# In Memoriam

During the making of this third edition of *The Comprehensive Sourcebook of Bacterial Protein Toxins*, Dr. Gianfranco Menestrina (Trento, Italy) unfortunately perished in a motorcycle accident on July 8, 2004. He was 50 years old. This has caused a deep loss and sadness for his family, friends, collaborators, and many of those who had any scientific exchange with him. Gianfranco Menestrina was always interested in membrane biophysics, membrane compounds, and associated regulation of osmotic compartments. He graduated in Physics in 1978 at the University of Trento, and had built his career (more than 95 published articles, many chapters of books, 30 graduated students, and 20 post-doctoral fellows) at the interface of Physics and Biology. In 2002, Gianfranco became the Director of the Section of Biophysics in Trento for the CNR Institute. He was a very active member of different Societies of Biophysics and Toxinology. He was awarded several times and received post-doctoral or visiting Professor Fellows at Universities of Bochum (G), London (UK), Wisconsin (USA), and La Habana (Cuba). His scientific interests swept across membrane-inserted polymers or peptides, with continual interest in pore-forming toxins. He was frequently chosen as a chairman in meetings and organized several meetings with recognized success.

Kind attention to anybody and caution in the language used were Gianfranco's marks. He provided a unanimous impression of an authentic man, of a true, honest, and rigorous scientist. Scientific collaboration with him and his lab was deeply fair, concerted, always sharing the goal of the best science of the moment with the environment provided. Presentation of a scientific problem or argument, an open mind, and explanations of experiments by him were always enriching, satisfying, or favoring scientific exchanges. Reliability, loyalty, friendship, fidelity, distinction, and a gentleman are words kept to the memory of Gianfranco.

Goodbye, Gianfranco; sympathies go to your family, and see you in a better world.

*Gilles Prévost and Collaborators*
*Joseph E. Alouf*
*Michel R. Popoff*

# Contents

## SECTION II: BACTERIAL PROTEIN TOXINS ACTING IN THE INTRACELLULAR COMPARTMENT OF EUKARYOTIC CELLS

## SECTION III: TOXINS ACTING ON THE SURFACE OF TARGET CELLS (EXCEPT SUPERANTIGENS)

# Preface to Third Edition

An increasingly rapid expansion of our knowledge of the multifaceted aspects of bacterial protein toxins since the end of the 20th century necessitated the publication of this third edition of *The Comprehensive Sourcebook of Bacterial Protein Toxins.*

Among the most important achievement and discovery of the past six years was the explosion of new information in many domains of toxinology, illustrated by the discovery of more than 50 novel toxins (many of them identified through genome screening), extensive bacterial genome mapping, the determination of the nucleotide sequence of encoding genes and corresponding amino acid sequences, genetic regulation of toxin expression, genomic pathogenicity islands, identification of many toxin receptors at the surface of eucaryotic cells, toxin-induced modulation of various components, and effectors of intracellular signal transduction pathways and apoptotic events. Establishment of the three-dimensional crystal structure of more than 20 toxins during the same period allowed deeper knowledge of structure-activity relationships and provided a framework for understanding how toxins recognize receptors, penetrate membranes, and interact with and modify intracellular substrates. Moreover, the study of the structure of newly identified toxins demonstrated that toxins, which modify the cellular signaling pathways, possess the same active sites (functional mimicry) as those of corresponding cell proteins but with a different folding conformation. These new findings allow a better understanding of the mechanism of action of bacterial toxins at the subcellular level. In addition, bacterial toxins are extremely specific and exquisite tools to unravel physiological cell processes.

Recent progress also contributed to a better definition of major issues, namely toxin transcytosis and trafficking in eucaryotic target cells, mechanisms of action at the cellular and molecular levels, genetic and molecular mechanisms of toxin involvement in the virulence and pathogenicity of the relevant bacteria in many human diseases (cholera, anthrax, whooping cough, tetanus, botulism, diptheria, clostridial gas gangrenes, severe diseases caused by superantigenic toxins, *Helicobacter pylori*-associated peptic ulcers and carcinomas, food poisons, etc.). In this respect, the targeting of immune system cells by various toxins led to a better evaluation of both their beneficial effects (for example as immunomodulators in the case of cholera toxin B subunit) and pathophysiolgical effects in certain diseases in connection with the immune system. Finally, the past years witnessed considerable progress on toxin applications in vaccinology, tumor therapy, and new approaches in the treatment of various diseases. Whether some wild-type toxins can be directly used as therapeutic agents, protein engineering permits us to model more specific and efficient molecules or molecules with a novel activity, or to target a restricted subset of cell population. Novel recombinant toxins are already proposed in the treatment of some diseases, as well as new vaccines. One should also not forget the emergence of certain bacterial toxins as biological weapons (era of bioterrorism threats). This issue is considered in chapters dedicated to the relevant toxins (anthrax toxins, botulinal neurotoxins, the Shiga-like plant toxin, ricin) and is also discussed in a specific chapter.

The third edition of the *Sourcebook* is a genuine, timely production comprising 62 chapters (compared to 40 and 20 of the 1999 and 1991 editions, respectively) that are organized into five sections. They are written by a panel of 137 international experts (senior authors and coauthors), who have significantly contributed to the progress within their featured disciplines. About 55% of all contributors are new specialists who did not contribute to the preceding editions of the *Sourcebook*. Authors are from Australia, Belgium, Canada, the Czech Republic, France, Germany, Italy, Japan, New Zealand, Norway, Sweden, Switzerland, the United Kingdom, and the U.S.A.

As editors, we are keen to provide the reader with a sound, authoritative, and interdisciplinary review highlighting the major advances in the field of bacterial protein toxins. Whenever possible, particular emphasis was placed on toxin involvement in the pathogenesis of the diseases caused by the relevant bacteria. At the same time, 14 totally new chapters were created to cover the historical and general aspects of toxinology.

We hope the *Sourcebook* will appeal to a wide readership, including microbiologists and particularly toxinologists, biochemists, cell biologists, clinicians, and medical students who wish to have a better understanding of bacterial toxins in relation to infectious diseases.

We are heavily indebted to all contributors who skillfully documented developments at the cutting edge of their disciplines. Their painstaking efforts are deeply appreciated.

We wish to express our deep thanks to Tessa Picknett, Senior Publisher at Academic Press, Elsevier and her coworkers, Bryony Lott, Victoria Lebedeva (London), and Jeff Freeland (Burlington, USA) for their encouragement and invaluable help through the preparation of this volume.

*Joseph E. Alouf and Michel R. Popoff*

# Preface to Second Edition

It is now eight years since the publication of the first edition of *The Comprehensive Sourcebook of Bacterial Protein Toxins*, and during that period many previously well-recognized toxins now constitute the prototypes of toxin families which share common mechanisms and, most probably, common evolutionary origins (e.g. the RTX toxins, STs and LTs of enterobacteria). Of great significance in this context was the recent recognition of pathogenicity islands which are responsible for the mobility and horizontal spread of toxins and other virulence genes between closely related species. Further remarkable progress has been made in the definition of molecular mechanisms of a wide range of toxins, with increasing numbers having enzymic mechanisms revealed, including ADP-ribosylation and glycosylation of novel targets (e.g. small Ras G-proteins). Among the most exciting discoveries of the 1990s, simply because it explained the potency of botulinum and tetanus toxins which have challenged toxinologists for over 100 years, was the demonstration that they consist of Zn-proteinases of exquisite specificity, cleaving proteins associated with vesicle fusion at presynaptic membranes. We now have the three-dimensional structure of botulinum toxin, which should yield further detailed information on the functional domains of these fascinating molecules.

The host immune system is not only the primary defence against colonization, and sometimes invasion, by toxigenic bacteria but it also constitutes the major target for a growing repertoire of bacterial toxins which can act either directly by cytoxicity towards immune effector cells (e.g. the leucocidins of *Staphylococci* and the leucotoxins of *Pasteurellae*) or by more subtle routes involving deregulation of cytokine production (e.g. the superantigenic toxins of *Staphylococci* and *Streptococci*).

Genome analysis promises to identify many more toxins over the next decade and should provide rich pastures for functional analysis in the next century. These analyses undoubtedly offer new opportunities for use as tools to dissect cellular processes as well as novel potential therapeutic agents.

A volume such as the *Sourcebook*, although attempting to cover the major groups of toxins at a relatively detailed level, inevitably has some gaps, and if these occur in your favorite area of research, then we can only apologize. The content of the book always reflects a compromise between what the editors would like and what they are able to include, yet still meet the deadlines set for the production of the book. We are greatly indebted to all the contributors, especially to those who met the first submission deadline. We wish to record our thanks to Tessa Picknett at Academic Press, who initiated the second edition, and to Lilian Leung who saw the project through to a successful conclusion with persistence and good humour. We also thank Mrs. Patricia Paul for invaluable secretarial work in compiling chapters and correspondence with authors.

# Preface to First Edition

Great strides have been made in the depth of our understanding of the structure and mechanisms of action of bacterial toxins over the last decade. The current pace of this advance in knowledge is particularly impressive, and results largely from the power that gene manipulation techniques have offered in experimental biology.

Recent research achievements in the field of bacterial toxins, which consist of about 240 protein toxins as well as a relatively small number of non-protein toxins, reflect the extensive and productive blending of disciplines such as molecular genetics, protein chemistry and crystallography, immunology, neurobiology, pharmacology and biophysics. Furthermore, the exciting developments in many areas of cell biology, and particularly in membrane-associated mechanisms relating to signalling and communication, export and import of proteins and to cytoskeletal functions, have been facilitated because critical steps in these processes constitute the targets for bacterial toxins. Thus, we have toxins available which can be used to probe many fundamental aspects of eukaryotic cell biology.

Disruption of these same central cellular processes *in vivo* can also be the critical event in the pathogenesis of infectious diseases for man or domestic animals. Many such infectious diseases have major social or economic impacts on man, and such considerations have quickened the pace of the search for therapeutic agents. Currently, a number of physically inactivated bacterial or hybrid engineered toxoids are used as immunogens in vaccination programmes, and there is a major international effort to develop new and more effective vaccines based on our deeper understanding of the molecular events in pathogenesis and the host response to infection.

Since the publication of the excellent multi-volume treatise on *Bacterial Toxins* edited by S. Ajl, S. Kadis and T. Montie (Academic Press) in the early 1970s, most of the books published in the past twenty years have covered the subject by presenting individual toxins or groups of toxins in separate chapters. This is not the main approach followed in this book. Our aim is not to give an exhaustive review of the wide spectrum of the protein toxin repertoire but rather to give an "in depth" critical review of the original and the newly expanding body of information accumulated during the past decade or so. The multifaceted aspects of toxin research and the multidisciplinary approaches adopted suggested to us that "state of the art" toxin research might best be presented by putting together in several chapters the common structural and/or functional aspects of toxin "families". Other chapters highlight the various physiological or genetic mechanisms regulating toxin expression and the therapeutic or vaccine applications of genetically engineered toxins.

The 22 chapters of this book have been written by 44 internationally known specialists who have significantly contributed to the progress in the domains covered. It is hoped that this book will appeal to a wide readership, including microbiologists, biochemists, cell biologists and physicians. Also, we hope it will arouse the interest of students and scientists in other disciplines who see the power of these fascinating biological agents, either as exquisitely specific probes of cellular processes or as extremely potent agents of infectious disease.

Finally, we would like to thank all the authors for their contributions, and particularly to those who delivered their manuscripts by the first deadline. We also express our appreciation to the editorial staff at Academic Press for their help and patience throughout the preparation of this book.

*J.E. Alouf and J.H. Freer*

# Introduction

Since the second edition of *The Comprehensive Sourcebook of Bacterial Protein Toxins* was published in 1999, major world events have impacted research on infectious agents, including pathogenic bacteria and their toxins. Most notably, the anthrax-tainted letters delivered via the United States Postal Service in the fall of 2001 sent a shock wave around the world. Although the letters produced only limited morbidity and mortality (22 cases of anthrax, 5 of which were fatal), they caused massive and costly disruption of the United States postal and legislative systems, and exacerbated the terror resulting from the attacks with airliners on the World Trade Center and the Pentagon. As a consequence, there has been a general widespread recognition of the threats from infectious diseases and a major reorientation in priorities for funding biological research. This is exemplified by the establishment of a set of Regional Centers of Excellence for Biodefense and Emerging Infectious Diseases Research across the United States under National Institutes of Health sponsorship. The number of laboratories performing research on the causative agents of anthrax, smallpox, and other diseases on the A, B, and C "select lists" has increased dramatically, of course.

In facing the threats of bioterrorism, emerging infectious diseases, and ancillary problems, such as antibiotic resistance, the international community of scientists is fortunate in being able to draw on a rapidly expanding body of knowledge about pathogenesis. The past several decades have seen a major rise in interest in infectious disease research, due perhaps more than anything else to the development and convergence of methods directed primarily towards answering questions in basic science. The protein toxins produced by bacteria represent an interesting focus to illustrate this point. These toxins have always been of interest from the biological and medical communities, but in recent decades have also attracted biochemists and biophysicists expert in the array of tools developed to examine protein structure and function—x-ray crystallography, fluorescence spectroscopy, directed mutagenesis, mass spectrometry, and so forth. As a result, we now know the atomic level structures of a great many of these proteins, and are rapidly coming to understand their conformational dynamics and the details of their molecular interactions with host molecules (receptors, substrates, etc.). Cell biologists have brought to the table a complementary set of tools—confocal microscopy and fluorescent markers, for example, to track the attachment, entry, and trafficking of toxins. Along the way, the neurobiologists have become interested because some toxins form pores, resembling ion channels, in membranes. And the details of the molecular structures and of molecular and cellular function present questions of mode of action at tissue and organismal levels in a new, more precisely defined form to the physiologists and pathologists. As all of this is occurring, questions pertaining to the array of toxins encoded in bacterial genomes, or in mobile genetic elements, and how their production is controlled, and how they are secreted from the bacteria, are being solved through the application of molecular genetics. This grand evolving body of knowledge presents the scientist seeking to develop new countermeasures to biological threat agents, be they microbes or their toxins, with unprecedented opportunities for dissecting their own individual systems.

As in the previous editions, the third edition of *The Comprehensive Sourcebook of Bacterial Protein Toxins* serves to compile the latest and most relevant information to inform, stimulate, and excite, the researcher, the teacher, and the student.

*R. John Collier*

# INTRODUCTORY SECTION

CHAPTER

# 1

# A 116-year story of bacterial protein toxins (1888–2004): from "diphtheritic poison" to molecular toxinology

*Joseph E. Alouf*

*To the physiologist the poison becomes an instrument which dissociates and analyzes the most delicate phenomenon of living structures and by attending carefully to their mechanism in causing death, he can learn indirectly much about the physiological processes of life.*

*Claude Bernard*, La Science Experimentales, *Paris, 1878*

## INTRODUCTION

The concept that pathogenic bacteria might elicit their harmful effects in humans and animals by means of poisons elaborated by these microorganisms in the infected host is almost as old as the notion of pathogenic bacteria itself (William Edward van Heyningen 1950, 1970). The heuristic impact of the concept of bacterial poisons was considerable after the discovery of bacteria and their relation to disease. It was undoubtedly influenced by the knowledge that other biological organisms do produce poisons such as animal venoms and plant alkaloids. Indeed, the idea that the harm caused by infectious disease might be due to microbial poisons was entertained long ago even before the germ theory of disease was established. Both endotoxins and exotoxins were foreseen in 1713 by Vallisnieri, who suggested on one page of his *Riposta* that the "little worms of the most atrocious pests are of themselves of a poisonous nature" (van Heyningen, 1955).

The first attempts to demonstrate experimentally the production of bacterial poisons were undertaken by Edwin Klebs (1834–1913) for staphylococci, Robert Koch (1843–1910) for *Vibrio cholereae*, and Friedrich Loeffler (1852–1915) for diphtheria bacillus, respectively. These attempts failed for methodological reasons that are now understandable.

Klebs (1872) suggested that chemical substances named "sepsins" were responsible for the lesions caused by staphylococci, but no evidence for the existence of such substances was found. The first experimental demonstrations of staphylococcal toxin(s) were reported later by von Leber (1888), De Christmas (1888), van de Velde (1894), and other microbiologists by the early 1900s (see Arbuthnott, 1970).

As concerns cholera, Koch (1884) expressed the view that the disease was a toxicosis, since the causative organism proliferated in the gut without appearing to invade or damage this organ or any of the neighboring tissues. Parenteral injection of *V. cholereae* filtrates did not produce any toxic effects in experimental animals, and the idea of an extracellular poison was abandoned. However, 75 years later, Koch's hypothesis was confirmed when two Indian researchers, De (1959) and Dutta *et al*. (1959) working independently of one another, showed that cell-free preparations from *V. cholerae* caused relevant symptomatology in animal models (adult rabbit ligated loop and infant rabbit, respectively). In 1969, the putative toxin was purified and biochemically characterized by

Finkelstein and Lo Spalluto (1969). Fourteen years later, the cloning and nucleotide sequence of the toxin was determined by Mekalanos *et al*. (1983). Cholera toxin, an 84-kDa oligomeric protein; is the prototype of a wide family of biochemically, immunologically, and pharmacologically related toxins found in human and porcine *E. coli* strains, non 01 *V. cholerae*, *V. mimicus*, *Aeromonas hydrophila*, *Campylobacter jejuni*, *Salmonella enterica serovar typhi*, and *typhimurium* and *Plesiomonas shigelloides* (Sears and Kaper, 1994 and Chapter 19 of this volume).

The same year of Koch's hypothesis, Loeffler (1884) suggested that a soluble poison was the causative agent of diphtheria. This author who had discovered diphtheria bacillus reported that in animals that died after experimental infection, the microorganism remained at the seat of inoculation and was totally absent from the internal organs. Nevertheless, these organs were profoundly damaged ("hemorrhagic edema, effusion into the pleural cavities, catarrhal inflammation of the kidneys, and deep reddening of the suprarenal capsules"). Loeffler concluded that "this clearly indicated that a poison at the seat of inoculation must have circulated in the blood." However the putative poison was not found.

## REPERTOIRE OF BACTERIAL PROTEIN AND PEPTIDE TOXINS (1888–2004)

This repertoire comprises so far 339 members including natural variants, serotypes, isoforms, and allelic forms, namely 160 (47%) from Gram-positive bacteria and 179 (52%) from Gram-negative bacteria. Most of them (85%) are extracellular or cell-associated and the rest (15%) are intracellular. As established in the past 30 years, many toxins were found to possess a variety of enzymatic activities (Table 1.1).

## DISCOVERY OF THE FIRST BACTERIAL PROTEIN TOXINS: DIPHTHERIA, TETANUS, AND BOTULINAL TOXINS (1888, 1890, 1896)

### Diphtheria toxin

In 1888, fortune smiled on Emile Roux (1853–1933) and Alexandre Yersin (1863–1943). At Pasteur Institute, these researchers discovered the first bacterial toxin, namely diphtheria toxin (Roux and Yersin, 1889), six months after the creation by Louis Pasteur (1822–1895) of this "Temple of Science." The "diphtherial poison" was detected in sterile filtrates of diphtheria bacillus (*Corynebacterium diphtheriae*). The filtrates or the material isolated by cadmium chloride precipitation from old alkaline cultures injected into guinea pigs, rabbits, and pigeons mimicked the symptoms and type of death produced by infection with living organisms. Moreover, Roux and Yersin demonstrated that the urine of children taken shortly before death from diphtheria may contain sufficient toxic material to kill guinea pigs with symptoms similar to those elicited by culture filtrates. The earlier prediction of Loeffler was thus verified. For the first time, the mechanism of pathogenicity of a microorganism in humans became clarified and could be explained in terms of a soluble toxic substance released by bacteria named for the first time a *toxin* by the authors (from Greek: τοξιχον, poison) (van Heyningen, 1970). However, according to Carl Lamanna (1990), the term *toxin* was first used in 1886 by E. Ray Lankester in *Science* to name "poisons for animals produced by pathogenic bacteria." Very likely, Roux and Yersin were not aware of Lankester's article.

#### *Rational design and serendipity*

The seminal discovery of the "diphtheritic poison" was the fruit of both rational design and serendipity. The culture medium used for bacterial growth was prepared with Paris city tap water, which was known to contain high amounts of calcium. Autoclaving led to the precipitation of calcium phosphate and thereby the lowering of iron concentration in the medium, which empirically favored diphtheria toxinogenesis, as reported ca. 40 years later by Locke and Main (1931), Pope (1932), and Pappenheimer and Johnson (1936). Toxin production was maximal under iron starvation conditions and was severely inhibited under high–iron growth conditions. It is interesting to report how Pappenheimer discovered the "iron effect." He found that cultures growing on a particular medium would produce toxin one day and fail to produce it on the "same" medium the next day. Then his laboratory received a supply of new hard-glass bottles, and in these, toxin was produced without fail. When small amounts of crushed glass from the soft-glass bottles were introduced in the new bottles, toxin production went down. It was found that the inhibition of toxinogenesis was due to the high iron content of the soft glass.

The discovery of the iron effect in the 1930s was a very important event in the history of bacterial toxins (Alouf and Raynaud, 1960). It paved the way for a number of major achievements in toxinology over the past 50 years.

Freeman (1951) discovered that diphtheria toxin is encoded by a bacteriophage gene *tox*+ called β (see

**TABLE 1.1** Toxins exhibiting enzyme activity

**1. ADP-RIBOSYLATING TOXINS**
Transferase and NADase activity
Ref. Han and Tainer (2002); Masignani *et al*. (2004) and Chapter 12 of this volume

**2. PHOSPHOLIPASES**
Cytolytic phospholipases C: *C. perfringens* zinc-dependent α-toxin, *C. sordellii* γ-toxin, *C. novyi* β and γ-toxins, *C. heamolyticus*, *P. aeruginosa*, *P. aureofaciens*, *A. hydrophila, B. cereus, Acinetobacter calcoaceticus* haemolysins
*Vibrio damsela* cytolytic phospholipase D
*Rickettsia prowazekii* haemolytic phospholipase A
*S. aureus* β-toxin (haemolysin, sphingomyelinase)
*Corynebacterium ovis* lethal toxin (phospholipase D)
*Yersinia pestis* murine toxin (phospholipase D)

**5. RNA *N* -GLYCOSIDASES**
*S. dysenteriae* shiga toxin, *E. coli* shiga-like toxins (verotoxins: Stx 1, 1c, 2, 2c, 2d, 2e) and similar toxins from *Aeromonas hydrophila, A. cassia, Enterobacter cloacae, Citrobacter freundii;* ricin and other plant toxins
Ref. Endo (1988); Tesh and O'Brien (1991); O'Loughlin and Robins-Brown (2001)

**6. GLUCOSYL TRANSFERASES**
*C. difficile* A, B toxins, *C. sordellii* and *C. novyi* lethal α-toxin
Ref. Aktories (2003); von Eichel-Streiber *et al*. (1996); Selzer *et al*. (1996)

**7. DEAMIDASE ACTIVITY**
*E. coli* cytotoxic necrotizing factor-1
Ref. Flatau *et al*. (1997); Schmidt *et al*. (1997)

**8. PROTEASE ACTIVITY**
*S. aureus* epidermolytic toxins (exfoliatins) serotypes A, B, C, D; *S. hyicus* exfoliatins at least six serotypes; SHETA, SHETB, Exha, Exhb, Exhc, Exhd
Enteroaggregative *E. coli* pet toxin; *S. pyogenes* cysteine proteinase
Ref. Melish *et al*. (1974); Yamaguchi *et al*., (2002); Ladhani *et al*. (2002); Hanakawa (2004); Ahrens and Andresen (2004); Villaseca *et al*. 2000; Gerlach *et al*. (1994) and Chapter 56 of this volume.

**9. DEOXYRIBONUCLEASE ACTIVITY**
Cytolethal distending toxins (18 members at least from various Gram-negative bacteria)
Ref. Johnson and Lior (1988a); Pickett and Whitehouse (1999); Dreyfus (2003); Thelestam and Frizan (2004) and Chapter 23 of this volume.

Groman, 1953; Barksdale and Arden, 1974). Then Murphy *et al*. (1978) and Welkos and Holmes (1981) demonstrated that the regulation of toxin expression by iron occurred at the level of *tox* gene transcription under the control of a chromosomal *dtxR* gene encoding a diphtheria toxin repressor (see White *et al*., 1998; Goranson-Siekierke and Holmes, 1999; and Chapter 13 of this volume).

Since the pioneering works on the involvement of iron in the regulation of bacterial toxingenesis, a great number of investigations have been undertaken for other toxins or virulence factors whose synthesis is negatively regulated by iron. This is the case of *Shigella dysenteriae* shiga toxin, *Escherichia coli* Shiga-like toxin-1, and hemolysin, *Vibrio cholerae* hemolysin, *Pseudomonas aeruginosa* exotoxin A, *Clostridium tetani* tetanus toxin, *Helicobacter pylori* VacA cytotoxin, *Plesiomonas shigelloides* CHO cell elongation factor (Hantke *et al*., 2001; Payne, 2003).

### *"What is the nature of the diphtheric poison? Is it an alkaloid or a diastase?"*

Roux and Yersin (1888) addressed these questions and suggested that because of its heat lability, the toxin resembled an enzyme ("diastase") more than an alkaloid. However, eighty years intervened before it was finally proved independently in two laboratories (Honjo *et al*., 1968; and Gill *et al*., 1969) that diphtheria toxin is, in fact, a highly active enzyme of a novel and unique type (Collier, 1975). The toxin inhibits eucaryotic protein synthesis by catalyzing the covalent transfer of the ADP-ribose portion of nicotinamide (NAD) to elongation factor 2, which in the case of diphtheria toxin leads to target cell death. Interestingly, prior to this very important achievement the pioneering experiments of Lennox and Kaplan (1957) and Placido-Souza and Evans (1957) showed that the toxin was lethal for cells in culture from sensitive animals. Then, the elegant experiments of Strauss and Hendee (1959) on HeLa cells provided the first indication that cell death resulted from the inhibition of protein synthesis by diphtheria toxin (see Collier, 1977 for a comprehensive review of this issue).

### *Diphtheria toxin: eponymous archetype of a vast class of bacterial toxins and virulence factors*

The pioneering discovery of the ADP-ribosyltransferase activity of diphtheria toxin opened a new era in

our knowledge of bacterial toxins, their mode of action, and their role in the pathogenesis of various infectious diseases (Barbieri and Burnes, 2003). Indeed, this toxin is the first member and the prototype of a vast family of conserved ADP-ribosyltransferases (ADPRTs) from various bacterial pathogens that display a variety of pharmacologic, physiologic, and toxic activities toward humans and (or) animals. These effectors constitute an immense potential for modern biomedical research.

## Discovery of clostridial neurotoxins

Two other major toxins were to follow soon after the discovery of diphtheria toxin: tetanus toxin in 1890 and botulinum toxin in 1896, produced by *Clostridium tetani* and *Clostridium botulinum*, respectively.

### *Tetanus toxin*

Tetanus was recognized since ancient times and described by Hippocrates who first reported the symptoms of a sailor affected by a syndrome characterized by hypercontraction of the skeletal muscles. He termed such a spastic paralysis "tetanus" (from the Greek word τετανυσ, tension).

A "clinical" description of the disease was remarkably illustrated by the Scottish surgeon Sir Charles Bell in his book *The Anatomy and Philosophy of Expression* published in 1832. In 1884, Carle and Rattone showed that tetanus could be transmitted from a human suffering from the disease to a rabbit injected with material from the wound. Implantation of soil samples into mice or rabbits caused symptoms of tetanus. In smears from the wound, *drumstick* forms (*clostridium* in Latin) of *C. tetani* were first observed by Nicolaier (1884), who noted that the microorganism was not distributed in the whole organism, but confined to the wound of entry. Simpson had already observed in 1856 that the symptoms of tetanus were similar (as confirmed later) to those of strychnine poisoning and in 1885 Nicolaier suggested that the microorganism brought about its pathological effects by producing a strychnine-like poison. In 1889, Shibasaburo Kitasato (1852–1931) obtained a pure culture of the bacterium in Robert Koch's laboratory in Berlin.

The toxin was discovered in 1890 in culture supernatents in Denmark by Knud Faber and in Italy by Tizzoni and Cattani (1890). Faber justified Nicholaier's suggestion by showing that it was possible to reproduce the spastic symptoms of tetanus in experimental animals by injecting them with sterile filtrates of cultures of the bacillus (van Heyningen and Mellanby, 1971). The toxin producing these effects was also named *tetanospasmin* (for other references see Rossetto *et al*., 2001; Lalli *et al*., 2003). The toxin was shown by Bruschettini (1897) to move retroaxonally and to act at the spinal-cord level. Active immunization with formaldehyde-treated tetanus toxin was undertaken by Ramon and Descombey (1925).

*Tetanus and diphtheria antitoxins: the birth of serotherapy and experimental immunology*

In December of the same year, Behring and Kitasato (1890) in Berlin rendered mice and rabbits resistant to the toxic effects of tetanus and diphtheria toxins by inoculating the animals with small doses of toxin preparations attenuated by "Gram liquor" (iodine). The sera of the "immunized" animals not only specifically neutralized the toxins, but still did so when transferred into the bodies of "native" animals challenged with the native toxins. This experiment revealed for the first time the production of neutralizing "Antikörper" (antibodies) and led to the development of serotherapy and to the birth of experimental immunology. In 1884, Emile Roux announced the large-scale production of horse immune sera (antitoxins) for the serotherapy of diphtheria (Roux and Martin, 1884). This was also the case for the preparation of large amounts of antitetanus antitoxins by Behring (1892).

*Diphtheria and tetanus toxoids*

Another epochal achievement was the independent development of toxoids by Glenny and Sudmersen (1921) in the United Kingdom and Gaston Ramon (1923; Ramon and Descombey, 1925) in France for use in human vaccination. Since then mass immunization with diphtheria and tetanus toxoids has led to a remarkable decrease of the two diseases in developed countries. Unfortunately, around 500,000 annual cases of tetanus (particularly neonatal) are still reported in countries of the Third World for lack of vaccination.

### *Botulinum toxins*

Botulism (*sausage poisoning* in Latin) is the term given to an acute food poisoning caused by the ingestion of spoiled sausages (*botulus)* that has been known as long as 1,000 years ago. The Byzantine Emperor Leo VI (886–911 A.D.) forbade the preparation and eating of blood sausages.

Centuries later (1793) in Württemberg, an outbreak affected 13 persons, six of whom died. The outbreak was attributed to blood sausage consumption; thereby the preparation of this food came under strict government regulation.

In 1820, Justinus Kerner, a poet turned physician and medical officer for the Duchy of Württemberg, reported 200 cases of sausage poisoning.

The etiology of botulism was elucidated in 1895 by the Belgian microbiologist van Ermengen of the University of Ghent in his investigation of a tragic outbreak of botulism in Ellezelles (Belgium) that involved 50 cases among members of a musical society who partook of a meal at a funeral. Three of them died and at least 10 were seriously ill (van Ermengen, 1897).

The outbreak was caused by a salt-cured uncooked ham. Portions of macerated ham fed to mice, guinea pigs, and monkeys caused paralytic signs of the illness observed in the patients and subsequently resulted in death. Filtered extracts of the ham had the same effects as the macerated ham.

Van Ermengem consistently found an anaerobic sporulating bacillus in cultures of the ham, as well as in a culture of the spleen from one of the deceased victims. The organism was named *Bacillus botulinus* and thereafter, *C. botulinum*. Culture filtrates had the same effect as did ham macerates (Sakagushi, 1986; Rossetto *et al*., 2001).

*Discovery of different types of botulinum toxins*

In 1904, 11 persons died from eating wax-bean salad in Darmstadt (Germany). The antitoxin serum prepared against the Ellezelles strain did not neutralize the toxin from the Darmstadt strain and reciprocally. Thus, the toxins from the two strains were immunologically distinct (Leuchs, 1910) and were later classified into types A and B (Meyer and Gunnison; 1929 in Sakaguchi's chapter). Type B corresponded to the Ellezelles strain. Types C and D were characterized by Bengston (1922) and Theiler (1927). Types E and F were identified by Gunnison (1936) and Dolman and Murakami (1961), respectively. Type G was isolated from a soil sample collected in Argentina (Giménez and Sicarelli, 1970). (See Sakagushi, 1986; Popoff and Marvaud, 1999; Herreros *et al*., 1999 for references.)

*Recent developments of the research on clostridial neurotoxins*

Great advances in our understanding of the molecular mechanisms of action of these neurotoxins have been made in the past 15 years. Both toxins are structurally related 150-kDa zinc-dependent metalloproteases consisting of three domains, endowed with different functions: neurospecific binding, membrane translocation, and specific proteolysis of three key components of the neuroexocytosis apparatus. After binding to the presynaptic membrane of motoneurons, tetanus neurotoxin (TeNT) is internalized and transported retroaxonally to the spinal cord, where it blocks neurotransmitter release from spinal inhibitory interneurons. In contrast, the seven botulinum neurotoxins (BoNT) act at the periphery and inhibit acetylcholine release from peripheral cholinergic nerve terminals. TeNT and BoNT-B, -D, -F, and -G cleave specifically at single but different peptide bonds, VAMP/synaptobrevin, a membrane protein of small synaptic vesicles. BoNT types -A, -C, and -E cleave SNAP-25 at different sites within the COOH-terminus, whereas BoNT-C also cleaves syntaxin. BoNTs are increasingly used in medicine for the treatment of human diseases characterized by hyperfunction of cholinergic terminals (see Rossetto *et al*., 2001; and Chapters 19 and 20 of this volume). The genes encoding botulinum and tetanus neurotoxins have been widely investigated during the past 25 years as recently reviewed by Raffestin *et al*. (2004). BoNT -A,-B, -E, and -F are encoded by chromosomal genes; BoNT -C and -D are encoded by bacteriophages, while BoNT-G and tetanus neurotoxin genes are localized on large plasmids in *C. argentinense* and *C. tetani*, respectively. Moreover, the regulatory genes involved in the production of clostridial neurotoxins have been recently identified (Raffestin *et al*., 2004). The three-dimensional crystal structure of BoNT-A, -B, and -E and tetanus toxin was determined by the end of the 1990s (Table 1.2).

## TOXIN RESEARCH BETWEEN 1900 AND 1975

Since the discovery of the first three major bacterial protein toxins, about 100 new protein toxins produced by a number of Gram-positive and to a lesser extent from Gram-negative bacteria were identified during the first half of the twentieth century. Much effort was particularly focused on anaerobic clostridial species and their toxins as a result of the experience gained during World War I gas gangrene on the battle field. Research on other toxins during the 1900–1965 period was also developed on toxinogenic anaerobes and certain aerobic bacterial pathogens, such as staphylococci, streptococci, *Bacillus anthracis*, and on various membrane-damaging toxins from both Gram-positive and Gram-negative bacteria.

### *Clostridia*

The genus *Clostridium* encompasses over 80 species of Gram-positive, anaerobic spore-forming bacteria. Fifteen account for a wide range of diseases in humans and animals by virtue of their capacity to produce highly potent extracellular protein toxins that are responsible for the pathogenicity of the microorganisms. The toxinogenic species listed below were identified over a period of about 100 years. To date, 60 toxins have been characterized (Hatheway, 1990 and Table 1.3).

**TABLE 1.2** Three-dimensional structure of crystallized toxins established to date (2004)

1. *P. aeruginosa* exotoxin A (1986). Allured,V.S. *et al. Proc. Nat. Acad. Sci*. **83**, 1320

### *Clostridial gas gangrene*

*C. perfringens* and *C. septicum* are the most representative among the five pathogenic species of the clostridia that cause gas gangrene. The latter causes a form of gangrene in the absence of any external trauma, while the former is the causative agent of traumatic gangrene after deep penetration, invasion, and destruction of healthy muscles (van Heyningen, 1955; Mac Lennan, 1962; and Chapter 56 of this volume).

*Clostridium perfringens*

This microorganism is historically the main source of one of the major bacterial protein toxins, namely the lethal and hemolytic α-toxin. *C. perfringens* has been known for decades as *Clostridium welchii* in honor of the American pathologist William Henry Welch (1850–1934), who provided the first extensive description of the microorganism. Although this organism was first cultured probably as early as 1891 by Achalme, this author did not make a connnection to gangrene. One year later, Welch and Nuttal (1892) reported the discovery of what they called a strain of *Bacillus aerogenes capsulatus* found in gas-containing blood vessels during post-mortem examination of a corpse of a 38-year-old bricklayer (see Derewenda and Martin, 1998). Gangrene made its most widespread appearance 22 years later during World War I (MacPherson *et al*., 1922). Using strains from the battlefront, Bull and Pritchett (1917) conducted a series of studies that led them to conclude that "the cause of death in the infection is not a blood invasion of the microorganisms but an intoxication with definite and very potent poisons produced in the growth of the bacilli in the tissues of the body." At the end of the 1960s, the bacterium was named *C. perfringens*.

It took two decades of research to conclude that the culture broth contained a varying number of toxins, among them α-toxin, the prominent toxin of this species. As many as 17 exotoxins have been described so far in the literature (McDonel, 1980; Hatheway, 1990; Songer, 1996). A crude *C. perfringens* toxoid vaccine was demonstrated to provide protection as early as 1937 by Penfold and Tolhurst.

*Discovery and characterization of C. perfringens α-toxin*

Historically, this toxin was one of the major bacterial protein toxins. The toxin was first characterized as a lethal and hemolytic toxin by Nagler (1939), Seiffert (1939), and van Heyningen (1941), who observed its interaction with serum lipids and egg yolk suspensions. An important breakthrough was the seminal discovery by Marjorie Giffen Macfarlane and Knight (1941) that the α-toxin is "a lecithinase which decomposes lecithin into phosphocholine and a diglyceride." This finding constitutes an important landmark in toxinology and for the first time, the mode of action of a protein toxin was elucidated at the molecular level. Other discoveries by Macfarlane were soon to follow (1948, 1950), as she identified the phospholipase activity of *C. oedematiens, C. sordellii*, and *C. haemolyticum. C. perfringens* α-toxin is currently considered as the prototype of the 15 cytolytic bacterial protein toxins so far identified that disrupt eucaryotic cell membranes by hydrolysis of their constitutive phospholipids (Table 1.1). This toxin belongs to the family of the zinc metallo-phospholipases (Titball, 2000; and Chapter 27 of this volume). Its crystal structure has been recently established (Naylor *et al*., 1998).

