X.; Zhang, J.-Y.; Cheng, J.-P. *Angew. Chem. Int. Ed.* **2006**, 45, 3954; Vianello, R.; Peran, N.; Maksić, Z.B. *Eur. J. Org. Chem.* **2007**, 5296.

cases, as in the conversion of cyclopentenone to cyclopentanol.⁶⁰⁸ The reagent NaBH_4 has a greater tendency than LiAlH_4 to effect this double reduction, although even with NaBH_4 the product of 1,2-reduction (of the $\text{C}=\text{O}$ bond) is usually formed in larger amount than the doubly reduced product. The $\text{C}=\text{C}$ unit proximal to the carbonyl in dienyl amides is selectively reduced with NaBH_4/I_2 .⁶⁰⁹ Mixed hydride reducing agents (e.g., $\text{NaBH}_4\text{—BiCl}_3$,⁶¹⁰ $\text{NaBH}_4\text{—InCl}_3$,⁶¹¹ and $\text{Dibal-H—Co(acac)}_2$)⁶¹² have been used. The $\text{InCl}_3\text{—NaBH}_4$ reagent was used to covert conjugated diene ketones ($\text{C}=\text{C—C}=\text{C—C}=\text{O}$) selectively to the nonconjugated alkenyl ketone ($\text{C}=\text{C—CH}_2\text{CH}_2\text{—C}=\text{O}$).⁶¹³ Lithium aluminum hydride also reduces the double bonds of allylic alcohols.⁶¹⁴

Transfer hydrogenation can be applied to the reduction of conjugated alkenes. Reduction of the $\text{C}=\text{C}$ unit of conjugated aldehydes is accomplished with an imidazolidinone catalyst⁶¹⁵ or an amino ester⁶¹⁶ in the presence of a *Hantzsch ester* (e.g., **58**). Nitroalkenes are hydrogenated using a thiourea catalyst in the presence of **58**.⁶¹⁷ Palladium/carbon with microwave heating is used for the transfer hydrogenation of conjugated carboxylic acids, using 1,4-cyclohexadiene as the hydrogen-transfer agent.⁶¹⁸ Solvent-free transfer hydrogenation is possible using a Ru complex, with formic acid or water⁶¹⁹ as the hydrogen donor.⁶²⁰ Palladium— $\text{P}(t\text{-Bu})_3$ has been used as a mild catalyst for transfer hydrogenation.⁶²¹ Titanium-catalyzed reductions are also known.⁶²²

Silanes reduce the $\text{C}=\text{C}$ unit in conjugated systems in the presence of Cu species.⁶²³ An asymmetric CuH catalyzed hydrosilation reaction is known.⁶²⁴ Phenylsilane (PhSiH_3) and

a Ni catalyst,⁶²⁵ CuCl,⁶²⁶ a Mn catalyst⁶²⁷ or a Mo⁶²⁸ catalyst have been used for hydrosilation reactions. Triphenylsilane was also used for the asymmetric reduction of nitro alkenes (C=C–NO₂).⁶²⁹ Poly(methylhydrosiloxane) with a chiral Cu catalyst gave conjugate reduction of conjugated esters to give the saturated derivative with high enantioselectivity.⁶³⁰ Polymethylhydrosiloxane, in the presence of a Co-catalyst reduces conjugated nitriles.⁶³¹ A β-bromo conjugated lactone was reduced to the β-bromolactone with modest enantioselectivity using an excess of Ph₃SiH and a CuCl catalyst with a chiral ligand.⁶³² Tributyltin hydride, in the presence of MgBr₂•OEt₂ gave 1,4-reduction of conjugated esters.⁶³³

Optically active homogeneous hydrogenation catalysts have been used to achieve the enantioselective hydrogenation⁶³⁴ of many prochiral conjugated substrates.⁶³⁵ For example,⁶³⁶ hydrogenation of **59** with a suitable catalyst gives the (+) or (–) amino ester (depending on which enantiomer of the catalyst is used) with an ee as high as 96%.⁶³⁷ Prochiral substrates that give such high optical yields generally contain functional groups (e.g., a carbonyl group,⁶³⁸ amide groups, cyano groups) or combinations of such groups as in **58**.⁶³⁹ The catalyst in such cases⁶⁴⁰ is usually a Ru⁶⁴¹ or Rh complex⁶⁴² with chiral

phosphine ligands.⁶⁴³ Good asymmetric induction⁶⁴⁴ has been achieved using chiral Rh complexes with other chiral additives.⁶⁴⁵ Iridium complexes have been used with excellent enantioselectivity.⁶⁴⁶ The role of solvent has been examined.⁶⁴⁷ A pressure-dependent enantioselective hydrogenation has been reported.⁶⁴⁸ Asymmetric catalytic hydrogenation has been reported for conjugated carboxylic acids⁶⁴⁹ and conjugated ketones.⁶⁵⁰ Asymmetric hydrogenation of conjugated carboxylic acids in an ionic liquid is known using a chiral Ru complex⁶⁵¹

See Reaction **19-36** for methods of reducing C=O bonds in the presence of conjugated C=C bonds.

The C=C unit of conjugated aldehydes has been reduced using AlMe₃ with a catalytic amount of CuBr⁶⁵² and with ammonium formate/Pd—C.⁶⁵³ Polymer-supported formate has been used for the 1,4-reduction of conjugated ketones⁶⁵⁴ and for conjugated acids using an Rh catalyst and microwave irradiation.⁶⁵⁵ Isopropyl alcohol and an Ir catalyst gives conjugate reduction of conjugated ketones.⁶⁵⁶ The reaction of conjugated ketones with aluminum chlorides, followed by treatment with water generates the saturated ketone.⁶⁵⁷

Enzymatic reduction of conjugated systems requires the reactivity with certain purified or whole cell enzymes. Baker's yeast reduces conjugated nitro compounds to nitroalkanes⁶⁵⁸ and also the C=C unit of conjugated ketones.⁶⁵⁹ Other enzymatic reductions are possible. A reductase from *Nicotiana tabacum* reduced a conjugated ketone to the

saturated ketone, with excellent enantioselectivity.⁶⁶⁰ Enzyme YNAR-I and NADP-H reduces conjugated nitro compounds to nitroalkanes.⁶⁶¹ Conjugated nitro compounds are reduced in the presence of *Clostridium sporogenes*.⁶⁶²

15-15 Reductive Cleavage of Cyclopropanes

Cyclopropanes can be cleaved by catalytic hydrogenolysis.⁶⁶³ Among the catalysts used have been Ni, Pd, Rh,⁶⁶⁴ and Pt. The reaction can often be run under mild conditions.⁶⁶⁵ Certain cyclopropane rings, especially cyclopropyl ketones and aryl-substituted cyclopropanes,⁶⁶⁶ can be reductively cleaved by an alkali metal (generally Na or Li) in liquid ammonia.⁶⁶⁷ Similar reduction has been accomplished photochemically in the presence of LiClO₄.⁶⁶⁸ This reaction is an excellent way to introduce a *gem*-dimethyl unit into a molecule. Hydrogenation of the cyclopropane ring in **60**, for example, gave the *gem*-dimethyl unit in **61** using PtO₂ (*Adam's catalyst*).⁶⁶⁹

F. A Metal on the Other Side

15-16 Hydroboration

When alkenes are treated with borane⁶⁷⁰ in ether solvents, BH₃ adds across the double bond.⁶⁷¹ The alkene reacts as a base with the boron essentially reacting as a Lewis acid. Borane cannot be prepared as a stable pure compound⁶⁷² (it dimerizes to diborane, B₂H₆),

but it is commercially available in the form of “ate” complexes with THF, Me_2S ,⁶⁷³ phosphines, or tertiary amines. The alkenes can be treated with a solution of one of these complexes. Tetrahydrofuran– BH_3 reacts at 0°C and is the most convenient to use and $\text{R}_3\text{N}–\text{BH}_3$ generally require temperatures of $\sim 100^\circ\text{C}$. The latter can be prepared as air-stable liquids or solids, while the former can only be used as relatively dilute solutions in THF and are decomposed by moisture (in air) or with a mixture of NaBH_4 and BF_3 etherate, which generates borane *in situ*.⁶⁷⁴ Pyridine–borane can be used for the hydroboration of alkenes at room temperature.⁶⁷⁵ With relatively unhindered alkenes, the process cannot be stopped with the addition of one molecule of BH_3 because the resulting RBH_2 adds to another molecule of alkene to give R_2BH , which in turn adds to a third alkene molecule, so that the isolated product is a trialkylborane (R_3B). The reaction can be performed on alkenes with one to four substituents, including cyclic alkenes, but when the alkene is moderately hindered, the product is the dialkylborane (R_2BH) or even the monoalkylborane (RBH_2).⁶⁷⁶ For example, **62** (*disiamylborane*) and **63** (*thexylborane*)⁶⁷⁷ have been prepared in this manner. Monoalkylboranes (RBH_2), which can be prepared from hindered alkenes, (as above) and dialkylboranes (R_2BH) also add to alkenes, to give the mixed trialkylboranes ($\text{RR}'_2\text{B}$ and $\text{R}_2\text{R}'\text{B}$), respectively. Surprisingly, when methylborane (MeBH_2),⁶⁷⁸ which is not a bulky molecule, adds to alkenes in the solvent THF, the reaction can be stopped with one addition to give dialkylboranes (RMeBH).⁶⁷⁹ Reaction of this with a second alkene produces the trialkylborane ($\text{RR}'\text{MeB}$).⁶⁸⁰ Other monoalkylboranes (*i*- PrBH_2 , *n*- BuBH_2 , *s*- BuBH_2 , and *t*- BuBH_2), behave similarly with internal alkenes, but not with alkenes of the type $\text{RCH}=\text{CH}_2$.⁶⁸¹

In all cases, the boron goes to the side of the double bond that has more hydrogen atoms (less substituted), whether the substituents are aryl or alkyl.⁶⁸² Technically, this follows *Markovnikov's rule*, since boron is more positive than hydrogen. The regioselectivity is caused mostly by steric factors, although electronic factors also play a part. Studies of the effect of ring substituents on rates and on the direction of attack in hydroboration of

substituted styrenes showed that the reaction with boron and the alkene has electrophilic character.⁶⁸³ When both sides of the double bond are monosubstituted or disubstituted, about equal amounts of each isomer are obtained. However, it is possible in such cases to make the addition regioselective by the use of a large borane molecule. For example, treatment of $i\text{PrCH}=\text{CHMe}$ with borane gave 57% of product with boron on the methyl-bearing carbon and 43% of the other, while treatment with **62** gave 95% **64** and only 5% of the other isomer.⁶⁸⁴

Another reagent with high regioselectivity is 9-borabicyclo[3.3.1]nonane (9-BBN, **65**), which is prepared by hydroboration of 1,5-cyclooctadiene,⁶⁸⁵ and has the advantage that it is stable in air. Borane is quite unselective and attacks all sorts of double bonds. Disiamylborane, 9-BBN, and similar molecules are far more selective and preferentially react at the less-hindered bonds, so it is often possible to hydroborate one double bond in a molecule and leave others unaffected or to hydroborate one alkene in the presence of a less reactive alkene.⁶⁸⁶ For example, 1-pentene can be removed from a mixture of 1- and 2-pentenes, and a *cis*-alkene can be selectively hydroborated in a mixture of the *cis* and *trans* isomers.

For most substrates, the addition in hydroboration is stereospecific and syn, with attack taking place from the less-hindered side.⁶⁸⁷ Note that organoboranes can be analyzed using ¹¹B NMR.⁶⁸⁸ The mechanism⁶⁸⁹ may be a cyclic four-center one:⁶⁹⁰

When the substrate is an allylic alcohol or amine, the addition is generally anti,⁶⁹¹ although the stereoselectivity can be changed to syn by the use of catecholborane and Rh complexes.⁶⁹² Because the mechanism is different, use of this procedure can result in a change in regioselectivity as well (e.g., styrene, $\text{PhCH}=\text{CH}_2$, gave $\text{PhCH}(\text{OH})\text{CH}_3$).⁶⁹³

Monochloroborane⁶⁹⁴ (BH_2Cl) coordinated with DMS shows greater regioselectivity than BH_3 for terminal alkenes or those of the form $\text{R}_2\text{C}=\text{CHR}$, and the hydroboration product is a dialkylchloroborane (R_2BCl).⁶⁹⁵ For example, 1-hexene gave 94% of the *anti-Markovnikov* product (the boron is on the less substituted carbon) with BH_3 —THF, but 99.2% with $\text{BH}_2\text{Cl}^-\text{SMe}_2$. Treatment of alkenes with dichloroborane—DMS (BHCl_2 — SMe_2) in the presence of BF_3 ⁶⁹⁶ or with BCl_3 and Me_3SiH ⁶⁹⁷ gives alkylidichloroboranes (RBCl_2). Extensions of this basic approach are possible with dihalo alkylboranes. The reaction of an alkene with allyl dibromoborane, incorporated an allyl group and the boron on adjacent carbons.⁶⁹⁸

An important use of the hydroboration reaction is oxidation of an organoborane to alcohols with H_2O_2 and NaOH (see Reaction 12-27). The synthetic result is an indirect way of adding H_2O across a double bond in an *anti-Markovnikov* manner. However, boranes undergo many other reactions as well. Among other things, they react with α -halo carbonyl compounds to give alkylated products (Reaction 10-73), with α,β -unsaturated carbonyl compounds to give *Michael-type* addition of R and H (Reaction 15-27), with CO to give alcohols and ketones (Reactions 18-23–18-24); they can be reduced with carboxylic acids (Reaction 15-11), or they can be oxidized with chromic acid or pyridinium chlorochromate to give ketones⁶⁹⁹ or aldehydes (from terminal alkenes),⁷⁰⁰ dimerized with silver nitrate and NaOH (Reaction 14-26), isomerized (Reaction 18-11), or converted to amines (Reaction 12-32), halides (Reaction 12-31), or carboxylic acids.⁷⁰¹ They are thus useful intermediates for the preparation of a wide variety of compounds. Intramolecular hydroboration reactions are possible.⁷⁰²

Such functional groups as OR, OH, NH_2 , SMe, halogen, and CO_2R may be present in the molecule,⁷⁰³ but not groups that are reducible by borane (e.g., COOH). Hydroboration of enamines with 9-BBN provides an indirect method for reducing an aldehyde or ketone to an alkene, for example,⁷⁰⁴

The presence of certain functional groups has directing effects on hydroboration reactions. Amides direct hydroboration reactions in alkenyl amides, for example.⁷⁰⁵ Intramolecular hydroboration is directed by amine groups in alkenyl amines.⁷⁰⁶ Alkenyl alcohols or ethers also undergo hydroboration, where delivery of boron is directed by the oxygen.⁷⁰⁷

Use of the reagent diisopinocampheylborane (**66**, prepared by treating optically active α -pinene with BH_3) results in enantioselective hydroboration–oxidation.⁷⁰⁸ Since both (+) and (–) α -pinene are readily available, both enantiomers can be prepared. Alcohols with moderate-to-excellent enantioselectivities have been obtained

in this way.⁷⁰⁹ However, **66** does not give good results with even moderately hindered alkenes; a better reagent for these compounds is isopinocampheylborane⁷¹⁰ although optical yields are lower. Limonylborane,⁷¹¹ 2- and 4-dicaranylboranes,⁷¹² a myrtanylborane,⁷¹³ and dilongifolylborane⁷¹⁴ have also been used. Other new asymmetric boranes have also been developed. The chiral cyclic boranes *trans*-2,15-dimethylborolanes (**67** and **68**) also add enantioselectively to alkenes (except alkenes of the form $\text{RR}'\text{C}=\text{CH}_2$) to give boranes of high optical purity.⁷¹⁵ When chiral boranes are added to trisubstituted alkenes of the form $\text{RR}'\text{C}=\text{CHR}''$, two new chiral centers are created, and, with **67** or **68**, only one of the four possible diastereomers is predominantly produced, in yields $>90\%$.⁷¹⁵ This has been called *double-asymmetric synthesis*.⁷¹⁶ An alternative asymmetric synthesis of alcohols involves the reaction of catechol borane with an alkene in the presence of a chiral Rh catalyst, giving the alcohol enantioselectivity after the usual oxidation.⁷¹⁷

The double bonds in a conjugated diene are hydroborated separately; that is, there is no 1,4-addition. However, it is not easy to hydroborate just one of a conjugated system, since conjugated double bonds are less reactive than isolated ones. Thexylborane⁶⁷⁷ (**63**) is particularly useful for achieving the cyclic hydroboration of dienes, conjugated or non-conjugated, as in the formation of **69**.⁷¹⁸

Rings of five, six, or seven members can be formed in this way. Similar cyclization can also be accomplished with other monoalkylboranes and, in some instances, with BH_3 itself.⁷¹⁹ One example is the formation of 9-BBN, shown above. Another is conversion of 1,5,9-cyclododecatriene to perhydro-9*b*-boraphenalene (**70**).⁷²⁰

Boronate esters are prepared from alkenes. The reaction of an alkene with pyridine iodoborane, followed by treatment with pinacol and NaOH, for example, leads to the pinacol boronate ester.⁷²¹

Triple bonds⁷²² can be monohydroborated to give vinylic boranes, which can be reduced with carboxylic acids to *cis*-alkenes or oxidized and hydrolyzed to aldehydes or ketones. Terminal alkynes give aldehydes by this method, in contrast to the mercuric or acid-catalyzed addition of water discussed in Reaction 15-4. However, terminal alkynes give vinylic boranes⁷²³ (and hence aldehydes) only when treated with a hindered borane (e.g., **62**, **63**, or catecholborane, Reaction 12-31 and Sec. 14.A.i),⁷²⁴ or with $\text{BHBr}_2-\text{SMe}_2$.⁷²⁵ The reaction between terminal alkynes and BH_3 produces 1,1-dibora compounds, which can be oxidized either to primary alcohols (with $\text{NaOH}-\text{H}_2\text{O}_2$) or to carboxylic acids (with *m*-chloroperoxybenzoic acid).⁷²⁶ Double bonds can be hydroborated in the presence of triple bonds if the reagent is 9-BBN.⁷²⁷ On the other hand, dimesitylborane selectively hydroborates triple bonds in the presence of double bonds.⁷²⁸ Furthermore, it is often

possible to hydroborate selectively one particular double bond of a nonconjugated diene.⁷²⁹ A triple bond can be hydroborated in the presence of a ketone, and treatment with acetic acid reduces the $\text{C}\equiv\text{C}$ unit to a *cis*-alkene (see Reaction 15-12).⁷³⁰ When the reagent is catecholborane, hydroboration is catalyzed by Rh complexes,⁷³¹ (e.g., *Wilkinson's catalyst*, **46**,⁷³² by SmI_2 ,⁷³³ or lanthanide reagents).⁷³⁴ Enantioselective hydroboration–oxidation has been achieved by the use of optically active Rh complexes.⁷³⁵

A chain extension variation involved the reaction of styrene with catecholborane and then $\text{Me}_3\text{SiCHN}_2$.⁷³⁶ Subsequent oxidation with $\text{NaOH}/\text{H}_2\text{O}_2$ and the reaction with Bu_4NF gave 3-phenyl-1-propanol.

15-17 Other Hydrometalation

Hydro-metallo-addition

Metal hydrides of Groups 13 and 14 of the periodic table (e.g., AlH_3 , GaH_3), as well as many of their alkyl and aryl derivatives (e.g., R_2AlH and Ar_3SnH) add to double bonds to give organometallic compounds.⁷³⁷ In each case, the alkene reacts with the Lewis acid. The hydroboration reaction (15-16) is the most important example but, as mentioned, other important metals in this reaction are Al,⁷³⁸ Sn,⁷³⁹ and Zr⁷⁴⁰ (a Group 4 metal). Some of these reactions are uncatalyzed, but in other cases various types of catalyst have been used.⁷⁴¹ Hydrozirconation is most commonly carried out with Cp_2ZrHCl (Cp = cyclopentadienyl),⁷⁴² known as *Schwartz's reagent*. The mechanism with Group 13 hydrides seems to be electrophilic (or four-centered pericyclic with some electrophilic characteristics) while with Group 14 hydrides a mechanism involving free radicals seems more likely. Dialkylmagnesium reagents have been obtained by adding MgH_2 to double bonds.⁷⁴³

With some reagents triple bonds⁷⁴⁴ can add 1 or 2 equiv.⁷⁴⁵ When 2 molar equivalents are added, electrophilic addition generally gives 1,1-dimetallic products (as with hydro-boration), while free radical addition usually gives the 1,2-dimetallic products.

G. Carbon or Silicon on the Other Side

15-18 Addition of Alkanes

Hydro-alkyl-addition

There are two important ways of adding alkanes to alkenes: direct heating, and acid catalysis.⁷⁴⁶ Both give mixtures, and neither is useful for the preparation of relatively pure compounds in reasonable yields. However, both are useful industrially. In the thermal method, the reactants are heated to high temperatures ($\sim 500^\circ\text{C}$) at high pressures (150–300 atm) without a catalyst. As an example, propane and ethylene gave 55.5% isopentane, 7.3% hexanes, 10.1% heptanes, and 7.4% alkenes.⁷⁴⁷ The mechanism is undoubtedly of a free radical type and can be illustrated by one possible sequence in the reaction between propane and ethylene:

There is kinetic evidence that the initiation takes place primarily by steps like 1, which are called *symproportionation* steps⁷⁴⁸ (the opposite of disproportionation, see Sec. 5.C.ii).

In the acid-catalysis method, a protonic or Lewis acid is used as the catalyst and the reaction is carried out at temperatures between -30 and 100°C . This is a *Friedel-Crafts* process that proceeds via a carbocation mechanism⁷⁴⁹ (illustrated for a proton acid catalyst):

Carbocation **72** often rearranges before a hydride is transferred, explaining, for example, why the principal product from the reaction between isobutane and ethylene is 2,3-dimethylbutane. Instead of abstracting a hydride, it is also possible for **71** (or **72**) to add to another molar equivalent of alkene, so that not only rearrangement products, but also dimeric and polymeric products, are frequent. If the tri- or tetrasubstituted alkenes are treated with Me_4Si , HCl , and AlCl_3 , protonation gives a tertiary carbocation, which reacts with the Me_4Si to give a product that is the result of addition of H and Me to the original alkene.⁷⁵⁰ (For a free radical hydro-methyl addition, see Reaction **15-28**.) An intramolecular cyclization of 1-dodecene to cyclododecane was reported using aluminum chloride in an ionic liquid.⁷⁵¹

Alkanes add to alkynes under photolysis conditions to give an alkene.⁷⁵² Tetrahydrofuran adds to alkynes to give the alkene with microwave irradiation.⁷⁵³

The reaction can also be base catalyzed, in which case there is nucleophilic addition and a carbanion mechanism.⁷⁵⁴ Carbanions most often used are those stabilized by one or more α -aryl groups. For example, toluene adds to styrene in the presence of sodium to give 1,3-diphenylpropane.⁷⁵⁵

Conjugated dienes give 1,4-addition.⁷⁵⁶ This reaction has also been performed with salts of carboxylic acids in what amounts to a method of alkylation of carboxylic acids⁷⁵⁷ (see also, Reaction **10-59**).

There are transition metal catalyzed addition reactions of alkyl units to alkenes,⁷⁵⁸ often proceeding with metal hydride elimination to form an alkene. An intramolecular cyclization reaction of an *N*-pyrrolidino amide alkene was reported using an iridium catalyst for addition of the carbon α to nitrogen at the alkene unit.⁷⁵⁹

Although silanes bearing at least one Si—H unit do not generally react with alkenes or alkynes, addition occurs to give the corresponding alkyl or vinyl silane in the presence of transition metal catalysts.⁷⁶⁰ This reaction is known as hydrosilation. The reaction of an alkylsilane and an alkene with a Ru,⁷⁶¹ Rh,⁷⁶² Pd,⁷⁶³ Re,⁷⁶⁴ La,⁷⁶⁵ Y,⁷⁶⁶ Pt⁷⁶⁷ Cu,⁷⁶⁸ or Sm⁷⁶⁹ catalyst leads to addition with high *anti-Markovnikov* selectivity. Silanes add to dienes with a Pd catalyst, and asymmetric induction is achieved by using a chiral binaphthyl additive.⁷⁷⁰ Alkenes react with Li metal and *t*-Bu₂SiCl₂ to give a three-membered ring silane.⁷⁷¹

Dienes react with zirconium compounds and silanes to produce cyclic compounds in which the silyl group has also added to one C=C unit.⁷⁷² With an Y catalyst, PhSiH₃ reacts with nonconjugated dienes to give cyclic alkenes with a pendant CH₂SiH₂Ph group.⁷⁷³ Rhodium compounds allow silanes to add to enamides to give the α -silylamide.⁷⁷⁴ Formation of silanes via reaction with alkenes can be followed by reaction with fluoride ion and then oxidation to give an alcohol⁷⁷⁵ (see Reaction 10-16; *Tamao–Fleming oxidation*). A variation of this reaction generated allylic silanes from terminal alkenes and a dianion-type zincate using a Ti catalyst.⁷⁷⁶

In the presence of BEt₃, silanes add to alkenes to give the alkylsilane with *anti-Markovnikov* selectivity,⁷⁷⁷ or to alkynes to give the corresponding vinyl silane.⁷⁷⁸ Similar selectivity was observed when a silylated zinc reagent was added to a terminal alkyne.⁷⁷⁹ Hydrosilation of alkynes is accomplished using transition metal catalysts (e.g., Ru⁷⁸⁰ Pt,⁷⁸¹ Ti,⁷⁸² or Ir).⁷⁸³ Organocatalysts have been used as well.⁷⁸⁴ Siloxanes [e.g., (RO)₃SiH] add to alkynes with a Ru catalyst to give the corresponding vinyl silane.⁷⁸⁵ The reaction of Cl₂MeSiH and terminal alkynes, in ethanol–triethylamine with a Ru catalyst, to give

primarily the *Markovnikov* vinyl silane.⁷⁸⁶ However, Et₃SiH adds to terminal alkynes with a Rh⁷⁸⁷ or a Pt⁷⁸⁸ catalyst to give the *anti-Markovnikov* vinyl silane. Using a 0.5 molar equivalent of HfClO₄ with alkynes bearing a dimethylphenylsilyl unit gave a cyclic vinyl silane with transfer of the phenyl group to carbon (see **73**).⁷⁸⁹

Silanes add to alkenes under radical conditions (using AIBN) with high *anti-Markovnikov* selectivity.⁷⁹⁰ An alternative route to alkylsilanes reacted an alkene with Li metal in the presence of 3 equiv of chlorotrimethylsilane, giving bis-1,2-trimethylsilyl compounds after treatment with water.⁷⁹¹ Silanes also add to alkenes to form the *anti-Markovnikov* alkylsilane (R₃Si—C—C—R') in the presence of a hyponitrite.⁷⁹²

In a reaction more related to those in Reaction **15-24**, vinyl silanes add to conjugated carbonyl compounds in the presence of a Ru catalyst,⁷⁹³ or to acrylonitriles with a Co catalyst.⁷⁹⁴ Silyl phosphines react with conjugated ynones directly to give an enone with an α -trimethylsilyl and a β -phosphine group.⁷⁹⁵ Siloxanes of the type (RO)₃SiH add to the α -carbon of enamines in the presence of a dirhodium catalyst.⁷⁹⁶ The uncatalyzed reaction of trimethylsilyl cyanide and ynamines, however, gave an enamine with a β -trimethylsilyl and an α -cyano group.⁷⁹⁷

bis(Silanes) add to alkylidene malonate derivatives (see Reaction **15-24**) in the presence of a Cu catalyst to give β -silyl malonates [RCH(SiR₃)CH(CO₂Me)₂].⁷⁹⁸ Alkylsilane units add using bis(trialkylsilyl)zinc reagents with a CuCN catalyst.⁷⁹⁹ Trimethylsilyl cyanide (Me₃SiCN) adds a cyano group to α,β -unsaturated amines with a specialized Al(salen)-Y catalyst.⁸⁰⁰

With certain substrates, alkenes can be dimerized by acid catalysts, so that the product is a dimer that contains one double bond.⁸⁰¹ A catalyst comprised of a combination of Zn and a CoCl_2 accomplished this type of coupling.⁸⁰² One alkene adds to another in the presence of a Ni catalyst.⁸⁰³ α -Alkenes add to dienes in a 1,4-manner in the presence of an Fe catalyst.⁸⁰⁴

This reaction is more often carried out internally, as in the formation of cyclohexene (**74**). A Pd catalyzed cyclization is known, in which dienes are converted to cyclopentene derivatives (e.g., **75**).⁸⁰⁵

Ring-forming reactions are possible. A Ru catalyzed version of this reaction gave the five-membered ring with an exocyclic double bond.⁸⁰⁶ Carbocyclization of an alkene unit to another alkene unit was reported using a Y,⁸⁰⁷ or a Ti catalyst.⁸⁰⁸ In some cases, internal coupling of two alkenes can form larger rings.⁸⁰⁹ Carbocyclization was reported using Pd,⁸¹⁰ Rh,⁸¹¹ Ru,⁸¹² Ir,⁸¹³ or a Zr catalyst.⁸¹⁴ Alkene allene substrates were cyclized to form cyclic products with an exocyclic double bond using a Pd catalyst.⁸¹⁵ An interesting variation adds a silyl enol ether to an alkyne using GaCl_3 to give an unconjugated ketone ($\text{O}=\text{C}-\text{C}=\text{C}=\text{C}$).⁸¹⁶ Alkenes and alkynes can also add to each other to give cyclic products in other ways (see Reaction **15-63** and **15-65**).

Processes of this kind are important in the biosynthesis of steroids and tetra- and pentacyclic terpenes. For example, squalene 2,3-oxide is converted by enzymatic catalysis to dammaradienol. The squalene \rightarrow lanosterol biosynthesis, which is a key step in the biosynthesis of cholesterol, is similar. The idea that the biosynthesis of

such compounds involves this type of multiple ring closing was proposed in 1955 and is known as the *Stork–Eschenmoser hypothesis*.⁸¹⁷ Such reactions can also be carried out in the laboratory, without enzymes.⁸¹⁸ By putting cation-stabilizing groups at positions at which positive charges develop, Johnson and co-workers⁸¹⁹ have been able to close as many as four rings stereoselectively and in high yield, in one operation. An example is formation of **76**,⁸²⁰ by what is known as the *Johnson polyene cyclization*.⁸²¹ Lewis acids can be used to initiate this cyclization,⁸²² including EtAlCl_2 used for the coupling of an alkyne and an alkene.⁸²³ A Pd catalyst has been used for a similar cyclization reaction.⁸²⁴ A radical cyclization approach (Reaction 15-30) to polyene cyclization using a seleno-ester anchor gave a tetracyclic system.⁸²⁵

The addition of alkenes to alkenes⁸²⁶ can also be mediated by bases.⁸²⁷ Coupling reactions can occur using transition metal catalyst systems⁸²⁸ (e.g., alkylaluminum

compounds, known as *Ziegler catalysts*),⁸²⁹ Rh,⁸³⁰ Fe,⁸³¹ or Ni⁸³² catalysts. The 1,4-addition of alkenes to conjugated dienes to give nonconjugated dienes⁸³³ occurs with various transition metal catalysts, as does the dimerization of 1,3-butadienes to octatrienes.⁸³⁴ A

molecule containing two distal conjugated diene units was cyclized to give a bicyclic molecule with an exocyclic double bond using a Pd catalyst.⁸³⁵ A Ni catalyst converted a similar system to a saturated five-membered ring containing an allylic and a vinyl group.⁸³⁶ Ethylene adds to alkenes to form a new alkene in the presence of a Ni⁸³⁷ or a Zr catalyst,⁸³⁸ and to alkynes in the presence of a Ru catalyst⁸³⁹ to form a diene. Allenes add to alkynes to give a diene with a Ti catalyst.⁸⁴⁰

In the presence of cuprous chloride and ammonium chloride, acetylene undergoes self-coupling to give vinylacetylene. Alkynes are coupled to dienes to give enynes in the presence of a Ni catalyst.⁸⁴¹

Another type of alkyne dimerization is the reductive coupling in which two molecules of alkyne, the same or different, give a 1,3-diene, as shown.⁸⁴² In this method, one alkyne is treated with *Schwartz's reagent* (see Reaction 15-17) to produce a vinylic zirconium intermediate. Addition of MeLi or MeMgBr, followed by the second alkyne, gives another intermediate, which, when treated with aq acid, gives the diene in moderate-to-good yields.⁸⁴³ If the second intermediate is treated with I₂ instead of aq acid, the 1,4-diiodo-1,3-diene is obtained, in comparable yield and isomeric purity. The reaction of an alkyne with a *Grignard reagent*, followed by an Fe complex and then an alkene leads to enynes.⁸⁴⁴ A Rh catalyzed coupling reaction of alkenes and electron-deficient internal alkynes leads to 1,3-dienes.⁸⁴⁵ A combination of Zr and Cr reagents allows the coupling of alkynes to form

linear polyenes.⁸⁴⁶ Alkynes can also be coupled to allylic silyl ethers with a Ru catalyst to give dienes.⁸⁴⁷ Other alkyne–allylic coupling reactions are known to give dienes.⁸⁴⁸

This reaction can also be done intramolecularly, as in the cyclization of diyne **77** to (*E*, *E*)-exocyclic dienes (**78**) by treatment with a Zr,⁸⁴⁹ Rh,⁸⁵⁰ Ru,⁸⁵¹ Au,⁸⁵² or Pt complex.⁸⁵³ A similar reaction was reported using a Ti catalyst from a diyne amide.⁸⁵⁴ Rings of four, five, and six members were obtained in high yield; seven-membered rings in lower yield. When the reaction is applied to enynes, compounds similar to **78** are formed using various catalysts, but with only one double bond⁸⁵⁵ Larger rings can be formed from the appropriate enyne, including forming cyclohexadiene compounds.⁸⁵⁶ Spirocyclic compounds can be prepared from enynes in this manner using formic acid and a Pd catalyst.⁸⁵⁷

The Rh catalyzed cyclization of 1,6-enynes, triggered by arylboronic acids, leads to rings with an exocyclic alkylidene group.⁸⁵⁸ Alkynes are coupled to give enynes using Ni,⁸⁵⁹ Pd,⁸⁶⁰ Lu,⁸⁶¹ and Ru⁸⁶² catalysts. Similar products are obtained by cross-coupling terminal alkynes with an allene, using a combination of Pd and CuI catalysts.⁸⁶³ The reaction has been carried out internally to convert diynes to large-ring cycloalkynes with an exocyclic double bond.⁸⁶⁴ Dienes have also been cyclized to form cyclic enynes (an endocyclic double bond) using a diruthenium catalyst with ammonium tetrafluoroborate in methanol.⁸⁶⁵ Enynes are similarly cyclized to cyclic alkenes with an endocyclic

C=C unit using a dicobalt catalyst.⁸⁶⁶

Enynes can also be converted to cyclic and bicyclic compounds using a Au⁸⁶⁷ Rh,⁸⁶⁸ Fe,⁸⁶⁹ or Pd⁸⁷⁰ catalyst. Enynes having a conjugated alkene unit also undergo this reaction in the presence of ZnBr₂.⁸⁷¹ Using mercury(II) triflate in water, cyclization leads to five-membered rings having an exocyclic double bond, and a pendant alcohol group.⁸⁷² Enynes give cyclic compounds with an endocyclic double bond conjugated to another alkene unit (a conjugated diene) when treated with GaCl₃⁸⁷³ or a Pt catalyst in an ionic liquid.⁸⁷⁴ Allene–alkenes give a similar product with a Pd⁸⁷⁵ or a Ru catalyst,⁸⁷⁶ as do alkyne–allenes with a dirhodium catalyst.⁸⁷⁷

There are many useful variations. Internal coupling of an alkyne with a vinyl halide, using triethylsilane and a Pd catalyst, gave the saturated cyclic compound with two adjacent exocyclic double bonds (a 2,3-disubstituted diene).⁸⁷⁸ Alkynes are added to propargyl acetates using Pd catalyst to give an alkyne–allene.⁸⁷⁹ Alkyne–alkenes were formed by coupling terminal alkynes and allenes in the presence of a Pd catalyst.⁸⁸⁰ An alkyne was coupled internally to give an allene using a Pd catalyst, to give a product that has an exocyclic methylene group and a vinyltin derivative.⁸⁸¹ A similar process occurred with RhCl(PPh₃)₃ to incorporate a vinyl chloride.⁸⁸² Allene–allylic halide systems reacted with phenylboronic acid and a Pd catalyst to give cyclopentane rings with two pendant vinyl groups, one of which contained a phenyl group.⁸⁸³

15-21 Addition of Organometallics to Double and Triple Bonds Not Conjugated to Carbonyls

Hydro-alkyl-addition

Neither *Grignard reagents* nor lithium dialkylcopper reagents generally add to ordinary C=C double bonds in the absence of a transition metal catalyst.⁸⁸⁴ *Grignard reagents* usually add only to double bonds susceptible to nucleophilic attack (e.g., fluoroalkenes and tetracyanoethylene).⁸⁸⁵ However, active *Grignard reagents* (benzylic, allylic) also add to the double bonds of allylic amines,⁸⁸⁶ and of allylic and homoallylic alcohols,⁸⁸⁷ as well as to the triple bonds of propargyl alcohols and certain other alkynols.⁸⁸⁸ Transition metal complexes facilitate the addition of *Grignard reagents* to alkenes. Examples include Ti,⁸⁸⁹ Mn,⁸⁹⁰ Zr,⁸⁹¹ Ni,⁸⁹² Fe,⁸⁹³ and Cu compounds.⁸⁹⁴ Cyclopropenes are an exception, and an excess of a Grignard reagent will add at low temperatures.⁸⁹⁵ Cyclopropene derivatives also react with CuI and then allyl bromide.⁸⁹⁶

Benzylic alkenes react with silylmethyl *Grignard reagents* in the presence of oxygen.⁸⁹⁷ It is likely that cyclic intermediates are involved in these cases, in which the Mg coordinates with the heteroatom. Allylic, benzylic, and tertiary alkyl *Grignard reagents* also add to 1-alkenes and strained internal alkenes (e.g., norbornene), if the reaction is carried out in a hydrocarbon solvent (e.g., pentane) rather than ether, or in the alkene itself as solvent, heated, under pressure if necessary, to 60–130 °C.⁸⁹⁸ Yields are variable.

Intramolecular addition of RMgX to completely unactivated double and triple bonds has been demonstrated.⁸⁹⁹ The reaction of tosylates bearing a remote alkene unit and a *Grignard reagent* leads to cyclization when a Zr catalyst is used.⁹⁰⁰ The intramolecular

addition of a CH_2Br unit to the $\text{C}=\text{C}$ unit of an allylic ether was accomplished using PhMgBr and a Co catalyst, give a functionalized THF and incorporation of the phenyl group on the $\text{C}=\text{C}$ unit as well.⁹⁰¹

In a useful variation, vinyl epoxides react with *Grignard reagents* and CuBr to give an allylic alcohol via reaction at the $\text{C}=\text{C}$ unit and concomitant opening of the epoxide.⁹⁰² Conjugated dienes react with arylmagnesium halides, Ph_3SiCl , and a Pd catalyst to give a coupling product involving the reaction of 2 equiv of the diene and incorporation of two SiPh_3 units.⁹⁰³ The Cr catalyzed formation of arylmagnesium compounds⁹⁰⁴ and the Rh catalyzed hydroarylation⁹⁰⁵ of alkynes are also known. The Pd catalyzed hydroarylation⁹⁰⁶ of alkynes is possible using arenediazonium salts⁹⁰⁷ as substrates or hydroarylation of 1,3-dienes with boronic acids.⁹⁰⁸

Organolithium reagents (primary, secondary, and tertiary alkyl and in some cases aryl) add to the double and triple bonds of allylic and propargylic alcohols,⁹⁰⁹ (tetramethylethylenediamine is a catalyst) and also to certain other alkenes containing hetero groups (e.g., OR, NR_2 , or SR). Mixing an organolithium reagent with transition metal compounds [e.g., CeCl_3 ⁹¹⁰ or $\text{Fe}(\text{acac})_3$]⁹¹¹ leads to addition of the alkyl group. Cyclopropane derivatives have been formed in this manner.⁹¹² The organolithium reagents can contain heteroatoms (e.g., nitrogen) elsewhere in the molecule, and the organolithium species can be generated from an intermediate organotin derivative.⁹¹³ Organolithium reagents add to the less substituted $\text{C}=\text{C}$ unit of conjugated dienes.⁹¹⁴ Addition of butyllithium to alkenes has been observed with good enantioselectivity when sparteine was added.⁹¹⁵

The intramolecular addition of RLi and R_2CuLi has been reported.⁹¹⁶ Organolithium reagents containing an alkene⁹¹⁷ or alkyne⁹¹⁸ unit cyclize⁹¹⁹ at low temperatures and

⁹¹⁹ A conformational radical clock has been developed to evaluate organolithium-mediated cyclization reactions. See Rychnovsky, S.D.; Hata, T.; Kim, A.I.; Buckmelter, A.J. *Org. Lett.* **2001**, *3*, 807.

quenching with methanol replaces the new C—Li bond with C—H. Tandem cyclization is possible with dienes and enynes to form more than one ring,⁹²⁰ including bicyclic compounds.⁹²¹ Tandem cyclization is possible with alkyne iodides⁹²² or alkynes with a homoallylic CH₂Li unit.⁹²³ The organolithium compound can be generated *in situ* by reaction of an organotin compound with butyllithium, allowing cyclization to occur upon treatment with an excess of LiCl.⁹²⁴

Unactivated alkenes or alkynes⁹²⁵ react with other organometallic compounds under certain conditions. The Pt catalyzed addition to alkynes leads to functionalized alkenes.⁹²⁶ Phenylboronic acids add to alkynes in the presence of a Co⁹²⁷ or a Pd catalyst.⁹²⁸ Trimethylaluminum reacts with 4-methyl-1-pentene, in the presence of Cl₂ZrCp₂, for example, and subsequent reaction with molecular oxygen leads to (2*R*),4-dimethyl-1-pentanol in good yield and 74% ee.⁹²⁹ These reagents also add to alkynes.⁹³⁰ Ruthenium catalysts have been used to mediate the addition of allylic alcohols to alkynes.⁹³¹ Samarium iodide (SmI₂) induces cyclization of a halide moiety to an alkyne unit⁹³² or an alkene unit⁹³³ to form cyclized products. Copper complexes can catalyze similar cyclization to alkenes, even when an ester unit is present in the molecule.⁹³⁴ Allyl manganese compounds add to allenes to give nonconjugated dienes.⁹³⁵

Organomanganese reagents add to alkenes.⁹³⁶ Manganese triacetate [Mn(OAc)₃], in the presence of cupric acetate, facilitates intramolecular cyclization of a halide unit to an alkene.⁹³⁷ Alkynes react with In reagents [e.g., (allyl)₃In₂I₃] to form dienes (allyl substituted alkenes from the alkyne).⁹³⁸ Allylic halides add to propargyl alcohols using In metal to form the aryl organometallic *in situ*.⁹³⁹ Allyltin reagents add to alkynes in a similar manner in the presence of ZrCl₄.⁹⁴⁰ Alkylzinc reagents add to alkynes to give substituted alkenes in the presence of a Pd catalyst.⁹⁴¹ Allylzinc reagents add to alkynes in

the presence of a Co catalyst.⁹⁴² A vinyltellurium reagent adds to alkynes in the presence of CuI/PdCl₂.⁹⁴³

Ketones with an α -hydrogen add to alkenes intramolecularly when heated in a sealed tube with CuCl₂ and a Pd catalyst.⁹⁴⁴ A similar reaction was reported using Yb(OTf)₃ and a Pd catalyst⁹⁴⁵ or an In catalyst.⁹⁴⁶ Keto esters add to alkynes using 10% benzoic acid and a Pd catalyst,⁹⁴⁷ or an In catalyst.⁹⁴⁸ 1,3-Diketones add to dienes (1,4-addition) using a Pd catalyst,⁹⁴⁹ a AuCl₃/AgOTf catalyst,⁹⁵⁰ and this addition has been done intramolecularly using 2.4 molar equivalents of CuCl₂ and a Pd catalyst.⁹⁵¹ The intermolecular addition of diesters (e.g., malonates) to alkynes was accomplished in acetic acid and a Pd catalyst under microwave irradiation.⁹⁵² The enolate anion derived from the reaction of a nitrile with potassium *tert*-butoxide added to the less substituted carbon of the C=C unit of styrene in DMSO.⁹⁵³ Silyl enol ethers add to alkynes using a W catalyst.⁹⁵⁴ Malonate derivatives add to alkenes in the presence of an Al(OR)₃ catalyst.⁹⁵⁵ 1,3-Dicarbonyl compounds add to allenes in the presence of a Pd catalyst.⁹⁵⁶

Aryl iodides add to alkynes using a Pt complex in conjunction with a Pd catalyst.⁹⁵⁷ A Pd catalyst has been used alone for the same purpose,⁹⁵⁸ and the intramolecular addition of a arene to an alkene was accomplished with a Pd⁹⁵⁹ or a GaCl₃ catalyst.⁹⁶⁰ Alkyl iodides add intramolecularly to alkenes with a Ti catalyst,⁹⁶¹ or to alkynes using In metal and additives.⁹⁶² The latter cyclization of aryl iodides to alkenes was accomplished with In and I₂⁹⁶³ or with SmI₂.⁹⁶⁴

Aromatic hydrocarbons (e.g., benzene) add to alkenes using a Ru catalyst⁹⁶⁵ a catalytic mixture of AuCl₃/AgSbF₆,⁹⁶⁶ or a Rh catalyst,⁹⁶⁷ and Ru complexes catalyze the addition

of heteroaromatic compounds (e.g., pyridine) to alkynes.⁹⁶⁸ Such alkylation reactions are clearly reminiscent of the *Friedel–Crafts* reaction (**11-11**). Palladium catalysts can also be used for the addition of aromatic compounds to alkynes,⁹⁶⁹ and Rh catalysts for addition to alkenes (with microwave irradiation).⁹⁷⁰ Note that vinylidene cyclopropanes react with furans and a Pd catalyst to give allylically substituted furans.⁹⁷¹

Arylboronic acids (see Reaction **13-13**) add to alkynes to give the substituted alkene using a Rh catalyst.⁹⁷² Allenes react with phenylboronic acid and an aryl iodide, in the presence of a Pd catalyst, to give a substituted alkene.⁹⁷³ 2-Bromo-1,6-dienes react with phenylboronic acid with a Pd catalyst to give a cyclopentane with an exocyclic double bond and a benzyl substituent.⁹⁷⁴

An indirect addition converts alkynes to an organozinc compound using a Pd catalyst, which then reacts with allylic halides.⁹⁷⁵ Similarly, the reaction of an alkyne with $\text{Ti}(\text{O}i\text{Pr})_4/2$ $i\text{PrMgCl}$ followed by addition of an alkyne leads to a conjugated diene.⁹⁷⁶

OS 81, 121.

15-22 The Addition of Two Alkyl Groups to an Alkyne

Dialkyl-addition

Two different alkyl groups can be added to a terminal alkyne⁹⁷⁷ in one laboratory step by treatment with an alkylcopper–magnesium bromide reagent (called *Normant reagents*)⁹⁷⁸ and an alkyl iodide in ether–HMPA containing triethylphosphite.⁹⁷⁹ The groups add stereoselectively syn. The reaction, which has been applied to primary⁹⁸⁰ R^1 and to primary, allylic, benzylic, vinylic, and α -alkoxyalkyl R^1 , involves initial addition of an intermediate alkylcopper reagent,⁹⁸¹ followed by a coupling reaction (**10-57**):

Acetylene itself ($\text{R}=\text{H}$) undergoes the reaction with R_2CuLi instead of the *Normant reagent*.⁹⁸² The use of R' containing functional groups has been reported.⁹⁸³ If the alkyl iodide is omitted, the vinylic copper intermediate (**79**) can be converted to a carboxylic acid by the addition of CO_2 (see Reaction **16-30**) or to an amide by the addition of an isocyanate, in either case in the presence of HMPA and a catalytic amount of triethyl phosphite.⁹⁸⁴ The use of I_2 results in a vinylic iodide.⁹⁸⁵

Similar reactions, in which two alkyl groups are added to a triple bond, have been carried out with trialkylalanes (R_3Al) and zirconium complexes as catalysts.⁹⁸⁶ Internal alkynes undergo bis(allylation) using a Ni catalysts and triallylindium.⁹⁸⁷ Allyl ethers and iodobenzene have also been added using a Zr complex.⁹⁸⁸ Similarly, allyl ethers and allyl chlorides have been added.⁹⁸⁹

Arylboronic acids (see Reaction **13-13**) react with alkynes and 1 equiv of an aryl iodide, with a Pd catalyst, to add two aryl groups across the triple bond.⁹⁹⁰

OS VII, 236, 245, 290.

15-23 The Ene Reaction

Hydro-allyl-addition

An interesting addition of RH to a double bond involves the reaction of alkenes with an alkene having an allylic hydrogen (**80**), and is called the *ene reaction* or the *ene synthesis*.⁹⁹¹ The reaction proceeds without a catalyst, but one of the components must

be a reactive dienophile (reacts with a diene; see Reaction **15-60** for a definition of this word), such as maleic anhydride, but the other (which supplies the hydrogen) may be a simple alkene (e.g., propene) as long as there is an allylic hydrogen atom. Rather high reaction temperatures (250–450 °C) are common unless the substrates are very activated, but steric acceleration of the uncatalyzed ene reaction is known.⁹⁹² The reaction is compatible with a variety of functional groups that can be appended to the ene and dienophile. N,N-Diallyl amides give an ene cyclization, for example.⁹⁹³ There has been much discussion of the mechanism of this reaction, and both concerted pericyclic (as shown above) and stepwise mechanisms have been suggested. The mechanism of the ene reaction of singlet (¹Δ_g) oxygen with simple alkenes was found to involve two steps, with no intermediate.⁹⁹⁴ A retro-ene reaction is known with allylic dithiocarbonate.⁹⁹⁵ An intramolecular ene reaction between oxazolones and enol ethers leads to functionalized oxazolones.⁹⁹⁶ The reaction between maleic anhydride and optically active PhCHMeCH=CH₂ gave an optically active product (**81**),⁹⁹⁷ which is strong evidence for a concerted rather than a stepwise mechanism.⁹⁹⁸ The reaction can be highly stereoselective.⁹⁹⁹

The reaction can be extended to less-reactive enophiles by the use of Lewis acid catalysts, especially alkylaluminum halides.¹⁰⁰⁰ Titanium catalysts,¹⁰⁰¹ Sc,¹⁰⁰² LiClO₄,¹⁰⁰³ Y,¹⁰⁰⁴ In,¹⁰⁰⁵ Pd,¹⁰⁰⁶ Co,¹⁰⁰⁷ Ni catalysts,¹⁰⁰⁸ as well as a combination of Ag and Au catalysts¹⁰⁰⁹ have also been used. A magnesium–ene cyclization stereochemically directed by an allylic oxyanionic group has been reported.¹⁰¹⁰ The Lewis acid catalyzed reaction

been reported.¹⁰⁷⁸ Cyanide ion adds to *Michael* acceptors, and TMSCN also adds in a *Michael* reaction.¹⁰⁷⁹

Intramolecular versions of *Michael* addition are known.¹⁰⁸⁰ The intramolecular *Michael* addition of an α -chloro ketone enolate anion, formed *in situ* using DABCO, leads to formation of a bicyclo[4.1.0] diketone.¹⁰⁸¹

An important cyclization procedure involves the acid-catalyzed addition of diene-ketones (e.g., **82**), where one conjugated alkene adds to the other conjugated alkene to form cyclopentenones (**83**). This is called the *Nazarov cyclization*.¹⁰⁸² While it may be categorized in Reaction 15-20 because one alkene unit adds to another, the addition is formally a *Michael* addition, and so is placed here. Structural variations are possible that prepare a variety of cyclopentenones. The steric influence of substituents has been discussed,¹⁰⁸³ and the rate-accelerating influence observed in N- and S-heterocycles.¹⁰⁸⁴ Substituents on the C=C units lead to cyclopentenones that bear those substituents. Gold¹⁰⁸⁵ and V catalyzed¹⁰⁸⁶ cyclizations have been reported, as well as a Sc catalyzed cyclization in water.¹⁰⁸⁷ Heating dienones in DME or an ionic liquid has been shown to give the *Nazarov* product without addition of a Lewis acid.¹⁰⁸⁸ Allenes participate in *Nazarov cyclization* reactions.¹⁰⁸⁹ A vinylogous *Nazarov* reaction is involved in the cyclization of cross-conjugated trienes¹⁰⁹⁰ (see Sec. 6.B for vinylogy). The use of a chiral ligand gave the cyclopentenone with modest enantioselectivity.¹⁰⁹¹ Reductive cyclization can also give the nonconjugated five-membered ring.¹⁰⁹² Note that a *retro-Nazarov* is possible with α -bromocyclopentanones.¹⁰⁹³ In one variation using an Al complex, a

cyclohexenone was formed.¹⁰⁹⁴ There is a so-called interrupted *Nazarov*, in which an amine is trapped after cyclization to give an α -amino conjugated cyclopentenone.¹⁰⁹⁵ Spirocycles have been prepared via a tandem *Nazarov–Wagner–Meerwein* sequence.¹⁰⁹⁶

In a *Michael reaction* with suitably different R groups, two new stereogenic centers may be created (see **84**). In a diastereoselective process, one of the two pairs is formed exclusively or predominantly as a racemic mixture.¹⁰⁹⁷ When either or both of the reaction components have a chiral substituent, the reaction can be enantioselective (only one of the four diastereomers formed predominantly).¹⁰⁹⁸ There are many examples of catalytic enantioselective Michael additions,¹⁰⁹⁹ often by the use of a chiral catalyst¹¹⁰⁰ or by using optically active enamines instead of enolates.¹¹⁰¹ Common chiral catalysts used with carbonyl substrates include Ru,¹¹⁰² Ni,¹¹⁰³ Sr,¹¹⁰⁴ and Al(salen) complexes.¹¹⁰⁵ Chiral organocatalysts¹¹⁰⁶ (e.g., oxazolidinones)¹¹⁰⁷ have been developed and chiral imines have also been used.¹¹⁰⁸ Certain antibodies have been used to facilitate chiral, intramolecular *Michael addition* reactions.¹¹⁰⁹ Enzymes have been used as for asymmetric *Michael reactions*.¹¹¹⁰ Addition of chiral additives to the reaction (e.g., metal–salen complexes,¹¹¹¹ proline derivatives,¹¹¹² or (–)-sparteine¹¹¹³) lead to product formation with good-to-excellent asymmetric induction. Ultrasound has been used to promote

asymmetric *Michael reactions*.¹¹¹⁴ In reactions of enolate anions, both the enolate anion and substrate can exist as (*Z*) or (*E*) isomers. With enolates derived from ketones or carboxylic esters, the (*E*) enolates gave the syn pair of enantiomers (Sec. 4.G), while (*Z*) enolates gave the anti pair.¹¹¹⁵

When the substrate contains *gem-Z* groups, (e.g., **86**), bulky groups can be added, if the reaction is carried out under aprotic conditions. For example, addition of enolate **85** to **86** gave **87** in which two adjacent quaternary centers have been formed.¹¹¹⁶

In certain cases, *Michael reactions* can take place under acidic conditions.¹¹¹⁷ *Michael-type* addition of radicals to conjugated carbonyl compounds is also known.¹¹¹⁸ Radical addition can be catalyzed by Yb(OTf)₃,¹¹¹⁹ but radicals add under standard conditions as well, even intramolecularly.¹¹²⁰ Electrochemical-initiated *Michael* additions are known.

Alkynes are reactive, and *Michael reactions* are sometimes applied to substrates of the type C≡C–Z, where the coproducts are conjugated systems of the type C=C–Z.¹¹²¹ Terminal alkynes add to conjugated systems.¹¹²² Due to the greater susceptibility of triple bonds to nucleophilic attack, it is even possible for nonactivated alkynes (e.g., acetylene), to be substrates in this reaction.¹¹²³

Silyl enol ethers (e.g., **88**) add to α,β-unsaturated ketones and esters when catalyzed¹¹²⁴ by TiCl₄¹¹²⁵ or InCl₃.¹¹²⁶ Aluminum compounds also catalyze this reaction¹¹²⁷ and the reaction has been done in neat tri-*n*-propylaluminum.¹¹²⁸ A solid-state version of the reaction used alumina•ZnCl₂.¹¹²⁹ Tin-enolates have been used.¹¹³⁰ This reaction has been performed with good diastereoselectivity,¹¹³¹ and silyl enol ethers have been used

15-25 1,4-Addition of Organocuprates and Other Organometallic Compounds to Activated Double Bonds

Hydro-alkyl-addition

Lithium dialkylcopper reagents (R_2CuLi reagents,¹¹³³ also known as *Gilman reagents*, see Reaction **10-57**) add to α,β -unsaturated aldehydes¹¹³⁴ and ketones ($\text{R}' = \text{H}, \text{R}, \text{Ar}$) and other systems of the form $\text{C}\equiv\text{C}-\text{C}=\text{O}$ ¹¹³⁵ to give conjugate addition products¹¹³⁶ in a reaction closely related to the *Michael reaction*. α,β -Unsaturated esters are less reactive,¹¹³⁷ and the corresponding acids do not react at all. The R group can be primary alkyl, vinylic,¹¹³⁸ or aryl. If Me_3SiCl is present, the reaction takes place much faster and in higher yield; in the example given, the product is the silyl enol ether of **89** (see Reaction **12-17**).¹¹³⁹ The use of Me_3SiCl also permits good yields with allylic R groups.¹¹⁴⁰ Conjugated alkynyl-ketones also react via 1,4-addition to give substituted alkenyl-ketones.¹¹⁴¹ Solvent effects are important for the reactivity of organocuprates,¹¹⁴² which

influence aggregation and aggregation state of the dialkyl cuprate.¹¹⁴³ Organocuprate reactions have been shown to undergo oscillations in complexation.¹¹⁴⁴

An excess of the cuprate reagent relative to the conjugated substrate is often required. In general, only one of the R groups of R_2CuLi adds to the substrate; the other is wasted with respect to the conjugated substrate. This can be a limitation where the precursor (RLi or RCu, see Reaction 12-36) is expensive or available in limited amounts, particularly if an excess of the reagent is required. The difficulty of group transfer can be overcome by using one of the mixed reagents $[R(R'C\equiv C)CuLi]$,¹¹⁴⁵ $R(O-t-Bu)CuLi$,¹¹⁴⁶ $R(PhS)CuLi$ ¹¹⁴⁷ each of which transfers only the R group. Mixed reagents are easily prepared by the reaction of RLi with $R'C\equiv CCu$ ($R' = n-Pr$ or $t-Bu$), $t-BuOCu$, or $PhSCu$, respectively. A further advantage of the mixed reagents is that good yields of addition product are achieved when R is tertiary, so that use of one of them permits the introduction of a tertiary alkyl group. The mixed reagents $R(CN)CuLi$ ¹¹⁴⁸ (prepared from RLi and CuCN) and $R_2Cu(CN)Li_2$ ¹¹⁴⁹ also selectively transfer the R group.¹¹⁵⁰ With mixed cuprates, one of the ligands may be less prone to transfer than the other, as $R(R'Se)Cu(CN)Li_2$, leading to selective transfer of the R group.¹¹⁵¹ This less transferable ligand is sometimes referred to as a “dummy ligand”. The selectivity of ligand transfer depends on two factors, thermodynamics of groups (e.g., alkyl or thioalkyl) and kinetic reactivity of groups (e.g., silylalkyl or vinyl).¹¹⁵² The selectivity arises in the Cu(III) intermediate formed by complexation of the cuprate and the unsaturated carbonyl compound.^{1150,1153} A Cu(III) complex has been detected using rapid injection NMR.¹¹⁵⁴

Various functional groups (e.g., OH and unconjugated C=O groups) may be present in the substrate when organocuprates are employed.¹¹⁵⁵ There is generally little or no competition from 1,2-addition (to the C=O). However, when R is allylic, 1,4-addition is observed with some substrates and 1,2-addition with others.¹¹⁵⁶ The R_2CuLi group also adds to α,β -unsaturated sulfones,¹¹⁵⁷ but not to simple α,β -unsaturated nitriles.¹¹⁵⁸ Organocopper reagents (RCu) as well as certain R_2CuLi add to α,β -unsaturated and acetylenic sulfoxides.¹¹⁵⁹ The reaction has been carried out¹¹⁶⁰ with α,β -acetylenic ketones,¹¹⁶¹ esters, and nitriles. Conjugate addition to α,β -unsaturated and acetylenic

acids and esters, as well as ketones, can be achieved by the use of the coordinated reagents $\text{RCu} \cdot \text{BF}_3$ (R = primary).¹¹⁶² Amine units have been transferred using α -lithio amides, CuCN , and various additives, which gave conjugate addition of an amidomethyl unit [$-\text{CH}_2\text{N}(\text{Me})\text{Boc}$].¹¹⁶³ Other amino-cuprates are known to give conjugate addition reactions.¹¹⁶⁴

Conjugate addition of the cuprate to the α,β -unsaturated ketone leads to an enolate ion (**89**), as noted above. It is possible for this enolate anion to react with an electrophilic species (*tandem vicinal difunctionalization*), in some cases at the O and in other cases at the C.¹¹⁶⁵ For example, if an alkyl halide R^2X is present (R^2 = primary alkyl or allylic), the enolate (**89**) can be alkylated directly to give **90**.¹¹⁶⁶ Thus, by this method, both the α and β positions of a ketone are alkylated in one synthetic operation (see also, Reaction **15-22**).

As with the *Michael reaction* (**15-24**) the 1,4-addition of organometallic compounds has been performed diastereoselectively¹¹⁶⁷ and enantioselectively.¹¹⁶⁸ The influence of solvent and additives on yield and selectivity has been examined.¹¹⁶⁹ Addition of chiral ligands to the organocuprate conjugate addition reaction leads to alkylation with good-to-excellent enantioselectivity.¹¹⁷⁰ The conjugate addition of dimethyl cuprate in the presence of a chiral ligand (e.g., **91**) is an example.¹¹⁷¹ Chiral bis(oxazoline) copper catalysts have been used for the conjugate addition of indoles to α,β -unsaturated esters.¹¹⁷² In the presence of a chiral additive and a Cu catalyst, conjugate addition to trisubstituted cyclohexenones leads to the formation of stereogenic quaternary centers.¹¹⁷³ Enantioselectivity was improved by the addition of styrene in the conjugate addition reactions of

α -halo enones.¹¹⁷⁴ Enantioselectivity is effectively controlled by the choice of ligand and its interaction with the copper compound, where different ligands on the metal may lead to differences in selectivity.¹¹⁷⁵ Chiral templates have also been used with *Grignard reagents*, directly¹¹⁷⁶ and in the presence of AlMe_2Cl .¹¹⁷⁷

Other organometallic compounds add to conjugated systems. *Grignard reagents* add to conjugated substrates (e.g., α,β -unsaturated ketones, cyano-ketones,¹¹⁷⁸ esters, and nitriles),¹¹⁷⁹ but 1,2-addition may seriously compete.¹¹⁸⁰ The extent of 1,4-addition of *Grignard reagents* can be increased by the use of a Cu catalyst [e.g., CuCl and $\text{Cu}(\text{OAc})_2$],¹¹⁸¹ forming a magnesium cuprate *in situ*. Formation of the conjugate addition product is often controlled by steric factors. Thus **92** with phenylmagnesium bromide gives 100% 1,4-addition, while **93** gives 100% 1,2-addition. In general, substitution at the carbonyl group increases 1,4-addition, while substitution at the double bond increases 1,2-addition. In most cases, both products are obtained, but α,β -unsaturated *aldehydes* nearly always give exclusive 1,2-addition when treated with *Grignard reagents*. *Grignard reagents* mixed with CeCl_3 generates a reactive species that gives primarily 1,4-addition.¹¹⁸² It is likely that alkylcopper reagents, formed from RMgX and Cu^+ (cupric acetate is reduced to cuprous ion by excess RMgX), are the actual reactive species in these cases.¹¹³⁴ Alkylidene malonic ester derivatives [$\text{C}=\text{C}(\text{CO}_2\text{R})$] increase the facility of 1,4-addition with the two electron-withdrawing groups.¹¹⁸³

A dialkyl copper–magnesium iodide complex ($\text{R}_2\text{Cu} \cdot \text{MgI}$) has been used for conjugate addition to chiral α,β -unsaturated amides.¹¹⁸⁴ Catalytic enantioselective conjugate addition has been reported with *Grignard reagents*.¹¹⁸⁵

Organolithium reagents¹¹⁸⁶ generally react with conjugated aldehydes, ketones, and esters by 1,2-addition,¹¹⁸⁷ but 1,4-addition was achieved with esters of the form

$\text{C}=\text{C}-\text{CO}_2\text{Ar}$, where Ar was a bulky group (e.g., 2,6-di-*tert*-butyl-4-methoxyphenyl).¹¹⁸⁸ Alkylolithium reagents can be made to give 1,4-addition with α,β -unsaturated ketones¹¹⁸⁹ and aldehydes,¹¹⁹⁰ if the reactions are conducted in the presence of HMPA.¹¹⁹¹ Among organolithium reagents that have been found to add 1,4 in this manner are 2-lithio-1,3-dithianes (see Reaction 10-71),¹¹⁹² vinylolithium reagents,¹¹⁹³ and α -lithio allylic amides.¹¹⁹⁴ Lithium-halogen exchange (12-22) generates an organolithium species that adds intramolecularly to conjugated esters to give cyclic and bicyclic products.¹¹⁹⁵ A reagent based on $\text{RMgX}-3\text{ MeLi}$ gave conjugate addition with α,β -unsaturated amides and carboxylic acid derivatives.¹¹⁹⁶ 1,4-Addition of alkylolithium reagents to α,β -unsaturated aldehydes can also be achieved by converting the aldehyde to a benzo-thiazole derivative (masking the aldehyde function),¹¹⁹⁷ from which the aldehyde group can be regenerated. α,β -Unsaturated nitro compounds undergo conjugate addition with aryllithium reagents, and subsequent treatment with acetic acid gives the α -aryl ketone.¹¹⁹⁸

If the organolithium reagent is complexed, 1,4-addition is more successful. The reaction of an aryllithium reagent with B(OMe)_3 , for example, led to a Rh catalyzed conjugate addition with excellent enantioselectivity when a chiral ligand was employed.¹¹⁹⁹ Allylic Te reagents that are treated with lithium diisopropyl amide and then conjugated esters give the 1,4-addition product, which cyclizes to form the corresponding cyclopropane derivative.¹²⁰⁰

Organozinc compounds add to conjugated systems, especially dialkyl zinc compounds (R_2Zn). Many dialkylzinc compounds can be used, including vinylzinc compounds.¹²⁰¹ The use of chiral ligands is effective for conjugate addition of dialkylzinc compounds to α,β -unsaturated ketones, esters, and so on,¹²⁰² including conjugated lactones.¹²⁰³ The addition of a chiral complex to dialkylzinc compounds leads to enantioselective conjugate addition in conjunction with Cu(OTf)_2 ¹²⁰⁴ CuCN ,¹²⁰⁵ or

phenylboronic acid and a Rh catalyst, leads to cyclic compounds.¹²²⁷ Lithium tetraalkylgallium reagents give 1,4-addition.¹²²⁸ Trimethyl(phenyl)tin and a Rh catalyst gives conjugate addition of a methyl group¹²²⁹ and tetraphenyltin and a Pd catalyst adds a phenyl group.¹²³⁰ Triphenylbismuth (Ph₃Bi) and a Rh catalyst give conjugate addition of the phenyl group upon exposure to air.¹²³¹ Similar reactivity is observed with a Pd catalyst in aqueous media.¹²³² Allyltin compounds add an allyl group in the presence of a Sc catalyst.¹²³³ Benzylic bromides add to conjugated nitriles using a 2:1 mixture of CrCl₃ and Mn metal.¹²³⁴ Aryl halides add in the presence of NiBr₂.¹²³⁵ Vinyl Zr complexes undergo conjugate addition when using a Rh catalyst.¹²³⁶

In certain cases, *Grignard reagents* add 1,4 to *aromatic* systems to give **94** after tautomerization (Sec. 2.N.i) of the initial formed enol.¹²³⁷ Such cyclohexadienes are easily oxidizable to benzenes (often by atmospheric oxygen), so this reaction becomes a method of alkylating and arylating suitably substituted (usually hindered) aryl ketones. A similar reaction has been reported for aromatic nitro compounds where 1,3,5-trinitrobenzene reacts with excess methylmagnesium halide to give 2,4,6-trinitro-1,3,5-trimethylcyclohexane.¹²³⁸

The mechanisms of most of these reactions are not well known. The 1,4-uncatalyzed *Grignard reaction* has been postulated to proceed by the cyclic mechanism shown, but there is evidence against it.¹²³⁹ The R₂CuLi¹²⁴⁰ and copper-catalyzed *Grignard additions* may

involve a number of mechanisms, since the actual attacking species and substrates are so diverse.¹²⁴¹ A free radical mechanism of some type (perhaps SET) has been suggested¹²⁴² although the fact that retention of configuration at R has been demonstrated in several cases completely rules out a free R[•] radical.¹²⁴³ For simple α,β -unsaturated ketones (e.g., 2-cyclohexenone and Me₂CuLi), there is evidence¹²⁴⁴ for this mechanism:

95 is a d, π^* complex, with bonding between copper, as a base supplying a pair of d electrons, and the enone as a Lewis acid using the π^* orbital of the allylic system.¹²⁴² The ¹³C NMR spectrum of an intermediate similar to **95** has been reported.¹²⁴⁵

15-26 The Sakurai Reaction

Allylic silanes (R₂C=CHCH₂SiMe₃) can be added to conjugated systems rather than silyl enol ethers in what is known as the *Sakurai reaction*.¹²⁴⁶ For example, an allyl group can be added to α,β -unsaturated carboxylic esters, amides and nitriles, with CH₂=CHCH₂SiMe₃ and F[−] ion (see Reaction **15-47**).¹²⁴⁷ This reagent gave better results than lithium diallylcuprate (Reaction **15-25**). Catalytic *Sakurai reactions* are known.¹²⁴⁸ The Pd catalyzed reaction of conjugated ketones with PhSi(OEt)₃ and SbCl₃ and Bu₄NF in acetic acid gave the 1,4-addition product.¹²⁴⁹ A similar reaction was reported using PhSi(OMe)₃ with a Rh catalyst.¹²⁵⁰ Silver fluoride was used to catalyze the reaction with allyl (trimethoxy)silane.¹²⁵¹ In a related reaction, Ph₂SiCl₂, NaF, and a Rh catalyst gives conjugate addition of a phenyl group to α,β -unsaturated ketones.¹²⁵² An interesting Rh catalyzed, conjugate addition of a phenyl group was reported using a siloxane polymer

bearing Si—Ph units.¹²⁵³ The *Sakurai reaction* has been used in multi-component reactions.¹²⁵⁴

15-27 Conjugate Addition of Boranes to Activated Double Bonds

Hydro-alkyl-addition (overall transformation)

Just as trialkylboranes add to simple alkenes (Reaction 15-16), they rapidly add to the double bonds of acrolein, methyl vinyl ketone, and certain related derivatives in THF to give enol borinates (also see Reaction 10-68), which can be hydrolyzed to aldehydes or ketones.¹²⁵⁵ If water is present in the reaction medium from the beginning, the reaction can be run in one laboratory step. Since the boranes can be prepared from alkenes (Reaction 15-16), this reaction provides a means of lengthening a carbon chain by three or four carbons, respectively. Compounds containing a terminal alkyl group [e.g., such as crotonaldehyde ($\text{CH}_3\text{CH}=\text{CHCHO}$) and 3-penten-2-one], fail to react under these conditions, as does acrylonitrile, but these compounds can be induced to react by the slow and controlled addition of O_2 or by initiation with peroxides or UV light.¹²⁵⁶ A disadvantage is that only one of the

three R groups of R_3B adds to the substrate, so that the other two are wasted. This difficulty is overcome by the use of a β -alkyl borinate (e.g., **96**),¹²⁵⁷ which can be prepared as shown. Borinate (**96**, $\text{R} = \text{tert-butyl}$) can be made by treatment of **96** ($\text{R} = \text{OMe}$) with *t*-BuLi. The use of this reagent permits *tert*-butyl groups to be added. β -1-Alkenyl-9-BBN compounds $\beta\text{-RCH}=\text{CR}'\text{-9-BBN}$ (prepared by treatment of alkynes with 9-BBN or of $\text{RCH}=\text{CR}'\text{Li}$ with β -methoxy-9-BBN¹²⁵⁸) add to methyl vinyl ketones to give, after hydrolysis, γ,δ -unsaturated ketones,¹²⁵⁹ although $\beta\text{-R-9-BBN}$, where $\text{R} = \text{a saturated group}$, are not useful here, because the R group of these reagents does not preferentially add to the substrate.¹²⁵³ Transition metals catalyze the addition of trialkylboranes to conjugated systems (e.g., the addition of allylboranes in the presence of a Ni catalyst).¹²⁶⁰ The Ni catalyzed addition was enhanced by the addition of methanol.¹²⁶¹

aryltrifluoroborates.¹²⁷⁹ The Rh catalyzed addition of vinyl tetrafluoroborates has been reported.¹²⁸⁰

In the presence of a Rh catalyst, LiBPh(OMe)₃ gave conjugate addition of the phenyl group to α,β -unsaturated esters.¹²⁸¹ The fact that these reactions are catalyzed by free radical initiators and inhibited by galvinoxyl¹²⁸² (a free radical inhibitor) indicates that free-radical mechanisms are involved.

15-28 Radical Addition to Activated Double Bonds

Hydro-alkyl-addition

In a reaction similar to **15-25**, alkyl groups can be added to alkenes activated by such groups as COR', CO₂R', CN, and even Ph.¹²⁸³ This is a radical addition reaction.¹²⁸⁴ In the method illustrated above, the R group comes from an alkyl halide (R = primary, secondary, or tertiary alkyl; X = Br or I) and the hydrogen from the tin hydride (H atom transfer agents). The reaction of tert-butyl bromide, Bu₃SnH and AIBN (Sec. 14.A.i), for example, adds a tert-butyl group to a conjugated ester via 1,4-addition.¹²⁸⁵ An alkene is converted to an alkylborane with catecholborane (Reaction **12-28**) and when treated with a conjugated ketone and O₂, radical conjugate addition leads to the β -substituted ketone.¹²⁸⁶ The Bu₃SnH can also be generated in situ, from R₃SnX and NaBH₄. Like Reaction **15-27**, these additions have free radical mechanisms. The reaction has been used for free radical cyclizations of the type discussed in Reaction **15-30**.¹²⁸⁷ Such cyclizations normally give predominant formation of five-membered rings, but large rings (11–20 members) have also been synthesized by this reaction.¹²⁸⁸

A BEt_3 (see Sec. 14.A.i) initiated reaction of conjugated amides with an alkyl iodide, in the presence of Bu_3SnH and O_2 , leads to conjugate addition of the alkyl group.¹²⁸⁹ Enantioselective radical addition has been reported.¹²⁹⁰

Conjugate addition is possible using photolysis. The photoinduced 1,4-addition of indoles to enones proceeds when irradiated at 350 nm.¹²⁹¹

OS VII, 105.

15-29 Radical Addition to Unactivated Double Bonds¹²⁹²

Alkyl-hydro-addition

Radical addition to alkenes is usually difficult, except when addition occurs to conjugated carbonyl compounds (Reaction 15-24). An important exception involves radicals bearing a heteroatom α to the carbon bearing the radical center. Such radicals are much more stable and can add to alkenes, usually with *anti-Markovnikov* orientation, as in the radical induced addition of HBr to alkenes (Reaction 15-2).¹²⁹³

Examples of this type of reaction include the use of alcohol-, ester-,¹²⁹⁴ amino-, and aldehyde-stabilized radicals.⁴⁸³ The alkyl group of alkyl iodides adds to alkenes with BEt_3/O_2 as the initiator and in the presence of a tetraalkylammonium hypophosphite.¹²⁹⁵ The radical generated from $(\text{EtO})_2\text{POCH}_2\text{Br}$ adds to alkenes to generate a new phosphonate ester.¹²⁹⁶ α -Bromo esters add to alkenes in the presence of BEt_3/air to give a γ -bromo ester.¹²⁹⁷ α -Bromo amides add the Br and the acyl carbon to an alkene using $\text{Yb}(\text{OTf})_3$ with BEt_3/O_2 as the radical initiator.¹²⁹⁸ α -Iodo amides add to alkenes using a water-soluble azobis initiator (see Sec. 14.A.i) to give the iodo ester, which cyclizes under the reaction conditions to give a lactone.¹²⁹⁹ β -Keto dithiocarbonates $[\text{RC}(=\text{O})-\text{C}-\text{SC}(=\text{S})\text{OEt}]$ generate the radical in the presence of a peroxide and add to alkenes.¹³⁰⁰ 2-Fluoropyridyl derivatives of allylic alcohols react with xanthates in the presence of lauroyl peroxide to give alkenes.¹³⁰¹ Malonate derivatives add to alkenes in the presence of a mixture of Mn/Co catalyst, in oxygenated acetic acid.¹³⁰²

Other radicals can add to alkenes, and the rate constant for the addition of methyl radicals to alkenes has been studied.¹³⁰³ The rate of radical additions to alkenes in general has also been studied.¹³⁰⁴ The kinetic and thermodynamic control of a radical addition regiochemistry has also been studied.¹³⁰⁵ Alkynes are generally less reactive than alkenes in radical coupling reactions.¹³⁰⁶ Nonradical nucleophiles usually react faster with alkynes than with alkenes, however.¹³⁰⁷

15-30 Radical Cyclization¹³⁰⁸

Alkyl-hydro-addition

ω -Haloalkenes generate radicals upon treatment with radical initiator reagents (e.g., AIBN) or under photolysis conditions,¹³⁰⁹ and the radical carbon adds to the alkene to form cyclic compounds.¹³¹⁰ This intramolecular addition of a radical to an alkene is called *radical cyclization*. In a typical example, haloalkene (**101**) reacts with the radical produced by AIBN to give radical **100**. The radical can add to the more substituted carbon to give **102** via a 5-exo-trig reaction (Sec. 6.E).¹³¹¹ If the radical adds to the less substituted carbon, **103** is formed via a 6-endo-trig reaction.¹³¹² In both cases, the product is another radical, which must be converted to an unreactive product. This is generally accomplished by adding a hydrogen-transfer agent¹³¹³ [e.g., tributyltin hydride (Bu_3SnH)], which reacts with **102** to form methylcyclopentane and $\text{Bu}_3\text{Sn}^\bullet$, or with **103** to give cyclohexane. The $\text{Bu}_3\text{Sn}^\bullet$ formed in both cases usually dimerizes to form $\text{Bu}_3\text{SnSnBu}_3$. Cyclization can compete with hydrogen transfer¹³¹⁴ from Bu_3SnH to **100** to give **99**, the reduction product. Atom-transfer cyclization is possible with other atoms (e.g., halogen), catalyzed by InCl_3 ¹³¹⁵ or CuBr .¹³¹⁶ Tin-free radical cyclizations are known using peroxyacids.¹³¹⁷

In general, formation of the five-membered ring dominates the cyclization, but if addition to the C=C unit is relatively slow, the reduction product is formed preferentially. Radical rearrangements can also diminish the yield of the desired product.¹³¹⁸ Given a choice between a larger and a smaller ring, radical cyclization generally gives the smaller ring,¹³¹⁹ but not always.¹³²⁰ Formation of other size rings is possible of course. A 4-exo-trig radical cyclization has been studied,¹³²¹ selectivity in a 7-endo versus 6-exo cyclization,¹³²² and also an 8-endo-trig reaction.¹³²³ In radical cyclization to form large rings, 1,5- and 1,9-hydrogen atom abstractions can pose a problem.¹³²⁴ Ring expansion during radical cyclization is possible when the terminal intermediate is a cyclobutylcarbinyl radical.¹³²⁵

The mechanism of this reaction has been discussed.¹³²⁶ Cyclization via 5-endo-dig transition states require reorientation of the radical orbital needed to reach the in-plane acetylene π orbital in the bond-forming step, with accompanying loss of conjugative stabilization, and an increase in the activation energy. Therefore, many 5-endo cyclizations undergo H abstraction or equilibration with an isomeric radical.¹³²⁷

In cases where hydrogen atom transfer gives primarily reduced products, one solution to promote cyclization generates the radical by photochemical cleavage of Bu₃Sn—SnBu₃ and the resulting carbon radical can cyclize (see Reaction 15-46).¹³²⁸ A halogen atom transfer agent (e.g., iodoethane) is used rather than a hydrogen-transfer agent, so the final product is an alkyl iodide.

A mixture of a *Grignard reagent* and CoCl₂ has been used to initiate aryl radical cyclizations.¹³²⁹ Titanium(III)-mediated radical cyclizations are known,¹³³⁰ and SmI₂

mediated reactions are possible in the presence of a Ni catalyst.¹³³¹ Organoborane-mediated radical cyclizations are known (see Sec. 14.A.i).¹³³² The influence of the halogen atom on radical cyclization has been studied.¹³³³

Both phenylthio¹³³⁴ and phenylseleno groups¹³³⁵ can be used as “leaving groups” for radical cyclization, where S or Se atom transfer leads to formation of the radical. A seleno ester ($R_2N-CH_2C(-O)SeMe$) has also been used with $(Me_3Si)_3SiH$ (tristrimethylsilyl-lane, TTMSS) and AIBN to generate $R_2NCH_2\cdot$.¹³³⁶ *O*-Phosphonate esters have also served as the leaving group.¹³³⁷ *N*-(2-bromophenylbenzyl)methylamino have been used as leaving groups for formation of a radical.¹³³⁸

Radical cyclization reaction often proceeds with high diastereoselectivity¹³³⁹ and high asymmetric induction when chiral precursors are used. Internal alkynes are good substrates for radical cyclization,¹³⁴⁰ but terminal alkynes tend to give mixtures of *exo/endo-dig* products (Sec. 6.E).¹³⁴¹ Radical cyclization has been used to transfer asymmetry from transient atropisomers to form lactams.¹³⁴²

Radical cyclization is compatible with the presence of other functional groups, and heterocyclic rings may be formed via radical cyclization.¹³⁴³ Aryl radicals participate in radical cyclization reactions when the aromatic ring has an alkene or alkyne substituent. *o*-Iodo aryl allyl ethers cyclize to benzofuran derivatives, for example, when treated with AIBN, $aq\ H_3PO_2$ and $NaHCO_3$ in ethanol.¹³⁴⁴ Cyclization of vinyl radicals¹³⁴⁵ and allenyl radicals¹³⁴⁶ are also well known. Treatment of $XCH_2CON(R)-C(R^1)=CH_2$ derivatives ($X = Cl, Br, I$) with Ph_3SnH and AIBN led to formation of a lactam via radical cyclization.¹³⁴⁷ Cyclization of *N*-iodoethyl-5-vinyl-2-pyrrolidinone led to the corresponding bicyclic lactam,¹³⁴⁸ and there are other examples of radical cyclization with molecules containing a lactam unit¹³⁴⁹ or an amide unit.¹³⁵⁰ β -Lactams can be produced by radical

cyclization, using $\text{Mn}(\text{OAc})_3$.¹³⁵¹ Radical cyclization occurs with enamines as well.¹³⁵² Radical cyclization occurs with oximes to form the corresponding heterocyclic ring.¹³⁵³ Phenylseleno *N*-allylamines led to cyclic amines.¹³⁵⁴ ω -Iodo acrylate esters cyclize to form lactones,¹³⁵⁵ and allylic acetoxy compounds of the type $\text{C}=\text{C}-\text{C}-\text{O}_2\text{C}-\text{CH}_2\text{I}$ cyclize in a similar manner to give lactones.¹³⁵⁶ Iodolactonization (see Reaction **15-41**) occurs under standard radical cyclization conditions using allylic acetoxy compounds¹³⁵⁷ and $\text{HGaCl}_2/\text{BEt}_3$ has been used to initiate the radical process.¹³⁵⁸ α -Bromo mixed acetals give α -alkoxy THF derivatives¹³⁵⁹ and α -iodoacetals cyclize to give similar products.¹³⁶⁰ The reaction of an *o*-alkynyl aryl isonitrile with AIBN and 2.2 equiv of Bu_3SnH gave an indole via 5-exo-dig cyclization.¹³⁶¹ Indole derivatives have also been prepared from *o*-iodoaniline derivatives, using AIBN and TTMSS.¹³⁶² Samarium(II) has been used to initial 5-exo-trig ketyl-alkene coupling, and the mechanism of the reaction has been examined.¹³⁶³

Acyl radicals can be generated and they cyclize in the usual manner.¹³⁶⁴ Molecular orbital calculations have shown that acyl, as well as silyl radicals, simultaneously use SOMO–LUMO (SOMO = singly occupied molecular orbital and LUMO = lowest unoccupied molecular orbital) and LUMO–HOMO interactions in reactions with alkenes.¹³⁶⁵ A polyene-cyclization reaction generated four rings, initiating the sequence by treatment of a phenylseleno ester with $\text{Bu}_3\text{SnH}/\text{AIBN}$ to form the acyl radical, which added to the first alkene unit.¹³⁶⁶ The newly formed carbon radical added to the next alkene, and so on. Acyl radicals generated from Ts(R)NCOSePh derivatives cyclize to form lactams.¹³⁶⁷

Radical cyclization of iodo aldehydes or ketones, at the carbon of the carbonyl, is effectively an acyl addition reaction (**16-24** and **16-25**). This cyclization is often reversible, and there are many fewer examples of addition to an alkene or alkyne. In one example, a δ -iodo aldehyde was treated with BEt_3/O_2 to initiate formation of the radical, and in the presence of Bu_3SnH cyclization gave a cyclopentanol.¹³⁶⁸ The reaction of an

aldehyde-alkene with AIBN, 0.5 PhSiH₃ and 0.1 Bu₃SnH generated a radical from the alkene, which cyclized at the aldehyde to give cyclopentanol derivatives.¹³⁶⁹ An aldehyde-*O*-methyloxime generated a radical adjacent to nitrogen under standard conditions, which cyclized at the carbonyl to give a cyclic α -hydroxy *N*-methoxyamine.¹³⁷⁰ Alternatively, an α -bromoacetal-*O*-methyl oxime cyclized at the C=NOMe unit under electrolytic conditions in the presence of cobaloxime.¹³⁷¹ Alkynyl-imines are cyclized to the imino carbon to form alkylidene lactams under radical conditions in the presence of CO.¹³⁷²

The attacking radical in radical cyclization reactions is not limited to a carbon, and a number of heterocycles can be prepared.¹³⁷³ Amidyl radicals are known and give cyclization reactions.¹³⁷⁴ Aminyl radical cyclizations have been reported.¹³⁷⁵ *N*-Chloroamine-alkenes give an aminyl radical when treated with TiCl₃·BF₃, and cyclization gave a pyrrolidine derivative with a pendant chloromethyl group.¹³⁷⁶ *N*-(*S*-substituted) amines give similar results using AIBN/Bu₃SnH.¹³⁷⁷ Oxime-alkenes cyclize to imines when treated with PhSSPh and TEMPO (Sec. 5.C.i).¹³⁷⁸ An oxygen radical can be generated under photochemical conditions, and they add to alkenes in a normal manner.¹³⁷⁹ Note that radical substitution occurs, and reaction of Ph₃SnH/AIBN and an *O*-amidyl compound having a phosphonate ester elsewhere in the molecule gave cyclization to a THF derivative.¹³⁸⁰

15-31 Conjugate Addition with Heteroatom Nucleophiles

Heteroatom nucleophiles add to conjugated systems to give *Michael-type* products. Conjugated carbonyl compounds react via conjugate addition with amines to give β -amino derivatives (See Reaction 15-31)¹³⁸¹ Conjugate addition of nitrogen-containing compounds is often called the *aza-Michael reaction*.¹³⁸² Amines add to conjugated systems in the presence of In,¹³⁸³ Pd,¹³⁸⁴ Sm,¹³⁸⁵ Bi,¹³⁸⁶ Cu,¹³⁸⁷

Ce,¹³⁸⁸ La,¹³⁸⁹ or Yb compounds¹³⁹⁰ to give β -amino derivatives. This reaction can be initiated photochemically¹³⁹¹ or with microwave irradiation.¹³⁹² Aniline derivatives add to conjugated aldehydes in the presence of a catalytic amount of DBU,¹³⁹³ and indeed, DBU promotes the *aza-Michael reaction*.¹³⁹⁴ Lithium amides add to conjugated esters to give the β -amino ester.¹³⁹⁵ Amidocuprates add to conjugated systems to give β -nitrogen compounds, and a β -silyl group has an activating effect of the amidocuprate.¹³⁹⁶ A solvent-free conjugate addition of amines occurs on alumina in the presence of a Ce catalyst.¹³⁹⁷ Boric acid has been used as a catalyst of *aza-Michael reactions* in water.¹³⁹⁸ An intramolecular addition of an amine unit to a conjugated ketone in the presence of a Pd catalyst, or photochemically, led to cyclic amines.¹³⁹⁹ Amines add to conjugated thiolactams.¹⁴⁰⁰

There are asymmetric versions of the *aza-Michael reaction*,¹⁴⁰¹ and high enantioselectivity is possible using an organocatalyst.¹⁴⁰² Chiral catalysts lead to enantioselective reactions.¹⁴⁰³ Chiral additives (e.g., chiral Cinchona alkaloids¹⁴⁰⁴ or chiral naphthol derivatives)¹⁴⁰⁵ have also been used. Chiral imines add in a highly stereoselective manner.¹⁴⁰⁶ Chiral catalysts have been used for the conjugated addition of carbamates.¹⁴⁰⁷ Indoles add to nitro alkenes in the presence of an organocatalyst.¹⁴⁰⁸ Other N-heterocycles add with good enantioselectivity in the presence of an organocatalyst.¹⁴⁰⁹

Lactams have been shown to add to conjugated esters in the presence of Si(OEt)₄ and CsF.¹⁴¹⁰ Phthalimide adds to alkylidene malononitriles via 1,4-addition with a Pd catalyst, and the resulting anion can be alkylated with an added allylic halide.¹⁴¹¹ Alkylidene

amido-amides, $C=C(NHAc)CONHR$, react with secondary amines in water to give the β -amino amido amide.¹⁴¹² Amines also add in a conjugate manner to alkynyl phosphonate esters, $C\equiv C-PO(OEt)_2$, using a CuI catalyst.¹⁴¹³ Hydroxylamines add to conjugated nitro compounds to give 2-nitro hydroxylamines.¹⁴¹⁴ *N,O*-Trimethylsilyl hydroxylamines add to conjugated esters, via nitrogen, using a Cu catalyst.¹⁴¹⁵ Trimethylsilyl azide with acetic acid reacts with conjugated ketones to give the β -azido ketone.¹⁴¹⁶ Sodium azide adds to conjugated ketones in aq acetic acid and 20% PBu_3 .¹⁴¹⁷ An interesting variation involves a double *Michael addition* of amido amines, amido alcohols or amido thiols to conjugated alkynes, forming pyrrolidine, oxazolidine, or thiazolidine derivatives.¹⁴¹⁸

The nitrogen of carbamates adds to conjugated ketones with a Pt,¹⁴¹⁹ Pd,¹⁴²⁰ Cu,¹⁴²¹ or with a bis(triflamide) organocatalyst.¹⁴²² The amine moiety of a carbamate adds to conjugated ketones with a polymer-supported acid catalyst,¹⁴²³ or with $BF_3 \cdot OEt_2$.¹⁴²⁴ The reaction of ammonium formate with 1,4-diphenylbut-2-en-1,4-dione, in PEG-200 and a Pd catalyst under microwave irradiation, gave 2,5-diphenylpyrrole.¹⁴²⁵

Phosphines react similarly to amines under certain conditions. Conjugate addition of R_2PH and a Ni catalyst give conjugate addition to α,β -unsaturated nitriles.¹⁴²⁶ A Pd catalyzed addition of diarylphosphines proceeds with good enantioselectivity to give chiral phosphines.¹⁴²⁷ Phosphites add to nitroalkenes in the presence of a chiral organocatalyst to give the corresponding nitro phosphite compound.¹⁴²⁸

Alcohols add to conjugated ketones with a PMe_3 catalyst to give the β -alkoxy ketone.¹⁴²⁹ This reaction is called an *oxy-Michael reaction*.¹⁴³⁰ Alcohol addition is catalyzed by *N*-heterocyclic carbenes¹⁴³¹ and other organocatalysts,¹⁴³² often with enantioselectivity.¹⁴³³ The conjugate addition of peroxide anions (HOO^- and ROO^-) to α,β -unsaturated carbonyl compounds is discussed in Reaction 15-48. An intramolecular variation is known that produces dihydropyrones.¹⁴³⁴

Thiophenol and butyllithium (lithium phenylthiolate) adds to conjugated esters.¹⁴³⁵ Similar addition is observed with selenium compounds (RSeLi).¹⁴³⁶ Thiols react with conjugated amides via 1,4-addition with the addition of 10% Hf(OTf)₄ or other lanthanide triflates¹⁴³⁷ or to conjugated ketones in ionic solvents.¹⁴³⁸ Alkyl thiols add to conjugated carbonyl compounds with high enantioselectivity using an organocatalyst.¹⁴³⁹ Iron(III)-catalyzed addition of thiols occurs under solvent-free conditions.¹⁴⁴⁰ Thiols add without a catalyst in water¹⁴⁴¹ in PEG,¹⁴⁴² or in ionic liquids.¹⁴⁴³ Thiol addition is also catalyzed by iodine under solvent-free conditions.¹⁴⁴⁴ Ceric ammonium nitrate promotes the conjugate addition of thiols.¹⁴⁴⁵ Thioaryl moieties can be added in the presence of Yb¹⁴⁴⁶ or a catalytic amount of (DHQD)₂PYR (a dihydroquinidine, see Reaction **15-48**).¹⁴⁴⁷ Thioalkyl units (e.g., BuS—) add to conjugated ketones using BuS—SnBu and In—I.¹⁴⁴⁸ Addition of conjugated lactones is possible to produce β-arylthiolated lactones.¹⁴⁴⁹ Dithiocarbamates are prepared by the reaction of an amine, CS₂, and a conjugated carbonyl compound.¹⁴⁵⁰ α,β-Unsaturated sulfones undergo conjugate addition of a cyano group using Et₂AlCN.¹⁴⁵¹

15-32 Acylation of Activated Double Bonds and of Triple Bonds

Hydro-acyl-addition

Under some conditions, acid derivatives add directly to activated double bonds. Acetic anhydride, Mg metal, and Me₃SiCl react with conjugated esters to give a γ-keto ester.¹⁴⁵² Similar reaction with vinyl phosphonate esters leads to a γ-keto phosphonate ester.¹⁴⁵³ Thioesters undergo conjugate addition to α,β-unsaturated ketones in the presence of SmI₂.¹⁴⁵⁴ Using DBU and a thioimidazolium salt, acyl silanes, Ar(C=O)SiMe₃, add in a

similar manner.¹⁴⁵⁵ Under microwave irradiation, aldehydes add to conjugated ketones using DBU/ Al_2O_3 and a thiazolium salt.¹⁴⁵⁶ The conjugate addition of acyl zirconium complexes in the presence of $\text{BF}_3\cdot\text{OEt}_2$ is catalyzed by palladium acetate.¹⁴⁵⁷

An acyl group can be introduced into the 4 position of an α,β -unsaturated ketone by treatment with an organolithium compound and nickel carbonyl¹⁴⁵⁸ to give a 1,4-diketone (**104**). The R group may be aryl or primary alkyl. The reaction can also be applied to alkynes, which need not be activated, in which case 2 molar equivalents add and the product is also a 1,4-diketone (e.g., $\text{R}'\text{C}\equiv\text{CH} \rightarrow \text{RCOCHR}'\text{CH}_2\text{COR}$).¹⁴⁵⁹ In a different procedure, α,β -unsaturated ketones and aldehydes are acylated by treatment at -110°C with $\text{R}_2(\text{CN})\text{CuLi}_2$ and CO. This method is successful for R = primary, secondary, and tertiary alkyl.¹⁴⁶⁰ For secondary and tertiary groups, $\text{R}(\text{CN})\text{CuLi}$, which does not waste an R group, can be used instead.¹⁴⁶¹

The reaction of an aldehyde and cyanide ion (See Reaction **16-52**) in a polar aprotic solvent (e.g., DMF or DMSO) leads to a cyanohydrin, which generates a diketone via loss of HCN.¹⁴⁶² This method has been applied to α,β -unsaturated ketones, esters, and nitriles to give the corresponding 1,4-diketones, γ -keto esters, and γ -keto nitriles, respectively (see also, Reaction **16-55**). The initial product of this reaction is ion **105**, which is a synthon for the unavailable $\text{R}^-\text{C}=\text{O}$ anion (see Reaction **10-68**). It is a masked $\text{R}^-\text{C}=\text{O}$ anion that upon reaction with the conjugated carbonyl gives **104** after loss of HCN from the cyanohydrin addition product. Other masked carbanions that have been used in this reaction are the $\text{RC}^-(\text{CN})\text{NR}$ ion,¹⁴⁶³ the EtSCRSOEt ion,¹⁴⁶⁴ the $\text{CH}_2=\text{C}^-\text{OEt}$ ion,¹⁴⁶⁵ $\text{CH}_2=\text{C}(\text{OEt})\text{CuLi}$,¹⁴⁶⁶ $\text{CH}_2=\text{CMe}(\text{SiMe}_3)$,¹⁴⁶⁶ and the $\text{RC}^-(\text{OCHMeOEt})\text{CN}$ ion.¹⁴⁶⁷ In the last case, best results are obtained when R is a vinylic group. Anions of 1,3-dithianes

(Reaction **10-71**) do not give 1,4-addition to these substrates (except in the presence of HMPA, see Reaction **15-25**), but add 1,2 to the C=O group instead (Reaction **16-38**).

Interestingly, acylation occurs at the α -position of an enone when an α,β -unsaturated ketone is treated with an acid chloride and Et_2Zn in the presence of a Rh catalyst.¹⁴⁶⁸

In another procedure, acyl radicals derived from phenyl selenoesters (ArCOSePh) (by treatment with Bu_3SnH) add to α,β -unsaturated esters and nitriles to give γ -keto esters and γ -keto nitriles, respectively.¹⁴⁶⁹

OS VI, 866; VIII, 620.

15-33 Addition of Alcohols, Amines, Carboxylic Esters, Aldehydes, and so on

Hydro-acyl-addition, and so on

Formates, primary and secondary alcohols, amines, ethers, alkyl halides, compounds of the type $\text{Z}-\text{CH}_2-\text{Z}'$, and a few other compounds add to double bonds in the presence of free radical initiators.¹⁴⁷⁰ This is formally the addition of RH to a double bond, but the “R” is not just any carbon, but one connected to an oxygen or a nitrogen, a halogen, or to two Z groups (defined as in Sec. 15.A.ii). Formates and formamides¹⁴⁷¹ add similarly:

Alcohols, ethers, amines, and alkyl halides add as follows (shown for alcohols):

The $\text{ZCH}_2\text{Z}'$ compounds react at the carbon bearing the active hydrogen¹⁴⁷²:

Similar additions have been successfully carried out with carboxylic acids, anhydrides,¹⁴⁷³ acyl halides, carboxylic esters, nitriles, and other types of compounds.¹⁴⁷⁴

Similar reactions have been carried out on acetylene.¹⁴⁷⁵ In an interesting variation, thiocarbonates add to alkynes in the presence of a Pd catalyst to give a β -phenylthio α,β -unsaturated ester.¹⁴⁷⁶ Aldehydes add to alkynes in the presence of a Rh catalyst to give

conjugated ketones.¹⁴⁷⁷ In a cyclic version of the addition of aldehydes, 4-pentenal was converted to cyclopentanone with a Rh complex catalyst.¹⁴⁷⁸ An intramolecular acyl addition to an alkyne was reported using silyl ketones, acetic acid, and a Rh catalyst.¹⁴⁷⁹ Formamides add to alkynes in the presence of a Pd catalyst to form conjugated amides.¹⁴⁸⁰

OS IV, 430; V, 93; VI, 587, 615.

15-34 Addition of Aldehydes

Alkyl-carbonyl-addition

In the presence of metal catalysts (e.g., Rh¹⁴⁸¹ or Yb¹⁴⁸²), aldehydes can add directly to alkenes to form ketones. Additives play an important role in such reactions.¹⁴⁸³ The reaction of ω -alkenyl aldehydes with a Rh catalyst leads to cyclic ketones,¹⁴⁸⁴ with high enantioselectivity if chiral ligands are employed. A carbene organocatalyst was used for an enantioselective intramolecular reaction.¹⁴⁸⁵ β,γ -Unsaturated ketones are prepared by the Rh catalyzed addition of aldehydes to dienes.¹⁴⁸⁶ The addition of aldehydes to activated double bonds, mediated by a catalytic amount of thiazolium salt in the presence of a weak base, is called the *Stetter reaction*,¹⁴⁸⁷ An internal addition of an alkynyl aldehyde, catalyzed by a Rh complex, led to a cyclopentenone derivative.¹⁴⁸⁸ These reactions are not successful when the alkene contains electron-withdrawing groups (e.g., halo or carbonyl groups). A free radical initiator is required,¹⁴⁸⁹ usually peroxides or UV light. The mechanism is illustrated for aldehydes, but is similar for the other compounds:

In the presence of BF_3 and a Ag salt, aldehydes add to alkynes to give the corresponding conjugated ketone.¹⁴⁹⁰ Polymers are often side products. Photochemical addition of aldehyde to conjugated $\text{C}=\text{C}$ units can be efficient when a triplet sensitizer (Sec. 7.A.vi, category 5, e.g., benzophenone) is used.¹⁴⁹¹

A variation that is more of an acyl addition (Reaction **16-25**) involves the reaction of an allylic alcohol with benzaldehyde. With a Ru catalyst and in an ionic liquid, the $\text{C}=\text{C}$ unit reacts with the aldehyde, with concomitant oxidation of the allylic alcohol unit, to give a β -hydroxy ketone, $\text{PhCHO} + \text{C}=\text{C}-\text{CH}(\text{OH})\text{R} \rightarrow \text{PhCH}(\text{OH})-\text{CH}(\text{Me})\text{COR}$.¹⁴⁹² In another variation, formate esters add to alkenes using a Ru catalyst to give an alkyl ester via a formylation process.¹⁴⁹³

15-35 Hydrocarboxylation

Hydro-carboxy-addition

The acid-catalyzed hydrocarboxylation of alkenes (the *Koch reaction*) can be performed in a number of ways.¹⁴⁹⁴ In one method, the alkene is treated with CO and water at 100–350°C and 500–1000-atm pressure with a mineral acid catalyst. However, the reaction can also be performed under milder conditions. If the alkene is first treated with CO and catalyst and then water added, the reaction can be accomplished at 0–50°C and 1–100 atm. If formic acid is used as the source of both the CO and the water, the reaction can be carried out at room temperature and atmospheric pressure.¹⁴⁹⁵ The formic acid procedure is called the *Koch–Haaf reaction* (the Koch–Haaf reaction can also be applied to alcohols, see Reaction **10-77**). Nearly all alkenes can be hydrocarboxylated by one of these procedures. However, conjugated dienes are polymerized under these conditions. Hydrocarboxylation can also be accomplished under mild conditions (160°C and 50 atm) by the use of nickel carbonyl as catalyst. Acid catalysts are used along with the nickel carbonyl, but basic catalysts can also be employed.¹⁴⁹⁶ The $\text{Ni}(\text{CO})_4$ catalyzed oxidative carbonylation with

CO and H₂O as a nucleophile is often called *Reppe carbonylation*.¹⁴⁹⁷ The toxic nature of nickel tetracarbonyl has led to development of other catalysts.¹⁴⁹⁸ Indeed, variations in the reaction procedure include the use of Pd,¹⁴⁹⁹ Pt,¹⁵⁰⁰ and Rh¹⁵⁰¹ catalysts. This reaction converts alkenes, alkynes, and dienes and is tolerant of a wide variety of functional groups. When the additive is alcohol or acid, saturated or unsaturated acids, esters, or anhydrides are produced (see Reaction 15-36). The transition metal catalyzed carbonylation has been done enantioselectively, with moderate-to-high optical yields, by the use of an optically active palladium-complex catalyst.¹⁵⁰² Alkenes also react with Fe(CO)₅ and CO to give carboxylic acids.¹⁵⁰³ Electrochemical carboxylation procedures have been developed, including the conversion of alkenes to 1,4-butanedicarboxylic acids.¹⁵⁰⁴ A reductive carboxylation of alkenes with CO and cesium carbonate has been reported.¹⁵⁰⁵

When applied to triple bonds, hydrocarboxylation gives α,β -unsaturated acids under very mild conditions. Triple bonds give unsaturated acids and saturated dicarboxylic acids when treated with CO₂ and an electrically reduced Ni complex catalyst.¹⁵⁰⁶ Alkynes also react with NaHFe(CO)₄, followed by CuCl₂ • 2 H₂O, to give alkenyl acid derivatives.¹⁵⁰⁷ A related reaction with CO and Pd catalysts in the presence of SnCl₂ leads to conjugated acid derivatives.¹⁵⁰⁸ Terminal alkynes react with CO₂ and Ni(cod)₂ (cod = 1,5-cyclooctadiene), and subsequent treatment with DBU gives the α,β -unsaturated carboxylic acid.¹⁵⁰⁹

When acid catalysts are employed, in the absence of nickel carbonyl, the mechanism¹⁵¹⁰ involves initial attack on a proton, followed by attack by CO on the resulting carbocation to give an acyl cation, and subsequent reaction with water gives the product **107**. *Markovnikov's rule* is followed, and carbon skeleton rearrangements and double-bond isomerizations (prior to attack by CO) are frequent.

For the transition metal catalyzed reactions, the nickel carbonyl reaction has been well studied and the addition is syn for both alkenes and alkynes.¹⁵¹¹ The following is the accepted mechanism:¹⁵¹¹

Step 3 is an electrophilic substitution. The principal step of the mechanism, step 4, is a rearrangement.

An indirect method for hydrocarboxylation involves the reaction of an alkene with a borate $[(\text{RO})_2\text{BH}]$ and a Rh catalyst. Subsequent reaction with LiCHCl_2 , and then NaClO_2 , gives the *Markovnikov* carboxylic acid $(\text{RC}=\text{C} \rightarrow \text{RC}(\text{CO}_2\text{H})\text{CH}_3)$.¹⁵¹² When a chiral ligand is used, the reaction proceeds with good enantioselectivity.