## Group A streptococci (*Streptococcus pyogenes*)

This species produces two types of toxins:

1. The membrane-damaging cytolysins, streptolysins O and S were discovered as early as 1902 by Marmorek and clearly differentiated in the 1920s and 1930s (Neill and Mallory, 1926; Todd 1938). These toxins are described in a comprehensive review (Alouf, 1980) and in Chapters 26, 38, and 42 of this volume.
2. A series of imunocytotropic toxins of the family of superantigens (see Alouf, 1980 section IV; and Chapters 51 and 53 of this volume), the prototype of which is the streptococcal erythrogenic toxin A, which plays an important role in streptococcal pathogenicity and diseases (Cunningham *et al*., 2000; Bisno *et al*., 2003).

### *Streptococcal erythrogenic toxin*

The pioneering work of George F. Dick and Gladys Henry Dick (1924), who provided the proof that streptococci, identified later as group A streptococci (*S. pyogenes)*, are the causative agent of scarlet fever, constitutes an important hallmark in bacterial toxinology and the microbiology of infectious diseases. The Dicks were also the discoverers of the so-called "scarlet fever toxin" (Dick and Dick, 1924 a, b) recently named streptococcal pyrogenic exotoxin (SPE) by certain authors (Schlievert and Gray, 1989; Mc Shan, 1997). Three immunologically different toxin serotypes A, B, and C have been reported (Watson, 1960). Toxin B was later found to be a cysteine proteinase devoid of superantigenic properties (Gerlach *et al.,* 1994). The three toxin serotypes are produced exclusively by group A streptococci, separately, simultaneously, or in various combinations, depending on culture media and strains (Knöll *et al*., 1991).

### *Streptococcal superantigens*

Erythrogenic toxins A and C are the prototypes of the family of structurally related streptococcal superantigens discovered in the past 10 years named streptococcal superantigen (SSA), streptococcal pyrogenic exotoxins G, H, I, J, L, M, and the "streptococcal mitogenic exotoxins" (SMEZ) 2, 3, . . . 24 (Proft *et al*., 2001; Alouf and Müller-Alouf, 2003; Petersson *et al*., 2004; and Chapters 51 and 53 of this volume).

An important discovery relevant to the erythrogenic toxin was the report of Frobisher and Brown as early as 1927 that a filterable agent from scarlet fever strains of group A streptococci induced toxin production by non-scarlatinal strains. This was confirmed by Bingel (1949) and Zabriskie (1964), who found that bacteriophage from streptococcal strain T12gl converted a non-lysogenic, toxin A–negative strain to a lysogenic, toxin A–positive one. Subsequently, Nida and Ferretti (1982) showed that toxic conversion is produced by a number of temperate streptococcal bacteriophages and conversion can be effected in many streptococci. The *speA* gene encoding the erythrogenic toxin A was cloned from bacteriophage T12 (Johnson and Schlievert, 1984) and its nucleotide sequence determined by Weeks and Ferretti (1986) and Johnson *et al*. (1986), respectively.

The demonstration that erythogenic toxin was encoded by a bacteriophagic gene was an important breakthrough in the genetics of bacterial toxins, as was also the case of the discovery of the bacteriophagic origin of the gene encoding diphtheria toxin (Freeman, 1951) below as described.

## The conundrum of *Bacillus anthracis* toxin complex

This complex plays a dominant role in the pathogenesis of anthrax disease. It constitutes a particularly interesting and somewhat unusual molecular structure characterized by binary combinations of three secreted proteins: the protective antigen (PA), the lethal factor (LT), a zinc-dependent protease that cleaves six of the seven known mitogen-activated protein kinase kinases (Klimpel *et al*., 1994; Vitale *et al*., 2000), and the edema factor (EF), a calmodulin-dependent adenylate cyclase (Leppla, 1982, 1988). The association of PA and LF constitutes the lethal toxin, while that of PA and EF constitutes the edema toxin. The three proteins are encoded by *pagA*, *lef*, and *cya* genes. These genes are borne by a large (182-kbp) plasmid called pXO1 (Mock and Fouet, 2001; Koehler, 2002).

### *Historical background*

Anthrax was recognized for many centuries as a severe disease of animals and humans. It is believed to have been one of the seven plagues suffered by the Egyptians in the time of Moses and was clearly described in ancient Greece (Lincoln and Fish, 1970).

The disease occurs in two main forms: localized cutaneous infections and septicemic (Lincoln *et al*., 1964, 1970). The most characteristic superficial feature of the cutaneous infections is the black eschar that gives its name to the disease and to the causative microorganism (in Greek, anthrakos ανθρακοσ, *coal*). The study of anthrax and its causative agent *Bacillus anthracis* has attracted the attention of microbiologists since the mid 1850s. In 1850, the French physicians François Rayer (1796–1867) and Casimir Joseph Davaine (1811–1882) detected microscopic rods in the blood of animals with anthrax. These "bodies" were named "bacteridies" by Davaine (1863) who contended that these organisms were the causative agents of the disease. Koch (1876) obtained pure cultures of *B.anthracis* for the first time. Louis Pasteur (1822–1895) isolated the bacterium in broth medium from which he inoculated experimental animals who died from anthrax (Pasteur and Joubert, 1878). He also used *B. anthracis* to develop an effective attenuated live vaccine (Pasteur 1880). Since that time, the production of a toxin was postulated by many authors throughout the first half of the twentieth century, particularly in the 1930s, but no lethal toxin had been demonstrated in either anthrax bacilli or filtrates from laboratory cultures (see Smith, 2002). As early as 1907, Eisenberg reported that the supernatant of a bacterial culture injected into guinea pigs and rabbits quickly killed the animals and evoked this effect as that of a "toxin." A major breakthrough occurred as of 1953 when Harry Smith, J. Kreppie, and their coworkers started intensive research in Porton Down (United Kingdom) and successfully resolved the conundrum of anthrax toxin (Stephen, 1986). The complex steps used by the authors to isolate the toxin from the plasma or exudates from dying mice or guinea pigs previously infected with *B. anthracis* has been reviewed recently by Smith (2002). The three components of the anthrax toxin complex were soon characterized by the British group (Smith *et al*., 1956; Stanley and Smith, 1961), who called them factors I, II, and III, corresponding to the edema factor, protective antigen (PA), and lethal factor (EF) of the American authors (Lincoln and Fish, 1970). Beall *et al*. (1962) independently discovered factor III.

The production and purification of the three components of anthrax toxin has been described in detail by Leppla (1988). Since then, great progress in the purification, genetics, cell biology, biochemistry, and immunological aspects of the toxin has been achieved (see Mock and Fouet, 2001; Turnbull, 2002; Koehler, 2002; Chaudry *et al*., 2002; Mourez *et al*., 2002, Mourez,

2004; and Chapter 8 of this volume). The crystal structures of PA (Petosa *et al*., 1997) and LF (Pannifer *et al*., 2001) have been determined (see Table 1.2).

### *B. anthracis* and bioterrorism

Unfortunately, *B. anthracis* and its spores and toxins recently became agents of bioterrorism after the deliberate release of anthrax in the United States of America in September and October 2001 (Jernigan *et al*., 2001). This criminal use of this toxin completely changed the international perception of the risk of bioterrorism.

## MAJOR ACHIEVEMENTS IN TOXIN RESEARCH FROM 1975 TO DATE

The major facets of toxin research of the past 29 years concerned mainly the discovery and characterization of roughly 120 novel toxins among them:

(a) *Helicobacter pylori* vacuolating cytotoxin (see Chapter 24 of this volume ).
(b) Several *Pseudomonas aeruginosa* exotoxins: three ADP-ribosyl transferases exotoxin A, Exo S, Exo T, the adenyl cyclase Exo Y, the phospholipase Exo U (Iglewski *et al*., 1977, 1978; Yahr *et al*., 1998; Krall *et al*., 2000; Maresso *et al*., 2004; and Chapter 14 of this volume).
(c) *Staphylococcus aureus* toxic shock syndrome toxin-1 (TSST-1) identified in 1981 by two independent groups from *S. aureus* strains isolated from patients with toxic shock syndrome (TSS) and found to be the cause of this disease (Schlievert *et al*., 1981; Bergdoll *et al*., 1981, McCormick *et al*., 2001; and Chapter 50 of this volume).
(d) Novel *S.aureus* enterotoxins and *S.pyogenes* superantingens.
(e) *Bacteroides fragilis* zinc protease enterotoxin (Van Tassel *et al*., 1992; Sears, 2001; and Chapter 28 of this volume).
(f) The cytolethal distending toxins (Johnson and Lior, 1987a, b; Pickett and Whitehouse, 1999; Thelestam and Frisan, 2004; and see Chapter 23 of this volume).
(g) The binary actin –ADP-ribosylating toxins from various species (see Chapter 12 of this volume).
(h) Novel *C. botulinum, C. baratii, C. butyricum,* and *C. argentinense* neurotoxins (Popoff and Marvaud, 1999; and Chapter 19 of this volume).
(i) *Yersinia pseudotuberculosis* superantigens YPMS for "*Y. pseudotuberculosis*-derived mitogens" (Uchiyama *et al*., 1993; Abe *et al*., 1993), designated YPMa after the discovery of two variants YPMb (Ramamurthy *et al*., 1997), and YPMc (Carnoy et *al*., 2002), respectively. YPMa was shown to behave as a virulence factor (Carnoy *et al*., 2000).
(j) *S. aureus* and *Staphylococcus hyicus* exfoliative toxins (Table 1 and Chapter 56 of this volume).
(k) *Clostridium difficile* toxins A and B (Wren, 1992; Sears and Kaper, 1996).
(l) *E. coli* shiga-like toxins (verotoxins) (see Chapter 17 of this volume).
(m) Enteric toxins from: *Aeromonas species*, *Bacillus cereus, Campylobacter jejuni, E. coli* enteroaggregative, enterohemorragic, enteroinvasive, enteropathogenic, and enterotoxigenic enterotoxins (heat-labile and heat-stable and other toxins), *Plesiomonas shigelloides, Samonella enterica* toxins, *Vibrio cholerae* and other *Vibrio* species toxins (see Sears and Kaper, 1996; Laohachai *et al*., 2003; and relevant chapters of this volume).
(n) Novel ADP-ribosyl transferases.
(o) Novel membrane-damaging toxins (Alouf, 2003).

### The cloning and determination of the nucleotide sequence of more than 200 toxin structural genes and a number of regulatory genes

The structural genes are mostly located on bacterial chromosomes (80%), but also on plasmids, bacteriophages, transposons, or pathogenicity islands (PAIs) recently considered as a subtype of genomic islands (GEIs). The discovery of the latter was a considerable breakthrough in the field of bacterial pathogenesis, since these complex genomic segments may carry genes encoding not only protein toxins but also other virulence and pathogenicity factors such as adhesins, secretion, or iron uptake systems (see Hacker and Kaper, 2000; Hacker *et al*., 2004; Chapters 2 and 3 and other relevant chapters of this volume).

Bacteriophage-borne genes encode, among other toxins, diphtheria and cholera toxin, *S. pyogenes* pyrogenic exotoxins A and C, *S. aureus* exfoliative toxin B and enterotoxins A and E, *Clostridium botulinum* neurotoxins C1 and D, and *E. coli* Shiga-like toxins I and II. Plasmid-borne genes encode tetanus neurotoxin and botulinum toxin G, anthrax toxin three-component factors (protective antigen, edema factor, lethal factor), *Enterococcus feacalis* cytolysin, *Shigella dysenteriae* enterotoxin 2, the *E. coli* RTX type enterohemorrhagic (EhxA) toxin, and both heat-labile and heat-stable enterotoxins. The latter

was also shown to be encoded by a transposon gene. On the other hand, the genetic determinants of *E. coli* alpha-hemolysin are generally found on large plasmids in animal isolates of this microorganism or on the chromosome of the strains causing urinary tract infections in humans. The gene encoding *C. perfringens* enterotoxin is located on a transposon integrated between two chromosomal house-keeping genes in human food-poisoning strains, while in animal strains the enterotoxin gene is carried on large plasmids (see relevant chapters of this volume).

***Genetic regulation of the expression of bacterial toxins***

This field witnessed recently important progress (Stibitz, 2003; Cotter and Jones, 2003; Raffestin *et al.*, 2004; and Chapter 4 of this volume and other relevant chapters). A variety of toxins and enzymes were found to be under the control of two-component regulatory systems consisting of membrane-associated sensor kinases and cytoplasmic response regulators, which are often DNA-binding proteins. This is the case for the BvgA/BvgS system for *Bordetella pertussis*, VirR/VirS for *C. perfringens*, and CovR/CovS for *S. pyogenes*. In the case of *S. aureus*, the production of various toxins and virulence factors is coordinately controlled by at least three genomic regulators, *agr* (accessory gene regulator), *sar* (staphylococcal accessory regulator), and *sae* (*S. aureus* exoprotein expression). Another interesting regulatory system concerns diphtheria toxin (DT), the synthesis of which has been known since the initial investigations of Pappenheimer and Johnson (1936) to take place in low iron concentration. As mentioned before, the structural gene for the toxin is found in a bacteriophage adjacent to the phage *att* site, mapping at the junction between the phage and bacterial chromosomal DNA. The investigations of the groups of Murphy and Holmes showed that DT synthesis is inhibited by a *trans*-acting factor encoded on *C. diphtheriae* chromosome. This led to the discovery of the bacterial *dtxR* gene encoding an 226 amino acid iron responsive repressor protein DtxR. This protein binds to the *tox* operator under conditions of high iron concentration and inhibits transcription of the *tox* gene. As mentioned above the synthesis of many other bacterial toxins and virulence factors is also negatively regulated by iron.

## Molecular structure and topology of protein toxins

The determination of the nucleotide sequence of encoding structural genes of bacterial toxins allowed the determination of the amino acid sequences of the encoded toxins, thus leading to the extraordinary development of toxin biochemistry. Most toxins are single-chain polypeptides with molecular sizes ranging from about 2–3 kDa for *E. coli* thermostable enterotoxins up to 300 kDa for *Clostridium difficile* toxins A and B, which are the largest single-chain bacterial protein toxins hitherto identified (Wren, 1992; von Eichel-Streiber *et al.*, 1996).

However, many toxins occur as oligomeric multimolecular complexes comprising two or more noncovalently bonded distinct subunits. Cholera toxin and *E. coli* heat-labile enterotoxins I and II form heterohexamers (A1-B5 complex) composed of one 28 kDa A-subunit (the ADP-ribosylating moiety of the toxin) and five identical 11.8-kDa B-subunits that allow the specific binding of the toxin to ganglioside GM1 at the surface of intestinal target cells. Shiga and *E. coli* Shiga-like toxins also form heterohexamers (A1-B5 complex) composed of a single 32-kDa A-subunit (the N-glycosidase moiety that cleaves a specific adenine residue in the 28 S rRNA component of the eucaryotic ribosomal complex) and five identical 7.7 kDa B-subunits that bind to the terminal galactose residues on globotriasoyl ceramide at the surface of target cells. Pertussis toxin produced by *Bordetella* species, the most complex structure known so far among bacterial toxins, is a multimolecular A1-B5 hexamer composed of five dissimilar subunits. Other A-B type toxins are the bipartite toxins (see Saelinger, 2003; Sandvig, 2003; and Popoff *et al.*, 1989).

## Three-dimensional crystal structure

In 1986, Allured and Collier reported the first determination of the three-dimensional (3D) structure of a crystallized bacterial toxin (*P. aeruginosa* exotoxin A). Since then, the 3D structure of more than 40 toxins has been established so far, namely that of diphtheria toxin, pertussis toxin *E. coli*, and *V. cholerae* enterotoxins, Shiga toxin, and various staphylococcal and streptococcal superantigenic toxins, anthrax toxin components, botulinum neurotoxins A, B, and E, etc. (Table 1.2). These important achievements paved the way to fathom in-depth structure-activity relationships.

## General paradigms of the mechanisms of bacterial protein toxins' action on eucaryotic cells

At the turn of the 1970s, two revolutionary paradigms heralded the onset of a new era in our understanding of the mechanism of the action of toxins at the subcellular and molecular levels on target human and animal cells. The two paradigms classified the mode of action

of the toxins into two general operational mechanisms: toxins acting ultimately on intracellular targets after crossing the cell membrane and toxins strictly acting at the surface of the cell membrane, respectively.

### *Protein toxins modifiying intracellular target molecules (the conundrum of the molecular action of A-B type toxins)*

Working with diphtheria toxin, R. J. Collier (1975, 1977) was the first to demonstrate that this toxin could enter inside cell cytosol and inactivate an intracellular target molecule leading to the impairment of cell functions. This discovery led to the paradigm that a great number of bacterial (and certain plant) protein toxins consist of two functionally different moieties designated A and B with the A part causing the intracellular damage and the B part serving to bind A to appropriate cell receptors and deliver it to the interior (Popoff, 1998 and Sandvig, 2003). This process involves endocytosis by several complex mechanisms and translocation and trafficking into the cytosol from different intracellular organelles. The A and B moieties can be located on two distinct domains of a single-chain polypeptide (e.g., diphtheria toxin, *P. aeruginosa* exotoxin A) or on two different proteins, example oligomeric toxins (e.g., cholera, pertussis, shiga, and Shiga-like toxins) or binary (bipartite) toxins consisting of two entirely distinct soluble proteins that only associate on the surface of their target cells (see Leppla: in Saelinger, 2003). The A moieties possess various enzymatic activities depending on the nature of the relevant toxins, namely ADP-ribosytransferases, adenylcyclases, metalloproteases, RNA *N*-glycosidases, glycosyl-transferases, and deamidases (see Table 1.1). Recent studies identified many toxin receptors, toxin-induced modulation of various, effectors of intracellular signal transduction pathways, and apoptotic events. The establishment in the past 15 years of the 3D crystal structure of many A-B type toxins (Table 1.2) provided a framework to understand how toxins recognize receptors, penetrate membranes, and interact with and modify intracellular substrates.

### *Protein toxins acting on cytoplasmic membrane components without intracellular penetration*

This process concerns two distinct types of toxins with totally different functional and molecular modes of action.

*Receptor-targeted toxins*

These toxins bind to appropriate cell receptors with subsequent triggering of intracellular processes via transmembrane signaling followed by harmful effects. Two main classes of toxins exhibit these properties:

1. Superantigenic toxins (see Chapters 49–53).
2. *E. coli* heat-stable ST enterotoxins and related toxins from other Gram-negative bacterial species.

These toxins bind to the guanylate cyclase receptor of target intestinal cells, leading to the activation of cellular guanylate cyclases, which are brush border membrane glycoproteins. The activation provokes an elevation of cyclic GMP that stimulates chloride secretion and/or inhibition of NaCl absorption resulting in net intestinal fluid secretion (diarrhea). A similar effect is observed with the hormone guanylin, which shares 50% homology with the toxin and activates the same receptor.

*E. coli* ST was first characterized by Kunkel and Robertson (1979) in enterotoxigenic *E. coli* (ETEC). Based on structure-function relationship, STs are divided into two distinct types, namely STa (or STI) and STb (or STII). STa differs from STb by its resistance to proteases, solubility in methanol, and its activity in the suckling mouse model. In enteroaggregative *E. coli* (EAEC), a heat-stable toxin named EAST1 was identified and shown to cause diarrhea in humans. This is often compared to STa. Apart from *E. coli,* other enteric bacteria produce ST toxins. These include *V. cholerae* O1, non O1 or non–O 139, *V. mimicus*, *Yersinia enterocolitica, Y. kristensii, Citrobacter freundii,* and *Klebsiella pneumoniae* (see Sears and Kaper, 1986; Laohachai *et al*., 2003; and Chapters 25 and 48 of this volume).

*Membrane-damaging (cytolytic) toxins*

Toxin-induced cell damage was historically identified by virtue of the cytolytic action of a great number of toxins on human and animal erythrocytes and to a lesser extent on other cells. These toxins known as *membrane-damaging toxins* (MDTs) or cytolysins produced by both Gram-positive and Gram-negative bacteria possess the ability to damage or disrupt the integrity of the plasma membrane of target cells, reflected by cell swelling and subsequently cell lysis. Many members of the MDTs are important virulence and pathogenicity factors and are sometimes lethal to humans and animals. This family of toxins, initially investigated by the pioneering studies of Alan Bernheimer over three decades since the 1940s (Bernheimer, 1944; Bernheimer and Rudy, 1986) and then by many other groups, constitutes the most important family of bacterial toxins. To date, this family comprises 117 members (35% of the whole repertoire of 337 toxins so far identified). Three types of MDTs can be distinguished, based on their action on cell membranes: (i) enzymically active cytotolysins (phospholipases), which degrade cell-membrane phospholipid bilayer (Table 1.1 and Chapter 27), (ii) tensioactive cytolysins, which solubilize certain cell-membrane components by

a detergent-like action, (iii) pore-forming cytolytic toxins (PFTs), which create channels (pores) through the cytoplasmic membrane.of targetcells. These three types of MDTs encompass 26, 10, and 81 cytolytic proteins, respectively (see Alouf, 2003). The "pore" concept (paradigm) for the last group of MDTs proposed by the end of the 1970s on biochemical and electron microscopic studies initiated by Bernheimer, Freer, Alouf, Bhakdi, and many other authors (see Alouf, 2001; van der Goot, 2003) witnessed a considerable development particularly through the determination of the 3D structures of many cytolysins (Table 1.2) .

The process of pore formation was consistent with the following *modus operandi:* the toxins are released by the bacteria as monomeric water-soluble proteins and bind to cell surface components. Toxin binding facilitates the concentration of the monomers and their transition to form non-covalently associated oligomers, leading to an amphipathic state of the oligomers followed by insertion into the membrane and the formation of protein-lined pores of various sizes, depending on the toxin involved. The various families of pore-forming toxins include particularly the RTX cytolysins ( Welch, 2001; Oxhamre and Richter-Dahlfors, 2003), *Aeromonas hydrophila* aerolysin and related toxins (Fivaz *et al*., 2001, and Cole *et al*., 2000) *S. aureus* leucocidins, alpha- and gamma-toxins (Prevost *et al*., 2001), the cholesterol-dependent cytolysins (Alouf, 2001; Billington *et al*., 2001; Tweten *et al*., 2001), the bi-component A/B-type cytolysins from *Serratia, Proteus, Edwardsiella, and Haemophilus* species (Braun and Hertle, 1999), *V. cholerae* and other *V*. species (Shinoda, 1999) (see Chapters 26 and 29 to 47 of this volume).

## RATIONAL/CANONICAL CLASSIFICATION OF BACTERIAL TOXINS

The considerable progress of our knowledge of the molecular, structural, and genetic aspects of bacterial protein toxins revealed common functional and/or molecular similarities, which allow a rational/canonical classification of these toxins into families. We briefly describe some major families.

### The family of the cytolethal distending toxins (CDTs)

This family (17 members at least) constitutes the most recently discovered group of toxins produced by a variety of Gram-negative bacteria (Thelestam and Fizan, 2001; Dreyfus *et al*., 2003; Nesic *et al*., 2004; and Chapter 23 of this volume). CDTs possess the unique ability to induce DNA double-strand breaks (DSBs) in both proliferating and nonproliferating cells, thereby causing irreversible cell cycle arrest or death of the target cells. CDTs are encoded by three linked genes (*cdtA, cdtB,* and *cdtC*). All three of these gene products are required to constitute the fully active holotoxin, and this is in agreement with the recently determined crystal structure of CDT. The toxin is endocytosed via clathrin-coated pits and requires an intact Golgi complex to exert the cytotoxic activity. Several issues remain to be elucidated regarding CDT biology, such as the detailed function(s) of the cdtA and cdtC subunits, the identity of the cell surface receptor(s) for CDT, the final steps in the cellular internalization pathway, and a molecular understanding of how CDT interacts with DNA. Moreover, the role of CDTs in the pathogenesis of diseases still remains unclear.

### The family of RNA *N*-glycosidases, glycosyltransferases, and deamidases: Shiga and Shiga-like toxins, ricin, and other plant toxins

Shiga toxin is an A-B type toxin produced by *Shigella dysenteriae* discovered in 1898 by Kiyoshi Shiga (1870–1957). The toxin is constituted by a ring of identical B-chains non-covalently associated with the A chain. The latter is responsible for the RNA *N*-glycosidase activity, which provokes the cleavage of a purine residue from eucaryotic cell 28S ribosomal RNA, resulting in blockage of protein synthesis and ultimate death of target cell (Endo *et al*., 1988; O'Loughlin and Robins-Browne, 2001; Melton-Celsa and O'Brien, 2003; and Chapter 17 of this volume). Similar structurally and functionally related toxins called *Shiga-like toxins* or *verotoxins* are produced by enterohemorragic *E. coli* (six variants: Stx 1, 1c, 2, 2c, 2d, 2e) and other bacteria such as *Aeromonas hydrophila, A. cavia, Citrobacter freundii,* and *Enterobacter cloacae*. Moreover, very similar toxins from various plants (ricin, abrin, etc.) have been widely investigated (Barbieri *et al*., 1993; Melton-Celsa and O'Brien, 2003).

### The family of the bacterial ADP-ribosylating toxins (ADP ribosyl transferases: ADPRTs)

These toxins constitute a class of functionally conserved enzymes produced by a variety of pathogenic Gram-positive and Gram-negative bacterial species, which display toxic and often lethal activity in humans and certain animals. These proteins share the ability to transfer the ADP ribose moiety of β-NAD+ to an eucaryotic target protein. This process impairs essential functions of target cells, thus modifying signal transduction pathways or causing rapid cell death (see

Pallen *et al*., 2001; Barbieri and Burns, 2003; Aktories and Barth, 2004; Masignani *et al*., 2004 for recent references; and Chapter 12 of this volume).

Diphtheria toxin and *Pseudomonas aeruginosa* exotoxin A inhibit protein synthesis by inactivating elongation factor 2 and subsequently cause cell death (Collier 1975, 1977). Other toxins in this family are *P. aeruginosa* cytotoxic exotoxin S, which uncouples Ras signal transduction, pertussis toxin, cholera toxin, and heat-labile enterotoxins LT-I and LT-II from *E. coli,* which interferes with the human host by ADP-ribosylating regulatory heterotrimreric G proteins (Barbieri and Burns, 2003 Masignani *et al*., 2004). The family of binary (bipartite) toxins include the mosquiticidal toxin (MTX) from *B. sphaericus* (Carpusca *et al*., 2004), *Clostridium botulinum* C2 toxin (Ohishi *et al*., 1980 Aktories and Barth, 2004), *C. perfringens* iota toxin (Stiles and Wilkins, 1986) Marvaud *et al*., 2001), *Clostridium spiroforme* toxin (Popoff *et al*., 1989), *C. difficile* ADP-ribosyl transferase (Perelle *et al*., 1997). Other members of the ADPRT family include the low molecular-weight (25–30 kDa) C3 and C3-like enzymes produced by *C. botulinum, C. limosum, B. cereus, S. aureus* respectively, the epidermal differentiation inhibitor (EDIN) from *S. aureus,* and the recently discovered ADPR, SpyA from *Streptococcus pyogenes*, which shares amino acid identity with EDIN and *C. botulinum* C3 (Pallen *et al*., 2001; Coye and Collins, 2004). Recently, the application of *in silico* analyses allowed the identification of more than 20 novel putative members of the ADPRT family and represents a novel challenge in the genomic era (Pallen *et al*., 2001; Masignani *et al*., 2004).

### *Common molecular features of the ADPRT family*

Bacterial ADPRTs have only limited overall amino acid sequence identity. However, the 3D crystal structure and computer modeling studies of those toxins investigated so far indicate that the active site domains of these proteins are related and contain a conserved NAD-binding catalytic domain formed of two perpendicular β-sheet cores and flanked by either one or two α-helices. Moreover, a catalytic glutamate residue is found in the active site of these molecules (Han and Tainer, 2002; Masignani *et al*., 2004).

## The family of the glycosylating and deamidating toxins

The family of the glycosylating toxins includes large single-chain proteins *C. difficile* toxins A and B, the lethal and the hemorrhagic toxins from *Clostridium sordellii*, the α-toxin from *C. novyi,* and various toxin isoforms mainly produced by *C. difficile*. These toxins share common features: they have high molecular weights (>250 kDa) and possess glucosyl or N-acetyl glucosaminyltransferase properties. They also share the same functional topology. and are about 40 to 90% identical in their amino acid residues (Aktories, 2003). The toxins inactivate Rho GTPases by glucolysation of a functionally essential threonine (Thr 37) residue. With the exception of *C. novyi* α-toxin, which uses UDP-GlcNAc, the other cytotoxins use UDP-glucose as a substrate. The toxins split the activated nucleotide sugar and transfer only one sugar moeity onto the hydroxyl group of Thr 37 leading to the mono-*O*-glucosylation or mono-*O*-*N*-acetylglucosaminylation of the eucaryotic target protein (von Eichel-Streiber *et al*., 1996; Selzer *et al*., 1996; Popoff *et al*., 1996).

Another process is the deamidation and transglutamination of Rho GTPases by the cytotoxic necrotizing factors (CNFs) 1 and 2 produced by certain *E. coli* strains and the dermonecrotizing toxin (DNT) from *Bordetella pertussis* (Flateau *et al*., 1997; Schmidt *et al*., 1997).

## The family of the superantigenic toxins

These toxins exhibit like other bacterial or viral superantigens (SAgs) highly potent, lymphocyte-transforming (mitogenic) activity toward human and/or other mammalian T lymphocytes. Unlike conventional antigens, SAgs bind to certain regions of major histocompatibility complex (MHC) class II molecules of antigen-presenting cells (APCs) outside the classical antigen-binding groove and concomitantly bind under their native form to T cells at the level of certain specific motifs of the variable region of the β chain (Vβ) of T cell receptor (TcR). This interaction triggers the activation (proliferation) of the targeted T lymphocytes and leads to the *in vivo* or *in vitro* release of high amounts of various cytokines and other effectors by immune cells. Each SAg interacts specifically with a characteristic set of Vβ motifs.The repertoire of the superantigenic toxins include: (i) the classical *S. aureus* enterotoxins A, B, C (and antigenic variants) D, E, and the recently discovered enterotoxins G to U, and toxic shock syndrome toxin-1,(ii) the *S. pyogenes* SAgs comprising the classical pyrogenic (erythrogenic) exotoxins A and C and the newly identified pyrogenic toxins G, H, I, J, L, M, as well as SMEZ and SSA, and (iii) the *Yersinia pseudotuberculosis* superantigens.

The structural and genomic aspects of these toxins and their molecular relatedness have been widely investigated (Proft *et al*., 2001; Alouf and Müller-Alouf, 2003; Petersson *et al*., 2004, and Chapters 51 to 55 of this

volume). The 3D crystal structure of many of them have been determined (Table 1.2) as well as that of certain of their complexes with MHC class II molecules and (or) TcR receptors. The production of SAgs by staphylococci and group A streptococci during host infection by these bacteria contributes to a broad spectrum of diseases ranging from mild to severe cutaneous and other tissue infections, to life-threatening septicemia, and toxic shock syndromes (McCormick *et al*., 2001; Llwelyn and Cohen, 2002; Alouf and Müller-Alouf, 2003; Krakauer, 2003; Petersson *et al*., 2004; and Chapters 49 to 53 of this volume).

## CONCLUSION

The discovery of the first and major bacterial protein toxins at the end of the nineteenth century paved the way for an outstanding development of a new field not only in microbiology but in many aspects of biological and medical sciences.

The wealth of information obtained during the past 114 years of research in bacterial toxinology has provided a great deal of knowledge regarding the molecular structure, the genetic aspects, and the interaction of these fascinating molecules with the various cellular systems and tissues of the human and animal organisms. The study of the biological effects of bacterial toxins at the subcellular and molecular levels revealed their highly complex implications in a variety of physiological and metabolic processes. The key role of bacterial toxins in the pathogenesis of various acute, chronic, and certain autoimmune diseases afforded new insights in our understanding of infectious diseases. Many questions remain unanswered as yet. Novel toxins will be discovered and new achievements will certainly emerge in the coming years, particularly the design and use of novel therapeutic strategies (drugs, vaccines, adjuvants) in the management of toxin-induced diseases and prophylaxis of susceptible populations. Moreover, several lines of experimental and clinical evidence recently allowed the design of engineered toxins for their potential use against certain tumours and virus-infected cells.

# BASIC GENOMIC AND PHYSIOLOGICAL ASPECTS OF BACTERIAL PROTEIN TOXINS

CHAPTER

# 2

# Evolutionary aspects of toxin-producing bacteria

*Brenda A. Wilson and Mengfei Ho*

The toxins and effectors produced by pathogenic bacteria are located on pathogenicity islands. Increasing evidence indicates that the evolution of toxin genes involves horizontal gene transfer and recombination events mediated through plasmids, phages, transposons, and other yet-undefined transmissible elements. In addition to the host environment, toxin evolution and transmission also can occur outside the human and animal host, including in soil and aquatic environments, in the phyllosphere, and in the guts of insects, parasites, and other vectors.

## INTRODUCTION

It had long been believed that microbes capable of causing human disease evolve over long periods of time through complex interactions between the microbes and their hosts. The prevailing view was that maintenance and amplification of mutations that might lead to increased virulence required a strong or persistent selective pressure, which could only be applied specifically from exposure to the host environment. However, new evidence suggests that acquisition of large DNA segments by horizontal gene transfer (HGT) may account for a much more rapid evolution of pathogens (Groisman and Ochman, 1996), particularly in terms of the origin of virulence factors such as toxins, than was previously thought. Indeed, the abundance of toxin genes associated with "foreign" DNA segments, called *pathogenicity islands* (PAIs), in the genomes of most of the sequenced toxin-producing pathogens, compared to their non-toxigenic and/or nonpathogenic counterparts, suggests that HGT must occur at a relatively high frequency in the "real world." Consequently, scientists are beginning to ask how many of the emerging or reemerging bacterial diseases are surfacing because of the acquisition of new toxin-containing PAIs or new combinations of PAI-encoded toxin genes? And, if HGT is a major driving force in the evolution of toxins and bacterial pathogens, where is it taking place?

## MOLECULAR ECOLOGY OF TOXIN-PRODUCING BACTERIA

### Pathogenicity islands, horizontal gene transfer, and the prevalence of toxins

Strong evidence now points to an important role for HGT (in the form of mobile PAIs) in contributing to genome variability and evolution of pathogens (Miao *et al*., 1999; Boyd and Brussow, 2002; Casjens, 2003; Omelchenko *et al*., 2003; Brussow *et al*., 2004; Novichkov *et al*., 2004). The structural genes encoding most bacterial protein toxins are located on extrachromosomal plasmids or within genomes as part of putative transposons, integrated conjugative plasmids, temperate bacteriophages, or remnants of these mobile elements (see Table 2.1). Possible mechanisms by which HGT contributes to bacterial pathogenesis include exchange and recombination of toxin and other virulence genes among different bacterial populations; one-step acquisition of toxin(s) and other virulence genes to increase survival against the host's immune

system or to provide means for dissemination within the host or between hosts; and provision of mechanisms to enhance survival in the external environment when outside the host body.

Phages or lysogenic strains carrying toxin prophages might serve as the natural reservoir for toxin genes, with lysogenization and conversion processes taking place not only in the human or animal host such as in the lungs or intestines, but also in the external environment such as in food, water, soil, or other vectors or hosts (e.g., insects, amoeba, or plants). HGT under any of these conditions could produce new pathogenic strains and may account for the prevalence of related toxins among diverse pathogens. Examples can readily be found in some of the emerging or reemerging pathogens, including superantigen production by group A streptococci, cholera toxin production by *Vibrio cholerae*, heat-labile enterotoxin (a homologue of cholera toxin) production by enterohemorrhagic (EHEC) strains of *Escherichia coli,* and the widespread Shiga toxin-production by *Shigella* and *E. coli* strains. Indeed, studies on Shiga toxin (*stx*) gene-containing phages indicate that they are transmitted not only by temperate bacteriophages between different bacteria *in vivo*, i.e., in the intestines of humans and animals (Acheson *et al*., 1998), but also extra-intestinally in aquatic environments, such as sewage and fecally contaminated rivers and lakes (Garcia-Aljaro *et al*., 2004; Muniesa *et al*., 2004), as well as contaminated irrigation water, soil, and crops (Solomon *et al*., 2002b).

New studies indicate that phage biology may additionally contribute to bacterial pathogenesis by allowing for export or release of toxins mediated by phage lysis or for toxin gene expression upon phage induction, particularly when optimal promoters for the toxin gene are lacking in the new host. Most phage-encoded toxin genes are located near the phage attachment site, supporting acquisition by a transduction mechanism. However, the Shiga toxin genes are an exception. The genes for Stx1 and Stx2 are downstream of the λ-like transcriptional activator Q homologue and upstream of the phage lysis and morphogenesis genes in H-19B and 933W phages, respectively. Recent studies have demonstrated that expression and release of the Stx proteins from the bacteria is mediated by phage induction and lysis (Wagner *et al*., 2001; Wagner *et al*., 2002; Livny and Friedman, 2004; Tyler *et al*., 2004). This came as a surprise since several groups had previously identified a functional Fur-like promoter that was directly upstream of the *stx1* gene, and had reported that toxin expression was regulated by iron through this promoter (Calderwood *et al*., 1987; Calderwood and Mekalanos, 1987; De Grandis *et al*., 1987; Jackson *et al*., 1987). However, subsequent studies indicated that phage induction by agents such as mitomycin C dramatically increased the production and release of Stx by STEC strains far above that observed under iron regulation (Hull *et al*., 1993; Wagner *et al*., 2001; Wagner *et al*., 2002). This was further confirmed by mutational analysis of the promoter regions (Hull *et al*., 1993; Wagner *et al*., 2001; Wagner *et al*., 2002; Tyler *et al*., 2004).