15-36 Carbonylation, Alkoxy carbonylation, and Aminocarbonylation of Double and Triple Bonds

Alkyl, Alkoxy, or Amino-carbonyl-addition

In the presence of certain metal catalysts, alkenes and alkynes can be carbonylated or converted to give an amide or an ester.¹⁵¹³ There are several variations. The reaction of an alkyl iodide and a conjugated ester with CO, $(\text{Me}_3\text{Si})_3\text{SiH}$, and AIBN in supercritical CO_2 (Sec. 9.D.ii) gave a γ -keto ester.¹⁵¹⁴ Terminal alkynes react with

CO and methanol in the presence of CuCl_2 and PdCl_2 to give a β -chloro- α,β -unsaturated methyl ester.¹⁵¹⁵ Conjugated dienes react with thiophenol, CO and $\text{Pd}(\text{OAc})_2$ to give the β,γ -unsaturated thioester.¹⁵¹⁶ Allene reacts with CO, CH_3OH , and a Ru catalyst to give methacrylic acid.¹⁵¹⁷ Alkynes react with thiophenol and CO with a Pd¹⁵¹⁸ or Pt¹⁵¹⁹ catalyst to give a conjugated thioester. Terminal alkynes react with CO and CH_3OH , using a combination of a palladium(II) halide and a copper(II) halide, to give a conjugated diester, $\text{MeO}_2\text{C}-\text{C}=\text{C}-\text{CO}_2\text{Me}$.¹⁵²⁰ A similar reaction with alkenes using a combination of a Pd and a Mo catalyst led to a saturated diester ($\text{MeO}_2\text{C}-\text{C}-\text{C}-\text{CO}_2\text{Me}$).¹⁵²¹ Alkenes were converted to the dimethyl ester of 1,4-butanedioic acid derivatives with CO/O_2 and a combination of PdCl_2 and CuCl catalysts.¹⁵²² Note that alkenes primarily are converted to the *anti-Markovnikov* ester upon treatment with arylmethyl formate esters (ArCH_2OCHO) and a Ru catalyst.¹⁵²³ Terminal alkynes react with tosyl azide, water, and a catalytic amount of CuI to give an *N*-tosyl amide.¹⁵²⁴

A bicyclic ketone was generated when 1,2-diphenylethyne was heated with carbon monoxide, methanol and a dirhodium catalyst.¹⁵²⁵ 2-Iodostyrene reacted at 100°C with CO and a Pd catalyst to give the bicyclic ketone 1-indanone.¹⁵²⁶ Another variation reacted a conjugated allene-alkene with 5 atm of CO and a Rh catalyst to give a bicyclic ketone.¹⁵²⁷ An intermolecular version of this reaction is known using a Co catalyst, giving a cyclopentenone¹⁵²⁸ in a reaction related to the *Pauson-Khand reaction* (see below). The reaction of a conjugated diene having a distal alkene unit and CO with a Rh catalyst led to a bicyclic conjugated ketone.¹⁵²⁹ When a *Stille coupling* (Reaction 12-15) is done in a CO atmosphere, conjugated ketones of the type $\text{C}=\text{C}-\text{CO}-\text{C}=\text{C}$ are formed,¹⁵³⁰ suitable for a *Nazarov cyclization* (Reaction 15-20). Alkynes were converted to cyclobutenones using $\text{Fe}_3(\text{CO})_{12}$ to form an initial complex, followed by reaction with copper(II) chloride.¹⁵³¹ An interesting variation treated cyclohexene with 5 molar equivalents of Oxone and a RuCl_3 catalyst to give 2-hydroxycyclohexanone.¹⁵³²

The reaction of dienes, diynes, or enynes with transition metals¹⁵³³ (usually Co)¹⁵³⁴ forms organometallic coordination complexes. Rhodium,¹⁵³⁵ Ti,¹⁵³⁶ Mo,¹⁵³⁷ and W¹⁵³⁸ complexes have been used for this reaction. In the presence of CO, the metal complexes derived primarily from enynes (alkene–alkynes) generate cyclopentenone derivatives in what is known as the *Pauson–Khand reaction*.¹⁵³⁹ This reaction involves (1) formation of a hexacarbonyldicobalt–alkyne complex and (2) decomposition of the complex in the presence of an alkene.¹⁵⁴⁰ A typical example is the preparation of **108**.¹⁵⁴¹ Cyclopentenones can be prepared by an intermolecular reaction of a vinyl silane and an alkyne using CO and a Ru catalyst.¹⁵⁴² Carbonylation of an alkene–diene using a Rh catalyst leads to cyclization to an α -vinyl cyclopentanone.¹⁵⁴³ An yne–diene can also be used for the *Pauson–Khand reaction*.¹⁵⁴⁴

The reaction can be promoted photochemically¹⁵⁴⁵ and the rate is enhanced by the presence of primary amines.¹⁵⁴⁶ Coordinating ligands also accelerate the reaction,¹⁵⁴⁷ polymer-supported promoters have been developed¹⁵⁴⁸ and there are many possible variations in reaction conditions.¹⁵⁴⁹ The *Pauson–Khand reaction* has been done under heterogeneous reaction conditions,¹⁵⁵⁰ with Co nanoparticles,¹⁵⁵¹ and in water.¹⁵⁵² A

dendritic Co catalyst has been used.¹⁵⁵³ Ultrasound promoted¹⁵⁵⁴ and microwave promoted¹⁵⁵⁵ reactions have been developed. Polycyclic compounds (tricyclic and higher) are prepared in a relatively straightforward manner using this reaction.¹⁵⁵⁶ Asymmetric *Pauson–Khand* reactions are known.¹⁵⁵⁷

The *Pauson–Khand reaction* is compatible with other groups or heteroatoms elsewhere in the molecule. These include ethers and aryl halides,¹⁵⁵⁸ esters,¹⁵⁵⁹ amides,¹⁵⁶⁰ alcohols,¹⁵⁶¹ diols,¹⁵⁶² and an indole unit.¹⁵⁶³ A silicon-tethered *Pauson–Khand reaction* is known.¹⁵⁶⁴ Allenes are reaction partners in the *Pauson–Khand reaction*.¹⁵⁶⁵ This type of reaction can be extended to form six-membered rings using a Ru catalyst.¹⁵⁶⁶ A double-*Pauson–Khand process* was reported.¹⁵⁶⁷ In some cases, an aldehyde can serve as the source of the carbonyl for carbonylation.¹⁵⁶⁸

The accepted mechanism was proposed by Magnus and Principe,¹⁵⁶⁹ shown for the formation of **109**,¹⁵⁷⁰ and supported by Krafft's work.¹⁵⁷¹ It has been shown that CO is lost from the *Pauson–Khand* complex prior to alkene coordination and insertion.¹⁵⁷² Calculations

concluded that the LUMO of the coordinated alkene plays a crucial role in alkene reactivity by determining the degree of back-donation in the complex.¹⁵⁷³

Other carbonylation methods are available. Carbonylation occurs with conjugated ketones to give 1,4-diketones, using phenylboronic acid (see Reaction **13-12**), CO and a Rh catalyst.¹⁵⁷⁴ A noncarbonylation route treated a conjugated diene with an excess of *tert*-butyllithium, and quenching with CO₂ led to a cyclopentadienone.¹⁵⁷⁵ When quenched with CO rather than CO₂, a nonconjugated cyclopentenone was formed.¹⁵⁷⁶ Note that a carbonylation reaction with CO, a diyne, and an Ir¹⁵⁷⁷ or a Co catalyst¹⁵⁷⁸ provided similar molecules.

With any method, if the alkene contains a functional group (e.g., OH, NH₂, or CONH₂), the corresponding lactone (Reaction **16-63**),¹⁵⁷⁹ lactam (Reaction **16-74**), or cyclic imide may be the product.¹⁵⁸⁰ Titanium,¹⁵⁸¹ Pd,¹⁵⁸² Ru,¹⁵⁸³ and Rh¹⁵⁸⁴ catalysts have been used to generate lactones. Allenic alcohols are converted to butenolides with 10 atm of CO and a Ru catalyst.¹⁵⁸⁵ Larger ring conjugated lactones can also be formed by this route using the appropriate allenic alcohol.¹⁵⁸⁶ Propargylic alcohols lead to β -lactones¹⁵⁸⁷ or to butenolides with CO/H₂O and a Rh catalyst.¹⁵⁸⁸ Allenic tosyl-amides are converted to *N*-tosyl α,β -unsaturated pyrrolidinones using 20 atm of CO and a Ru catalyst.¹⁵⁸⁹ Conjugated imines are converted to similar products with CO, ethylene, and a Ru catalyst.¹⁵⁹⁰ Propargyl alcohols generate lactones when treated with a chromium pentacarbonyl carbene complex.¹⁵⁹¹ Amines add to allenes, in the presence of CO and a Pd catalyst, to form conjugated amides.¹⁵⁹²

The reaction of a secondary amine, CO, a terminal alkyne, and *t*-BuMe₂SiH with a Rh catalyst led to a conjugated amide bearing the silyl group of the C=C unit.¹⁵⁹³ Reaction of a molecule containing an amine and an alkene unit was carboxylated with CO in the presence of a Pd catalyst to give a lactam.¹⁵⁹⁴ A similar reaction with a molecule containing an amine and an alkyne also generated a lactam, in the presence of CO and

a Rh catalyst.¹⁵⁹⁵ An intramolecular carbonylation reaction of a conjugated imine, with CO, ethylene and a Ru catalyst, led to a highly substituted β,γ -unsaturated lactam.¹⁵⁹⁶

15-37 Hydroformylation

Hydro-formyl-addition

Alkenes can be hydroformylated¹⁵⁹⁷ by treatment with CO and hydrogen over a catalyst, usually a Co carbonyl (see below for a description of the mechanism) or a Rh complex,¹⁵⁹⁸ but other transition metal compounds have also been used. Cobalt catalysts are less active than the Rh type, and catalysts of other metals are generally less active.¹⁵⁹⁹ Commercially, this is called the *oxo process*, but it can be carried out in the laboratory in an ordinary hydrogenation apparatus. The order of reactivity is straight-chain terminal alkenes > straight-chain internal alkenes > branched-chain alkenes. With terminal alkenes, for example, the aldehyde unit is formed on both the primary and secondary carbon, but proper choice of catalyst and additive leads to selectivity for the secondary¹⁶⁰⁰ or primary product.¹⁶⁰¹ Alkylidenecyclopropane derivatives undergo hydroformylation to give aldehydes with a quaternary center.¹⁶⁰²

Good yields for hydroformylation have been reported using Rh catalysts in the presence of certain other additives.¹⁶⁰³ Among the side reactions are the *aldol Reaction* (**16-34**), acetal formation, the *Tischenko Reaction* (**19-82**), and polymerization. In one case using a Rh catalyst, 2-octene gave nonanal, presumably via a η^3 -allyl complex (Sec. 3.C).¹⁶⁰⁴ Conjugated dienes give dialdehydes when Rh catalysts are used¹⁶⁰⁵ but saturated monoaldehydes (the second double bond is reduced) with cobalt carbonyls. Both 1,4- and 1,5-dienes may give cyclic ketones.¹⁶⁰⁶

Hydroformylation of triple bonds proceeds very slowly, and few examples have been reported.¹⁶⁰⁷ However, in the presence of a Rh catalyst, the triple bond of a conjugated

enyne is formylated.¹⁶⁰⁸ The Rh catalyzed reaction can be regioselective.¹⁶⁰⁹ Many functional groups (e.g., OH, CHO, CO₂R,¹⁶¹⁰ CN), can be present in the molecule, although halogens usually interfere. Stereoselective syn addition has been reported,¹⁶¹¹ and also stereoselective anti addition.¹⁶¹²

Asymmetric hydroformylation of alkenes has been accomplished with a chiral catalyst,¹⁶¹³ and in the presence of chiral additives.¹⁶¹⁴ The choice of ligand is important in such reactions.¹⁶¹⁵ Cyclization to prolinal derivatives has been reported with allylic amines.¹⁶¹⁶

When dicobalt octacarbonyl [Co(CO)₄]₂ is the catalyst, the species that actually adds to the double bond is tricarbonylhydrocobalt [HCo(CO)₃].¹⁶¹⁷ Carbonylation [RCo(CO)₃ + CO → RCo(CO)₄] takes place followed by a rearrangement and a reduction of the C–Co bond, similar to steps 4 and 5 of the nickel carbonyl mechanism shown in Reaction 15-35. The reducing agent in the reduction step is tetracarbonylhydrocobalt [HCo(CO)₄],¹⁶¹⁸ or, under some conditions, H₂.¹⁶¹⁹ When HCo(CO)₄ was the agent used to hydroformylate styrene, the observation of CIDNP (Sec. 5.C.i) indicated that the mechanism is different, and involves free radicals.¹⁶²⁰ Key intermediates have been detected in the Co catalyzed hydroformylation reaction.¹⁶²¹ Alcohols can be obtained by allowing the reduction to continue after all the CO is used up. It has been shown¹⁶²² that the formation of alcohols is a second step, occurring after the formation of aldehydes, and that HCo(CO)₃ is the reducing agent.

OS VI, 338.

15-38 Addition of HCN

Hydro-cyano-addition

Ordinary alkenes do not react with HCN, but polyhalo alkenes and alkenes of the form C=C–Z add HCN to give nitriles.¹⁶²³ The reaction is therefore a nucleophilic addition

and is base catalyzed. Hydrogen cyanide can be added to ordinary alkenes in the presence of dicobalt octacarbonyl¹⁶²⁴ or certain other transition metal compounds.¹⁶²⁵ When Z is COR or, more especially, CHO, 1,2-addition (Reaction **16-53**) is an important competing reaction and may be the only reaction. An acid-catalyzed hydrocyanation is also known.¹⁶²⁶ Triple bonds react very well when catalyzed by an aqueous solution of CuCl, NH₄Cl, and HCl or by Ni or Pd compounds.¹⁶²⁷ The HCN can be generated *in situ* from acetone cyanohydrin (see Reaction **16-52**), avoiding the use of the poisonous HCN.¹⁶²⁸ Alkenes react with HCN via this procedure to give a nitrile in the presence of a Ni complex.¹⁶²⁹

One or 2 molar equivalents of HCN can be added to a triple bond, since the initial product is a *Michael-type* substrate. Acrylonitrile is commercially prepared this way, by the addition of HCN to acetylene. Alkylaluminum cyanides (e.g., Et₂AlCN), or mixtures of HCN and trialkylalanes (R₃Al) are especially good reagents for conjugate addition of HCN¹⁶³⁰ to α,β -unsaturated ketones and α,β -unsaturated acyl halides. An indirect method for the addition of HCN to ordinary alkenes uses an isocyanide (RNC) and *Schwartz's reagent* (see Reaction **15-17**); this method gives anti-Markovnikov addition.¹⁶³¹ *tert*-Butyl isocyanide and TiCl₄ have been used to add HCN to C=C—Z alkenes.¹⁶³² Pretreatment with NaI/Me₃SiCl followed by CuCN converts alkynes to vinyl nitriles.¹⁶³³

When an alkene is treated with Me₃SiCN and AgClO₄, followed by aq NaHCO₃, the product is the isonitrile (RNC) formed with *Markovnikov* selectivity.¹⁶³⁴ Enantioselective cyanation using TMSCN and HCN, and a Gd catalyst, leads to β -cyano amides.¹⁶³⁵

A. Halogen on One or Both Sides

15-39 Halogenation of Double and Triple Bonds (Addition of Halogen, Halogen)

Dihalo-addition

Most double bonds are easily halogenated¹⁶³⁶ with bromine, chlorine, or inter-halogen compounds.¹⁶³⁷ Substitution can compete with addition in some cases.¹⁶³⁸ Iodination has also been accomplished, but the reaction is slower.¹⁶³⁹ Under free radical conditions, iodination proceeds more easily.¹⁶⁴⁰ However, *vic*-diiodides are generally unstable and tend to revert to iodine and the alkene.

The mechanism is usually electrophilic (see Sec. 15.A.i), involving formation of an halonium ion (Reaction **110**),¹⁶⁴¹ followed by nucleophilic ring opening to give the *vic*-dihaloalkane. Nucleophilic attack occurs with selectivity for the less substituted carbon. When free radical initiators (or UV light) are present, addition can occur by a free radical mechanism.¹⁶⁴² Once Br^\bullet or Cl^\bullet radicals are formed, however, substitution may compete (Reactions **14-1** and **14-3**). This is especially important when the alkene has allylic or benzylic hydrogen atoms. Under free radical conditions (UV light) bromine or chlorine adds to a benzene substituent to give, respectively, hexabromo- and hexachlorocyclohexane. These are mixtures of stereoisomers (see Sec. 4.K.ii).¹⁶⁴³

Under ordinary conditions fluorine itself is too reactive to give simple addition, and mixtures are obtained.¹⁶⁴⁴ However, F_2 has been successfully added to certain double bonds in an inert solvent at low temperatures (-78°C), usually by diluting the F_2 gas with Ar or N_2 .¹⁶⁴⁵ Addition of fluorine has also been accomplished with other reagents (e.g., *p*-Tol- $\text{IF}_2/\text{Et}_3\text{N}\cdot 5\text{ HF}$),¹⁶⁴⁶ and a mixture of PbO_2 and SF_4 .¹⁶⁴⁷ The Au catalyzed reaction of $\text{Et}_3\text{N}\text{--HF}$ with alkynes gives vinyl fluorides.¹⁶⁴⁸

The reaction with bromine is very rapid and is easily carried out at room temperature,¹⁶⁴⁹ although the reaction is reversible under some conditions.¹⁶⁵⁰ In the case of bromine, an alkene $\cdot\text{Br}_2$ complex has been detected in at least one case.¹⁶⁵¹ Bromine is often used as a qualitative or quantitative test for unsaturation¹⁶⁵² because the vast majority of double bonds can be successfully brominated. Even when functions (aldehyde, ketone, amine, etc.) are present in the molecule, they do not interfere, since the reaction with double bonds is faster. Bromination has been carried out in an ionic liquid.¹⁶⁵³

Several reagents other than chlorine gas add Cl_2 to double bonds, among them $\text{Me}_3\text{SiCl}^-\text{MnO}_2$,¹⁶⁵⁴ $\text{BnNEt}_3\text{MnO}_4/\text{Me}_3\text{SiCl}$,¹⁶⁵⁵ and KMnO_4 -oxalyl chloride.¹⁶⁵⁶ A convenient reagent for the addition of Br_2 to a double bond on a small scale is the commercially available pyridinium bromide perbromide ($\text{C}_5\text{H}_5\text{NH}^+\text{Br}_3^-$).¹⁶⁵⁷ Potassium bromide with ceric ammonium nitrate, in water/dichloromethane, gives the dibromide.¹⁶⁵⁸ A combination of KBr and Selectfluor also give the dibromide.¹⁶⁵⁹ A combination of CuBr_2 in aq THF and a chiral ligand led to the dibromide with good enantioselectivity.¹⁶⁶⁰ Either Br_2 or Cl_2 can also be added using CuBr_2 or CuCl_2 in the presence of acetonitrile, methanol, or triphenylphosphine.¹⁶⁶¹ Alkenes are brominated using KBr and diacetoxiodobenzene.¹⁶⁶² Note that theoretical and experimental studies have shown that in nonpolar solvents the bromination of acetylene via a covalent tribromide adduct is strongly favored over the textbook mechanism via a bridged bromonium ion.

Mixed halogenations have also been achieved, and the order of activity for some of the reagents is $\text{BrCl} > \text{ICl}^{1663} > \text{Br}_2 > \text{IBr} > \text{I}_2$.¹⁶⁶⁴ Mixtures of Br_2 and Cl_2 have been used to give bromochlorination,¹⁶⁶⁵ as has tetrabutylammonium dichlorobromate ($\text{Bu}_4\text{NBrCl}_2$).¹⁶⁶⁶ Iodochlorination has been achieved with KICl_2 ,¹⁶⁶⁷ CuCl_2 , and either I_2 , HI , or CdI_2 ; iodofluorination¹⁶⁶⁸ with mixtures of AgF and I_2 ,¹⁶⁶⁹ and mixtures of N -bromo amides in anhydrous HF give bromofluorination.¹⁶⁷⁰ Bromo-, iodo-, and

chlorofluorination have also been achieved by treatment of the substrate with a solution of Br_2 , I_2 , or an *N*-halo amide in polyhydrogen fluoride–pyridine;¹⁶⁷¹ while addition of I along with Br, Cl, or F has been accomplished with the reagent bis(pyridine)iody(I) tetrafluoroborate $[\text{I}(\text{Py})_2\text{BF}_4]$ and Br^- , Cl^- , or F^- , respectively.¹⁶⁷² This reaction, which is also successful for triple bonds,¹⁶⁷³ can be extended to addition of I and other nucleophiles (e.g., NCO , OH , OAc , and NO_2).¹⁶⁷³

Conjugated systems give both 1,2- and 1,4-addition.¹⁶⁴⁴ Triple bonds add bromine, although generally more slowly than double bonds (see Sec. 15.B.i). Molecules that contain both double and triple bonds are preferentially attacked at the double bond. Addition of 2 molar equivalents of bromine to triple bonds gives tetrabromo products. There is evidence that the addition of the first molar equivalent of bromine to a triple bond may take place by a nucleophilic mechanism.¹⁶⁷⁴ Molecular diiodine on Al_2O_3 adds to triple bonds to give good yields of 1,2-diiodoalkenes.¹⁶⁷⁵ Interestingly, 1,1-diiodo alkenes are prepared from an alkynyltin compound, via initial treatment with $\text{Cp}_2\text{Zr}(\text{H})\text{Cl}$, and then 2.15 equiv of iodine.¹⁶⁷⁶ A mixture of NaBO_3 and NaBr adds two bromine atoms across a triple bond.¹⁶⁷⁷ With allenes it is easy to stop the reaction after only 1 equiv has added, to give $\text{X}-\text{C}=\text{C}-\text{CX}=\text{C}$.¹⁶⁷⁸ Addition of halogen to ketenes gives α -halo acyl halides, but the yields are not good.

double bonds, if the reaction is carried out in tetramethylene sulfone–CHCl₃¹⁶⁸² or if an oxidizing agent (e.g., HIO₃) is present.¹⁶⁸³ Iodine and cerium sulfate in aq acetonitrile generates iodohydrins,¹⁶⁸⁴ as do iodine and ammonium acetate in acetic acid,¹⁶⁸⁵ or NaIO₄ with sodium bisulfite.¹⁶⁸⁶

The HOBr can also be conveniently added by the use of a reagent consisting of an *N*-bromo amide (e.g., NBS or *N*-bromoacetamide) and a small amount of water in a solvent (e.g., DMSO or dioxane).¹⁶⁸⁷ *N*-Iodosuccinimide in aq dimethoxyethane leads to the iodohydrin.¹⁶⁸⁸ An especially powerful reagent for HOCl addition is *tert*-butyl hydroperoxide (or di-*tert*-butyl peroxide) along with TiCl₄.¹⁶⁸⁹ Chlorohydrins can be conveniently prepared by treatment of the alkene with Chloramine T (TsNCl[−] Na⁺)¹⁶⁹⁰ in acetone–water.¹⁶⁹¹ The compound HOI can be added by treatment of alkenes with periodic acid and NaHSO₃.¹⁶⁹² There are Se catalyzed iodohydrin forming reactions.¹⁶⁹³ The reaction of an alkene with polymeric (SnO)_m and then HCl with Me₃SiOOSiMe₃, leads to the chlorohydrin.¹⁶⁹⁴ Hypervalent iodine compounds react with an alkene and iodine in aqueous media to give the iodohydrin.¹⁶⁹⁵ Halohydrins are produced in ionic liquids.¹⁶⁹⁶ *N*-Bromo and *N*-iodosaccharin have been used to prepare the corresponding halohydrins.¹⁶⁹⁷

The compound HOF has also been added, but this reagent is difficult to prepare in a pure state and *explosions have occurred*.¹⁶⁹⁸

The mechanism of HOX addition is electrophilic, with initial attack by the alkene on the positive halogen end of the HOX dipole. Following *Markovnikov's rule*, the positive halogen goes to the side of the double bond that has more hydrogen atoms (forming a more stable carbocation). This carbocation (or bromonium or iodonium ion in the absence of an aqueous solvent) reacts with [−]OH or H₂O to give the product. If the substrate is treated with Br₂ or Cl₂ (or another source of positive halogen, e.g., NBS) in an alcohol or a carboxylic acid solvent, it is possible to obtain, directly C—C—C—OR or X—C—C—OCOR, respectively (see also, Reaction 15-48).¹⁶⁹⁹ Even the weak nucleophile CF₃SO₂O[−] can participate in the second step. The addition of Cl₂ or Br₂ to alkenes in the presence of this ion resulted in the formation of some β-haloalkyl triflates.¹⁷⁰⁰ There is evidence that the mechanism with Cl₂ and H₂O is

different from that with HOCl.¹⁷⁰¹ Both HOCl and HOBr can be added to triple bonds to give dihalo carbonyl compounds ($-\text{CX}_2-\text{CO}-$).

Alcohols and halogens react with alkenes to form halo ethers. When a homoallylic alcohol is treated with bromine, cyclization occurs to give a 3-bromotetrahydrofuran derivative.¹⁷⁰² *tert*-Butyl hypochlorite (Me_3COCl), hypobromite, and hypoiodite¹⁷⁰³ add to double bonds to give halogenated *tert*-butyl ethers ($\text{X}-\text{C}-\text{C}-\text{OCMe}_3$). This is a convenient method for the preparation of tertiary ethers. Iodine and ethanol convert some alkenes to iodo-ethers.¹⁷⁰⁴ Iodine, alcohol, and a $\text{Ce}(\text{OTf})_2$ catalyst also generates the iodo-ether.¹⁷⁰⁵ When Me_3COCl or Me_3COBr is added to alkenes in the presence of excess ROH, the ether $\text{X}-\text{C}-\text{C}-\text{OR}$ is produced.¹⁷⁰⁶ Vinylic ethers give β -halo acetals.¹⁷⁰⁷ Chlorine acetate [solutions of which are prepared by treating Cl_2 with $\text{Hg}(\text{OAc})_2$ in an appropriate solvent] adds to alkenes to give acetoxy chlorides.¹⁷⁰⁸ Acetoxy fluorides have been obtained by treatment of alkenes with CH_3COOF .¹⁷⁰⁹

For a method of iodoacetyl addition, see Reaction 15-48.

15-41 Halolactonization and Halolactamization

Halo-alkoxylation

Halo esters can be formed by addition of halogen atoms and ester groups to an alkene. Alkene carboxylic acids give a tandem reaction of formation of a halonium ion followed by intramolecular displacement of the carboxylic group to give a halo lactone. This tandem addition of X and OCOR is called *halolactonization*.¹⁷¹⁰

The most common version of this reaction is known as *iodolactonization*,¹⁷¹¹ and a typical example is the conversion of **111** to **112**.¹⁷¹² Bromo lactones and, to a lesser extent, chloro lactones have also been prepared. In general, addition of the halogen to an alkenyl acid, as shown, leads to the halo-lactone. Other reagents include $\text{I}^+(\text{collidine})_2\text{PF}_6^-$,¹⁷¹³ KI/sodium

persulfate.¹⁷¹⁴ The Ti^{1715} and Y^{1716} reagents, along with the halogen, have also been used. An enantioselective 5-endo-halolactonization procedure has been reported using systems, such as iodobis(collidine) hexafluorophosphate or AgSbF_6 , followed by iodine.¹⁷¹⁷ When done in the presence of a chiral Ti reagent, I_2 , and CuO , lactones are formed with good enantioselectivity.¹⁷¹⁸ Iodine monochloride (ICl) has been used, with formation of a quaternary center at the oxygen-bearing carbon of the lactone.¹⁷¹⁹ Organocatalysts have also been used to mediate asymmetric halolactonization reactions.¹⁷²⁰ Enantioselective iodolactonization occurs with pentenoic acid derivatives in the presence of a chiral $\text{Co}(\text{salen})$ complex.¹⁷²¹

In the case of γ,δ -unsaturated acids, five-membered rings (γ -lactones) are predominantly formed (as shown above; note that *Markovnikov's rule* is followed), but six-membered and even four-membered lactones have also been made by this procedure. There is a *gem-dimethyl effect* that favors formation of 7–11 membered ring lactones by this procedure.¹⁷²²

Formation of halo-lactams (Reaction **15-43**) by a procedure similar to halolactonization is difficult, but the problems have been overcome. Formation of a triflate from **113** followed by treatment with iodine leads to the iodolactam (**114**).¹⁷²³ A related cyclization of *N*-sulfonyl-amino alkenes and NBS gave the bromo-lactam,¹⁷²⁴ and a dichloro-*N,N*-bis(allylamide) was converted to a dichloro-lactam with FeCl_2 .¹⁷²⁵ Note that lactone formation is possible from unsaturated amides

¹⁷²⁶ When a general group (e.g., halo) is used, its priority is that of the lowest member of its group (see Ref. 1680). Thus the general name for this transformation is halo-alkylsulfonyl addition because “halo” has the same priority as “fluoro”, its lowest member.

Sulfonyl halides add to double bonds to give β -halo sulfones, in the presence of free radical initiators or UV light. A particularly good catalyst is cuprous chloride.¹⁷²⁷ In the presence of TsCl, AIBN and a Ru catalyst, β -chloro sulfones are generated from alkenes.¹⁷²⁸ A combination of the anion ArSO_2Na , NaI, and ceric ammonium nitrate converts alkenes to vinyl sulfones.¹⁷²⁹ Triple bonds behave similarly, to give β -halo- α,β -unsaturated sulfones.¹⁷³⁰ In a similar reaction, sulfonyl chlorides, (RSCl) give β -halo thioethers.¹⁷³¹ The latter may be free radical or electrophilic additions, depending on conditions. The addition of MeS and Cl has also been accomplished by treating the alkene with Me_3SiCl and Me_2SO .¹⁷³² The use of Me_3SiBr and Me_2SO does not give this result; dibromides (Reaction 15-39) are formed instead.

β -Iodothiocyanates can be prepared from alkenes by treatment with I_2 and isothiocyanatotributylstannane (Bu_3SnNCS).¹⁷³³ Bromothiocyation can be accomplished with Br_2 and thallium(I) thiocyanate.¹⁷³⁴ Lead(II) thiocyanate reacts with terminal alkynes in the presence of PhICl_2 to give the bis(thiocyanato) alkene $[\text{ArC}(\text{SCN})-\text{CHSCN}]$.¹⁷³⁵ Such compounds were also prepared from alkenes using KSCN and FeCl_3 ¹⁷³⁶ or iodine thiocyanate.¹⁷³⁷ β -Halo disulfides, formed by addition of arenethiosulfonyl chlorides to double-bond compounds, are easily converted to thiiranes by treatment with sodium amide or sodium sulfide.¹⁷³⁸

OS VIII, 212. See also, OS VII, 251.

15-43 Addition of Halogen and a Nitrogen Group (Addition of Halogen, Nitrogen)

Dialkylamino-chloro-addition

The groups R_2N and Cl can be added directly to alkenes, allenes, conjugated dienes, and alkynes, by treatment with dialkyl-*N*-chloroamines and acids.¹⁷³⁹ *N*-Halo amides (RCONHX) add RCONH and X to double bonds under the influence of UV light or chromous chloride.¹⁷⁴⁰ *N*-Bromoamides add to alkenes in the presence of a transition metal

catalyst (e.g., SnCl_4) to give the corresponding β -bromo amide.¹⁷⁴¹ The reaction of TsNCl_2 and a ZnCl_2 catalyst gave the chloro tosylamine.¹⁷⁴² Aminochlorination of alkenes occurs in a CO_2 promoted reaction with Chloramine-T ($\text{ToISO}_2\text{N}^-\text{—Cl}$).¹⁷⁴³ These are free radical additions, with initial attack by the $\text{R}_2\text{NH}^{\bullet+}$ radical ion.¹⁷⁴⁴ Amines add to allenes in the presence of a Pd catalyst.¹⁷⁴⁵ A mixture of N -(2-nosyl) NCl_2 and sodium N -(2-nosyl) NH^- with a CuOTf catalyst reacted with conjugated esters to give the *vicinal* (*E*)-3-chloro-2-amino ester.¹⁷⁴⁶ A variation of this latter reaction was done in an ionic liquid.¹⁷⁴⁷

15-44 Addition of NOX and NO_2X (Addition of Halogen, Nitrogen)

Nitroso-chloro-addition

There are three possible products when NOCl is added to alkenes, a β -halo nitroso compound, an oxime, or a β -halo nitro compound.¹⁷⁴⁸ The initial product is always the β -halo nitroso compound,¹⁷⁴⁹ but these are stable only if the carbon bearing the nitrogen has no hydrogen. If it has, the nitroso compound tautomerizes to the oxime, $\text{H—C—N=O} \rightarrow \text{C=N—OH}$. With some alkenes, the initial β -halo nitroso compound is oxidized by the NOCl to a β -halo nitro compound.¹⁷⁵⁰ Many functional groups may be present without interference (e.g., CO_2H , CO_2R , CN , OR). The mechanism in most cases is probably simple electrophilic addition, and the addition is usually anti, although syn addition has been reported in some cases.¹⁷⁵¹ *Markovnikov's rule* is followed, the positive NO going to the carbon that has more hydrogen atoms.

Nitryl chloride (NO_2Cl) also adds to alkenes, to give β -halo nitro compounds, but this is a free radical process. The NO_2 goes to the less-substituted carbon.¹⁷⁵² Nitryl chloride also adds to triple bonds to give the expected 1-nitro-2-chloro alkenes.¹⁷⁵³ The compound FNO_2 can be added to alkenes¹⁷⁵⁴ by treatment with HF in HNO_3 ¹⁷⁵⁵ or by addition of the alkene to a solution of nitronium tetrafluoroborate ($\text{NO}_2^+ \text{BF}_4^-$; see Reaction 11-2) in 70% polyhydrogen fluoride–pyridine solution¹⁷⁵⁶ (see also, Reaction 15-37).

15-45 Addition of XN_3 (Addition of Halogen, Nitrogen)**Azido-iodo-addition**

The addition of iodine azide to double bonds gives β -iodo azides.¹⁷⁵⁷ The reagent can be prepared *in situ* from $\text{KI}—\text{NaN}_3$ in the presence of Oxone–wet alumina.¹⁷⁵⁸ The addition is stereospecific and anti, suggesting that the mechanism involves a cyclic iodonium ion intermediate.¹⁷⁵⁹ The reaction has been performed on many double-bond compounds, including allenes¹⁷⁶⁰ and α,β -unsaturated ketones. Similar reactions can be performed with BrN_3 ¹⁷⁶¹ and ClN_3 . 1,4-Addition has been found with acyclic conjugated dienes.¹⁷⁶² In the case of BrN_3 , both electrophilic and free radical mechanisms are important,¹⁷⁶³ while with ClN_3 the additions are chiefly free radical.¹⁷⁶⁴ Iodine monoazide (IN_3) also adds to triple bonds to give β -iodo- α,β -unsaturated azides.¹⁷⁶⁵

β -Iodo azides can be reduced to aziridines (**115**) with LiAlH_4 ¹⁷⁶⁶ or converted to *N*-alkyl- or *N*-arylaziridines (**116**) by treatment with an alkyl- or aryl-dichloroborane followed by a base.¹⁷⁶⁷ In both cases the azide is first reduced to the corresponding amine (primary or secondary, respectively) and ring closure (Reaction **10-31**) follows. With Chloramine T ($\text{TsNCl}^- \text{Na}^+$) and 10% of pyridinium bromide perbromide, however, the reaction with alkenes give an *N*-tosyl aziridine directly.¹⁷⁶⁸

Alkyl halides can be added to alkenes in the presence of a *Friedel–Crafts catalyst*, most often AlCl_3 .¹⁷⁶⁹ The yields are best for tertiary R. Secondary R can also be used, but primary R give rearrangement products (as with Reaction 11-11). The reactive species is the carbocation formed from the alkyl halide and the catalyst (see Reaction 11-11).¹⁷⁷⁰ The reaction with an alkene follows *Markovnikov's rule*, and generates the more stable carbocation from the alkene after reaction with the carbocation. Methyl and ethyl halides, which cannot rearrange to a more stable secondary or tertiary carbocation, give no reaction at all. Substitution is a side reaction, arising from loss of hydrogen from the carbocation (117). Conjugated dienes give 1,4-addition.¹⁷⁷¹ Triple bonds also undergo the reaction, to give vinylic halides.¹⁷⁷²

Simple polyhalo alkanes (e.g., CCl_4 , BrCCl_3 , ICF_3 and related molecules) add to alkenes in good yield.¹⁷⁷³ These are free radical additions and require initiation, for example,¹⁷⁷⁴ by peroxides, metal halides (e.g., FeCl_2 , CuCl),¹⁷⁷⁵ Ru catalysts,¹⁷⁷⁶ or UV light. The initial reaction generates the more stable radical intermediate, as in most free radical reactions with alkenes:

Polyhalo alkanes add to halogenated alkenes in the presence of AlCl_3 by an electrophilic mechanism. This has been called the *Prins reaction* (not to be confused with the other *Prins Reaction*, 16-54).¹⁷⁷⁷

α -Iodolactones add to alkenes in the presence of BEt_3/O_2 to give the addition product.¹⁷⁷⁸ Other α -iodoesters add under similar conditions to give the lactone.¹⁷⁷⁹ Iodoesters also add to alkenes in the presence of BEt_3 to give iodo-esters that have not cyclized.¹⁷⁸⁰

A variant of the free radical addition method has been used for ring closure (see Reaction 15-30).

For another method of adding R and I to a triple bond, see Reaction 15-23.

15-47 Addition of Acyl Halides (Addition of Halogen, Carbon)**Acyl-halo-addition**

Acyl halides add to many alkenes using *Friedel–Crafts* catalysts, although polymerization is a problem. The reaction has been applied to straight-chain, branched, and cyclic alkenes, but to very few containing functional groups, other than halogen.¹⁷⁸¹ The mechanism is similar to that of Reaction 15-46, and, as in that case, substitution competes (Reaction 12-16). Increasing temperature favors substitution,¹⁷⁸² but good yields of addition products can be achieved if the temperature is kept under 0°C. The reaction usually fails with conjugated dienes, since polymerization predominates.¹⁷⁸³ Iodo acetates have been formed from alkenes using iodine and Pb(OAc)₂ in acetic acid.¹⁷⁸⁴ Rhodium-catalyzed variations are known.¹⁷⁸⁵ The reaction can be performed on triple-bond compounds, producing compounds of the form RCO–C≡C–Cl.¹⁷⁸⁶ A *formyl* group and a halogen can be added to triple bonds by treatment with *N,N*-disubstituted formamides and POCl₃ (*Vilsmeier conditions*, Reaction 11-18).¹⁷⁸⁷ Chloroformates add to allenes in the presence of a Rh catalyst to give a β-chloro, β,γ-unsaturated ester.¹⁷⁸⁸

substituted double bonds are oxidized more rapidly than more substituted alkenes.¹⁷⁹³ Permanganate adds to alkenes to form an intermediate manganate ester (Reaction **118**), which is decomposed under alkaline conditions. Transition state structures and the energetics of the permanganate oxidation of alkenes has been studied using molecular mechanics.¹⁷⁹⁴ Bases catalyze the decomposition of **118** by coordinating with the ester. Note that there are alternative Mn complexes that may be used for *cis*-dihydroxylation of alkenes.¹⁷⁹⁵ Osmium tetroxide adds rather slowly but almost quantitatively to form a cyclic osmate ester (e.g., **119**) as an intermediate,¹⁷⁹⁶ which may be isolated in some cases, but is usually decomposed in solution with sodium sulfite (Na₂SO₃) in ethanol or other reagents.¹⁷⁹⁷

The chief drawbacks to the use of OsO₄ are the facts that it is expensive and toxic, but the reaction is made catalytic in OsO₄ by using *N*-methylmorpholine-*N*-oxide (NMO),¹⁷⁹⁸ *tert*-butyl hydroperoxide in alkaline solution,¹⁷⁹⁹ H₂O₂,¹⁸⁰⁰ peroxyacid,¹⁸⁰¹ K₃Fe(CN)₆,¹⁸⁰² and non-heme iron catalysts.¹⁸⁰³ Polymer-bound OsO₄,¹⁸⁰⁴ and encapsulated OsO₄ have been shown to give the diol in the presence of NMO,¹⁸⁰⁵ as well as OsO₄²⁻ on an ion exchange resin.¹⁸⁰⁶ Dihydroxylation has also been reported in ionic liquids.¹⁸⁰⁷ Other metals have been used to catalyze dihydroxylation, including Fe¹⁸⁰⁸ or Ru catalyzed¹⁸⁰⁹ reactions with H₂O₂. A catalytic amount of K₂OsO₄ with a Cinchona alkaloid on an ordered inorganic support, in the presence of K₃Fe(CN)₆, gives the *cis*-diol.¹⁸¹⁰

The end product of the reaction is a 1,2-diol. Potassium permanganate is a strong oxidizing agent and can oxidize the glycol product¹⁸¹¹ (see Reaction **19-7** and **19-10**). In acidic and neutral solution, it always does so; hence glycols must be prepared with alkaline¹⁸¹² permanganate, but the conditions must be mild. Even so, yields are seldom >50%, although they can be improved with phase-transfer catalysis¹⁸¹³ or increased stirring.¹⁸¹⁴ The use of ultrasound with permanganate has resulted in good yields of the diol.¹⁸¹⁵ This reaction is the basis of the *Baeyer test* for the presence of double bonds. The oxidation is compatible with a number of functional groups, including trichloroacetamides.¹⁸¹⁶

Anti-hydroxylation can be achieved by treatment with H₂O₂ and formic acid. In this case, epoxidation (Reaction **15-50**) occurs first, followed by an S_N2 reaction, which results in overall anti addition:

The same result can be achieved in one step with *m*-chloroperoxybenzoic acid and water.¹⁸¹⁷ Overall anti addition can also be achieved by the method of Prévost (the *Prévost reaction*). In this method, the alkene is treated with iodine and silver benzoate in a 1:2 molar ratio. The initial addition is anti and results in a β-halo benzoate, as shown. These can be isolated, and this represents a method of addition of IOCOPh. However, under normal reaction conditions, the iodine is replaced by a second PhCOO group. This is a nucleophilic substitution reaction via the neighboring-group mechanism (Sec. 10.C), so the groups are still anti:

Hydrolysis of the ester does not change the configuration. The *Woodward modification* of the Prévost reaction is similar, but results in overall syn hydroxylation.¹⁸¹⁸ In this procedure, the alkene is treated with iodine and silver acetate in a 1:1 molar ratio in acetic acid containing water. Here again, the initial product is a β-halo ester; the addition is anti and a nucleophilic replacement of the iodine occurs. However, in the presence of water, neighboring-group participation is prevented or greatly decreased by solvation of the ester function, and the mechanism is the normal S_N2 process,¹⁸¹⁹ so the monoacetate is syn and

hydrolysis gives the diol as the product, with overall syn addition. Although the *Woodward* method results in overall syn addition, the product may be different from that with OsO_4 or KMnO_4 , since the overall syn process is from the *more hindered side* of the alkene.¹⁸²⁰ Both the *Prévost* and the *Woodward* methods¹⁸²¹ have been carried out in high yields with thallium(I) acetate and thallium(I) benzoate instead of the silver carboxylates.¹⁸²² Note that cyclic sulfates can be prepared from alkenes by reaction with PhIO and $\text{SO}_3 \cdot \text{DMF}$.¹⁸²³ Diacetates have been prepared from alkenes using a Cu catalyzed reaction with $\text{PhI}(\text{OAc})_2$ as the oxidizing agent.¹⁸²⁴ A similar Pd/Cu catalyzed reaction is known using O_2 as the oxidant.¹⁸²⁵

Dialkoxylation reactions are possible. The reaction of an aryl alkene with CH_3OH , O_2 , and a Pd catalyst leads to the dimethoxy compound (see Reaction **120**), with moderate enantioselectivity if a chiral ligand is used.¹⁸²⁶ Dihydroxylation to alkenes of the form $\text{RCH}=\text{CH}_2$ has been made enantioselective, and addition to $\text{RCH}=\text{CHR}'$ both diastereoselective¹⁸²⁷ and enantioselective,¹⁸²⁸ using chiral additives or chiral catalysts¹⁸²⁹ (e.g., **121** or **122**, derivatives of the naturally occurring quinine and quinuclidine),¹⁸³⁰ along with OsO_4 , in what is called

*Sharpless asymmetric dihydroxylation.*¹⁸³¹ Other chiral ligands¹⁸³² have also been used, as well as polymer¹⁸³³ and silica-bound¹⁸³⁴ *Cinchona* alkaloids. These amines bind to the OsO_4 *in situ* as chiral ligands, causing it to add asymmetrically.¹⁸³⁵ This has been done both with the stoichiometric and with the catalytic method.¹⁸³⁶ The catalytic method has been extended to conjugated ketones¹⁸³⁷ and to conjugated dienes, which give tetrahydroxy products diastereoselectively.¹⁸³⁸ Asymmetric dihydroxylation has also been reported with chiral alkenes.¹⁸³⁹ Ligands **121** and **122** not only cause enantioselective addition, but also accelerate the reaction, so that they may be useful even where enantioselective addition is not required.¹⁸⁴⁰ Although **121** and **122** are not enantiomers, they give enantioselective addition to a given alkene in the opposite sense; for example, styrene predominantly gave the (*R*) diol with **121**, and the (*S*) diol with **122**.¹⁸⁴¹ Note that ionic liquids have been used in asymmetric dihydroxylation.¹⁸⁴²

Two phthalazine derivatives,¹⁸⁴³ (DHQD)₂PHAL (**123**) and (DHQ)₂PHAL (**124**) are used in conjunction with an Os reagent to improve the efficiency and ease of use, and are commercially available as AD-mix- β (using **123**) and AD-mix- α (using **124**). Catalyst **123** is prepared from dihydroquinidine (DHQD) and 1,4-dichlorophthalazine (PHAL), and **124** is prepared from dihydroquinine (DHQ) and PHAL. The actual oxidation using AD-mix α or β uses **124** or **123**, respectively, mixed with potassium osmate [$\text{K}_2\text{OsO}_2(\text{OH})_6$], powdered $\text{K}_3\text{Fe}(\text{CN})_6$, and powdered K_2CO_3 in an aqueous solvent mixture.¹⁸⁴³ One study

showed that osmylation does not always occur preferentially on the most electron-rich double bond. There are examples of the less-rich double bond reacting preferentially, and such preferences may be amplified using AD type reagents, which adds significant steric hindrance to the overall system.¹⁸⁴⁴

These additives have been used in conjunction with microencapsulated OsO₄,¹⁸⁴⁵ and polymer bound **123** has been used.¹⁸⁴⁶ An asymmetric dihydroxylation was reported catalyzed by ionic polymer-supported OsO₄.¹⁸⁴⁷ A catalytic amount of flavin has been used.¹⁸⁴⁸ Both **123**¹⁸⁴⁹ and **124**¹⁸⁵⁰ have been used to generate diols with high enantioselectivity. Oxidation of a terminal alkene with AD-mix and then oxidation with TEMPO/NaOCl/NaOCl₂ leads to α -hydroxyl carboxylic acids with high enantioselectivity.¹⁸⁵¹

Enantioselective and diastereoselective addition have also been achieved by using preformed derivatives of OsO₄, already containing chiral ligands,¹⁸⁵² and by the use of OsO₄ on alkenes that have a chiral group elsewhere in the molecule.¹⁸⁵³ A Rh catalyzed diboration of alkenes in the presence of a chiral ligand, leads to the corresponding diol with good enantioselectivity after oxidation.¹⁸⁵⁴

Alkenes can also be oxidized with metallic acetates [e.g., lead tetraacetate¹⁸⁵⁵ or thallium(III) acetate]¹⁸⁵⁶ to give bis(acetates) of glycols.¹⁸⁵⁷ Oxidizing agents (e.g., benzoquinone, MnO₂, or O₂), along with palladium acetate, have been used to convert conjugated dienes to 1,4-diacetoxy-2-alkenes (1,4-addition).¹⁸⁵⁸

1,2-Diols are also generated from terminal alkynes by two sequential reactions with a Pt catalyst and then a Pd catalyst, both with HSiCl₃, and a final oxidation with H₂O₂—KF.¹⁸⁵⁹ The dihydroxylation of a vinyl ether, derived from an alkyne, leads to α -hydroxy aldehydes.¹⁸⁶⁰ Dihydroxylation of alkenes has been reported using a lipase and hydrogen peroxide, under microwave irradiation.¹⁸⁶¹ A Pd catalyzed diacetoxylation is also known.¹⁸⁶²

15-49 Dihydroxylation of Aromatic Rings

Dihydroxy-addition

One π bond of an aromatic ring can be converted to a cyclohexadiene 1,2-diol by reaction with enzymes associated with *P. putida*.¹⁸⁶⁴ A variety of substituted aromatic compounds can be oxidized, including bromobenzene, chlorobenzene,¹⁸⁶⁵ and toluene.¹⁸⁶⁶ In these latter cases, introduction of the hydroxyl groups generates a chiral molecule that can be used as a template for asymmetric syntheses.¹⁸⁶⁷

OS X, 217.

15-50 Epoxidation (Addition of Oxygen, Oxygen)

epi-Oxy-addition

Alkenes are converted to epoxides (oxiranes) by reaction with many peroxyacids.¹⁸⁶⁸ The reaction, called the *Prilezhaev reaction*, has wide utility.¹⁸⁶⁹ The most common is probably *m*-chloroperoxybenzoic acid, but peroxyacetic and peroxybenzoic are available, and trifluoroperoxyacetic acid¹⁸⁷⁰ and 3,5-dinitroperoxybenzoic acid¹⁸⁷¹ are particularly reactive. The limiting factor concerning choice of the peroxyacid is usually whether or not it is commercially available because an in-lab preparation is potentially rather dangerous. Magnesium monoperoxyphthalate (MMPP)¹⁸⁷² is commercially available, and has been shown to be a good substitute for *m*-chloroperoxybenzoic acid in a number of reactions.

Alkyl, aryl, hydroxyl, ester, and other groups may be present, but not amino groups since they are oxidized by the reagent. The presence of electron-donating groups increases the rate, and the reaction is particularly rapid with tetraalkyl alkenes. Conditions are mild and yields are high. Transition metal catalysts can facilitate epoxidation of alkenes at low temperatures or with alkenes that may otherwise react sluggishly.¹⁸⁷³

The one-step mechanism involving a transition state (e.g., **125**)¹⁸⁷⁴ was proposed by Bartlett.¹⁸⁷⁵ Evidence for this concerted mechanism is as follows¹⁸⁷⁶: (1) The reaction is second order. If ionization were the rate-determining step, it would be first order in peroxyacid. (2) The reaction readily takes place in nonpolar solvents, where formation of ions is inhibited.¹⁸⁷⁷ (3) Measurements of the effect on the reaction rate of changes in the substrate structure show that there is no carbocation character in the transition state.¹⁸⁷⁸ (4) The addition is stereospecific (i.e., a *trans*-alkene gives a *trans*-epoxide and a *cis*-alkene gives a *cis*-epoxide) even in cases where electron-donating substituents would stabilize a hypothetical carbocation intermediate.¹⁸⁷⁹ However, where there is an OH group in the allylic or homoallylic position, the stereospecificity diminishes or disappears, with both *cis* and *trans* isomers giving predominantly and exclusively the product where the incoming oxygen is syn to the OH group. This probably indicates a transition state in which there is hydrogen bonding between the OH group and the peroxyacid.¹⁸⁸⁰

In general, peroxides (HOOH¹⁸⁸¹ and ROOH) are poor reagents for epoxidation of simple alkenes since OH and OR are poor leaving groups in the concerted mechanism shown above.¹⁸⁸² Transition metal catalysts¹⁸⁸³ have been used with alkyl hydroperoxides,¹⁸⁸⁴

using H_2O_2 in a strong alkaline solution) is common. Cinchona-derived phase-transfer catalysts, initially used by Wynberg, are now common.¹⁹¹¹ Enantioselectivities can be significantly improved by changes of the catalyst structure, as well as the type of oxidant.¹⁹¹² A Yb—BINOL complex, with *t*-BuOOH led to epoxidation of conjugated ketones with high asymmetric induction,¹⁹¹³ as did a mixture of NaOCl and a *Cinchona* alkaloid.¹⁹¹⁴ Treatment with aq NaOCl¹⁹¹⁵ or with an alkyl hydroperoxide¹⁹¹⁶ and a chiral phase-transfer agent leads to chiral nonracemic epoxy-ketones. Epoxides can also be prepared by treating alkenes with oxygen or with an alkyl peroxide¹⁹¹⁷ catalyzed by a complex of a transition metal (e.g., V, Mo, Ti, La,¹⁹¹⁸ Y,¹⁹¹⁹ or Co).¹⁹²⁰ The use of chiral additive leads to enantioselective epoxidation,¹⁹²¹ and organocatalysts have been used as well.¹⁹²² Chiral hydroperoxides have been used for enantioselective epoxidation.¹⁹²³

Other epoxidation methods are available. Dioxiranes,¹⁹²⁴ (e.g., dimethyl dioxirane, **126**),¹⁹²⁵ either isolated or generated *in situ*,¹⁹²⁶ are important epoxidation reagents. With dimethyloxirane, C—H insertion reactions can occur preferentially.¹⁹²⁷ The reaction with alkenes is rapid, mild, safe, and a variety of methods have been developed using an oxidant as a coreagent. Substituent effects in such reactions have been studied¹⁹²⁸ and also substrate variations.¹⁹²⁹ The most commonly used coreagent is probably potassium peroxomonosulfate (KHSO_5). Oxone ($2\text{KHSO}_5 \cdot \text{KHSO}_4 \cdot \text{K}_2\text{SO}_4$) is a common source of KHSO_5 . Oxone reacts with ketones¹⁹³⁰ and sodium bicarbonate to convert an alkene to

an epoxide. Oxone converts alkenes to epoxides in the presence of certain additives (e.g., *N,N*-dialkylalloxans).¹⁹³¹ Oxone, with hydrogen peroxide or a similar oxidant, can be used with chiral ketones¹⁹³² or aldehydes to convert alkenes to chiral, nonracemic epoxides.¹⁹³³ This reaction probably converts alkenes to epoxides with good enantioselectivity by *in situ* generation of dioxirane.¹⁹³⁴ Chiral dioxiranes have reportedly given nonracemic epoxides.¹⁹³⁵ This transformation with chiral carbohydrates is sometimes called *Shi epoxidation*.¹⁹³⁶ Epoxidation does not occur in good yields with these reagents in most other solvents, and it is suggested that the active agent that generates dioxirane is peroxyimide acid [MeC(=NH)OOH].¹⁹³⁷ Note that benzaldehyde with Chloramine-M¹⁹³⁸ will convert alkenes to epoxides.¹⁹³⁹

Oxone oxidizes iminium salts to an oxaziridinium intermediate (**127**), which can transfer oxygen to an alkene to form an epoxide and regenerate the iminium salt.¹⁹⁴⁰ This variation has been applied to asymmetric¹⁹⁴¹ epoxidations using chiral iminium salt precursors.¹⁹⁴² Other asymmetric epoxidation reactions of alkenes use chiral ketones and iminium salts with an organocatalyst.¹⁹⁴³ Direct epoxidation of alkenes has been done using oxaziridinium salts.¹⁹⁴⁴

Although cis–trans isomerization of epoxides is not formally associated with this section, it is a potential issue in the conversion of an alkene to an epoxide. There are several catalysts for this process.¹⁹⁴⁵

It would be useful if triple bonds could be similarly epoxidized to give oxirenes (see oxirene, above), but they are not stable compounds.¹⁹⁴⁶ Two oxirenes have been trapped in solid argon matrices at very low temperatures, but they decayed upon warming to 35 K.¹⁹⁴⁷ Oxirenes probably form in the reaction,¹⁹⁴⁸ but react further before they can be isolated. Note that oxirenes bear the same relationship to cyclobutadiene that furan does to benzene and may therefore be expected to be antiaromatic (Sec. 2.B and 2.K.ii).

Conjugated dienes can be epoxidized (1,2-addition), although the reaction is slower than for corresponding alkenes, but α,β -unsaturated ketones do not generally give epoxides when treated with peroxyacids.¹⁹⁴⁹ The epoxidation of α,β -unsaturated ketones with H_2O_2 under basic conditions is known as the *Waits–Scheffer epoxidation*, discovered in 1921.¹⁹⁵⁰ This fundamental reaction has been extended to α,β -unsaturated ketones (including quinones), aldehydes, and sulfones.¹⁹⁵¹ This is a nucleophilic addition by a *Michael-type* mechanism, involving attack by HO_2^- ¹⁹⁵²: This reaction is another example of 1,4-addition of a heteroatom-containing species, as discussed in Reaction 15-31.

α,β -Unsaturated compounds can be epoxidized alkyl hydroperoxides and a base,¹⁹⁵³ or with H_2O_2 and a base¹⁹⁵⁴ or heteropoly acids.¹⁹⁵⁵ The reaction has been done with LiOH and polymer-bound quaternary ammonium salts.¹⁹⁵⁶

Another important asymmetric epoxidation of a conjugated system is the reaction of alkenes with polyleucine,¹⁹⁵⁷ DBU, and urea– H_2O_2 , giving an epoxy–carbonyl compound with good enantioselectivity.¹⁹⁵⁸ The hydroperoxide anion epoxidation of conjugated

carbonyl compounds with a polyamino acid (e.g., poly-L-alanine or poly-L-leucine is known as the *Juliá–Colonna epoxidation*.¹⁹⁵⁹ Epoxidation of conjugated ketones to give nonracemic epoxy-ketones was done with aq NaOCl and a Cinchona alkaloid derivative as catalyst.¹⁹⁶⁰ A triphasic phase-transfer catalysis protocol has also been developed.¹⁹⁶¹ β -Peptides have been used as catalysts in this reaction.¹⁹⁶²

When a carbonyl group is elsewhere in the molecule, but not conjugated with the double bond, the *Baeyer–Villiger Reaction* (**18-19**) may compete. Allenes¹⁹⁶³ are converted by peroxyacids to allene oxides¹⁹⁶⁴ or spiro dioxides, both of which species can in certain cases be isolated,¹⁹⁶⁵ but more often are unstable under the reaction conditions and react further to give other products.¹⁹⁶⁶

Allylic alcohols can be converted to epoxy-alcohols with *tert*-butylhydroperoxide on molecular sieves,¹⁹⁶⁷ or with peroxyacids.¹⁹⁶⁸ The addition of an appropriate chiral ligand to the metal-catalyzed hydroperoxide epoxidation of allylic alcohols leads to high enantioselectivity. This important modification is known as the *Sharpless asymmetric epoxidation*,¹⁹⁶⁹ where allylic alcohols are converted to optically active epoxides with excellent enantioselectivity by treatment with *t*-BuOOH, titanium tetrakisopropoxide, and optically active diethyl tartrate.¹⁹⁷⁰ The $\text{Ti}(\text{OCHMe}_2)_4$ and diethyl tartrate can be present in catalytic amounts (15–10 mol%) if molecular sieves are present.¹⁹⁷¹ Polymer-supported catalysts have also been reported.¹⁹⁷² The use of a tartrate–PEG reagent (PEG₃₅₀ or PEG₇₅₀) allows generation of both enantiomers.¹⁹⁷³ Both (+) and (–) diethyl tartrate are readily available, so either enantiomer of the product can be prepared. The method has been successful for a wide range of primary allylic alcohols, including substrates where the double bond is mono-, di-, tri-, and tetrasubstituted,¹⁹⁷⁴ and is highly useful in natural product synthesis. The mechanism of the Sharpless epoxidation is believed to involve attack on the substrate by a compound¹⁹⁷⁵ formed from the titanium

alkoxide and the diethyl tartrate to produce a complex that also contains the substrate and the *t*-BuOOH.¹⁹⁷⁶

Ordinary alkenes (without an allylic OH group) do not give optically active alcohols by the Sharpless protocol because binding to the catalyst is necessary for enantioselectivity. Homoallylic alcohols have been converted to the epoxide, however, using a V catalyst in the presence of a chiral bis(hydroxyamide).¹⁹⁷⁷ Simple alkenes can be epoxidized enantioselectively with sodium hypochlorite (NaOCl, commercial bleach) and an optically active manganese complex catalyst.¹⁹⁷⁸ Apart from the commonly used NaOCl, urea-H₂O₂ has been used.¹⁹⁷⁹

The use of a manganese-salen complex¹⁹⁸⁰ with various oxidizing agents, in what is called the *Jacobsen-Katsuki reaction*.¹⁹⁸¹ Simple alkenes can be epoxidized with high enantioselectivity.¹⁹⁸² In addition to Mn, Cr-salen,¹⁹⁸³ Ti-salen,¹⁹⁸⁴ and Ru-salen complexes¹⁹⁸⁵ have been used for epoxidation.¹⁹⁸⁶ Note that salen ligands are based on salen. The mechanism of this reaction has been examined.¹⁹⁸⁷ Radical intermediates have been suggested for this reaction.¹⁹⁸⁸ A polymer-bound Mn(III)-salen complex, in conjunction with NaOCl, has been used for asymmetric epoxidation,¹⁹⁸⁹ and manganese porphyrin complexes have also been used.¹⁹⁹⁰ Cobalt complexes give similar results.¹⁹⁹¹ A related epoxidation reaction used an iron complex with molecular oxygen and isopropanol.¹⁹⁹² Nonracemic epoxides can be prepared from racemic epoxides with (salen) cobalt(II) catalysts following a modified procedure for kinetic resolution.¹⁹⁹³

In a different type of reaction, alkenes are photooxygenated (with singlet O_2 , see Reaction 14-7) in the presence of a Ti, V, or Mo complex to give epoxy alcohols (e.g., **128**), formally derived from allylic hydroxylation followed by epoxidation.¹⁹⁹⁴ In other cases, modification of the procedure gives simple epoxidation.¹⁹⁹⁵ Alkenes react with aldehydes and oxygen, with Pd-on-silica¹⁹⁹⁶ or a Ru catalyst,¹⁹⁹⁷ to give the epoxide.

Thiiranes can be prepared directly from alkenes using specialized reagents.¹⁹⁹⁸ Thiourea with a tin catalyst gives the thiirane, for example.¹⁹⁹⁹ Interestingly, internal alkynes were converted to 1,2-dichorothiiranes by reaction with S_2Cl_2 (sulfur monochloride).²⁰⁰⁰ Note that epoxides are converted to thiiranes with ammonium thiocyanate and a cerium complex.²⁰⁰¹ A trans-thiiration reaction occurs with a Mo catalyst, in which an alkene reacts with styrene thiirane to give the new thiirane.²⁰⁰²

with a disulfide (RSSR) and BF_3 -etherate.²⁰⁰⁶ This reaction has been carried out intramolecularly.²⁰⁰⁷ In a similar manner, the reaction of alkenes with ceric ammonium nitrate and diphenyl diselenide in methanol leads to vicinally substituted phenylselenenyl methyl ethers.²⁰⁰⁸ Dimethyl diselenide adds to alkenes to form vicinal bis(methylselenenyl) compounds, in the presence of tin tetrachloride.²⁰⁰⁹

Halo-ethers can be formed by the reaction of alkenyl alcohols with various reagents. Hept-6-en-1-ol reacts with $(\text{collidine})_2\text{I}^+\text{PF}_6^-$, for example, to form 2-iodomethyl-1-oxacycloheptane.²⁰¹⁰

15-52 Oxyamination (Addition of Oxygen, Nitrogen)

Tosylamino-hydroxy-addition

N-Tosylated β -hydroxy alkylamines, which can be easily hydrolyzed to β -hydroxy-amines²⁰¹¹, can be prepared²⁰¹² by treatment of alkenes with the trihydrate of Chloramine-T (*N*-chloro-*p*-toluenesulfonamide sodium salt)¹⁶⁹⁰ and a catalytic amount of OsO_4 .²⁰¹³ In some cases, yields can be improved by the use of phase-transfer catalysis.²⁰¹⁴ The reaction has been carried out enantioselectively.²⁰¹⁵ Alkenes can be converted to amido alcohols enantioselectivity by modification of this basic scheme. The *Sharpless asymmetric aminohydroxylation* employs a catalyst consisting of *Cinchona* alkaloid derived ligands and an osmium species in combination with a stoichiometric nitrogen source that also functions as the oxidant.²⁰¹⁶ The Cu catalyzed reaction of an alkene with a *N*-sulfone oxaziridine leads to an oxazolidine.²⁰¹⁷ *N*-Chlorosulfonyl isocyanate has been used to prepare 1,2-amino alcohols.²⁰¹⁸ The Cu catalyzed hydroxyamination of alkenes was reported using Boc-hydroxylamine.²⁰¹⁹

The reaction of a carbamate with $(\text{DHQ})_2\text{PHAL}$ (**124**) and the osmium compound, with NaOH and *tert*-butyl hypochlorite, leads to a diastereomeric mixture of amido alcohols **129** and **130**, each formed with high enantioselectivity.²⁰²⁰ An enantioselective amino-hydroxylation of acrylamides has been reported.²⁰²¹

In general, the nitrogen adds to the less sterically hindered carbon of the alkene to give the major product. *N*-Bromoamides, in the presence of a catalytic amount of (DHQ)₂PHAL and LiOH converts conjugated esters to β-amido-α-hydroxy esters with good enantioselectivity.²⁰²² Another oxyamination reaction involves treatment of a Pd complex of the alkene with a secondary or primary amine, followed by lead tetraacetate or another oxidant.²⁰²³

The organolanthanide-catalyzed alkene hydroamination has been reported.²⁰²⁴ With this approach, amino alkenes (not enamines) can be cyclized to form cyclic amines,²⁰²⁵ and amino alkynes lead to cyclic imine.²⁰²⁶ The use of synthesized C-1²⁰²⁷ and C-2 symmetric²⁰²⁸ chiral organolanthanide complexes give the amino alcohol with good enantioselectivity.

β-Amino alcohols can be prepared by treatment of an alkene with a reagent prepared from HgO and HBF₄ along with aniline to give an aminomercurial compound (PhHN—C—C—HgBF₄, aminomercuriation; see Reaction 15-7), which is hydrolyzed to PhHN—C—C—OH.²⁰²⁹ The use of an alcohol instead of water gives the corresponding amino ether. β-Azido alcohols are prepared by the reaction of an alkene with Me₃SiOOSiMe₃, Me₃SiN₃, and 20% (Cl₂SnO)_n, followed by treatment with aqueous acetic acid.²⁰³⁰

OS VII, 223, 375.

15-53 Diamination (Addition of Nitrogen, Nitrogen)

Di(alkylaryl)amino)-addition

Primary (R = H) and secondary aromatic amines react with alkenes in the presence of thallium(III) acetate to give *vic*-diamines in good yields.²⁰³¹ The reaction is not successful for primary aliphatic amines. In another procedure, alkenes can be diaminated by treatment

with the Os compounds R_3NOsO ($R = t\text{-Bu}$) and R_2NOsO_2 ,²⁰³² analogous to the Os compound mentioned at Reaction 15-52.²⁰³³ The Pd promoted method of Reaction 15-52 has also been extended to diamination.²⁰³⁴ Alkenes can also be diaminated²⁰³⁵ indirectly by treatment of the aminomercurial compound mentioned in Reaction 15-52 with a primary or secondary aromatic amine.²⁰³⁶ The reaction of an alkene with *N*-arylsulfonyl dichloroamines ($ArSO_2NCl_2$) followed by reaction with aq Na_2SO_3 , gives the *anti*-vic-diacetamide.²⁰³⁷ The Pd catalyzed addition of saccharin and $H(NTs)_2$ with an alkene, in the presence of a hypervalent iodine oxidant leads to a precursor that can be converted to a 1,2-diamine.²⁰³⁸

Two azido groups can be added to double bonds by treatment with sodium azide and iodosobenzene in acetic acid, $C=C + NaN_3 + PhIO \rightarrow N_3-C-C-N_3$.²⁰³⁹

Dienes react with ureas in the presence of a Pd catalyst, to give an oxazolidinone.²⁰⁴⁰ A Pd catalyzed reaction of dienes with di-*tert*-butyldiaziridinone also leads to an oxazolidinone.²⁰⁴¹

Alkynes react with the bis(tosylate) of ethylenediamine, in the presence of a CuI catalyst, to give a dihydropiperazine.²⁰⁴²

15-54 Formation of Aziridines (Addition of Nitrogen, Nitrogen)

epi-Arylimino-addition, and so on

Aziridines can be prepared directly from double-bond compounds by photolysis or thermolysis of a mixture of the substrate and an azide.²⁰⁴³ The reaction has been carried out with $R = \text{aryl, cyano, EtOOC, and RSO}_2$, as well as other groups. The reaction can take place by at least two pathways.

In one pathway, a 1,3-dipolar addition (Reaction 15-58) takes place to give a triazoline, which can be isolated, followed thermal by extrusion of nitrogen (Reaction 17-34). Evidence for the nitrene pathway is most compelling for $R = \text{acyl groups}$. In the other, the azide is converted to a nitrene, which adds to the double bond in a manner analogous to

that of carbene addition (Reaction **15-64**). Sulfonyloxy amines (e.g., $\text{ArSO}_2\text{ONHCO}_2\text{Et}$) form an aziridine when treated with CaO in the presence of a conjugated carbonyl compound.²⁰⁴⁴ In the presence of Cu ,²⁰⁴⁵ Co ,²⁰⁴⁶ or Rh complexes,²⁰⁴⁷ ethyl diazoacetate adds to imines to give aziridines. Diazirenes (Sec. 5.D.ii) with *n*-butyllithium converted conjugated amides to the α,β -aziridino amide.²⁰⁴⁸ Calcium oxide has also been used to generate the nitrene,²⁰⁴⁹ including nitrene precursors that have an attached chiral ester.²⁰⁵⁰ Other specialized reagents have also been used.²⁰⁵¹ As discussed in Section 5.E, singlet nitrenes add stereospecifically while triplet nitrenes do not. Aminonitrenes ($\text{R}_2\text{NN:}$) have been shown to add to alkenes²⁰⁵² to give *N*-substituted aziridines and to triple bonds to give 1-azirines, which arise from rearrangement of the initially formed 2-azirines.²⁰⁵³ *N*-Aminophthalimide generates a nitrene in the presence of a Pd catalyst, giving an *N*-phthalimido aziridine upon reaction with electron-deficient alkenes.²⁰⁵⁴ Alkyl azides add to conjugated alkenes in the presence of an acid.²⁰⁵⁵ Intramolecular aziridination reactions are known (e.g., the Pd catalyzed addition of *N*-tosyloxycarbamates to alkenes to form the bicyclic oxaziridinone).²⁰⁵⁶ Tosylamines react with alkenes in the presence of a Rh catalyst²⁰⁵⁷ or with iodine/ $\text{PhI}(\text{OAc})_2$.²⁰⁵⁸ Trichloroethylsulfamate esters react with $\text{PhI}(\text{OAc})_2$ and a Rh catalyst to give the corresponding *N*-sulfonyl aziridine.²⁰⁵⁹

Like oxirenes (see Reaction **15-50**), 2-azirines are unstable. 1-Azirines can be reduced to give chiral aziridines.²⁰⁶⁰

²⁰⁶⁰ Roth, P.; Andersson, P.G.; Somfai, P. *Chem. Commun.* **2002**, 1752.

An alternative preparation of aziridines reacts an alkene with iodine and Chloramine-T, generating the corresponding *N*-tosyl aziridine.²⁰⁶¹ Chloramine T and NBS also give the *N*-tosyl aziridine,²⁰⁶² and Bromamine-T (TsNBr⁻Na⁺) or TsNIK and have also been used in a similar manner.^{2063,2064} Diazoalkanes react with imines to give aziridines.²⁰⁶⁵ Another useful reagent is NsN=IPh, which reacts with alkenes in the presence of Rh compounds²⁰⁶⁶ or Cu complexes²⁰⁶⁷ to give *N*-Ns aziridines. Other sulfonamide reagents can be used,²⁰⁶⁸ including PhI=NTs.²⁰⁶⁹ Enantioselective aziridination is possible using this reaction with chiral ligands.²⁰⁷⁰ This reagent has been used in ionic liquids with a Cu catalyst.²⁰⁷¹ Palladium catalyzes such reactions²⁰⁷² and we can also use methyl trioxorhenium (MeReO₃).²⁰⁷³ Manganese(salen) catalysts have also been used with this reagent.²⁰⁷⁴ A nitrido Mn(salen) complex was used with ditosyl anhydride, converting a conjugated diene to an allylic *N*-tosylaziridine.²⁰⁷⁵ Arylsulfonamides react with alkenes via the nitrene using an Au²⁰⁷⁶ or a Cu catalyst.²⁰⁷⁷

Organocatalysts have been used for the enantioselective aziridination of the C=C unit in conjugated aldehydes.²⁰⁷⁸

Nitrenes can add to aromatic rings to give ring-expansion products analogous to those mentioned in Reaction 15-62.²⁰⁷⁹

15-55 Aminosulfenylation (Addition of Nitrogen, Sulfur)

Arylamino-arylthio-addition

An amino and an arylthio group can be added to a double bond by treatment with a sulfenanilide (PhSNHAr) in the presence of BF_3 -etherate.²⁰⁸⁰ The addition is anti, and the mechanism probably involves a thiiranium ion.²⁰⁸¹ In another aminosulfenylation procedure, the substrate is treated with dimethyl(methylthio)sulfonium fluoroborate ($\text{MeSSMe}_2 \text{BF}_4^-$) and ammonia or an amine,²⁰⁸² the latter acting as a nucleophile. This reaction was extended to other nucleophiles:²⁰⁸³ N_3^- ,²⁰⁸⁴ NO_2^- , CN^- , OH^- , and OAc^- to give $\text{MeS}-\text{C}-\text{C}-\text{A}$, where $\text{A} = \text{N}_3$, NO_2 , CN , OH , and OAc , respectively. An RS ($\text{R} = \text{alkyl or aryl}$) and an NHCome group have been added in an electrochemical procedure.²⁰⁸⁵

15-56 Acylacyloxylation and Acylamidation (Addition of Oxygen, Carbon, or Nitrogen, Carbon)

Acyl-acyloxy-addition

An acyl and an acyloxy group can be added to a double bond by treatment with an acyl fluoroborate and acetic anhydride.²⁰⁸⁶ As expected, the addition follows Markovnikov's rule, with the electrophile Ac^+ going to the carbon with more hydrogen atoms. In an analogous reaction, an acyl and an amido group can be added to give **131**, if a nitrile is used in place of the anhydride. Similarly, halo-acetoxylation is known.²⁰⁸⁷ This reaction has also been carried out on triple bonds, to give the unsaturated analogues of **131** (syn addition).²⁰⁸⁸

15-57 The Conversion of Alkenes or Alkynes to Lactones (Addition of Oxygen, Carbon)

This reaction is clearly related to forming esters and lactones by reaction of carboxylic acids with alkenes (Reaction 15-6), but the Mn reagent leads to differences. Alkenes react with manganese(III) acetate to give γ -lactones.²⁰⁸⁹ The mechanism is probably free radical, involving addition of $\bullet\text{CH}_2\text{COOH}$ to the double bond. Ultrasound improves the efficiency of the reaction.²⁰⁹⁰ In a related reaction, cyclohexene reacted with $\text{MeO}_2\text{CCH}_2\text{CO}_2\text{K}$ and $\text{Mn}(\text{OAc})_3$ to give an α -carbomethoxy bicyclic lactone.²⁰⁹¹ The use of dimethyl malonate and ultrasound in this reaction gave the same type of product.²⁰⁹² Lactone formation has also been accomplished by treatment of alkenes with α -bromo carboxylic acids in the presence of benzoyl peroxide as catalyst,²⁰⁹³ and with alkylidene $\text{Cr}(\text{CO})_5$ complexes.²⁰⁹⁴ Alkenes can also be converted to γ -lactones by indirect routes.²⁰⁹⁵ Chromium carbene complexes add to alkenes to give β -lactones using ultrasound.²⁰⁹⁶

Cyclic dienes react with β -keto esters, in the presence of a Ga²⁰⁹⁷ catalyst and water, to give an α -acyl bicyclic lactone.

Alkenyl acids cyclize to the corresponding lactone upon treatment with sodium hypochlorite and a Lewis acid.²⁰⁹⁸ Alkynyl acids cyclize upon treatment with PIFA [phenyliodine(III)-bis(trifluoroacetate)] to give ω -acyl lactones.²⁰⁹⁹ A variation of this reaction also employs a diselenide.²¹⁰⁰ Treatment of alkynyl acids with a Au catalyst²¹⁰¹ leads to an alkylidene lactone.

An intramolecular variation of this reaction is known, involving amides, which generate a lactam.²¹⁰²

15.C.iv. Cycloaddition Reactions

15-58 1,3-Dipolar Addition (Addition of Oxygen, Nitrogen, Carbon)

There are a large group of reactions ([3 + 2]-cycloadditions) in which five-membered heterocyclic compounds are prepared by addition of 1,3-dipolar compounds to double bonds. This reaction is quite useful in the synthesis of alkaloids,²¹⁰³ including asymmetric syntheses.²¹⁰⁴ These dipolar compounds have a sequence of three atoms $a-b-c$, of which a has a sextet of electrons in the outer shell and c has an octet with at least one unshared pair (see Table 15.3).²¹⁰⁵ The reaction can then be formulated as shown to generate **132**. Note that the initial reaction of potassium permanganate (Reaction **15-48**) occurs by [3 + 2]-cycloaddition to give a manganate ester (**119**).²¹⁰⁶ [3 + 2]-Cycloaddition occurs with other metal oxides.²¹⁰⁷ Hydrazones have also been reported to give [3 + 2]-cycloadditions.²¹⁰⁸

1,3-Dipoles of the type shown in Table 15.3 have an atom with six electrons in the outer shell, which is usually unstable. Such compounds will delocalize the charge to alleviate this electronic arrangement (they are resonance stabilized). 1,3-Dipolar compounds can be divided into two main types:

1. Those in which the dipolar canonical form has a double bond on the sextet atom and the other canonical form has a triple bond on that atom:

TABLE 15.3 Some Common 1,3-Dipolar Compounds

Compound	Reaction
Type 1	
Azide	$\text{R}-\text{N}^--\text{N}=\text{N}^+ \longleftrightarrow \text{R}-\text{N}^--\text{N}^+\equiv\text{N}$
Diazoalkane ^a	$\text{R}_2\text{C}^--\text{N}=\text{N}^+ \longleftrightarrow \text{R}_2\text{C}^--\text{N}^+\equiv\text{N}$
Nitrous oxide	$\text{O}^--\text{N}=\text{N}^+ \longleftrightarrow \text{O}^--\text{N}^+\equiv\text{N}$
Nitile imine ^b	$\text{R}-\text{N}^--\text{N}=\text{CR}'^+ \longleftrightarrow \text{R}-\text{N}^--\text{N}^+\equiv\text{CR}'$
Nitrile ylid ^c	$\text{R}_2\text{C}^--\text{N}=\text{CR}'^+ \longleftrightarrow \text{R}_2\text{C}^--\text{N}^+\equiv\text{CR}'$
Nitrile oxide ^d	$^-\text{O}-\text{N}=\text{CR}^+ \longleftrightarrow ^-\text{O}-\text{N}^+\equiv\text{CR}$
Type 2	
Azomethine imine ^e	$\text{R}_2\text{C}^--\text{N}(\text{R}^2)-\text{N}^+\text{R}' \longleftrightarrow \text{R}_2\text{C}^--\text{N}^+(\text{R}^2)=\text{NR}'$
Azoxy compound	$^-\text{O}-\text{N}(\text{R})-\text{N}^+\text{R}' \longleftrightarrow ^-\text{O}-\text{N}^+(\text{R})=\text{NR}'$
Azomethine ylid ^f	$\text{R}_2\text{C}^--\text{N}(\text{R}^2)-\text{CR}'_2^+ \longleftrightarrow \text{R}_2\text{C}^--\text{N}^+(\text{R}^2)=\text{CR}'_2$
Nitrone	$^-\text{O}-\text{N}(\text{R}')-\text{CR}_2^+ \longleftrightarrow ^-\text{O}-\text{N}^+(\text{R}')=\text{CR}_2$
Carbonyl oxide ^g	$^-\text{O}-\text{O}-\text{CR}_2^+ \longleftrightarrow ^-\text{O}-\text{O}^+=\text{CHR}_2$
Ozone	$^-\text{O}-\text{O}-\text{O}^+ \longleftrightarrow ^-\text{O}-\text{O}^+=\text{O}$
Carbonyl ylid ^h	$\text{H}_2\text{C}^--\text{O}^+=\text{CR}_2 \longleftrightarrow \text{H}_2\text{C}=\text{O}^+-\text{CR}_2$

If the discussion is limited to the first row of the periodic table, b can only be nitrogen, c can be carbon or nitrogen, and a can be carbon, oxygen, or nitrogen; hence there are six types. Among these are azides ($a = b = c = \text{N}$) and diazoalkanes.

2. Those in which the dipolar canonical form has a single bond on the sextet atom and the other form has a double bond:

Here b can be nitrogen or oxygen, and a and c can be nitrogen, oxygen, or carbon, but there are only 12 types, since, for example, $\text{N} - \text{N} - \text{C}$ is only another form of $\text{C} - \text{N} - \text{N}$. Examples are shown in Table 15.3.

Of the 18 systems, some of which are unstable and must be generated *in situ*,²¹¹⁷ the reaction has been accomplished for at least 15, but not in all cases with a carbon–carbon double bond (the reaction also can be carried out with other double bonds²¹¹⁸). Not all alkenes undergo 1,3-dipolar addition equally well. The reaction is most successful for those that are good dienophiles in the *Diels–Alder Reaction* (15-60).

The addition is stereospecific and syn, and the mechanism is probably a one-step concerted process,²¹¹⁹ as illustrated above,²¹²⁰ largely controlled by Frontier Molecular Orbital considerations.²¹²¹ Reactivity has been shown to correlate with the energy required to distort 1,3-dipole and dipolarophiles to the transition state.²¹²² In-plane aromaticity has been invoked for these dipolar cycloadditions.²¹²³ As expected for this type of mechanism, the rates do not vary much with changes in solvent,²¹²⁴ although rate acceleration has been observed in ionic liquids.²¹²⁵ Nitrile oxide cycloadditions have also been done in supercritical carbon dioxide.²¹²⁶ There are no simple rules covering orientation in 1,3-dipolar additions. The regioselectivity has been explained by MO treatments,²¹²⁷ where overlap of the largest orbital coefficients of the atoms forming the new bonds leads to the major regioisomer. When the 1,3-dipolar compound is a thiocarbonyl ylid ($\text{R}_2\text{C}=\text{S}^{+}-\text{CH}_2^{-}$) the addition has been shown to be nonstereospecific with certain

²¹¹⁷ For a review of some aspects of this, see Grigg, R. *Chem. Soc. Rev.* **1987**, 16, 89.

substrates, but stereospecific with others, indicating a nonsynchronous mechanism in these cases, and in fact, a diionic intermediate (see mechanism *c* in Reaction **15-63**, category 4) has been trapped in one such case.²¹²⁸ In a theoretical study of the 1,3-dipolar cycloadditions (diazomethane and ethene; fulminic acid $[H-C\equiv N-O]$ and ethyne),²¹²⁹ calculations based on valence bond descriptions suggest that many concerted 1,3-dipolar cycloaddition reactions follow an electronic heterolytic mechanism where the movement of well-identifiable orbital pairs is retained along the entire reaction path from reactants to product.²¹³⁰

An antibody-catalyzed $[3+2]$ -cycloaddition has been reported.²¹³¹ Metal-assisted dipolar additions are also known.²¹³² In a different metal-mediated reaction, alkenyl *Fischer carbene complexes* react with alkynes, in the presence of a Ni catalyst, to give cyclopentenones.²¹³³ Fischer carbene complexes take the form $R_2C=M(CO)_x$,²¹³⁴ and the metals include those of low oxidation state, and Fe, Mo, Cr, or W. Ligands include π -electron acceptors and π -donor substituents on methylene groups (e.g., alkoxy and amino groups).

Many of the cycloadducts formed from the dipoles in Table 15.3 are unstable, which lead to other products. The reaction of alkyl azides with alkenes generates triazolines (Reaction **15-54**), which extrude nitrogen ($N\equiv N$) upon heating or photolysis to give an aziridine.²¹³⁵ With a transition metal catalyst, alkyl azides add to alkynes to give triazoles.²¹³⁶ Retro $[3+2]$ -cycloaddition reactions are also known.²¹³⁷ Cycloaddition of azides to allenes leads to pyrrolidines.²¹³⁸

$[3+2]$ -Cycloaddition reactions occur intramolecularly to generate bicyclic and polycyclic compounds.²¹³⁹ The intramolecular cycloaddition of azomethine imines give bicyclic pyrazolidines, for example.²¹⁴⁰ When diazoalkanes (including diazo acetates, e.g., ethyl diazoacetate, N_2CHCO_2Et) react with an alkene and a Cr catalyst the initially formed product is a five-membered ring, a pyrazoline.²¹⁴¹ Pyrazolines are generally unstable and extrusion of nitrogen leads to a cyclopropane.²¹⁴² Rhodium-catalyzed cycloaddition using chiral ligands leads to formation of cyclopropanes with good enantioselectivity.²¹⁴³

There are many cases where the [3 + 2]-cycloaddition leads to cycloadducts with high enantioselectivity.²¹⁴⁴ Cycloaddition of diazo esters with a Co catalyst having a chiral ligand leads to cyclopropane derivatives with good enantioselectivity.²¹⁴⁵ Cycloaddition of nitrones and pyrazolinones with a Cu catalyst and a chiral ligand leads to pyrrolidine derivatives with good enantioselectivity.²¹⁴⁶ In the presence of a Ni catalyst and a chiral ligand, nitrones react with activated cyclopropanes to give a tetrahydro-1,2-oxazine, with high enantioselectivity.²¹⁴⁷ Nitrones react with conjugated carbonyl compounds, with a transition metal catalyst (e.g., a Ti complex) to give an 1,2-oxazoline.²¹⁴⁸

Conjugated dienes generally give exclusive 1,2-addition, although 1,4-addition (a 3 + 4 cycloaddition) has been reported.²¹⁴⁹ Carbon–carbon triple bonds can also undergo 1,3-dipolar addition.²¹⁵⁰ For example, azides react to give triazoles, (**133**).

The 1,3-dipolar reagent can in some cases be generated by the *in situ* opening of a suitable three-membered ring system. For example, aziridines open to give a zwitterion (e.g., **134**), which can add to activated double bonds to give pyrrolidines.²¹⁵¹

Aziridines also add to $\text{C}\equiv\text{C}$ triple bonds, as well as to other unsaturated linkages, including $\text{C}=\text{O}$, $\text{C}=\text{N}$, and $\text{C}\equiv\text{N}$.²¹⁵² In some of these reactions, it is a C—N bond of the aziridine that opens rather than the C—C bond.

For other [3 + 2]-cycloadditions, see Reaction **15-59**.

C. Carbon on Both Sides

Reactions 15-58–15-64 are cycloaddition reactions.²¹⁵³

15-59 All-Carbon [3 + 2]-Cycloadditions²¹⁵⁴

Several methods have been reported for the formation of cyclopentanes by [3 + 2]-cycloadditions.²¹⁵⁵ Heating conjugated ketones with trialkylphosphines generates an intermediate that adds to conjugated alkynes.²¹⁵⁶ One type involves reagents that produce intermediates **135** or **136**.²¹⁵⁷ A synthetically useful example²¹⁵⁸ uses 2-[(trimethylsilyl)methyl]-2-propen-1-yl acetate (**139**), which is commercially available, and a Pd or other transition metal catalyst to generate **135** or **136**, which adds to double bonds to give cyclopentanes

with an exocyclic double bond. The reaction occurs with **139** to generate trimethylenemethane *in situ*, which reacts with alkenes to give methylenecyclopentane derivatives.²¹⁵⁹ A similar reaction occurs with imines to give methylene pyrrolidines.²¹⁶⁰ The Pd catalyzed reaction with CO₂ leads to butenolides.²¹⁶¹

Note that **136** also reacts with *N*-tosyl aziridines, with 20% *n*-butyllithium and 10% of Pd(OAc)₂, to give a vinylidene piperidine derivative.²¹⁶² Similar or identical intermediates generated from bicyclic azo compounds **137** (see Reaction 17-34) or methylenecyclopropane (**138**)²¹⁶³ also add to activated double bonds. With suitable substrates the addition can be enantioselective.²¹⁶⁴

In a different type of procedure, [3 + 2]-cycloadditions are performed with allylic anions. Such reactions are called 1,3-anionic cycloadditions.²¹⁶⁵ For example, α -methylstyrene adds to stilbene on treatment with the strong base LDA.²¹⁶⁶

The mechanism can be outlined as:

In the case above, **140** is protonated in the last step by the acid HA, but if the acid is omitted and a suitable nucleofuge is present, it may leave, resulting in a cyclopentene.²¹⁶⁷ In these cases, the reagent is an allylic anion, but similar [3 + 2]-cycloadditions involving allylic cations have also been reported.²¹⁶⁸

OS VIII,173, 347.

15-60 The Diels–Alder Reaction

(4 + 2) cyclo- Ethylene-1/4/addition or **(4 + 2) cyclo-**[Bu *t*-2-ene-1,4-diyl]-1/2/addition, and so on

In the prototype *Diels–Alder reaction*, the double bond of an alkene adds 1,4- to a conjugated diene (a [4 + 2]-cycloaddition),²¹⁶⁹ so the product is always a cyclohexene. The cycloaddition is not limited to alkenes or to dienes (see Reaction **15-61**), but the substrate that reacts with the diene is called a *dienophile*. The reaction is of very broad scope²¹⁷⁰ and reactivity of dienes and dienophiles can be predicted based on analysis of the HOMOs²¹⁷¹ and LUMOs of these species (FMO theory).²¹⁷² Ethylene and simple alkenes make poor dienophiles, unless high temperatures and/or pressures are used. Most dienophiles are of the form —C=C—Z or Z—C=C—Z' , where Z and Z' are

electron-withdrawing groups²¹⁷³ (e.g., CHO, COR,²¹⁷⁴ CO₂H, CO₂R, COCl, COAr, CN,²¹⁷⁵ NO₂,²¹⁷⁶ Ar, CH₂OH, CH₂Cl, CH₂NH₂, CH₂CN, CH₂CO₂H, halogen, PO (OEt)₂,²¹⁷⁷ or C=C). In the last case, the dienophile is itself a diene.²¹⁷⁸

The low reactivity of simple alkenes can be overcome by incorporating an electron-withdrawing group to facilitate the cycloaddition, as indicated above. Electron-withdrawing groups may be incorporated to facilitate the *Diels–Alder reaction* and then removed after cycloaddition. An example is phenyl vinyl sulfone (PhSO₂CH=CH₂),²¹⁷⁹ and the PhSO₂ group can be easily removed with Na–Hg after the ring-closure reaction. Similarly, phenyl vinyl sulfoxide (PhSOCH=CH₂) can be used as a synthon for acetylene.²¹⁸⁰ In this case, PhSOH is lost from the sulfoxide product (Reaction 17-12).

Electron-donating substituents in the diene accelerate the reaction; electron-withdrawing groups retard it.²¹⁸¹ For the dienophile, it is just the reverse: donating groups decrease the rate, and withdrawing groups increase it. The s-cis (cisoid) conformation is required for the cycloaddition,²¹⁸² and acyclic dienes are conformationally mobile so the s-cis conformation will be available.²¹⁸³ Cyclic dienes, in which the s-cis conformation is built in, usually react faster than the corresponding open-chain compounds, which have to achieve the s-cis conformation by rotation.²¹⁸⁴ Dienes can be open-chain, inner-ring (e.g., **141**), outer-ring²¹⁸⁵ (e.g., **142**), across rings (e.g., **143**), or inner–outer (e.g., **145**), except that they may not be frozen into a s-trans (transoid) conformation (see category 3). They need no special activating groups, and nearly all conjugated dienes undergo the reaction with suitable dienophiles.²¹⁸⁶

While *Diels–Alder reactions* generally require no catalyst, Lewis acids are effective catalysts,²¹⁸⁷ particularly those in which Z in the dienophile is a C=O or C=N group.²¹⁸⁸ Chemoselectivity is related to the choice of Lewis acid or Brønsted–Lowry acid catalyst.²¹⁸⁹ A Lewis acid catalyst usually increases both the regioselectivity of the reaction (in the sense given above) and the extent of endo addition,²¹⁹⁰ and, in the case of enantioselective reactions, the extent of enantioselectivity. Copper catalysts have been used.²¹⁹¹ Brønsted acids have also been used to accelerate the rate of the *Diels–Alder reaction*.²¹⁹² *Diels–Alder reactions* have been done in ionic liquids (see Sec. 9.D.iii).²¹⁹³ Lanthanum triflate [La(OTf)₃] has been reported as a reusable catalyst²¹⁹⁴ and Me₃SiNTf₂ has been used as a green Lewis acid catalyst.²¹⁹⁵ Cationic *Diels–Alder* catalysts have been developed (e.g., oxazaborolidine catalysts).²¹⁹⁶ Some *Diels–Alder reactions* can also be catalyzed by the addition of a stable cation radical,²¹⁹⁷ for example, tris(4-bromophenyl)aminium hexachloroantimonate (Ar₃N^{•+} SbCl₆[−]).²¹⁹⁸ Zirconocene-catalyzed cationic *Diels–Alder reactions* are known.²¹⁹⁹ Certain antibodies have been developed that catalyze *Diels–Alder reactions*.²²⁰⁰ Photochemically induced *Diels–Alder reactions* are also known.²²⁰¹

A number of other methods have been reported for the acceleration of *Diels–Alder reactions*,²²⁰² including the use of microwave irradiation,²²⁰³ ultrasound,²²⁰⁴ absorption of the reactants on chromatographic absorbents,²²⁰⁵ via encapsulation techniques,²²⁰⁶ and the

use of an ultracentrifuge²²⁰⁷ (one of several ways to achieve reaction at high pressures).²²⁰⁸ Solid-state *Diels–Alder reactions* are known.²²⁰⁹ One of the most common methods is to use water as a solvent or a cosolvent (a hydrophobic effect).²²¹⁰ Catalysts have been developed for aq *Diels–Alder reactions*²²¹¹ that are suitable for ionic *Diels–Alder reactions*.²²¹² There are cases of hydrogen-bonding acceleration.²²¹³ The influence of the hydrophobicity of reactants on the reaction has been examined,²²¹⁴ as has micellar effects.²²¹⁵ Another alternative reaction medium is the use of 5M LiClO₄ in Et₂O as solvent.²²¹⁶ An alternative to lithium perchlorate in ether is lithium triflate in acetonitrile.²²¹⁷ The addition of HPO₄[−] to an aq ethanol solution has also been shown to give a small rate enhancement.²²¹⁸ This appears to be the only case where an anion is responsible for a rate enhancement. The *retro-Diels–Alder reaction* has also been done in water.²²¹⁹

Note that *Diels–Alder reactions* have been done with supercritical carbon monoxide²²²⁰ and with supercritical water²²²¹ as solvents. *Diels–Alder reactions* on solid supports also have been reported,²²²² and zeolites have been used in conjunction with catalytic agents.²²²³ Alumina has been used to promote *Diels–Alder reactions*.²²²⁴ *Diels–Alder reactions* can be done in ionic liquids,²²²⁵ including asymmetric *Diels–Alder reactions*.²²²⁶ Note that the rate of *Diels–Alder reactions* is faster in water than in ionic liquids.²²²⁷

When an unsymmetrical diene adds to an unsymmetrical dienophile, regioisomeric products (not counting stereoisomers) are possible. Rearrangements have been encountered in some cases.²²²⁸ In simple cases, 1-substituted dienes give cyclohexenes with a 1,2-

and a 1,3- substitution pattern. 2-Substituted dienes lead to 1,4- and 1,3-disubstituted products.

Although mixtures are often obtained, one usually predominates (the one shown lower major above), but selectivity depends on the nature of the substituents on both diene and alkene. This regioselectivity, in which the “ortho” or “para” product is favored over the “meta”, has been explained by molecular orbital considerations.²²²⁹ When X = NO₂, regioselectivity to give the “ortho” or “para” product was very high at room temperature. This method, combined with subsequent removal of the NO₂ (see Reaction **19-67**), has been used to perform regioselective *Diels–Alder reactions*.²²³⁰ Competing reactions are polymerization of the diene or dienophile, or both, and [1,2]-cycloaddition (**15-63**).

The stereochemistry of the *Diels–Alder reaction* can be considered from several aspects:²²³¹

1. With respect to the dienophile, the addition is stereospecifically syn, with very few exceptions.²²³² This means that groups that are *cis* in the alkene will be *cis* in the cyclohexene ring (A—B and C—D) and groups that are *trans* in the alkene will be *trans* in the cyclohexene ring (A—D and C—B).

2. With respect to 1,4-disubstituted dienes, fewer cases have been investigated, but here too the reaction is stereospecific and syn. Thus, *trans,trans*-1,4-diphenylbutadiene gives *cis*-1,4-diphenylcyclohexene derivatives. This selectivity is predicted by disrotatory motion of the substituent in the transition state²²³³ of the reaction (see **18-27**).
3. The diene must be in the *s-cis* conformation. If it is frozen into the *s-trans* conformation, as in **144**, the reaction does not take place. The diene either must be frozen into the *s-cis* conformation or must be able to achieve it during the reaction.

4. There are two possible ways in which addition can occur to a cyclic diene, if the dienophile is not symmetrical: say a monosubstituted alkene. The substituent on the dienophile (usually an electron-withdrawing substituent) may approach under the ring (*endo addition*), or away from the ring (*exo addition*):

Most of the time, the addition is predominantly *endo*; that is, the more bulky side of the alkene is under the ring, and this is probably true for open-chain dienes also.²²³⁴ However, exceptions are known, and in many cases mixtures of *exo* and *endo* addition products are found.²²³⁵ An imidazolidone catalyst was used to give a 1:1.3 mixture favoring the *exo* isomer in a reaction of conjugated aldehydes and cyclopentadiene.²²³⁶ Secondary orbital interactions,²²³⁷ have been invoked, but this approach has been called into question.²²³⁸ There has been a direct evaluation of such interactions, however.²²³⁹ It has been argued that facial selectivity is not due to torsional angle decompression.²²⁴⁰ The *endo/exo* ratio can be influenced by the nature of the solvent.²²⁴¹

5. As seen previously, the *Diels–Alder reaction* can be both stereoselective and regioselective.²²⁴² In some cases, the *Diels–Alder reaction* can be made enantioselective,²²⁴³ as described above. Solvent effects are important in such reactions.²²⁴⁴ The role of reactant polarity on the course of the reaction has been examined.²²⁴⁵ Most enantioselective *Diels–Alder reactions* have used a chiral dienophile (e.g., **145**) and an achiral diene,²²⁴⁶ along with a Lewis acid catalyst (see below). In such cases, addition of the diene to the two

faces²²⁴⁷ of **145** takes place at different rates, and **146** and **147** are formed in different amounts.²²⁴⁸ An achiral compound can be converted to a chiral compound by a chemical reaction with a compound that is enantiopure. After the reaction, the resulting diastereomers can be separated, providing enantiopure compounds, each with a bond between the molecule of interest and chiral compound (a chiral auxiliary). Common chiral auxiliaries include chiral carboxylic acids, alcohols, or sultams. In the case illustrated, hydrolysis of the product removes the chiral R group, making it a chiral auxiliary in this reaction. Asymmetric *Diels–Alder reactions* have also been carried out with achiral dienes and dienophiles, but with an optically active catalyst.²²⁴⁹ Many chiral catalysts have been developed.²²⁵⁰ In many cases, asymmetric Lewis acids form a chiral complex with the dienophile.²²⁵¹ Chiral organocatalysts are increasingly important.²²⁵²

Triple bond compounds ($-C\equiv C-Z$ or $Z-C\equiv C-Z'$) may be dienophiles,²²⁵³ generating nonconjugated cyclohexadienes (**148**). This reaction can be catalyzed by transition metal compounds.²²⁵⁴ Aromatic rings can be generated by cycloaddition of aryl alkynes.²²⁵⁵ Allenes react as dienophiles, but without activating groups are

²²⁵⁵ This type of Diels–Alder reaction has been called the Dehydro-Diels–Alder. See Wessig, P.; Gunnar Müller, G. *Chem. Rev.* **2008**, *108*, 2051; Dunetz, J.R.; Danheiser, R.L. *J. Am. Chem. Soc.* **2005**, *127*, 5776; Dai, M.; Sarlah, D.; Yu, M.; Danishefsky, S.J.; Jones, G.O.; Houk, K.N. *J. Am. Chem. Soc.* **2007**, *129*, 645.

very poor dienophiles.²²⁵⁶ Ketenes, however, do not undergo *Diels–Alder reactions*.²²⁵⁷

Many interesting compounds can be prepared by the *Diels–Alder reaction*,²²⁵⁸ some of which would be hard to make in any other way. Some aromatic compounds can behave as dienes,²²⁵⁹ but benzene is very unreactive toward dienophiles,²²⁶⁰ and very few dienophiles (one of them is benzyne) have been reported to give *Diels–Alder* adducts with it.²²⁶¹ Benzyne (e.g., **149**), although not isolable, act as dienophiles and can be trapped with dienes.²²⁶² The interesting compound triptycene can be prepared by a *Diels–Alder reaction* between benzyne and anthracene.²²⁶³ Naphthalene and phenanthrene are poor reaction partners, although naphthalene has given *Diels–Alder addition* at high pressures.²²⁶⁴ Anthracene and other compounds with at least three linear benzene rings give *Diels–Alder reactions* readily.

For both all-carbon and hetero systems, the “diene” can be a conjugated enyne. If the geometry of the molecule is suitable, the diene can even be nonconjugated, for example,²²⁶⁵

This last reaction is known as the *homo-Diels–Alder reaction*. A similar reaction has been reported with alkynes, using a mixture of a Co complex, ZnI_2 , and tetrabutylammonium borohydride.²²⁶⁶

Intramolecular versions of the *Diels–Alder reaction* are well known,²²⁶⁷ and this is a powerful method for the synthesis of mono- and polycyclic compounds.²²⁶⁸ There are many examples and variations, including Lewis acid catalysis.²²⁶⁹ The origin of cis/trans stereoselectivity has been examined using density functional theory.²²⁷⁰

Internal *Diels–Alder reactions* can be viewed as linking the diene and alkene by a tether, usually of carbon atoms. Dienophile twisting and substituent effects influence the rate of cycloaddition.²²⁷¹ If the tether is replaced by functional groups that allow the selectivity inherent to the intramolecular cycloaddition, but can be cleaved afterward, a powerful modification is available. Indeed, such tethered cycloaddition reactions are increasingly common. After cycloaddition, the tether can be cleaved to give a functionalized cyclohexene derivative. Such tethered reactions allow enhancement of stereoselectivity²²⁷² and sometimes reactivity, relative to an untethered reaction, giving an indirect method for enhancing those parameters. Tethers or linkages include C—O—SiR₂—C²²⁷³ or a C—O—SiR₂—O—C,²²⁷⁴ or hydroxamides.²²⁷⁵ The nature of the tether plays a role in cis/trans selectivity for the intramolecular reaction.²²⁷⁶ Transient tethers can be used, as in the reaction of a diene having an allylic alcohol unit in a reaction with allyl alcohol, with AlMe₃ to give the cycloadduct with good selectivity.²²⁷⁷

The *Diels–Alder reaction* is usually reversible, although the retro reaction typically occurs at significantly higher temperatures than the forward reaction. However, the reaction is reversible²²⁷⁸ and this fact has been used. A convenient substitute for butadiene in the *Diels–Alder reaction* is the compound 3-sulfolene, since the latter is a solid, which is easy to handle while the former is a gas.²²⁷⁹ Butadiene is generated *in situ* by a reverse *Diels–Alder reaction* (see 17-20).

There are, broadly speaking, three possible mechanisms that have been considered for the uncatalyzed *Diels–Alder reaction*.²²⁸⁰ In mechanism *a*, there is a cyclic six-centered transition state and no intermediate. The reaction is concerted and occurs in one step. In mechanism *b*, one end of the diene fastens to one end of the dienophile first to give a diradical, and then, in a second step, the other ends become fastened.²²⁸¹ A diradical formed in this manner must be a singlet; that is, the two unpaired electrons must have opposite spins, by an argument similar to that outlined in Section 5.C.i. The third mechanism (*c*, not shown) is similar to mechanism *b*, but the initial bond and the subsequent bond are formed by movements of electron pairs and the intermediate is a diion. Electrophilicity–nucleophilicity indices have been analyzed to understand the mechanism of polar *Diels–Alder reactions*.²²⁸² There have been many mechanistic investigations of the *Diels–Alder reaction*. The bulk of the evidence suggests that most *Diels–Alder reactions* take place by the one-step cyclic mechanism *a*,²²⁸³ although it is possible that a diradical²²⁸⁴ or even a diion²²⁸⁵ mechanism may be taking place in some cases. Radical cation *Diels–Alder reactions* have been considered.²²⁸⁶ The main evidence in support of mechanism *a* is as follows: (1) the reaction is stereospecific in both the diene and dienophile. A completely free diradical or diion probably would not be able to retain its configuration. (2) In general, the rates of *Diels–Alder reactions* depend very little on the nature of the solvent. This would rule out a diion intermediate because polar solvents increase the rates of reactions that develop charges in the transition state. (3) It was shown that, in the decomposition of **150**, the isotope effect k_I/k_{II} was equal to 1.00 within experimental error.²²⁸⁷ If bond *x* were

to break before bond *y*, there should surely be a secondary isotope effect. This result strongly indicates that the bond breaking of *x* and *y* is simultaneous. This is the reverse of a *Diels–Alder reaction*, and by the principle of microscopic reversibility, the mechanism of the forward reaction should involve simultaneous formation of bonds *x* and *y*.