Phage induction may also contribute to the release of toxins when specific protein secretion systems do not exit for the toxin or when the toxin is too large for efficient export. Phage induction is known to be triggered by bacterial stress responses, including SOS-inducing antibiotics and oxidative stress, which are known to trigger phage induction and subsequent release of Shiga toxins (Kimmitt *et al*., 2000), as well as the large clostridial toxins, ToxA and ToxB, from *Clostridium difficile* responsible for nosocomial antibiotic-induced

enterocolitis (Onderdonk *et al*., 1979; Ketley *et al*., 1984; Lyerly *et al*., 1988; Giannasca and Warny, 2004). The structural similarity of the toxin-encoding regions of different *C. difficile* strains and their absence in non-toxinogenic strains suggests that they may be part of a transmissible PAI (Braun *et al*., 1996; Hundsberger *et al*., 1997; Dupuy and Sonenshein, 1998; Mani *et al*., 2002). Another example where this may be relevant, albeit not yet demonstrated, is for the *Pasteurella multocida* toxin (PMT), whose structural gene (*toxA*) was recently shown to reside on a temperate bacteriophage (Pullinger *et al*., 2004). PMT is responsible for the symptoms of atrophic rhinitis in animals, a disease that is most prevalent and more severe when animals are under stressful conditions or during co-infections (Foged, 1992).

## Toxins encoded by plasmids, bacteriophages, and other pathogenicity islands

The clinical profile of diarrheal diseases caused by pathogenic *E. coli* strains is a composite of the various toxins and other virulence factors produced by those strains (Nataro and Kaper, 1998). Enterotoxigenic *E. coli* (ETEC) strains are characterized by the presence of two different plasmid-encoded enterotoxins, the heat-labile toxin (HLT), which is an $AB_5$-type ADP-ribosylating toxin closely related to cholera toxin, and the heat-stable toxin (HST), which is one of several related small peptide toxins produced by different strains of *E. coli* that bind and activate intestinal guanylate cyclase receptors. ETEC and extra-intestinal strains of *E. coli* from animals also often carry another Vir plasmid, which encodes the gene for cytotoxic necrotizing factor 2 (*cnf2*) (Oswald *et al*., 1991; Oswald *et al*., 1994a; Oswald *et al*., 1994b), as well as the gene for cytolethal distending toxin (*cdt*) (Peres *et al*., 1997; Toth *et al*., 2000; Mainil *et al*., 2003). Uropathogenic *E. coli* (UPEC) strains, on the other hand, carry the *cnf1* gene, which is homologous to the *cnf2* gene, but is located along with the gene for α-hemolysin (*hly*) on a chromosomal PAI (Blum *et al*., 1995). Many extra-intestinal *E. coli* strains contain variants of the α-hemolysin genes on different plasmids or chromosomal PAIs (Muller *et al*., 1983). The plasmid-encoded enterohemolysin (*ehxABD*) of enterohemorrhagic *E. coli* (EHEC) strains also has strong homology to α-hemolysin, but the N- and C-termini are different in the two proteins (Bauer and Welch, 1996; Schmidt *et al*., 1996).

Shiga toxin–producing *E. coli* (STEC) strains have emerged as a major group of food-borne pathogens (Karmali, 1989; Griffin and Tauxe, 1991; Boerlin, 1999). Nearly all of the Shiga toxin genes are carried by temperate bacteriophages (Newland and Neill, 1988; Unkmeir and Schmidt, 2000). The two classes of Shiga toxins found in STEC, Stx1 and Stx2, have similar structures and mechanisms of action. The *stx1* gene is highly conserved and nearly identical to the *stx* gene from *Shigella dysenteriae*, whereas the *stx2* gene shares ~58% DNA sequence homology with *stx1* and has many distinct variants among different STEC isolates, with some isolates containing multiple variants (Boerlin, 1999). In addition, some *stx* genes contain mosaic structures, suggesting that recombination between *stx-phages* can also occur in nature (Bastian *et al*., 1998).

The spore-forming, neurotoxin-producing *Clostridia* are strict anaerobic Gram-positive bacteria that are found ubiquitously in the environment. Neurotoxin-producing strains of *Clostridium botulinum* are defined by which one of the closely related but antigenically distinct botulinum neurotoxins (BoNT) that they produce (A1, A2, B, C1, D, E, F, or G) (Collins and East, 1998; Johnson and Bradshaw, 2001). These toxins are also related to the tetanus neurotoxin (TeNT) produced by *Clostridium tetani*. The diverse locations of the genes for these toxins are illustrative of the degree of HGT that has occurred during their evolution. Comparative phylogenic analysis has revealed the strong likelihood that HGT of BoNT genes has occurred not only within *C. botulinum* species, but also with other species, including *C. butyricum* and *C. baratti*. The genes for BoNT/A1, BoNT/A2, BoNT/B, and BoNT/F are located in gene clusters on the chromosome (Collins and East, 1998; East *et al*., 1998; Rodriguez Jovita *et al*., 1998; Santos-Buelga *et al*., 1998; Dineen *et al*., 2003); the gene for BoNT/G is plasmid encoded (Zhou *et al*., 1995); the genes for BoNT/C1 and BoNT/D are encoded by prophages (Eklund *et al*., 1971; Eklund *et al*., 1972; Hariharan and Mitchell, 1976; Hauser *et al*., 1995); and the gene for BoNT/E has been found on both phage and plasmids (Hauser *et al*., 1992; Zhou *et al*., 1993).

Some phages carrying the BoNT/C1 and BoNT/D also encode one or more C3 ADP-ribosyltransferase exoenzyme genes (Popoff *et al*., 1990; Hauser *et al*., 1993; Moriishi *et al*., 1993). Certain strains of *C. botulinum* have been reported to contain mixtures of toxin types. For example, there are reports of strains that harbor both *botB* and *botF* gene clusters, as well as strains that harbor both *botA* and *botF* gene clusters (Collins and East, 1998). Many type A strains have both the *botA1* gene cluster and a *botB* cluster, although the *botB* cluster in these cases often has a cryptic *botB* gene (Franciosa *et al*., 1994; Hutson *et al*., 1996; Rodriguez Jovita *et al*., 1998). A strain containing a chimeric gene for BoNT/Dsa, which was a composite between *botC*

and *botD* genes, has also been reported (Moriishi *et al*., 1996a; Moriishi *et al*., 1996b).

## PAI-encoded toxins delivered by type III and type IV secretion systems

A new class of PAI-encoded virulence factors includes the type III secretion systems (TTSS) and their translocated effector proteins (see Table 2.2). Although they are not called toxins per se, these effector proteins can be considered as toxins since they mediate cytotoxic effects in host cells upon being directly delivered to the host cell cytosol by the TTSS. Virulence plasmids of pathogenic *Shigella*, *E. coli*, and *Yersinia* harbor conserved clusters of genes for one or more TTSS and their associated effector proteins (Hueck, 1998; Anderson and Schneewind, 1999; Winstanley and Hart, 2001). For example, the three pathogenic strains of *Yersinia* (*Y. pestis, Y. enterocolitica*, and *Y. pseudotuberculosis*) all contain a large virulence plasmid (pYV) that encodes the TTSS and Yop (*Yersinia* outer proteins) effector proteins, which inhibit macrophage function once delivered to the macrophage by the TTSS (Cornelis *et al*., 1998). An analogous set of TTSS (Mxi/Spa) and effector (Ipa) proteins are encoded on the large invasion plasmid (pInv, pWR100 in *S. flexneri*) harbored by *Shigella* and enteroinvasive *E. coli* (EIEC) strains (Parsot and Sansonetti, 1996; Nhieu and Sansonetti, 1999; Buchrieser *et al*., 2000).

*Salmonella enterica* serovar Typhimurium harbor a number of PAIs and prophages, two of which encode TTSS and effector proteins that are directly injected into the host cell at different stages of the infection cycle (Galan and Collmer, 1999; Lostroh and Lee, 2001). The TTSS encoded by the *Salmonella* pathogenicity island-1 (SPI-1) is involved in mediating invasion of

macrophages (Wallis and Galyov, 2000), while the TTSS encoded by SPI-2 is required for survival within the macrophage and during systemic infection (Hansen-Wester and Hensel, 2001). The effector proteins injected by the SPI-1 TTSS, all of which affect various intracellular signaling processes in the macrophage, include SopB, SopE2 (encoded by a phage remnant), AvrA, SipB, SptP, SipC, SipA, SspH1 (encoded by the GIFSY-3 prophage), SspH2 (encoded by a phage remnant), SopD, SlrP, SopA, and sometimes SopE (encoded by another phage in some strains) (Galan, 2001; Zhang *et al*., 2002). The effector proteins translocated by the SPI-2 TTSS include SspH1, SspH2, SlrP, SseI, SseJ, SifA, and SifB, and they are also encoded in distinct regions on the chromosome (Miao *et al*., 1999; Miao and Miller, 2000; Galan, 2001; Zhang *et al*., 2002). Analysis of the *sopE* gene among various *S. enterica* subspecies indicates that HGT can occur between different phage families (Mirold *et al*., 2001a; Mirold *et al*., 2001b; Zhang *et al*., 2002), suggesting that shuffling of the effector protein repertoires in *Salmonella* species can and has occurred to create new epidemic strains.

## MOLECULAR EVOLUTION OF TOXINS THROUGH GENETIC EXCHANGE

### Genetic exchange and toxin evolution

If HGT is a major player in the evolution of toxin-producing pathogens, where do most of these transfers occur? Could it be that the host body is not the only setting where this type of evolution occurs? This is of particular interest because many pathogens, including those that produce toxins, spend a substantial amount of their life cycle outside the host body.

### Toxin evolution and transmission in the host

Microbes are defined by their environment, and for pathogens, that environment is believed to be predominantly the human or animal host. Pathogenic bacteria establish infections in widely diverse host environments, ranging from the skin to various mucosal surfaces such as the oral cavity, lungs, gut, and vagina. Consequently, specific host *in vivo* signals might be expected to modulate bacteria gene transfer events (Mel and Mekalanos, 1996). There are ample studies demonstrating that transfer of antibiotic resistance genes between different Gram-negative and Gram-positive bacteria can occur in the intestinal tracts of humans and animals (Nijsten *et al*., 1995; Scott and Flint, 1995; Igimi *et al*., 1996; Shoemaker *et al*., 2001). A number of genetic analyses of the plasmid profiles from clinical fecal isolates indicate that HGT most likely occurred within the human gut (Tauxe *et al*., 1989; Balis *et al*., 1996; Prodinger *et al*., 1996; Shoemaker *et al*., 2001). Conjugal gene transfer between different *Salmonella* strains has also been shown to occur within cultured human epithelial cells (Ferguson *et al*., 2002), suggesting that the phagocytic vacuoles or cytosol of animal cells could be a niche for HGT if bacteria conjugate within the intracellular environment. An interesting example of HGT can be found in the genetic evidence for homologous recombination within the vacuolating cytotoxin gene, *vacA*, which occurred between different *Helicobacter pylori* strains co-inhabiting the stomach and resulted in chimeric *vacA* genes (Atherton *et al*., 1995; Atherton *et al*., 1997; Atherton *et al*., 1999; Letley *et al*., 1999; Ji *et al*., 2002; Aviles-Jimenez *et al*., 2004).

There is considerable evidence now that continuing evolution of the Gram-positive streptococci and staphylococci is occurring via phage-mediate HGT (Hakenbeck *et al*., 2001; Kuroda *et al*., 2001; Banks *et al*., 2002; Fitzgerald *et al*., 2003; Novick, 2003). For example, Group A *Streptococcus* (GAS) strains can produce one or more of three pyrogenic exotoxins (SpeA-C), which are related to members of the so-called superantigen family found in staphylococci (Bohach *et al*., 1990). The phage-encoded genes for SpeA (the scarlet fever toxin) and SpeC are variably present in clinical isolates (Yu and Ferretti, 1989; Musser *et al*., 1991; Yu and Ferretti, 1991a; Yu and Ferretti, 1991b), and there is genetic evidence that they undergo HGT and recombination (Kapur *et al*., 1992; Beres *et al*., 2002; Smoot *et al*., 2002).

A similar evolutionary story of high variability and evidence of extensive HGT is told for the staphylococci, particularly in relation to the various toxin gene clusters for superantigens (*set*), exfoliative toxins (*eta*, *etb*), and toxic shock syndrome toxins (*tst*) found in pathogenic strains (Yamaguchi *et al*., 2000; Kuroda *et al*., 2001; Yamaguchi *et al*., 2002; Fitzgerald *et al*., 2003). The human pharyngeal cell has been shown to release a soluble factor that stimulates the lytic activation of *Streptococcus pyogenes* prophage, as well as expression of a phage-encoded extracellular DNase (Broudy *et al*., 2001; Broudy *et al*., 2002). Indeed, using a mouse model of *S. pyogenes* infection, the mammalian host was shown to promote both efficient phage induction at the mucosal surface, as well as subsequent lysogenic conversion of the non-toxigenic streptococci occupying the same niche (Broudy and Fischetti, 2003).

The vast majority of epidemic *Vibrio cholerae* strains, which are responsible for the massive diarrheal disease cholera, do not produce cholera toxin (CT) or TCP pili when they are outside of the human or animal host,

e.g., under laboratory conditions. However, all clinical isolates do make these virulence factors in the host intestines. The *ctxAB* genes that encode the A and B subunits of CT were found to be located on a putative transmissible element (called *CTX*) on the chromosome (Mekalanos *et al*., 1983; Pearson *et al*., 1993). Surprisingly, this CTX element was later demonstrated to actually be a filamentous bacteriophage (CTXϕ) that could undergo lysogenic conversion under certain laboratory conditions, but the most efficient transfer occurred in the host intestines (Waldor and Mekalanos, 1996). What was even more remarkable was the finding that CTXϕ uses as its receptor the TCP pilus, which itself is a colonization factor in the gut (Taylor *et al*., 1987; Karaolis *et al*., 1999). While classical pandemic strains of *V. cholerae* express TCP under a variety of conditions, more recent El Tor pandemic strains only express TCP in the infected mammalian host (Mekalanos *et al*., 1997). In addition, generalized transduction of CTXϕ by yet another phage (CP-T1) was found to be an alternative mechanism by which CTXϕ-carrying strains could transfer the CTX prophage into non-toxigenic strains (Boyd and Waldor, 1999).

Pathogenic *Bordetella* species (*B. pertussis, B. parapertussis,* and *B. bronchiseptica*) are closely related Gram-negative bacteria that colonize the respiratory tracts of mammals (Preston *et al*., 2004). *B. pertussis* is a strict human pathogen responsible for whooping cough; *B. parapertussis* is a recently emerged variant that infects both humans and sheep; and *B. bronchiseptica* is a broad host-range pathogen that infects primarily animals and occasionally humans. Comparative genome sequence analysis suggests that *B. pertussis* and *B. parapertussis* evolved from *B. bronchiseptica* in the recent past (Arico *et al*., 1987; Rappuoli *et al*., 1987; van der Zee *et al*., 1996a; van der Zee *et al*., 1996b; Parkhill *et al*., 2003). Interestingly, many of the genes encoding virulence factors, including the genes for pertussis toxin (*ptxA-E*), adenylate cyclase hemolysin (*cya*), dermonecrotic toxin (*dnt*), and tracheal cytotoxin (*tct*), can be found on distinct regions of the chromosomes in all three species, although some of these virulence factors, e.g., PT, may be expressed *in vitro* only by *B. pertussis* (Arico and Rappuoli, 1987). It was previously thought that PT expression differences in the strains were due to inactivating mutations in the promoter regions in *B. parapertussis* and *B. bronchiseptica* (Arico and Rappuoli, 1987). However, recent genetic analysis suggests that PT may be more tightly regulated in *B. parapertussis* and *B. bronchiseptica* and therefore is expressed only *in vivo* by these strains, while the recent mutations in the promoter region increased the transcription of the gene in *B. pertussis* (Hausman *et al*., 1996; Parkhill *et al*., 2003; Preston *et al*., 2004).

## Vaccines and toxin evolution

Despite high vaccination coverage, the once nearly eradicated diseases diphtheria and pertussis have unfortunately reemerged as a health threat in the developed countries (Bass and Stephenson, 1987; Bass and Wittler, 1994; De Serres *et al*., 1995; Galazka *et al*., 1995; Wilson, 1995; Andrews *et al*., 1997; de Melker *et al*., 1997; Baron *et al*., 1998). One possible explanation for this reemergence is that the constant selective pressure imposed by immunization might have resulted in increased antigenic divergence in the remaining bacterial population. Consequently, the effects of vaccination on toxin evolution are beginning to be examined (Pappenheimer and Murphy, 1983; Mencarelli *et al*., 1992; van der Zee *et al*., 1996b; Mooi *et al*., 1998; Guiso *et al*., 2001; Weber *et al*., 2001; von Hunolstein *et al*., 2003).

Comparative genetic analysis of the genes for *B. pertussis* PT and pertactin (an outer membrane protein) between recent epidemic isolates and the vaccine strains revealed that expansion of strains antigenically distinct from vaccine strains has occurred (Khattak and Matthews, 1993; Mooi *et al*., 1998; Weber *et al*., 2001). These findings strongly implicate vaccination as a strong driving force in the continuous evolution of the *B. pertussis* population and may forebode the emergence of novel variants resistant to vaccination. Moreover, since pertactin and PT are the primary bacterial components in acellular pertussis vaccines (ACV) that were introduced in the 1970s and have replaced the whole-cell vaccines (WCV) in some countries, these findings place into question the long-term efficacy of both ACV and WCV.

As a result of long-standing immunization programs using the diphtheria toxoid, most current isolates of *Corynebacterium diphtheriae* or *C. ulcerans* are non-toxigenic (Galazka and Robertson, 1995; Galazka, 2000a; Holmes, 2000; von Hunolstein *et al*., 2003). Of these non-toxigenic strains, most are devoid of the *tox* gene; however, these strains could potentially be converted into toxigenic strains by exposure to a corynebacteriophage β carrying the *tox* gene (Pappenheimer and Murphy, 1983; Buck *et al*., 1985; Cianciotto and Groman, 1985; Cianciotto and Groman, 1997). While there are no definite examples of this sort of genetic transfer having occurred for diphtheria, there is fear that the continued presence of non-toxigenic strains in immunized populations (Galazka and Robertson, 1995; Reacher *et al*., 2000) and the potential import of toxigenic strains from endemic areas such as Russia (Galazka, 2000b; Skogen *et al*., 2002) might allow for phage conversion to occur. In addition, it is possible that recombination events might occur within *tox*

genes between non-toxigenic strains that harbor defective *tox* genes, and, even though this has not yet been experimentally observed (Cianciotto and Groman, 1997), the possibility still remains that this could result in reversion to full toxigenicity.

## Toxin evolution and transmission in the soil environment

Many bacterial pathogens, even those for which humans or animals can serve as the natural or primary reservoir, spend a substantial amount of time outside the host body in the external environment. This suggests that the evolution of pathogens through HGT may not occur only in the host environment. For example, it is now well recognized that the selective pressure of xenobiotic pollutants in soil and water can lead to the acquisition by soil bacteria of plasmids encoding xenobiotic-degrading enzymes (Davison, 1999; Demaneche *et al*., 2001b; Ashelford *et al*., 2003). There is even some evidence that natural electro-transformation, as might occur during a thunder-lightning storm, might be a feasible mechanism for increasing the frequency of HGT in soil microcosms (Demaneche *et al*., 2001a).

*Bacillus* species are common spore-forming soil bacteria barely distinguishable at the genome sequence level (Helgason *et al*., 2000; Read *et al*., 2003; La Duc *et al*., 2004), yet this group of bacteria differs considerably in their virulence properties. *B. subtilis* is commonly used as a nonpathogenic laboratory model system for studying bacterial sporulation; *B. thuringiensis* produces a number of insecticidal toxins widely used as pesticides in agriculture and more recently in genetically modified plants to confer insect resistance; *B. cereus* is a food-borne pathogen capable of causing human and animal gastrointestinal disease; and *B. anthracis* is a human and animal pathogen that causes anthrax disease and has received much attention recently because of its potential use as a bioterror agent.

The structural genes encoding the major virulence factors of *B. anthracis* responsible for anthrax, the anthrax lethal toxin and edema toxin genes (*pag, lef, cya*) and the poly-D-glutamate capsule biosynthetic genes (*capBCA*), reside on two large plasmids, pXO1 and pXO2, respectively (Okinaka *et al*., 1999a; Okinaka *et al*., 1999b). Loss of the pXO2 plasmid resulted in the greatly attenuated Sterne vaccine strain. Although it does not appear that these plasmids are self-transmissible, there are reports that suggest conjugative plasmids from other *Bacillus* species might be able to supply the conjugal transfer functions in trans for these two virulence plasmids (Andrup *et al*., 1996; Pannucci *et al*., 2002). If this is true, then it is conceivable that other *Bacillus* species may serve as an environmental reservoir for the anthrax toxin genes. And, indeed, HGT is reported to be quite common among *Bacillus* species (La Duc *et al*., 2004), with an intriguing example being the finding that several of the *B. anthracis* pXO1 genes have homologues on the *B. cereus* chromosome Helgason *et al*., 2000) and that pXO1 contains 15 ORFs with sequence similarity to transposases, integrases, or recombinases, as well as a number of insertion (IS) elements with high homology to IS sequences found in *B. thuringiensis* and *B. cereus* (Okinaka *et al*., 1999a; Okinaka *et al*., 1999b). However, within the *B. anthracis* group there appears to be surprisingly little genetic variation, as illustrated by sequence analysis of the protective antigen toxin gene, *pag*, which revealed only five point mutations among 26 diverse *B. anthracis* isolates (Price *et al*., 1999). This finding was consistent with a previous report that used chromosomal markers (Keim *et al*., 1999), and may reflect a very recent origin of this species or other unknown population constrictions that warrant further study (Keim *et al*., 1999; Okinaka *et al*., 1999a; Okinaka *et al*., 1999b).

*B. thuringiensis* produces a considerable arsenal of toxins directed against insects and nematodes, with multiple toxin-encoding genes on plasmids and various mobilizable genetic elements on the chromosome (de Maagd *et al*., 2003). HGT, combined with recombination and shuffling between toxin genes (resulting in domain swapping) and sequence divergence, has yielded a wide range of host specificities for these insecticidal toxins (Lee *et al*., 1995; Bravo, 1997; de Maagd *et al*., 2001). The genes encoding the crystal protein toxins, for example, are frequently clustered on different transmissible plasmids or transposable elements (Schnepf *et al*., 1998; de Maagd *et al*., 2001), and conjugation between different strains has been observed in the soil environment and within insect guts (Thomas *et al*., 2001). Individual toxins have insecticidal activity only against a limited range of insect species, i.e., usually only within certain insect orders. The composite of the toxins produced by a particular strain thus defines the total insecticidal specificity and activity spectrum of that bacterial strain (de Maagd *et al*., 2001).

## Toxin evolution and transmission in aquatic environments

Other studies have shown that the concentrations of bacteriophages in natural aquatic environments can be high enough to be conducive for phage transduction (Miller, 2001; Paul *et al*., 2002), but can be especially high in contaminated water systems (Davison, 1999; Chee-Sanford *et al*., 2001; Teuber, 2001). A recent study

showed that a broad range of *E. coli* strains harboring *stx2*, and to a lesser extent *stx1*, genes are commonly found in municipal sewage and various animal wastewaters (Garcia-Aljaro *et al*., 2004). Moreover, of the *E. coli* strains in this study testing positive for toxin genes (only one out of 59 representative strains was typed as O157:H7), about 50% of those from animal wastewater and 10% of those from human sewage were also able to produce the toxin proteins. These findings not only indicate the presence of a significant exchange of these genes between bacterial populations in these environments, but also suggest a potential health risk in that the bacteria also make the toxins.

There is now strong genetic evidence that epidemic strains of *Vibrio cholerae*, the etiological agent of cholera, have been acquiring CT, TCP, and other virulence factor genes through bacteriophage transduction and conjugal transfer (Faruque *et al*., 1998; Beaber *et al*., 2002; Davis and Waldor, 2003). As mentioned above, the genes encoding CT (ctxAB) are transferred by the bacteriophage CTXϕ (Waldor and Mekalanos, 1996; Davis and Waldor, 2003). Moreover, the genes encoding the bacterial toxin co-regulated pili (TCP) that are the receptors for CTXϕ are also encoded by another putative prophage, VPIϕ (Karaolis *et al*., 1999; Davis and Waldor, 2003). Recent studies support that HGT has occurred between *V. cholerae* and other environmental *Vibrio* species, such as *V. mimicus* (Boyd *et al*., 2000), suggesting that these environmental strains might serve as reservoirs for genetic exchange, thereby contributing to the emergence of new toxigenic *Vibrio* strains.

Since HGT occurs at maximal frequencies when bacterial densities are high (Hausner and Wuertz, 1999; Hohnstock *et al*., 2000; Lilley *et al*., 2003), one might ask how genetic exchange can occur in aquatic environments, where *Vibrio* spend most of their time and where their concentrations are expected to be too low to be conducive to HGT. Studies have shown, however, that most bacteria found in marine environments are adherent to marine animals or particles, such as zooplankton or marine snow (Azam and Long, 2001). Indeed, *Vibrio* strains are often found in close association with zooplankton (Chiavelli *et al*., 2001) as dense bacterial biofilms (Watnick *et al*., 1999). This finding correlates with the observation that zooplankton blooms frequently precede cholera outbreaks and that simple water filtration to remove zooplankton can significantly reduce the incidence of cholera cases in endemic areas (Colwell *et al*., 2003). Similar findings have been observed for other environmental bacteria. The presence of particulate matter in aqueous environments was found to increase *Pseudomonas*-phage interactions and thereby stimulate transduction (Ripp *et al*., 1994; Miller, 2001).

## Toxin evolution and transmission in the phyllosphere

Other environmental settings could also serve as ideal locations for biofilm formation and consequent HGT (Davison, 1999; Miller, 2001). One such important setting is the phyllosphere, i.e., plant surfaces. Numerous examples of relatively high conjugal transfer rates on the phylloplane of plants have been observed within and between species of *Pseudomonas* and *Rhizobium*, especially when humidity was high (Davison, 1999). The soil bacterium *Ralstonia solanacearum*, a plant pathogen, even develops a state of natural competence in plant tissues and readily exchanges genetic material (Bertolla and Simonet, 1999). Aggregation or clustering of the bacteria into microhabitats in the interstices and stomata of the leaf surface has been found to stimulate bacterial survival and conjugal transfer (Normander *et al*., 1998).

Evidence for phage-mediated transduction among bacterial strains on the phylloplane has also been documented for the plant and opportunistic human pathogen *Pseudomonas aeruginosa* (Kidambi *et al*., 1994) and the indigenous plant microbes, *P. fluorescens* and *Serratia liquefaciens* (Ashelford *et al*., 2000; Ashelford *et al*., 2002; Ashelford *et al*., 2003). The transmission of *E. coli* O157:H7 from manure-contaminated soil and irrigation water to lettuce plants has been demonstrated (Solomon *et al*., 2002a; Solomon *et al*., 2002b). Indeed, the toxin-producing bacteria were found not only on the plant surfaces, but also throughout the root system and within the edible portions of the plant tissues. The implications of this, in terms of the spread of human disease through fresh produce, are alarming, and may account for a number of reported outbreaks. For instance, irrigation water contaminated with the feces of cattle from an adjacent field was implicated as the source of *E. coli* O137:H7 during a multi-state outbreak associated with consumption of mesclun lettuce (Hilborn *et al*., 1999).

## Toxin evolution in biofilms and regulation by quorum sensing

Evidence is accumulating that the high rates of HGT observed in bacterial biofilms may be attributable to quorum sensing control of conjugation and production of exoenzymes/toxins and other virulence factors, in addition to biofilm formation (Zhang *et al*., 1993; Fuqua and Winans, 1994; Hausner and Wuertz, 1999; de Kievit and Iglewski, 2000; Brelles-Marino and Bedmar, 2001). The finding that *Roseobacter* species and other bacteria associated with marine snow also produce acyl homoserine lactones (Gram *et al*., 2002) suggests

that environmental microbes may use quorum sensing to regulate phenotypic traits (e.g., biofilm formation, metabolite/toxin production, conjugation) only when their populations in the marine snow environment reach adequate densities.

The strong conservation of virulence determinants (e.g., toxins) among clinical and environmental isolates of *P. aeruginosa* supports the notion that conserved selective pressures for the maintenance of the virulence traits exist in the environmental reservoir (Wolfgang *et al*., 2003). Recent evidence suggests that quorum sensing regulation of the formation of biofilms and the production of toxins may have played a critical evolutionary advantage in the environment by providing a protective mechanism through which the bacteria are able to resist flagellate and other protozoan predation and thereby persist outside the human host (Matz *et al*., 2004). Similarly, the effector protein toxins that are delivered by the Icm/Dot type IV secretion system of *Legionella pneumophila* appear to be equally effective in mammalian cells and in amoeba (Hilbi *et al*., 2001; Molmeret *et al*., 2002).

Another well-characterized example of biofilm and toxin regulation through quorum sensing can be found for the opportunistic pathogen *P. aeruginosa* in the lungs of cystic fibrosis (CF) patients, where *P. aeruginosa* forms both aerobic and anaerobic biofilms. Each type of biofilm that *P. aeruginosa* forms differs significantly in its virulence and phenotypic properties (Hassett *et al*., 2002; Yoon *et al*., 2002; Hogardt *et al*., 2004; Matz *et al*., 2004). In the CF lung, quorum-sensing systems regulate the formation of these two types of biofilms (Singh *et al*., 2000; Yoon *et al*., 2002), as well as toxin/exoenzyme production (Hogardt *et al*., 2004). Interestingly, whereas the expression of exotoxin A (ExoA) and various protease and phospholipase exoenzymes are up-regulated by quorum sensing in biofilms, the type III secretion system and its translocated effectors (ExoS, ExoT, ExoY, and ExoU), which are only important when the bacteria are in direct contact with the host cells, are down-regulated by quorum sensing (Hogardt *et al.*, 2004).

One exception to the strong conservation of virulence genes in *P. aeruginosa* is the presence of the genes for ExoS and ExoU, with isolates from different clinical and environmental settings possessing one or the other of the *exoS* or *exoU* genes, but not both (Yahr *et al*., 1996; Feltman *et al*., 2001; Wolfgang *et al*., 2003). It has been suggested that one possible explanation may be that expression and delivery of one or the other toxin might provide a selective advantage in a particular, as yet unidentified, target host or tissue site (Wolfgang *et al*., 2003).

### Toxin evolution in the guts of insects and other vectors

New evidence is accumulating that bacteriophages and other mobile genetic elements could also play important evolutionary roles in bacterial endosymbiont systems of insect hosts (Werren *et al*., 1995; Heath *et al*., 1999; Vavre *et al*., 1999; Masui *et al*., 2000; Sandstrom *et al*., 2001; Dyson *et al*., 2002; Kondo *et al*., 2002; Hoffmeister and Martin, 2003; Fujii *et al*., 2004). There is significantly elevated frequency of HGT between bacteria while within the digestive vacuoles of protozoan cells such as *Tetrahymena pyriformis* (Schlimme *et al*., 1995). The bacteriophage WO from parasitic arthropod bacterial symbionts (*Wolbachia*) was shown to undergo recent lateral transfers between *Wolbachia* strains that co-infect a diverse set of insect host cells (Wernegreen, 2002; Wernegreen *et al*., 2003; Degnan *et al*., 2004; Fujii *et al*., 2004). Plasmid transfer from *Erwinia herbicola* to *E. cloacae* was observed in the guts of silkworms (Watanabe and Sato, 1998).

Both conjugative and mobilizable plasmids from *E. coli* could likewise be transferred to a wide variety of *Proteobacteria* in the gut of the soil microarthropod (Hoffmann *et al*., 1998), which could play host to HGT of toxin genes in *E. coli*-contaminated water or soil. *Yersinia pestis*, the causative agent of plague, has also been demonstrated to be capable of interacting with and acquiring plasmids from *E. coli* in the midgut of the flea at transfer frequencies of ~$10^{-3}$ per recipient (Hinnebusch *et al*., 2002). One might ask whether toxin gene-encoding plasmids or mobile elements might also be transferred within the guts of insects, and, indeed, such transfers can and have occurred. For example, efficient gene transfer of plasmids encoding δ-endotoxin has been observed between different strains of *Bacillus thuringiensis* in various arthropod hosts (Jarrett and Stephenson, 1990).

## CONCLUSION

The evolution of bacterial toxins involves HGT and recombination through exposure to a combination of both the host and external environments. Most toxin genes are located on PAIs on plasmids or in the bacterial chromosome as prophages or transmissible elements. Genome sequencing and genetic analysis of toxin genes in epidemiological isolates may provide more information on the extent and limitations, as well as regulatory mechanisms that influence HGT and their impact on toxin evolution.

CHAPTER

# 3

# Mobile genetic elements and pathogenicity islands encoding bacterial toxins

*Ulrich Dobrindt and Jörg Hacker*

## INTRODUCTION: THE GENOME STRUCTURE OF PROKARYOTES

Pathogenicity correlates with the expression of disease-related factors present in pathogenic bacteria but usually absent from non-pathogenic bacteria. The analyses of complete prokaryotic genome sequences have shown that the bacterial genome size and organization is considerably variable. Different numbers of circular or linear chromosomes, extrachromosomal linear or circular replicons, as well as different combinations thereof, exist in bacteria (Bentley and Parkhill, 2004). The bacterial chromosome is considered to be composed of a conserved "core" gene pool harboring genetic information required for essential cellular functions and of a "flexible" gene pool. The latter encodes additional traits that contribute to the adaptation of microbes under certain circumstances, e.g., resistance to antibiotics, production of toxic compounds, as well as other virulence factors. The chromosomal organization of the "core" regions is similar in closely related species and is not transferable *per se*. Genes located within this chromosomal backbone exhibit a relatively homogenous G+C content and a specific codon usage (Sharp, 1991). In contrast, the "flexible" gene pool consists of variable chromosomal regions which may be beneficial under certain circumstances, e.g., bacterial toxins and other virulence factors. This gene pool includes mobile and accessory genetic elements such as bacteriophages, plasmids, genomic islands, IS elements, transposons, and integrons.

Genomic islands (GEIs) represent a group of distinct genetic entities. Depending on the functions and their role for a specific lifestyle of a bacterium, GEIs may be called pathogenicity, symbiosis, fitness, metabolic, or resistance islands (Hentschel and Hacker, 2001; Hacker and Carniel, 2001; Hacker and Kaper, 2002). Furthermore, the presence of identical genes in pathogenic and non-pathogenic variants of one species, e.g., in extraintestinal pathogenic and commensal *E. coli*, implies that some of these encoded factors rather contribute to general adaptability, fitness, and competitiveness than to particular virulence traits (Grozdanov *et al*., 2004; Dobrindt *et al*., 2004). Other accessory components have been described like the transposable Insertion Sequence (IS) elements and transposons (Deonier, 1996). They are restricted to moving themselves and sometimes additional sequences, by recombination events from one site of their genome to other sites of the same genome (Berg, 1989). In addition to the chromosome(s), many prokaryotes can contain genetic information on plasmids, which are extrachromosomal DNA elements with the ability of autonomous replication. The genetic information encoded by plasmids can contain valuable genes, which may be beneficial under certain conditions, such as toxin genes, but also resistance determinants and genes coding for specific metabolic properties. Many different plasmid types can be transferred between

bacteria. Some have the ability to become integrated into the chromosome, thereby losing control of their own replication (Hardy, 1986; Lüneberg *et al*., 2001). Other genetic elements frequently found in association with the genome are integrons, retrophages, and lysogenic bacteriophages. Transferable genetic elements, such as bacteriophages and plasmids, can function as vehicles laterally transporting genetic information, thus playing an important role in bacterial evolution. Bacteriophages, as viruses that infect prokaryotes, can genetically modify their host in becoming part of the genome. They may carry genes that bring about new functions or modify existing ones. Interestingly, toxin-specific genes are often located on bacteriophage genomes (Travisano and Inouye, 1995; Mazel *et al*., 1998; Rowe-Magnus *et al*., 2001; Brüssow *et al*., 2004).

With respect to the above-mentioned structure of bacterial chromosomes and the different classes of mobile elements frequently found in prokaryotic genomes, it can be concluded that the genome of prokaryotes constantly undergoes structural variations due to the potential of mobile elements to integrate into different sites of the chromosome and to promote chromosomal rearrangements via recombinational mechanisms. Genome plasticity, i.e., the frequently occurring acquisition or loss of genetic information, is of great importance for adaptive evolution of disease-causing bacteria as simultaneous acquisition of many genes by HGT allows the inheritance of complex disease-related characteristics, including protein toxins, in a single step (Ochman *et al*., 2000; Ochman and Moran, 2001; Hacker *et al*., 2003).

The accumulation of prokaryotic gene and genome sequences has shed light on many aspects of microbiology. The current knowledge of more than 200 complete microbial genome sequences (http://www.ncbi.nlm.nih.gov/genomes/MICROBES/Complete.html) has proven particularly useful for comparative studies between different bacterial species and the evolutionary processes that drive their differentiation. Comparative genomics reveals that a striking correlation exists between the distribution of protein toxins and movable genetic elements in bacteria. Indeed, a great number of bacterial protein toxin determinants are associated with plasmids, bacteriophages, or pathogenicity islands. Together with gene loss and other genomic alterations, gene acquisition plays an important role for adaptive evolution of prokaryotes. Considerable insight has been gained into the contribution of mobile and accessory genetic elements to these processes. In this review, we will show that there is a structural and functional interdependence between many bacterial protein toxin genes and mobile and accessory genetic elements that promotes adaptive evolution of pathogenic bacteria.

## PROTEIN TOXINS ENCODED BY MOBILE GENETIC ELEMENTS

### Protein toxins encoded by plasmids

Many bacterial pathogens harbor plasmids carrying protein toxin determinants. They frequently contribute to specific combinations of virulence factors present in these strains. This argues for a co-evolution of specific factors in different pathotypes. Some of these plasmids have been shown to integrate into the chromosome (Zagaglia *et al*., 1991; Colonna *et al*., 1995). Important plasmid-encoded protein toxins are given in Table 3.1.

#### *Gram-negative bacteria*

Intestinal *E. coli* bacteria may cause different types of diarrheal diseases. The differences in the clinical pictures reflect the different pathotypes of intestinal *E. coli*, such as ETEC (enterotoxigenic *E. coli*), EPEC (enteropathogenic *E. coli*), and others (see Table 3.1). A main feature of the different intestinal *E. coli* pathotypes is the presence of pathotype-specific plasmids, which often encode protein toxins. Enterotoxigenic *E. coli* (ETEC) strains cause diarrhea through the action of two different plasmid-encoded types of enterotoxins, the heat-labile enterotoxin (LT) and the heat-stable enterotoxin (ST). These strains usually contain the determinant for an LT only, an ST only, or both toxin types (Gyles *et al*., 1974; Levine, 1987; Gyles, 1992). Heat-labile toxins (LTs) are closely related to the cholera toxin of *Vibrio cholerae* (Spangler, 1992; Sixma *et al*., 1993). Two unrelated classes of plasmid-encoded heat-stable toxins without sequence homology exist (STa and STb). The STb encoding gene (*estB*) is found on heterogenous plasmids, which may also contain other properties (Harnett and Gyles, 1985; Echeverria *et al*., 1985; Dubreuil, 1997).

The low-molecular-weight ST called *EAST1 of enteroaggregative E. coli* (EAEC) strains (Savarino *et al*., 1991, 1993) exhibits 50% protein identity to STa and is encoded on so-called EAF-plasmids, which range from 50–70 MDa in size (Nataro *et al*., 1987). This enterotoxin can also be expressed in addition to STa from some ETEC, EHEC, and many EPEC strains as well (Nataro *et al*., 1987; Savarino *et al*., 1996; Yamamoto and Echeverria, 1996).

Enteroinvasive *E. coli* produce an enterotoxin that is also expressed by *Shigella flexneri*. Therefore, it has been designated ShET2 (*Shigella* enterotoxin 2) as well. The toxin-encoding gene (*sen*) is located on the 140-MDa pInv-plasmid (Nataro *et al*., 1995; Sears and Kaper, 1996).

**TABLE 3.1** Protein toxins encoded by bacterial plasmids

| Organism | Pathotype[1] | Plasmid-encoded property | Gene symbol | Other plasmid-encoded factors |
|---|---|---|---|---|
| *Escherichia coli* | ETEC | Heat-labile enterotoxin (LT) | *elt*, *etx* | ST, CFAs, drug resistance, colicins |
| | ETEC | Heat-stable enterotoxin (ST)[2] | *est* | ST, LT, CFAs, drug resistance, colicins |
| | EAEC, ETEC, EHEC, EPEC | EAST1 | *ast* | Type IV adhesin "bundle forming pili" |
| | ExPEC | Alpha-hemolysin (Hly) | *hly* | - |
| | EHEC | Enterohemolysin (Ehx) | *ehx* | - |
| | ExPEC, ETEC | Cytotoxic necrotizing factor 2 (CNF2) | *cnf*2 | F17-, AFA/Dr adhesins, cytolethal distending toxin (CDT) |
| | EIEC | EIEC enterotoxin ( = *Shigella* enterotoxin 2) | *sen* | Genes required for invasion, Ipa proteins, type III secretion system |
| *Yersinia spp*. | | Yop proteins | *yop* | Genes required for invasion, Yop proteins, type III secretion system |
| *Shigella spp*. | | *Shigella* enterotoxin 2 (shET2-2, OspD2) | *senA* | Genes required for invasion, Ipa proteins, type III secretion system |
| | | *Shigella* enterotoxin SenA (OspD3) | | |
| *Enterococcus faecalis* | | Cytolysin | *cyl* | - |
| *Staphylococcus aureus* | | Enterotoxin type D and J | *entD, -J* | Penicillin and cadmium resistance |
| | | Exfoliative toxin B | *etb* | Cadmium resistance, bacteriocin |
| | | ADP-ribosyltransferase EDIN-C | *edin-C* | see above |
| *Clostridium tetani* | | Tetanus neurotoxin (TeTx) | *tetX* | Collagenase (ColT) |
| *Clostridium botulinum* | | Botulinum neurotoxin type G (BoNT/G) | *botG* | Bacteriocin (Boticin G) |
| *Bacillus anthracis* | | Anthrax toxin (lethal factor, edema factor, protective antigen) | *lef*, *cya*, *pag* | - |

[1]EAEC, enteroaggregative *E. coli*; EHEC, enterohemorrhagic *E. coli*; EPEC, enteropathogenic *E. coli*; ETEC, enterotoxigenic *E. coli*
[2]Genes encoding for STa (*estA*) and STb (*estB*) have been found on Tn1681 (So and McCarthy, 1980) and Tn4521(Lee et al., 1985; Hu et al., 1987; Hu and Lee, 1988), respectively.

ETEC strains and extraintestinal *E. coli* from animals often carry the structural gene for CNF2 (*cnf*2) on the F-like Vir-plasmid (Oswald and De Rycke, 1990; Oswald *et al*., 1994). The Vir-plasmid can also contain sequences that are homologous to adhesins as well as cytolethal distending toxin (CDT) determinants (Mainil *et al*., 1997; Peres *et al*., 1997). Interestingly, *cnf1*, which is a homologous gene of *cnf*2, is located on pathogenicity islands of uropathogenic *E. coli* strains (Blum *et al*., 1995; Donnenberg and Welch, 1995; Swenson *et al*., 1996).

Extraintestinal *E. coli*, a major cause of urinary tract infections (UTI), sepsis, and newborn meningitis (NBM) in humans, often carry pathogenicity islands (PAIs) that contain the α-hemolysin gene cluster (*hly*) (Hacker and Hughes, 1985). Some *E. coli* strains contain *hly* determinants on plasmids, which are heterogenous in size (50 to 160 kb), conjugational behavior, and incompatibility group (De la Cruz *et al*., 1980). The plasmid- and chromosomally encoded *hly* determinants show a high overall homology (De la Cruz *et al*., 1980; Müller *et al*., 1983). Nevertheless, the sequences of the upstream regions differ significantly (Knapp *et al*., 1985; Hess *et al*., 1986). The enterohemolysin determinant (*ehxABD*) of enterohemorrhagic *E. coli* strains is encoded on plasmids (pO157) that range in size from 93–104 kb (Schmidt *et al*., 1995, 1996). Although this toxin has a high overall similarity to α-hemolysin, the amino- and carboxy-termini of both proteins are different (Schmidt and Karch, 1996; Bauer and Welch, 1996).

Virulence plasmids of pathogenic *Yersinia*, *Shigella*, and *Salmonella* species all have in common the fact that they lack genes encoding conventional protein toxins. The *Yersinia* and *Shigella* virulence plasmids code for a conserved type III protein secretion system (Lindler *et al*., 1998; Buchrieser *et al*., 2000). All pathogenic species of *Yersinia* (*Y. pestis*, *Y. pseudotuberculosis*, and

*Y. enterocolitica*) harbor a virulence plasmid (pYV) of about 70 kb in size. This plasmid encodes the Yop virulon that organizes the secretion of several proteins termed Yops (*Yersinia* outer proteins), which are essential for virulence (Portnoy and Falkow, 1981; Galyov *et al*., 1993; Straley *et al*., 1993). Some of the Yops are considered as "unconventional toxins," i.e., the cytotoxin YopE, YopH, and YopO (Bliska *et al*., 1992), as well as YopB which shows sequence similarity to contact hemolysins, like IpaB of *Shigella* species (Beuscher *et al*., 1995). All virulent *Shigellae* and enteroinvasive *E. coli* strains harbor a 220-kb pInv plasmid that encodes all genes which are essential for epithelial cell invasion (Parsot and Sansonetti, 1996). The effectors of the invasion process, termed *invasion plasmid antigens* (Ipa), are encoded on this plasmid (Venkatesan *et al*., 1988; Sasakawa *et al*., 1989; Venkatesan *et al*., 1991), as well as the invasin IpaB, which has homology to pore-forming toxins (Ménard *et al*., 1994; Beuscher *et al*., 1995). In addition, the invasion plasmid contains the *sen* gene encoding the *Shigella* enterotoxin 2, which is also called *EIEC enterotoxin*. The *sen* gene from *Shigella flexneri* 2a and EIEC share 99% identity (Nataro *et al*., 1995).

### *Gram-positive bacteria*

The *Clostridium tetani* structural gene encoding the tetanus neurotoxin (TeTx) is located on a 74-kb plasmid (e.g., pCL1, pE88) (Laird *et al*., 1980; Finn *et al*., 1984; Brüggemann *et al*., 2003). All *Cl. botulinum* type G strains investigated, contain an 81-MDa plasmid (Strom *et al*., 1984), which presumably encodes either the structural gene (*botG*) of the botulinum neurotoxin type G (BoNT/G) or regulatory genes important for BoNT/G expression (Eklund *et al*., 1988; Minton, 1995).

Virulent *Bacillus anthracis* strains contain two large plasmids, pXO1 and pXO2, which are both required for virulence (Kaspar and Robertson, 1987). The genes for the three-component anthrax exotoxin are located on pXO1 (Mikesell *et al*., 1983; Thorne, 1985), whereas plasmid pXO2 contains genes coding for another virulence factor of *B. anthracis*, the D-glutamic acid–composed capsule (Green *et al*., 1985; Uchida *et al*., 1985). The "pathogenicity region" of pXO1 is flanked by mobile genetic elements that are supposed to be involved in acquisition of this region by pXO1 (Okinaka *et al*., 1999). Comparative analysis of the complete genome sequence of *B. anthracis* strain Ames and of its non-pathogenic relative *B. cereus* strain ATCC10987 demonstrated that pXO1 (~182 kb) is similar to plasmid pBc10987 (~208 kb) of *B. cereus*. Roughly 65% of the encoded proteins were homologous and about 50% of them were in a syntenic location. Interestingly, the region of pXO1 comprising the genes that code for the lethal factor, protective antigen, edema factor, and the transcriptional regulator AtxA is absent from pBc10987. Instead, a *B. cereus*-specific region can be found that is not flanked by mobile genetic elements (Rasko *et al*., 2004). Similar observations have been made by comparative genome hybridization of 19 different isolates of the *B. cereus*/*B. thuringiensis* group to a DNA array based on the *B. anthracis* strain Ames genome sequence. The results obtained indicate that pXO1 homologues that lack the pathogenicity region were detectable in 50% of the tested *B. cereus*/*B. thuringiensis* strains (Read *et al*., 2003). These data underline that variability in plasmid gene content and the acquisition of plasmid-encoded virulence factors play an important role in evolution of pathogenic bacteria.

Cytolytic strains of *Enterococcus faecalis* produce a cytolysin that shows a homology to lantibiotics. The cytolysin determinant (*cyl*) consists of six tandemly arranged genes. These are encoded in one operon on large ( 60 kb), transmissible, and pheromone-responsive plasmids (Jett *et al*., 1994; Gilmore *et al*., 1994). Cytolysin determinants have also been located on the chromosome of *Enterococcus* (Ike and Clewell, 1992; Shankar *et al*., 2002).

The structural gene (*entD*) coding for the staphylococcal enterotoxin D (SED) has been located on the 27.6-kb penicillinase plasmid pIB485 (Bayles and Iandolo, 1989). The two exfoliative toxin determinants responsible for the staphylococcal scalded skin syndrome have been assigned to different genetic loci. The gene for exfoliative toxin A (*eta*) has been mapped on the chromosome and that for the exfoliative toxin B (*etb*) on the plasmid pRW0019 (Warren *et al*., 1975; Jackson and Iandolo, 1985).

## Protein toxins encoded by bacteriophage

Bacteriophages encode a variety of toxin genes of pathogenic bacteria. The toxin genes are frequently located next to the bacteriophage attachment site, which argues for acquisition by mechanism of transduction. The bacteriophage-encoded toxins are given in Table 3.2.

### *Gram-negative bacteria*

Full virulence of *Vibrio cholerae* depends on two coordinately expressed factors: the cholera toxin (CT) and toxin-co-regulated pili (TCP). The CT encoding genes (*ctxAB*) are located on the CTX element, which ranges from 7 to 9.7 kb in size and occurs frequently in multiple, tandemly arranged copies. This element has been identified as a lysogenic filamentous bacteriophage designated CTXϕ (Mekalanos, 1983; Waldor and Mekalanos, 1996) and is restricted to toxigenic strains

**TABLE 3.2** Protein toxins encoded by bacteriophages

| Host organism | Bacteriophage-encoded toxin | Gene symbol | Phage designation |
|---|---|---|---|
| *Vibrio cholerae* | Cholera toxin (CT) | *ctx* | CTXϕ |
| *E. coli* (EHEC) | Shiga toxin (Stx) | *stx* | H19, 933 |
| *E. coli* | Enterohaemolysin | *hly*2 | ϕFC3208 |
| *E. coli* | Cytolethal distending toxin | *cdt* | – |
| *Pseudomonas aeruginosa* | Cytotoxin (CTX) | *ctx* | ϕCTX[1] |
| *Pasteurella multocida* | *Pasteurella multocida* toxin (PMT) | *toxA* | – |
| *Corynebacterium diphtheriae* | Diphtheria toxin (DT) | *tox* | β, ω[2] |
| *Clostridium botulinum* | Botulinum neurotoxin type C1 and D (BoNT/C1, BoNT/D) | *botC, botD* | C1 |
| *Streptococcus pyogenes* | Pyrogenic exotoxins A, C,G, H, I, M, L, K | *speA, -C, -I, -H, -M, -L, -K* | SPE-phage, CS112, T12[3] 8232.1, 315.5, 370.1, 370.2, 8232.3, 315.4 |
| | Streptococcal superantigen | *ssa* | 315.2 |
| *Staphylococcus aureus* | Enterotoxin A | *entA* | PS42D, ϕ13 |
| | Enterotoxin A | *sea* | ϕMu50A |
| | Enterotoxin G | *seg* | ϕSa3ms |
| | Enterotoxin K | *sek* | ϕSa3ms |
| | Enterotoxin P | *sep* | ϕN315 |
| | Exfoliative toxin A | *eta* | ϕETA |
| | Pantone-Valentine leukocidin | *lukSF*-PV | ϕPVL |
| | Staphylokinase | *sak* | ϕ13, ϕSa3ms |

[1]The chromosomal attachment site (*attB*) of ϕCTX has been mapped to the 3′-end of a $tRNA^{Ser}$-encoding gene (Hayashi et al., 1993).
[2]The chromosomal attachment sites (*attB1* and *attB2*) of β and ω overlap with a duplicate tRNA gene encoding the $tRNA_2^{Arg}$ (Ratti et al., 1997).
[3]The chromosomal attachment site (*attB*) of T12 has been mapped to the 3′-end of a $tRNA^{Ser}$-encoding gene (McShan et al., 1997).

(Miller and Mekalanos, 1984; Kovach *et al*., 1996). Structurally, the CTX element resembles a compound transposon (Pearson *et al*., 1993). The core region of the CTX element encodes several toxins, such as CT (*ctxAB*), zonula occludens toxin (*zot*), and the accessory cholera toxin (*ace*). The complete CTX element is self-transmissible and can replicate as a plasmid as well as lead to the production of extracellular virions (Waldor and Mekalanos, 1996). Transmission of CTXϕ requires the expression of TCP pili. The *tcp* genes are located on a separate pathogenicity island (Kovach *et al*., 1996; Faruque *et al*., 2003).

Shiga toxin (Vero toxin) is the major virulence factor of enterohemorrhagic *E. coli* strains. Two immunologically non-cross-reactive groups of Stx can be distinguished (Stx1 and Stx2). One EHEC strain expresses Stx1 only, Stx2 only, both toxin types, or multiple forms of Stx2 (O'Brien *et al*., 1992; Nataro and Kaper, 1998). The Stx1 of EHEC is essentially identical to Shiga toxin from *Shigella dysenteriae* (Takeda, 1995). Sequence variation exists among the members of the Stx1 and Stx2 groups (Jackson *et al*., 1987; O'Brien *et al*., 1992; Asakura *et al*., 2001; Zhang *et al*., 2002; Friedrich *et al*., 2002). The identically organized structural genes for Stx1 and Stx2 are located on lysogenic lambdoid phages, whereas those for Stx2v are encoded on the chromosome (Marques *et al*., 1987; Herold *et al*., 2004). Several variant Stx genes from human Shiga toxin–producing *E. coli* strains do not appear to be phage-encoded as well, but they may be carried on defective bacteriophages (Paton *et al*., 1992, 1993). Some *Citrobacter freundii* and *Enterobacter spp*. strains contain a *stx2* gene, which is homologous to that of *E. coli* (Schmidt *et al*., 1993).

The mitogenic *Pasteurella multocida* toxin PMT is also an example of a bacteriophage-encoded toxin. The coding gene *toxA* is located within a prophage genome that is chromosomally inserted at a tRNA-Leu gene in *P. multocida* strain LFB3 (Pullinger *et al*., 2004).

Certain *Pseudomonas aeruginosa* strains produce a cytotoxin (Ctx). The corresponding structural gene (*ctx*) is carried by a temperate bacteriophage (ϕCTX), which is able to convert non-toxigenic into toxigenic strains. The chromosomal attachment site (*attB*) of ϕCTX has been mapped to the 3′-end of the $tRNA^{Ser}$ (Hayashi *et al*., 1993; Nakayama *et al*., 1999).

### *Gram-positive bacteria*

The determinant encoding diphtheria toxin (*tox*) is part of the genome of corynephage β, which converts non-toxigenic *C. diphtheriae* strains into toxinogenic strains (Barksdale and Pappenheimer, 1954; Collier, 1982). Various different corynephages are known, including some non-converting phages. The corynephages ω and

β are able to form polylysogens by inserting into two different bacterial attachment sites, *attB1* and *attB2*. As a result, the level of toxigenicity is increased as the *tox* gene dose also influences the toxin production (Rappuoli and Ratti, 1984). Both attachment sites overlap with a duplicate tRNA gene encoding the $tRNA_2^{Arg}$ (Ratti *et al*., 1997).

Although many different *Cl. botulinum* strains carry bacteriophages, only in the case of the structural genes of BoNT/C1 and BoNT/D (*botC* and *botD*) has it been proven that they are part of the genomes of bacteriophages (Inoue and Iida, 1970; Eklund *et al*., 1971).

Streptococcal pyrogenic exotoxins and related exotoxins of *Staphylococcus aureus* belong to a family of molecules also designated pyrogenic toxin superantigens (PTSAgs) (Marrack and Kappler, 1990). Eight different types of SAgs have been identified for group A streptococci (GAS). The genome sequences of five GAS strains have been analyzed and indicate that each strain harbors four to eight prophages or prophage-like elements, most of which encode PTSAgs. The structural genes of the streptococcal pyrogenic exotoxins (SPE) type A, C, H, I, L, M, and K, as well as that of the streptococcal superantigen Ssa, have been shown to be phage-encoded. The prophages, which represent a small fraction of the complete GAS genome, account for up to 74% of the gene content variation among different strains. Only three out of 21 GAS prophage elements currently sequenced do not encode virulence-associated factors. Accordingly, they have been important for evolution and genome diversification of GAS genomes and may also be responsible for the spread of related toxins among related species (Weeks and Ferretti, 1984; McShan and Ferretti, 1997; Feretti *et al*., 2001; Smoot *et al*., 2002; Beres *et al*., 2002; Nakagawa *et al*., 2003; Banks *et al*., 2004). The description of the *S. dysgalactiae* mitogen (SDM) underlines that similar toxins exist in other streptococci as well (Miyoshi-Akiyama *et al*., 2003). Furthermore, two pyrogenic superantigens have been detected in *S. equi* (SePE-H and SePE-I), which are closely related to SPE H and I of *S. pyogenes* and the *Staphylococcus aureus* superantigens SEL, SEI, and SEM, respectively (Artiushin *et al*., 2002).

The staphylococcal enterotoxins A–Q also belong to the PTSAg family. The majority of them are encoded by (formerly) mobile genetic elements, but only the *sea*, *see*, *seg*, and *sek* genes are located on bacteriophages. The structural gene (*sak*) for the staphylokinase of *Staphylococcus aureus* is encoded by a bacteriophage (Sako and Tsuchida, 1983), as well as those coding for the exfoliating toxin A and Panton-Valentine leukocidin (Betley and Mekalanos, 1985; Yamaguchi *et al*., 2000; Kaneko *et al*., 1998; Narita *et al*., 2001; Sumby and Waldor, 2003).

## Protein toxin genes and other mobile genetic elements

Plasmids and bacteriophages are elements that increase the genetic flexibility of bacteria. They contribute to the evolution of pathogens upon horizontal gene transfer followed by integration into the chromosome. The fact that toxin genes have the capacity to spread among bacterial strains and even between species is underlined by the occurrence of identical toxin determinants or those with similar functions on different genetic elements, such as chromosomes, phages, and plasmids (see also Table 3.3). Thus, the

**TABLE 3.3** The location of protein toxin encoding genes and their homologues[1]

| Toxin | Location | Organism | Homologue | Location | Organism |
|---|---|---|---|---|---|
| Cholera toxin (CT) | Phage | *V. cholerae* | Heat-labile enterotoxin (LT) | Plasmid, chromosome | *E. coli* |
| α-Hemolysin | Chromosome, PAI | *E. coli* | α-Hemolysin | Plasmid | *E. coli* |

| SEA | Phage | *S. aureus* | SED | Plasmid | *S. aureus* |

[1]Not all homologues are listed for each toxin.

*E. coli* heat-labile enterotoxin (LT) genes (*elt*, *etx*) are located on plasmids (Nataro and Kaper, 1998), while the related cholera toxin (CT) structural gene (*ctxAB*) of toxigenic *V. cholerae* strains is phage-associated (Waldor and Mekalanos, 1996). A similar situation is reported for the Shiga toxin structural genes of *Sh. dysenteriae* (chromosomally encoded) (Hale, 1991) and *E. coli* (phage-encoded). The genes encoding α-hemolysin and CNF- toxins of pathogenic *E. coli* may be located either on plasmids (Waalwijk *et al*., 1984; Hess *et al*., 1986; Oswald *et al*., 1994) or as part of PAIs on the chromosome (Knapp *et al*., 1984, 1986; Falbo *et al*., 1993; Blum *et al*., 1995; Swenson *et al*., 1996). Similar findings have been reported for clostridial neurotoxin genes (Hauser *et al*., 1992; Whelan *et al*., 1994; Minton, 1995), for some enterotoxins, the exfoliative toxins A and B, as well as for ADP-ribosyltransferases B and C (EDIN-B, EDIN-C) of staphylococci (Altboum *et al*., 1985; Betley and Mekalanos, 1985; Couch *et al*., 1988; Johns and Khan, 1988; Zhang *et al*., 1998; Bayles and Iandolo, 1989; Iandolo, 1989; Yamaguchi *et al*., 2001; Yamaguchi *et al*., 2002; Alouf and Müller-Alouf, 2003). The cytolethal distending toxin (CDT) is produced by many pathogenic *E. coli* (Johnson *et al*., 2002; Tóth *et al*., 2003). Whereas the *cdt*-III determinant of septicemic *E. coli* isolate 1404 has been described to be plasmid-encoded (Peres *et al*., 1997), highly similar genes have been detected in the *E. coli* O157:H$^-$ strain 493/89 chromosome where they are flanked by genes with homology to late genes of lambdoid bacteriophages. This indicates that *cdt*-III may have been acquired by bacteriophage transduction (Janka *et al*., 2003).

The location of identical or highly related toxin encoding genes on different genetic elements raises the question of that whether toxin determinants may be part of transposons or other genetic structures that have the capacity to jump between different genetic elements. A transposon location was only reported for the ST enterotoxin structural genes of *E. coli*, which have been found on Tn*1681* (So and McCarthy, 1980) and on Tn*4521* (Lee *et al*., 1985; Hu *et al*., 1987; Hu and Lee, 1988). Interestingly, both enterotoxin genes (*sta* and *stb*), earlier described as part of different transposons, have been reported to be linked within a 40-kb mobile DNA region of virulence plasmid pTC isolated from a porcine enterotoxigenic *E. coli* strain (Fekete *et al*., 2003). Recently, the *Bacteroides fragilis* pathogenicity islet carrying the *B. fragilis* toxin (*bft*) gene has been described to be part of a new family of conjugative transposons. This may explain how this gene could be transferred from toxigenic to non-toxigenic *B. fragilis* isolates (Franco, 2004). Many protein toxin genes such as those encoding α-hemolysin, CNF1, LT enterotoxins, cholera toxin, and others are located next to intact IS elements, which may form complex transposons similar to Tn*5* or Tn*10*.

## TOXINS ENCODED BY PATHOGENICITY ISLANDS

### Pathogenicity islands

Virulence genes are frequently located on mobile or formerly mobile genetic elements, including PAIs (Hacker and Kaper, 2000; Hacker and Kaper, 2002). PAIs have evolved from former lysogenic bacteriophages and plasmids and are defined as large genomic regions present in pathogenic variants but less frequently present in closely related non-pathogenic bacteria. They carry one or more virulence-associated gene(s), have a G+C content differing from that of the rest of the chromosome, and are frequently associated with tRNA genes as well as flanked by repeat structures. PAIs are often unstable and contain mobility genes coding for integrases or transposases. Virulence genes located on PAIs can be divided into several groups according to their function: (i) adherence factors enable bacteria to attach to host surfaces; (ii) siderophores ensure sufficient solubilization and uptake of Fe (III) ions; (iii) capsules avoid phagocytosis and protect against other defense lines of the host immune system; (iv) the endotoxin (LPS) of Gram-negative organisms activates the host complement pathway and is a potent inducer of inflammation; (v) exotoxins destroy or affect eukaryotic cells; (vi) invasins mediate bacterial entry into eukaryotic cells; and (vii) type III and IV secretion systems are required for the targeted delivery of toxins or modulins into eukaryotic cells and modulate host contact, interfere with the host signal transduction pathways, promote apoptosis and entry into non-phagocytic cells. Similar structures have since been discovered in many Gram-negative and Gram-positive human, animal, and plant pathogens. However, several of these traits can be important for non-pathogenic, symbiotic, and environmental bacteria alike (Dobrindt *et al*., 2004).

### Pathogenicity island-encoded toxins

#### *Enterobacteria*

Initially, PAIs were discovered in uropathogenic *E. coli* (UPEC) by Goebel, Hacker, and co-workers (Hacker *et al*., 1990; Blum *et al*., 1994). Typical PAI-encoded protein toxins of UPEC and other extraintestinal pathogenic *E. coli* (ExPEC) are α-hemolysin and the cytotoxic necrotizing factor 1 (CNF-1) (see Table 3.4). In many ExPEC isolates, the corresponding *hly* and

**TABLE 3.4** Protein toxin-encoding pathogenicity islands (PAIs) of Gram-negative bacteria

| Organism | | Designation | Encoded toxin(s) | Other important encoded traits | Junction | Insertion site |

DR- direct repeat
ND- not determined

*cnf*1 determinants are closely associated, thus underlining a possible co-evolution of these genes (Falbo *et al*., 1992; Swenson *et al*., 1996; Bingen-Bidois *et al*., 2002).

Genes coding for autotransporters are usually located on mobile genetic elements, such as plasmids, bacteriophages, and PAIs. Autotransporters constitute a distinct protein family that represent virulence factors, e.g., adhesions, proteases, and toxins (Guyer *et al*., 2000; Dutta *et al*., 2002; Henderson and Nataro, 2001). Vat, a Serine Protease Autotransporter of Enterobacteriaceae (SPATE), is a vacuolating toxin and was initially isolated from avian pathogenic *E. coli* strain Ec222. This gene is located on a 22-kb PAI, chromosomally inserted at the tRNA locus *thrW* that also serves as a chromosomal insertion site for several other

PAIs and bacteriophages. The Vat toxin induces cytotoxic effects as known for the VacA toxin of *Helicobacter pylori* (Parreira and Gyles, 2003). Vat shows high homology to other PAI-encoded autotransporters of pathogenic *E. coli*, e.g., the putative hemoglobin protease Hbp (accession numbers: Q83W66 and Q8FKM0) of uropathogenic *E. coli* O6 strains (95% identity on the protein level) (Dobrindt *et al*., 2002; Welch *et al*, 2002) or the hemagglutinin Tsh (accession number: Q47692) of an avian pathogenic *E. coli* isolate (78% identity on the protein level) (Stathopoulos *et al*., 1999). The enterotoxin EspC is also an autotransporter protein and is encoded by the *espC*-PAI in EPEC strains (Mellies *et al*., 2001).

Another protein toxin–encoding gene is located on a pathogenicity island of *Shigella flexneri*, termed *she* locus. The *she* locus of *S. flexneri* 2a codes for the protein ShMu, which has hemagglutinin and mucinase activities. ShMu shares homology with the virulence-related immunoglobulin A protease-like family of secreted proteins. Within the *she* locus, the two *Shigella* enterotoxin 1 encoding genes *set1B* and *set1A* are tandemly located in the opposite orientation. This element is part of a 51-kb deletable chromosomal element, which has been termed *she* PAI. The flanking regions of this PAI contain several IS elements like IS*2*, IS*600*, and a copy of IS*629*, which was disrupted by the insertion of a bacterial group II intron (Rajamukar *et al*., 1997). The *Shigella* enterotoxin gene (*senA*) has also been detected on a "locus of enterocyte effacement" (LEE)-PAI variant of a rabbit EPEC isolate (Tauschek *et al*., 2002).

### *Other Gram-negative bacteria*

*Photorhabdus luminescens* is pathogenic to a wide range of insects and has a complex symbiotic relationship with nematodes. The *P. luminescens* genome comprises more toxin genes than any other bacterial genome sequenced so far. Additionally, a large number of adhesins, proteases, and lipases, which also may be expressed during the pathogenic phase of its complex lifecycle, was predicted from the complete genome sequence. A multitude of so-called "toxin complex" (*tc*) loci exist on the chromosome of *P. luminescens* strains. All of them code for different high-molecular-weight insecticidal Tc toxins that exhibit oral and injectable activity against several insects. It is anticipated that some of the Tc proteins may function to destroy the insect midgut (ffrench-Constant *et al*., 2000). The so-called *tcd* locus inhibits several features of a pathogenicity island or similar (formerly) mobile genetic element. This DNA stretch comprises multiple tandem repeats of *tcdAB*-like genes interspersed with *tcc*-like sequences. The entire locus is chromosomally inserted at a tRNA-Asp gene and is also associated with multiple enteric repetitive intergenic consensus (ERIC)–like sequences and with a *tcdA*-like pseudogene. This indicates that the *tcdAB* island represents an unstable DNA region (ffrench-Constant *et al*., 2003; Duchaud *et al*., 2003). This is supported by the fact that deletions within this locus have been observed in other *Photorhabdus* strains (Waterfield *et al*., 2002). The genetic structure of "*tc*-island" sequences in several *Photorhabdus* strains is variable, and furthermore, *tc*-like genes are localized on the chromosome or a plasmid of pathogenic microorganisms, e.g., *Xenorhabdus* spp., *Serratia entomophila*, *Yersinia pestis, Ps. syringae pv. tomato, Fibrobacter succinogenes, Treponema denticola*, several of which are insect-associated. Two other toxin determinants are localized on PAI-like structures (see Table 3.4). The *mcf* gene coding for the probably pro-apoptotic Mcf protein is inserted near a tRNA-Phe gene and located next to the *palAB* genes that code for a HecAB-like adhesin or hemolysin. The chromosomal insertion site as well as the number of *mcf* loci differs between individual *Photorhabdus* strains. Cytonecrosis-like toxin (*cnt*-like) and macrophage toxin-like (*mt*-like) genes have also been described to be located on chromosomal islands (ffrench-Constant *et al*., 2000; ffrench-Constant *et al*., 2003; Duchaud *et al*., 2003).

*Bordetella pertussis*, the causative agent of whooping cough, secretes several toxins implicated in this disease. The major virulence factor produced by *B. pertussis* is the pertussis toxin PTX. The five genes encoding the different subunits of the toxin (*ptx*) and the nine accessory genes required for the PTX (type IV-) secretion system (*ptl*) are organized as a polycistronic operon (Locht and Keith, 1986; Weiss *et al*., 1993; Farizo *et al*., 1996), which has some characteristics of a PAI. In *B. pertussis*, the upstream region of the *ptx-ptl* locus was found to contain a truncated IS element similar to IS*481* of *B. pertussis*. The last gene of *ptx-ptl* locus (*ptlH*) is followed by a tRNA gene coding for an asparagine-specific tRNA and by an inverted repeat. When the chromosomal insertion point of the *ptx-ptl* locus of *B. pertussis* is compared to that of *B. parapertussis* and *B. bronchiseptica*, this site appears to be different in *B. pertussis* from *B. parapertussis* and *B. bronchiseptica* (Antoine *et al*., 1998).

Enterotoxigenic strains of *Bacteroides fragilis* produce a metalloprotease toxin designated fragilysin or *B. fragilis* toxin (BFT). The encoding gene is located on a DNA region termed a "fragilysin pathogenicity islet" (see below), which contains an open reading frame coding for a second metalloprotease (MPII) and another ORF that encodes a protein with homology to a snake cytotoxin. The fragilysin pathogenicity islet is 6,033 bp in size, contains nearly perfect 12-bp direct repeats near

both ends of the islet, and is not present in non-toxigenic strains of *Bacteroides fragilis* (Moncrief *et al*., 1998). A recent study demonstrated that the *B. fragilis* pathogenicity islet is contained in putative new conjugative transposons (CTn). If these CTns are transmissible, the *bft* gene could be transferred to non-toxigenic *B. fragilis* strains (Franco, 2004).

### *Gram-positive bacteria*

The majority of the toxins encoded by pathogenicity islands have been described for Gram-negative bacteria. In the last few years, however, an increasing number of Gram-positive bacteria with PAIs have been detected (see Table 3.5).

In *Staphylococcus aureus*, several types of island-like chromosomal regions have been characterized that can be distinguished due to their mobility (Lindsay and Holden, 2004). *S. aureus* pathogenicity islands (SaPIs) can move with high frequency, which is mediated by helper phages, whereas other island-like DNA stretches are extremely stable. Nine SaPIs have been identified in human and bovine isolates (Kuroda *et al*., 2001; Baba *et al*., 2002; Holden *et al*., 2004; Lindsay *et al*., 1998; Yarwood *et al*., 2002; Fitzgerald *et al*., 2001; Ubeda *et al*., 2003). These SaPIs often carry the toxic shock syndrome toxin 1 (TSST-1)–encoding gene (*tstH*). SaPI1, for example, is 15.2 kb in size and is flanked by 17 bp direct repeats. This island integrates site- and orientation-specific into the chromosome and also contains, in addition to *tstH*, a gene with homology to another superantigenic toxin (*ent*), a *D. nodosus vapE* homologue as well as a putative integrase gene (Lindsay *et al*., 1998). The staphylococcal enterotoxins SEB, SEC, SEK, SEL, and SEP are also SaPI-encoded, e.g., on SaPI3, SaPI4, SaPIbov (Alouf and Müller Alouf, 2003). Furthermore, the *S. aureus* exfoliative toxin D (ETD) is, together with the ADP-ribosyltransferase EDIN-B, encoded on a pathogenicity island (Yamaguchi *et al*., 2002). Additionally, there are other extremely stable island-like regions within the *S. aureus* chromosome that may carry determinants coding for superantigenic staphylococcal exotoxin-like proteins (SET), proteases, leukocidins, lantibiotics, lipoproteins, and proteases. They are always localized in the same chromosomal location. However, they can markedly differ with regard to gene content and structural organization between individual strains (Kuroda *et al*., 2001; Baba *et al*., 2002; Fitzgerald *et al*., 2003).

The cytolysin of *Enterococcus faecalis* contributes to the severity of enterococcal infection and is distantly related to lantibiotics (Shankar *et al*., 2004). The corresponding *cyl* genes can be located on either pheromone-responsive plasmids, e.g., pAD1 (Haas *et al*., 2002) or on the chromosome within a PAI. In *E. faecalis* strain MMH594, the cytolysin operon is part of a 150-kb PAI that also encodes other virulence-associated factors, e.g., the surface proteins Esp and aggregation substance (Ike and Clewell, 1992; Shankar *et al*., 2002). Extensive nucleotide sequence identity between the cytolysin operons of pAD1 and strain MMH594 suggest that the PAI-located gene cluster resulted from a transfer of the operon from pAD1 into the chromosome of strain MMH594 (Shankar *et al*., 2004). Gilmore and coworkers were able to show that a cytolysin- and Esp-positive *E. faecalis* strain can develop into a cytolysin- and Esp-negative variant at a high frequency, most likely due to homologous recombination between IS*905*-like elements located within the *cyl* operon and downstream of the *esp* gene (Shankar *et al*., 2002).