Subsequently, a similar experiment was carried out on the forward reaction²²⁸⁸ and the result was the same. There is other evidence for mechanism *a*.²²⁸⁹ However, the fact that the mechanism is concerted does not necessarily mean that it is synchronous.²²⁹⁰ In the transition state of a synchronous reaction both new σ bonds would be formed to the same extent, but a *Diels–Alder reaction* with nonsymmetrical components might very well be nonsynchronous;²²⁹¹ that is, it could have a transition state in which one bond has been formed to a greater degree than the other.^{2291,2292} A biradical mechanism has been proposed for some *Diels–Alder reactions*.²²⁹³

In another aspect of the mechanism, the effects of electron-donating and electron-withdrawing substituents (see above) indicate that the diene behaves as a nucleophile and the dienophile as an electrophile. However, this can be reversed. Perchlorocyclopentadiene reacts better with cyclopentene than with maleic anhydride and not at all with tetracyanoethylene, although the latter is normally the most reactive dienophile known. This diene is said to be the electrophile in its *Diels–Alder reactions*.²²⁹⁴ Reactions of this type are said to proceed with *inverse electron demand*.²²⁹⁵ It is known that alkynylboronates participate in inverse electron demand cyclization.²²⁹⁶

The *Diels–Alder reaction* generally takes place rapidly and conveniently. In sharp contrast, the apparently similar dimerization of alkenes to cyclobutanes (Reaction 15-63) gives very poor results in most cases, except when photochemically induced. Woodward and Hoffmann²²⁹⁷ showed that these contrasting results can be explained by the *principle of conservation of orbital symmetry*, which predicts that certain reactions are allowed and others are forbidden. The orbital-symmetry rules (also called the *Woodward–Hoffmann rules*)²²⁹⁸ apply only to concerted reactions (e.g., mechanism *a*) and are based on the principle that reactions take place in such a way as to maintain maximum bonding throughout the course of the reaction. In a separate work, Fukui used MO arguments to

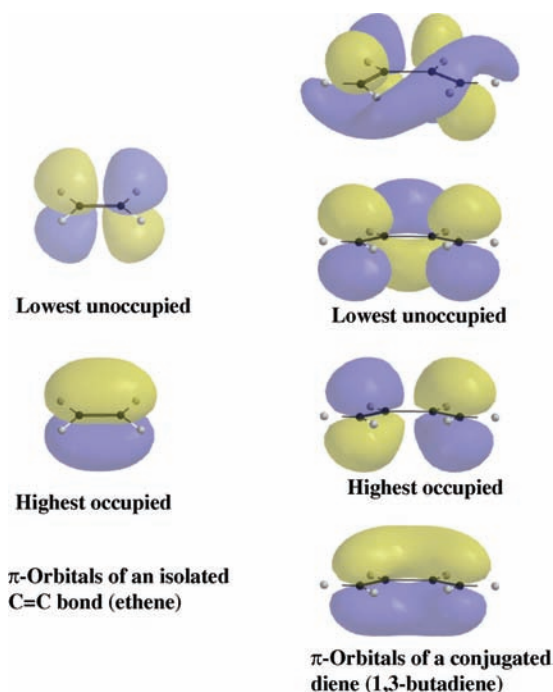

FIG. 15.2. Schematic drawings of the π orbitals of an isolated C=C bond and a conjugated diene explain these reactions. There are several ways of applying the orbital-symmetry principle to cycloaddition reactions, three of which are used more frequently than others.²²⁹⁹ Of these three, two will be discussed: the FMO and the Möbius–Hückel method. The third, called the correlation-diagram method,²³⁰⁰ is less convenient to apply than the other two.

The Frontier-Orbital Method²³⁰¹

As applied to cycloaddition reactions, the rule is that *reactions are allowed only when all overlaps between the HOMO of one reactant and the LUMO of the other are such that a positive lobe overlaps only with another positive lobe and a negative lobe only with another negative lobe*.²³⁰² Recall that monoalkenes have two π molecular orbitals (Sec. 1.D) and that conjugated dienes have four (Sec. 2.C), as shown in Fig. 15.2. A concerted cyclization of two monoalkenes (a [2 + 2] reaction) is not allowed because it would require that a positive lobe overlap with a negative lobe (Fig. 15.3). On the other

FIG. 15.3. Overlap of orbitals in a thermal $[2 + 2]$ -cycloadditionFIG. 15.4. Two ways for orbitals to overlap in a thermal $[4 + 2]$ -cycloaddition

hand, the *Diels–Alder reaction* (a $[4 + 2]$ reaction) is allowed, when considered from either direction (Fig. 15.4).

These considerations are reversed when the ring closures are photochemically induced, since in such cases an electron is promoted to a vacant orbital before the reaction occurs. Obviously, the $[2 + 2]$ reaction is now allowed (Fig. 15.5) and the $[4 + 2]$ -reaction is disallowed. The reverse reactions follow the same rules, by the principle of microscopic reversibility. In fact, *Diels–Alder* adducts are usually cleaved quite readily, while cyclobutanes, despite the additional strain, require more strenuous conditions.

The Möbius–Hückel Method²³⁰³

In this method, the orbital symmetry rules are related to the *Hückel aromaticity* rule discussed in Chapter 2.²³⁰⁴ *Hückel's rule*, which states that a cyclic system of electrons is aromatic (hence, stable) when it consists of $4n + 2$ electrons, applies of course to molecules in their ground states. In applying the orbital symmetry principle, we are not concerned with ground states, but with transition states. In the present method, do not examine the molecular orbitals themselves, but rather the *p* orbitals before they overlap to form the molecular orbitals. Such a set of *p* orbitals is called a *basis set* (Fig. 15.6). In investigating the possibility of a concerted reaction, the basis sets are put into the position they would occupy in the transition state. Figure 15.7 shows this for both the $[2 + 2]$ and the $[4 + 2]$ ring closures, looking for *sign inversions*. In Fig. 15.7, there are no sign inversions in either case. That is, the dashed line connects only lobes with a minus sign. Systems with *zero or*

FIG. 15.5. Overlap of orbitals in a photochemical $[2+2]$ -cycloaddition

FIG. 15.6. Some basis sets

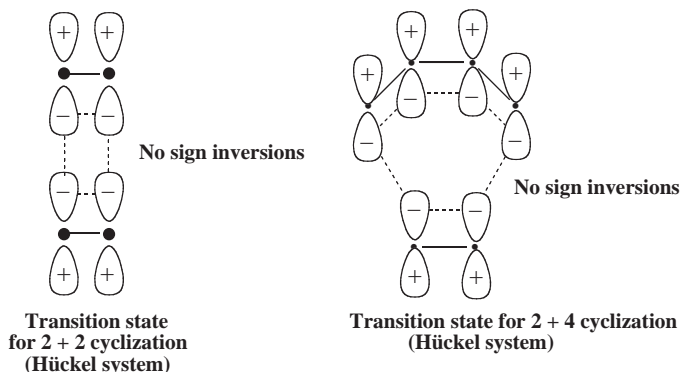

FIG. 15.7. Transition states illustrating Hückel–Möbius rules for cycloaddition reactions

an even number of sign inversions are called *Hückel systems*. Because they have no sign inversions, both of these systems are Hückel systems. Systems with an odd number of sign inversions are called *Möbius systems* (because of the similarity to the Möbius strip, which is a mathematical surface, shown in Fig. 15.8).²³⁰⁵ Möbius systems do not enter into either of these reactions, but an example of such a system is shown in Reaction 18.-28, B. Double-twist *Möbius* aromaticity has been invoked in the *Diels–Alder* transition state for the reaction of a 5,6-di-*tert*-butyl substituted decapentaene.²³⁰⁶

The rule may then be stated: A thermal pericyclic reaction involving a Hückel system is allowed only if the total number of electrons is $4n+2$. A thermal pericyclic reaction involving a Möbius system is allowed only if the total number of electrons is $4n$. For photochemical reactions, these rules are reversed. Since both the $[4+2]$ - and $[2+2]$ -cycloadditions are *Hückel* systems, the *Möbius–Hückel method* predicts that the $[4+2]$ -reaction, with

FIG. 15.8. A Möbius strip. Such a strip is easily constructed by twisting a thin strip of paper 180° and fastening the ends together

FIG. 15.9. Transition states of $[2+2]$ - and $[4+2]$ -cyclizations involving other basis sets

6 electrons, is thermally allowed, but the $[2+2]$ -reaction is not. On the other hand, the $[2+2]$ -reaction is allowed photochemically, while the $[4+2]$ -reaction is forbidden.

Note that both the $[2+2]$ and $[4+2]$ transition states are *Hückel* systems no matter what basis sets were chosen. For example, Fig. 15.9 shows other basis sets we might have chosen. In every case there will be zero or an even number of sign inversions.

Thus, the FMO and *Hückel-Möbius* methods (and the correlation-diagram method as well) lead to the same conclusions: Thermal $[4+2]$ -cycloadditions and photochemical $[2+2]$ -cycloadditions (and the reverse ring openings) are allowed, while photochemical $[4+2]$ - and thermal $[2+2]$ -ring closings (and openings) are forbidden.

Application of the same procedures to other ring closures shows that $[4+4]$ - and $[2+6]$ -ring closures and openings require photochemical induction while the $[4+6]$ - and $[2+8]$ -reactions can take place only thermally (see Reaction 15-53). In general, cycloaddition reactions allowed thermally are those with $4n+2$ electrons, while those allowed photochemically have $4n$ electrons.

It must be emphasized once again that the rules apply only to cycloaddition reactions that take place by cyclic mechanisms, which is where two σ bonds are formed (or broken) at about the same time.²³⁰⁷ The rule does not apply to cases where one bond is clearly formed (or broken) before the other. It must further be emphasized that the fact that the thermal *Diels-Alder reaction* (mechanism *a*) is allowed by the principle of conservation of orbital symmetry does not constitute proof that any given *Diels-Alder reaction* proceeds by this mechanism. The principle merely says the mechanism is allowed, not that it must go by this pathway. However, the principle does say that thermal $[2+2]$ -cycloadditions in

²³⁰⁷ See Lehr, R.E.; Marchand, A.P. in Marchand, A.P.; Lehr, R.E. *Pericyclic Reactions*, Vol. 1, Academic Press, NY, 1977, pp. 1-51.

FIG. 15.10. Overlap of orbitals in an antarafacial thermal $[4+2]$ -cycloaddition

which the molecules assume a face-to-face geometry cannot²³⁰⁸ take place by a cyclic mechanism because their activation energies would be too high (however, see below). In Reaction 15-62 it will be seen that such reactions largely occur by two-step mechanisms. Similarly, $[4+2]$ -photochemical cycloadditions are also known, but the fact that they are not stereospecific indicates that they also take place by the two-step diradical mechanism (mechanism *b*).²³⁰⁹

In all of the above discussions, it has been assumed that a given molecule forms both the new σ bonds from the same face of the π system. This manner of bond formation, called *suprafacial*, is certainly most reasonable and almost always takes place. The subscript *s* is used to designate this geometry, and a normal *Diels–Alder reaction* would be called a $[\pi 2_s + \pi 4_s]$ -cycloaddition (the subscript π indicates that π electrons are involved in the cycloaddition). However, there is another approach in which the newly forming bonds of the diene lie on *opposite* faces of the π system, that is, they point in opposite directions. This type of orientation of the newly formed bonds is called *antarafacial*, and the reaction would be a $[\pi 2_s + \pi 4_a]$ -cycloaddition (*a* stands for antarafacial). The FMO method shows that this reaction (and consequently the reverse ring-opening reactions) are thermally forbidden and photochemically allowed. Thus in order for a $[\pi 2_s + \pi 4_a]$ reaction to proceed, overlap between the highest-occupied π orbital of the alkene and the lowest-unoccupied π orbital of the diene would have to occur as shown in Fig. 15.10, with a +lobe overlapping a –lobe. Since like signs are no

FIG. 15.11. Overlap of orbitals in $[4 + 2]$ -cycloaddition of 1,3-butadiene with acrolein

longer overlapping, the thermal reaction is now forbidden. Similarly, thermal $[\pi 4_s + \pi 2_a]$ and $[\pi 2_s + \pi 4_a]$ -cyclizations are forbidden, while thermal $[\pi 4_a + \pi 2_a]$ - and $[\pi 2_s + \pi 2_a]$ -cyclizations are allowed. These considerations are reversed for the corresponding photochemical processes. Of course, an antarafacial approach is highly unlikely in a $[4 + 2]$ -cyclization,²³¹⁰ but larger ring closures could take place by such a pathway, and $[2 + 2]$ -thermal cyclizations, where the $[\pi 2_s + \pi 2_s]$ -pathway is forbidden, can also do so in certain cases (see Reaction 15-63). Whether a given cycloaddition is allowed or forbidden depends on the geometry of approach of the two molecules involved.

Symmetry considerations have also been advanced to explain predominant endo addition.²³¹¹ In the case of $[4 + 2]$ -addition of butadiene to acrolein, the approach can be exo or endo. It can be seen (Fig. 15.11) that whether the HOMO of the diene overlaps with the LUMO of acrolein or vice versa, the endo orientation is stabilized by additional secondary overlap of orbitals²³¹² of like sign (dashed lines between heavy dots). Addition from the exo direction has no such stabilization since the sign of the orbitals do not match. Evidence for secondary orbital overlap as the cause of predominant endo orientation, at least in some cases, is that $[4 + 6]$ -cycloaddition is predicted by similar considerations to

²³¹⁰ A possible photochemical $[2 + 4]$ cycloaddition has been reported: Hart, H.; Miyashi, T.; Buchanan, D.N.; Sasson, S. *J. Am. Chem. Soc.* **1974**, *96*, 4857.

proceed with predominant exo orientation, and that is what is found.²³¹³ However, this explanation does not account for endo orientation in cases where the dienophile does not possess additional π orbitals, and a number of alternative explanations have been offered.²³¹⁴

15-61 Heteroatom Diels–Alder Reactions

Alkenes, alkynes, and dienes are not the only units that can participate in *Diels–Alder reactions*. Other double- and triple-bond compounds can be dienophiles and they give rise to heterocyclic compounds.²³¹⁵ Among these are $\text{N}\equiv\text{C}-$, $-\text{N}=\text{C}-$,²³¹⁶ iminium salts,²³¹⁷ $-\text{N}=\text{N}-$, $\text{O}=\text{N}-$,²³¹⁸ and $-\text{C}=\text{O}$ compounds,²³¹⁹ and even molecular oxygen (Reaction 15-62). Several catalysts can be used, depending on the nature of the heteroatoms incorporated into the alkene or diene.²³²⁰ Intramolecular cycloaddition with a diene–imine substrate leads to pyrrolidines.²³²¹

Aldehydes react with suitably functionalized dienes (e.g., **151**), known as *Danishefsky's diene*,²³²² and the reaction usually requires a Lewis acid catalyst (e.g., lanthanide compounds).²³²³ The *Diels–Alder reaction* of aldehydes with dienes can be catalyzed by many transition metal compounds, including Co ²³²⁴ and In ²³²⁵ catalysts. Aldehydes react using a chiral Ti ²³²⁶ or a Zr ²³²⁷ catalyst to give the dihydropyran with good

enantioselectivity. Copper(I) catalysts have been used as well.²³²⁸ Note that the reaction of *Danishefsky's diene* with an imine,²³²⁹ formed *in situ* by reaction of an aryl aldehyde and an aniline derivative, proceeds without a Lewis acid.²³³⁰ Ketones also react with suitably functionalized dienes.²³³¹ Indium trichloride (InCl₃) is a good catalyst for imino-*Diels–Alder reactions*.²³³² Hetero-*Diels–Alder reactions* involving carbonyls have been done in water.²³³³ Ultrasound has been used to promote the *Diels–Alder reactions* of 1-azadienes.²³³⁴ Polymer-supported dienes have been used.²³³⁵

Hetero-*Diels–Alder reactions* that proceed with good-to-excellent asymmetric induction are well known.²³³⁶ Asymmetric *Diels–Alder reactions* of carbonyl compounds are well known.²³³⁷ Chiral 1-aza-dienes have been developed as substrates, for example.²³³⁸ Azadienes also react with chiral dienophiles.²³³⁹ Chiral catalysts have been developed.²³⁴⁰

Dienes related to **151** are known, and their reactivity has been examined. Amino-substituted dienes undergo what is known as hydrogen-bonding catalyzed reactions.²³⁴¹ Imines react with other substrates (e.g., allenes), to give tetrahydropyridine derivatives, with good enantioselectivity in the presence of a chiral ligand.²³⁴² Azo compounds (—N=N—) react as dienophiles in the presence of an Ag catalyst.²³⁴³ Iminium ions undergo *Diels–Alder cycloaddition*.²³⁴⁴

Azadienes undergo *Diels–Alder reactions* to form pyridine, dihydro- and tetrahydropyridine derivatives.²³⁴⁵ *Aza-Diels–Alder reactions* have been done in ionic liquids.²³⁴⁶ Similarly, acyl iminium salts (C=N(R)—C=O) react with alkenes via cycloaddition.²³⁴⁷ *N*-Vinyl lactim ethers undergo *Diels–Alder reactions* with a limited set of dienophiles.²³⁴⁸ Brønsted acids can catalyze inverse electron demand *aza-Diels–Alder reactions*.²³⁴⁹

Thioketones react with dienes to give *Diels–Alder cycloadducts*.²³⁵⁰ The carbonyl group of lactams has also been shown to be a dienophile.²³⁵¹ Certain heterocyclic aromatic

15-62 Photooxidation of Dienes (Addition of Oxygen, Oxygen)

[4 + 2] *OC,OC-cyclo-Peroxy-1/4/addition*

Conjugated dienes react with oxygen under the influence of light to give cyclic peroxides (**152**).²³⁵⁶ The reaction has mostly²³⁵⁷ been applied to cyclic dienes.²³⁵⁸ Cycloaddition of furan has been reported using singlet oxygen.²³⁵⁹ The scope extends to certain aromatic compounds (e.g., phenanthrene).²³⁶⁰ Besides those dienes and aromatic rings that can be photooxidized directly, there is a larger group that gives the reaction in the presence of a photosensitizer (see Sec. 7.A.vi, category 5; e.g., eosin, a red xanthene dye). Among these is α -terpinene, which is converted to ascaridole:

As in Reaction 14-7, it is not the ground-state oxygen (the triplet), that reacts, but the excited singlet state,^{2361,2362} so the reaction is actually a *Diels–Alder reaction* (see Reaction 15-60) with singlet oxygen as dienophile:²³⁶³

Like Reaction 15-60, this reaction is reversible.

As previously discussed, the reaction of singlet oxygen with double-bond compounds gives hydroperoxides (Reaction 14-7), but singlet oxygen can also react with double bonds in another way to give a dioxetane intermediate²³⁶⁴ (Reaction 153), which usually cleaves to aldehydes or ketones,²³⁶⁵ but has been isolated.²³⁶⁶ Both the six-membered cyclic peroxides²³⁶⁷ and the four-membered **205**²³⁶⁸ have been formed from oxygenation reactions that do not involve singlet oxygen. If cyclic peroxides (e.g., **205**) are desired, better reagents²³⁶⁹ are triphenyl phosphite ozonide [(PhO)₃PO₃] and triethylsilyl hydrotrioxide [(Et₃SiOOOH)], but yields are not high.²³⁷⁰

Two alkene molecules react under thermal conditions to give cyclobutane derivatives in what is known as a $[2 + 2]$ -cycloaddition. The cycloaddition occurs when the alkenes are the same or different, but the reaction is not general for all alkenes.²³⁷¹ Certain transition metal complexes can catalyze the cycloaddition.²³⁷² Benzyne undergo cycloaddition to give biphenylene derivatives (**154**),²³⁷³ activated alkenes (e.g., styrene, acrylonitrile, butadiene), and certain methylenecyclopropanes.²³⁷⁴ Alkenes react with alkynes²³⁷⁵ or with activated alkynes, with a Ru catalyst, to give cyclobutenes.²³⁷⁶ Dimerization of allenes leads to bis(alkylidene) cyclobutenes.²³⁷⁷ Substituted ketenes can dimerize to give cyclobutenone derivatives, although ketene itself dimerizes in a different manner, to give an unsaturated β -lactone (Reaction **16-95**).²³⁷⁸

Intramolecular $[2 + 2]$ -cycloadditions are common in which a diene is converted to a bicyclic compound with a four-membered ring fused to another ring. Transition metal catalyzed reactions have been reported, including the use of Fe complexes.²³⁷⁹ Heating *N*-vinyl imines, where the vinyl moiety is a silyl enol, gives β -lactams.²³⁸⁰ Apart from photochemical initiation of such reactions (see below), intramolecular cycloaddition of two conjugated ketone units, in the presence of PhMeSiH_2 and catalyzed by Co compounds, leads to the bicyclic compound with two ketone substituents.²³⁸¹ In a variation of this reaction, a diyne was treated with $\text{Ti}(\text{O}i\text{Pr})_4/2$ $i\text{PrMgCl}$ to generate a bicyclic cyclobutene with two vinylidene units.²³⁸²

Ketenes react with many alkenes to give cyclobutanone derivatives²³⁸³ and intermolecular cycloadditions are well known.²³⁸⁴ A typical reaction of dimethylketene and ethene gives 2,2-dimethylcyclobutanone, as shown.²³⁸⁵ Ketenes react with imines via

[2 + 2]-cycloaddition to produce β -lactams.²³⁸⁶ Cycloaddition of an imine with a conjugated ester in the presence of Et_3MeSiH and an Ir catalyst also gives a β -lactam.²³⁸⁷ See Reaction **19-66** for a discussion of reactions that give β -lactams.

Different alkenes combine as follows:

1. $\text{F}_2\text{C}=\text{CX}_2$ (X = F or Cl), especially $\text{F}_2\text{C}=\text{CF}_2$, form cyclobutanes with many alkenes. Compounds of this type even react with conjugated dienes to give four-membered rings rather than undergoing normal *Diels–Alder reactions*.²³⁸⁸
2. Allenes²³⁸⁹ and ketenes²³⁹⁰ react with activated alkenes and alkynes. Ketenes give 1,2-addition, even with conjugated dienes.²³⁹¹ Ketenes also add to unactivated alkenes if sufficiently long reaction times are used.²³⁹² Allenes and ketenes also add to each other.²³⁹³
3. Enamines²³⁹⁴ form four-membered rings with *Michael-type* alkenes²³⁹⁵ and ketenes.²³⁹⁶ In both cases, only enamines from aldehydes give stable four-membered rings:

Generating the ketene *in situ* from an acyl halide and a tertiary amine is a convenient way to carry out the reaction of enamines with ketenes.

4. Alkenes with electron-withdrawing groups may form cyclobutanes with alkenes containing electron-donating groups.²³⁹⁷ The enamine reactions, mentioned above, are examples of this, but it has also been accomplished with tetracyanoethylene and similar molecules, which give substituted cyclobutanes when treated with alkenes of the form $C=C-A$, where A may be OR,²³⁹⁸ SR (enol and thioenol ethers),²³⁹⁹ cyclopropyl,²⁴⁰⁰ or certain aryl groups.²⁴⁰¹

Enantioselective [2 + 2]-cycloaddition reactions are known. Chiral organocatalysts lead to chiral cyclobutane derivatives.²⁴⁰²

Solvents are not necessary for [2 + 2]-cycloadditions. They can be carried out at 100–225 °C under pressure, although the reactions in Group 4 occur under milder conditions. However, the choice of solvent can control the distribution of products in photochemical [2 + 2]-cycloaddition.²⁴⁰³

It has been found that certain [2 + 2]-cycloadditions that do not occur thermally can be made to take place without photochemical initiation using certain catalysts, usually transition metal compounds.²⁴⁰⁴ Among the catalysts used are Lewis acids²⁴⁰⁵ and phosphine–Ni complexes.²⁴⁰⁶ The role of the catalyst is not certain and may be different in each case. One possibility is that the presence of the catalyst causes a forbidden reaction to become allowed, through coordination of the catalyst to the π or s bonds of the substrate.²⁴⁰⁷ In such a case, the reaction would of course be a concerted [$2_s + 2_s$] process.²⁴⁰⁸ However, the available evidence is more consistent with nonconcerted mechanisms involving metal–carbon σ -bonded intermediates, at least in most cases.²⁴⁰⁹ For example, such an intermediate was isolated in the dimerization of norbornadiene, catalyzed by Ir complexes.²⁴¹⁰ Photochemical [$\pi 2 + s 2$]-cycloadditions have also been reported. Visible light mediates cycloaddition in the presence of a Rh catalyst.²⁴¹² Some reverse cyclobutane ring openings can also be catalytically induced (Reaction 18-38).

Thermal cycloadditions leading to four-membered rings can also take place between a cyclopropane ring and an alkene or alkyne²⁴¹³ bearing electron-withdrawing groups.²⁴¹⁴

These reactions are $[\pi 2 + {}_s 2]$ -cycloadditions. Ordinary cyclopropanes do not undergo the reaction, but it has been accomplished with strained systems (e.g., bicyclo[1.1.0]butanes²⁴¹⁵ and bicyclo[2.1.0]pentanes). For example, bicyclo[2.1.0]pentane reacts with maleonitrile (or fumaronitrile) to give all three isomers of 2,3-dicyanonorbornane, as well as four other products.²⁴¹⁶ The lack of stereospecificity and the negligible effect of solvent on the rate indicate a diradical mechanism.

If dienes are involved in the reaction, the *Diels–Alder reaction* may compete, although most alkenes react with a diene either entirely by 1,2- or entirely by 1,4-addition. Three mechanisms have been proposed for $[2 + 2]$ -cycloaddition.²⁴¹⁷

Mechanism *a* is a concerted pericyclic process, and mechanisms *b* and *c* are two-step reactions involving, respectively, a diradical (**155**) and a diion (**156**) intermediate. As in Reaction **15-60**, a diradical intermediate must be a singlet. In searching for ways to tell which mechanism is operating in a given case, mechanism *c* is expected to be sensitive to changes in solvent polarity, while mechanisms *a* and *b* should be insensitive. Mechanism *a* is expected to be stereospecific, while mechanisms *b* and *c* probably would not be stereospecific. However, if the second step of these processes takes place very rapidly, before **155** or **156** have a chance to rotate about the newly formed single bond, stereospecificity might be observed. Because of entropy considerations, such rapid ring closure might be more likely here than in a $[4 + 2]$ -cycloaddition.

There is evidence that the reactions can take place by all three mechanisms, depending on the structure of the reactants. A thermal $[\pi 2_s + \pi 2_s]$ mechanism is ruled out for most of these substrates by the orbital symmetry rules, but a $[\pi 2_s + \pi 2_a]$ mechanism is allowed (see above), and there is much evidence that ketenes and certain other linear molecules²⁴¹⁸ in which the steric hindrance to such an approach is minimal can and often do react by this mechanism. In a $[\pi 2_s + \pi 2_a]$ cycloaddition, the molecules must approach each other in such a way (Fig. 15.12*a*) that the HOMO–LUMO overlap requires that the groups of one molecule project *into* the plane of the other. This does not happen with ordinary alkenes,²⁴¹⁹ but if one molecule is a ketene (Fig. 15.12*b*), a group on the carbon of the C=C unit is missing (relative to an alkene) and the $[\pi 2_s + \pi 2_a]$ -reaction can take place.

FIG. 15.12. Steric interactions in $[\pi 2_s + \pi 2_s]$ -cycloaddition between (a) two alkene molecules and (b) a ketene and an alkene

Among the evidence²⁴²⁰ for this mechanism²⁴²¹ is the following: (1) the reactions are stereospecific.²⁴²² (2) The isomer that forms is the *more hindered one*. Thus the reaction of methylketene plus cyclopentadiene gave only

the endo product (**157**, A = H, R = CH₃).²⁴²³ Even more remarkably, when haloalkyl ketenes $RXC=C=O$ were treated with cyclopentadiene, the endo/exo ratio of the product (**157**, **158**, A = halogen) actually *increased* substantially when R was changed from Me to *i*Pr to *t*-Bu!²⁴²⁴ One would expect preferential formation of the exo products (**158**) from $[\pi 2_s + \pi 2_s]$ -cycloadditions where the molecules approach each other face-to-face. However, a $[\pi 2_s + \pi 2_a]$ -process leads to endo products because the ketene molecule (which for steric reasons would approach with its smaller group, methyl in the figure, directed toward the alkene) must twist as shown in Fig. 15.13 (*tert*-butyl = larger; methyl = smaller group) in order for the π lobes to interact. This process swings the larger group (*tert*-butyl) into the endo position.²⁴²⁵ The experimental results in which the amount of endo isomer increases with the increasing size of the R group appears to be contrary to what would be expected from steric hindrance considerations (called *masochistic steric effects*), but they are just what is predicted for a $[\pi 2_s + \pi 2_a]$ reaction. (3) There is only moderate polar solvent acceleration.²⁴²⁶ (4) The rate of the reaction is not very sensitive to the presence of electron-withdrawing or electron-donating substituents.²⁴²⁷ Because cycloadditions involving allenes are often stereospecific, it has been suggested that these also take place

by the $[\pi 2_s + \pi 2_a]$ mechanism,²⁴²⁸ but the evidence in these cases is more consistent with the diradical mechanism *b*.²⁴²⁹

The diradical mechanism *b* is most prominent in the reactions involving fluorinated alkenes.²⁴³⁰ These reactions are generally not stereospecific²⁴³¹ and are insensitive to solvent effects. Further evidence that a diion is not involved is that head-to-head coupling is found when an unsymmetrical molecule is dimerized. Thus dimerization of $F_2C=CFCl$ gives **159**, not **160**. If one pair of electrons moved before the other, the positive end of one molecule would be expected to attack the negative end of the other.²⁴³²

The diion mechanism²⁴³³ *c* has been reported for at least some of the reactions²⁴³⁴ in categories 3 and 4,²⁴³⁵ as well as some ketene dimerizations.²⁴³⁶ The rate of the reaction between 1,2-bis(trifluoromethyl)-1,2-dicyanoethene and ethyl vinyl ether, for example, was strongly influenced by changes in solvent polarity.²⁴³⁷ Some of these reactions are nonstereospecific, but others are stereospecific.²⁴³⁸ As previously indicated, it is likely that in the latter cases the diionic intermediate closes before rotation can take place. Such rapid ring closure is more likely for a diion than for a diradical because of the attraction between the opposite charges. Other evidence for the diion mechanism in these cases is that reaction rates are greatly dependent on the presence of electron-donating and electron-withdrawing groups and that it is possible to trap the diionic intermediates.

Whether a given alkene reacts by the diradical or diion mechanism depends, among other things, on the groups attached to it. For example, phenyl and vinyl groups at the α positions of **155** or **156** help to stabilize a diradical, while donors (e.g., oxygen and nitrogen) favor a diion (they stabilize the positively charged end).²⁴³⁹ A table in Ref. 2439 (see p. 451) shows which mechanism is more likely for [2 + 2]-cycloadditions of various pairs of alkenes.

Thermal cleavage of cyclobutanes²⁴⁴⁰ to give two alkene molecules (*cycloreversion*,²⁴⁴¹ the reverse of [2 + 2]-cycloaddition) operates by the diradical mechanism, and the [$\sigma 2_s + \sigma 2_a$]-pathway has not been found²⁴⁴² (the subscripts σ indicate that σ bonds are involved in this reaction).

In some cases, double bonds add to triple bonds to give cyclobutenes, apparently at about the same rate that they add to double bonds. The addition of triple bonds to triple bonds would give cyclobutadienes, and this has not been observed, except where these rearrange before they can be isolated (see Reaction **15-65**)²⁴⁴³ or in the presence of a suitable coordination compound, so that the cyclobutadiene is produced in the form of a complex (Sec. 2.K.ii).²⁴⁴⁴

Although thermal [2 + 2]-cycloaddition reactions are essentially limited to the cases described above, many (although by no means all) double-bond compounds react *when photochemically excited* (either directly or by a photosensitizer, see Sec. 7.A.vi,

category 5), even if they are not in the above categories.²⁴⁴⁵ Simple alkenes absorb in the far-UV (Sec. 7.A.iii), which is difficult to reach experimentally, although this problem can sometimes be overcome by the use of suitable photosensitizers. The reaction has been applied to simple alkenes²⁴⁴⁶ (especially to strained compounds, e.g., cyclopropenes and cyclobutenes), but more often the double-bond compounds involved are conjugated dienes,²⁴⁴⁷ α,β -unsaturated ketones,²⁴⁴⁸ conjugated acids or acid derivatives, and quinones. Since these compounds, are conjugated, they absorb at longer wavelengths (Sec 7.A.iii). Both dimerizations and mixed additions are common. Some examples follow:

See also, Section 7.A.vii (Reaction 7-9). Photochemical [2 + 2]-cycloadditions can also take place intramolecularly if a molecule has two double bonds that are properly oriented.²⁴⁵¹ The cyclization of the quinone dimer shown above is one example. Other examples are

Ref. 2453

It is obvious that many molecules can be constructed in this way that would be difficult to make by other procedures. However, attempted cyclizations of this kind are not always successful. In many cases, polymeric or other side products are obtained instead of the desired product.

The photochemical cycloaddition of a carbonyl, generally from an aldehyde or ketone and an alkene, is called the *Paternò-Büchi reaction*.²⁴⁵⁴ This $[2 + 2]$ -cycloaddition gives an oxetane (**161**) and the reaction is believed to proceed via a diradical intermediate. Silyl enol ethers react with aldehydes under nonphotochemical conditions using ZnCl_2 at 25°C or SnCl_4 at -78°C .²⁴⁵⁵

It is possible that some of these photochemical cycloadditions take place by a $[\pi 2_s + \pi 2_s]$ -mechanism, which is of course allowed by orbital symmetry; when and if they do, one of the molecules must be in the excited singlet state (S_1) and the other in the ground state.²⁴⁵⁶ The nonphotosensitized dimerizations of *cis*- and *trans*-2-butene are stereospecific,²⁴⁵⁷ making it likely that the $[\pi 2_s + \pi 2_s]$ -mechanism is operating in these reactions. However, in most cases it is a triplet excited state that reacts with the ground-state molecule; in these cases the diradical (or in certain cases, the diionic) mechanism is taking place.²⁴⁵⁸ In one intramolecular case, the intermediate diradical has been trapped.²⁴⁵⁹ Photosensitized $[2\pi + 2\pi]$ -cycloadditions almost always involve the triplet state, and hence a diradical (or diionic) mechanism.

The photochemical diradical mechanism is not quite the same as the thermal diradical mechanism. In the thermal mechanism, the initially formed diradical must be a singlet, but in the photochemical process a triplet excited state is adding to a ground state, which is of course a singlet. Thus, in order to conserve spin,²⁴⁶⁰ the initially formed diradical must be a triplet; that is, the two electrons must have the same spin. Consequently, the second, or ring closing, step of the mechanism cannot take place at once, because a new bond cannot form

²⁴⁶⁰ This is an example of the *Wigner spin conservation rule* (Sec. 7.A.vi, category 5). Note that spin conservation is something entirely different from symmetry conservation.

from a combination of two electrons with the same spin, and the diradical has a reasonably long lifetime before collisions with molecules in the environment allow a spin inversion to take place and the diradical to cyclize. The prediction is nonstereospecificity, and that is what is found.²⁴⁶¹ It has been believed that at least some [2 + 2] photocycloadditions take place by way of exciplex intermediates²⁴⁶² [an *exciplex*²⁴⁶³ is an excited EDA complex (Sec. 7.A.vii) that is dissociated in the ground state; in this case one double bond is the donor and the other is the acceptor], but there is evidence against this.²⁴⁶⁴

In Reaction **15-60**, the principle of conservation of orbital symmetry was used to explain why certain reactions take place readily and others do not. The orbital-symmetry principle can also explain why certain molecules are stable although highly strained. Quadricyclane and hexamethylprismane²⁴⁶⁵ are thermodynamically much less stable (because they are much more strained), for example, than their corresponding isomeric dienes, norbornadiene and

hexamethylbicyclo[2.2.0]hexadiene (**162**).²⁴⁶⁶ Yet the former two compounds can be kept indefinitely at room temperature, although in the absence of orbital-symmetry considerations it is not easy to understand why the electrons simply do not move over to give the more stable diene isomers. The reason is that both these reactions involve the conversion of a cyclobutane ring to a pair of double bonds (a $s_2 + s_2$ process) and, as seen previously, a thermal process of this sort is forbidden by the *Woodward–Hoffmann rules*. The process is allowed photochemically, so both quadricyclane and hexamethylprismane are photochemically converted to the respective dienes at room temperature or below.²⁴⁶⁷ It is also possible to conceive of simple bond rearrangements whereby hexamethylprismane is converted to hexamethylbenzene (as shown below), which of course is far more stable than either hexamethylprismane or **162**. It has been calculated that hexamethylbenzene is at least 90 kcal mol^{-1} (380 kJ mol^{-1}) more stable than hexamethylprismane. A correlation diagram for this reaction²⁴⁶⁸ discloses that it too is a symmetry-forbidden process. All three of these “forbidden” reactions do take place when the compounds are heated, but the diradical mechanism is likely under these conditions.²⁴⁶⁸

Bicyclo[2.2.0]hexadienes and prismanes are *valence isomers* of benzenes.²⁴⁶⁹ These compounds actually have the structures that were proposed for benzenes in the nineteenth century. Prismanes have the Ladenburg formula, and bicyclo[2.2.0]hexadienes have the *Dewar* formula. Because of this, bicyclo[2.2.0]hexadiene is often called *Dewar benzene*. In the paragraph prior to Section 2.A, it was mentioned that Dewar formulas are canonical forms (although not very important) of benzenes. Yet they also exist as separate compounds in which the positions of the nuclei are different from those of benzenes.

15-64 The Addition of Carbenes and Carbenoids to Double and Triple Bonds

epi-Methylene-addition

Carbenes and substituted carbenes add to double bonds to give cyclopropane derivatives by what can be considered as a formal [1 + 2]-cycloaddition.²⁴⁷⁰ Many carbene derivatives [e.g., PhCH, ROCH,²⁴⁷¹ Me₂C=C, and C(CN)₂] have been added to double bonds, but the reaction is often performed with CH₂ itself, with halo and dihalocarbenes,²⁴⁷² and with carbalkoxycarbenes²⁴⁷³ (generated from diazoacetic esters). Alkylcarbenes (HCR) have been added to alkenes,²⁴⁷⁴ but more often these rearrange to give alkenes (Sec. 5.D.ii, category 4). The carbene can be generated in any of the ways normally used (Sec. 5.D.ii). However, most reactions in which a cyclopropane is formed by treatment of an alkene with a carbene “precursor” do not actually involve free carbene intermediates. In some cases, it is certain that free carbenes are not involved, and in other cases there is doubt. Because of this, the term *carbene transfer* is often used to cover all reactions in which a double bond is converted to a cyclopropane, whether a carbene or a carbenoid (Sec. 5.D.ii) is actually involved.

Carbene itself (:CH₂) is extremely reactive and gives many side reactions, especially insertion reactions (12-21), which greatly reduce yields. This competition is also true with Rh catalyzed diazoalkane cyclopropanations²⁴⁷⁵ (see below). When: CH₂ must be added for preparative purposes, a free carbene is not used, but the *Simmons–Smith procedure*

(see **167**) or some other method that does not involve free carbenes is employed instead. Halocarbenes are less active than carbenes, and this reaction proceeds quite well, since insertion reactions do not interfere.²⁴⁷⁶ Vinyldiazolactone is a vinylcarbene precursor for a reaction with alkenes to give spirolactones.²⁴⁷⁷

The absolute rate constant for addition of selected alkoxychlorocarbene to butenes has been measured to range from 330 to $1 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$.²⁴⁷⁸ Both entropy and enthalpy play a role in addition of some carbenes.²⁴⁷⁹ Shown are a few of the many ways²⁴⁸⁰ in which halocarbenes or carbenoids are generated,²⁴⁸¹ and most involve formal elimination (for the first two steps of the S_N1cB mechanism, see Sec. 10.G.iii):

The reaction between CHCl_3 and HO^- is often carried out under phase-transfer conditions.²⁴⁸⁵ It has been shown that the reaction between PhCHCl_2 and $t\text{-BuOK}$ produces a carbenoid, but when the reaction is run in the presence of a crown ether, the carbene $[\text{Ph}(\text{Cl})\text{C}:]$ is formed instead.²⁴⁸⁶ The reaction of iodoform and CrCl_2 leads to iodocyclopropanes upon reaction with alkenes.²⁴⁸⁷ Dihalocyclopropanes are very useful compounds²⁴⁸⁸ that can be reduced to cyclopropanes, treated with Mg or Na to give allenes (Reaction **18-3**), or converted to a number of other products.

Alkenes of all types can be converted to cyclopropane derivatives by this reaction, but difficulty may be encountered with sterically hindered ones.²⁴⁸⁹ Even tetracyanoethylene, which responds very poorly to electrophilic attack, gives cyclopropane derivatives with carbenes.²⁴⁹⁰ Conjugated dienes give 1,2-addition to give a vinylcyclopropane.²⁴⁹¹ Addition of a second molar equivalent gives bicyclopentyl derivatives.²⁴⁹² 1,4-Addition is rare but has been reported in certain cases.²⁴⁹³ Carbene adds to ketene to give cyclopropanone.²⁴⁹⁴ Allenes react with carbenes to give cyclopropanes with exocyclic unsaturation.²⁴⁹⁵

A second equivalent gives spiropentanes. In fact, any size ring with an exocyclic double bond can be converted by a carbene to a spiro compound.²⁴⁹⁶

Free carbenes can also be avoided by using transition metal–carbene complexes ($L_nM=CRR'$, L = a ligand, M = a metal),²⁴⁹⁷ which add the group CRR' to double bonds.²⁴⁹⁸ An example is the reaction of iron carbene (**163**).²⁴⁹⁹ These complexes can be isolated in some cases; in others they are generated *in situ* from appropriate precursors, of which diazo compounds are among the most important. Chromium complexes have been used for the cyclopropanation of alkenes.²⁵⁰⁰

Diazo compounds, including CH_2N_2 and other diazoalkanes, react with metals or metal salts (Cu, Pd,²⁵⁰¹ Ag,²⁵⁰² La,²⁵⁰³ and Rh²⁵⁰⁴ are commonly used) to give the carbene complexes that add CRR' to double bonds.²⁵⁰⁵ Polymer-supported benzenesulfonyl azides

have been developed as a safe diazo-transfer reagent.²⁵⁰⁶ Diazoketones and diazoesters react with alkenes to give the cyclopropane derivative, usually with a transition metal catalyst (e.g., a Cu complex).²⁵⁰⁷ The Ru catalyst reaction of diazoesters with an alkyne gives a cyclopropene.²⁵⁰⁸ An X-ray structure of an Os catalyst intermediate has been determined.²⁵⁰⁹ Electron-rich alkenes react faster than simple alkenes.²⁵¹⁰

Asymmetric cyclopropanation reactions are a growing area of interest,²⁵¹¹ and chiral complexes have been used for enantioselective cyclopropane synthesis.²⁵¹² Decomposition of diazoalkanes in the presence of chiral Rh²⁵¹³ Cu,²⁵¹⁴ Ir,²⁵¹⁵ Co,²⁵¹⁶ Au,²⁵¹⁷ or Ru²⁵¹⁸ complexes leads to optically active cyclopropanes. Diazosulfonate esters have been used in asymmetric cyclopropanations.²⁵¹⁹ The use of chiral additives or auxiliaries with a metal complex also leads to cyclopropanes enantioselectively.²⁵²⁰ An important chiral species is Rh₂(S-DOSP)₄,²⁵²¹ which leads to cyclopropanes with excellent enantioselectivity in carbene cyclopropanation reactions.²⁵²² Chiral organocatalysts have been used.²⁵²³ The Cu catalyzed diazoester cyclopropanation was reported in an ionic liquid.²⁵²⁴ Phosphonate esters have been incorporated into the diazo compound.²⁵²⁵ *Fischer carbene* compounds (see Reaction **15-58**) react with enolate anions to

give cyclopropane derivatives.²⁵²⁶ A Cr promoted cyclopropanation of conjugated amides has been reported.²⁵²⁷

Asymmetric, intramolecular cyclopropanation reactions have been reported.²⁵²⁸ Note that the reaction of a diazoester with a chiral dirhodium catalyst leads to β -lactones with modest enantioselectivity.²⁵²⁹

Triple-bond compounds²⁵³⁰ react with carbenes to give cyclopropenes, except that in the case of acetylene itself, the cyclopropenes first formed cannot be isolated because they rearrange to allenes.²⁵³¹ Cyclopropenones (Sec. 2.K.i) are obtained by hydrolysis of dihalocyclopropenes.²⁵³²

Most carbenes are electrophilic, and, in accord with this, electron-donating substituents on the alkene increase the rate of the reaction, and electron-withdrawing groups decrease it,²⁵³³ although the range of relative rates is not very great.²⁵³⁴ As discussed in Section 5.D.i, carbenes in the singlet state, which is the most common state, react stereospecifically and syn,²⁵³⁵ probably by a one-step mechanism,²⁵³⁶ similar to mechanism *a* of Reactions **15-60** and **15-63**:

Infrared spectra of a carbene and the cyclopropane product have been observed in an Ar matrix at 12–45 K.²⁵³⁷ Carbenes in the triplet state react nonstereospecifically,²⁵³⁸ probably by a diradical mechanism, similar to mechanism *b* of Reactions **15-49** and **15-63**:

For carbenes or carbenoids of the type $R-C-R'$ there is another aspect of stereochemistry.²⁵³⁹ When these species are added to all but symmetrical alkenes, two isomers

are possible, even if the four groups originally on the double-bond carbons maintain their configurations:

Which isomer is predominantly formed depends on R, R', and on the method by which the carbene or carbenoid is generated. Most studies have been carried out on monosubstituted species (R' = H), and in these studies it is found that aryl groups generally prefer the more substituted side (syn addition) while carbethoxy groups usually show antistereoselectivity. When R = halogen, free halocarbenes show little or no stereochemical preference, while halocarbenoids exhibit a preference for syn addition. Beyond this, it is difficult to make simple generalizations.

Carbenes are so reactive that they add to the “double bonds” of aromatic rings.²⁵⁴⁰ The products are usually unstable and rearrange to give ring expansion. Carbene reacts with benzene to give cycloheptatriene (**164**),²⁵⁴¹ but not all carbenes are reactive enough to add to benzene. The norcaradiene intermediate cannot be isolated in this case²⁵⁴² (it undergoes an electrocyclic rearrangement, Reaction **18-27**), although certain substituted norcaradienes, [e.g., the product of addition of $\text{:C}(\text{CN})_2$ to benzene],²⁵⁴³ have been isolated.²⁵⁴⁴ With :CH_2 , insertion is a major side reaction, and, for example, benzene gives toluene as well as cycloheptatriene. A method of adding :CH_2 to benzene rings without the use of free carbene is the catalytic decomposition of diazomethane (CH_2N_2) in the aromatic compound as a solvent with CuCl or CuBr.²⁵⁴⁵ By this method, better yields of cycloheptatrienes are obtained without insertion of side products. *Picosecond optical grating calorimetry* has been used to investigate the photochemical decomposition of diazomethane in benzene, and it appears that a transient is formed that is consistent with a weak complex between singlet methylene and benzene.²⁵⁴⁶ Chlorocarbene (:CHCl) is active enough to add to benzene, but dihalocarbenes do not add to benzene or toluene, only to rings with greater electron density. Pyrroles and indoles can be expanded, respectively, to pyridines and quinolines by treatment with halocarbenes²⁵⁴⁷ via the initially formed adduct **165** in the case of the indole. In such cases, a side reaction that sometimes occurs is expansion of the *six-membered* ring. Ring

expansion can occur even with nonaromatic compounds, when the driving force is supplied by relief of strain (see Reaction 166).²⁵⁴⁸

As previously mentioned, free carbene is not very useful for additions to double bonds since it gives too many side products. The *Simmons–Smith procedure* accomplishes the same result without a free carbene intermediate and without insertion of side products.²⁵⁴⁹ This is known as a *carbenoid* reaction. Intramolecular variations are known.²⁵⁵⁰ This procedure involves treatment of the double-bond compound with CH_2I_2 and a $\text{Zn}—\text{Cu}$ couple and leads to cyclopropane derivatives in good yields.²⁵⁵¹ The $\text{Zn}—\text{Cu}$ couple can be prepared in several ways,²⁵⁵² and heating Zn dust with CuCl in ether under nitrogen²⁵⁵³ is particularly convenient. The reaction has also been done with unactivated Zn and ultrasound.²⁵⁵⁴ When TiCl_4 is used along with Zn and CuCl , CH_2I_2 can be replaced by the cheaper CH_2Br_2 .²⁵⁵⁵

The actual attacking species is an organozinc intermediate, probably $(\text{ICH}_2)_2\text{Zn} \cdot \text{ZnI}_2$, which is stable enough for isolable solutions.²⁵⁵⁶ An X-ray crystallographic investigation of the intermediate, complexed with a diether, has been reported.²⁵⁵⁷ The addition is stereospecifically syn, and a concerted mechanism²⁵⁵⁸ is likely, perhaps involving **167**.²⁵⁵⁹ An iodomethylzinc phosphate has also been used for cyclopropanation reactions.²⁵⁶⁰ Diiodomethane gives cyclopropanes in a reaction mediated by indium.²⁵⁶¹

Asymmetric induction is possible when chiral additives are used.²⁵⁶² Chiral complexes also lead to enantioselectivity in the cyclopropanation reaction.²⁵⁶³ Organocatalysts have been used.²⁵⁶⁴

With the *Simmons–Smith procedure*, as with free carbenes, conjugated dienes give 1,2-addition,²⁵⁶⁵ and allenes give methylenecyclopropanes or spiropentanes.²⁵⁶⁶

An alternative way of carrying out the *Simmons–Smith reaction* is by treatment of the substrate with CH₂I₂ or another dihalomethane and Et₂Zn in ether.²⁵⁶⁷ This method can be adapted to the introduction of RCH and ArCH by the use of RCHI₂ or ArCHI₂ instead of the dihalomethane.²⁵⁶⁸ The reaction is compatible with other functionality in the carbenoid complex. The reaction of RCO₂CH₂I with diethyl zinc and an alkene under photolysis conditions give a cyclopropane.²⁵⁶⁹ In another method, CH₂I₂ or MeCHI₂ is used along with an alane (R₃Al) to transfer CH₂ or CHMe.²⁵⁷⁰ Titanium complexes have been used similarly.²⁵⁷¹ Samarium and CH₂I₂ has been used for the cyclopropanation of conjugated amides.²⁵⁷² For the conversion of enolate anions to cyclopropanols, CH₂I₂ has been used along with SmI₂.²⁵⁷³ Diodomethane in the presence of isopropylmagnesium chloride has been used to cyclopropanate allyl alcohols.²⁵⁷⁴

The *Simmons–Smith reaction* is the basis of a method for the indirect α methylation of a ketone.²⁵⁷⁵ The ketone (illustrated for cyclohexanone) is first converted to an enol ether, an enamine (Reaction 16-13) or silyl enol ether²⁵⁷⁶ (Reaction 12-17), and cyclopropanation via the *Simmons–Smith reaction* is followed by hydrolysis to give the α methylated ketone. A related procedure using diethylzinc and diiodomethane allows ketones to be chain-extended by one carbon.²⁵⁷⁷ In another variation, phenols can be ortho methylated in one laboratory step, by treatment with Et₂Zn and CH₂I₂.²⁵⁷⁸

Diazoesters react with amines with a Rh catalyst to give α -amino esters.²⁵⁷⁹ Diazoesters also react with aldehydes and a Rh catalyst. The product is an α,β -epoxy ester.²⁵⁸⁰

15-65 Trimerization and Tetramerization of Alkynes

Aromatic compounds can be prepared by cyclotrimerization of alkynes²⁵⁸² or triynes.²⁵⁸³ Cyclotrimerization is possible by heating to 450–600 °C with no catalyst.²⁵⁸³ The *spontaneous* (no catalyst) trimerization of *t*-BuC≡CF gave 1,2,3-tri-*tert*-butyl-4,5,6-trifluorobenzene (**169**), which the first time was three adjacent *tert*-butyl groups put onto a benzene ring.²⁵⁸⁴ The fact that this is a head-to-head joining allows formation of **169** from two alkynes. The fact that **168** (a *Dewar benzene*) was also isolated lends support to this scheme.²⁵⁸⁵

When acetylene is heated with nickel cyanide, other Ni(II) or Ni(0) compounds, or similar catalysts, it gives benzene and cyclooctatetraene.²⁵⁸⁶ It is possible to get more of either product by a proper choice of catalyst. Substituted acetylenes give substituted benzenes,²⁵⁸⁷ and this reaction has been used to prepare very crowded molecules. Dialkylalkynes were trimerized over $\text{CO}_2(\text{CO})_8$ ²⁵⁸⁸ and over $\text{Hg}[\text{Co}(\text{CO})_4]_2$ to give hexaisopropylbenzene.²⁵⁸⁹ The six isopropyl groups are not free to rotate, but are lined up perpendicular to the plane of the benzene ring. Highly substituted benzene derivatives have also been prepared via cyclotrimerization using a Rh,²⁵⁹⁰ Ni,²⁵⁹¹

Ti,²⁵⁹² Mo,²⁵⁹³ Ru,²⁵⁹⁴ Co,²⁵⁹⁵ or a Pd²⁵⁹⁶ catalyst. Alkynes react with allenes and a Ni catalyst to give highly substituted benzene derivatives.²⁵⁹⁷ Conjugated ketones react with internal alkynes with Me₃Al and a Ni catalyst²⁵⁹⁸ to give an aromatic ring fused to a cyclic ketone after reaction with DBU and air.²⁵⁹⁹ N-Aryl chloroimines react with alkynes and a Rh catalyst to give quinolines,²⁶⁰⁰ as do N-aryl alkynyl imines with a W complex.²⁶⁰¹

Intramolecular cyclotrimerizations have been reported by condensation of a diyne²⁶⁰² with an alkyne in the presence of a Pd,²⁶⁰³ Mo,²⁶⁰⁴ Ni,²⁶⁰⁵ Rh,²⁶⁰⁶ Ir,²⁶⁰⁷ Ag,²⁶⁰⁸ Co,²⁶⁰⁹ or Ru catalyst.²⁶¹⁰ Triynes have been similarly condensed with a Rh catalyst.²⁶¹¹ Note that this type of cyclization has been labeled as a [2 + 2 + 2]-cycloaddition reaction, which is discussed in Reaction **15-66**. The internal cyclotrimerization of a triyne, utilizing a siloxy tether and a Co catalyst has been reported.²⁶¹² Fused-ring aromatic compounds are prepared by this method. Similar results were obtained from diynes and allenes with a Ni catalyst.²⁶¹³ Solid-supported cyclotrimerizations have been reported.²⁶¹⁴ Endiynes are cyclized to bicyclic arenes using a Pd²⁶¹⁵ or Ru²⁶¹⁶ catalyst, as are yndienes with a Ru catalyst.²⁶¹⁷ Alkynyl biaryls are cyclized to phenanthrene derivatives using ICl.²⁶¹⁸ In the presence of PhMe₂SiH, CO, and a Rh catalyst, a nonconjugated triyne leads to a tricyclic compound in which a benzene ring is fused to two carbocyclic rings.²⁶¹⁹ Internal cyclotrimerization of an aryl alkynyl ketone where the aryl group has an *ortho*

trimethylsilylalkyne substituent gives a tetracyclic naphthalene derivative with a fused cyclopentanone unit.²⁶²⁰ Benzene derivatives with ortho alkyne units can be converted to naphthalene derivatives in aq NaOH with hydrazine, Te, NaBH₄ and sonication.²⁶²¹ Vinyl and alkyne substituents with a Ru catalyst lead to naphthalene derivatives.²⁶²² Cyclo-trimerization occurs with alkynyl boronic esters.²⁶²³

Imino and iodo substituents with a silyl alkyne and a Pd catalyst leads to an isoquinoline.²⁶²⁴ Benzene derivatives having ortho imine and alkyne substituents give an isoquinoline when treated with iodine²⁶²⁵ or with a Pd catalyst.²⁶²⁶ Diynes with nitriles and a Ru catalyst lead to isoquinolines.²⁶²⁷ Pyridines fused to carboxylic rings can be prepared by similar methodology using a cyanoamine and a Co catalyst.²⁶²⁸ An isocyanate (Ar—N=C=O) reacts with a diyne and a Ru catalyst to give a bicyclic pyridone.²⁶²⁹ Isocyanides and alkynes also react with a phosphine catalyst to give pyrroles.²⁶³⁰ Ortho alkynyl and epoxy substituents leads to β -naphthols using a Ru catalyst.²⁶³¹

Nitriles react with 2 molar equivalents of acetylene, in the presence of a Co catalyst, to give 2-substituted pyridines.²⁶³² Propargyl amines react with cyclohexanone derivatives and a Au complex to give tetrahydroquinolines.²⁶³³ Treatment of alkynes with Cp₂ZrEt₂ followed by reaction with acetonitrile and then a second alkyne with a Ni catalyst gives a highly substituted pyridine.²⁶³⁴ This reaction can be done intramolecularly using a photochemically induced reaction with a Co catalyst and *p*-TolCN to give pyridines incorporated into macrocycles.²⁶³⁵ Diynes react with *N*-heterocyclic carbenes in the presence of a Ni catalyst to give pyridines.²⁶³⁶ Alkynyl esters react with enamino esters with a ZnBr₂ catalyst to give substituted pyridines.²⁶³⁷ α -Halo oxime ethers react with alkynes and *Grignard reagents*, with a mixture of Pd and Cu catalysts, to give pyrimidines.²⁶³⁸ Triketones fix nitrogen gas in the presence of TiCl₄ and Li metal to form bicyclic pyrrole derivatives.²⁶³⁹

In contrast to the spontaneous reaction, the catalyzed process seldom gives the 1,2,3-trisubstituted benzene isomer from an acetylene (RC \equiv CH). The chief product is usually

the 1,2,4-isomer,²⁶⁴⁰ with lesser amounts of the 1,3,15-isomer also generally obtained, but little if any of the 1,2,3-isomer. The mechanism of the catalyzed

reaction to form benzenes²⁶⁴¹ is believed to go through a species **170** in which two molecules of alkyne coordinate with the metal, and another species (**171**), a five-membered heterocyclic intermediate.²⁶⁴² Such intermediates (where M = Rh, Ir, Zr,²⁶⁴³ or Ni) have been isolated and are shown to give benzenes (**172**) when treated with alkynes.²⁶⁴⁴ Note that this pathway accounts for the predominant formation of the 1,2,4-isomer. Two possibilities for the last step are a *Diels–Alder reaction*, and a ring expansion, each followed by extrusion of the metal.²⁶⁴⁵

In at least one case, the mechanism is different, going through a cyclobutadiene–nickel complex (see Sec. 2.K.ii), which has been isolated.²⁶⁴⁶ Similar results were obtained with a Ti complex.²⁶⁴⁷ Using a mixture of PdCl₂ and CuCl₂, however, aliphatic alkynes are converted to the 1,3,5-trialkyl benzene derivative.²⁶⁴⁸

Alkoxy chromium carbenes (*Fischer carbene complexes*, see Reaction **15-58**) react with phenylalkynes to give naphthalene derivatives.²⁶⁴⁹ These Cr carbenes react with

alkynyl boronates, cerium(IV) compounds, and then PhBr and a Pd catalyst to give a naphthoquinone.²⁶⁵⁰ Diynes react to give cyclotrimerization.²⁶⁵¹ Note that vinyl Chromium carbenes react directly with alkynes to give spirocyclic compounds (spiro [4.4]nona-1,3,6-trienes).²⁶⁵² Benzofurans can be prepared using methoxy carbenes.²⁶⁵³ Amino-substituted chromium carbenes react with alkynes and then silica to give substituted benzene derivatives that have an aminoalkyl ($-\text{NR}_2$) substituent.²⁶⁵⁴ Imino-substituted Chromium carbenes react with alkynes to give pyrrole derivatives.²⁶⁵⁵ Fischer carbene complexes react with alkynes to give the *Dötz benzannulation*,²⁶⁵⁶ giving *p*-alkoxyphenol derivatives. Modification of this basic technique can lead to eight-membered ring carbocycles (see Reaction 15-66).²⁶⁵⁷

When benzene, in the gas phase, was adsorbed onto a surface of 10% rhodium-on-alumina, the reverse reaction took place, and acetylene was formed.²⁶⁵⁸

Heating ketones in the presence of TiCl_3OTf leads to 1,3,5-trisubstituted arenes.²⁶⁵⁹ Heating acetophenone with TiCl_4 gives 1,3,5-triphenylbenzene.²⁶⁶⁰

OS VII, 256; IX, 1; 80, 93.

15-66 Other Cycloaddition Reactions

cyclo-[But-2-en-1,4-diyl]-1/4/addition, and so on

Cycloaddition reactions other than $[4 + 2]$, $[3 + 2]$, or $[2 + 2]$ are possible, often providing synthetically useful routes to cyclic compounds. Conjugated dienes can be dimerized or trimerized at the 1,4-positions (formally, $[4 + 4]$ and $[4 + 4 + 4]$ cycloadditions) by treatment with certain complexes or other transition metal compounds.²⁶⁶¹ Thus butadiene gives 1,5-cyclooctadiene and 1,5,9-cyclododecatriene.²⁶⁶² The relative amount of each product can be controlled by use of the proper catalyst. For example, $\text{Ni:P}(\text{OC}_6\text{H}_4\text{-}o\text{-Ph})_3$ gives predominant dimerization, while $\text{Ni}(\text{cyclooctadiene})_2$ gives mostly trimerization. The products arise, not by direct 1,4 to 1,4 attack, but by stepwise

mechanisms involving metal–alkene complexes.²⁶⁶³ The Rh catalyzed intramolecular cycloaddition of a furan with a conjugated diazoester gives a [3 + 4]-cycloadduct.²⁶⁶⁴ The suprafacial thermal addition of an allylic cation to a diene (a [4 + 3] cycloaddition) is allowed by the *Woodward–Hoffmann rules* (this reaction would be expected to follow the same rules as the *Diels–Alder reaction*²⁶⁶⁵). Pyrroles react with allylic diazo compounds, in the presence of a Rh catalyst, to give bicyclic amines in a [4 + 3]-cycloaddition.²⁶⁶⁶ A different [4 + 3]-cycloaddition involves the intramolecular reaction of a diene with an alkylidenecyclopropane unit, in the presence of a Pd catalyst, to give a seven-membered ring as part of a bicyclic system.²⁶⁶⁷ A [3 + 2 + 2]-cycloaddition was reported with an alkyne and an alkene–alkylidenecyclopropane substrate, in the presence of a Rh catalyst.²⁶⁶⁸ Reaction with a chiral Rh catalyst converts dienes and diazo compounds to cycloheptadienes.²⁶⁶⁹ Chiral cations have been used in [4 + 3] cycloadditions.²⁶⁷⁰ A [5 + 2]-cycloaddition of vinylcyclopropanes and alkenes, in the presence of a Rh catalyst, leads to seven-membered rings.²⁶⁷¹ The reaction of a conjugated carbonyl compound with a diazo ester, in the presence of a Cu catalyst, leads to a dihydropyran in what is labeled a [4 + 1]-cycloaddition.²⁶⁷² Dienes react with nitriles in a Ti mediated [4 + 1]-cycloaddition.²⁶⁷³ Cycloheptatriene reacts with terminal alkynes, using a complex catalyst involves Co and Zn compounds, to give a bicyclic triene via a [6 + 2]-cycloaddition.²⁶⁷⁴

As seen in Reaction **15-60**, the *Woodward–Hoffmann rules* allow suprafacial concerted cycloadditions to take place thermally if the total number of electrons is $4n + 2$ and photochemically if the number is $4n$. Furthermore, forbidden reactions become allowed if one molecule reacts antarafacially. It would thus seem that syntheses of many large rings could easily be achieved. However, when the newly formed ring is eight membered or greater, concerted mechanisms, although allowed by orbital symmetry for the cases stated, become difficult to achieve. Due to the entropy factor the two ends of one system must simultaneously encounter the two ends of the other, unless one or both components are cyclic, in which case the molecule has many fewer possible conformations. There have been a number of reports of cycloaddition reactions leading to eight membered and larger rings, some thermally and some photochemically induced, but (apart from the dimerization and trimerization of butadienes mentioned above, which are known not to involve direct

[4 + 4]- or [4 + 4 + 4]-cycloaddition) in most cases evidence is lacking to indicate whether they are concerted or stepwise processes. Some examples follows:

Benzene rings can undergo photochemical cycloaddition with alkenes.²⁶⁷⁹ The major product is usually the 1,3 addition product (**173**, in which a three-membered ring has also been formed), although some of the 1,2-product (**174** Reaction **15-63**) is sometimes formed as well. Compound **174** is usually the main product where the alkene bears electron-withdrawing groups and the aromatic compound electron-donating groups, or vice versa. The 1,4-product (**175**) is rarely formed. The reaction has also been run with benzenes substituted with alkyl, halo, OR, CN, and other groups, and with acyclic and cyclic alkenes bearing various groups.²⁶⁸⁰

[2 + 2 + 2]-Cycloaddition reactions are known²⁶⁸¹ (also see Reaction **15-65**), usually with diynes, enynes, or intermolecular reactions of alkynes or alkenes with an alkyne, and facilitated by Ni²⁶⁸² Ru,²⁶⁸³ or a Co catalyst.²⁶⁸⁴ A mechanistic density functional study has been reported for this reaction.²⁶⁸⁵ With a Co catalyst, an intramolecular [2 + 2 + 2]-cycloaddition of diynes with nitriles leads to bicyclic pyridines.²⁶⁸⁶ Alkenyl isocyanates and alkynes react via [2 + 2 + 2]-cycloaddition, in the presence of a Ru catalyst, to form bicyclic conjugated lactams.²⁶⁸⁷ Pyridines can also be prepared by metal-catalyzed [2 + 2 + 2]-cycloaddition.²⁶⁸⁸ Alkynes and isocyanates react with CO in the presence of a Ru catalyst to give imides,²⁶⁸⁹ and other [2 + 2 + 1]-cycloadditions are known.²⁶⁹⁰ A Co catalyst is used for a [4 + 2 + 2]-cycloaddition of 1,3-butadiene and bicyclo[2.2.2]octa-2,5-diene.²⁶⁹¹ Eight-membered rings are produced by a Rh catalyzed [4 + 2 + 2] cycloaddition.²⁶⁹² Yne-dienes undergo [4 + 2 + 1]-cycloaddition in the presence of a Ni catalyst.²⁶⁹³ Chromium catalysts are available for [6 + 4]-cycloadditions.²⁶⁹⁴ Ene-diynes undergo [2 + 2 + 2 + 1]-cycloaddition to form seven-membered ring ketones, in the presence of CO and a Rh catalyst.²⁶⁹⁵ Nickel catalyzed [2 + 2 + 2 + 2]-cycloadditions of alkynes lead to eight-membered rings.²⁶⁹⁶

Allenenes and vinylcyclopropanes undergo [5 + 2]- and [5 + 2 + 1]-cycloadditions in the presence of a Rh catalyst.²⁶⁹⁷ A reductive elimination step determines the selectivity for various substrates in Rh catalyzed catalyzed [5 + 2]-cycloadditions.²⁶⁹⁸

Addition to Carbon–Hetero Multiple Bonds

16.A. MECHANISM AND REACTIVITY

The reactions considered in this chapter involve addition to the carbon–oxygen, carbon–nitrogen, and carbon–sulfur double bonds, as well as the carbon–nitrogen triple bond. The mechanistic study of these reactions is much simpler than that of the additions to carbon–carbon multiple bonds considered in Chapter 15.¹ Since C=O, C=N, and C≡N bonds are strongly polar, with the carbon always the positive end (except for isocyanides, see Sec. 16.B.iv), there is never any doubt about the *orientation* of unsymmetrical addition to these bonds (the regiochemical preference). Nucleophilic attacking species always go to the carbon and electrophilic species to the oxygen or nitrogen. Additions to C=S bonds are much less common,² but in these cases the addition is sometimes in the other direction (reaction at sulfur is called *thiophilic addition* and addition to the carbon is called *carbophilic addition*).³ For example, the reaction of phenyllithium with thiobenzophenone (Ph₂C=S) gives, after hydrolysis, benzhydryl phenyl sulfide (Ph₂CHSPh).⁴

The normal acyl addition of YH to a ketone gives an alkoxide, and hydrolysis gives **1**. Note that the product has a stereogenic carbon, but unless there is chirality in R or R', or YH is optically active, the product must be a racemic mixture because there is no facial bias for addition to the carbonyl. The same holds true for C=N and C=S bonds. The stereochemistry of addition of a single YH to the carbon–nitrogen triple bond could be investigated, since the product can exist in (*E*) and (*Z*) forms (Sec. 4.K.i), but these reactions generally give imine products that undergo further reaction. Of course, if R or R' is chiral, a mixture of diastereomers

will result, and the stereochemistry of addition can be studied in such cases. *Cram's rule* or the *Felkin–Anh model* (Sec. 4.H) allows the direction of attack of Y to be predicted in many cases.⁵ However, the relative directions of attack of Y and H are not determined, but only the direction of attack of Y with respect to the rest of the substrate molecule.

In Section 15.B.iii, electronic effects were shown to play a part in determining which face of a carbon–carbon double bond is attacked. The same applies to additions to carbonyl groups. For example, in 5-substituted adamantanones (**2**) electron-withdrawing (–I) groups W cause the attack to come from the syn face, while electron-donating groups cause it to come from the anti face.⁶ In 5,6-disubstituted norborn-2-en-7-one systems, the carbonyl appears to tilt away from the π bond, with reduction occurring from the more hindered face.⁷ An *ab initio* study of nucleophilic addition to 4-*tert*-butylcyclohexanones attempted to predict π -facial selectivity.⁸

The mechanistic picture is further simplified by the fact that free radical additions to carbon–heteroatom double bonds are not as prevalent (but see Reaction **16-31**).⁹ In most cases, the nucleophile forms the first new bond to carbon, and these reactions are regarded as *nucleophilic additions*, which can be represented as:

The electrophile shown in step 2 is the proton. In almost all the reactions considered in this chapter the electrophilic atom is either hydrogen or carbon. Note that step 1 is exactly the same as step 1 of the tetrahedral mechanism of nucleophilic substitution at a carbonyl carbon (Sec. 16.A.i), but carbon groups (A, B = H, alkyl aryl, etc.) are poor leaving groups so that substitution does not compete with addition. For carboxylic acid derivatives, there are leaving groups (B = Cl, OR, NH₂, etc.) and acyl substitution predominates (Sec. 16.A.i). *The nature of A and B determines whether a nucleophilic attack at a carbon–heteroatom multiple bond will lead to substitution or addition.*

Both acids and bases can catalyze many of these reactions.¹⁰ Bases catalyze the reaction by converting a reagent YH to the more powerful nucleophile Y[–] (see Sec. 10.G.ii). Acids

catalyze it by converting the substrate to an heteroatom-stabilized cation (oxocarbenium ion **3** from C=O) in step 1, thus making it more attractive to nucleophilic attack and making the reverse reaction somewhat less favorable. Similar catalysis can also be achieved with metallic ions (e.g., Ag^+), which act as Lewis acids.¹¹

In step 1 of the acid-catalyzed mechanism, the carbonyl reacts as a base with the proton to give **3**, which is known as an *oxocarbenium ion*. In Section 5.A.ii, it was pointed out that oxocarbenium ions are comparatively stable carbocations because the positive charge is delocalized on the oxygen by resonance.¹² Intermediate **3** then reacts with the nucleophile in step 2 to give the acyl addition product. The rate-determining step is usually the one involving nucleophilic attack. If one heteroatom (e.g., oxygen) stabilizes an adjacent carbocation, as in **3**, a second heteroatom (X) will stabilize an oxocarbenium ion ($-\text{X}-\text{C}^+-\text{X}-$) to a greater extent.¹³

Reactivity factors for carbon–heteroatom multiple bonds are similar to those for the tetrahedral mechanism of nucleophilic substitution.¹⁴ If A and/or B are electron-donating groups (e.g., alkyl groups), rates are decreased. Electron-attracting substituents increase rates. This means that aldehydes are more reactive than ketones. Aryl groups are somewhat deactivating compared to alkyl, because of resonance that stabilizes the substrate molecule, but is lost on going to the intermediate. Double bonds in conjugation with the carbon–heteroatom multiple bond also lower addition rates, for similar reasons but, more important, may provide competition from 1,4-addition (Sec. 15.A.ii). Steric factors are also quite important and contribute to the decreased reactivity of ketones compared with aldehydes. Highly hindered ketones like hexamethylacetone and dineopentyl ketone either do not undergo many of these reactions or require extreme conditions.

16.A.i. Nucleophilic Substitution at an Aliphatic Trigonal Carbon: The Tetrahedral Mechanism

All the mechanisms discussed in previous chapters for substitution take place at a saturated carbon atom. Nucleophilic substitution is also important at trigonal carbons, especially when the carbon is double bonded to an oxygen, a sulfur, or a nitrogen. Substitution at a carbonyl group (or the corresponding nitrogen and sulfur analogues) most often proceeds by a second-order mechanism, which in this book is called the *tetrahedral*¹⁵ *mechanism*.¹⁶

¹⁵ This mechanism has also been called the "addition–elimination mechanism".

¹⁶ See Talbot, R.J.E. in Bamford, C.H.; Tipper, C.F.H. *Comprehensive Chemical Kinetics*, Vol. 10, Elsevier, NY, **1972**, pp. 209–223; Jencks, W.P. *Catalysis in Chemistry and Enzymology*, McGraw-Hill, NY, **1969**, pp. 463–554; Satchell, D.P.N.; Satchell, R.S. in Patai, S. *The Chemistry of Carboxylic Acids and Esters*, Wiley, NY, **1969**, pp. 375–452; Johnson, S.L. *Adv. Phys. Org. Chem.* **1967**, 5, 237.

The IUPAC designation is $A_N + D_N$. The S_N1 mechanisms, involving carbocations, are sometimes found with these substrates, especially with essentially ionic substrates (e.g., $\text{RCO}^+ \text{BF}_4^-$; there is evidence that in certain cases simple S_N2 mechanisms can take place, especially with a very good leaving group (e.g., Cl^-);¹⁷ and an SET mechanism has also been reported.¹⁸ However, the tetrahedral mechanism is by far the most prevalent. Although this mechanism displays second-order kinetics, it is not the same as the S_N2 mechanism discussed in Section 10.A.i. In the tetrahedral mechanism, first Y attacks to give an intermediate containing both X and Y (**4**), and then X leaves. This sequence, impossible at a saturated carbon, is possible at an unsaturated one because the central carbon can release a pair of electrons to the oxygen and so preserve its octet:

When reactions are carried out in acid solution, there may also be a preliminary and a final step:

The hydrogen ion is a catalyst. The reaction rate is increased because it is easier for the nucleophile to attack the carbon when the electron density of the latter has been decreased.¹⁹

Evidence for the existence of the tetrahedral mechanism is as follows:²⁰

1. The kinetics are first order each in the substrate and in the nucleophile, as predicted by the mechanism.
2. There is other kinetic evidence in accord with a tetrahedral intermediate. For example, the rate “constant” for the reaction between acetamide and hydroxylamine is not constant, but decreases with increasing hydroxylamine concentration.²¹ This

²⁰ Also see Guthrie, J.P. *J. Am. Chem. Soc.* **1978**, 100, 5892; Kluger, R.; Chin, J. *J. Am. Chem. Soc.* **1978**, 100, 7382; O’Leary, M.H.; Marlier, J.F. *J. Am. Chem. Soc.* **1979**, 101, 3300.

²¹ Jencks, W.P.; Gilchrist, M. *J. Am. Chem. Soc.* **1964**, 86, 5616.

is not a smooth decrease; there is a break in the curve. A straight line is followed at low hydroxylamine concentration and another straight line at high concentration. This means that the identity of the rate-determining step is changing. Obviously, *this cannot happen if there is only one step: there must be two steps, and hence an intermediate*. Similar kinetic behavior has been found in other cases as well;²² in particular, plots of rate against pH are often bell-shaped.

3. Basic hydrolysis has been carried out on carboxylic esters labeled with ^{18}O in the carbonyl group.²³ If this reaction proceeded by the normal $\text{S}_{\text{N}}2$ mechanism, all the ^{18}O would remain in the carbonyl group, even if, in an equilibrium process, some of the carboxylic acid formed went back to the starting material:

On the other hand, if the tetrahedral mechanism operates

then the intermediate **5** reacts with an acid (e.g., water) and is converted to the conjugate acid, symmetrical intermediate **6**. In this intermediate, the OH groups are equivalent, and (except for the small $^{18}\text{O}/^{16}\text{O}$ isotope effect) either one can lose a proton with equal facility:

The intermediates **5** and **7** can now lose OR' to give the carboxylic acid (not shown in the equations given), or they can lose OH to regenerate the carboxylic ester. If **5** reverts back to an ester, the ester will still be labeled, but if **7** reverts to an ester, the ^{18}O will be lost. A test of the two possible mechanisms is to stop the reaction before completion and to analyze the recovered ester for ^{18}O . Experiments by Bender²⁴ found that in alkaline hydrolysis of methyl, ethyl, and isopropyl benzoates, the esters had lost ^{18}O . A similar experiment carried out for acid-catalyzed hydrolysis of ethyl benzoate showed that here too the ester lost ^{18}O . However, alkaline hydrolysis of substituted benzyl benzoates showed *no* ^{18}O loss.²⁴ This result does not necessarily mean that no tetrahedral intermediate is involved in this case. If **5** and **7** do not revert to an ester, but go entirely to an acid, no ^{18}O loss will be found even with a tetrahedral intermediate. In the case of benzyl benzoates, this may very well be happening, because formation of the acid relieves steric strain. Another possibility is that **5** loses OR' before it can become

²² Kevill, D.N.; Johnson, S.L. *J. Am. Chem. Soc.* **1965**, 87, 928; Leinhard, G.E.; Jencks, W.P. *J. Am. Chem. Soc.* **1965**, 87, 3855; Schowen, R.L.; Jayaraman, H.; Kershner, L.D. *J. Am. Chem. Soc.* **1966**, 88, 3373.

protonated to **6**.²⁵ Even the experiments that *do* show ^{18}O loss do not *prove* the existence of the tetrahedral intermediate, since it is possible that ^{18}O is lost by some independent process not leading to ester hydrolysis. To deal with this possibility, Bender and Heck²⁶ measured the rate of ^{18}O loss in the hydrolysis of ethyl trifluorothioacetate- ^{18}O :

This reaction had previously been shown²⁷ to involve an intermediate by the kinetic methods mentioned above. Bender and Heck²⁶ showed that the rate of ^{18}O loss and the value of the partitioning ratio k_2/k_3 as determined by the oxygen-exchange technique were exactly in accord with these values as previously determined by kinetic methods. Thus the original ^{18}O exchange measurements showed that there is a tetrahedral species present, but not necessarily on the reaction path, while the kinetic experiments showed that there is some intermediate present, but not necessarily tetrahedral. Bender and Heck's²⁶ results demonstrate that there is a tetrahedral intermediate and that it lies on the reaction pathway.

4. In some cases, tetrahedral intermediates have been isolated²⁸ or detected spectrally.²⁹

Several studies have been made of the directionality of approach by the nucleophile.³⁰ Menger³⁰ has proposed for reactions in general, and specifically for those that proceed by the tetrahedral mechanism, that there is no single definable preferred transition state, but rather a "cone" of trajectories. All approaches within this cone lead to reaction at comparable rates; it is only when the approach comes outside of the cone that the rate falls.

Directionality has also been studied for the second step. Once the tetrahedral intermediate (**4**) is formed, it loses Y (giving the product) or X (reverting to the starting compound). Deslongchamps has proposed that one of the factors affecting this choice is the conformation of the intermediate; more specifically, the positions of the lone pairs. In this view, a leaving group X or Y can depart only if the other two atoms on the carbon both have an orbital antiperiplanar to the C—X or C—Y bond. For example, consider an intermediate **8** formed by attack of ^-OR on a substrate $\text{R}'\text{COX}$. Cleavage of the C—X bond with loss of X can take place from conformation **A**, because the two lone-pair orbitals

³⁰ See Menger, F.M. *Tetrahedron* **1983**, 39, 1013; Liotta, C.L.; Burgess, E.M.; Eberhardt, W.H. *J. Am. Chem. Soc.* **1984**, 106, 4849.

marked * are antiperiplanar to the C—X bond, but not from **B** because only the O[−] has such an orbital. If the intermediate is in conformation **B**, the OR may leave (if X has a lone-pair orbital in the proper position) rather than X. This factor is called *stereoelectronic control*.³¹ Free rotation in acyclic intermediates leads to many conformations, but some are preferred, and cleavage reactions may take place faster than rotation, so stereoelectronic control can be a factor in some situations. Much evidence has been presented for this concept.³² More generally, the term *stereoelectronic effects* refers to any case in which orbital position requirements affect the course of a reaction. The backside attack in the S_N2 mechanism is an example of a stereoelectronic effect.

Some nucleophilic substitutions at a carbonyl carbon are *catalyzed* by nucleophiles.³³ There occur, in effect, two tetrahedral mechanisms:

(For an example, see Reaction 16-58). When this happens internally, it is a neighboring-group mechanism at a carbonyl carbon.³⁴ For example, the hydrolysis of phthalamic acid (**9**) takes place as follows:

Evidence comes from comparative rate studies.³⁵ Thus **9** was hydrolyzed $\sim 10^5$ times faster than benzamide (PhCONH₂) at about the same concentration of hydrogen ions. That this enhancement of rate was not caused by the resonance or field effects of COOH (an electron-withdrawing group) was shown by the fact both *o*-nitrobenzamide and terephthalamic acid (the para isomer of **9**) were hydrolyzed more slowly than benzamide. Other examples of neighboring-group participation at a carbonyl carbon have been reported.³⁶ It is likely that nucleophilic catalysis is involved in enzyme catalysis of ester hydrolysis.

The attack of a nucleophile on a carbonyl group can result in substitution or addition, depending on the substituents, but the first step of each mechanism is the same. The main factor that determines the product is the identity of the group X in RCOX. When X is alkyl or hydrogen, addition usually takes place. When X is halogen, OCOR, NH₂, and so on, the

³¹ It has also been called the “antiperiplanar lone-pair hypothesis (ALPH)”. For a reinterpretation of this factor in terms of the principle of least nuclear motion (see Reaction 15-10), see Hosie, L.; Marshall, P.J.; Sinnott, M.L. *J. Chem. Soc. usual reaction is substitution. When $X = OH$, protonation to generate OH_2^+ is usually required before the group can be lost.

In both the S_N1 and S_N2 mechanisms, the leaving group departs during the rate-determining step and so directly affects the rate. In the tetrahedral mechanism at a carbonyl carbon, the bond between the substrate and leaving group is still intact during the slow step. Nevertheless, the nature of the leaving group still affects the reactivity in two ways: (1) By altering the electron density at the carbonyl carbon, the rate of the reaction is affected. The greater the electron-withdrawing character of X , the greater the partial positive charge on C and the more rapid the attack by a nucleophile. (2) The nature of the leaving group affects the *position of equilibrium*. In the intermediate **4**, there is competition between X and Y as to which group leaves. If X is a poorer leaving group than Y , then Y will preferentially leave and **4** will revert to the starting compounds. Thus there is a partitioning factor between **4** going on to product (loss of X) or back to starting compound (loss of Y). The sum of these two factors causes the sequence of reactivity to be $RCOCl > RCOOCOR' > RCOOAr > RCOOR' > RCONH_2 > RCONR'_2 > RCOO^-$.³⁷ Note that this order is approximately the order of decreasing stability of the leaving-group anion. If the leaving group is bulky, it may exert a steric effect and retard the rate for this reason.

For a list of some of the more important reactions that operate by the tetrahedral mechanism, see Table 16.1, which shows the main reactions that proceed by the tetrahedral mechanism.

TABLE 16.1 The More Important Synthetic Reactions That Take Place by the Tetrahedral Mechanism.^a

Reaction Number	Reaction
16-57	$RCOX + H_2O \longrightarrow RCOOH$
16-58	$RCOOCOR' + H_2O \longrightarrow RCOOH + R'COOH$
16-59	$RCO_2R' + H_2O \longrightarrow RCOOH + R'OH$
16-59	$RCONR'_2 + H_2O \longrightarrow RCOOH + R'_2NH$ ($R' = H, \text{alkyl, aryl}$)
16-61	$RCOX + R'OH \longrightarrow RCO_2R'$
16-62	$RCOOCOR + R'OH \longrightarrow RCO_2R'$
16-63	$RCOOH + R'OH \longrightarrow RCO_2R'$
16-64	$RCO_2R' + R''OH \longrightarrow RCO_2R'' + R'OH$
16-66	$RCOX + R'COO^- \longrightarrow RCOOCOR'$
10-21	$RCOX + H_2O_2 \longrightarrow RCO_3H$
16-69	$RCOX + R'SH \longrightarrow RCOSR'$
16-72	$RCOX + NHR'_2 \longrightarrow RCONR'_2$ ($R' = H, \text{alkyl, aryl}$)
16-73	$RCOOCOR + NHR'_2 \longrightarrow RCONR'_2$ ($R' = H, \text{alkyl, aryl}$)
16-74	$RCOOH + NHR'_2 \xrightarrow[\text{agent}]{\text{coupling}} RCONR'_2$ ($R' = H, \text{alkyl, aryl}$)
16-75	$RCO_2R' + NHR^2 \xrightarrow{\text{agent}} RCONR^2$ ($R^2 = H, \text{alkyl, aryl}$)
16-79	$RCOOH + SOCl_2 \longrightarrow RCOCl$
19-39	$RCOX + LiAlH(O-t-Bu)_3 \longrightarrow RCHO$
19-41	$RCONR'_2 + LiAlH_4 \longrightarrow RCHO$
16-81	$RCOX + R_2CuLi \longrightarrow RCOR'$
16-85	$2RCH_2CO_2R' \longrightarrow RCH_2COCHR'CO_2R'$

^aCatalysts are not shown.

³⁷ The compound $RCOOH$ would belong in this sequence just after $RCOOAr$, but it fails to undergo many reactions for a special reason. Many nucleophiles, instead of attacking the $C=O$ group, are basic enough to take a proton from the acid, converting it to the unreactive $RCOO^-$.

16.B. REACTIONS

Many of the reactions in this chapter are simple additions to carbon–hetero multiple bonds, with the reaction ending when the two groups have been added. But in many other cases subsequent reactions take place. There are generally two types:

In type A, the initially formed adduct loses water (or, in the case of addition to $\text{C}=\text{NH}$, ammonia, etc.), and the net result of the reaction is the substitution of $\text{C}=\text{Y}$ for $\text{C}=\text{O}$ (or $\text{C}=\text{NH}$, etc.). In type B there is a rapid substitution, and the OH (or NH_2 , etc.) is replaced by another group Z, which is often another YH moiety. This substitution is nucleophilic in most cases: Y usually has an unshared pair and $\text{S}_{\text{N}}1$ reactions occur very well on this type of compound (Sec. 10.G.i, category 2), even when the leaving group is as poor as OH or NH_2 . In this chapter, reactions will be classified according to what is initially adding to the carbon–heteroatom multiple bond, even if subsequent reactions take place so rapidly that it is impossible to isolate the initial adduct.

Most of the reactions considered in this chapter can be reversed. In many cases, we will consider the reverse reactions with the forward ones, in the same section. The reverse of some of the other reactions are considered in other chapters. In still other cases, one of the reactions in this chapter is the reverse of another (e.g., 16-2 and 16-13). For reactions that are reversible, the principle of microscopic reversibility (Sec. 6.H) applies.

First, reactions in which hydrogen or a metallic ion (or in one case phosphorus or sulfur) adds to the heteroatom will be discussed. Second, reactions in which carbon adds to the heteroatom will be discussed. Within each group, the reactions are classified by the nature of the nucleophile. Additions to isocyanides, which are different in character, follow. Acyl substitution reactions that proceed by the tetrahedral mechanism, which mostly involve derivatives of carboxylic acids, are treated at the end.

16.B.i. Reactions in which Hydrogen or a Metallic Ion Adds to the Heteroatom

A. Attack by OH (Addition of H_2O)

16-1 The Addition of Water to Aldehydes and Ketones: Formation of Hydrates

O-Hydro-*C*-hydroxy-addition

The adduct formed upon addition of water to an aldehyde or ketone is called a hydrate or *gem*-diol.³⁸ These compounds are usually stable only in water solution and decompose on

³⁸ See Bell, R.P. *The Proton in Chemistry*, 2nd ed., Cornell University Press, Ithaca, NY, 1973, pp. 183–187; *Adv. Phys. Org. Chem.* 1966, 4, 1; Le Hénaff, P. *Bull. Soc. Chim. Fr.* 1968, 4687.

distillation; that is, the equilibrium shifts back toward the carbonyl compound, usually via formation of an enol and tautomerization to the carbonyl. The position of the equilibrium is greatly dependent on the structure of the hydrate. Thus, formaldehyde in water at 20 °C exists 99.99% in the hydrated form, while for acetaldehyde this figure is 58%, and for acetone the hydrate concentration is negligible.³⁹ It has been found, by exchange with ¹⁸O, that the reaction with acetone is quite rapid when catalyzed by acid or base, but the equilibrium lies on the side of acetone and water.⁴⁰ Since methyl, a +I group, inhibits hydrate formation, it may be expected that electron-attracting groups would have the opposite effect, and this is indeed the case. The hydrate of chloral (trichloroacetaldehyde)⁴¹ is a stable crystalline substance. In order for it to revert to chloral, ⁻OH or H₂O must leave. This is made difficult by the electron-withdrawing character of the Cl₃C group and by the absence of a proton on the α carbon, which is required for loss of water to form an enol. Some other⁴² polychlorinated and polyfluorinated aldehydes and ketones⁴³ and α-keto aldehydes also form stable hydrates, as do cyclopropanones.⁴⁴ In the last case,⁴⁵ formation of the hydrate relieves some of the I strain (Sec. 9.B) of the parent ketone.

The reaction is subject to both general-acid and general-base catalysis; the following mechanisms can be written for basic (B) and acidic (BH) catalysis, respectively:⁴⁶

In mechanism *a*, as the H₂O attacks, the base pulls off a proton, and the net result is addition of ⁻OH. This can happen because the base is already hydrogen bonded to the H₂O molecule before the attack. In mechanism *b*, because HB is already hydrogen bonded to the oxygen of the carbonyl group, it gives up a proton to the oxygen as the water attacks. In this way, B and HB accelerate the reaction even beyond the extent that they form ⁻OH or H₃O⁺ by reaction with water. Reactions in which the catalyst donates a proton to the electrophilic reagent (in this case the aldehyde or ketone) in one direction and removes it in the other are called class e reactions. Reactions in which the catalyst does the same to the nucleophilic reagent are called class n reactions.⁴⁷ Thus the acid-catalyzed process here is a class e reaction, while the base-catalyzed process is a class n reaction.

16-2 Hydrolysis of the Carbon–Nitrogen Double Bond⁴⁸

Oxo-de-alkylimino-bisubstitution, and so on

Compounds containing carbon–nitrogen double bonds can be hydrolyzed to the corresponding aldehydes or ketones.⁴⁹ For imines ($\text{W} = \text{R}$ or H) the hydrolysis is easy and can be carried out with water. When $\text{W} = \text{H}$, the imine is seldom stable enough for isolation, and in aqueous media hydrolysis usually occurs *in situ*, without isolation. The hydrolysis of *Schiff bases* ($\text{W} = \text{Ar}$) is more difficult and requires acid or base catalysis. Oximes ($\text{W} = \text{OH}$), arylhydrazones ($\text{W} = \text{NHAr}$), and, most easily, semicarbazones ($\text{W} = \text{NHCONH}_2$) can also be hydrolyzed. Often a reactive aldehyde (e.g., formaldehyde), is added to combine with the liberated amine.

A number of reagents⁵⁰ have been used to cleave $\text{C}=\text{N}$ bonds, especially those not easily hydrolyzable with acidic or basic catalysts or those that contain other functional groups that are attacked under these conditions.

Oximes have been converted to the corresponding aldehyde or ketone⁵¹ by treatment with aq phosphoric acid without an organic cosolvent,⁵² periodic acid,⁵³ DABCO– Br_2 ,⁵⁴ NBS in water,⁵⁵ Chloramine-T⁵⁶ HCO_2H on SiO_2 with microwave irradiation,⁵⁷ and 20% I_2 in water containing SDS (sodium dodecyl sulfate)⁵⁸ or in an ionic liquid on SiO_2 .⁵⁹ Transition metal compounds have been used, including those of Sb,⁶⁰ Co,⁶¹ Hg,⁶² Bi,⁶³ Cu,⁶⁴ or Zn.⁶⁵ Oxidizing agents can be quite effective, including KMnO_4 on Al_2O_3 ,⁶⁶ tetraalkylammonium permanganates,⁶⁷ and quinolinium dichromate.⁶⁸ Alkaline H_2O_2 ⁶⁹ has also been used.

Phenylhydrazones can be converted to a ketone using Oxone and KHCO_3 ,⁷⁰ polymer-bound iodonium salts,⁷¹ or KMnO_4 on wet SiO_2 .⁷² Dimethylhydrazones have been converted to ketones with $\text{FeSO}_4 \cdot 7 \text{H}_2\text{O}$ in chloroform,⁷³ and $\text{Me}_3\text{SiCl}/\text{NaI}$ in acetonitrile with 1% water.⁷⁴ Hydrazones (e.g., RAMP or SAMP, Reaction **10-68**, category 4) can be hydrolyzed with aq CuCl_2 .⁷⁵ Tosylhydrazones can be hydrolyzed to the corresponding ketones with aq acetone and BF_3 –etherate,⁷⁶ as well as with other reagents.⁷⁷

Semicarbazones have been cleaved with ammonium chlorochromates on alumina⁷⁸ ($\text{Bu}_4\text{N})_2\text{S}_2\text{O}_8$,⁷⁹ $\text{Mg}(\text{HSO}_4)_2$ on wet silica,⁸⁰ or by SbCl_3 with microwave irradiation.⁸¹

The hydrolysis of carbon–nitrogen double bonds involves initial addition of water and elimination of a nitrogen moiety:

It is thus an example of reaction type A (see above). The sequence shown is generalized.⁸² In specific cases, there are variations in the sequence of the steps, depending on acid or basic catalysis or other conditions.⁸³ Which step is rate determining also depends on acidity and on the nature of W and of the groups connected to the carbonyl.⁸⁴

Iminium ions (**10**)⁸⁵ would be expected to undergo hydrolysis quite readily, since there is a resonance contributor with a positive charge on the carbon. Indeed, they react with water at room temperature.⁸⁶ Acid-catalyzed hydrolysis of enamines (the last step of the *Stork enamine reaction*, **10-69**, involves conversion to iminium ions).⁸⁷

16-3 Hydrolysis of Aliphatic Nitro Compounds

Oxo-de-hydro,nitro-bisubstitution

Primary or secondary aliphatic nitro compounds can be hydrolyzed, respectively, to aldehydes or ketones, by treatment of their conjugate bases with sulfuric acid. This is called the *Nef reaction*.⁸⁸ Tertiary aliphatic nitro compounds do not give the reaction because they cannot be converted to their conjugate bases. Like 16-2, this reaction involves hydrolysis of a C=N double bond. A possible mechanism involves initial formation of the *aci form* of the nitro compound (11):⁸⁹

Intermediates of type 12 have been isolated in some cases.⁹⁰

The conversion of nitro compounds to aldehydes or ketones has been carried out with better yields and fewer side reactions by several alternative methods.⁹¹ Among these are treatment of the nitro compound with basic H_2O_2 in an ionic liquid,⁹² or 30% H_2O_2 — K_2CO_3 ,⁹³ DBU in acetonitrile,⁹⁴ or CAN.⁹⁵

When *primary* nitro compounds are treated with sulfuric acid without previous conversion to the conjugate bases, they give carboxylic acids. Hydroxamic acids are intermediates and can be isolated, so that this is also a method for their preparation.⁹⁶ Both the *Nef reaction* and the hydroxamic acid process involve the *aci form*; the difference in products arises from

higher acidity. For example, a difference in sulfuric acid concentration from 2 to 15.5 M changes the product from the aldehyde to the hydroxamic acid.⁹⁷ The mechanism of the hydroxamic acid reaction is not known with certainty, but if higher acidity is required, it may be that the protonated *aci form* of the nitro compound is further protonated.

OS VI, 648; VII, 414. See also, OS IV, 573.

16-4 Hydrolysis of Nitriles

Nitriles can be hydrolyzed to give either amides or carboxylic acids.⁹⁸ The amide is formed initially, but since amides are also hydrolyzed with acid or basic treatment, the carboxylic acid is readily formed. When the acid is desired,⁹⁹ the reagent of choice is aq NaOH containing ~6–12% H₂O₂, but acid-catalyzed hydrolysis is also carried out. The reaction of nitriles with TFA–acetic acid–sulfuric acid, followed by treatment with water gives the corresponding amide.¹⁰⁰ A Rh catalyzed hydrolysis with aq isopropyl alcohol leads to the amide.¹⁰¹ A "dry" hydrolysis of nitriles has been reported.¹⁰² Enzymatic hydrolysis to give the amide was reported with nitrilase (ZmNIT2).¹⁰³ Nitriles can be hydrolyzed to the carboxylic acids without disturbing carboxylic ester functions also present, by the use of tetrachloro- or tetrafluorophthalic acid.¹⁰⁴

Hydrolysis of cyanohydrins [RCH(OH)CN] is usually carried out under acidic conditions, because basic solutions cause competing reversion of the cyanohydrin to the aldehyde and CN[–]. However, cyanohydrins have been hydrolyzed under basic conditions with borax or alkaline borates.¹⁰⁵

There are a number of procedures for stopping at the amide stage,¹⁰⁶ among them the use of concentrated H₂SO₄; 2 molar equivalents of chlorotrimethylsilane followed by H₂O,¹⁰⁷ aq NaOH with PEG-400 and microwave irradiation,¹⁰⁸ heating on neutral alumina,¹⁰⁹ or dry HCl followed by H₂O. The same result can also be obtained by use

B. Attack by OR (Addition of ROH)

16-5 The Addition of Alcohols to Aldehydes and Ketones

Dialkoxy-de-oxo-bisubstitution

Dithioalkyl-de-oxo-bisubstitution

Acetals and ketals are formed by treatment of aldehydes and ketones, respectively, with alcohols in the presence of acid catalysts.¹²⁰ Lewis acid derivatives of Ti,¹²¹ Cu,¹²² In,¹²³ Ru,¹²⁴ or Co¹²⁵ can be used in conjunction with alcohols. Organocatalysts have been used for this conversion under acid-free conditions.¹²⁶ This reaction is reversible, and acetals and ketals can be hydrolyzed by treatment with acid.¹²⁷ With small unbranched aldehydes the equilibrium lies to the right. If ketals or acetals of larger molecules must be prepared the equilibrium must be shifted, usually by removal of water. This can be done by azeotropic distillation, ordinary distillation, or the use of a drying agent (e.g., Al₂O₃ or a molecular sieve).¹²⁸ The reaction is not

catalyzed in either direction by bases, so most acetals and ketals are quite stable to bases, though they are easily hydrolyzed by acids. This reaction is therefore a useful method of protection of aldehyde or ketone functions from attack by bases. The reaction is of wide scope.

Most aldehydes are easily converted to acetals,¹²⁹ but the reaction with ketones is more difficult, presumably for steric reasons. While the reaction often fails, many ketals, especially from cyclic ketones, have been made in this manner.¹³⁰ Many functional groups may be present without being affected. 1,2- and 1,3-Diols form cyclic acetals and ketals (1,3-dioxolanes¹³¹ and 1,3-dioxanes,¹³² respectively), and these are often used to protect aldehydes and ketones. Chiral dioxolanes have been prepared from chiral diols.¹³³ Dioxolanes have been prepared from ketones in ionic liquids.¹³⁴ Ketones are converted with dimethyl ketals by electrolysis with NaBr in methanol.¹³⁵ Intramolecular reactions are possible in which a keto diol or an aldehyde diol generates a bicyclic ketal or acetal.

The conversion of acetals back to aldehydes or ketones is accomplished by many reagents, including aq acid. Heating with water under microwave irradiation converts acetals to the corresponding carbonyl compound.¹³⁶ Transition metal compounds of Bi¹³⁷ catalyze this conversion as well.

The mechanism for acetal/ketal formation involves initial formation of a *hemiacetal*,¹³⁸ and it is the reverse of that given for acetal hydrolysis:

In a study of the acid-catalyzed formation of the hemiacetal, Grunwald¹³⁹ showed that the data best fit a mechanism in which the three steps shown here are actually all concerted; that is, the reaction is simultaneously catalyzed by acid and base, with water acting as the base:¹⁴⁰

Hemiacetals themselves are no more stable than the corresponding hydrates (Reaction 16-1). If the original aldehyde or ketone has an α hydrogen, it is possible to lose water from the hemiacetal, and enol ethers can be prepared in this manner:

Similarly, treatment with an anhydride and a catalyst can give an enol ester (see Reaction 16-6).¹⁴¹ As with hydrates, it is noted that hemiacetals of cyclopropanones¹⁴² and of polychloro and polyfluoro aldehydes and ketones may be quite stable.

When acetals or ketals are treated with an alcohol of higher molecular weight than the one already there, transacetalation is possible (see Reaction 10-13). In another type of transacetalation, aldehydes or ketones can be converted to acetals or ketals by treatment with another acetal or ketal or with an ortho ester,¹⁴³ in the presence of an acid catalyst (shown for an ortho ester):

This method is useful for the conversion of ketones to ketals, since the direct reaction of a ketone with an alcohol often gives poor results. Alternatively, the substrate is treated with an alkoxy silane (ROSiMe_3) in the presence of trimethylsilyl trifluoromethanesulfonate.¹⁴⁴ Formic acid reacts with alcohols to give orthoformates.

1,4-Diketones give furans when treated with acids. This is actually an example of an intramolecular addition of an alcohol to a ketone, since it is the enol form that adds:

Similarly, 1,5-diketones give pyrans. Conjugated 1,4-diketones (e.g., 1,4-diphenylbut-2-en-1,4-dione) are converted to 2,5-diphenylfuran with formic acid, 5% Pd/C, PEG-200, and a sulfuric acid catalyst with microwave irradiation.¹⁴⁵ Note that alkynyl ketones are converted to furans with palladium(II) acetate.¹⁴⁶

16-6 Acylation of Aldehydes and Ketones

O-Acyl-*C*-acyloxy-addition

Aldehydes can be converted to *acylals* by treatment with an anhydride in the presence of proton acids,¹⁴⁷ NBS,¹⁴⁸ ceric ammonium nitrate,¹⁴⁹ BF₃, LiBF₄,¹⁵⁰ and Lewis acid compounds of Fe,¹⁵¹ In,¹⁵² Cu,¹⁵³ Bi,¹⁵⁴ W,¹⁵⁵ or Zr.¹⁵⁶ *N*-Chlorosuccinimide with thiourea is a highly efficient catalyst.¹⁵⁷ Silica supported perchloric acid is useful for the preparation of acylals.¹⁵⁸ Conjugated aldehydes are converted to the corresponding acylal by reaction with acetic anhydride and a FeCl₃ catalyst.¹⁵⁹ The reaction cannot normally be applied to ketones, though an exception has been reported when the reagent is trichloroacetic anhydride, which gives acylals with ketones without a catalyst.¹⁶⁰

OS IV, 489.

16-7 Reductive Alkylation of Alcohols

C-Hydro-*O*-alkyl-addition

Aldehydes and ketones can be converted to ethers by treatment with an alcohol and triethylsilane in the presence of a strong acid¹⁶¹ or by hydrogenation in alcoholic acid in the presence of a Pt catalyst.¹⁶² The process can formally be regarded as addition of ROH to give a hemiacetal [RR'C(OH)OR²], followed by reduction of the OH. In this respect, it is similar to Reaction 16-17. Homoallylic ethers are formed by the Fe catalyzed reaction of acetals and aldehydes,¹⁶³ and by reactions in ionic liquids.¹⁶⁴ The In catalyzed reaction of aldehydes with allyltriethoxysilane leads to the corresponding ether.¹⁶⁵

Ethers have also been prepared by the reductive dimerization of two molecules of an aldehyde or ketone (e.g., cyclohexanone \rightarrow dicyclohexyl ether). This was accomplished by treatment of the substrate with a trialkylsilane and a catalyst.¹⁶⁶

16-8 The Addition of Alcohols to Isocyanates

N-Hydro-C-alkoxy-addition

The reaction of an isocyanate with alcohols gives a carbamate (a substituted urethane). This is an excellent reaction of wide scope that gives good yields. Isocyanic acid (HNCO) gives unsubstituted carbamates. Addition of a second equivalent of HNCO gives *allophanates*.

The isocyanate can be generated *in situ* by the reaction of an amine and oxalyl chloride, and subsequent reaction with HCl and then an alcohol gives the carbamate.¹⁶⁷ Combining compounds with two NCO groups with compounds containing two OH groups makes polyurethanes. Cyclic carbamates (e.g., 1,3-oxazine-2-ones), are generated by the reaction of an isocyanate with an oxetane, in the presence of a Pd catalyst.¹⁶⁸ Isothiocyanates similarly give thiocarbamates (RNHCSOR'),¹⁶⁹ but they react slower than the corresponding isocyanates. Isocyanates react with LiAlHSeH and then iodomethane to give the corresponding selenocarbonate (RNHCOSeMe).¹⁷⁰

The details of the mechanism are poorly understood,¹⁷¹ but the oxygen of the alcohol certainly attacks the carbon of the isocyanate. Hydrogen bonding complicates the kinetic picture.¹⁷² Metallic compounds, can also catalyze the addition of ROH to isocyanates¹⁷³ by light,¹⁷⁴ or, for tertiary ROH, by lithium alkoxides¹⁷⁵ or *n*-butyllithium.¹⁷⁶

The addition of dry HCl to a mixture of a nitrile and an alcohol in the absence of water leads to the hydrochloride salt of an imino ester (imino esters are also called imidates and imino ethers). This reaction is called the *Pinner synthesis*.¹⁷⁷ The salt can be converted to the free imino ester by treatment with a weak base (e.g., sodium bicarbonate) or it can be hydrolyzed with water and an acid catalyst to the corresponding carboxylic ester. If the latter is desired, water may be present from the beginning, in which case aq HCl can be used and the need for gaseous HCl is eliminated. Imino esters can also be prepared from nitriles with basic catalysts.¹⁷⁸

This reaction is of broad scope and is good for aliphatic, aromatic, and heterocyclic R and for nitriles with oxygen-containing functional groups. The application of the reaction to nitriles containing a carboxyl group constitutes a good method for the synthesis of mono esters of dicarboxylic acids with the desired group esterified and with no diester or diacid present.

Cyanogen chloride reacts with alcohols in the presence of an acid catalyst (e.g., dry HCl or AlCl₃), to give carbamates:¹⁷⁹

ROH can also be added to nitriles in another manner (Reaction **16-91**).

OS I, 5, 270; II, 284, 310; IV, 645; VI, 507; VIII, 415.

16-10 The Formation of Carbonates and Xanthates

Di-C-alkoxy-addition; S-Metallo-C-alkoxy-addition

The reaction of phosgene with an alcohol generates haloformic esters, and reaction with a second equivalent of alcohol gives a carbonate. This reaction is related to the acyl addition reactions of acyl chlorides in Reaction **16-98**. An important example is the preparation of carbobenzoxy chloride (PhCH₂OCOCI; CbzCl) from phosgene and benzyl alcohol. When CbzCl reacts with an amine, the product is the benzyl carbamate, *N*-Cbz, which is widely used for protection of amino groups during peptide synthesis. When an alcohol reacts with certain alkyl halides (e.g., benzyl chloride) and CO₂, in the presence of Cs₂CO₃ and tetrabutylammonium iodide, a mixed carbonate is formed.¹⁸⁰

The addition of alcohols to carbon disulfide (S=C=S) in the presence of a base produces xanthates.¹⁸¹ The base is often HO[−], but in some cases better results can be obtained by using methylsulfinyl carbanion (MeSOCH₂[−]).¹⁸² If an alkyl halide (RX) is present, the xanthate ester (ROCSSR') can be produced directly. In a similar manner, alkoxide ions add to CO₂ to give carbonate ester salts (ROCO₂[−]).