The pathogenic species of *Listeria* (*L. monocytogenes*, *L. ivanovii*), as well as the non-pathogenic *L. seeligeri*,

**TABLE 3.5** Protein toxin determinants located on pathogenicity islands of Gram-positive bacteria

| Organism | PAI designation | Encoded toxins | Other PAI-encoded genes | Boundary sequences |
|---|---|---|---|---|
| *S. aureus* | SaPI1 | Enterotoxin B, K, Q | *int*, orf11 (homology to *D. nodosus vapE*) | DR 17 bp |
| | SaPI2 | Toxic shock syndrome toxin 1, enterotoxin L, L2, C3, C4 | | |
| | SaPI3 | Enterotoxin C4, L2 | | |
| | SaPIbov | Toxic shock syndrome toxin-1, enterotoxin C | | DR 74 bp |
| | *etd*-PAI | Exfoliative toxin D | orf2 (homology to serine proteases), *edin-B* | DR 5 bp |
| *Enterococcus faecalis* | *E. faecalis* PAI | Cytolysin | Surface protein (Esp), aggregation substance | DR 10 bp |
| *L. monocytogenes* | LIPI-1 | Listeriolysin | PrfA-dependent virulence gene cluster (phospholipases, ActA) | - |
| | LIPI-2 | - | Internalins, sphingomyelinase C | - |
| *L. ivanovii* | Pathogenicity locus | Enterotoxin | | |
| *Cl. difficile* | | Cytotoxin | - | - |

DR- direct repeat

harbor a 10-kb virulence cluster containing the listeriolysin gene (*hly*), which is flanked on one side by the *plcA-prfA* region and on the other side by the lecithinase operon, which are required for intercellular spread during infection (Portnoy *et al*., 1992; Gouin *et al*., 1994). In *L. seeligeri*, this gene cluster is not properly expressed due to a reduced transcription of *prfA*, which encodes the transcriptional activator of *Listeria* virulence genes. The same genes that are located at both ends of the virulence cluster of *Listeria* (*ldh*, *prs*) are present in avirulent strains, but instead of the virulence gene cluster, housekeeping genes are located between *ldh* and *prs* (Glaser *et al*., 2001). Another putative pathogenicity region of *Listeria* has recently been described. The *inlC* gene of *L. monocytogenes* and the *i-inlC* gene of *L. ivanovii* show high sequence similarities, but they differ with respect to their chromosomal localization. Whereas *inlC* of *L. monocytogenes* is a monocistronic gene located between two housekeeping genes (*rplS* and *infC*), the *i-inlC* of *L. ivanovii* is associated with another small internalin gene (*i-inlD*) and has been inserted into a minor threonine-specific tRNA as part of a larger DNA fragment. This tRNA belongs to a rRNA/tRNA locus with a similar organization to the *rrnB* locus of *B. subtilis* (Engelbrecht *et al*., 1998).

The 19-kb *Clostridium difficile* pathogenicity locus (PaLoc), which exhibits several features of a PAI, is specific for virulent strains of *Cl. difficile* and comprises the genes encoding the enterotoxin (*tcdA*), the cytotoxin (*tcdB*), as well as the accessory genes *tcdC–E* (Braun *et al*., 1996). The integration site of the PaLoc was defined as a 115-bp fragment, which forms a 20-bp hairpin loop. This stretch is only found in non-toxinogenic strains and is replaced by the PaLoc in toxinogenic strains (Braun *et al*., 1996).

## Instability of pathogenicity islands

The flanking regions of several PAIs are often characterized by the occurrence of direct repeats what can be involved in recombinational events leading to the deletion of the PAI (see Table 3.4, 3.5). In case of the PAIs of UPEC strains 536 and one PAI of strain J96, respectively, it has been shown that they can spontaneously delete from the chromosome at high frequencies upon site-specific recombination between short direct repeats (Blum *et al*., 1994; Blum *et al*., 1995; Swenson *et al*., 1996; Middendorf *et al*., 2004). IS elements or RS-sequences can also be responsible for the excision and maybe integration of genetic elements. In *Y. pestis*, homologous recombination between IS*100* elements flanking the HPI leads to the deletion of this PAI (Fetherston *et al*., 1992). PAI excision is accompanied by the loss of PAI-encoded determinants (*cnf*1, *hly*, *pap*, *pgm* locus) and reduced virulence of the resulting strains (Fetherston *et al*., 1992; Blum *et al*., 1994; Blum *et al*., 1995; Swenson *et al*., 1996). It is suggested that such deletion events may represent a specific form of adaptation of these pathogens to certain niches, hosts, tissues or during transition of the pathogen from an acute state of infection to a chronic state where expression of highly antigenic factors may be disadvantageous. More generally, pathogens with a relatively high genetic flexibility may be more competent in the colonization of new ecological niches and may have a selective advantage over organisms with less flexible genomes (Hacker *et al*., 2003).

Genome plasticity and gene loss, e.g., in *E. coli*, can be detected in different nuances: in addition to the loss of complete PAIs, deletion of distinct regions within genomic islands may frequently occur due to homologous recombination of IS elements and also results in phenotypic changes. Comparison of the genome content of non-pathogenic and uropathogenic *E. coli* O6 strains demonstrated that the gene content and the general genetic structure of the *pheV*-associated islands of UPEC strain CFT073 and non-pathogenic strain Nissle 1917 are highly similar. In the latter strain, however, the α-hemolysin and P fimbriae determinants, present on this island in UPEC strain CFT073, are deleted. This is supposed to be one of the reasons for this strain's non-pathogenic phenotype relative to strain CFT073 (Grozdanov *et al*., 2004).

# CONCLUSION

## Evolution of new pathogenic variants caused by pathogenicity islands and mobile genetic elements

Genes encoding toxins and other virulence factors can be located on PAIs and/or on mobilizable genetic elements such as plasmids, transposons, and bacteriophages. This is especially true for microorganisms, which lack the capacity to take up foreign DNA because of natural competence. The presence of so-called "mobility sequences," e.g., direct repeats, sequences with homology to integrases or to plasmid origins of replication near the borders of PAIs, imply that PAIs are derived from integrated mobile elements such as bacteriophages and plasmids (Hacker and Kaper, 2002). Plasmids and phages are able to form co-integrates. This has been found frequently in *Streptomyces* (Leblond and Decaris, 1994) and may be an explanation for the existence of features of plasmids and phages on PAIs. Therefore, integrated plasmids and bacteriophages have been considered as "PAI precursors" or "Pre-PAIs." This underlines the strong

mutual dependence between plasmids, bacteriophages, and pathogenicity islands. This interdependence not only contributes to the genetic flexibility of bacteria carrying these genetic elements but to the fast evolution of new pathogenic variants as well (see also Figure 3.1) (Groisman and Ochman, 1996; Hacker *et al*., 2003; Dobrindt *et al*., 2004).

The spread of specific genomic regions through lateral gene transfer followed by integration into the bacterial genome is a mechanism by which new variants of microbes could be generated. This can occur by lysogenic conversion in which the prophage confers specific changes in the bacterial phenotype or by the uptake of plasmids or DNA fragments by conjugation or transformation. A genomic island or its more specified variant (PAI) may be the result of such transfer processes and subsequently generated point mutations. Such spontaneous point mutations in "mobility genes" may lead to a fixation of laterally acquired genes in specific strains. Under specific selective pressure a "homing" of new variants by inactivation of mobility genes could be advantageous, resulting in some structures of PAIs described in this article (see Figure 3.1). An interesting exception is *Cl. perfringens*: the complete genome sequence revealed that all known and putative virulence-associated genes of this pathogen are not located on PAIs, as IS element-, transposon- or bacteriophage-related sequences have not been found in their flanking regions. In addition, their G+C content does not significantly differ from that of other genes, indicating that acquisition of these genes via horizontal gene transfer did not occur or was not a recent event (Shimizu *et al*., 2002). Another exception is the superantigen-encoding genes *ypm* (*Y. pseudotuberculosis*-derived mitogen) of *Y. pseudotuberculosis* that, unlike other superantigenic toxin genes, are not associated with mobile genetic elements but are localized in unstable regions of the chromosome. This explains why deletion of the *ypm* genes can occur with significantly increased frequency (Carnoy *et al*., 2002).

## Horizontal gene transfer and the evolution of toxin families

The existence of toxin families with common properties and sequence homologies in the relevant genes argues that such a distribution of genetic information is a result of lateral gene transfer. The most prominent examples of genetically related toxin families are ADP ribosylating toxins (diphtheria toxin, pertussis toxin, cholera toxin, *E. coli* LT, *Pseudomonas* exotoxin A and S, and others) and other AB toxins (Shiga toxins), pore-forming RTX toxins (i.e., various hemolysins, *Pasteurella haemolytica* leucotoxin, *B. pertussis* adenylate cyclase-hemolysin), clostridial neurotoxins (*Cl. botulinum* and *Cl. tetani* neurotoxins), enterobacterial autotransporters and proteins secreted by a type III secretion system. Many of them are encoded on plasmids, phages, or pathogenicity islands. There are various reasons that demonstrate that members of these toxin families can be transferred by mobile genetic elements or may have formerly been transferred by them. Other examples, such as the occurrence of many different proteins that share functional features of superantigens, may argue for convergent evolution of proteins with similar toxic characteristics in different bacteria. This is less probable in the case of toxin families than the acquisition by horizontal gene transfer because of the complexity of mutational and evolutionary events on the DNA level that would have to occur in order to result in functionally and structurally similar proteins. In *S. aureus*, the superantigenic toxins SEG and SEI-encoding genes (*seg*, *sei*) are linked by a DNA region, the enterotoxin gene cluster (*egc*), that comprises three enterotoxin-like open reading frames (ORFs) *sek*, *sel*, and *sem*, as well as two pseudogenes. The *egc* gene cluster was detectable in many other *S. aureus* isolates, and phylogenetic analyses of staphylococcal enterotoxin-encoding genes implied that they all potentially derive from the *egc* cluster. It has been speculated that the existing great variety of superantigens in *S. aureus* may represent an enterotoxin "nursery" that enables expression of a broad variety of toxin variants when needed (Jarraud *et al*., 2001). Phylogenetic analysis of staphylococcal exotoxin-like protein determinants (*set*) localized on island-like region RD13 within a variety of *S. aureus* isolates that gene loss as well as recombination contributed to the diversification of this island (Fitzgerald *et al*., 2003).

The great similarity in the protein sequences of the *E. coli* LT and *V. cholerae* CT led to the assumption that CT, LT I, and LT II originally derived from the same ancestral gene. Other toxins immunologically related to CT can be found in *Salmonella*, *Pseudomonas*, *Campylobacter*, and *Aeromonas*. This may suggest that this is the result of different evolutionary pathways that this gene followed in different species (Rappuoli and Pizza, 1991).

The pattern of distribution of genes involved in toxin expression on plasmids relative to the chromosome indicates that they may derive from a common ancestor, such as the type III protein secretion systems of various bacterial animal or plant pathogens (*Yersinia spp*., *Shigella flexneri*, *Salmonella typhimurium*, EPEC, *Ps. aeruginosa*, *Chlamydia spp*., *Erwinia spp*., *Ps. syringae*, *Ralstonia solanacearum*, *Xanthomonas campestris*) (Mecsas and Strauss, 1996; Yahr *et al*., 1996; Hsia *et al*., 1997; Bonas, 1994; Collmer and Bauer, 1994). Although

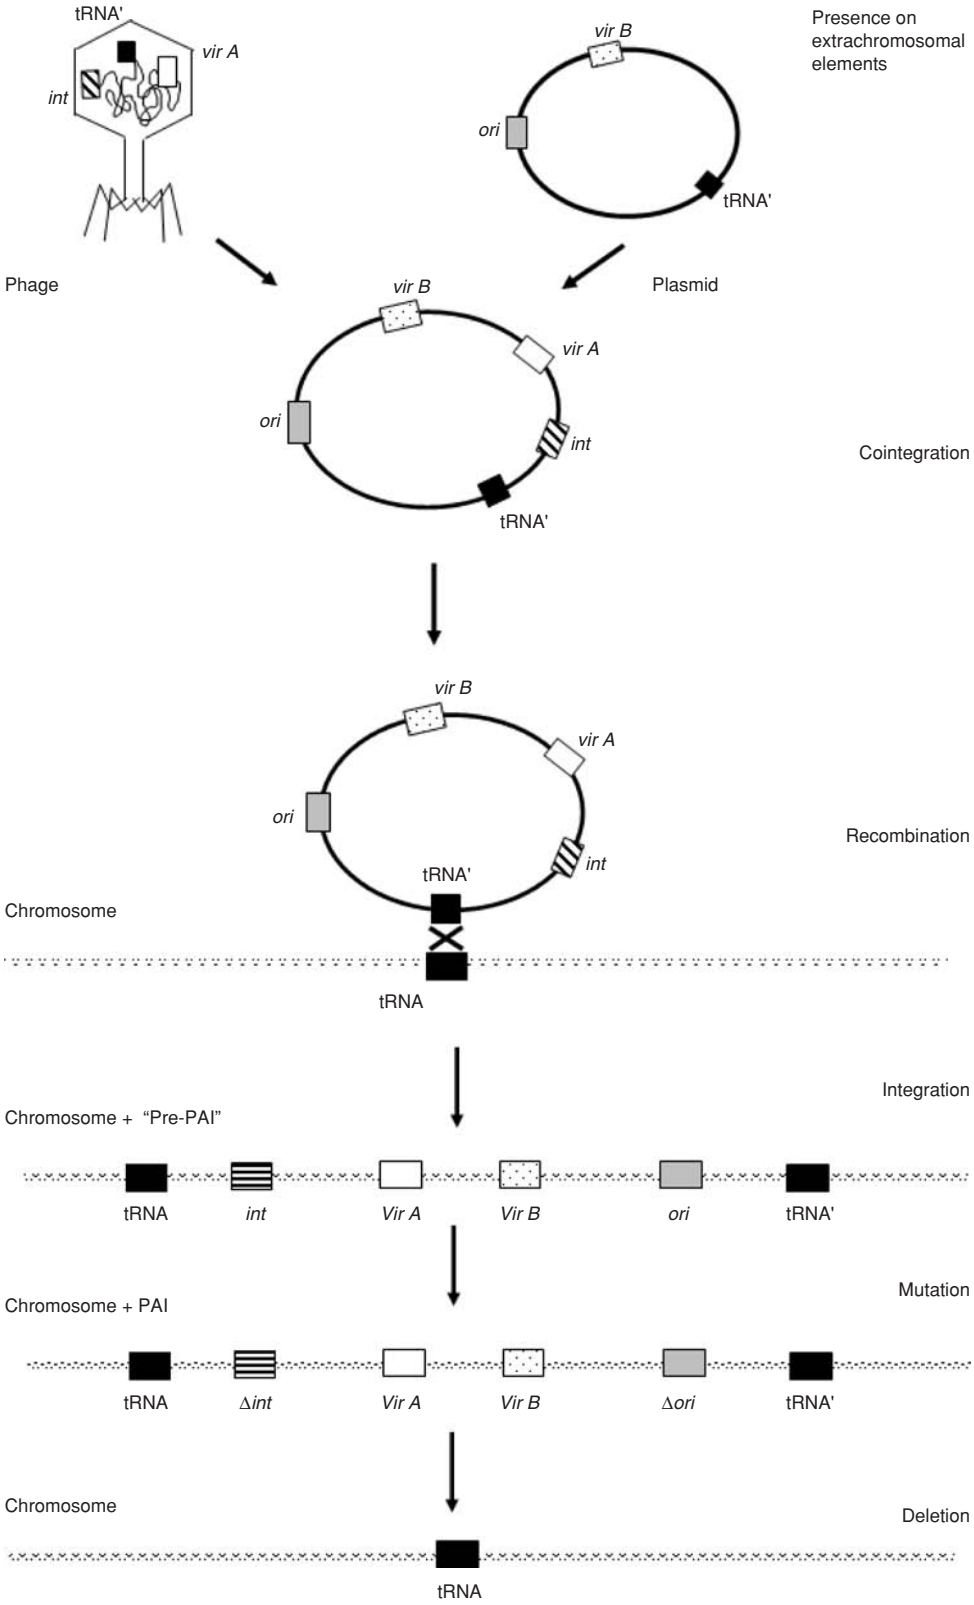

**FIGURE 3.1** Model illustrating the impact of mobile genetic elements on the evolution of pathogenicity islands (PAIs). A chromosomal integration of mobile genetic elements into the chromosome can occur upon recombination of homologous sites. A stabilization of the integrated DNA may occur by mutations in integrase genes (*int*) and/or origins of replication (*ori*). The deletion of PAIs may lead to avirulent variants.

the pathogenicity mechanisms and therefore the secreted effector molecules of these bacteria differ, the type III secretion apparatus is conserved and effector molecules from one pathogen can be translocated by another system when the appropriate chaperons are present (Mecsas and Strauss, 1996).

Taken together, virulence determinants in general and protein toxin genes in particular are frequently encoded by mobile genetic elements. They are encoded on large genomic regions as well, designated pathogenicity islands (PAIs), which often contain clusters of virulence-associated genes. These genetic elements with the capacity to spread by horizontal gene transfer contribute to the rapid evolution of bacterial pathogens as the rearrangement, excision, and acquisition of large genomic regions creates new pathogenic variants. The occurrence of protein toxin–encoding genes on various interdepending mobile genetic elements, their ability to delete from and integrate into chromosomal DNA, and the existence of toxin families among a wide variety of bacterial species show that the continuing process of the evolution of new pathogens is significantly connected with the transfer of foreign DNA harboring toxin determinants.

CHAPTER

# 4

# Regulation systems of toxin expression

*Camille Locht, Didier Lereclus, Julian I. Rood, and Bénédicte Fournier*

## INTRODUCTION

As important virulence factors, the production of bacterial protein toxins is generally tightly regulated (see Table 4.1). Their genes are often members of regulons that include additional genes encoding other virulence determinants, such as adhesins, invasins, iron uptake systems, and many others. These regulons are usually controlled at the transcriptional level by virtue of repression and/or transactivation via specific regulatory proteins. In some cases, the regulons are part of a complex regulatory network involving several activator or repressor proteins that may act in cascade. In this chapter, we have chosen to describe four different examples of the regulation of toxin production. As an example of regulation via a transcriptional activator, the *Bacillus cereus* PlcR regulon is presented. Regulation via a two-component system is exemplified by the *Bordetella pertussis* BvgA/S system, and complex networks involving several different regulatory systems are described using the examples of *Clostridium* and *Staphylococcus aureus*.

## REGULATION OF VIRULENCE GENE EXPRESSION IN *BACILLUS CEREUS*

The genus *Bacillus*, first described in 1872 by Ferdinand Cohn, includes a large number of Gram-positive bacterial species, all of which form resistant spores when they encounter unfavorable growth conditions. *Bacillus* spores are ubiquitous and are common in soil; however, not all *Bacillus* species are able to grow in this environment. Members of the genus *Bacillus* colonize various ecological niches including plants, insects, and mammals, depending on their properties. The genetics of *Bacillus* are very well known due to the extensive studies performed on *Bacillus subtilis* in recent decades (Sonenshein *et al.*, 1993, 2002).

The *Bacillus cereus* group includes a large number of bacteria distributed in six highly related species: *Bacillus anthracis*, *Bacillus cereus* (*sensu stricto*), *Bacillus mycoides*, *Bacillus pseudomycoides*, *Bacillus thuringiensis*, and *Bacillus weihenstephanensis* (Lechner *et al.*, 1998; Nakamura, 1994; Priest *et al.*, 1994). These species were originally determined on the basis of characteristic features such as the presence of a capsule and toxins (*B. anthracis*), the formation of rhyzoid colonies (*B. mycoides* and *B. pseudomycoides*), the presence of a parasporal crystal (*B. thuringiensis*), and psychrotolerance (*B. weihenstephanensis*).

The *B. anthracis* genes specifying the capsule and the toxic factors responsible for anthrax are located on two plasmids, pXO1 and pXO2. The transcription of these genes is activated by the regulator AtxA during vegetative multiplication. The genes encoding the insecticidal toxins of *B. thuringiensis* are located on large conjugative plasmids and are expressed during the stationary phase or during sporulation. The roles and expression patterns of these *B. anthracis*- and *B. thuringiensis*-specific toxin genes have been extensively studied and reviewed (Agaisse and Lereclus, 1995; Koehler, 2002; Mock and Fouet, 2001; Schnepf *et al.*, 1998).

**TABLE 4.1** Main genetic regulatory systems of bacterial toxin production

| Species | Toxins regulated | Production phase | Regulatory system | Environmental factors | Reference |
|---|---|---|---|---|---|
| | | | **Two-component system** | | |
| *Bordetella pertussis* | Pertussis toxin<br>Adenylate cyclase toxin<br>Dermonecrotic toxin | exponential growth | BvgS/BvgA | Temperature<br>Nicotinic acid<br>$MgSO_4$ | (Stibitz, 2003) |
| *Clostridium perfringens* | Perfringolysin O<br>Alpha-toxin<br>Collagenase<br>Beta2 toxin | exponential growth | VirS/VirR<br>VirS/VirR-dependent VR-RNA | | (Rood, 1998) |
| *Staphylococcus aureus* | Haemolysins<br>Enterotoxins<br>Toxic shock syndrome toxin<br>Exfoliative toxins<br>Proteases | Post-exponential growth | AgrA/AgrC<br>AgrA/AgrC-dependent regulated RNA (RNAIII) | | |
| *Streptococcus pyogenes* | Streptolysin S<br>Streptokinase<br>Mitogenic factor | exponential growth | CovS/CovR | | (Stibitz, 2003) |
| | | | **Iron-dependent regulators** | | |

Besides these species-specific traits, members of the *B. cereus* group also share a large pool of genes, which constitutes a common genetic background representing about 75% of their genomes (Ivanova *et al.*, 2003; Kolstø *et al.*, 2002; Rasko *et al.*, 2004). Several of these genes encode extracellular compounds that might contribute to the virulence of *B. cereus* and *B. thuringiensis*. These compounds are degradative enzymes (phospholipases C, proteases, collagenases, etc.), cytotoxic proteins (hemolysins, enterotoxins, and cytotoxins), and cell surface proteins. Here, we briefly review the transcriptional mechanisms that control the expression of these virulence factors thought to be involved in gastrointestinal or nongastrointestinal infections.

## PlcR, a pleiotropic transcriptional activator

The PlcR regulator was first identified in *B. thuringiensis*, in which it was found to be required for transcription of the *plcA* gene, which encodes phosphatidylinositol-specific phospholipase C (PI-PLC) (Lereclus *et al.*, 1996). PlcR activates its own transcription and that of *plcA* at the end of the exponential growth phase. This regulator is a 34-kDa polypeptide, which contains a helix-turnhelix DNA-binding domain at its amino-terminal end. Analysis of the molecule reveals that PlcR contains structural motifs related to tetratricopeptide repeats (TPRs), which are domains putatively involved in protein-protein interaction (Perego and Hoch, 2002).

A genetic screening approach was used to detect *B. thuringiensis* genes regulated by PlcR (Agaisse *et al.*, 1999). This revealed that PlcR is a pleiotropic regulator that controls the transcription of several genes encoding exported proteins putatively involved in virulence, including the hemolytic and non-hemolytic enterotoxins, Hbl and Nhe. Alignment of the promoter regions activated by PlcR revealed a highly conserved palindromic sequence (TATGNANNNNANCATA). The –10 region of the PlcR-regulated promoters resembles that of promoters bound by an RNA polymerase associated with the sigma A factor. The –35 region of these promoters can significantly diverge from the –35 sequence generally recognized by sigma A. The transcriptional start site of the genes positively regulated by PlcR can be located at various positions downstream of the palindromic sequence (from a few nucleotides up to about 200 nucleotides in the case of the *hbl* and *nhe* operons).

Genetic experiments and DNase I footprinting have demonstrated that this 16-bp palindromic sequence (called the *PlcR box*) is the specific recognition site for PlcR (Slamti and Lereclus, 2002). However, analysis of two PlcR-regulated genes, encoding the metalloprotease InhA2 and the cytotoxin CytK, indicated that mutations in the consensus sequence do not necessarily affect PlcR activation (Brillard and Lereclus, 2004; Fedhila *et al.*, 2003). A recent study in which the PlcR box was subject to site-directed mutagenesis showed

that modification of the first or last nucleotide of the 16-bp palindrome does not drastically reduce PlcR activation (M. Gominet and D. Lereclus, unpublished data).

PlcR is active in *B. cereus* and *B. thuringiensis*, and most of the PlcR-regulated genes are found in both species (Agaisse *et al.*, 1999; Ivanova *et al.*, 2003; Økstad *et al.*, 1999). The PlcR-regulated genes are scattered throughout the chromosome rather than being clustered in a pathogenicity island. However, they tend to be arranged in pairs of genes that are transcribed in opposite orientations from a single, central PlcR box.

## Role and size of the PlcR regulon in *B. cereus* and *B. thuringiensis*

*In silico* analysis, based on the published PlcR box (TATGNANNNNTNCATA), suggested the presence of about 100 PlcR-regulated genes in the *B. cereus* genome (Ivanova *et al.*, 2003; Rasko *et al.*, 2004). Although not exact due to the inaccuracy of the PlcR box sequence, this result reflects the importance of the PlcR regulon in *B. cereus*. This was also clearly shown by the comparison of the extracellular proteomes of a *B. cereus* wild-type strain and a Δ*plcR* mutant strain. It appears that about 80% of all extracellular proteins depend on PlcR (Gohar *et al.*, 2002). The following major genes (and their products) unambiguously belong to the PlcR regulon, based on experimental evidence (transcriptional or 2D-electrophoresis analysis): *plcA* (PI-PLC), *plcB* (PC-PLC), *cerB* (sphingomyelinase), *hblCDA* (enterotoxic hemolysin BL), *nheABC* (non-hemolytic enterotoxin), *cytK* (cytotoxin), *inhA2*, *nprB*, and *nprP2* (metalloproteases), *colB* (collagenase), *sfp* (protease), *clo* and *tlo* (cereolysin O and thuringiolysin O, in *B. cereus* and *B. thuringiensis*, respectively).

The properties of the proteins encoded by the PlcR-regulated genes (degradative enzymes and toxins) suggest that the PlcR regulon plays an important role in the adaptation of the bacteria to their environment and in the virulence of the bacteria in susceptible hosts. Deletion of the *plcR* gene in *B. thuringiensis* and *B. cereus* drastically reduces their virulence in orally infected insects, in mice infected by nasal instillation, and in endophthalmitis (Callegan *et al.*, 2003; Salamitou *et al.*, 2000). The precise role of each PlcR-regulated gene in pathogenicity has not been determined. However, a *B. cereus* strain overproducing CytK has been shown to cause severe gastroenteritis (Lund *et al.*, 2000), and the metalloprotease InhA2 is necessary for the virulence of *B. thuringiensis* in insects (Fedhila *et al.*, 2002; Fedhila *et al.*, 2003).

## The PlcR regulon is not functional in *B. anthracis* and in a few *B. cereus* strains

*B. anthracis* and about 1% of *B. cereus* and *B. thuringiensis* strains are devoid of hemolytic and lecithinase activities. In *B. anthracis*, a nonsense mutation in the *plcR* gene results in a truncated inactive product (Agaisse *et al.*, 1999). A nonsense mutation (mapping at a different nucleotide position to the mutation in *B. anthracis*), and deletion or point mutations have been identified in the *plcR* sequences of Hly$^-$, Lec$^-$ *B. cereus*, and *B. thuringiensis* strains (Slamti *et al.*, 2004). Introduction of the active *plcR* gene from *B. thuringiensis* strain 407 restored the hemolytic and lecithinase activities of these strains (Mignot *et al.*, 2001; Slamti *et al.*, 2004). Thus, the genes of the PlcR regulon are present and potentially functional in these strains. This also indicates that major distinctive traits of *B. anthracis* (*i.e.*, absence of hemolytic, lecithinase, and protease activities) result from a single mutation in a pleiotropic regulator. However, for unknown reasons, the introduction of the active *plcR* gene from *B. cereus* strain 569 does not restore hemolytic and lecitinase activities in *B. anthracis* (Pomerantsev *et al.*, 2003).

## Expression of the PlcR regulon is controlled by quorum sensing

A small PlcR-regulated gene, *papR*, located 70 bp downstream from *plcR*, is required for the expression of the PlcR regulon genes. Deletion of the *papR* gene abolishes the production of hemolysins and degradative enzymes, and results in a large decrease in virulence (Slamti and Lereclus, 2002). The *papR* gene product is secreted and diffusible in the extracellular medium. A processed form of PapR, corresponding to the carboxy-terminal end of the peptide (which may contain as few as 5 residues), is subsequently imported into the bacterial cells. The oligopeptide permease Opp is necessary for *plcR* expression (Gominet *et al.*, 2001), suggesting that the uptake of the C-terminal part of PapR is ensured by Opp. Once inside the bacteria, the processed form of PapR (presumably a pentapeptide) interacts with PlcR to facilitate its binding to its DNA targets (Slamti and Lereclus, 2002). The mechanism leading to the PlcR-PapR interaction and to the consequent activation of PlcR is not known. However, a translational fusion between PlcR and PapR is functional, suggesting that the interaction between the two peptides involves the C-terminal part of PlcR (Pomerantsev *et al.*, 2004).

The activation of PlcR by PapR is strain-specific, and this specificity is determined by the first residue of the pentapeptide (Slamti and Lereclus, 2002). Alignment

of PapR sequences from various strains of the *B. cereus* group and PlcR activation assays using various PapR pentapeptides have led to the identification of specificity groups. Four types of pentapeptide (LPFEF, VPFEF, MPFEF, LPFEH) have been identified in the bacteria forming the *B. cereus* group. A strain producing the pentapeptide LEFEF is able to activate the PlcR regulon of a strain belonging to the same specificity group. However, this PlcR regulon is not activated by the strains producing the pentapeptides LPFEH, VPFEF, or MPFEF (Slamti and Lereclus, 2002, 2005). Hence, the bacteria belonging to a given PlcR-PapR group are able to produce simultaneously a set of virulence factors in response to the same molecular signal.

A general model for the regulation of PlcR expression is presented in Figure 4.1. First, this model assumes that low but constant amounts of PlcR and PapR are produced during the vegetative growth phase. At the onset of the stationary phase, the increase in the intracellular concentration of PapR leads to the activation of PlcR and consequently to the expression of the PlcR regulon genes. This regulatory system, which coordinates gene expression and cell density, is designated quorum-sensing. Second, in response to severe nutriment deprivation, the concentration of Spo0A~P increases in the bacterial cells and activates the sporulation process. Spo0A~P is also a repressor of *plcR* transcription (Lereclus *et al.*, 2000), and consequently the expression of the PlcR regulon is switched off or strongly reduced during sporulation. The expression of the PlcR regulon is thus controlled at both the transcriptional level (with Spo0A) and the post-transcriptional level (with PapR). This double regulation allows the bacteria to adapt to various parameters like cell density and nutriment availability. The selection and the maintenance of this regulatory system allows the bacteria of the *B. cereus* group to start the infection process when the environmental conditions are favorable and when, and only when, the number of bacteria is "estimated" to be sufficient to elicit infection.

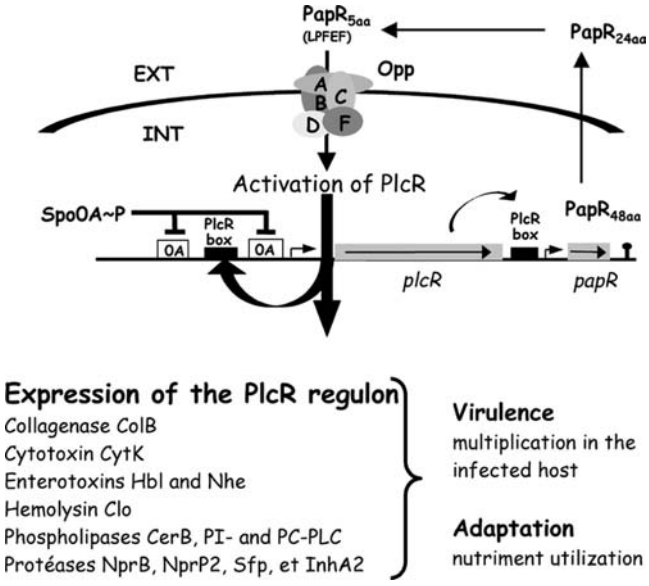

**FIGURE 4.1** Model for the regulation of PlcR expression.The *plcR* and *papR* genes are expressed at a low and basal level during the exponential growth phase. PapR (48 amino acids) is secreted into the extracellular medium, presumably via the SecA system. The exported peptide (24 amino acids) is then processed to give a smaller peptide, thought to be a pentapeptide. This small PapR peptide diffuses in the extracellular medium and is imported into the bacteria via Opp. Once inside the cell, the peptide interacts with PlcR, allowing it to bind the PlcR boxes. This binding activates the transcription of the PlcR regulon. When the bacteria encounter unfavorable environmental conditions (nutriment deprivation), the phosphorylation status of the protein Spo0A increases in the cells. As a consequence, Spo0A~P activates the sporulation process and blocks the transcription of *plcR*. Consequently, the expression of the PlcR regulon is switched off during sporulation.

## THE *BORDETELLA* BVGA/S SYSTEM

Many bacterial pathogens regulate the production of their virulence factors at the transcriptional level by signal-transducing two-component systems. In its minimal structure, these systems comprise a membrane-associated sensor protein and a cytoplasmic transcriptional activator (Stock *et al.*, 1989). Extracellular, but sometimes also intracellular signals, are sensed by the sensor protein. This information is then transmitted to the activator protein by a phosphorylation cascade that results in the activation of the transcription factor and, consequently, in the transcription, or sometimes repression, of the genes regulated by the two-component system.

### Phenotypic modulation and phase variation

The genes coding for the *Bordetella* protein toxins, as well as those encoding most of the other *Bordetella* virulence factors are under the control of the BvgA/S (for **B***ordetella* **v**irulence **g**ene) two-component system. BvgS represents the sensor component, and BvgA is the transcriptional activator. That the *Bordetella* virulence genes are coordinately regulated was suggested more than 40 years ago when Lacey (1960) reported that the *Bordetella pertussis* growth conditions strongly influence the overall virulence of the organism. When grown at 25°C or in the presence of $MgSO_4$ or of nicotinic acid, the virulence factors are collectively not

produced, and *B. pertussis* is in the C mode. In contrast, when grown at 37°C and in the absence of $MgSO_4$ and nicotinic acid, the organism is in the X mode, and the virulence factors are produced. This reversible phenomenon is termed *phenotypic modulation*. In addition to the reversible phenotypic modulation, it was already known in the early 1930s that *B. pertussis* could undergo essentially irreversible phase variation (Leslie and Gardner, 1931). Virulent (phase I) organisms can become avirulent (phase IV) at a frequency of $10^{-3}$ to $10^{-6}$, depending on the strain and on the culture conditions. Phase IV organisms are characterized by the loss of essentially all virulence factors.

The molecular mechanism of phase variation has been elucidated by Stibitz *et al.* (1989), who showed that the transition from phase I to phase IV in *B. pertussis* can be explained by the insertion or deletion of a cytosine in a string of six consecutive cytosines located in the coding sequence of a gene, subsequently called *bvgS*. In other *Bordetella* strains, in particular in *B. bronchiseptica*, other deletions or insertions in the *bvg* locus are responsible for phase variation (Monack *et al.*, 1989). Although the precise molecular mechanisms have not yet been identified, phenotypic modulation is probably due to the ability of BvgS to sense the different environmental conditions to which *Bordetella* can be exposed and to transmit this information via phosphorylation to BvgA.

Phenotypic modulation can readily be induced in laboratory conditions, but it is not clear yet what role it plays during natural infection, nor which modulatory signals are perceived within the host environment. However, it has been shown that the precise regulation of *Bordetella* virulence genes is essential for pathogenesis, as ectopic expression of the virulence genes results in loss of virulence (Akerley *et al.*, 1995). In addition to the $Bvg^+$ (phase I) and $Bvg^-$ (phase IV) phases, an intermediate phase has been identified for *B. bronchiseptica* (Cotter and Miller, 1997). This phase, named Bvgi, is characterized by the production of certain virulence factors, such as filamentous hemagglutinin and fimbriae, but not of others, such as the adenylate cyclase toxin. Furthermore, a set of Bvgi-specific antigens is produced by *B. bronchiseptica* during this intermediate phase. Recent studies suggest that this phase may be important for biofilm formation (Irie *et al.*, 2004). The signals sensed by the BvgA/S system may perhaps be related to the metabolic pathways and growth state of the bacterium. When grown at high density, sulfure-containing amino acids accumulate in the media, which can result in elevated $SO_4^{2-}$ release (Bogdan *et al.*, 2001). This finally can then result in BvgA/S-mediated modulation of *Bordetella* virulence gene expression.

## Structure-function relationship of BvgA and BvgS

Compared to classical two-component systems, the BvgA/S system presents an "unorthodox" modular structure. Whereas in its simplest form the sensor proteins are composed of two domains, the extracytoplasmic sensor domain and the cytoplasmic transmitter domain, BvgS contains two additional cytoplasmic domains. These additional domains comprise another receiver and another transmission domain (Uhl and Miller, 1994). All three cytoplasmic domains play a crucial role in phosphorylation-mediated signal transmission from BvgS to BvgA, as mutations in either module abolish activation of BvgA. The three cytoplasmic domains are separated by alanine/proline-rich sequences and participate in a phosphorylation cascade in which the first transmitter domain is autophosphorylated, and the receiver domain regulates the transfer of the phosphoryl group from the autophosphorylated transmitter to the C-terminal, second transmitter domain. Only the phosphorylated C-terminal transmitter domain is then able to transfer the phosphoryl group to BvgA. A similar modular structure and phosphorelay system has been found for the *Escherichia coli* drug efflux regulatory system EvgA/S (Eguchi *et al.*, 2003). However, despite the strong sequence similarities between BvgS and EvgS, these two proteins display a high degree of specificity for their cognate regulators, BvgA and EvgA, respectively, and this specificity is due to the C-terminal, second transmitter domain of these sensor proteins (Perraud *et al.*, 1998).

The N-terminal, periplasmic domain of BvgS is likely to be involved in environmental sensing. Exchange experiments between the *B. pertussis* and the *B. bronchiseptica* BvgS of discrete fragments have indicated that signal sensitivity, such as the concentration of $MgSO_4$ required for phenotypic modulation, depends on the N-terminal, periplasmic domain of BvgS (Martinez de Tejada *et al.*, 1996). However, a short linker region, located between the transmembrane and the cytoplasmic domains of BvgS, appears also to be involved in environmental sensing, as amino acid substitutions in this linker region may cause insensitivity to modulating agents, such as nicotinic acid (Goyard *et al.*, 1994; Manetti *et al.*, 1994). How exactly these two regions operate during signal transduction is not yet known. It is possible that they are required for oligomerization of BvgS, as the isolated cytoplasmic domain alone is not able to oligomerize (Perraud *et al.*, 2000). The active form of BvgS has been shown by transcomplementation studies and by a dominant negative phenotype observed after overexpression of a

mutant *bvgS* allele to be oligomeric (Stibitz and Yang, 1991). In addition to the periplasmic domain and the linker region, the cytoplasmic domain of BvgS may also constitute a target site of the sensor properties of the protein, as the kinase activity of BvgS has been shown to be very sensitive to the oxidation status of ubiquinone. Oxidized ubisuinone is a strong inhibitor of the kinase activity, whereas the reduced form of the quinone has no effect on the enzymatic activity (Bock and Gross, 2002), indicating that the BvgA/S system is also sensitive to the oxidation status of the cell.

The transfer of the phosphoryl group from the C-terminal domain of BvgS to the N-terminal receiver domain of BvgA results in activation of the transcription factor. The C-terminal, output domain of phosphorylated BvgA, is then able to bind specifically to the promoter regions of the *Bordetella* virulence genes (Boucher *et al.*, 1994). Phosphorylation of BvgA enhances DNA binding, although unphosphorylated BvgA may still bind to a subset of *bvg*-regulated promoters. DNA binding alone is not sufficient for transactivation. Transactivation requires synergistic binding of RNA polymerase and phosphorylated BvgA to the DNA target sites (Boucher and Stibitz, 1995). The interaction of BvgA with RNA polymerase involves the alpha subunit of the polymerase (Stibitz, 1998), and in particular its C-terminal domain (Carbonetti *et al.*, 2000). The minimal functional BvgA unit is probably a dimer. Detailed analyses of one of the *bvg*-regulated promoters have shown that, at least for the *fha* promoter, three dimers, formed by head-to-head association of the monomers, bind to one face of the DNA helix, whereas the C-terminal domain of the RNA polymerase alpha subunit binds to the opposite face of the helix (Boucher *et al.*, 2003). This is then believed to result in the initiation of transcription of the target genes.

## The BvgA/S regulon

Most of the identified virulence genes of *Bordetella* are activated by the BvgA/S system and are collectively called *vag*s (for ***v***irulence ***a***ctivated ***g***enes). They include the genes that encode the classical virulence factors, such as pertussis toxin (PTX), adenylate cyclase toxin (AC), dermonecrotic toxin, filamentous hemagglutinin (FHA), fimbriae, pertactin, tracheal colonization factor, Vag8, Brk, and type III secretion systems. The promoter structure and BvgA-binding sites of a limited set of *vag*s has been analyzed in detail, such as those of the *fha*, the *cya*, and *ptx* genes. Although a clear consensus BvgA-binding site has not been identified, studies on the *cya*, *bvg* (Karimova and Ullmann, 1997), and *ptx* promoters (Marques and Carbonetti, 1997) have shown that they consist of inverted repeats. However, in some promoter regions, the BvgA-binding sites may also contain direct repeats. They are generally located from 50 to 150 nucleotides upstream of the transcriptional start site and usually comprise multiple BvgA-binding sites, as has most extensively been demonstrated in the *fha* promoter region (Boucher *et al.*, 2003). The *fha* promoter is up to now probably the most well characterized *bvg*-dependent promoter (Boucher *et al.*, 2001a, b). Studies on the *fha* promoter have indicated that the nucleotides at positions 3, 4, and 7 of the BvgA-binding heptad are crucial for the binding of the transcription factor, and that the promoter contains both high- and low-affinity sites for phosphorylated BvgA, the latter of which shows limited DNA specificity (Boucher *et al.*, 2001a). Binding to the primary, high-affinity site and to the secondary, low-affinity region is cooperative.

Whereas BvgA can bind to some promoters in the unphosphorylated form, phosphorylation is essential for binding to other promoters, such as the *ptx* promoter, suggesting that differential binding of BvgA may govern different regulatory mechanisms of *bvg*-activated genes. Upon the induction of the *bvg*-activated genes, some genes such as *fha* are transcribed within minutes, while others such as *prn* are transcribed only after one hour, and others, such as *ptx*, require several hours before they are expressed (Kinnear *et al.*, 2001). The precise kinetics of activation of the individual genes appear to be critical for the expression of *B. pertussis* virulence in mouse models.

In addition to the classical virulence genes, the BvgA/S system may also regulate other genes, such as those that encode lipid A modifying enzymes (Preston *et al.*, 2003) and proteins involved in iron uptake (Passerini de Rossi *et al.*, 2003). The availability of the entire genome sequence (Parkhill *et al.*, 2003) combined with new tools, such as DNA microarrays (Hot *et al.*, 2003) makes it now possible to identify all the members of the Bvg regulon.

BvgA also regulates the production of a series of transcription factors, one of which, BvgR, represses a set of genes named *vrg*s (for *v*irulence *r*epressed *g*enes). BvgR is a 32-kDa protein that probably binds to the operator sites of the *vrg*s (Merkel *et al.*, 1998a, b). The role of the *vrg*s in pathogenesis is not clear. While a BvgR-deficient mutant is strongly affected in virulence (Merkel *et al.*, 1998b), suggesting that it is important to repress *vrg*s during the infectious cycle, the mutational inactivation of individual *vrg*s does not appear to affect *Bordetella* virulence (Martinez de Tejada *et al.*, 1998). These observations indicate that down-regulation of *vrg*s, but not their expression, is involved in pathogenesis.

## GENETIC REGULATION IN CLOSTRIDIA

Gene regulation in Clostridia is a complex topic with many subtle intricacies and variations, far too many to be included in a chapter of this broad nature. This section will therefore focus on giving an overview of the regulation of toxin production in four pathogenic clostridial species, *Clostridium perfringens*, *Clostridium difficile*, *Clostridium botulinum*, and *Clostridium tetani*. It concentrates on three major mechanisms by which clostridial toxin gene expression is controlled, namely by two-component signal transduction, DNA bending, and by the use of alternative sigma factors.

### The global VirS/VirR two-component signal transduction system of C. *perfringens*

*C. perfringens* is the causative agent of clostridial myonecrosis (gas gangrene) and several gastrointestinal diseases. The essential toxin involved in clostridial myonecrosis is the α-toxin, with perfringolysin O (θ toxin) playing a secondary synergistic role (Titball and Rood, 2002). The VirS/VirS system regulates the production of α-toxin, perfringolysin O (θ-toxin), collagenase, and numerous housekeeping genes (Rood, 1998). It consists of the sensor histidine kinase, VirS, and its cognate response regulator, VirR. The regulatory cascade is triggered by an unknown growth phase or environmental signal, most likely a secreted peptide that is part of a classical Gram-positive quorum sensing system. Binding of the signal molecule to an external domain of the VirS transmembrane protein is proposed to lead to a change in VirS conformation and autophosphorylation of a conserved His residue in its cytoplasmic C-terminal domain. Phosphorylated VirS then interacts with the cytoplasmic VirR molecule, and the phosphate residue is then transferred to a conserved Asp residue in the N-terminal domain of VirR.

In *C. perfringens* strain 13, the sequenced paradigm strain used in most genetic studies, VirS-activated VirR has been shown to directly activate the transcription of five genes that are located at different sites in the genome (Ba-Thein *et al*., 1996; Shimizu *et al*., 2002a; Cheung *et al*., 2004). These genes include the perfringolysin O structural gene, *pfoA*, the α-clostripain cysteine protease gene, a gene encoding the regulatory RNA molecule, VR-RNA, and two genes of unknown function (Rood, 1998; Banu *et al*., 2000; Shimizu *et al*., 2002b). Each of these genes has two 13 bp imperfect direct repeats, or VirR boxes, located just upstream of the -35 box of the promoter (Shimizu *et al*., 2002a).

VirR binds independently to each VirR box (Cheung and Rood, 2000), but both VirR boxes are essential for transcriptional activation of the downstream promoter (Cheung *et al*., 2004). Both the spacing between the VirR boxes and the distance between these boxes and the -35 box are important for biological activity. Experimental evidence indicates that VirR binding is required for the binding of *C. perfringens* RNA polymerase to the promoter (Cheung *et al*., 2004). Other studies have shown that the FxRxHrS and SKHR motifs, which are located in the C-terminal activator domain of VirR, are required for DNA binding and biological activity (McGowan *et al*., 2002; McGowan *et al*., 2003).

VirR also activates other toxin and housekeeping genes indirectly, as a result of its ability to activate the transcription of the VR-RNA molecule (Banu *et al*., 2000; Shimizu *et al*., 2002c). The VirS/VirR regulon therefore represents an extensive regulatory cascade that is involved in more than toxin gene regulation; even plasmid-encoded genes can be regulated by this system (Ohtani *et al*., 2003). The VR-RNA molecule partially activates transcription of the α-toxin structural gene, *plc*, the collagenase gene, *colA*, the beta-2 toxin gene *cbp2*, which is encoded on the cryptic plasmid pCP13, a cyclic nucleotide phosphodiesterase gene, *cpd*, the *ptp* gene, and other genes identified from proteomic studies (Shimizu *et al*., 2002b). In addition, it negatively regulates the transcription of an operon involved in cysteine metabolism and the pCP13-determined *cna* gene. The mechanism by which VR-RNA mediates these pleiotropic effects is not known, but it is likely to involve a specific VR-RNA-binding protein. The elucidation of the mechanism of action of VR-RNA and the analysis of the signaling molecule that triggers the VirS/VirR cascade represent major challenges for researchers in this field.

### DNA curvature and α-toxin production in C. *perfringens*

The expression of the major *C. perfringens* extracellular toxin, the α-toxin, is down-regulated at temperatures greater than 20°C, which is consistent with the concept that this toxin has a major degradative role in the normal soil environment. Temperature-dependent regulation is mediated not by the VR-RNA molecule but by DNA bending induced by three phased poly(A)$_{5\text{-}6}$ tracts located upstream of the *plc* promoter (Toyonaga *et al*., 1992; Matsushita *et al*., 1996). Because of the presence of these poly(A) sequences, DNA curvature or bending is more pronounced at lower temperatures, resulting in higher *plc* expression (Katayama *et al*., 1999). Reduction of the number of poly(A) tracts

reduces the amount of DNA bending, with a concomitant reduction in *plc* expression.

Gel retardation and footprinting studies showed that poly(A) tract-mediated DNA bending stimulates the formation of a more stable RNA polymerase – $P_{plc}$ complex and leads to increased transcriptional activity. Subsequent studies showed that the C-terminal domain of the α-subunit of *C. perfringens* RNA polymerase binds to the minor grooves of the poly(A) tracts with increased binding being observed at lower temperatures (Katayama *et al*., 2001). This regulatory system is not restricted to the *plc* gene in *C. perfringens* since a similar biological effect is observed for the *C. perfringens* ferredoxin gene, *fdx*, which also has three phased poly(A) tracts upstream of the -35 box of the promoter, in addition to an additional two tracts located within the promoter (Kaji *et al*., 2003).

### Alternative sigma factors and toxin production

In recent years it has been shown that alternative sigma factors play an important regulatory role in the control of toxin production, particularly in *C. difficile*, *C. botulinum*, and *C. tetani*. These proteins include BotR, which regulates botulinum neurotoxin (BoNT) expression, TetR, which controls tetanus neurotoxin (TeNT) production, and TcdR (previously called TxeR or TcdD) (Rupnik *et al*., 2005), the toxin A and toxin B regulator from *C. difficile*. These proteins, together with the bacteriocin regulator UviA from *C. perfringens*, form a novel family of alternative sigma factors.

Botulinum toxin is released from the cell in the form of a complex that contains BoNT and several non-toxic proteins, including a hemagglutinin (Johnson, 2000). These proteins are all encoded by a contiguous gene locus that includes the *bont* toxin gene and the *botR* regulatory gene. Although the precise location and transcriptional orientation of *botR* varies in the different *C. botulinum* toxin types, it is always located within this locus, upstream of the *ntnh* and *bont* genes. Overexpresson of the BotR protein leads to increased production of both BoNT and its associated proteins, a process that is mediated at the transcriptional level by the binding of BotR to the relevant promoters (Marvaud *et al*., 1998a). Partial inhibition of *botR* expression with antisense mRNA leads to decreased toxin production. There is a closely related gene, *tetR*, located upstream of the TeNT structural gene, *tetX* (Marvaud *et al*., 1998b). The TetR protein has 50–65% identity to the equivalent BotR proteins and, as expected, overexpression of TetR leads to increased -TeNT production, again as a result of transcriptional activation. The BotR protein was also able to activate *tetX* expression in *C. tetani*, but less efficiently.

More recent studies have shown that BotR and TetR, like TcdR and UviA, are alternative sigma factors rather than positive regulators (Raffestin *et al*., 2005). They require RNA polymerase core enzyme to bind to the promoter region and to catalyze transcription *in vitro*. Deletion of a helix-turn-helix motif located in BotR did not affect the ability of the sigma factor to bind the RNAP core, but eliminated the binding of the resultant holoenzyme to bind to the promoter. Although the use of alternative sigma factors is an excellent mechanism for ensuring that specific gene products are only produced when required, the signals that lead to the functional activation of these factors are not known.

Initial studies showed that the *tcdR* gene (then called *txeR*), which is located immediately upstream of the toxin B structural gene *tcdB,* could activate the expression of *C. difficile* toxin gene fusions in *E. coli* (Moncrief *et al*., 1997). The TcdR dependent promoters have been identified and shown to have similarity to the UviA-dependent promoter of the *C. perfringens bcn* gene (Dupuy and Sonenshein, 1998). Subsequently, it was shown that the TcdR protein was an alternative sigma factor, the first member of this clostridial protein family to be identified as a sigma factor (Mani and Dupuy, 2001). TcdR is required for the specific binding of *C. difficile* RNA polymerase to the *tcdA* and *tcdB* promoters and activates transcription from these promoters *in vitro*, in the presence of RNA polymerase. It has been shown that TcdR regulates toxin reporter gene expression in both *C. perfringens* (Dupuy and Sonenshein, 1998; Mani and Dupuy, 2001) and *C. difficile* (Mani *et al*., 2002); in both species this regulatory process is subject to catabolite repression by glucose. TcdR also regulates its own expression (Mani *et al*., 2002) in a temperature-dependent manner (Karlsson *et al*., 2003). It was proposed that TcdR was the prototype member of an alternative sigma factor family that also included BotR, TetR, and UviA (Mani and Dupuy, 2001). Subsequent studies have confirmed this proposal, and these four proteins are now considered a distinct subgroup of the extracytoplasmic (ECF) family of $\sigma^{70}$ factors (Dupuy *et al*., 2005; Raffestin *et al*., 2005).

## GENETIC REGULATION OF *STAPHYLOCOCCUS AUREUS* EXOTOXINS

*Staphylococcus aureus* is a major human pathogen that causes a variety of infections, ranging from superficial lesions to life-threatening diseases, due to the wide repertoire of toxins, exoenzymes, adhesins, and immune-modulating proteins that it produces. With

the exception of diseases caused by specific toxins, no single virulence factor has been found to be sufficient to cause a staphylococcal infection. Thus, staphylococcal infections are attributable to the coordinated actions of several different factors. Some of these proteins, including cytotoxins and exoenzymes, are secreted. Others, including protein A and various adhesins, remain attached to the cell wall. The *Staphylococcus* virulence factors have been divided into three classes on the basis on their potential roles in the infectious process (Projan and Novick, 1997): (i) factors that allow the bacteria to attach to host cells or extracellular matrices; (ii) factors that allow them to evade the host defense system, i.e. factors that inhibit phagocytosis, and factors that decrease the activity of antistaphylococcal antibodies; and (iii) factors involved in invasion, i.e., factors that degrade cell or extracellular matrix components allowing dissemination of *S. aureus*.

*S. aureus* exotoxins can be divided into two general groups: (i) membrane-active agents or cytotoxins and (ii) toxins with superantigen activity.

- The membrane-active group contains α-, β-, and δ toxins, which are hemolytic, and bi-component toxins, which include leukocidins and have cytolytic effects on polymorphonuclear leukocytes, monocytes, and/or erythrocytes. The membrane-active toxins participate in the invasion phase of infection (Bronner *et al.*, 2004).
- One subset of staphylococcal diseases results primarily from a single toxin exhibiting superantigen activity. Among these toxinoses, toxic shock syndrome is provoked mostly by toxic-shock syndrome toxin-1 (TSST-1) and less frequently by enterotoxins such as enterotoxin A (SEA), B (SEB), C (SEC), or D (SED). In addition, enterotoxins (A to E and G to R) cause staphylococcal food poisoning. Finally, the exfoliative (epidermolytic) toxins of *S. aureus* are responsible for staphylococcal scalded skin syndrome, which generally affects young children. These superantigen toxins are encoded by mobile genetic elements such as plasmids, bacteriophages, and pathogenicity islands (McCormick *et al.*, 2001).

Relatively little is known about the regulation of virulence gene expression during infection. However, in recent years, many groups have investigated the regulatory systems that control the expression of these genes *in vitro*. Various studies of virulence factor production by *S. aureus* in batch cultures have shown that most exoproteins, including exotoxins, are secreted in only the post-exponential phase of bacterial growth, whereas cell wall–associated virulence factors, such as protein A, are produced during logarithmic phase (Projan and Novick, 1997) (See Figure 4.2). Their production is controlled by a complex global regulatory network of genes, the expression of which *in vitro* is temporally and coordinately regulated and generally influenced, directly or indirectly, by environmental signals.

## Virulence regulators

Several global regulators regulate the production of virulence-associated exoproteins. Some of them are two-component systems and are sensitive to environmental signals.

### *The Agr system*

The *a*ccessory *g*ene *r*egulator (Agr) is one of the best-characterized global regulatory systems. The Agr system is a two-component system responding to quorum sensing (Ji *et al.*, 1995). The *agr* locus produces two distinct and divergent transcripts, RNAII and RNAIII, which are initiated from two promoters (P2 and P3, respectively) (Novick *et al.*, 1995) (Figure 4.3). RNAIII overlaps the *hld* open reading frame encoding the δ toxin, but RNAIII itself functions as the regulatory signal of the Agr system (Morfeldt *et al.*, 1995; Novick *et al.*, 1993). The main role of RNAIII is to regulate the transcription of target genes directly or indirectly (Novick *et al.*, 1993). The mechanism by which RNAIII modulates transcription is unknown. However, RNAIII up-regulates *hla* (encoding the α-toxin) expression at the transcriptional and translational levels (Novick *et al.*, 1993). Indeed, an increase in RNAIII induces α- and β-toxin gene expression under *agr* regulation (Recsei *et al.*, 1986). At the level of translation, RNAIII serves as an antisense RNA. *hla* mRNA contains a secondary structure probably blocking translation. RNAIII base pairs with sequences on *hla* mRNA upstream of the translational start site and releases the ribosome-binding site and start codon necessary for translation of the mRNA molecule (Morfeldt *et al.*, 1995).

The principal role of the RNAII transcript is to regulate the transcription of RNAIII. The RNAII transcript potentially encodes four proteins, AgrB, AgrD, AgrC, and AgrA. RNAIII and RNAII synthesis depends on each of the four proteins (Novick *et al.*, 1995) (Figure 4.3). This suggests that the *agr* locus belongs to an autocatalytic feedback system. AgrA and AgrC constitute the response regulator and histidine kinase components, respectively, of a two-component system (Lina *et al.*, 1998; Novick *et al.*, 1995). During the exponential growth phase, the *agrD*-encoded propeptide is processed by proteolytic digestion and the formation of a thioester bond resulting in an autoinducing peptide (AIP). It was subsequently demonstrated that

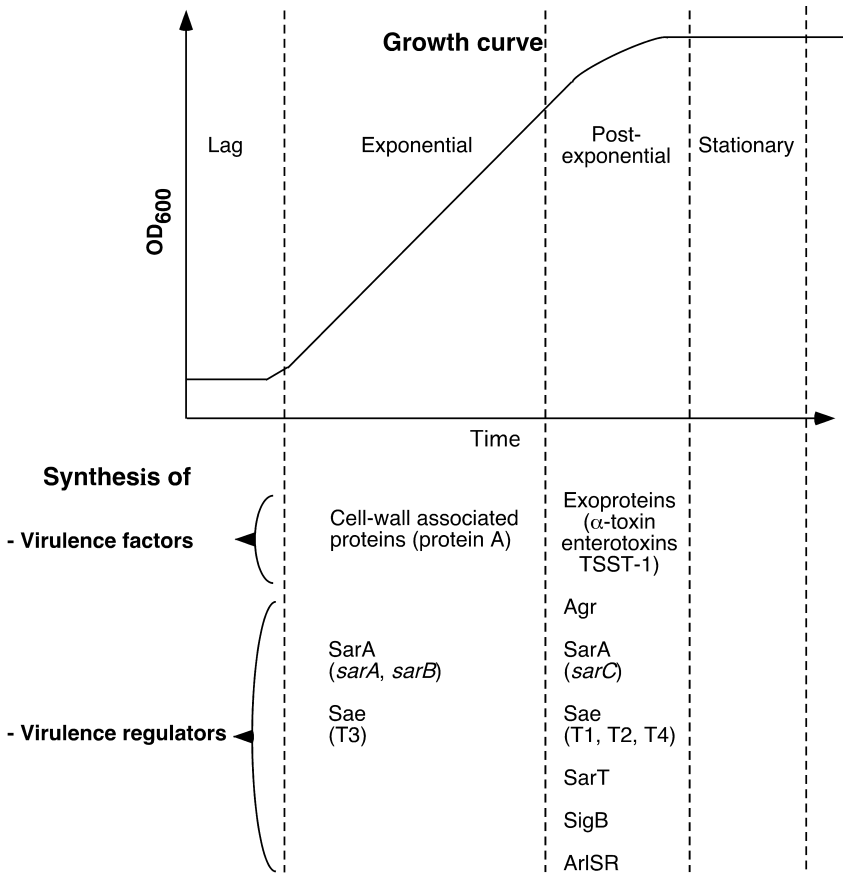

**FIGURE 4.2** Regulation of virulence factors in *S. aureus*. Synthesis of virulence factors and regulators is temporally regulated. A standard *in vitro* growth curve indicates the different growth phases.

the specific peptide modification corresponds to the formation of a cyclic thiolactone bond by a cyclization reaction between an internal cysteine residue and the C terminus of the peptide (Ji *et al.*, 1997). AIP, which is composed of seven to nine residues, is secreted into the extracellular compartment. Maturation and secretion of AIPs are probably provided by the transmembrane protein AgrB (Ji *et al.*, 1995; Zhang *et al.*, 2002). AIP is the ligand for the AgrC sensory component, and RNAIII synthesis is triggered when AIP reaches a threshold concentration that is directly related to cell density (Figures 4.2 and 4.3). This autocrine regulation mechanism indicates that the *agr* locus functions as a quorum-sensing system that detects cell density.

*S. aureus* strains have been classified into four allelic groups (Ji *et al.*, 1997), corresponding to four classes of AIPs, all encoded by the same region of the corresponding *agrD* gene, but distinct in their sequence and/or modification (Mayville *et al.*, 1999). One specific aspect of the Agr system is that AIPs that activate virulence expression in one group of *S. aureus* strains also inhibit the *agr* signaling pathway of all strains with other AIP groups (Lyon *et al.*, 2000).

### *The sarA locus*

A second global regulatory locus, termed the *s*taphylococcal *a*ccessory *r*egulatory (*sarA*) locus, has been described. This locus is also necessary for α-toxin production (Cheung and Ying, 1994). The *sarA* gene encodes the 15-kDa protein SarA transcribed by three overlapping transcripts (Cheung and Projan, 1994). These transcripts (*sarA*, *sarC,* and *sarB*) are initiated from three different promoters, *sarA* at P1, *sar*C at P3, and *sarB* at P2, but are probably terminated at the same stem-loop sequence (Figure 4.3) (Bayer *et al.*, 1996; Manna *et al.*, 1998). P1 and P2 are $\sigma^A$-specific promoters, whereas P3 is recognised by the stress response $\sigma^B$ factor. The SarA protein is produced during all growth phases since *sarA* and *sarB* are synthesised from mid to exponential phase and *sarC* during late-exponential and stationary phase (Manna *et al.*, 1998) (Figure 4.2). SarA, which is a DNA-binding protein, recognizes and binds to a conserved A/T-rich binding site present upstream of the promoter sequence of its target genes (Chien *et al.*, 1999). The SarA protein directly interacts with the *agr* locus by binding to several binding sites present in the *agr-P2-P3* promoter region and up-

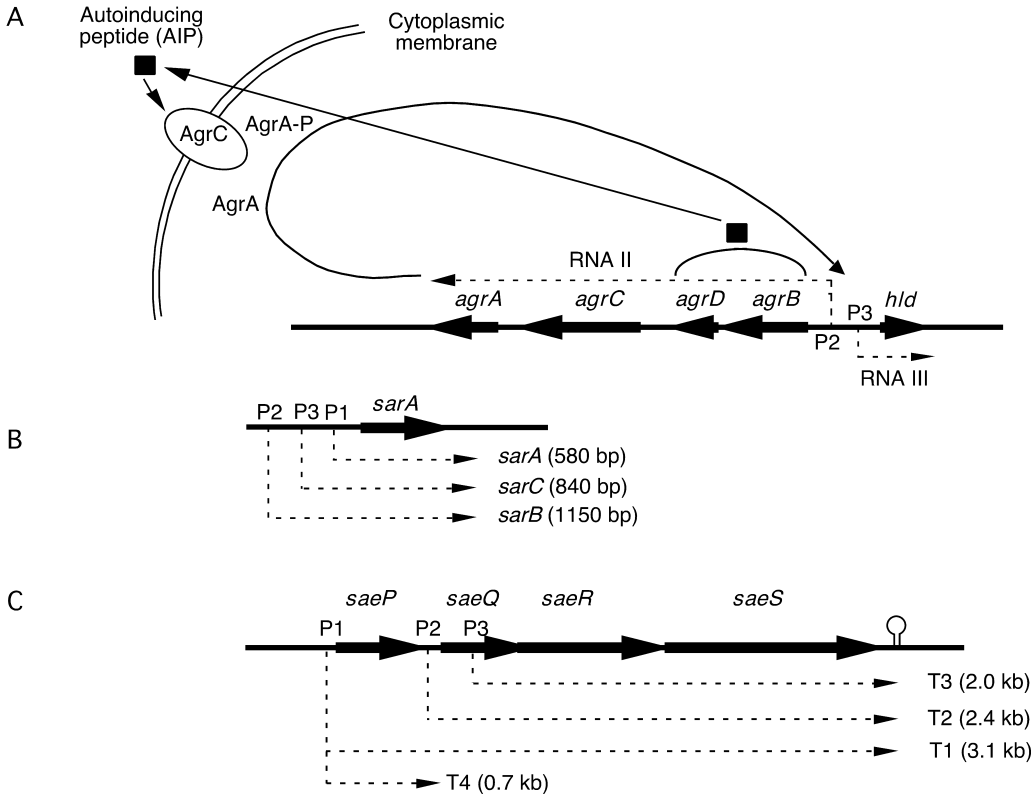

**FIGURE 4.3** Genetic organization of several global regulator genes involved in the regulation of *hla* expression. Dotted lines represent the transcripts. A. The *agr* locus. B. The *sarA* locus. C. The *sae* locus.

regulates the *agr-P2-P3* promoters (Chien *et al.*, 1999; Morfeldt *et al.*, 1996; Rechtin *et al.*, 1999).

### *The Sae system*

The *sae* locus (for *s*taphylococcal *a*ccessory *e*lement) is a four-component system composed of SaeP (or ORF4) and SaeQ (or ORF3), the functions of which are unknown (Novick and Jiang, 2003; Steinhuber *et al.*, 2003), and SaeR and SaeS, which show strong sequence similarity to the response regulators and histidine kinases of two-component systems (Giraudo *et al.*, 1999). These ORFs are transcribed by four overlapping transcripts (T1 to T4) initiated from three promoters (P1 to P3) (Novick and Jiang, 2003; Steinhuber *et al.*, 2003) (Figure 4.3). The T1 transcript initiates at P1 upstream of *saeP*, T2 initiates at P2 upstream of *saeQ*, and T3 initiates at P3 upstream of *saeR*. T1, T2, and T3 mRNAs have a common 3′ end corresponding to a terminator downstream of *saeS*. T4 is a small monocistronic mRNA that includes *saeP* (Steinhuber *et al.*, 2003) (Figure 4.3). The expression of the *sae* genes is controlled by growth phase. T3 is mainly expressed during the exponential phase and disappears when T1, T2, and T4 appear during the post-exponential phase (Figure 4.2). The four transcripts are up-regulated by *agr* and *sarA* (Novick and Jiang, 2003). The Sae system is required for full expression of α- and β-toxin genes (Giraudo *et al.*, 1997; Giraudo *et al.*, 1994) and the action of Sae on *hla* appears to be independent from *agr* and *sarA* (Giraudo *et al.*, 1997).

### *SarA homologues*

Another regulator Rot (*r*epressor *o*f *t*oxin) (15.6 kDa) modifies the expression of toxin genes. Mutation in *rot* partially restores α-toxin production when *agr* is deleted (McNamara *et al.*, 2000). Rot belongs to the Sar family of transcriptional factors of *S. aureus*. Rot activity is down-regulated by the Agr system, whereas the transcription of *rot* is not modified by the Agr system. The mechanism by which the Agr system controls Rot regulation is not known (McNamara *et al.*, 2000).

SarT (16.1 kDa) is another homologue of SarA and is also a DNA-binding protein. The *sarT* transcript is mainly detected during the post-exponential phase (Figuew 4.2) and down-regulates *hla* expression (Schmidt *et al.*, 2001).

Finally, another Sar homologue has an indirect role in the regulatory network of toxin gene expression.

SarU (29 kDa) consists of two distinct domains, each showing sequence similarities with SarA and SarT. Mutation in *sarU* has been shown to attenuate the synthesis of RNAII and RNAIII and consequently the expression of *agr*-target genes such as *hla* (Manna and Cheung, 2003).

### *The Sigma factor B ($\sigma^B$)*

The RNA polymerase core enzyme consists of four subunits ($\alpha^2\beta\beta'$). The interaction between this core enzyme and a σ factor results in an RNA polymerase holoenzyme that can detect specific promoter sequences and activate transcription in various conditions. *S. aureus* has only one of these alternative sigma factors, $\sigma^B$ (Wu *et al.*, 1996). $\sigma^B$ plays a major role in bacterial response to environmental stress and energy depletion. In *S. aureus*, $\sigma^B$ is part of a complex network of regulatory genes controlling the expression of accessory genes. It interacts with other regulatory genes such as transcriptional factors to modulate gene expression, but it is also able to directly regulate the expression of several genes that possess $\sigma^B$-dependent promoters (Kullik *et al.*, 1998).

The *sigB* gene encoding SigB ($\sigma^B$) belongs to a chromosomal regulon of four *S. aureus* genes (*rsbU*, *rsbV*, *rsbW,* and *sigB*) (Wu *et al.*, 1996). Regulation of SigB depends on the phosphorylation state of RsbV. RsbW, an anti-sigma factor, binds to RsbV, an anti-anti-sigma factor, or to SigB depending on the culture conditions encountered (Bronner *et al.*, 2004). In the absence of stress, RsbV is phosphorylated and unable to bind to RsbW. Thus, RsbW binds to SigB, and the resulting RsbW-SigB complexes inactivate SigB. In conditions of stress, RsbV is dephosphorylated and thus able to interact with RsbW, releasing activated SigB (Giachino *et al.*, 2001; Miyazaki *et al.*, 1999). The *sigB* gene is regulated by two different pathways. The first pathway dependent of RsbU is initiated in response to environmental stress such as salt or heat shock. RsbV is dephosphorylated by RsbU and binds to RsbW (Miyazaki *et al.*, 1999). The second pathway independent of RsbU is activated when conditions such as stationary growth phase decrease the intracellular ATP/ADP ratio. In these conditions, RsbV is not phosphorylated and associates with RsbW (Palma and Cheung, 2001). $\sigma^B$ is mainly active during the late exponential phase and its activity decreases upon entry to the stationary phase (Figure 4.2). The expression of *hla* is up-regulated in *sigB*$^-$ mutants (Giachino *et al.*, 2001; Palma and Cheung, 2001; Ziebandt *et al.*, 2001). Furthermore, $\sigma^B$ up-regulates the *sarC* transcript of the *sarA* locus and down-regulates *agr* expression (Bischoff *et al.*, 2001).

### *Other two-component systems*

The ArlSR system (for *a*utolysis-*r*elated *l*ocus) is a two-component system (Fournier *et al.*, 2001). Expression of the *arlRS* locus is growth-phase dependent and peaks in the post-exponential phase. The ArlSR system decreases the production of virulence factors by down-regulating the transcription of some of these genes including α- and β-toxin genes (*hlb*). The Arl system may act on *hla* and *hlb* expression by down-regulating RNAII and RNAIII transcription, consequently decreasing the expression of virulence genes regulated by RNAIII (Fournier *et al.*, 2001).

The SrrAB system (for *s*taphylococcal *r*espiratory *r*esponse) (or SrhSR) is another two-component system (Throup *et al.*, 2001; Yarwood *et al.*, 2001). SrrAB regulates the expression of virulence factors, especially in microaerobic conditions. It also modulates the production of several proteins implicated in energy metabolism The *srrAB* gene is up-regulated in anaerobic conditions. SrrAB regulates the expression of virulence genes such as the TSST-1 gene either by modification of the RNAIII level or by a pathway independent of RNAIII synthesis (Yarwood *et al.*, 2001).

## *In vitro* genetic regulation of toxins

### *Regulation of Cytotoxins*

Most studies have found that α-toxin mRNA levels are directly linked to extracellular toxin levels, indicating that toxin production is mostly regulated at the transcriptional level. The α-toxin is produced at the transition from late exponential to post-exponential phase (Figure 4.2). Regulation of *hla* expression is complex: regulatory elements such as RNAIII and SarA act directly by binding to the promoter region of *hla* (Chien *et al.*, 1999; Novick *et al.*, 1993), whereas others act indirectly. At the beginning of the growth phase, the transcription of *hla* is repressed by Rot and/or SarT (Bronner *et al.*, 2004) (Figure 4.4). The *agr* AIP reaches its threshold around mid-exponential phase, activating *agr* expression and RNAIII synthesis. RNAIII stimulates the expression of *hla*. SarA also induces *hla* and *hlb* expression (Cheung and Ying, 1994), and it is likely that SarA up-regulates *hla* either directly or by down-regulating the *hla* repressor, SarT (Schmidt *et al.*, 2001). Furthermore, during the exponential and post-exponential phases, RNAIII synthesis is induced by SarA and SarU and decreased by ArlSR. The Sae system seems to act independently of the SarA and Agr pathways, whereas SigB modifies *hla* expression by an unknown pathway (possibly Agr) (Figure 4.4).

### *Regulation of superantigens*

The regulation of the TSST-1 and enterotoxin genes is not as well understood as that of the α-toxin gene. The genes encoding these proteins are all expressed at the mid-exponential phase, like the genes encoding most exoproteins (Novick, 2000) (Figure 4.2). The *tst* gene, which encodes TSST-1, is up-regulated mostly by Agr and slightly by SarA (Chan and Foster, 1998; Recsei *et al.*, 1986). The gene encoding enterotoxin A (*sea*) is not regulated by *agr*, unlike *seb*, *sec,* and *sed*, which all need a functional *agr* for full expression (Tremaine *et al.*, 1993; Tseng *et al.*, 2004).

## *In vivo* regulations of exotoxins

Since exotoxins theorically degrade host tissues, erythrocytes, and phagocytic cells, they may be involved in the dissemination and the spread of bacteria to surrounding tissues. Thus, exotoxin gene expression within the host may be affected by micro-environmental factors such as pH and/or host-specific factors such as the presence of fibrinogen, erythrocytes, or leukocytes. In a guinea pig model of device-related infection, only small amounts of RNAIII are synthesized, whereas *hla* expression is high. Furthermore, mutations in *agr* and *sarA* do not modify *hla* expression, whereas mutation in *sae* down-regulates *hla* expression dramatically (Goerke *et al.*, 2001). In subcutaneous chambers implanted in rabbits, expression of secreted virulence factor genes such as *tst* or *hla* is increased, whereas RNAIII expression is considerably decreased (Yarwood *et al.*, 2002). However, in an experimental abscess infection model, depletion of fibrinogen, which participates in the inflammatory response, significantly represses RNAIII expression and *hla* expression (Rothfork *et al.*, 2003). Thus, *S. aureus* within different host niches may use different regulatory pathways to provide exotoxin synthesis.