C. Sulfur Nucleophiles

16-11 The Addition of H₂S and Thiols to Carbonyl Compounds

O-Hydro-*C*-mercapto-addition, thioxo-de-oxo-bisubstitution, dimercapto-de-oxo-bisubstitution, and carbonyl-trithiane transformation

The addition of H₂S to an aldehyde or ketone can result in a variety of products. The most usual product is the trithiane **16**.¹⁸³ *gem*-Dithiols (**15**) are much more stable than the corresponding hydrates or α -hydroxy thiols.¹⁸⁴ They have been prepared by the treatment of ketones with H₂S under pressure¹⁸⁵ and under mild conditions with HCl as a catalyst.¹⁸⁶ A much more useful application is the addition of thiols to aldehydes and ketones to give hemi-mercaptals [CH(OH)SR] and dithioacetals [CH(SR)₂] (Reaction **16-5**). This reaction is generally not a good route to thioketones (**14**). α -Hydroxythiols (**13**) can be prepared from polychloro and polyfluoro aldehydes and ketones.¹⁸⁷ Apparently *gem*-hydroxy thiols (e.g., **13**) are rather unstable and quite difficult to prepare.

Thiols add to aldehydes and ketones to initially give hemi-mercaptals and dithioacetals. Hemi-mercaptals are ordinarily unstable,¹⁸⁸ but they are usually more stable than the corresponding hemiacetals and can be isolated in certain cases.¹⁸⁹ The isolated product of this reaction is most often the dithioacetal, which like the acetals obtained by reaction with an alcohol, are stable in the presence of base. However, a sufficiently strong base can remove a proton from the carbon between the sulfur atoms (—S—CHR—S—)¹⁹⁰ to form the corresponding carbanion (see Reaction **10-71**). The $\text{p}K_a$ of such protons is typically 31–37,¹⁹¹ requiring a strong base, and deprotonation is often quite slow. The reaction of aldehydes or ketones with thiols most commonly uses a Lewis acid catalyst (e.g., boron trifluoride etherate, BF₃•OEt₂)¹⁹² to give the dithioacetal¹⁹³ or dithioacetal. Dithioacetals can also be prepared from aldehydes or ketones by treatment with thiols in the presence of TiCl₄,¹⁹⁴ SiCl₄,¹⁹⁵ LiBF₄,¹⁹⁶ Al(OTf)₃,¹⁹⁷ tosic acid on silica gel in dichloromethane,¹⁹⁸

and oxalic acid promotes the reaction.¹⁹⁹ Similarly reactions that use 1,2-ethanedithiol or 1,3-propanedithiol lead to 1,3-dithiolanes (**17**)²⁰⁰ or 1,3-dithianes.²⁰¹ 3-(1,3-Dithian-2-ylidene)pentane- 2,4-dione has been used as a thioacetalization reagent for reactions in water.²⁰²

Dithioacetals and dithioketals are used as protecting groups for aldehydes and ketones, and after subsequent reactions involving the R or R' group, deprotection regenerates the carbonyl.²⁰³ Simple hydrolysis is the most common method for converting thiocarbonyls to carbonyls, but there are a variety of reagents for this conversion.²⁰⁴ Lewis acids (e.g., aluminum chloride, AlCl₃) and mercuric salts are common reagents (the *Corey–Seebach procedure*).²⁰⁵ Other reagents include BF₃·OEt₂ in aq THF containing mercuric oxide (HgO),²⁰⁶ ceric ammonium nitrate [Ce(NH₄)₂(NO₃)₆],²⁰⁷ chlorotrimethylsilane and H₂O₂,²⁰⁸ PhI(OAc)₂ in aq acetone,²⁰⁹ and Cu salts.²¹⁰ When aldehydes and ketones react with mercapto–alcohols, mixed acetals or ketals are formed.

Thioamides are converted to amides with *Caro's acid* (H₂SO₅) on SiO₂.²¹¹ The use of 2-mercaptoethanol (HSCH₂CH₂OH), for example, leads to an oxathiolane²¹² and 3-mercaptopropanol (HSCH₂CH₂CH₂OH) leads to an oxathiane. Alternatively, the dithioketal can be desulfurized with Raney nickel (Reaction **14-27**), giving the overall conversion C=O → CH₂ (Reaction **19-70**).

Thioketones (**14**) can be prepared from certain ketones (e.g., diaryl ketones) by treatment with H₂S and an acid catalyst, usually HCl. They are often unstable and usually trimerize (to **16**) or react with air. Thioaldehydes²¹³ are even less stable and simple ones²¹⁴ apparently have never been isolated, although *tert*-BuCHS has been prepared in solution, where it exists for several hours at 20 °C.²¹⁵ A high-yield synthesis of thioketones involves

treatment of acyclic²¹⁶ ketones with 2,4-bis(4-methoxyphenyl)-1,3,2,4-dithiadiphosphetane-2,4-disulfide²¹⁷ (**18**, known as *Lawesson's reagent*).²¹⁸ Thioketones can also be prepared by treatment of ketones with P_4S_{10} ,²¹⁹ P_4S_{10} and hexamethyldisiloxane,²²⁰ P_4S_{10} on alumina,²²¹ and from oximes or various types of hydrazone (overall conversion $C=N \rightarrow C=S$).²²² Reagent **18** converts the $C=O$ groups of amides and carboxylic esters²²³ to $C=S$ groups.²²⁴ Lactones react with **18** in the presence of hexamethyldisiloxane an microwave irradiation to give the thiolactone.²²⁵

Other reagents may be used for this transformation including $POCl_3$ followed by $S(TMS)_2$, which converts lactams to thiolactams.²²⁶ Treatment with triflic anhydride, and then H_2S ²²⁷ or aq $S(NH_4)_2$ ²²⁸ converts amides to thioamides, as does the microwave assisted reaction with $PSiCl_2/H_2O/Et_3N$, without solvent.²²⁹ Carboxylic acids ($RCOOH$) can be converted directly to dithiocarboxylic esters ($RCSSR'$),²³⁰ in moderate yield, with P_4S_{10} and a primary alcohol ($R'OH$).²³¹

If an aldehyde or ketone possesses an α hydrogen, it can be converted to the corresponding enol thioether (**19**) by treatment with a thiol in the presence of $TiCl_4$.²³² Aldehydes and ketones have been converted to sulfides by treatment with thiols and pyridine–borane, $RCOR' + R^2SH \rightarrow RR'CHSR^2$,²³³ in a reductive alkylation reaction, analogous to Reaction 16-7.

16-12 Formation of Bisulfite Addition Products

O-Hydro-*C*-sulfonato-addition

Bisulfite addition products are formed from aldehydes, methyl ketones, cyclic ketones (generally seven-membered and smaller rings), α -keto esters, and isocyanates, upon treatment with sodium bisulfite (NaHSO_3). Most other ketones do not undergo the reaction, probably for steric reasons. The reaction is reversible (by treatment of the addition product with either acid or base)²³⁴ and is useful for the purification of the starting compounds, since the addition products are soluble in water and many of the impurities are not.²³⁵

16-13 The Addition of Amines to Aldehydes and Ketones

Alkylimino-de-oxo-bisubstitution

The addition of ammonia²³⁶ to aldehydes or ketones does not generally give useful products. According to the pattern followed by analogous nucleophiles, the initial products would be expected to be *hemiaminals*,²³⁷ but these compounds are generally unstable. In addition, many imines with a hydrogen on the nitrogen spontaneously polymerize.²³⁸

In contrast to ammonia, primary, secondary, and tertiary amines can add to aldehydes²³⁹ and ketones to give different kinds of products. Primary amines give imines²⁴⁰ and secondary amines give enamines (for reactions, see 10-69). Such imines are stable enough for isolation, but in some cases, especially with simple R groups, they rapidly decompose

²³⁴ For cleavage with ion-exchange resins, see Khosid, A.Kh.; Chizhova, N.V. *J. Org. Chem. USSR* **1985**, 21, 37. For a discussion of the mechanism, see Young, P.R.; Jencks, W.P. *J. Am. Chem. Soc.* **1978**, 100, 1228.

²³⁵ The reaction has also been used to protect an aldehyde group in the presence of a keto group: Chihara, T.; Wakabayashi, T.; Taya, K. *Chem. Lett.* **1981**, 1657.

²³⁶ For a review of this reagent in organic synthesis, see Jeyaraman, R. in Pizey, J.S. *Synthetic Reagents*, Vol. 5, Wiley, NY, **1983**, pp. 9–83.

²³⁷ These compounds have been detected by ^{13}C NMR: Chudek, J.A.; Foster, R.; Young, D. *J. Chem. Soc. Perkin Trans. 2* **1985**, 1285.

²³⁸ Methanimine $\text{CH}_2=\text{NH}$ is stable in solution for several hours at -95°C , but rapidly decomposes at -80°C : Braillon, B.; Lasne, M.C.; Ripoll, J.L.; Denis, J.M. *Nouv. J. Chim.*, **1982**, 6, 121. See also, Bock, H.; Dammel, R. *Chem. Ber.* **1987**, 120, 1961.

²³⁹ For a review of the reactions between amines and formaldehyde, see Farrar, W.V. *Rec. Chem. Prog.*, **1968**, 29, 85. For a synthesis of imines, see Kwon, M.S.; Kim, S.; Park, S.; Bosco, W.; Chidrala, R.K.; Park, J. *J. Org. Chem.* **2009**, 74, 2877; Kim, J.W.; He, J.; Yamaguchi, K.; Mizuno, N. *Chem. Lett.* **2009**, 38, 920.

²⁴⁰ See Dayagi, S.; Degani, Y. in Patai, S. *The Chemistry of the Carbon–Nitrogen Double Bond*, Wiley, NY, **1970**, pp. 64–83; Reeves, R.L. in Patai, S. *The Chemistry of the Carbonyl Group*, pt. 1, Wiley, NY, **1966**, pp. 600–614. Also see Ku, Y.-Y.; Grieme, T.; Pu, Y.-M.; Bhatia, A.V.; King, S.A. *Tetrahedron Lett.* **2005**, 46, 1471; Guzen, K.P.; Guarezemini, A.S.; Órfão, A.T.G.; Cella, R.; Pereira, C.M.P.; Stefani, H.A. *Tetrahedron Lett.* **2007**, 48, 1845.

or polymerize unless there is at least one aryl group on the nitrogen or the carbon. When there is an aryl group, the compounds are quite stable. They are usually called *Schiff bases*, and this reaction is the best way to prepare them.²⁴¹ Even sterically hindered imines can be prepared.²⁴² The initial N-substituted hemiaminals²⁴³ lose water to give the stable *Schiff bases*.

In general, ketones react more slowly than aldehydes, and higher temperatures and longer reaction times are often required.²⁴⁴ In addition, the equilibrium must often be shifted, usually by removal of the water, either azeotropically by distillation, or with a drying agent (e.g., TiCl_4),²⁴⁵ or by addition of a molecular sieve.²⁴⁶ Imines have been formed from aldehydes and amines in an ionic liquid.²⁴⁷

The reaction is often used to effect ring closure.²⁴⁸ The *Friedländer quinoline synthesis*²⁴⁹ is an example where ortho alkenyl aniline derivatives give the quinoline (**20**).²⁵⁰ The alkene derivative can be prepared *in situ* from an aldehyde and a suitably functionalized ylid.²⁵¹ Pirylium ions react with ammonia or primary amines to give pyridinium ions²⁵² (see Reaction 10-57). Primary amines react with 1,4-diketones, with microwave irradiation, to give N-substituted pyrroles.²⁵³ Similar reactions in the presence of Montmorillonite KSF²⁵⁴ or by simply heating the components with tosic acid²⁵⁵ have been reported.

The reaction of secondary amines with ketones leads to enamines (see 10-69).²⁵⁶ When secondary amines are added to aldehydes or ketones, the initially formed N,N-disubstituted hemiaminals (**21**) cannot lose water in the same way since the iminium ion intermediate does not have a proton on nitrogen, and in some cases it is possible to isolate them.²⁵⁷ However, they are generally unstable, and under the reaction conditions usually react further. If no α hydrogen is present, **21** is converted to the more stable *aminal* (**22**).²⁵⁸

of product is especially important for aromatic aldehydes:

However, in some cases azines can be converted to hydrazones by treatment with excess hydrazine and NaOH.²⁷² Arylhydrazines, especially phenyl, *p*-nitrophenyl, and 2,4-dinitrophenyl,²⁷³ are used much more often and give the corresponding hydrazones with most aldehydes and ketones.²⁷⁴ Since these are usually solids, they make excellent derivatives and were commonly employed for this purpose in the past, before the advent of modern spectroscopy methods. Cyclic hydrazones are known,²⁷⁵ as are conjugated hydrazones.²⁷⁶ Azides react with *N,N*-dimethylhydrazine and ferric chloride to give the *N,N*-dimethylhydrazone.²⁷⁷ Alkenes react with CO/H₂, phenylhydrazine and a diphosphine catalyst to give a regioisomeric mixture of phenylhydrazones that favored “anti-Markovnikov” addition.²⁷⁸ Oximes are converted to hydrazones with water and hydrazine in refluxing ethanol.²⁷⁹

α -Hydroxy aldehydes and ketones and α -dicarbonyl compounds give *osazones*, in which two adjacent carbons have carbon–nitrogen double bonds:

Osazones are particularly important in carbohydrate chemistry, and the *osazone test*²⁸⁰ with phenylhydrazine is used to test for the presence of sugars with an adjacent stereogenic carbon. In contrast to this behavior, β -diketones and β -keto esters give *pyrazoles* and *pyrazolones*, respectively (the latter is illustrated for β -keto esters). No azines are formed under these conditions.

Other hydrazine derivatives frequently used to prepare the corresponding hydrazone are semicarbazide (NH₂NHCONH₂), in which case the hydrazone is called a semicarbazone: *Girard's reagents T and P* are hydrazones that are water soluble because of the ionic group. Girard's reagents are often used for purification of carbonyl compounds.²⁸¹

16-15 The Formation of Oximes

Hydroxyimino-de-oxo-bisubstitution

In a reaction very much like **16-14**, oximes can be prepared by the addition of hydroxylamine (NH_2OH) to aldehydes or ketones. Derivatives of hydroxylamine [e.g., $\text{H}_2\text{NOSO}_3\text{H}$ and $\text{HON}(\text{SO}_3\text{Na})_2$] have also been used. For hindered ketones (e.g., 2,2,4,4-tetramethyl-3-pentanone), high pressures (as high as 10,000 atm) may be necessary.²⁸³ The reaction of hydroxylamine with unsymmetrical ketones or with aldehydes leads to a mixture of (*E*)- and (*Z*)-isomers. For aromatic aldehydes, heating with K_2CO_3 led to the (*E*)- isomer, whereas heating with CuSO_4 gave the (*Z*)-hydroxylamine.²⁸⁴ Hydroxylamines react with ketones in ionic liquids²⁸⁵ and on silica gel.²⁸⁶

It has been shown²⁸⁷ that the rate of formation of oximes is at a maximum at a pH that depends on the substrate but is usually ~ 4 . The rate also decreases as the pH is either raised or lowered from this point (a bell-shaped curve). In Section 16.A.i, bell-shaped curves like this were shown to be caused by changes in the rate-determining step in many cases. In this case, at low pH values step 2 is rapid (because it is acid catalyzed), and

step 1 is slow (and rate determining), because under these acidic conditions most of the NH_2OH molecules have been converted to the conjugate $^+\text{NH}_3\text{OH}$ ions, which cannot attack the substrate. As the pH is slowly increased, the fraction of free NH_2OH molecules increases and consequently so does the reaction rate, until the maximum rate is reached at $\sim \text{pH } 4$. As the rising pH causes an increase in the rate of step 1, it also causes a *decrease* in

the rate of the acid-catalyzed step 2, although this latter process has not affected the overall rate since step 2 was still faster than step 1. However, when the pH goes above ~ 4 , step 2 becomes rate determining, and although the rate of step 1 is still increasing (as it will until essentially all the NH_2OH is unprotonated), it is now step 2 that determines the rate. This step is slowed by the decrease in acid concentration. Thus the overall rate decreases as the pH rises beyond ~ 4 . It is likely that similar considerations apply to the reaction of aldehydes and ketones with amines, hydrazines, and other nitrogen nucleophiles.²⁸⁸ There is evidence that when the nucleophile is 2-methylthiosemicarbazide, there is a second change in the rate-determining step: $> \text{pH} \sim 10$ basic catalysis of step 2 has increased the rate of this step to the point where step 1 is again rate determining.²⁸⁹ Still a third change in the rate-determining step has been found at $\sim \text{pH} 1$, showing that at least in some cases step 1 actually consists of two steps: formation of a zwitterion (e.g., $\text{HOH}_2\text{N}^+ - \text{C} - \text{O}^-$ in the case shown above) and conversion of this to **25**.²⁹⁰ The intermediate **25** has been detected by NMR in the reaction between NH_2OH and acetaldehyde.²⁹¹

16-16 The Conversion of Aldehydes to Nitriles

Nitrilo-de-hydro,oxo-tersubstitution

Aldehydes can be converted to nitriles in one step by treatment with hydroxylamine hydrochloride and either formic acid,²⁹² $\text{KF}-\text{Al}_2\text{O}_3$,²⁹³ or $\text{NaHSO}_4 \cdot \text{SiO}_2$ with microwave irradiation.²⁹⁴ Heating in *N*-methylpyrrolidinone (NMP) is also effective with aryl aldehydes²⁹⁵ and heating on dry alumina with aliphatic aldehyde.²⁹⁶ The reaction is a combination of **16-15** and **17-29**. Direct nitrile formation has also been accomplished with certain derivatives of NH_2OH , notably, $\text{NH}_2\text{OSO}_2\text{OH}$.²⁹⁷ Treatment with hydroxylamine and NaI ²⁹⁸ or certain carbonates²⁹⁹ also converts aldehydes to the nitrile. Another method involves treatment with hydrazoic acid, although the *Schmidt reaction* (**18-16**) may compete.³⁰⁰ Microwave irradiation has been used with $\text{NH}_2\text{OH} \cdot \text{HCl}$ and another reagent, which includes phthalic anhydride³⁰¹ or $\text{H}-\text{Y}$ zeolite.³⁰² The reaction of an aldehyde with hydroxylamine followed by diethyl

chlorophosphate (EtOPOCl₂) gives the nitrile.³⁰³ Heating with hydroxylamine in DMSO³⁰⁴ and using hydroxylamine and oxalyl chloride³⁰⁵ have been used. *tert*-Butanesulfinyl imines are also used for the conversion of aldehydes to nitriles.³⁰⁶ Other reagents include trimethylsilyl azide,³⁰⁷ hydroxylamine hydrochloride/MgSO₄/TsOH,³⁰⁸ or I₂ with aq ammonia.³⁰⁹ The reaction of a conjugated aldehyde with ammonia, CuCl, and 50% H₂O₂ gave the conjugated nitrile.³¹⁰ Aldehydes with IBX (*o*-iodoxybenzoic acid) and liquid ammonia gives the nitrile.³¹¹ Tetrabutylammonium tribromide in aq ammonia has also been used.³¹² Trichloroisocyanuric acid with a catalytic amount of TEMPO (Sec. 5.C.i) converts aldehydes to nitriles at 0 °C in dichloromethane.³¹³ Aromatic aldehydes are converted to the nitrile by heating 2.2 molar equivalents of NaN(SiMe₃)₂ in 1,3-dimethylimidazolidin-2-one, in a sealed tube.³¹⁴ The aldehydes employed had a hydroxy substituent.

In a related reaction, the reaction of primary alcohols with iodine in ammonia water gives the corresponding nitrile.³¹⁵ Upon treatment with 2 molar equivalents of dimethylaluminum amide (Me₂AlNH₂), carboxylic esters give nitriles: RCO₂R' → RCN.³¹⁶ This is likely a combination of Reaction 16-75 and 17-30 (see Reaction 19-5).

OS V, 656.

16-17 Reductive Alkylation of Ammonia or Amines

Hydro,dialkylamino-de-oxo-bisubstitution

When an aldehyde or a ketone is treated with ammonia or a primary or secondary amine in the presence of hydrogen gas and an appropriate catalyst (e.g., Rh or Ir; heterogeneous or homogeneous),³¹⁷ *reductive alkylation* of ammonia or the amine (or *reductive amination* of the carbonyl compound) takes place.³¹⁸ The reaction can formally be regarded as occurring in the following manner (shown for a primary amine), which probably does correspond to the actual sequence of steps:³¹⁹ In this regard, the reaction of an aldehyde

with an amine to give an iminium salt (**16-31**) can be followed in a second chemical step of reduction of the C=N unit (**19-42**) using NaBH_4 or a variety of other reagents.³²⁰

Primary amines have been prepared from many aldehydes with at least five carbons and from many ketones by treatment with ammonia and a reducing agent. Smaller aldehydes are usually too reactive to permit isolation of the primary amine. Secondary amines have been prepared by both possible procedures: 2 molar equivalents of ammonia and 1 molar equivalent of aldehyde or ketone, and 1 molar equivalent of primary amine and 1 molar equivalent of carbonyl compound, the latter method being better for all but aromatic aldehydes. Tertiary amines can be prepared in three ways. In general, they are prepared from primary or secondary amines.³²¹ The method is seldom carried out with 3 molar equivalents of ammonia and 1 molar equivalent of carbonyl compound. When the reagent is ammonia, it is possible for the initial product to react again and for this product to react again, so that secondary and tertiary amines are usually obtained as side products. Similarly, primary amines give tertiary as well as secondary amines. In order to minimize this, the aldehyde or ketone is treated with an excess of ammonia or primary amine (unless of course the higher amine is desired).

For ammonia and primary amines there are two possible pathways, but when secondary amines are involved, only the hydrogenolysis pathway is possible. The reaction is compatible with amino acids, giving the N-alkylated amino acid.³²² Other reducing agents³²³ can be used instead of hydrogen and a catalyst, among them boranes,³²⁴ PhSiH_3 with 2% Bu_2SnCl_2 ,³²⁵ triethylsilane with an Ir³²⁶ or an In catalyst,³²⁷ zinc and HCl, or Zn (with formaldehyde for reductive methylation),³²⁸ and polymethylhydrosiloxane.³²⁹ Several hydride reducing agents can be used, including

NaBH_4 ,³³⁰ NaBH_4 with $\text{Ti}(\text{O}i\text{Pr})_4$,³³¹ or NiCl_2 ,³³² $\text{NaBH}_4/\text{H}_3\text{BO}_4$,³³³ BER,³³⁴ polymer-bound triethylammonium acetoxymethylborohydride,³³⁵ LiBH_4 ,³³⁶ ZnBH_4 -*N*-methylpiperidine,³³⁷ ZrBH_4 ,³³⁸ NaBH_3CN ,³³⁹ or sodium triacetoxymethylborohydride,³⁴⁰ Aldehydes and primary amines react with allylic halides, in the presence of Zn dust, to give a homoallylic secondary amine.³⁴¹ A *Hantzsch dihydropyridine* in conjunction with a Sc catalyst has been used,³⁴² and the use of a *Hantzsch ester* in a reductive amination is sometimes called a hydrogen-bond catalyzed reaction.³⁴³ The reaction of an aldehyde and an amine in isopropyl alcohol, in the presence of Ni nanoparticles, undergoes reductive amination via hydrogen transfer.³⁴⁴

Formic acid is an effective reagent for reductive amination³⁴⁵ in what is called the *Wallach reaction*. Secondary amines react with formaldehyde and NaH_2PO_3 to give the *N*-methylated tertiary amine³⁴⁶ and microwave irradiation has also been used.³⁴⁷ Conjugated aldehydes are converted to alkenyl-amines with the amine/silica gel followed by reduction with zinc borohydride.³⁴⁸ In the particular case where primary or secondary amines are reductively methylated with formaldehyde and formic acid, the method is called the *Eschweiler–Clarke procedure*. Heating with paraformaldehyde and oxalyl chloride has been used to give the same result.³⁴⁹ It is possible to use ammonium (or amine) salts of formic acid,³⁵⁰ or formamides, as a substitute for the *Wallach conditions*. This method is called the *Leuckart reaction*,³⁵¹ and in this case the products obtained are often the *N*-formyl derivatives of the amines instead of the free amines. A Rh catalyzed variation has been reported.³⁵²

Allylic silanes react with aldehydes and carbamates, in the presence of Bi catalysts,³⁵³ or $\text{BF}_3 \cdot \text{OEt}_2$ ³⁵⁴ to give the corresponding allylic *N*-carbamoyl derivative. The reaction can be done with aromatic amines in the presence of vinyl ethers and a Cu complex to give β -amino ketones.³⁵⁵ Reductive amination of an aryl amine and an aryl aldehyde that contains an ortho conjugated ketone substituent gives the amine, which adds 1,4- (Reaction 15-AA) to the α,β -unsaturated ketone unit to give a bicyclic amine.³⁵⁶ Alternative methods of reductive alkylation have been developed. Alkylation of an imine formed *in situ* is also possible.³⁵⁷

Enantioselective reductive amination reactions are known, generating chiral amines. Ketones and anilines react in the presence of an organocatalyst and a catalytic amount of a chiral phosphoric acid to give the chiral amine.³⁵⁸ The reaction of an aldehyde with a chiral amine initiated a reaction that gave a chiral primary amine.³⁵⁹ A Yb catalyzed reaction with a ketone gave a chiral secondary amine.³⁶⁰ Aldehydes react with *N*-diphenylphosphinoyl-imines and Et_2Zn , in the presence of a chiral Cu precatalyst, to give a chiral amine.³⁶¹ Asymmetric biocatalytic reductive amination reactions are known.³⁶² Asymmetric reductive amination has been attempted using a *Hantzsch ester* mediated reaction.³⁶³

Reductive alkylation has also been carried out on nitro, nitroso, azo, and other compounds that are reduced *in situ* to primary or secondary amines. Azo compounds react with aldehydes, in the presence of proline, and subsequent reduction with NaBH_4 gives the chiral hydrazine derivative.³⁶⁴

16-18 Addition of Amides to Aldehydes

Alkylamido-de-oxo-bisubstitution

Amides can add to aldehydes in the presence of bases (so the nucleophile is actually RCONH^-) or acids to give acylated amino alcohols, which often react further to give alkylidene or arylidene bisamides.³⁶⁵ If the R' group contains an α hydrogen, water may split out.

Sulfonamides add to aldehydes to give the *N*-sulfonyl imine. Benzaldehyde reacts with TsNH₂ (e.g., with trifluoroacetic anhydride, TFAA) in CH₂Cl₂ at reflux,³⁶⁶ or with TiCl₄ in refluxing dichloroethane,³⁶⁷ to give the *N*-tosylimine (Ts–N=CHPh). In a similar manner, the reaction of TolSO₂Na + PhSO₂Na with an aldehyde in aq formic acid gives the *N*-phenylsulfonyl imine.³⁶⁸ The reaction of an aldehyde with Ph₃P=NTs and a ruthenium catalyst gives the *N*-tosyl imine.³⁶⁹

Primary and secondary amines add to ketenes to give, respectively, *N*-substituted and *N*, *N*-disubstituted amides:³⁷⁰ and to ketenimines to give amidines, (**26**).³⁷¹

16-19 The Mannich Reaction

Acyl,amino-de-oxo-bisubstitution, and so on

In the *Mannich reaction*, formaldehyde (or sometimes another aldehyde) is condensed with ammonia, in the form of its salt, and a compound containing an active hydrogen.³⁷² This can formally be considered as an addition of ammonia to give H₂NCH₂OH, followed by a nucleophilic substitution. The reaction can be carried out with salts of primary or secondary amines,³⁷³ or with amides³⁷⁴ rather than ammonia, in which cases the product is substituted on the nitrogen with R, R², and RCO, respectively. The product is referred to as a *Mannich base*. The imine can be generated *in situ*, and the reaction of a ketone, formaldehyde, and diethylamine with microwave irradiation gave the *Mannich* product, a β-amino ketone.³⁷⁵ Many active hydrogen compounds give the reaction, including ketones and aldehydes, esters, nitroalkanes,³⁷⁶ and nitriles as well as ortho-carbon atoms of phenols, the carbon of terminal alkynes, the oxygen of alcohols and the sulfur of thiols.³⁷⁷

Arylamines do not normally give the reaction, but hydrazines can be used.³⁷⁸ Vinylogous *Mannich reactions* are known³⁷⁹ (see Sec. 6.B for vinylogy).

The *Mannich base* product can react further in three ways. If it is a primary or secondary amine, it may condense with one or two additional molecules of aldehyde and an active compound, for example,

If the active hydrogen compound has two or three active hydrogen atoms, the *Mannich base* may condense with one or two additional molecules of aldehyde and ammonia or amine, for example,

Another reaction consists of condensation of the *Mannich base* with excess formaldehyde:

Sometimes it is possible to obtain these products of further condensation as the main products of the reaction. At other times, they are side products.

When the *Mannich base* contains an amino group β to a carbonyl (and it usually does), ammonia is easily eliminated. This is a route to α,β -unsaturated aldehydes, ketones, esters, and so on.

Studies of the reaction kinetics have led to the following proposals for the mechanism of the *Mannich reaction*.³⁸⁰ The base-catalyzed reaction:

The acid-catalyzed reaction:

According to this mechanism, it is the free amine, not the salt that reacts, even in acid solution; and the active-hydrogen compound (in the acid-catalyzed process) reacts as the enol when that is possible. This latter step is similar to what happens in Reaction 12-4. There is kinetic evidence for the intermediacy of the iminium ion (27).³⁸¹

When an unsymmetrical ketone is used as the active-hydrogen component, two products are possible. Regioselectivity has been obtained by treatment of the ketone with

preformed iminium ions:³⁸² the use of $\text{Me}_2\text{N}^+=\text{CH}_2$ CF_3COO^- in CF_3COOH gives substitution at the more highly substituted position, while with $(i\text{Pr})_2\text{N}^+=\text{CH}_2$ ClO_4^- the reaction takes place at the less highly substituted position.³⁸³ The preformed iminium compound dimethyl(methylene)ammonium iodide ($\text{CH}_2=\text{N}^+\text{Me}_2 \text{I}^-$), called an *Eschenmoser's salt*,³⁸⁴ has also been used in *Mannich reactions*.³⁸⁵ The analogous chloride salt has been condensed with an imine to give a β,β' -dimethylamino ketone after acid hydrolysis.³⁸⁶

Another type of preformed reagent (**29**) has been used to carry out diastereoselective *Mannich reactions*. The lithium salts (**28**) are treated with TiCl_4 to give **29**, which is then treated with the enolate anion of a ketone.³⁸⁷ The Pd catalyzed Mannich reaction of enol ethers to imines is also known.³⁸⁸ The reaction of silyl enol ethers and imines³⁸⁹ is catalyzed by HBF_4 in aq methanol.³⁹⁰ Similarly, silyl enol ethers react with aldehydes and aniline in the presence of InCl_3 to give the β -amino ketone.³⁹¹

Enantioselective *Mannich reactions* are known.³⁹² Chiral catalysts are commonly used,³⁹³ including proline,³⁹⁴ proline derivatives, or proline analogues,³⁹⁵ a Pybox-La catalyst,³⁹⁶ chiral aminosulfonamides,³⁹⁷ or Cinchona alkaloids,³⁹⁸ and other chiral amines.³⁹⁹ Chiral

Brønsted acids are also used as catalysts,⁴⁰⁰ as well as chiral ammonium salts.⁴⁰¹ Chiral diamine⁴⁰² or phosphine-imine⁴⁰³ ligands have been used, and chiral dinuclear zinc compounds.⁴⁰⁴ Chiral auxiliaries on the carbonyl fragment can be used.⁴⁰⁵ Chiral imines, in the form of chiral hydrazones, have been used with silyl enol ethers and a Sc catalyst.⁴⁰⁶ Chiral amines react with aldehydes, with silyl enol ethers and an InCl_3 catalyst in ionic liquids, to give the *Mannich* product with good enantioselectivity.⁴⁰⁷ A chiral thiourea catalyst has been used with a vinylogous *Mannich reaction*⁴⁰⁸ (see Sec. 6.B for vinylogy).

The reaction of nitroalkanes and amines, usually in the presence of a metal catalyst (e.g., CuBr),⁴⁰⁹ has been called the nitro-*Mannich reaction*.⁴¹⁰ An asymmetric nitro-*Mannich reaction* used a Cu—Sm catalyst,⁴¹¹ a Cu catalyst,⁴¹² or a chiral thiourea catalyst.⁴¹³

16-20 The Addition of Amines to Isocyanates

N-Hydro-*C*-alkylamino-addition

Ammonia and primary and secondary amines can be added to isocyanates⁴¹⁴ to give substituted ureas.⁴¹⁵ Isothiocyanates give thioureas.⁴¹⁶ This is an excellent method for the preparation of ureas and thioureas. These compounds are often used as derivatives for primary and secondary amines. Isocyanic acid (HNCO) also gives the reaction; usually its salts (e.g., NaNCO) are used. Wöhler's famous synthesis of urea involved the addition of ammonia to a salt of this acid.⁴¹⁷

16-21 The Addition of Ammonia or Amines to Nitriles

N-Hydro-*C*-amino-addition

Unsubstituted amidines (in the form of their salts) can be prepared by addition of ammonia to nitriles.⁴¹⁸ Many amidines have been made in this way. Dinitriles of suitable chain length can give imidines (30).⁴¹⁹

Primary and secondary amines can be used instead of ammonia, to give substituted amidines, but only if the nitrile contains electron-withdrawing groups; for example, Cl₃CCN gives the reaction. Ordinary nitriles do not react, and, in fact, acetonitrile is often used as a solvent in this reaction.⁴²⁰ Ordinary nitriles can be converted to amidines by treatment with an alkylchloroaluminum amide [MeAl(Cl)NR₂; R = H or Me].⁴²¹ The addition of ammonia to cyanamide (NH₂CN) gives guanidine [(NH₂)₂C=NH]. Guanidines can also be formed from amines.⁴²²

If water is present, in the presence of a Ru⁴²³ or a Pt catalyst,⁴²⁴ the addition of a primary or secondary amine to a nitrile gives an amide: RCN + R¹NHR² + H₂O → RCONR¹R² + NH₃ (R² may be H). When benzonitrile reacts with H₂PO₃Se[−] in aq methanol, a selenoamide [Ph(C=Se)NH₂], is formed after treatment with aq potassium carbonate.⁴²⁵

16-22 The Addition of Amines to Carbon Disulfide and Carbon Dioxide

S-Metallo-*C*-alkylamino-addition

Salts of dithiocarbamic acid can be prepared by the addition of primary or secondary amines to carbon disulfide.⁴²⁶ This reaction is similar to 16-10. Hydrogen sulfide can be eliminated from the product, directly or indirectly, to give isothiocyanates (RNCS). Isothiocyanates can be obtained directly by the reaction of primary amines and CS₂ in

E. Halogen Nucleophiles

16-23 The Formation of *gem*-Dihalides from Aldehydes and Ketones

Dihalo-de-oxo-bisubstitution

Aliphatic aldehydes and ketones can be converted to *gem*-dichlorides⁴³² by treatment with PCl₅. The reaction fails for perhalo ketones.⁴³³ If the aldehyde or ketone has an α hydrogen, elimination of HCl may follow and a vinylic chloride is a frequent side product, as shown,⁴³⁴ or even the main product.⁴³⁵ Phosphorus pentabromide (PBr₅) does not give good yields of *gem*-dibromides,⁴³⁶ but these can be obtained from aldehydes, by the use of Br₂, and triphenyl phosphite.⁴³⁷ *gem*-Dichlorides can be prepared by reacting an aldehyde with BiCl₃.⁴³⁸

The mechanism of *gem*-dichloride formation involves initial attack on PCl₄⁺, which is present in solid PCl₅, by the carbonyl oxygen, followed by addition of Cl[−] to the carbon:⁴³⁹

This chloride ion may come from PCl_6^- , which is also present in solid PCl_5 . There follows a two-step $\text{S}_{\text{N}}1$ process. Alternatively, **31** can be converted to the product without going through the chlorocarbenium ion, by an $\text{S}_{\text{N}}i$ process.

This reaction has sometimes been performed on carboxylic esters, though these compounds very seldom undergo any addition to the $\text{C}=\text{O}$ bond. An example is the conversion of F_3CCOOPh to $\text{F}_3\text{CCCl}_2\text{OPh}$.⁴⁴⁰ However, formates commonly give the reaction.

Many aldehydes and ketones have been converted to *gem*-difluoro compounds with sulfur tetrafluoride (SF_4),⁴⁴¹ including quinones, which give 1,1,4,4-tetrafluorocyclohexadiene derivatives. With ketones, yields can be raised and the reaction temperature lowered, by the addition of anhydrous HF .⁴⁴² Carboxylic acids, acyl chlorides, and amides react with SF_2 to give 1,1,1-trifluorides. In these cases, the first product is the acyl fluoride, which then undergoes the *gem*-difluorination reaction:

The acyl fluoride can be isolated. Carboxylic esters also give trifluorides, but more vigorous conditions are required. In this case, the carbonyl group of the ester is attacked first, and $\text{RCF}_2\text{OR}'$ can be isolated from $\text{RCO}_2\text{R}'$ ⁴⁴³ and then converted to the trifluoride. Anhydrides can react in either manner. Both types of intermediate are isolable under the right conditions, and SF_4 even converts CO_2 to CF_4 . A disadvantage of reactions with SF_4 is that they require a pressure vessel lined with stainless steel. Selenium tetrafluoride (SeF_4) gives similar reactions, but atmospheric pressure and ordinary glassware can be used.⁴⁴⁴ Another reagent that is often used to convert aldehydes and ketones to *gem*-difluorides is the commercially available diethylaminosulfur trifluoride (**DAST**, Et_2NSF_3), and CF_2Br_2 in the presence of zinc.⁴⁴⁵ The mechanism with SF_4 is probably similar in general nature, if not in specific detail, to that with PCl_5 . Some dithianes can be converted to *gem*-difluorides with a mixture of fluorine and iodine in acetonitrile.⁴⁴⁶ Oximes give *gem*-difluorides with NO^+BF_4^- and pyridinium polyhydrogen fluoride.⁴⁴⁷

Treatment with hydrazine to give the hydrazone, and then $\text{CuBr}_2/t\text{-BuOLi}$, generated the *gem*-dibromide.⁴⁴⁸ Oximes give *gem*-dichlorides upon treatment with chlorine and $\text{BF}_3\cdot\text{OEt}_2$, and then HCl .⁴⁴⁹

In a related process, α -halo ethers can be prepared by treatment of aldehydes and ketones with an alcohol and HX . The reaction is applicable to aliphatic aldehydes and ketones and to primary and secondary alcohols. The addition of HX to an aldehyde or

F. Attack at Carbon by Organometallic Compounds⁴⁵¹

16-24 The Addition of Grignard Reagents and Organolithium Reagents to Aldehydes and Ketones

O-Hydro-C-alkyl-addition

Organomagnesium compounds, commonly known as *Grignard reagents* (RMgX), are formed by the reaction of alkyl, vinyl, or aryl halides with magnesium metal, usually in ether solvents (e.g., diethyl ether or THF; Reaction 12-38). Halogen–Mg exchange can generate a *Grignard reagent* by reaction of aryl halides with reactive aliphatic *Grignard reagents*.⁴⁵² Microwave irradiation has been used to facilitate the formation of *Grignard reagents* from aryl chlorides that are slow to react otherwise.⁴⁵³

The addition of *Grignard reagents* to aldehydes and ketones⁴⁵⁴ is known as the *Grignard reaction*.⁴⁵⁵ The initial product of reaction with a carbonyl is a magnesium alkoxide, requiring a hydrolysis step to generate the final alcohol product. Formaldehyde gives primary alcohols; other aldehydes give secondary alcohols; and ketones give tertiary alcohols. The reaction is of very broad scope. In many cases, the hydrolysis step is carried out with dilute HCl or H₂SO₄, but this cannot be done for tertiary alcohols in which at least one R group is alkyl because such alcohols are easily dehydrated under acidic conditions (Reaction 17-1). In such cases (and often for other alcohols as well), an aqueous solution of ammonium chloride is used instead of a strong acid. *Grignard reagents* have been used in solid-phase synthesis.⁴⁵⁶ Ionic liquids have been used for the *Grignard reaction*.⁴⁵⁷

Transition metal catalysts can promote 1,2-addition of Grignard reagents to ketones. A catalytic amount of Zn(II) compounds promote the reaction, for example.⁴⁵⁸ In the presence of a catalytic amount of InCl₃, *Grignard reagents* react to give a mixture of 1,2- and 1,4-addition products with the 1,4-product predominating, but there was an increased 1,2-addition relative to the uncatalyzed reaction.⁴⁵⁹

Diastereoselective addition⁴⁶⁰ has been carried out with achiral reagents and chiral substrates,⁴⁶¹ similar to the reduction shown in Reaction 19-36.⁴⁶² Because the attacking atom in this case is carbon, diastereoselective addition is possible with an achiral substrate and an optically active reagent.⁴⁶³ The use of suitable reactants creates, in the most general case, two new stereogenic centers, so the product can exist as two pairs of enantiomers, as shown. Even if the organometallic compound is racemic, it still may be possible to get a diastereoselective reaction; that is, one pair of enantiomers is formed in greater amount than the other.⁴⁶⁴

Asymmetric *Grignard reactions* are possible under certain circumstances.⁴⁶⁵ Chiral ligands with a chiral Cu catalyst⁴⁶⁶ or a chiral Ti complex⁴⁶⁷ give alcohols with good enantioselectivity. An interesting method formed using an alkylmagnesium halide, dibutylmagnesium (Bu₂Mg) and a chiral diamine, and subsequent reaction with an aldehyde led to the alcohol derived from acyl addition of a butyl group with good enantioselectivity.⁴⁶⁸ N-Heterocyclic carbenes have been used as organocatalysts for asymmetric *Grignard reactions*.⁴⁶⁹ Aryl iodides undergo halogen–magnesium exchange when pretreated with PhMgCl, and subsequent reaction with an aldehyde gives the alcohol.⁴⁷⁰

The reaction of aldehydes or ketones with alkyl and aryl *Grignard reagents* was done in the earliest work without preliminary formation of RMgX, by mixing RX, the carbonyl compound, and magnesium metal in an ether solvent. This approach preceded Grignard's work, and is now known as the *Barbier reaction*.⁴⁷¹ The organolithium analogue of this process is also known.⁴⁷² Yields were generally satisfactory. Carboxylic ester, nitrile, and imide groups in the R are not affected by the reaction conditions.⁴⁷³ Modern versions of the

Barbier reaction employ other metals and/or reaction conditions, and will be discussed in Reaction **16-25**. However, *Mg–Barbier reactions* are catalyzed by other metal complexes (e.g., Cu compounds).⁴⁷⁴ Some transition metal compounds are stable in water, so some *Grignard–Barbier reactions* can be done in water.⁴⁷⁵ A *retro-Barbier reaction* has been reported in which a cyclic tertiary alcohol was treated to an excess of bromine and potassium carbonate to give 6-bromo-2-hexanone from 1-methylcyclopentanol.⁴⁷⁶

The reaction of RMgX or RLi with α,β -unsaturated aldehydes or ketones can proceed via 1,4-addition as well as normal 1,2-addition (see *Michael addition* in Reaction **15-25**).⁴⁷⁷ In general, alkyl lithium reagents give less 1,4 addition than the corresponding *Grignard reagents*.⁴⁷⁸ In a compound containing both an aldehyde and a ketone, it is possible to add RMgX chemoselectively to the aldehyde without significantly disturbing the carbonyl of the ketone group⁴⁷⁹ (see also, Reaction **16-24**). *Grignard reagents* have been shown to add to some conjugated cyclic ketones with an α,β -OTf group via 1,2-addition, followed by cleavage to give an alkynyl ketone.⁴⁸⁰

In some cases, a *Grignard reaction* can be performed intramolecularly.⁴⁸¹ For example, treatment of 5-bromo-2-pentanone with magnesium and a small amount of mercuric chloride in THF produced 1-methyl-1-cyclobutanol in 60% yield.⁴⁸² Other four- and five-membered ring compounds were also prepared by this procedure. Similar closing of five- and six-membered rings was achieved by treatment of a δ - or ϵ -halocarbonyl compound, not with a metal, but with a dianion derived from nickel tetraphenylporphyrine⁴⁸³ (see Reaction 16-25).

The gem-disubstituted Mg compounds formed from CH_2Br_2 or CH_2I_2 (Reaction **12-38**) react with aldehydes or ketones to give alkenes in moderate-to-good yields.⁴⁸⁴ *Wittig-type reactions* also produce alkenes and are discussed in Reaction **16-44**. The reaction could not be extended to other *gem*-dihalides. Similar reactions with *gem*-dimetallic compounds prepared with metals other than magnesium also have produced alkenes.⁴⁸⁵

Organolithium reagents (RLi), prepared from alkyl halides and Li metal or by exchange of an alkyl halide with a reactive organolithium (Reaction **12-38**) react with aldehydes and ketones by acyl addition to give the alcohol,⁴⁸⁶ after hydrolysis. Organolithium reagents are more basic than the corresponding *Grignard reagent*, which leads to problems of

deprotonation in some cases. Organolithium reagents are generally more nucleophilic, however, and can add to hindered ketones with relative ease when compared to the analogous *Grignard reagent*.⁴⁸⁷ These reagents tend to form aggregates, which influences the reactivity and selectivity of the addition reaction.⁴⁸⁸ The addition of lithium amide–butyllithium mixed aggregates has been studied.⁴⁸⁹

Alkyl, vinyl,⁴⁹⁰ and aryl organolithium reagents can be prepared and undergo acyl addition. Structural variations are also possible, including enantioselective 1,2-addition.⁴⁹¹ 1-Bromo-1-lithioethene was prepared, and reacts with an aldehyde to give an allylic alcohol bearing a vinyl bromide unit.⁴⁹² An interesting variation of the fundamental acyl addition reaction of organolithium reagents treated an aldehyde with an acyl-lithio amide [LiC(=O)N(Me)CH₂Me] to give an α -hydroxy amide derivative.⁴⁹³

As with the reduction of aldehydes and ketones (Reaction 19-36), the addition of organometallic compounds to these substrates can be carried out enantioselectively and diastereoselectively.⁴⁹⁴ Chiral secondary alcohols have been obtained with high enantioselectivity by addition of *Grignard* and organolithium compounds to aromatic aldehydes, in the presence of optically active amino alcohols as ligands.⁴⁹⁵

An interesting variation is the reaction of methyllithium and CH₂I₂ with an aliphatic aldehyde to give an epoxide.⁴⁹⁶ A lithio-epoxide was formed by treating an epoxide with *sec*-butyllithium in the presence of sparteine,⁴⁹⁷ or with *n*-butyllithium/TMEDA,⁴⁹⁸ and subsequent reaction with an aldehyde led to an epoxy alcohol. Alkylidene oxetanes react with lithium, and then with an aldehyde to give a conjugated ketone.⁴⁹⁹ The reaction of *gem*-dihalides with a carbonyl compound and Li or BuLi give epoxides⁵⁰⁰ (see also, Reaction 16-46).

In other uses of *gem*-dihalo compounds, aldehydes and ketones add the CH₂I group [R₂CO \rightarrow R₂C(OH)CH₂I] when treated with CH₂I₂ in the presence of SmI₂,⁵⁰¹ and the

CHX₂ group when treated with methylene halides and lithium dicyclohexylamide at low temperatures.⁵⁰²

It is possible to add an acyl group to a ketone to give (after hydrolysis) an α-hydroxy ketone.⁵⁰³ This can be done by adding RLi and CO to the ketone at -110°C :⁵⁰⁴

When the same reaction is carried out with carboxylic esters (R'COOR²), α-diketones (RCOCOR') are obtained.⁵⁰³

Most aldehydes and ketones react with most *Grignard reagents*, but there are several potential side reactions⁵⁰⁵ that occur mostly with hindered ketones and with bulky *Grignard reagents*. The two most important of these are *enolization* and *reduction*. The former requires that the aldehyde or ketone have an α hydrogen, and the latter requires that the *Grignard reagent* have a β hydrogen:

Enolization is an acid–base reaction (**12-24**) in which a proton is removed from the α carbon by the *Grignard reagent*, which is a strong base. The carbonyl compound is converted to its enolate anion, which, on hydrolysis, gives the original ketone or aldehyde. Enolization is important not only for hindered ketones but also for those that have a relatively high percentage of enol (e.g., β-keto esters).

The carbonyl compound can be reduced to an alcohol (Reaction **16-24**) by the *Grignard reagent*, which itself undergoes elimination to give an alkene. The *Grignard reagent* must have a β-carbon that bears a hydrogen atom.

Two other side reactions are condensation (between enolate ion and excess ketone) and *Wurtz-type coupling* (**10-64**). Addition of *Grignard reagents* to ketones cannot be used to prepare highly hindered tertiary alcohols (e.g., triisopropylcarbinol, tri-*tert*-butylcarbinol, and diisopropylneopentylcarbinol) or they can be prepared only in extremely low yields, because reduction and/or enolization become prominent.⁵⁰⁶ However, these alcohols can

be prepared by the use of alkyllithium reagents at $-80\text{ }^{\circ}\text{C}$ ⁵⁰⁷ because enolization and reduction are much less important.⁵⁰⁸ Other methods of increasing the degree of addition at the expense of reduction include complexing the *Grignard reagent* with LiClO_4 or $\text{Bu}_4\text{N}^+\text{Br}^-$,⁵⁰⁹ or using benzene or toluene instead of ether as solvent.⁵¹⁰ Both reduction and enolization can be avoided by adding CeCl_3 to the *Grignard reagent*.⁵¹¹

There has been controversy regarding the mechanism of addition of *Grignard reagents* to aldehydes and ketones.⁵¹² The reaction is difficult to study because of the variable nature of the species present in the *Grignard* solution (Sec. 5.B.ii) and because the presence of small amounts of impurities in the Mg seems to have a great effect on the kinetics of the reaction, making reproducible experiments difficult.⁵¹³ There seem to be two basic mechanisms, depending on the reactants and the reaction conditions. In one of these, the R group is transferred to the carbonyl carbon with its electron pair. A detailed mechanism of this type has been proposed by Ashby *et al.*,⁵¹⁴ based on the discovery that this reaction proceeds by two paths: one first order in MeMgBr and the other first order in Me_2Mg .⁵¹⁵ According to this proposal, both MeMgBr and Me_2Mg add to the carbonyl carbon, though the exact nature of the step by which MeMgBr or Me_2Mg reacts with the substrate is not certain. One possibility is a four-centered cyclic transition state:⁵¹⁶

The other type of mechanism is a SET process⁵¹⁷ with a ketyl intermediate:⁵¹⁸

This mechanism, which has been mostly studied with diaryl ketones, is more likely for aromatic and other conjugated aldehydes and ketones than it is for strictly aliphatic ones.

Among the evidence⁵¹⁹ for the SET mechanism are ESR spectra⁵²⁰ and the fact that $\text{Ar}_2\text{C}(\text{OH})\text{C}(\text{OH})\text{Ar}_2$ side products are obtained (from dimerization of the ketyl; see *pinacol coupling* in Reaction 19-76).⁵²¹ In the case of addition of RMgX to benzil (PhCOCOPh), ESR spectra of two different ketyl radicals were observed, both reported to be quite stable at room temperature.⁵²² Note that a separate study failed to observe freely diffusing radicals in the formation of *Grignard reagents*.⁵²³ Carbon isotope effect studies with $\text{Ph}^{14}\text{COPh}$ showed that the rate-determining step with most *Grignard reagents* is the carbon–carbon bond-forming step (marked A), although it is the initial electron-transfer step with allylmagnesium bromide.⁵²⁴ In the formation of *Grignard reagents* from bromocyclopropane, diffusing cyclopropyl radical intermediates were found.⁵²⁵ The concerted versus stepwise mechanism has been probed with chiral *Grignard reagents*.⁵²⁶

Note that there are similarities in reactivity for the $\text{S}_{\text{RN}}1$ (see Sec. 13.A.iv) and *Grignard mechanisms*.⁵²⁷ Experimental evidence from this work suggests a linear rather than a chain mechanism.