The expression of *S. aureus* exotoxin genes is thus modulated by a complex regulatory network. The interactions between the different regulators probably play a major role in the pleiotropic regulation of the virulence factors required to adapt to changes in the extracellular environment and to survive within host niches. The role of this regulatory network *in vivo* is still not clear and awaits further study to elucidate how

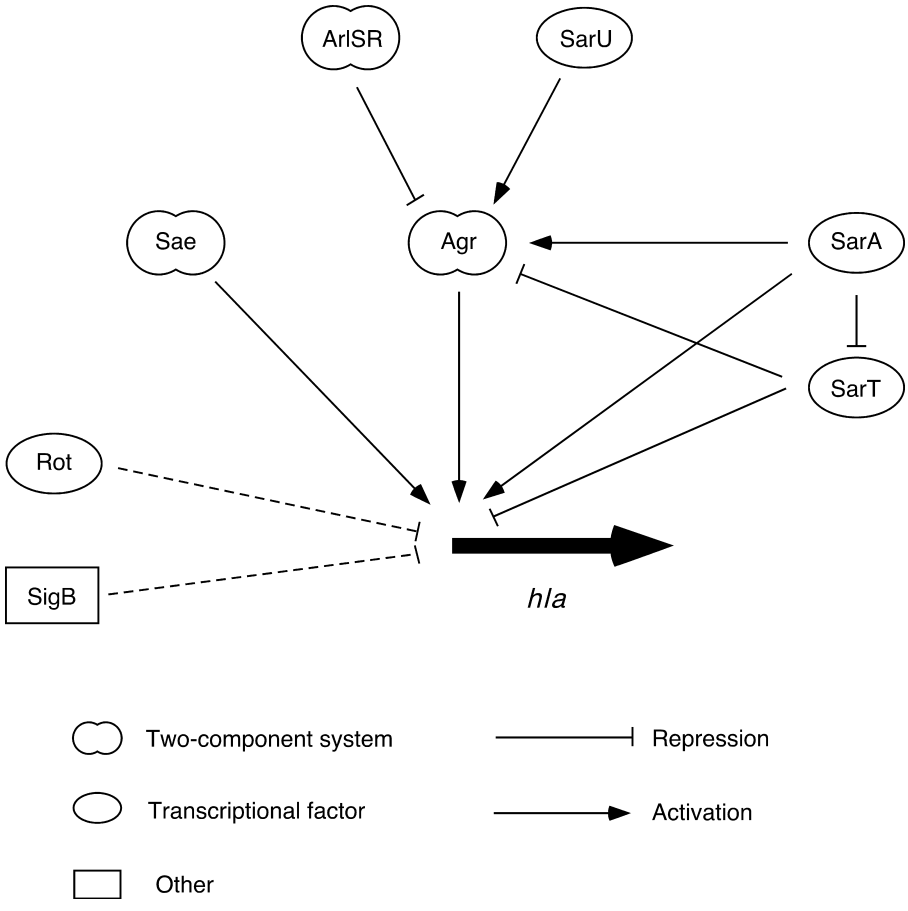

**FIGURE 4.4** Schematic representation of the different pathways regulating *hla* expression. Arrows and perpendicular bars indicate positive and negative regulation, respectively. Dotted lines indicate a possible indirect effect by an unknown pathway. Details of the model are described in the text.

staphylococcal virulence genes are controlled by regulatory factors within the host.

CHAPTER

# 5

# Toxin secretion systems

*Maria Scott and Maria Sandkvist*

## INTRODUCTION

Toxins and other effector molecules enhance the virulence characteristics of bacteria and play a pivotal role in host disease processes. These proteins must be transported outside of the cell if bacteria are to garner any infective or survival advantage of their production. Bacteria may release these factors into the extracellular milieu, inject the secreted proteins directly into the host cells or attach these proteinaceous substances to their outer surface. Proteins exported by Gram-positive bacteria have only one lipid-bilayer to transverse so it is generally believed that secretion in these organisms is rather simplistic in comparison to Gram-negative organisms. This is because secreted proteins produced by Gram-negative organisms must cross two barriers, the cytoplasmic (inner) and outer membranes. Despite that, both classes of organisms utilize signal-sequence dependent Sec and Tat pathways for export of proteins across the cytoplasmic membrane. Consequently, Gram-negative bacterial evolution diverged to provide complex and highly specialized systems for secretion of bacterial proteins across the outer membrane.

Five extracellular secretion systems produced by Gram-negative organisms have been described to date and they are designated as types I-V. Two of these pathways shuttle proteins that arrive in the periplasmic compartment via the Sec or Tat pathways across the outer membrane. Type V system, consisting of the autotransporter proteins, appears by comparison to be the least complicated. However the autotransporter proteins represent the largest group and may actually exemplify the most flexible system of all secretion pathways since autotransporter proteins, following export across the cytoplasmic membrane, transverse the outer membrane largely without accessory proteins. The type II system transports fully folded proteins across the outer membrane. This system is much more complex and consists of 12-16 proteins that comprise a macromolecular structure that is thought to span both the inner and outer membranes. The type IV secretion system is also complex, consisting of up to 11 proteins, and is thought to be ancestrally related to the type II system yet is distinctly different. Case in point, the type IV system transports ssDNA as well as proteins across the cell envelope. Proteins secreted via the type I and type III pathways completely bypass the periplasmic compartment. They do not rely on Sec or Tat for cytoplasmic membrane transport; they transverse the cell envelope in a single step. In the type I system proteins cross the two membrane barriers through a channel formed by one of three accessory proteins. The type III system, made of approximately 25 components, is one of the most intriguing systems and is commonly called the molecular syringe because proteins secreted via this pathway are injected directly from the cytosol of the bacterial cell into the host cell without encountering the extracellular environment.

In the next few sections important features of the protein secretion pathways known to play a key role in secretion of housekeeping proteins as well as virulence factors will be presented. Salient facts about export of proteins across the cytoplasmic membrane by way of the Sec machinery and twin arginine translocation (Tat) pathway will be described. Also the type V and II secretion systems will be discussed, followed by the type IV system, ending with an overview of types I and III pathways.

## INNER MEMBRANE TRANSLOCATION

### Sec-mediated export of proteins across the cytoplasmic membrane

Proteins emerging from ribosomes must be sorted, sometimes before synthesis is complete, for insertion into the cytoplasmic membrane, delivery to the periplasmic compartment or retention in the cytoplasm. The Sec protein export pathway has an essential role in the sorting and biogenesis of secreted proteins that cross or insert into the cytoplasmic membrane. Nascent polypeptides carry a typical signal-sequence at the amino-terminal end that targets them to the Sec translocon (Dalbey and Kuhn, 2000). The signal sequence is about 20 amino acids long with a short stretch of flanking positively charged residues followed by a hydrophobic region and a consensus proteolytic cleavage site (Dalbey and Kuhn, 2000). Both Gram-negative and Gram-positive organisms utilize the Sec system as the first step in secretion of many proteinaceous factors. The protein-conducting channel and the accessory proteins have been studied extensively in both *Escherichia coli* and *Bacillus subtilis* and comparative analyses reveal a highly conserved pathway. In fact, both eukaryotes and archaea carry homologues of the Sec translocon.

The Sec machinery consists of several components that coordinate export of precursor proteins (see Figure 5.1). First, as the signal sequence of the precursor protrudes from the ribosome it is recognized by the holdase chaperone, SecB, which binds in close proximity to the signal sequence slowing polypeptide rate of folding (Kumamoto and Beckwith, 1983) (Collier *et al.*, 1988) (Hartl *et al.*, 1990). Next, transient but high affinity molecular interactions between SecB and SecA bring the precursor in contact with SecA (Fekkes *et al.*, 1997). The SecA component recognizes the signal sequence of the nascent protein and prevents its folding (Oliver and Beckwith, 1981) (Hunt *et al.*, 2002). Translocation of the nascent protein is initiated following contact of SecA with the SecYEG complex, which causes a dramatic conformational change in the SecA protein. The subsequent binding of ATP drives SecA into the lipid bilayer (Wang *et al.*, 2004). Continued

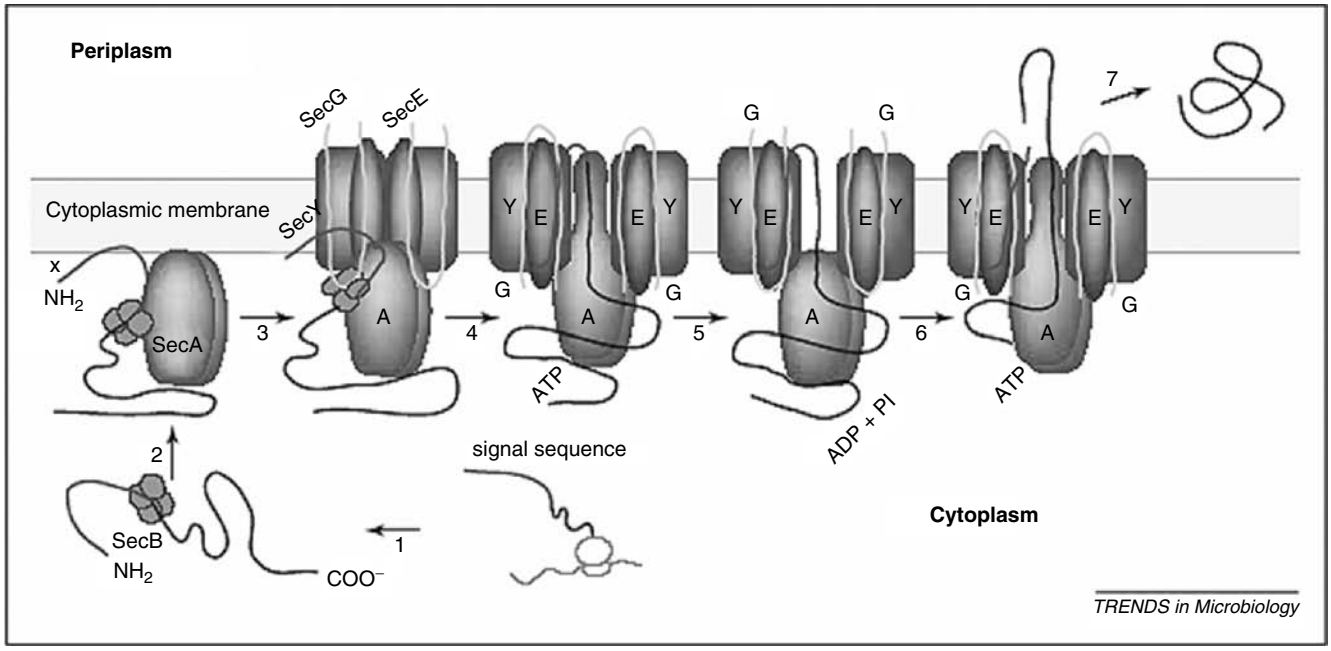

**FIGURE 5.1** Diagram of the Sec translocation process. The nascent polypeptide is represented by the black line. Step 1-3, targeting: The signal sequence of the polypeptide protrudes from the ribosome and is recognized by the SecB chaperone which binds close to the target sequence slowing the rate of polypeptide folding. Transient but high affinity intermolecular interactions between SecB and SecA bring the precursor protein to the translocase. SecA bound to the nascent polypeptide binds to the membrane and docks with the SecYEG heterotrimeric complex. Steps 4 and 5, initiation: The initiation step follows ATP binding to the SecA component resulting in a dramatic conformation change in the SecA protein driving it into the lipid bilayer. Step 6 consists of continued cycles of ATP hydrolysis by SecA in conjunction with the proton motive force to energize unidirectional translocation of the nascent protein across the membrane. Step7, termination occurs on the periplasmic side followed by cleavage of the signal peptide, folding and release of the substrate to the periplasmic space. "Reprinted from *Trends in Microbiology, Vol. 9(10)*, Hiroyuki Mori and Koreaki Ito, The Sec protein-translocation pathway, 494-500©2001, with permission from Elsevier Science Ltd.

cycles of ATP hydrolysis by SecA in conjunction with the proton motive force, energizes unidirectional translocation of the nascent protein across the membrane (Vrontou and Economou, 2004). Steps leading to termination of the process are not clearly defined. However accessory proteins, SecDF-YajC, have been suggested to interact with SecYEG and stabilize transfer of the protein to the periplasmic side of the inner membrane (Duong and Wickner, 1997). When the preprotein emerges on the other side of the membrane the signal sequence is cleaved off by the signal peptidase and folding of the mature protein occurs (Schiebel *et al.*, 1991) (Dalbey *et al.*, 1997).

### *The* E. coli *Sec translocase*

The prevailing model is that the *E. coli* Sec translocon consists of the heterotrimeric complex SecYEG. SecY is an essential component of the translocon in that it forms the protein translocation pore. It is a 48 kDa integral membrane protein that spans the cytoplasmic membrane ten times (Clemons, Jr. *et al.*, 2004). Another principal factor of the translocon is SecE, a 14 kDa inner membrane protein. Mutational analyses and crosslinking studies indicate that SecY and SecE form a stable complex through several points of contact. Equimolar concentrations of SecE and SecY are maintained within the cell (Veenendaal *et al.*, 2001) and any excess SecY is rapidly degraded by membrane bound FtsH (Kihara *et al.*, 1995). SecG (11.5 kDa) spans the membrane twice and also contains a somewhat hydrophobic cytosolic segment (Nishiyama *et al.*, 1996). In addition SecG has the unique capacity to flip-flop in the membrane reversing its topology during membrane insertion of SecA. Thus, SecG is thought to augment SecA ATP binding cycles and play an important role in the SecA membrane insertion-deinsertion process (Nishiyama *et al.*, 1996).

Recently the crystal structure of the Secαγβ complex of *Methanococus jannaschii* was solved to a resolution of 3.2 Å (van den *et al.*, 2004). The archaeal Secαγβ complex corresponds to SecYEG, where Secα and Secγ have exact counterparts in bacterial SecY and SecE; respectively. The Seca and SecG, on the other hand, are not homologues, but may perform similar functions. The archaeal Sec complex is more homologous to eukaryotes then to bacteria. The α-subunit contains 10 transmembrane (TM) alpha-helices divided into two domains that contain TMs 1-5 and TMs 6-10. The γ- and β-subunits span the membrane once each. Visualization of the Secαγβ complex from the cytoplasmic side reveals the α-subunit as a rectangular shape with three of its four sides surrounded by the γ- and β-subunits (van den *et al.*, 2004). One single α-subunit (SecY) forms an hourglass-shaped translocation channel, which is plugged by one of its short alpha-helices. Binding of a signal peptide is thought to result in displacement of the plug and opening of the channel. As the channel expands and the signal peptide intercalates between TM2 and TM7, the mature portion of the polypeptide moves through the aqueous channel. The hydrophobic residues in the channel constriction may form a gasket-like seal around the polypeptide as it translocates through the channel thus preventing the passage of other molecules. Once the translocating polypeptide exits the channel, the plug returns to its original position. The structure of the Sec complex also suggests a model for transport of membrane proteins (van den *et al.*, 2004). The transmembrane domain of membrane proteins is thought to exit the channel laterally to partition into the lipid bilayer. As the α-subunit channel is blocked on three of its four sides by the γ- and β-subunits, the free side is likely the place where the channel may open to allow for escape of membrane proteins.

Not all Sec dependent precursors engage the translocase through interactions with SecB. It is generally thought that resident inner membrane proteins require a divergent method of entry into the Sec pathway. There are two pathways known to exist in *E. coli*. One requires targeting of ribosome-nascent chains (RNC) through interactions with the signal recognition particle (SRP). SRP carries the nascent chain to the Sec translocon, which is associated with YidC. The other pathway completely bypasses the Sec translocon and directly targets RNC to YidC (Luirink and Sinning, 2004) (de Gier and Luirink, 2003).

### *Twin-arginine translocation (Tat) pathway*

The Sec pathway supports export of unfolded proteins across the inner membrane. However several bacterial proteins that incorporate cofactors such as NADP, metal ions like copper and complex metal cofactors (e.g. molybdopterin) must do so as they fold into their native state. Cofactors normally reside in the cytoplasm. Therefore cofactor-containing proteins must fold in the cytoplasm before they are exported across the inner membrane. Pre-folded proteins can not utilize the Sec machinery for transport. A recently described system, the twin-arginine transport (Tat) pathway, distinct from the Sec apparatus, recognizes and exports folded proteins across the membrane (Robinson and Bolhuis, 2004). In addition to cofactor-containing proteins, the Tat machinery also transports other proteins such as phospholipase, a virulence factor secreted by *Pseudomonas aeruginosa* (Ochsner *et al.*, 2002). A similar system was recognized first in the thylakoid membrane of plant chloroplasts (Settles *et al.*, 1997).

Evidence indicates that Tat substrates are recognized and sorted via a signal peptide. The signal sequence varies in length (up to 58 amino acids) but contain common features. The signal peptide has three domains, a basic amino-terminal region (n-region) followed by a hydrophobic h-region and a hydrophilic domain (c-region) that contains the recognition site for the enzyme signal peptidase (Berks, 1996). In addition, the Tat signal peptides contain a conserved amino acid sequence motif at the n-region/h-region site which is defined as S-R-R-x-F-L-K (Stanley *et al.*, 2000). Although the vast majority of Tat substrates carry the twin arginine motif within the signal sequence, site-directed mutagenesis show that not all Tat translocation competent proteins require the presence of the arginine pair (Dreusch *et al.*, 1997) (Gross *et al.*, 1999) (Halbig *et al.*, 1999). In fact the Tat pathway exports an *E. coli* penicillin amidase even though it has no obvious twin-arginine-like motif (Ignatova *et al.*, 2002). The signal peptide sequence requirement for Tat sorting and transport has been explored by a series of fusion protein studies. For example, a fusion between the Sec-dependent c-cytochrome and a Tat signal peptide diverted this recombinant protein to fold in the cytoplasm and to be recognized and transported by the Tat pathway (Sanders *et al.*, 2001). All together evidence gleaned by several investigators reinforces the concept that the entire signal sequence in context with the rest of the protein may well be important and not just the arginine motif (Robinson and Bolhuis, 2004). Furthermore, heterologous signal sequences may not be recognized as Tat substrates by unrelated bacteria (Berks *et al.*, 2000a). For example, while glucose-fructose oxidoreductase (GFOR) of *Zymomonas mobilis* is exported by the Tat pathway in its native host it is not exported when expressed in *E. coli* (Blaudeck *et al.*, 2001). Yet when the *Z. mobilis* signal sequence was replaced by the signal sequence used to target an *E. coli* enzyme, trimethylamine N-oxide reductase (TorA), the GFOR-fusion protein was readily exported by *E. coli* (Blaudeck *et al.*, 2001).

Recent studies indicate that soluble chaperons, proteins that bind newly synthesized polypeptide chains to prevent incorrect folding, may carry Tat substrates to the machinery for export. These chaperons may have a proofreading function that rejects unfolded and incorrectly folded proteins (Robinson and Bolhuis, 2004), and proteins that do not bear the proper signal sequence thereby blocking their entry into the Tat pathway (DeLisa *et al.*, 2003) (Jack *et al.*, 2004). One example of a recently discovered putative molecular chaperone is DmsD. This protein specifically binds to the precursor form of dimethylsulfoxide reductase (Ray *et al.*, 2003) prior to its interaction with the Tat translocase. DmsD was shown not to bind the mature form of the DmsA protein (Papish *et al.*, 2003) and in a strain lacking DmsD the biogenesis of DmsA was severely affected (Oresnik *et al.*, 2001) (Ray *et al.*, 2003). DmsD appears to assist in proper folding and targeting of the DmsA precursor to the Tat apparatus (Papish *et al.*, 2003). As of yet no global chaperons have been identified that participate in Tat substrate biogenesis (Robinson and Bolhuis, 2004).

### *Characteristics of the components of the Tat translocase*

Four gene products, TatA, TatB, TatC, and TatE, have been identified that participate in Tat export (Weiner *et al.*, 1998) (Sargent *et al.*, 1998) (Bogsch *et al.*, 1998) (Bolhuis *et al.*, 2001). Generally TatAB and C are found in most Gram-negative bacteria but there is some variability amongst Gram-positive bacteria (Robinson and Bolhuis, 2004). In *E. coli, TatABC* are located in a polycistronic locus on the chromosome whereas *tatE* has a different chromosomal location (Robinson and Bolhuis, 2004). TatE and TatA are homologous proteins with approximately 50% sequence identity and *tatE* may be a gene duplication of *tatA* (Robinson and Bolhuis, 2004). Genetic evidence indicates that TatE and TatA have overlapping functions because single deletions of either TatA or TatE decrease the number of Tat-dependent proteins exported but does not abolish it. The reason for the redundancy of function for TatA and TatE in *E. coli* is unclear since some species of bacteria do not carry the *tatE* gene at all and those that do so express TatA at much higher levels than TatE (Sargent *et al.*, 2001) (Jack *et al.*, 2001). TatA, TatB, and TatE are integral membrane proteins each with one transmembrane domain (TM) (De *et al.*, 2001). TatC is predicted to have 6 TMs (Sargent *et al.*, 1998) (Bogsch *et al.*, 1998), but recent data indicates that TatC may have only 4 TMs (Drew *et al.*, 2002) (Jack *et al.*, 2004).

Evidence indicates that the Tat pathway relies on the transmembrane proton electrochemical gradient across the inner membrane for protein export (Robinson and Bolhuis, 2004). The stoichiometry and composition of the functional Tat complex is under investigation.

Tat substrates are thought to be exported across the inner membrane through a gated pore. TatA is a good candidate to form the protein translocation channel because it is expressed in large molar excess over other Tat components. TatA forms oligomers and is not involved in signal peptide-binding. Furthermore, negative stain electron microscopy of isolated TatAB complexes revealed that TatA was in 25 molar excess and formed ring-like structures that contained a central pore of approximately 70Å. These results are very

provocative since inspection of folded Tat substrates indicates that in order to transport them the channel must be at least 70Å wide (Berks *et al.*, 2000b) (Sargent *et al.*, 2002). Finally, in support of these findings antibodies to the TatA orthologue, Tha4 of plant chloroplasts, prevent protein transport but does not block its association with precursor proteins (Cline and Mori, 2001) indicating that TatA does not participate in substrate recognition but functions in protein export. The totality of evidence to date suggests a model in which the TatBC complex functions to bind substrate while the large TatA complex forms the pore in association with TatBC to export the prefolded protein across the inner membrane (Robinson and Bolhuis, 2004). The exact mechanism of protein translocation and the precise configuration of the Tat machinery remain to be discovered.

## OUTER MEMBRANE TRANSLOCATION

### *Autotransporters: Members of the type V secretion system*

Many pathogenic microorganisms use the simplicity of the type V pathway for extracellular transport of effector molecules, which have profound effects on eukaryotic cells. This diverse group of effector proteins consists of the cytolytic serine protease autotransporters secreted by the Enterobacteriaceae, adhesive type proteins such as pertactin of *Bordetella pertussis*, phospholipase of *P. aeruginosa*, and VacA of *Helicobacter pylori*. Autotransporters are a large family of diverse proteins produced by Gram-negative bacteria specifically the α-β-γ and ε classes of proteobacteria (except *Actinobacillus* and *Vibrio*), and by *Chlamydiae*. The autotransporter secretion modality was first described in 1987 for the IgA1 protease produced by *Neisseria gonorrhoeae* (Pohlner *et al.*, 1987). Since then several others have been identified. Only pathogenic bacteria appear to produce these autotransporters. In some cases a direct link to the pathology of the disease can be correlated as for the vacuolating toxin (VacA) of *H. pylori* (Reyrat *et al.*, 1999) and the IcsA autotransporter important for intracellular motility of *Shigella flexneri* (Goldberg and Sansonetti, 1993). In many cases however, no definitive role in the disease process can be attributed to the autotransporter even when its function is known (Henderson and Nataro, 2001).

Autotransporters are unique because they contain, programmed into their structure, all the information required for self-transport across the outer membrane without accessory proteins. These proteins are synthesized as large pre(pro)proteins with three distinct regions: a Sec- sorting amino terminal signal peptide, a passenger domain (effector region of the protein) and a C-terminal β-domain dedicated for outer membrane translocation of the passenger domain. Once synthesized, the autotransporters are transferred across the inner membrane in a sec-dependent manner. Following removal of the leader peptide, the (pro)protein is released into the periplasm and self-translocated across the outer membrane (Desvaux *et al.*, 2004a). The primary features of an autotransporter are discussed below.

Some autotransporters contain an 18-27 amino acid residue leader peptide (Desvaux *et al.*, 2004a). Others have an atypical Sec sorting sequence that is unusually long (up to 50 residues). The signal sequences display three distinct features: the n-domain contains residues with a positive charge; a hydrophobic group of residues designated as the h-domain; and consensus signal peptidase recognition site that consist of the c-domain. In addition, these sorting sequences contain at the beginning of the n-domain two specific motifs: MNKIYSLKY (S/C/H) followed by conserved hydrophobic residues, GLIAVSELAR (Oliver *et al.*, 2003a) (Desvaux *et al.*, 2004a). Cross-linking experiments between the hemoglobin protease autotransporter (Hbp) and components such as SRP, trigger factor, SecA, and SecY, along with pulse chase and mutational analysis of the Hbp leader sequence yielded evidence that the additional residues were sorting sequences for recruitment of SRP. In fact, this was the first time an outer membrane protein was shown to use the SRP-Sec pathway to cross the inner membrane (Sijbrandi *et al.*, 2003).

After the autotransporter reaches the periplasm the hydrophobic residues of the C-terminal β-domain interacts with the lipid bilayer of the outer membrane to initiate self-insertion (Henderson *et al.*, 1998). A consenus motif (Y/V/I/F/W)X(F/W) at the end of the β-domain appears to be extremely important for folding, formation and stabilization of the translocation pore. The β-domains form β-barrels that consist of 14 antiparallel amphipathic strands consisting of 9-12 residues (Desvaux *et al.*, 2004a). The translocation pore forms an aqueous channel such that the hydrophobic domains of the alternating residues are embedded into the lipid bilayer of the outer membrane and the hydrophilic residues face toward the center of the pore. The exact configuration of the pore in the outer membrane is under debate. Some evidence suggests that the pore is formed by oligomers of the β-domain (Veiga *et al.*, 2002), but this structure is still speculative as other studies point to a monomeric conformation (Oomen *et al.*, 2004).

As the β-domain begins to fold into a β-barrel, its most stable and favorable conformation, the tethered

unfolded passenger domain is exposed to the periplasmic space (Desvaux *et al.*, 2004a). That situation makes this domain susceptible to proteases unless pore formation and passenger domain translocation are temporally coupled so that the periplasmic stage is short-lived. Recently it was hypothesized that a periplasmic chaperone aided the translocation process. Indeed a study by Voulhox and colleagues revealed that depletion of the periplasmic chaperone Omp85 resulted in poor cell viability and resulted in significant reduction of processed IgA1 protease on the cell surface. Taken together the data suggests that Omp85 plays a crucial role in the biogenesis of outer membrane proteins (Voulhoux *et al.*, 2003).

A linker region located between the passenger domain and the β-domain is essential for threading the unfolded passenger domain through the pore of the transporter (Oliver *et al.*, 2003b) (Velarde and Nataro, 2004). Once at the cell surface, the passenger domain folds (Ohnishi *et al.*, 1994). A short amino acid segment present in the passenger domain was found to act as a molecular chaperone (even when supplied in trans) to trigger or direct folding of the effector domain (Ohnishi *et al.*, 1994) (Oliver *et al.*, 2003b).

After folding, the effector molecule can remain intact and stay associated with the β-domain or may be cleaved. The cleavage occurs upstream of or within the linker region by proteolytic activity associated with the autotransporter itself (Serruto *et al.*, 2003) or by an exogenous membrane associated protease (Shere *et al.*, 1997). Although cleaved, some proteins remain noncovalently associated with the β-domain. In other cases, further maturation of cleaved and released protein can occur to achieve an active state. For example, VacA is cut into two subdomains, one 33 kDa and the other 55 kDa. These two subunits oligomerize into a large functional complex (Lupetti *et al.*, 1996).

### *Two-partner secretion pathway*

The two-partner secretion pathway contains members of a subgroup of the type V secretion family. Extracellular transport of these proteins is similar to other members of the autotransporter family with a few differences summarized here. The two-partner secretion system is distinctive in that the effector protein (secreted protein) and the transporter are the products of two separate genes. These genes are located in an operon or can be found at different loci (Jacob-Dubuisson *et al.*, 2001). Each transporter is dedicated to transport of one specific exoprotein. The secreted proteins can be grouped by their functions although there are limited identifiable similarities within the secretion domain of these proteins (Jacob-Dubuisson *et al.*, 2001). The effector proteins are produced as large pre(pro)-proteins which transverse the inner membrane in a Sec-dependent manner. The transporter has dual functions; it transports the pro-proteins released into the periplasm and acts as a chaperone to prevent premature folding prior to translocation. Once at the cell surface the proteins fold, followed by processing when necessary to yield functional proteins (Jacob-Dubuisson *et al.*, 2001).

## The type II secretion pathway

The type II secretion system (T2SS) has also been referred to as the main terminal branch of the general secretion pathway because in the past it was believed to be the main route across the outer membrane (Pugsley *et al.*, 1997) (Pugsley, 1993). Over time the discovery that only a subset of proteins produced by Gram-negative bacteria are secreted by the type II machinery has revised this assumption (Desvaux *et al.*, 2004b). Even so, many pathogenic and non-pathogenic Gram-negative bacteria produce functional T2SSs to transport proteins across the outer membrane. Since the identification of the T2SS as crucial for secretion of pullulanase by *Klebsiella oxytoca* (d'Enfert *et al.*, 1987) (d'Enfert and Pugsley, 1989) several human pathogens such as *Vibrio cholerae*, *Yersinia pestis*, Shiga-toxin producing *E. coli*, *P. aeruginosa*, and plant pathogens like *Erwinia chrysanthemi* and *Xantomonas campestris* have been shown to have adapted this method for secretion of key virulence factors such as toxins, proteases, chitinases, lipases, and other hydrolytic enzymes out of the cell (Sandkvist, 2001b) (Sandkvist, 2001a). The T2SS has also been identified in *Legionella pneumophila* where it promotes growth of Legionella at temperatures at or below 30°C (Soderberg *et al.*, 2004). It is suggested that a diffusible factor secreted by the type II machinery is required for survival of Legionella at those temperatures.

Secretion via the type II machinery occurs, just like secretion via the type V pathway, in two distinct stages (Hirst and Holmgren, 1987a). First, nascent polypeptides destined for transport cross the inner membrane via the Sec or Tat pathway (Filloux *et al.*, 1990) (Voulhoux *et al.*, 2001), the signal peptide is cleaved and the proteins are released. Second, after entry into the periplasm exoproteins fold and assemble into their native or near- native states. Lastly, these substrates engage the type II secretion apparatus (secreton) in the periplasmic compartment prior to translocation across the outer membrane.

### *Substrate recognition by the type II machinery.*

Type II-dependent proteins secreted by various species of bacteria are quite divergent in function with very little similarity at the amino acid level. As an example, *V. cholerae* secretes 6 distinct proteins that include

cholera toxin and hemagglutinin-protease. Cholera toxin is a multisubunit protein that consists of 5 identical B subunits (the binding domain) and one A subunit (catalytic domain) that fold and assemble in the periplasm into $AB_5$ holotoxin with the help of disulfide isomerase (DsbA) (Findlay *et al.*, 1993) prior to translocation across the outer membrane. On the other hand hemagglutinin-protease secreted by *V. cholerae* is a monomeric protein. Notwithstanding these differences, the type II secretion machinery discriminates between resident periplasmic and secreted proteins and allows only type II dependent substrates to enter into the secreton. How are type II-dependent proteins selected? Information gleaned from mutational analyses of amino acid residues at the amino and carboxy-terminus of secreted products has been ambiguous and did not distinguish residues that were identifiable as signal sequences but suggested that residues at both ends were important and might include two different signals that act synergistically (McVay and Hamood, 1995) (Lu and Lory, 1996). Internal deletions of exotoxin A that preserved the functional domains of the protein were secretion defective (Voulhoux *et al.*, 2000). Likewise internal deletions or insertions within cellulose (Chapon *et al.*, 2001) that preserved function prevented secretion by the *Erwinia* type II machinery (Py *et al.*, 1993). When disulfide bond formation, which normally occurs in the periplasm, was blocked cellulase (Chapon *et al.*, 2001) and cholera toxin were not secreted by their cognate type II machinery but accumulated in the periplasm and were eventually degraded (Bortoli-German *et al.*, 1994) (Shevchik *et al.*, 1997) (Hirst and Holmgren, 1987b) (Hardy *et al.*, 1988). On total these experiments indicated that accurate folding in the periplasmic compartment is crucial for secretion. Analysis of exotoxin A and elastase supports the premise that, exclusive of disulfide bond formation proper periplasmic folding is a prerequisite for type II-dependent secretion and that a secretion motif is likely presented by the three-dimensional structure of the substrate (Braun *et al.*, 1996) (Lu and Lory, 1996) (Sauvonnet and Pugsley, 1996). Even distant residues that converge after folding may play a role in forming a structural secretion motif (Voulhoux *et al.*, 2000) (Chapon *et al.*, 2001). The *E. coli* heat-labile enterotoxin (LT-II) B subunit shares only 11 % identity with the B subunit of cholera toxin yet when expressed in *V. cholerae* it was recognized and secreted via the T2SS (Connell *et al.*, 1995). Comparison of the molecular structure of the B subunits of cholera toxin and LT-II reveals that the structures are nearly identical which probably explains why LT-II B was secreted by *Vibrio*. The pivotal finding by Connell and coworkers showed that conformation of the substrate is crucial to secretion competence. Yet to date no conspicuous three-dimensional motif has been identified by sequence analysis, chimeric protein technology or mutational analysis. One caveat certain to be considered is that chaperon(s) may be involved in presentation of substrates to the secretion apparatus. For instance the membrane anchored lipase-specific foldase, Lif, forms a complex with *P. aeruginosa* lipase to aid its folding, recognition, uptake and secretion by the type II machinery (El *et al.*, 1999).

Substrates transported by one species of bacteria by and large can not be secreted by an unrelated species, but this stringent restriction can be overcome when closely related species are considered. For example the *K. oxytoca* pullulanase can not be secreted by *P. aeruginosa* (de *et al.*, 1991) but lipase of *P. alcaligenes* is recognized and secreted by *P. aeruginosa* (de *et al.*, 2001).

### *The type II machinery: a supramolecular complex*

The species of bacteria that produce type II secretion apparatus are quite diverse and as a consequence the number of genes necessary for type II secretion varies from 12 to 15. These genes are designated as A-O and S (except in *Pseudomonas* where the genes are designated Q-Z and O). See Sandkvist for more details (Sandkvist, 2001a). The type II genes C-N generally cluster in an operon and the arrangement of those genes within the operon is fairly conserved (Sandkvist, 2001a). There is some variability as to which genes are essential for secretion depending on which species of bacteria is considered. Of note, when genes encoding the T2SS of *K. oxytoca* were transformed into laboratory strains of *E. coli* all but pulB, pulH, and pulN were found to be essential for secretion of pullulanase (Possot *et al.*, 2000). The A and B genes are not present in all species and variability in the need for A and B gene products have been noted for *Erwinia* and *Aeromonas* spp. (Howard *et al.*, 1996) (Jahagirdar and Howard, 1994). Protein S is thought to be important for stability and outer membrane insertion of protein D but may only be essential for secretion in *Erwinia* and *K. oxytoca* (Shevchik *et al.*, 1997) (Hardie *et al.*, 1996). In contrast, the O gene product is essential in all species tested thus far and is required for processing of proteins G, H, I, J, and K (Strom *et al.*, 1993) (Nunn and Lory, 1993) (Bleves *et al.*, 1998).

Various techniques such as mutational analysis, co-immunoprecipitation, yeast-two hybrid, cross-linking studies, and hunt for suppressor mutations have identified many protein-protein interactions and recognized the function for some key proteins of the T2SS (Sandkvist, 2001b). In addition, fractionation experiments have determined the subcellular location for most of these components. Based on localization data

and intermolecular interactions the evidence supports the hypothesis that a supramolecular complex is formed and that this apparatus spans the cell envelope from the inner membrane to the outer membrane (see Figure 5.2).

### *Protein D: the type II secretin*

It is predictable that the translocation pore would have to be large in view of the fact that proteins transported through the type II machinery are folded prior to secretion. The D gene product is an integral outer membrane protein believed to be the translocation pore (Akrim *et al.*, 1993) (Bitter *et al.*, 1998). It forms a homomultimeric complex and the C-terminal portion of the protein appears to be important for oligomerization (Bitter *et al.*, 1998). Electron microscopic analysis revealed that both the intact D protein and its isolated C-terminal domain form hexagonal-like ring-shaped oligomers that consist of 12-14 monomers (Linderoth *et al.*, 1997) (Brok *et al.*, 1999) (Nouwen *et al.*, 2000). D multimers have a central pore size of approximately 95 Å, large enough to accommodate pre-folded proteins such as elastase which has a diameter of 60 Å when folded (Thayer *et al.*, 1991) (Bitter *et al.*, 1998). The pore must be gated to preserve the membrane integrity of the cell but the mechanism of gating is unknown (Brok *et al.*, 1999). The C-terminal domain is embedded within the outer membrane and forms a 13 stranded β-barrel in a manner reminiscent of other integral outer membrane proteins (Bitter *et al.*, 1998). The N-terminal domain extends into the periplasm where it may contact other components of the type II machinery (Brok *et al.*, 1999). There are normally 50-100 complexes per cell as estimated by semi-quantitative immunoblotting (Brok *et al.*, 1999). The C-terminal portion of the D protein shares a high level of identity to a large family of proteins called secretins. Secretins are not only critical for type II secretion but are also important for biogenesis of type IV pili, surface appendages that play important roles in pathogenesis and participate in twitching motility, social gliding, and biofilm formation. Other members of the secretin family are involved in type III secretion and filamentous phage extrusion.

### *The NTPase of the type II apparatus*

Protein E associates peripherally with the cytoplasmic membrane in the presence of protein L (Sandkvist *et al.*, 1995) (Ball *et al.*, 1999) (Py *et al.*, 1999) (Possot *et al.*,

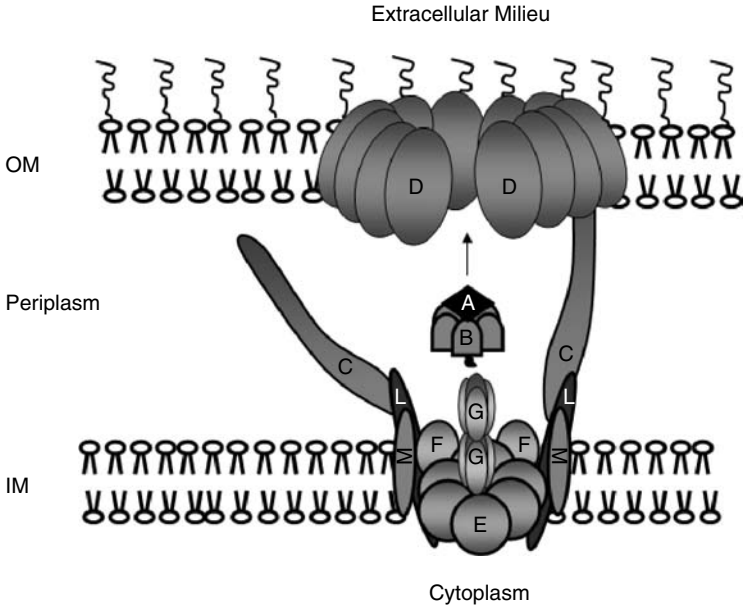

**FIGURE 5.2** A model of *c*holera *t*oxin (CT) secretion by the type II secretion pathway. Individual precursor subunits of cholera toxin are exported across the inner membrane by the Sec pathway and then the signal sequence is removed. In the periplasm the individual A and B subunits fold, assemble into holotoxin with the help of disulfide isomerase DsbA and the holotoxin is then targeted to the secretion machinery by way of the B subunit. The C protein with D may gate the entrance to the secretion pore. Following engagement by CT conformational changes in the apparatus facilitate translocation of the toxin. Secretion may proceed as a result of polymerization of component G and other pilin-like proteins into a piston-like structure that extends from the E/F/L/M platform found in the inner membrane. Protein E may be crucial for regulation or energizing polymerization of the pilin subunits so that CT is translocated across the outer membrane. This model does not include proteins A, B, N, and S because they are not present in all every organism that encode and produce the type II apparatus. IM refers to the inner membrane and OM to the outer membrane.