Mechanisms for the addition of organolithium reagents have been investigated much less.⁵²⁸ Addition of a cryptand that binds Li^+ inhibited the normal addition reaction, showing that the lithium is necessary for the reaction to take place.⁵²⁹

There is general agreement that the mechanism leading to reduction⁵³⁰ is usually as follows:

There is evidence that the mechanism leading to enolization is also cyclic, but involves prior coordination with magnesium:⁵³¹

16-25 Addition of Other Organometallics to Aldehydes and Ketones

O -Hydro-*C*-alkyl-addition

A variety of organometallic reagents other than RMgX and RLi add to aldehydes and ketones. A simple example is formation of Na, or K alkyne anions (e.g., $\text{RC}\equiv\text{C-M}$, Reaction 16-38), which undergo acyl addition to ketones or aldehydes to give the propargylic alcohol.⁵³⁴ In the reaction with terminal acetylenes,⁵³⁵ sodium acetylides are the most common reagents (when they are used, While Na is the metal of choice for the addition of acetylenic groups, vinylic alanes (prepared as in Reaction 15-17) are the reagents of choice for the addition of vinylic groups.⁵³⁶ The reagent $\text{Me}_3\text{Al}/\text{C}\equiv\text{CH Na}^+$ also adds to aldehydes to give the ethynyl alcohol.⁵³⁷ A solvent-free reaction was reported that mixed a ketone, a terminal alkyne and potassium *tert*-butoxide.⁵³⁸ The reaction is often called the *Nef reaction*, but Li,⁵³⁹ Mg, and other metallic acetylides have also been used. A particularly convenient reagent is the lithium acetylide–ethylenediamine complex,⁵⁴⁰ a stable, free-flowing powder that is commercially available. Alternatively, the substrate may be treated with the alkyne itself in the presence of a base, so that the acetylide is generated *in situ*. This procedure is called the *Favorskii reaction*, not to be confused with the *Favorskii rearrangement* (18-7).⁵⁴¹ Zinc(II) chloride facilitates the addition of a terminal alkyne to an aldehyde to give a propargylic alcohol.⁵⁴² Zinc(II) triflate can also be

used for alkyne addition to aldehydes,⁵⁴³ and in the presence of a chiral ligand leads to good enantioselectivity in the propargyl alcohol product.⁵⁴⁴

The reagents Et₃Al, Et₂Zn, and a terminal alkyne react with ketones, and in the presence of a cinchona alkaloid gives the alkynyl alcohol in moderate ee.⁵⁴⁵ Other enantioselective alkynylation reactions are known using various catalysts.⁵⁴⁶ Terminal alkynes add to aryl aldehydes in the presence of InBr₃ and NEt₃,⁵⁴⁷ SmI₂,⁵⁴⁸ or Me₂Zn.⁵⁴⁹ A Zn mediated reaction using iodoalkynes is known.⁵⁵⁰ Catalytically generated zinc acetylides add to aldehydes.⁵⁵¹ An In catalyzed addition of alkynes to aldehydes used a catalytic amount of BINOL and gave the alkynyl alcohol with high enantioselectivity.⁵⁵² Other enantioselective addition reactions of terminal alkynes are known.⁵⁵³ The reaction with In is compatible with the presence of a variety of other functional groups in the molecule, including phosphonate,⁵⁵⁴ propargylic sulfides.⁵⁵⁵

Many organometallic reagents have been reported for the addition of allylic groups,⁵⁵⁶ and there are enantioselective reactions.⁵⁵⁷ One of the most common methods is the *Barbier reaction* noted in Reaction 16-24, which includes metals and metal compounds other than Mg or Li, although the method is not limited to allylic compounds. Common reagents are allylic In compounds,⁵⁵⁸ which add to aldehydes or ketones in various solvents,⁵⁵⁹ Enantioselective In mediated *Barbier reactions* are known.⁵⁶⁰ Indium reacts with allylic bromides and ketones in water⁵⁶¹ and in aqueous media. The reaction of a

propargyl halide, In, and an aldehyde in aq THF leads to an allenic alcohol.⁵⁶² When allyl iodide is mixed with In and TMSCl, reaction with a conjugated ketone proceed by 1,4-addition, but in the presence of 10% CuI, the major product is that of 1,2-addition.⁵⁶³ Allyl bromide reacts with Mn/TMSCl and an In catalyst in water to give the homoallylic alcohols from aldehydes.⁵⁶⁴ Indium metal is used for the acyl addition of allylic halides with a variety of aldehydes and ketones, including aliphatic aldehydes,⁵⁶⁵ aryl aldehydes,⁵⁶⁶ and α -keto esters.⁵⁶⁷ Elimination of the homoallylic alcohol to a conjugated diene can accompany the addition in some cases.⁵⁶⁸

Allyl bromide reacts with a ketone and Sm⁵⁶⁹ or SmI₂,⁵⁷⁰ to give the homoallylic alcohol. Other metals can be used with allylic halides to give homoallylic alcohols from aldehydes or ketones,⁵⁷¹ including Zn,⁵⁷² La,⁵⁷³ or Mg–Cd⁵⁷⁴ and compounds of Ti,⁵⁷⁵ Mn,⁵⁷⁶ Fe,⁵⁷⁷ Ga,⁵⁷⁸ Ge,⁵⁷⁹ Zr,⁵⁸⁰ Nb,⁵⁸¹ Cd,⁵⁸² Sb,⁵⁸³ Te,⁵⁸⁴ Ba,⁵⁸⁵ Ce,⁵⁸⁶ Nd,⁵⁸⁷ Hg,⁵⁸⁸ Bi,⁵⁸⁹ In,⁵⁹⁰ and Pb.⁵⁹¹

In addition, $\text{BiCl}_3/\text{NaBH}_4$,⁵⁹² $\text{Mg}-\text{BiCl}_3$,⁵⁹³ and $\text{CrCl}_2/\text{NiCl}_2$,⁵⁹⁴ have been used. Allylic alcohols have been converted to organometallic reagents with diethylzinc and a Pd⁵⁹⁵ or a Ru catalyst,⁵⁹⁶ leading to the homoallylic alcohol upon reaction with an aldehyde. Allylic acetates add to aldehydes in the presence of a Ru catalyst.⁵⁹⁷

Enantioselective reactions are known.⁵⁹⁸ A Cu catalyzed reaction is known that proceeds with good enantioselectivity.⁵⁹⁹ Allylzinc bromide adds to aldehydes under solvent-free conditions.⁶⁰⁰ A chiral Cr–Mn complex has been used with allylic bromides in conjunction with trimethylsilyl chloride.⁶⁰¹ Reagents of the type $\text{R}-\text{Yb}$ have been prepared from RMgX .⁶⁰² The alkyl group of trialkyl aluminum compounds (e.g., AlEt_3) add to aldehydes, enantioselectively in the presence of chiral transition metal complexes.⁶⁰³ Furthermore, organotitanium reagents can be made to add chemoselectively to aldehydes in the presence of ketones.⁶⁰⁴ Organomanganese compounds are also chemoselective in this way.⁶⁰⁵ In a related reaction, organocerium reagents, generated from cerium chloride (CeCl_3 and a *Grignard reagent* or an organolithium reagent) gives an organometallic reagent that adds chemoselectively.⁶⁰⁶ Aryl halides that have a pendant ketone unit react with a Pd catalyst to give cyclization via acyl addition.⁶⁰⁷

As noted in Reaction 16-24, enolate formation and reduction complicate some *Grignard reactions*. One way to avoid complications is to add $(\text{RO})_3\text{TiCl}$, TiCl_4 ,⁶⁰⁸ $(\text{RO})_3\text{ZrCl}$, or $(\text{R}_2\text{N})_3\text{TiX}$ to the *Grignard* or organolithium reagent. This produces organotitanium or organozirconium compounds that are much more selective than *Grignard* or organolithium reagents.⁶⁰⁹ An important advantage of these reagents is that they do not react with NO_2 or CN functions that may be present in the substrate, as *Grignard* and organolithium reagents do. The reaction of a β -keto amide with TiCl_4 , for example, gives a complex that allows selective reaction of the ketone unit with $\text{MeMgCl}-\text{CeCl}_3$ to give the corresponding alcohol.⁶¹⁰ Premixing an allylic *Grignard reagent* with ScCl_3 prior to reaction with the

aldehyde gives direct acyl addition without allylic rearrangement as the major product, favoring the *trans*-alkene unit.⁶¹¹

Allyltin compounds readily add to aldehydes and ketones.⁶¹² Maleic acid promotes the reaction in aqueous media.⁶¹³ Allylic bromides react with Sn to generate the organo-metallic *in situ*, which then adds to aldehydes.⁶¹⁴ Allylic chlorides react with aldehydes in the presence of ditin compounds (e.g., Me₃Sn—SnMe₃ and a Pd catalyst).⁶¹⁵ Allyltrialkyltin compounds⁶¹⁶ and tetraallyltin react with aldehydes or ketones in the presence of BF₃—etherate,⁶¹⁷ or compounds of Cu,⁶¹⁸ Ce,⁶¹⁹ Bi,⁶²⁰ Pb,⁶²¹ Ag,⁶²² Cd,⁶²³ Cr,⁶²⁴ Pd,⁶²⁵ Re,⁶²⁶ Gd,⁶²⁷ Ti,⁶²⁸ Rh,⁶²⁹ Zr,⁶³⁰ Co,⁶³¹ or La.⁶³² Propargylic tin compounds react with aldehydes to give the alcohol, with good antiselectivity.⁶³³ Tetraallyltin reacts via 1,2-addition to conjugated ketones in refluxing methanol.⁶³⁴ Tetraallyltin reacts with aldehydes in ionic liquids⁶³⁵ and on wet silica.⁶³⁶ In addition, allyltributyltin adds to aldehydes in ionic liquids with InCl₃.⁶³⁷ Tetraallyltin adds to ketones or aldehydes to give homoallylic alcohols with good enantioselectivity in the presence of a chiral Ti complex⁶³⁸ or a chiral In

complex.⁶³⁹ Allylic alcohols and homoallylic alcohols add to aldehydes in the presence of $\text{Sn}(\text{OTf})_2$ ⁶⁴⁰ In/InCl_3 ,⁶⁴¹ or with a Rh catalyst.⁶⁴²

The tin compound can be prepared *in situ* using an α -iodo ketone with an aldehyde and $\text{Bu}_2\text{SnI}_2\text{—LiI}$.⁶⁴³ A similar addition occurs with $(\text{allyl})_2\text{SnBr}_2$ in water.⁶⁴⁴ Asymmetric induction has been reported.⁶⁴⁵ The use of a chiral Rh⁶⁴⁶ or Ti⁶⁴⁷ catalyst leads to enantioselective addition of allyltributyltin to aldehydes. Allyltributyltin reacts with aldehydes in the presence of SiCl_4 and a chiral phosphoramidate to give the homoallylic alcohol with moderate enantioselectivity.⁶⁴⁸ Tetravinyltin adds to ketones in the presence of an In catalyst.⁶⁴⁹ Allenyl tin compounds ($\text{CH}_2=\text{C}=\text{CHSnBu}_3$) also react with aldehydes in the presence of $\text{BF}_3\cdot\text{OEt}_2$ to give a 2-dienyl alcohol.⁶⁵⁰ Selectfluor has been used to induce 1,2-addition of the allyl group of allyltributyltin to a conjugated aldehyde.⁶⁵¹

Both aluminum and titanium reagents have been used. Aluminum catalysts, (e.g., [methylaluminum bis(4-bromo-2,6-di-*tert*-butylphenoxide)]), MABR), facilitate addition of allyltributyltin to aldehydes.⁶⁵² Triphenylaluminum reacts with aryl aldehydes in the presence of a Ti catalyst.⁶⁵³ Trimethylaluminum⁶⁵⁴ and dimethyltitanium dichloride⁶⁵⁵ exhaustively methylate ketones to give *gem*-dimethyl compounds⁶⁵⁶ (see also, Reaction 10-63):

The Ti reagent also dimethylates aromatic aldehydes.⁶⁵⁷ Triethylaluminum reacts with aldehydes, however, to give the mono-ethyl alcohol, and in the presence of a chiral additive the reaction proceeds with good asymmetric induction.⁶⁵⁸ A complex of $\text{Me}_3\text{Ti}\cdot\text{MeLi}$ has

been shown to be selective for 1,2-addition with conjugated ketones, in the presence of nonconjugated ketones.⁶⁵⁹

Chiral amides react with aldehydes in the presence of TiCl_4 to give syn-selective addition products.⁶⁶⁰ Titanium-catalyzed enantioselective additions are also known.⁶⁶¹ High %ee values have been obtained with organometallics,⁶⁶² including organotitanium compounds (methyl, aryl, allylic) in which an optically active ligand is coordinated to the Ti,⁶⁶³ allylic boron compounds, and organozinc compounds. Chiral dendritic Ti catalysts have been used to give moderate enantioselectivity.⁶⁶⁴

Organozinc compounds add to aldehydes and ketones. An example is the reaction of an alkylzinc chloride (RZnCl) to give the corresponding alcohol.⁶⁶⁵ Enantioselective reaction of a carbonyl with a dialkylzinc is possible when chiral catalysts are employed,⁶⁶⁶ or when chiral ligands⁶⁶⁷ are employed.⁶⁶⁸ A comparison of the stereoselectivity for reactions of diphenylzinc and diethylzinc has been reported.⁶⁶⁹ Dialkylzinc reagents, in the presence of a chiral Ti complex⁶⁷⁰ a Zn complex,⁶⁷¹ an Al complex,⁶⁷² a chiral Cr complex,⁶⁷³ a chiral Schiff base,⁶⁷⁴ or a chiral bis(sulfonamide)⁶⁷⁵ and other chiral complexes⁶⁷⁶ react with aldehydes or ketones to give

the corresponding alcohol with good enantioselectivity.⁶⁷⁷ High enantioselectivity was obtained from R_2Zn reagents ($R = \text{alkyl}$)⁶⁷⁸ and aromatic⁶⁷⁹ aldehydes by the use of a small amount of various catalysts.⁶⁸⁰ The enantioselectivity is influenced by additives (e.g., $LiCl$).⁶⁸¹ Silica-immobilized chiral ligands⁶⁸² can be used in conjunction with dialkylzinc reagents, and polymer-supported ligands have been used.⁶⁸³

Propargylic acetate adds to aldehydes with good antiselectivity in the presence of Et_2Zn and a Pd catalyst.⁶⁸⁴ With other organometallic compounds, active metals (e.g., alkylzinc reagents)⁶⁸⁵ are useful and compounds, such as alkylmercurys, do not react. Dimethylzinc and diethylzinc are probably the most common reagents. An intramolecular version is possible by reaction of an allene–aldehyde with dimethylzinc. Aryl halides react with Zn – Ni complexes to give acyl addition of the aryl group to an aldehyde.⁶⁸⁶ The reaction of an allylic halide and Zn ⁶⁸⁷ or $Zn/TMSCl$ ⁶⁸⁸ leads to acyl addition of aldehydes.

Organochromium compounds add to aldehydes or ketones.⁶⁸⁹ The reaction of an organochromium reagent with an aldehyde or ketone is known as the *Nozaki–Hiyama reaction*. In the original version, a $Cr(II)$ solution was prepared by reduction of chromic chloride by $LiAlH_4$. This product was subsequently treated with an aldehyde and an allylic halide.⁶⁹⁰ The coupling of allylic halides and aldehydes or ketones in the presence of a Cr catalyst and a chiral ligand gives products with good enantioselectivity.⁶⁹¹ Enantioselective coupling reactions catalyzed by Cr compounds are of increasing interest.⁶⁹² The organochromium reagent may be derived from vinyl halides, triflates, or aryl derivatives.⁶⁹³

Other metals facilitate addition of groups to an aldehyde, including the coupling of an alkene to an aldehyde using a Ni catalyst.⁶⁹⁴ Vinyl bromides react with $\text{NiBr}_2/\text{CrCl}_3/\text{TMSCl}$ to give a reagent that adds to aldehydes to give the allylic alcohol.⁶⁹⁵ Vinyl complexes generated from alkynes and SmI_2 add intramolecularly, and eight-membered rings have been formed in this way.⁶⁹⁶ Vinyl reagents are formed *in situ* via organozirconium compounds with Me_2Zn , Ti compounds, and terminal alkynes.⁶⁹⁷

Lithium dimethylcopper (Me_2CuLi) reacts with aldehydes⁶⁹⁸ and with certain ketones⁶⁹⁹ to give the expected alcohols. The $\text{RCu}(\text{CN})\text{ZnI}$ reagents also react with aldehydes, in the presence of BF_3 –etherate, to give secondary alcohols. Vinyltellurium compounds react with $\text{BF}_3\cdot\text{OEt}_2$ and cyanocuprates $[\text{R}(2\text{-thienyl})\text{CuCNLi}_2]$ to give a reagent that adds 1,2- to the carbonyl of a conjugated ketone.⁷⁰⁰ Vinyl tellurium compounds also react with *n*-butyllithium to give a reagent that adds to nonconjugated ketones.⁷⁰¹ In conjunction with BeCl_2 , organolithium reagents add to conjugated ketones. In THF, 1,4- addition is observed, but in diethyl ether the 1,2-addition product is formed.⁷⁰²

Alkenes and alkynes add to aldehydes or ketones via the π bond by conversion to a reactive organometallic. A radical-type addition is possible using alkenes with BEt_3 . Alkynes add to aldehydes elsewhere in the same molecule in the presence of BEt_3 and a Ni catalyst to give a cyclic allylic alcohol.⁷⁰³ Alkene aldehydes react similarly using Me_3SiOTf .⁷⁰⁴ In a similar manner, dienes⁷⁰⁵ or alkynes⁷⁰⁶ add to aldehydes in the presence of a Ni catalyst. Allenes add to aldehydes in the presence of a Ni catalyst, using a chiral imidazolynil carbene ligand, and the product is trapped as the triethylsilyl ether by addition of Et_3SiI .⁷⁰⁷ Ketenimines add to aldehydes, in the presence of SiCl_4 and an achiral ligand, to give the β -cyanohydrin with good enantioselectivity.⁷⁰⁸ Allylic acetates react with ketones to give the homoallylic alcohol under electrochemical conditions that include bipyridyl, tetrabutylammonium tetrafluoroborate, and FeBr_2 .⁷⁰⁹ Terminal alkynes react with Zr complexes and Me_2Zn to give an allylic tertiary alcohol.⁷¹⁰ Internal alkynes also give allylic alcohols in the presence of BEt_3 and a Ni catalyst.⁷¹¹ Reaction of an aldehyde containing a conjugated diene unit with diethylzinc and a Ni catalyst leads to cyclic

alcohols having a pendant allylic unit.⁷¹² A similar reaction was reported using a Cu catalyst.⁷¹³ The intramolecular addition of an alkene to an aldehyde leads to a saturated cyclic alcohol using PhSiH_3 and a Co catalyst.⁷¹⁴

Aryl halides react with a Ni complex under electrolytic conditions to add the aryl group to aldehydes.⁷¹⁵ The C position of an indole adds to aldehydes in the presence of a Pd catalyst.⁷¹⁶ The addition of trifluoromethyl to an aldehyde was accomplished photochemically using CF_3I and $(\text{Me}_2\text{N})_2\text{C}=\text{C}(\text{NMe}_2)_2$.⁷¹⁷ α -Iodo phosphonate esters react with aldehydes and SmI_2 to give a β -hydroxy phosphonate ester.⁷¹⁸ Addition to the allene in the presence of a Ni catalyst⁷¹⁹ or a CeCl_3 catalyst⁷²⁰ is followed by addition of the intermediate organometallic to the aldehyde to give the cyclic product.

Intramolecular addition of a conjugated ester (via the β -carbon) to an aldehyde generates a cyclic ketone.⁷²¹ This type of coupling has been called the *Stetter reaction*,⁷²² which actually involves the addition of aldehydes to activated double bonds (Reaction 15-34), mediated by a catalytic amount of thiazolium salt in the presence of a weak base. The intramolecular addition of the allene moiety to an aldehyde is catalyzed by a Pd complex in the presence of $\text{Me}_3\text{SiSnBu}_3$.⁷²³ A highly enantio- and diastereoselective intramolecular *Stetter reaction* has been developed.⁷²⁴ Alkynyl aldehydes react with silanes (e.g., Et_3SiH) and a nickel catalyst to give a cyclic compound having a silyl ether and an exocyclic vinylidene unit.⁷²⁵ Alkene-aldehydes give cyclic alcohols via intramolecular addition of the $\text{C}=\text{C}$ unit to the carbonyl under electrolytic conditions using a phase-transfer catalyst.⁷²⁶ A similar cyclization was reported using SnCl_4 .⁷²⁷ Vinylidene cycloalkanes react with aldehydes in the presence of a Pd catalyst to give a homoallylic alcohol where addition occurs at the carbon exocyclic to the ring.⁷²⁸ Allenes react with benzaldehyde using $\text{HCl}-\text{SnCl}_2$ with a Pd catalyst.⁷²⁹ Silyl allenenes react with aldehydes in the presence of a chiral Sc catalyst to give homopropargylic alcohols with good enantioselectivity.⁷³⁰ Intramolecular addition of an allene to aldehyde via addition of phenyl when treated with PhI and a Pd catalyst.⁷³¹ Allenes add to ketones to give homoallylic alcohols in the

presence of SmI_2 and HMPA.⁷³² Alkenes having an allylic methyl group in the presence of $\text{BF}_3 \cdot \text{OEt}_2$ add to formaldehyde to give a homoallylic alcohol.⁷³³ Conjugated dienes react with aldehyde via acyl addition of a terminal carbon of the diene, in the presence of $\text{Ni}(\text{acac})_2$ and Et_2Zn .⁷³⁴

Although organoboranes do not generally add to aldehydes and ketones,⁷³⁵ allylic boranes are exceptions.⁷³⁶ When they add, an allylic rearrangement always takes place. Allylic rearrangements may take place with the other reagents as well. The use of a chiral catalyst leads to asymmetric induction⁷³⁷ and chiral allylic boranes have been prepared.⁷³⁸ Addition of trialkylboranes to aldehydes is catalyzed by a Ni complex.⁷³⁹ Note that chloroboranes (R_2BCl) react with aldehydes via acyl addition of the alkyl group, giving the corresponding alcohol after treatment with water.⁷⁴⁰ Treatment with catecholborane gives addition to the conjugated ketone, and subsequent cyclization of the resulting organo-metallic at the nonconjugated ketone gives a cyclic alcohol with a pendant ketone unit, after treatment with methanol.⁷⁴¹ In the presence of Ru ,⁷⁴² Cu ,⁷⁴³ Ni ,⁷⁴⁴ or Pd ⁷⁴⁵ compounds, $\text{RB}(\text{OH})_2$ and arylboronic acids [$\text{ArB}(\text{OH})_2$, see Reaction 12-28] add to aldehydes to give the corresponding alcohol. Arylboronic acids add to aldehydes in the presence of a chiral ligand to give an alcohol with good enantioselectivity.⁷⁴⁶ An enantioselective intramolecular reaction of an arylboronic acid to a pendant ketone moiety used a Pd catalyst.⁷⁴⁷ Polymer-bound aryl borates add an aryl group to aldehydes in the presence of a Rh catalyst.⁷⁴⁸ An intramolecular version of the phenylboronic acid induced reaction is known, where a molecule with ketone and conjugated ketone units is converted to a cyclic alcohol using a chiral Rh catalyst.⁷⁴⁹ Allylic boronates add to aldehydes,⁷⁵⁰ and

there are enantioselective reactions.⁷⁵¹

A number of optically active allylic boron compounds have been used, including⁷⁵² B-allylbis(2-isocaranyl)borane (**32**),⁷⁵³ (*E*)- and (*Z*)-crotyl-(*R,R*)-2,5-dimethylborolanes (**33**),⁷⁵⁴ and the borneol derivative **34**,⁷⁵⁵ all of which add an allyl group to aldehydes, with good enantioselectivity. A recyclable 10-TMS-9-borabicyclo[3.3.2]decane has been used for asymmetric allyl and crotyl addition to aldehydes.⁷⁵⁶ Where the substrate possesses an aryl group or a triple bond, using a metal carbonyl complex of the substrate enhances enantioselectivity.⁷⁵⁷

Potassium alkynyltrifluoroborates (Reaction **12-28**) react with aldehydes and a secondary amine, in an ionic liquid, to give a propargylic amine.⁷⁵⁸ Allylic trifluoroborates (Reaction **12-28**) react with aldehydes to give the homoallylic alcohol. The Pd catalyzed reaction of aryl aldehydes with PhBF₃K gave a diaryl alcohol.⁷⁵⁹ A Ru catalyzed reaction of aryltrifluoroborates led to sterically hindered diaryl ketones.⁷⁶⁰ Aliphatic aldehydes react with this reagent, in the presence of BF₃•OEt₂, to give the homoallylic alcohol with allylic rearrangement and a preference for the syn diastereomer.⁷⁶¹ Aryl aldehydes react as well.⁷⁶²

16-26 Addition of Trialkylallylsilanes to Aldehydes and Ketones

O-Hydro-*C*-alkyl-addition

Allylic trialkyl, trialkoxy, and trihalosilanes add to aldehydes to give the homoallylic alcohols in the presence of a Lewis acid⁷⁶³ (including TaCl₅⁷⁶⁴ and YbCl₃⁷⁶⁵), fluoride

ion,⁷⁶⁶ proazaphosphatranes,⁷⁶⁷ or a catalytic amount of iodine.⁷⁶⁸ A Ru catalyst has been used in conjunction with an arylsilane and an aldehyde.⁷⁶⁹ Allyl(trimethoxy)silane adds an allyl group to aldehydes using a CdF_2 ⁷⁷⁰ catalyst or a chiral AgF complex.⁷⁷¹ Allyltrichlorosilanes have also been used in addition reactions with aldehydes.⁷⁷² Hünig's base ($i\text{Pr}_2\text{NEt}$) and a sulfoxide have also been used to facilitate the addition of an allyl group to an aldehyde from allyltrichlorosilane.⁷⁷³ The mechanism of this reaction has been examined.⁷⁷⁴

Allyltrichlorosilane reacts with aldehydes in the presence of certain additives to give the corresponding alcohol,⁷⁷⁵ and the reaction proceeds with good enantioselectivity by addition of a chiral additive.⁷⁷⁶ Other chiral additives have been used,⁷⁷⁷ as well as chiral catalysts,⁷⁷⁸ and chiral complexes of allyl silanes.⁷⁷⁹ Trimethoxyallylsilanes react with aldehydes in the presence of a Cu catalyst and a chiral ligand to give the chiral alcohol.⁷⁸⁰ Chiral allylic silyl derivatives add to aldehydes to give the chiral homoallylic alcohol.⁷⁸¹

Allylic silanes react with *gem*-diacetates in the presence of InCl_3 to give a homoallylic acetate⁷⁸² or with dimethyl acetals and TMSOTf in an ionic liquid to give the homoallylic methyl ether.⁷⁸³ Allylic alcohols can be treated with $\text{TMS}-\text{Cl}$ and NaI , and then Bi to give an organometallic reagent that adds to aldehydes.⁷⁸⁴

16-27 Addition of Conjugated Alkenes to Aldehydes (the Baylis–Hillman Reaction)⁷⁸⁵*O*-Hydro-*C*-alkenyl-addition

In the presence of a base⁷⁸⁶ (1,4-diazabicyclo[2.2.2]octane, DABCO) or trialkylphosphines, conjugated carbonyl compounds (ketones, esters, including lactones)⁷⁸⁷ thioesters,⁷⁸⁸ and amides⁷⁸⁹) add to aldehydes via the α carbon to give α -alkenyl- β -hydroxy esters or amides. This sequence is called the *Baylis–Hillman reaction* (or *Morita–Baylis–Hillman*),⁷⁹⁰ and a simple example is the formation of **35**.⁷⁹¹ Mechanistic investigations of the reaction have been reported.⁷⁹² Methyl vinyl ketone gave other products in the *Baylis–Hillman reaction*, whereas conjugated esters do not.⁷⁹³ Methods that are catalytic in base have been developed for the *Baylis–Hillman reaction*.⁷⁹⁴ Both microwave irradiation⁷⁹⁵ and ultrasound⁷⁹⁶ have been used to induce the reaction.⁷⁹⁷ *Baylis–Hillman reactions* have been done in aqueous acidic media.⁷⁹⁸ There is a protein-catalyzed reaction.⁷⁹⁹ Under certain conditions, rate enhancements have been observed.⁸⁰⁰ The reaction has been done in ionic liquids⁸⁰¹ and PEG⁸⁰² or sulfolane,⁸⁰³ and without an organic solvent.⁸⁰⁴ Rate

acceleration occurs with bis(arylthio)ureas in a DABCO promoted reaction.⁸⁰⁵ Transition metal compounds can facilitate the *Baylis–Hillman reaction*,⁸⁰⁶ and $\text{BF}_3 \cdot \text{OEt}_2$ has been used.⁸⁰⁷ A sila variation is known, involving the reaction of vinylsilanes and aldehydes.⁸⁰⁸ An *aza-Baylis–Hillman reaction* is discussed in Reaction 16-31.

An intramolecular version of the *Baylis–Hillman reaction* generated cyclopentenone derivatives from alkyne-aldehydes and a Rh catalyst.⁸⁰⁹ Other intramolecular cyclization reactions are known.⁸¹⁰ Cyclization of a conjugated ester using DABCO, where the “alcohol” group contained an aldehyde unit (an α -hydroxy aldehyde derivative) gave a lactone with a hydroxy unit at C-3 relative to the carbonyl and an α -vinylidene.⁸¹¹

Enantioselective *Baylis–Hillman reactions*⁸¹² are possible using a chiral auxiliary via an amide⁸¹³ or ester.⁸¹⁴ Organocatalysts can be used to give products with good enantioselectivity.⁸¹⁵ Sugars have been used as ester auxiliaries, and in reaction with aryl aldehydes and 20% DABCO gave the allylic alcohol with modest enantioselectivity.⁸¹⁶

Another variation is the *Rauhut–Currier cyclization* reaction,⁸¹⁷ which involves the reaction of a conjugated carbonyl with the allylic site of a second conjugated system. Intramolecular variations of this latter method are known.⁸¹⁸ With the boron trifluoride induced reaction between an aldehyde and a conjugated ketone, a saturated β -hydroxy ketone was formed with good antiselectivity.⁸¹⁹ The coupling of aldehydes with conjugated ketones used TiCl_4 ,⁸²⁰ dialkylaluminum halides,⁸²¹ and with (polymethyl)hydro-siloxane and a Cu catalyst.⁸²² Conjugated esters were coupled to aldehydes with DABCO and a La catalyst.⁸²³ Aldehydes are coupled to conjugated esters with a chiral quinuclidine catalyst and a Ti catalyst, as well as in the presence of tosylamine, the final product was the allylic *N*-tosylamine formed with modest enantioselectivity.⁸²⁴

Alkyl halides are coupled with conjugated carbonyls to give the alkylated derivative in what is known as *Morita–Baylis–Hillman alkylation*.⁸²⁵ α -Bromomethyl esters react with conjugated ketones and DABCO to give a coupling product, (**34**).⁸²⁶ A similar DBU induced reaction was reported using α -bromomethyl esters and conjugated nitro compounds.⁸²⁷

The reaction can be modified to give additional products, as with the reaction of *o*-hydroxybenzaldehyde and methyl vinyl ketone with DABCO, where the initial *Baylis–Hillman product* cyclized via conjugate addition of the phenolic oxygen to the conjugated ketone (Reaction **15-31**).⁸²⁸ Aldehydes and conjugated esters can be coupled with a sulfonamide to give an allylic amine.⁸²⁹

See OS **2010**, 87, 201

16-28 The Reformatsky Reaction

O-Hydro-*C*- α -ethoxycarbonylalkyl-addition

The *Reformatsky reaction*⁸³⁰ is very similar to Reaction **16-24**. An aldehyde or ketone is treated with Zn and a halide; the halide is usually an α -halo ester or a vinyllog (see Sec. 6. B) of an α -halo ester (e.g., $\text{RCHBrCH}=\text{CHCOOEt}$), although α -halo nitriles,⁸³¹ α -halo ketones,⁸³² and α -halo *N,N*-disubstituted amides have also been used. Especially high reactivity can be achieved with activated Zn,⁸³³ and with Zn and ultrasound.⁸³⁴ The reaction is catalytic in Zn in the presence of iodine and ultrasound.⁸³⁵ Metals other than Zn can be used, including In,⁸³⁶ Mn,⁸³⁷ low valent Ti,⁸³⁸ metal compounds of Ti,⁸³⁹ Sn,⁸⁴⁰

Sm⁸⁴¹ or Sc.⁸⁴² The use of additives (e.g., Ge⁸⁴³ or Me₂Zn)⁸⁴⁴ can lead to highly selective reactions.⁸⁴⁵ A combination of Zn and an α -bromo ester can be used in conjunction with BF₃·OEt₂, followed by reaction with dibenzoyl peroxide.⁸⁴⁶ The aldehyde or ketone can be aliphatic, aromatic, or heterocyclic, or contain various functional groups. Solvents used are generally ethers, including Et₂O, THF, and 1,4-dioxane, although the reaction can be done in water⁸⁴⁷ using dibenzoyl peroxide and MgClO₄.

With the use of chiral auxiliaries⁸⁴⁸ or chiral catalysts,⁸⁴⁹ good enantioselectivity⁸⁵⁰ can be achieved.

Dialkylzinc compounds are an alternative source of Zn in the *Reformatsky reaction*. The reaction of an α -bromo ester, an aldehyde, and diethylzinc in THF with a Rh catalyst, gave a β -hydroxy ester.⁸⁵¹

Formally, the reaction is somewhat analogous to the *Grignard reaction* (16-24), with EtO₂C—C—ZnBr (37) as an intermediate analogous to RMgX.⁸⁵² There is an intermediate derived from Zn and the ester, the structure of which has been shown to be 38, by X-ray crystallography of the solid intermediate prepared from *t*-BuOCOCH₂Br and Zn.⁸⁵³ As can be seen, it has some of the characteristics of 37.

After hydrolysis, the alcohol is the usual product, but sometimes (especially with aryl aldehydes) elimination follows directly and the product is an alkene. By the use of Bu₃P along with Zn, the alkene can be made the main product,⁸⁵⁴ making this an alternative to the *Wittig reaction* (16-44). The alkene is also the product when K₂CO₃/NaHCO₃ is used

with 2% PEG–telluride.⁸⁵⁵ Since *Grignard reagents* cannot be formed from α -halo esters, the method is quite useful, but competing reactions sometimes lead to low yields. A similar reaction (called the *Blaise reaction*) has been carried out on nitriles⁸⁵⁶:

Carboxylic esters have also been used as substrates, but then, as might be expected (Sec. 16.A), the result is substitution and not addition:

The product in this case is the same as with the corresponding nitrile, though the pathways are different. The reaction is compatible with amine substituents, and α -(*N,N*-dibenzyl) amino aldehydes have been used to prepare β -hydroxy- γ -(*N,N*-dibenzylamino) esters with good antiselectivity.⁸⁵⁷

For an alternative approach involving ester enolates, see Reaction 16-36.

16-29 The Conversion of Carboxylic Acid Salts to Ketones with Organometallic Compounds

Alkyl-de-oxido-substitution

Good yields of ketones can often be obtained by treatment of the lithium salt of a carboxylic acid with an alkyl lithium reagent, followed by hydrolysis.⁸⁵⁸ The carboxylate salt is formed by reaction of the carboxylic acid with 1 molar equivalent of R^1Li . The R^1 group may be aryl or primary, secondary, or tertiary alkyl and R may be alkyl or aryl. The compounds MeLi and PhLi have been employed most often. Tertiary alcohols are side products. Lithium acetate can be used, but generally gives low yields. Using $\text{R}(\text{PrNH})\text{Mg}$, carboxylic acid salts react to form ketones.⁸⁵⁹

A variation of this transformation reacts the acid with lithium naphthalenide in the presence of 1-chlorobutane. The product is the ketone.⁸⁶⁰ A related reaction treats the lithium carboxylate with lithium metal and the alkyl halide, with sonication, to give the ketone.⁸⁶¹ Phenylboronic acid (Reaction 12-28) reacts with aryl carboxylic acids in the presence of a Pd catalyst and disuccinoyl carbonate to give a diaryl ketone.⁸⁶²

16-30 The Addition of Organometallic Compounds to CO₂ and CS₂**C-Alkyl-O-halomagnesio-addition**

Grignard reagents add to one C=O bond of CO₂ exactly as they do to an aldehyde or a ketone,⁸⁶³ but the product is the salt of a carboxylic acid. The reaction is usually performed by adding the *Grignard reagent* to dry ice. Many carboxylic acids have been prepared in this manner, and this constitutes an important way of increasing a carbon chain by one unit. Since labeled CO₂ is commercially available, this is a good method for the preparation of carboxylic acids labeled in the carboxyl group. Other organometallic compounds have also been used (RLi,⁸⁶⁴ RNa, RCaX, RBa,⁸⁶⁵ etc.), but much less often. The formation of the salt of a carboxylic acid after the addition of CO₂ to a reaction mixture is regarded as a positive test for the presence of a carbanion or of a reactive organometallic intermediate in that reaction mixture (see also, Reaction **16-42**).

Aryl organoboronates react with CO₂, in the presence of a Ru catalyst, to give the corresponding aryl carboxylic acid.⁸⁶⁶ Aryl and alkenyl boronic esters are carboxylated in the presence of a Cu catalyst.⁸⁶⁷ Vinyl halides react with CO and water, with a Pd catalyst in an ionic liquid, to give the conjugated carboxylic acid.⁸⁶⁸ Organozinc compounds are carboxylated with CO₂ and a Ni catalyst.⁸⁶⁹ Metal-free carboxylation of organozinc reagents is also known.⁸⁷⁰ In the presence of CO₂ and an organocatalyst, aromatic aldehydes are converted to the corresponding carboxylic acid.⁸⁷¹ Direct carboxylation of aryl bromides is possible using CO₂ and a Pd catalyst.⁸⁷² Allenes are converted to β,γ-unsaturated acids with CO₂ in the presence of Et₂Zn.⁸⁷³

When chiral additives (e.g., (–)-sparteine) have added to the initial reaction with the organolithium reagent, quenching with CO₂ produces carboxylic acids with good asymmetric induction.⁸⁷⁴

In a closely related reaction, *Grignard reagents* add to CS₂ to give salts of dithiocarboxylic acids.⁸⁷⁵ These salts can be trapped with amines to form thioamides.⁸⁷⁶ Two other reactions are worthy of note. (1) Lithium dialkylcopper reagents react with

dithiocarboxylic esters to give tertiary thiols.⁸⁷⁷ (2) Thiono lactones can be converted to cyclic ethers,⁸⁷⁸ for example:

This is a valuable procedure because medium and large ring ethers are not easily made, while the corresponding thiono lactones can be prepared from the readily available lactones (see, e.g., Reaction 16-63) by reaction 16-11.

A terminal alkyne can be converted to the anion under electrolytic conditions, in the presence of CO_2 , to give propargylic acids ($\text{R}-\text{C}\equiv\text{C}-\text{CO}_2\text{H}$).⁸⁷⁹

16-31 The Addition of Organometallic Compounds to $\text{C}=\text{N}$ Compounds

N-Hydro-*C*-alkyl-addition

Aldimines can be converted to secondary amines by treatment with *Grignard reagents*.⁸⁸⁰ Ketimines generally react with *Grignard reagents* to give reduction instead of addition. However, organolithium compounds give the normal addition product with both aldimines and ketimines.⁸⁸¹ The solvent and the aggregation state of the organolithium play a role in the addition, however.⁸⁸² For the addition of an organometallic compound to an imine to give a primary amine, R' in $\text{RCH}=\text{NR}'$ would have to be H, and such compounds are seldom stable. However, the conversion has been done for $\text{R} = \text{aryl}$, by the use of the masked reagents $(\text{ArCH}=\text{N})_2\text{SO}_2$ [prepared from an aldehyde, RCHO , and sulfamide, $(\text{NH}_2)_2\text{SO}_2$]. Addition of R^2MgX or R^2Li to these compounds gives $\text{ArCHR}^2\text{NH}_2$ after hydrolysis.⁸⁸³ An intramolecular version of the addition of organolithium reagents is known that gave 2-phenylpyrrolidine.⁸⁸⁴ *Grignard reagents* add to imines in the presence of various transition metal catalysts, including $\text{Sc}(\text{OTf})_3$ ⁸⁸⁵ or Cp_2ZrCl_2 .⁸⁸⁶ Alkynes add to imines yielding propargylic amines.⁸⁸⁷

When chiral additives are used in conjunction with the organolithium reagent, chiral amines are produced⁸⁸⁸ with good asymmetric induction.⁸⁸⁹ Chiral auxiliaries have been used in addition reactions of organometallic compounds to imines,⁸⁹⁰ and to oxime derivatives.⁸⁹¹ Transition metal asymmetric alkylation of imines uses metal compounds of Cu.⁸⁹² Chiral catalysts lead to enantioselective addition of alkynes to imines to give the amine.⁸⁹³ Chiral *N*-sulfinylimines reaction with lithium silanes give the α -silylsulfinylamine.⁸⁹⁴

Zinc metal reacts with allylic bromides to form an allylic zinc complex, which reacts with imines to give the homoallylic amine.⁸⁹⁵ This reaction is catalyzed by TMSCl.⁸⁹⁶ Dialkylzinc reagents add to functionalized imines to give the functionalized amine, often with transition metal catalysts (e.g., Ni compounds).⁸⁹⁷ Dialkylzinc reagents add to *N*-tosyl imines to give the alkylated tosylamine.⁸⁹⁸ In the presence of a chiral ligand, the metal-catalyzed reaction proceeds with good enantioselectivity.⁸⁹⁹ With a Cu catalyst and a chiral ligand the product is formed with good enantioselectivity.⁹⁰⁰ The reaction of imines (e.g., $\text{ArN}=\text{CHCO}_2\text{Et}$), where R = a chiral benzylic substituent and ZnBr_2 , followed by $\text{R}'\text{ZnBr}$ leads to a chiral α -amino ester.⁹⁰¹ Terminal alkynes add to imines using ZnCl_2 and TMSCl, and with a chiral ligand attached to nitrogen the reaction proceeds with some enantioselectivity.⁹⁰² Dimethylzinc has been used to mediate the addition of terminal alkynes to *N*-tosylimines.⁹⁰³

compound.⁹²⁸ Diynes add to *N*-sulfinyl imines in the presence of a chiral Rh catalyst to give the corresponding allylic sulfynylamine.⁹²⁹ Alkenes add to *N*-sulfinyl imines in the presence of a chiral Rh catalyst to give the alkylated sulfonamide.⁹³⁰

Triethylaluminum adds an ethyl group to an imine in the presence of a Eu catalyst. Reaction with PhSnMe₃ and *N*-tosylimines with a Rh catalyst leads to addition of a phenyl group to the carbon of the C=N bond.⁹³¹ Other *N*-sulfonyl imines react similarly to give the corresponding sulfonamide, and in the presence of a chiral ligand the reaction proceeds to good enantioselectivity.⁹³² *N*-Tosyl imines also react with dialkylzinc reagents, giving the sulfonamide with modest enantioselectivity.⁹³³ *N*-Sulfinyl imines [R₂CH=NS(=O)R']⁹³⁴ react with Grignard reagents at carbon to give the corresponding *N*-sulfynylamine.⁹³⁵ Furan derivatives add via C-2 with good enantioselectivity using a chiral phosphoric acid catalyst.⁹³⁶ Alkenes add to *N*-tosyl imines with a Yb catalyst⁹³⁷ and allenes add to *N*-carbamoyl imines in the presence of a V catalyst.⁹³⁸ *N*-Carbamoyl imines, formed *in situ*, react with allylic silanes in the presence of an iodine catalyst.⁹³⁹ *N*-Carbamoyl imines add acetonitrile (via carbon) using DBU and a Ru catalyst.⁹⁴⁰

Arylboronates (Reaction 12-28) add to *N*-sulfonyl imines in the presence of a Rh catalyst to give the corresponding sulfonamide.⁹⁴¹ Chiral Cu complexes have also been used for effective allylation of ketimines.⁹⁴² Aryl boronic acids (Reaction 12-28) add the aryl group to *N*-tosyl imines using a Rh⁹⁴³ or Pd⁹⁴⁴ catalyst. Arylboronic acids react similarly, and in the presence of a chiral Rh⁹⁴⁵ or Ir⁹⁴⁶ catalyst give a chiral sulfinamide or sulfonamide. Allylic boronates also add to aldehydes, and subsequent treatment with ammonia gives the homoallylic amine.⁹⁴⁷ Vinyl boronates add to nitrones in the presence of Me₂Zn, transferring the vinyl group to the C=N unit.⁹⁴⁸ Potassium allyltrifluoroborates react with *N*-tosylimines in the presence of a Pd catalyst.⁹⁴⁹

Allylic silanes (e.g., allyltrimethylsilane) add to *N*-substituted imines in the presence of a Pd catalyst to give the homoallylic amine.⁹⁵⁰ Similar results are obtained when the allylic silane and imine are treated with a catalytic amount of tetrabutylammonium fluoride.⁹⁵¹ Allylic trichlorosilanes add to hydrazones to give homoallylic hydrazine derivatives with excellent antiselectivity⁹⁵² and with good enantioselectivity using a chiral ligand.⁹⁵³ Chiral allylic silane derivatives have been developed, and add to hydrazones with good enantioselectivity.⁹⁵⁴

There is an *aza-Baylis–Hillman reaction* that converts imines and conjugated carbonyl derivatives to the α -amino conjugated derivative.⁹⁵⁵ *N*-Tosyl imines can be used in place of aldehydes, and the reaction of the imine, a conjugated ester and DABCO gave the allylic *N*-tosylimine.⁹⁵⁶ A “double *Baylis–Hillman*” reaction has also been reported using *N*-tosylimines and conjugated ketones.⁹⁵⁷ The use of chiral catalysts leads enantioselective product formation.⁹⁵⁸ An enantioselective *aza-Baylis–Hillman reaction*⁹⁵⁹ was reported using as chiral reaction medium.⁹⁶⁰ Aldehydes add via the α carbon using proline, to give β -amino aldehydes with good selectivity to give chiral β -amino aldehydes.⁹⁶¹

Silyl enol ethers add to hydrazones in the presence of ZnF_2 and a chiral ligand to give chiral β -hydrazino ketones.⁹⁶² Similar addition to imine derivatives was accomplished using ketene silyl acetals and Amberlyst-15.⁹⁶³ Alternatively, an imine is reacted first with $\text{Zn}(\text{OTf})_2$ and then with a ketene silyl acetal.⁹⁶⁴

Nitro compounds add to *N*-carbamoyl imines with a chiral diamine catalyst with some enantioselectivity.⁹⁶⁵ Nitro compounds add via carbon using a Cu catalyst, and with good enantioselectivity when a chiral ligand is used.⁹⁶⁶ The conjugate bases of nitro compounds (formed by treatment of the nitro compound with BuLi) react with Grignard reagents in the presence of $\text{ClCH}=\text{NMe}_2^+ \text{Cl}^-$ to give oximes: $\text{RCH}=\text{N}(\text{O})\text{OLi} + \text{R}'\text{MgX} \rightarrow \text{RR}'\text{C}=\text{NOH}$.⁹⁶⁷

Iminium salts⁹⁶⁸ give tertiary amines directly, via 1,2-addition to the C=N unit. Chloroiminium salts [ClCH=NR₂'Cl[−], generated *in situ* from an amide (HCONR₂') and phosgene (COCl₂)] react with 2 molar equivalents of a *Grignard reagent* RMgX, one adding to the C=N and the other replacing the Cl, to give tertiary amines R₂CHNR₂'.⁹⁶⁹

Many other C=N systems (phenylhydrazones, oxime ethers, etc.) give 1,2-addition when treated with *Grignard reagents*, while some gave reductions and others gave miscellaneous reactions. Organocerium reagents add to hydrazones.⁹⁷⁰ Indium metal promotes the addition of alkyl iodides to hydrazones.⁹⁷¹ A hydrazone can be formed *in situ* by reacting an aldehyde with a hydrazine derivative. In the presence of tetralyltin and a Sc catalysts, homoallylic hydrazine derivatives are formed.⁹⁷² Hydrazone derivatives react with iodoalkenes in the presence of InCl₃ and Mn₂(CO)₁₀ under photochemical conditions to give the hydrazine derivative.⁹⁷³ Ketene dithioacetals add to hydrazones using a chiral Zr catalyst to give a pyrazolidine.⁹⁷⁴ Oximes can be converted to hydroxylamines (**39**) by treatment with 2 molar equivalents of an alkyllithium reagent, followed by methanol.⁹⁷⁵ Oxime ethers add an allyl group upon reaction with allyl bromide and In metal in water.⁹⁷⁶ Nitrones [R₂C=N⁺(R')—O[−]] react with allylic bromides and Sm to give homoallylic oximes,⁹⁷⁷ and with terminal alkynes and a Zn catalyst to give propargylic oximes.⁹⁷⁸ *Grignard reagents* also add to nitrones.⁹⁷⁹ Nitrones react with CH₂=CHCH₂InBr in aq DMF to give the homoallylic oxime⁹⁸⁰ and silyl ketene acetals add in the presence of a chiral Ti catalyst to good enantioselectivity.⁹⁸¹

Allylic alcohols add to imines in the presence of a Pd catalyst to give the homoallylic amine.⁹⁸²

16-32 Addition of Carbenes and Diazoalkanes to C=N Compounds

In the presence of metal catalysts [e.g., Yb(OTf)_3], diazoalkanes add to imines to generate aziridines.⁹⁸³ The reaction is somewhat selective for the *cis*-diastereomer. The use of chiral additives in this reaction leads to aziridines enantioselectively.⁹⁸⁴ Imines can be formed by the reaction of an aldehyde and an amine, and subsequent treatment with Me_3SiI and butyllithium gives an aziridine.⁹⁸⁵ *N*-Tosyl imines react with diazoalkenes to form *N*-tosyl aziridines, with good *cis* selectivity⁹⁸⁶ and modest enantioselectivity in the presence of a chiral Cu catalyst,⁹⁸⁷ but give excellent enantioselectivity with a chiral Rh catalyst⁹⁸⁸ or with the use of an organocatalyst.⁹⁸⁹ Note that *N*-tosyl aziridines are formed by the reaction of an alkene with PhI=NTs and a Cu catalyst.⁹⁹⁰ *N*-Acylimines react with diazoesters via C—H insertion using a Pt catalyst.⁹⁹¹ The reaction of alkenes with diazo compounds is discussed in Reaction 15-53.

16-33 The Addition of Grignard Reagents to Nitriles and Isocyanates

Alkyl,oxo-de-nitrilo-tersubstitution (Overall transformation)

*N*-Hydro-C-alkyl-addition

Ketones can be prepared by addition of *Grignard reagents* to nitriles, followed by hydrolysis of the initially formed imine anion. Many ketones have been made in this manner, though when both R groups are alkyl, yields are not high.⁹⁹² Yields can be improved by the use of Cu(I) salts⁹⁹³ or by using benzene containing 1 equiv of ether as the

solvent, rather than ether alone.⁹⁹⁴ In general, the ketimine salt does not react with *Grignard reagents*: Hence, tertiary alcohols or tertiary alkyl amines are not often side products.⁹⁹⁵ By careful hydrolysis of the salt, it is sometimes possible to isolate ketimines ($\text{RR}'\text{C}=\text{NH}$),⁹⁹⁶ especially when R and R' = aryl. The addition of *Grignard reagents* to the $\text{C}\equiv\text{N}$ group is normally slower than to the $\text{C}=\text{O}$ group, and cyano group containing aldehydes add the *Grignard reagent* without disturbing the CN group.⁹⁹⁷ Organolithium reagents add to nitriles, mediated by LiBr, to form N-acetyl enamines.⁹⁹⁸ Other metal compounds have been used, including Sm with allylic halides⁹⁹⁹ and organocerium compounds (e.g., MeCeCl_2).¹⁰⁰⁰ Allylic halides react with an excess of Zn metal in the presence of 40% AlCl_3 and in the presence of a nitrile, to give homoallylic ketones after hydrolysis.¹⁰⁰¹

Addition of *Grignard reagents*¹⁰⁰² or organolithium reagents¹⁰⁰³ to ω -halo nitriles leads to 2-substituted cyclic imines.

The *Blaise reaction* is the reaction of the organozinc reagent derived from a α -bromoester with Zn metal and a nitrile to give the corresponding β -ketoester.¹⁰⁰⁴

The following mechanism has been proposed for the reaction of the methyl *Grignard reagent* with benzonitrile¹⁰⁰⁵:

Arylboronic acids add to nitriles in the presence of a Pd catalyst.¹⁰⁰⁶ Aryl and alkenylboronic acids add to isocyanates in the presence of a Pd¹⁰⁰⁷ or Rh¹⁰⁰⁸ catalyst.

Arenes add to nitriles in the presence of a Pd catalyst in DMSO/trifluoroacetic acid to give a diaryl ketone.¹⁰⁰⁹

The addition of *Grignard reagents* to isocyanates gives, after hydrolysis, *N*-substituted amides.¹⁰¹⁰ This is a very good reaction and can be used to prepare derivatives of alkyl and aryl halides. The reaction has also been performed with alkyllithium compounds.¹⁰¹¹

G. Carbon Attack by Active Hydrogen Compounds

Reactions **16-34–16-50** are base-catalyzed condensations (although some of them are also catalyzed to acids).¹⁰¹⁴ In Reactions **16-34–16-44**, a base removes a C—H proton to give a carbanion, which then adds to a C=O. The oxygen acquires a proton, and the resulting alcohol may or may not be dehydrated, depending on whether an α hydrogen is present and on whether the new double bond would be in conjugation with double bonds already present:

The reactions differ in the nature of the active hydrogen component and the carbonyl component. Table 16.2 illustrates the differences. Reaction **16-50** is an analogous reaction involving addition to $C\equiv N$.

16-34 The Aldol Condensation¹⁰¹⁵

O-Hydro-*C*-(α -acylalkyl)-addition; α -Acylalkylidene-de-oxo-bisubstitution

In the *aldol reaction* or *aldol condensation*¹⁰¹⁶ the α carbon of one aldehyde or ketone molecule adds to the carbonyl carbon of another.¹⁰¹⁷ Although acid-catalyzed aldol reactions are known,¹⁰¹⁸ the most common form of the reaction uses a base. There is evidence that an SET mechanism can intervene when the substrate is an aromatic