2000). It is believed to be the energy- generating component of the T2SS (Sandkvist, 2001b) and recently it was unequivocally shown that *V. cholerae* protein E (EpsE) possesses ATPase activity (Camberg and Sandkvist, 2005). The crystal structure of EpsE that contained an N-terminal truncation was determined and revealed a two-domain structure (Robien *et al.*, 2003). The C-terminal domain containing the C1 subdomain displays characteristic features noted for other $AAA^+$ ATPases. Namely, the Walker A box necessary for nucleotide binding, an atypical Walker B box and also present in between the Walker boxes the aspartate-rich motif. Furthermore, downstream of the Walker B box the histidine box was identified along with a unique motif that contains a protruding loop that forms when four cysteines come together to coordinate a zinc ion (Robien *et al.*, 2003;Camberg and Sandkvist, 2005). Protein E is a member of the ATPase subfamily that includes distant relatives VirB11 and HP0525 that participate in type IV secretion. Previous structural and electron microscopy data showed that members of the VirB11 subfamily such as TrwB and HP0525 form hexameric rings. The structural homology between HP0525 and EpsE supports the assertion that EpsE forms homo-hexamers and suggests that the hexamer may be the physiologically relevant form of EpsE that interacts with the rest of the type II complex (Robien *et al.*, 2003).

#### *Pseudo-pilin components: G, H, I, J, and K*

Amino acid similarity at the N-terminus indicates that type II pseudo-pilins have a common ancestry with pilin subunits of the type IV pilus system and exhibit similar properties. As a matter of fact, the major pseudo-pilin protein, G can polymerize when over expressed to form pilus-like structures (Sauvonnet *et al.*, 2000) (Durand *et al.*, 2003). Protein G interacts with H, I, and J, and interactions with E have also been suggested (Kagami *et al.*, 1998) (Possot *et al.*, 2000). Consequently one model suggests energy supplied by protein E might drive polymerization of the major pilin-like component, G, to form a pilus-like structure to propel substrates through the outer membrane pore (Sandkvist, 2001b) (See Figure 2). The roles of H, I, J, and K are not known. Recently yeast-two hybrid system revealed interactions of J with proteins G, D, L, and I (Douet *et al.*, 2004).

#### *Inner membrane subassembly*

Proteins C, L, and M have no recognizable homologues in the type IV pilus biogenesis system (Peabody *et al.*, 2003) and may be unique to T2SS. Protein C can be found in both inner and outer membrane fractions, and cross-linking studies show that it forms stable contacts with D (Possot *et al.*, 1999). Most other components of the type II apparatus are found in the inner membrane, and well documented evidence indicates that these interacting partners include E, L, M, and F; [E and L interactions: (Sandkvist *et al.*, 1995), (Py *et al.*, 1999), (Ball *et al.*, 1999), (Possot *et al.*, 2000)] [L and M interactions (Michel *et al.*, 1998), (Sandkvist *et al.*, 1999), (Possot *et al.*, 2000)] [E,L, and F interactions (Py *et al.*, 2001)]. Protein C may interact with both L and M. Taken together the data imply that protein C probably connects the outer membrane secretion pore (protein D) with the rest of the inner membrane type II components thereby forming the supramolecular complex that spans both inner and outer membranes.

## Type IV secretion pathways

The type IV secretion system (T4SS) comprises three distinct subgroups, which share structural homologies but secrete different substrates. One subgroup includes systems involved in DNA transfer such as the conjugal system found in both Gram-negative and Gram-positive bacteria. Conjugative transfer of DNA is an effective method of spreading antibiotic resistance genes carried on conjugative plasmids between related and unrelated bacteria (Lawley *et al.*, 2003). Another form of conjugation system transfers genetic material among organisms from different kingdoms. Such a system was first identified in the phytopathogen *Agrobacterium tumefaciens* as a means of transferring oncogenic T-DNA directly into susceptible plant cells (Zupan *et al.*, 2000). The second subgroup consists of DNA uptake and DNA release systems in which transfer does not require immediate contact with a target cell. This DNA uptake modality is used by *Campylobacter jejuni* and *H. pylori* to provide a method of genetic transformation between related species of bacteria to augment pathogenesis (Hofreuter *et al.*, 2001). *N. gonorrhoeae* is infamous for its capacity to undergo horizontal gene transfer between species and encodes a type IV secretion system involved in DNA release (Dillard and Seifert, 2001). The third subgroup has evolved to support translocation of proteinaceous virulence factors directly from the cytosol of pathogenic bacteria into human or animal host cells. The pathogens include both intracellular and extracellular organisms such as *L. pneumophila*, *Brucella* spp., *Bartonella* spp. and *H. Pylori,* which rely on effector molecules secreted by the type IV machinery for virulence and survival (Cascales and Christie, 2003). The T4SS of *Bordetella*, Ptl, employs a variation of this scheme and does not require cell contact because pertussis toxin (a type IV substrate) is released into the environment, binds to its receptor and is then internalized by the host cell (Burns, 2003).

### *Gene products necessary for type IV translocation and regulation*

The most well characterized T4SS is Vir carried by *A. tumefaciens*, and consequently this system will be the focus of the discussion on type IV mediated secretion. Comparisons will be made to other systems where appropriate. The T4SS of *A. tumefaciens* consists of 11 products of the *virB* and *virD* operons. The gene products VirB2–11 are required for assembly of a cell envelope spanning complex, for T-pilus formation, and for substrate transfer. The protein channel and the T-pilus together are designated as the mating pair formation [Mpf] (Cascales and Christie, 2003). The DNA transfer replication (Dtr) proteins, VirD1 and VirD2, process DNA substrate (Shirasu *et al.*, 1994) for transfer (Cascales and Christie, 2003). VirD4, referred to as the coupling protein (CP), is important for T-DNA recognition and targeting to the Mpf structure for translocation (Cascales and Christie, 2003).

The expression of *virB* and *virD* genes is regulated by environmental signals. Wound released phenolic compounds such as acetosyringone and sugars like monosaccharides activate the two-component regulator system of which VirA is the sensor and VirG is the transcription factor (Chang and Winans, 1992). Other factors such as phosphate starvation and extracellular pH below 6 also activate the two-component system, which in turn induces the expression of the *virB* and *virD* genes. In the case of *L. pneumophila* and *Brucella* spp., VirB homologues may be induced by amino acid depletion and acidic pH as a consequence of host cell internalization (Bachman and Swanson, 2001) (Rouot *et al.*, 2003). In contrast, the pertussis toxin (*ptx*) genes and the *ptl* genes carried by *B. pertussis* are co-transcribed as they share a common promoter upstream of *ptx* (Ricci *et al.*, 1996). Ptx has been shown to be expressed following an increase in temperature from 25°C to 37°C and is probably induced upon entry of bacteria into the host (Melton and Weiss, 1989).

### *Recruitment of type IV substrates*

Protein translocation by the T4SS begins with recruitment of cognate DNA or protein substrates, continues with transfer of substrate to the secretion machinery and ends with translocation across the bacterial cell envelope. In most cases effectors are delivered directly to target cells following cell-to-cell contact during infection (Cascales and Christie, 2003). The exact mechanism of substrate recognition by the CP and exactly how type IV substrates are transferred to the translocation machinery is not known. There has been no distinct transport signal identified but protein fusion data indicates that the C-terminal region contains residues important for translocation (Vergunst *et al.*, 2000) (Schrammeijer *et al.*, 2003). For example, fusion proteins composed of Cre/loxP and C-terminal portions of RalF or LidA, two proteins secreted by the T4SS Dot/Icm in *L. pneumophila*, but not N-terminal fusions of these proteins were competent for translocation into recipient cells (Luo and Isberg, 2004). Other findings from studies of the *A. tumefaciens* effector proteins VirE2, VirE3, and VirF, suggest that a cluster of positively charged amino acids present within the last 30-50 residues of the C-terminus play a role in defining the recognition signal (Vergunst *et al.*, 2003). Experimental evidence suggest that the function of the coupling protein, VirD4, is to interact with and bind substrate (T-DNA or effector molecules) and transfer these materials from the cytoplasm to the Mpf complex for translocation across the cell envelope (Llosa *et al.*, 2002). A novel cytological fluorescent screen in conjunction with immunoprecipitation analysis revealed direct interactions between the substrate, VirE2, and VirD4 indicating that substrates are recruited to the coupling protein (Atmakuri *et al.*, 2003). All the evidence taken together indicates that the role of coupling proteins is to serve as a connector between the proteins (or DNA) to be secreted and the secretion apparatus (Llosa *et al.*, 2003). This finding may be important to understanding effector translocation by other pathogenic bacteria such as *H. pylori* and *L. pneumophila* that also utilize CPs to recruit substrate to the translocation machinery (Cascales and Christie, 2003). In contrast the *Bordetella* Ptl system bypasses the CP step and uses the Sec pathway for export of Ptx subunits across the inner membrane (Cascales and Christie, 2003). Likewise *Brucella* and *Bartonella* do not use a CP mechanism for the recruitment of substrates to the secretion machinery, but the method used is unknown (Cascales and Christie, 2003).

### *Components of the type IV machinery*

Various methods employed in studying components of the type IV apparatus have reinforced the belief that the type IV assembly is a multi-protein complex that spans the cell envelope (Cascales and Christie, 2003). In deed use of a novel method called transfer DNA immunoprecipitation (TrIP) showed that the T-DNA/VirD2 complex interacts in a sequential manner with the VirD4 coupling protein, VirB11 ATPase, and the inner membrane channel components VirB6 and VirB8 and exiting byway of contacts with the secretin and pilin proteins, VirB9 and VirB2 (Cascales and Christie, 2004). The totality of evidence available has allowed a picture of the apparatus to take shape (Figure 5.3).

### *Coupling protein*

As discussed above CP is crucial for recruitment of substrates to some, but not all T4SSs. The CP is an inte-

gral membrane protein that contains two membrane-spanning domains at its N-terminus, a small periplasmic region and a significant portion of the C-terminus protruding into the cytoplasm (Cascales and Christie, 2003). The N-terminal portion of the protein is important for homo-oligomerization and X-ray crystallography of a VirD4 homolog from *H. pylori* indicates that CPs may transition between monomeric and hexameric states as a consequence of substrate or nucleotide binding (Cascales and Christie, 2003).

### *Energy couplers: VirB11 and VirB4*

VirB11 associates peripherally with the cytoplasmic face of the inner membrane (Cascales and Christie, 2003). This protein belongs to the superfamily of NTPases that function in various secretion systems present in both Gram-negative and Gram-positive bacteria and Archaea (Cascales and Christie, 2003). X-ray crystallography and electron microscopy comparisons of the VirB11-like type IV proteins, TrwB and HP0525, suggest a hexameric pore conformation (Gomis-Ruth and Coll, 2001) (Gomis-Ruth *et al.*, 2002) (Yeo *et al.*, 2000). The opening and closing of the pore appears to be regulated by ATP binding and hydrolysis resulting in dynamic conformational changes that may drive substrate across the inner membrane or aid the assembly of the translocation machinery (Savvides *et al.*, 2003). Recent information indicates that substrate is transferred from VirD4 to VirB11 in a process that does not require ATP binding or hydrolysis (Atmakuri *et al.*, 2004). On the other hand subsequent transfer of substrate from VirB11 to core proteins of the channel, VirB6 and VirB8, is driven by ATP hydrolysis (Atmakuri *et al.*, 2004).

VirB4 is an integral membrane protein that possesses two transmembrane domains and may function as a homomultimer (Rabel *et al.*, 2003). It also contains a centrally located Walker A box however ATP hydrolysis has not yet been demonstrated (Dang and Christie, 1997). Yeast-two hybrid analysis indicates that VirB4 and VirB11 interact (Ward *et al.*, 2002), suggesting that these two proteins may cooperate to drive substrate translocation. However the exact function of VirB4 has not been determined.

### *Inner membrane components: VirB6, VirB8, and VirB10*

These proteins have no known homologues outside of type IV secretion systems (Cascales and Christie, 2003) and probably forms the inner membrane portion of the secretion channel. VirB8 brings together a subcomplex that consists of itself, VirB9 and VirB10 and without VirB8, interactions between VirB9 and VirB10 not occur

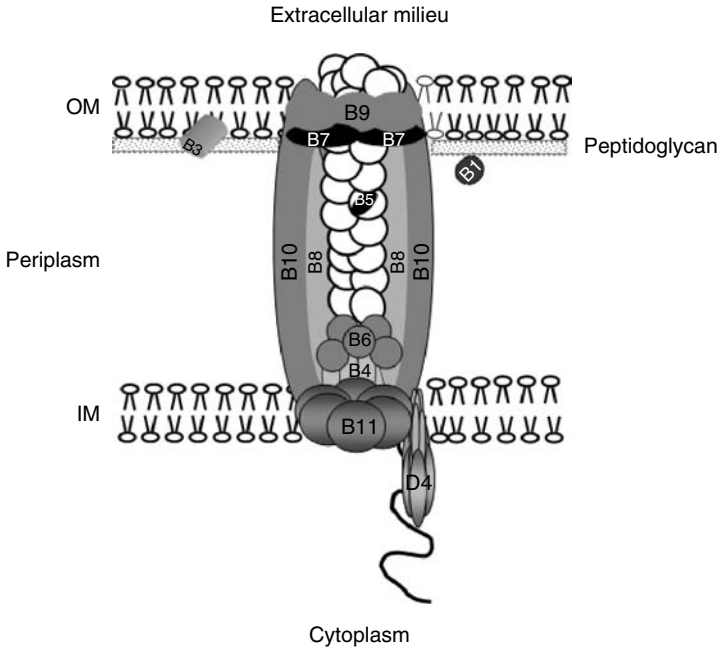

**FIGURE 5.3** Illustration of the *A. tumefaciens* type IV secretion apparatus. This rendering of the structure as a multimolecular membrane-spanning apparatus is based on recent data obtained from yeast or bacterial dihybrid screens and other biochemical analyses. The stoichiometry of the components that cooperate to form the secretion apparatus and the exact configuration of the structure within the lipid bilayer is not known. Molecules are not drawn to scale. VirB1 is not part of the macromolecular complex but is a transglycosylase that degrades the peptidoglycan layer and aids assembly of the pilus. VirB3 is an outer membrane protein thought to stabilize assembly or function of the apparatus. Inner membrane (IM) and outer membrane (OM) are shown.

(Christie, 2004). Both VirB8 and VirB10 are bitopic integral membrane proteins with large C-terminal periplasmic domains (Christie, 2004). The VirB6 constituent has 5 transmembrane spanning domains with the N-terminus located in the periplasm and the C-terminus in the cytoplasm (Jakubowski *et al.*, 2004). Studies revealed interactions between VirB6 and two outer membrane proteins, VirB7 and VirB9 (Jakubowski *et al.*, 2003). VirB6 through cooperation with VirB7/8/9/10 forms a portion of the protein translocation channel that directly interacts with the T-DNA/VirD2 complex (Jakubowski *et al.*, 2004). In fact VirB6 participates in the relay of T-DNA/VirD2 transfer from VirD4/VirB11/VirB4 subunits to VirB8 thus enabling the subsequent transfer of the nucleoprotein complex by VirB8 to VirB9 and VirB2 for translocation across the outer membrane (Jakubowski *et al.*, 2004).

### *T-pilus constituents and outer membrane accessory proteins*

VirB2 is the major pilin subunit and uses the Sec pathway for export across the inner membrane. Afterwards VirB2 undergoes a unique event that covalently links the amino acid residues present at the N- and C-terminal ends to create a closed circular protein (Lai *et al.*, 2002). Subcellular fractionation detected VirB2 and VirB5 in both the inner membrane/ periplasm and outer membrane fractions. In addition, these proteins were also found as extracellular products. VirB5 interacts with and stabilizes VirB2 and plays a role in biogenesis of the T-pilus (Krall *et al.*, 2002). VirB3 and VirB5 are required for substrate transfer; however, no protein-protein interactions are noted for VirB3 (Cascales and Christie, 2003). The T-pilus is thought to protrude through the protein channel and it is through the pilus that DNA passes from *A. tumefaciens* into susceptible plants (Cascales and Christie, 2004).

Protein VirB9 is predicted to contain nine β-strands that span the outer membrane and based on sequence analysis appears to be related to other known secretins (Christie, 2004). It is postulated to form the outer membrane secretion pore and to form intermolecular disulfide bonds with the lipoprotein, VirB7 (Spudich *et al.*, 1996) (Anderson *et al.*, 1996) (Baron *et al.*, 1997). Relevance of the presence of VirB9 in the outer membrane is suggested by evidence which shows contact between the T-DNA substrate and the VirB9 protein (Cascales and Christie, 2004), but passage of substrate through a pore formed by VirB9 has not yet been shown.

The working model has been that the pilus is the protein conduit through which type IV substrates exit the cell. Mutational analysis of various VirB components in *A. tumefaciens* revealed that substrate transfer can occur even in the absence of pilus. This lead Christie to suggest that a pilus-like organelle may not be a mandatory feature necessary to achieve type IV mediated secretion (Christie, 2004). On the other hand, novel extracellular appendages have been identified in pathogens that produce T4SS for effector molecule secretion. For example when *H. pylori* are grown on solid media it elaborates rigid needle-like projections that protrude from the poles (Rohde *et al.*, 2003). These are quite different from conjugative pili in that they are thicker with a diameter of 45 nm as opposed to 7 nm for the average conjugative pili (Yoshida *et al.*, 1998). The filaments made by *H. pylori* are unique because when cells are attached to host cells they are covered in a sheath made of VirB10-like proteins which are antigenically variable proteins (Rohde *et al.*, 2003). It was postulated that the sheath is changeable in order to evade the host immune response. Also *L. pneumophila* T4SS produces a morphologically unique surface structure that consist of a diffuse web of fibrous material around the cell composed of DotO and DotH effectors (Watarai *et al.*, 2001). This material does not resemble conjugative pili at all and is noted only before the bacterium bursts from the macrophage to spread to other cells (Watarai *et al.*, 2001). The role of the newly identified surface organelles in type IV secretion is unknown.

## Type I protein secretion

Several toxins and exoenzymes utilize the type I secretion system (T1SS) for extracellular transport. They include but are not limited to the *B. pertussis* adenylate cyclase toxin (Sory *et al.*, 1995), *E. coli* colicin (CvaC), leukotoxin (Ltka) of *Pseudomonas hemolytica*, and hemolysin (HlyA) produced by *E. coli*. The T1SS produced by *E. coli* has been studied extensively and will be used in this discussion as the model system. The translocase that transports HlyA consists of three proteins, the ATP binding cassette (ABC) transporter HlyB, the membrane fusion protein HlyD and the outer membrane component TolC (Andersen, 2003). The genes of the hemolysin operon are arranged as *hlyCABD*. The *tolC* gene is not linked to the *hlyA* operon but is part of the *mar-sox* regulon (Andersen, 2003).

Type I secretion systems are a significant group of structurally and functionally related complexes identified in almost all Gram-negative bacteria described to date. A major feature of proteins secreted via the T1SS is the presence of a variable number of glycine- and aspartic-rich repeats located at the C-terminal half of the secreted protein (Coote, 1992). This repeat in toxin (Coote, 1992) motif does not serve as the primary signal sequence. Instead, type I secreted proteins are

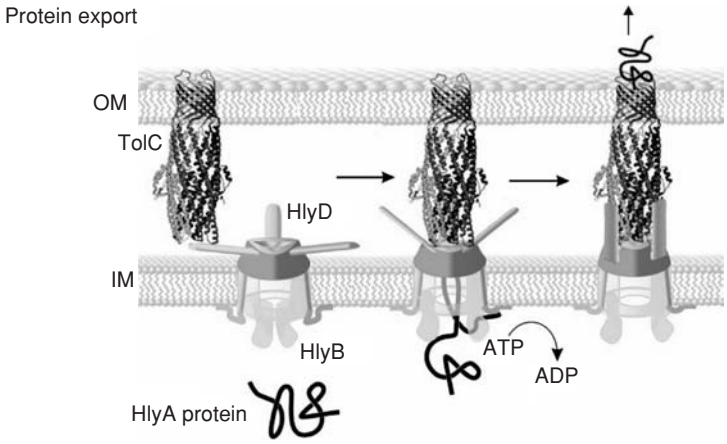

**FIGURE 5.4** Assembly of TolC-dependent export machinery. This model shows recruitment of TolC by the inner membrane translocase. Protein translocation occurs across the inner membrane (IM), outer membrane (OM), and the intervening periplasmic space. The accessory protein (Pimenta *et al.*, 1999) interacts with the ATP binding cassette (HlyB) transporter protein. Binding of substrate (HlyA) to the HlyD-HlyB subunit results in a conformational change in HlyD followed by recruitment of TolC. These interactions result in a tight trimolecular complex which spans the cell envelope. Simultaneously the protein translocation tunnel opens and substrate is secreted. Reprinted, with permission, from the *Annual Review of Biochemistry*, Volume 73 © 2004 by Annual Reviews www.annualreviews.org.

selected for entry into the pathway by recognition of a signal sequence located within the last 60 residues of the carboxy terminus. The recognition signal consists of three distinct features. Moving from the amino terminus is a 22 residue amphipathic α-helical domain, then next to that is a 13 amino acid uncharged sequence, followed by an eight residue hydrophobic region at the extreme carboxy terminus (Stanley *et al.*, 1991). Recognition of the signal sequence is believed to rely not only on the specific amino acid sequence but also on secondary structure (Stanley *et al.*, 1991) (Zhang *et al.*, 1993). The T1SS sorting sequence is not generally cleaved following translocation. The only known exception, to date, is the sorting sequence of the HasA protein, which is cleaved off during or after secretion to the extracellular environment (Izadi-Pruneyre *et al.*, 1999). The *E. coli* hemolysin T1SS has an additional feature in that a leader peptide located at the amino terminus and characterized by a double glycine motif is recognized by SecB and cleaved from the protein by the ABC transporter following translocation. This property is not a common attribute of other T1SS.

The hallmark of T1SS is that proteins are transported from the cytoplasm directly through the cell envelope to the extracellular environment without entering the periplasm (Koronakis *et al.*, 1989) (Andersen, 2003). Type I secretion occurs in distinct stages. First the accessory protein interacts with the ABC transporter. Then this heterodimer recognizes and binds to the signal recognition sequence of the protein to be secreted. This institutes a conformational change in the accessory protein allowing recruitment of TolC thus forming a tight trimolecular complex. Simultaneously, the protein translocation tunnel opens and the substrate is secreted. Following translocation of the protein TolC disassociates from the ABC transporter/accessory protein complex (Andersen, 2003) (Koronakis *et al.*, 2004).

Since the type I secretion substrates do not enter the periplasm, they have no access to disulfide bond (Dsb) forming enzymes commonly found in the periplasm or bound to the inner membrane facing the periplasm. Nonetheless some RTX toxins contain cysteine residues and lack of access of type I dependent proteins to Dsb enzymes do not affect their activity. For instance, colicin V was shown to contain disulfide bonds post secretion (Andersen, 2003). However, where and when disulfide bonds are formed is not known. Few proteins form stable disulfide bonds in the cytoplasm, and cytoplasmic enzymes such as thioredoxins (trxA, trxC), glutaredoxins (grxA, grxB, grxC) and glutathione, keep cysteine-containing proteins in their reduced state while in the cytoplasm (Zheng *et al.*, 1998).

### *ABC transporter*

The ABC transporter is a member of one of the largest protein superfamilies. There are 80 ABC transporters identified in *E. coli*, which are subdivided based on their substrate specificity and whether or not they participate in efflux or influx of materials. The type I specific ABC transporter assembles in the inner membrane as a homodimer. Self association results in four protein domains that consist of 2 hydrophobic membrane- spanning domains (MSD) and 2 cytoplasmic nucleotide-binding domains (NBD) (Saurin *et al.*, 1999). The NBD contains conserved sequences like the Walker A and Walker B motifs found in other ATPases. There is also a distinctive and conserved LSGGQ motif (linker peptide) present in almost all ABC transporters identified to date, that also participates in nucleotide binding (Hung *et al.*, 1998). Loss of function mutations in one nucleotide binding site results in no ATPase activity (Davidson and Chen, 2004) suggesting a level of cooperativity between the two subunits. Residues from both monomers are required to form the nucleotide binding site (Jones and George, 1999). X-ray crystallography of ABC transporters

reveals that ATP binds to a site that consists of residues in the Walker A box of one subunit and LSGGQ linker residues in the other subunit. It is still debated whether it is ATP binding or hydrolysis coupled to conformational changes in the membrane- spanning domains of the ABC transporter that mediates unidirectional transport of substrate (Davidson and Chen, 2004). Indeed whether both nucleotide-binding sites must be occupied before the ATPase becomes catalytically active (i.e. capable of transporting substrate) or whether ATP binding at one site promotes hydrolysis at the other is unclear (Davidson and Chen, 2004).

***The accessory protein***

The role of the accessory protein is to link the inner membrane ABC transporter to the outer membrane translocon and to stabilize the tripartite assembly during protein translocation across the outer membrane. The accessory protein is a bitopic protein with a large periplasmic domain and a short cytoplasmic domain anchored by a membrane- spanning region (Pimenta *et al.*, 1999) (Balakrishnan *et al.*, 2001). The short cytoplasmic domain has been implicated in substrate binding. The accessory protein forms homotrimers and is known to form a stable complex in the inner membrane with the ABC transporter. In fact, the ABC transporter is unstable in the absence of the accessory protein (Thanabalu *et al.*, 1998) (Pimenta *et al.*, 1999). Crosslinking studies reveal that prior to secretion type I dependent proteins independently bind both the accessory protein and the ABC transporter resulting in a conformational change that brings this complex into tight association with the outer membrane translocon, TolC (Thanabalu *et al.*, 1998) (Hwang *et al.*, 1997). Electrophysiological studies indicate that the open configuration of the translocation tunnel formed by TolC is stabilized in the presence of accessory protein.

***TolC: the protein translocation tunnel***

TolC is a multifunctional protein which has a role in hemolysin secretion, colicin import and multidrug efflux that removes toxic substances like antibiotics from the bacterial cell (Sulavik *et al.*, 2001). In fact one of the most important and effective multidrug efflux pumps produced by *E. coli*, AcrB, requires TolC (Fralick, 1996). Specifics of the mechanism of type I secretion was greatly enhanced after the X-ray crystallographic structure of TolC was solved to 2.1 Å resolution. Evidence indicates that monomers of TolC come together to form a loosely packed 12-stranded α/β barrel (Koronakis *et al.*, 2000). The TolC cylinder is comprised of 3 domains designated as the 40Å long channel region, 100Å tunnel domain, and the equatorial region (Koronakis *et al.*, 2000). The β-barrel channel is embedded in the outer membrane; the α-helical tunnel, which is an extension of the channel domain, spans the periplasm and is surrounded at the middle by a band of both α- and β-helices. The β-barrel channel portion of the cylinder is vastly different from other porins in that three TolC monomers together form one contiguous barrel whereas other known outer membrane porins normally form one β-barrel per monomer (Koronakis *et al.*, 2004). Moreover the large periplasmic α-helical barrel domain of TolC is distinctive in that the trimer forms a tapered cylinder measuring 140Å in length and is wide enough to transverse the periplasmic space. The average accessible interior diameter of the TolC pore is 19.8Å across its entire length except at the end that faces the periplasm (3.9 Å). The TolC β-barrel portion of the channel-tunnel is always open to the external environment. By contrast, the tapered arrangement of the α-helical coiled-coils at the bottom of the tunnel domain effectively seals the periplasmic entrance against passage of large molecules out of the cell, and the entire barrel follows a left-handed superhelical twist (Koronakis *et al.*, 2000) (Andersen *et al.*, 2002a) (Koronakis *et al.*, 2004).

A circular network of intra- and intermolecular bonding between six conserved aspartate residues and other charged amino acid residues located at the bottom of the tunnel keep the coiled coil packing configuration intact pulling the three inner coils close together to create the closed conformation. Site-directed mutagenesis and electrophysiological studies implicated residues D371 and D 374 located at consecutive helical turns in each of the three TolC monomers as crucial for maintenance of the closed state (Andersen *et al.*, 2002a). This electronegative inner surface is highly conserved in all TolC homologues (Koronakis *et al.*, 2000). A conformational change would be required to open the pore (Koronakis *et al.*, 2000). Mutational analyses indicate that a slight twisting of the α-helices of the three inner coiled coils realigns them with the outer coiled coil so that the entrance widens enough to allow entry of large molecules (Koronakis *et al.*, 2000) (Andersen *et al.*, 2002a) (Andersen *et al.*, 2002b) (Eswaran *et al.*, 2003). In fact, locked-mutants (inner coiled coils are no longer flexible) still bind hemolysin substrate to the HlyB/HlyD translocase and recruit TolC. Yet hemolysin is not secreted in the locked mutants suggesting that untwisting of the inner coil is required to open the gateway for substrate secretion (Eswaran *et al.*, 2003).

## The type III secretion pathway

Secretion via the type III secretion system (T3SS) occurs, just like the T1SS, in one step and completely

bypasses the periplasm. The T3SS is one of the most complex schemes identified to date for translocation of toxins across the bacterial outer membrane. This is a mechanism used by bacteria to transport proteins from the bacterial cytosol and following contact with host cells deliver these toxic molecules directly into the eukaryotic cell. Gram-negative bacteria pathogenic for human, animals and plants possess and utilize T3SSs. Indeed it is through the use of specialized effector proteins secreted by T3SS that some highly pathogenic organisms establish their niche. For example, *Yersinia pestis* injects effectors that target macrophages and allow this bacterium to evade phagcocytosis and survive the primary immune response of the host while it grows unfettered in lymphoid tissue. The hallmarks of disease of frank pathogens like *Salmonella typhi*, *Shigella flexneri, Y. pestis*, and enteropathogenic *E. coli* (EPEC) and plant pathogens like *Pseudomonas syringae, Erwinia* spp., and *Xanthomonas campestris* can be traced to type III dependent-effector molecules. Even opportunistic *P. aeruginosa* exploits this secretion modality with devastating consequences to patients with preexisting conditions such as extensive burns and cystic fibrosis.

Three *Yersinia* species are pathogenic for humans and rodents. Like the infamous agent of bubonic plague, *Y. pestis, Y. pseudotuberculosis*, and *Y. enterocolitica* have a marked tropism for lymphatic tissue, and all three species are capable of evading the host primary immune response and avoiding phagocytosis (Hueck, 1998). The type III pathway was first discovered in *Yersinia* (Rosqvist *et al.*, 1994) and has since been studied extensively. Therefore the *Yersinia* system will be used as the model for discussion and comparisons will be made where appropriate. In the case of *Yersinia* spp. and *S. flexneri* the T3SS genes are clustered together on large virulence plasmids whereas the genes carried by *Salmonella* spp. and EPEC are on the chromosome grouped within pathogenicity islands (Hueck, 1998). The overall genetic organization of type III gene clusters is conserved only within the different subgroups (Hueck, 1998) and there is no standard nomenclature used to identify these loci across species. Specifically, *S. typhimurium* carry two T3SSs called SPI-1 and SPI-2, which contribute to pathogenesis at different stages of infection. The SPI-1 genes are identified as *inv, spa, prg*, and *org*, and the most recently discovered SPI-2 genes are called *ssa* for secretion system apparatus. *S. flexneri* genes are designated as *mxi* and *spa* (Hueck, 1998).

### *Genes of the Yersinia T3SS*

The Yop proteins are split into two groups (Hueck, 1998). The first group includes the secreted effector proteins: YopE, YopH, YopM, YopO/YpkA, YopP/YopJ, and YopT. The second group is composed of secreted proteins that form the translocation pore in the plasma membrane of the host cell to allow delivery of toxins. They include– YopB, YopD, and LcrV. The Yersinia secretion machinery is encoded by four loci: *virC* (*yscA–M*), *virG* (*yscW*), *virB* (*yscN–U*) and *virA* (*yopN, tyeA, yscV* [formerly *lcrD*]) and *lcrR*. The *yop, syc*, and *ysc* genes are located on the 70 kb plasmid called pYV.

Six Yop chaperones (Iriarte and Cornelis, 1999) are each known to stabilize and support secretion of specific Yop proteins. They are designated as SycE (i.e. serves YopE), SycH (Sory *et al.*, 1995), SycC (formerly LcrH and serves both YopD and YopB), and SycT (YopT) (Hueck, 1998). YscB behaves as a chaperone for YopN and is expressly required for its normal secretion (Jackson *et al.*, 1998). YopN is not an effector protein but is rather a secreted factor that controls the release of other Yop proteins. Together YopN, LcrG and Tye may form a stop valve that regulates the opening and closing of the translocation pore. YscY is the chaperone of YscX the function of which is still under investigation (Iriarte and Cornelis, 1999).

### *Events that precede protein translocation.*

Upon entering the host, the temperature shift from ambient to 37˚C results in a change in the bending of the large virulence plasmid DNA harbored by *Yersinia* so that the promoters of type III secretion genes are more accessible to the positive regulator, VirF (Lambert de *et al.*, 1992) (Rohde *et al.*, 1999). This results in the expression of both the *ysc* and *yop* genes. However, an increase in temperature is not sufficient to induce Yop secretion. Other environmental signals such as serum albumin, specific amino acids, and low calcium ion concentration may be required to trigger substrate translocation (Lee *et al.*, 2001). Historical evidence shows that Yersinia grown at 26˚C in rich medium with calcium then shifted to 37˚C with calcium ions depleted resulted in Yop secretion (Michiels *et al.*, 1990) (Straley *et al.*, 1993). The physiological significance of calcium ion depletion for triggering Yop translocation is not readily apparent because *Yersinia* remains extracellular during infection in a calcium rich environment (Cornelis, 2003). On the other hand strong experimental evidence indicates that it is intimate contact of bacterial cells with the target cell that activates translocation of proteins into the eukaryotic cell (Pettersson *et al.*, 1996).

### *Chaperone and Yop targeting to the type III secretion machine*

The synthesis of Yops is believed to be controlled by a feedback inhibition mechanism and to involve both

Yops and specific chaperones (Cornelis *et al.*, 1987) (Francis *et al.*, 2002). Although the mechanisms involved in the feedback process are not well understood experiments showed that the concentration of specific chaperones is directly linked to the rate of secretion of the Yop that they control (Darwin and Miller, 2001). The Yop proteins do not contain a classical signal peptide (Michiels *et al.*, 1990) but they do possess a recognizable sorting signal that allows the T3SS to discriminate between its substrates and other proteins (Hueck, 1998) (Cornelis and Van, 2000) (Galan, 2001). There are two different models proposed for targeting substrates to the type III machinery. One model suggests that ~20 residues contained at the amino terminus are important for translocation (Sory *et al.*, 1995) (Anderson and Schneewind, 1997). Whether or not this signal is defined by the polypeptide sequence or the mRNA structure has been a matter of some debate since there is some evidence that supports both conclusions (Lloyd *et al.*, 2001) (Anderson and Schneewind, 1997) (Anderson and Schneewind, 1999).

The second model relies on the presence of a group of specific chaperones that bind to distinct domains on the proteins to be secreted to maintain them in a state fit for translocation (Wattiau *et al.*, 1996). Inactivation of chaperones results in loss of secretion and unstable effector proteins that are poorly expressed. There is also some suggestion that binding of chaperones results in the formation of a three-dimensional sorting signal important for uptake and transport through the type III pathway (Birtalan *et al.*, 2002). Most chaperones are acidic cytosolic proteins between 15–20 kDa. This group of proteins does not share amino acid sequence homology although they all have a common putative amphiphilic alpha-helix at their carboxy-terminus (Wattiau *et al.*, 1994). Comparison of the crystal structures of effector/chaperone complexes, SycE-YopE and SptP-SicP, of *Yersinia* and *Salmonella* respectively, indicates remarkable stereochemical conservation (Birtalan *et al.*, 2002) (Stebbins and Galan, 2001). The similarity may be indicative of a generalized mode of substrate-chaperone interaction and recognition. Work by Stebbins and Galán provide evidence that chaperones prevent substrates from pre-mature folding prior to translocation (Stebbins and Galan, 2001). Conversely YopE bound to SycE was shown to be active which suggests that it was already folded prior to translocation (Birtalan *et al.*, 2002). This clearly illustrates that there is much work to be done to learn the exact mechanism and function of the chaperones and to discern whether or not molecules fold before they enter the translocon.

Several laboratories have focused on defining the domains of type III substrates crucial for translocation. For instance, the SopE catalytic domain mapped to residues 78-240 (Buchwald *et al.*, 2002) and the first ~100 amino acids of SopE was sufficient to target a heterologous protein for secretion through the type III machinery (Evans *et al.*, 2003). Removal of the chaperone binding domain of both SptP and SopE made them incompetent for secretion by their specific type III systems (Lee and Galan, 2004) and exposed a cryptic flagella-uptake signal that shunted both SptP and SopE into the flagella export pathway. Thus the authors concluded that chaperones may endow their cognate substrates with type III secretion specificity (Lee and Galan, 2004).

### *Supramolecular protein secretion apparatus*

Several genes that encode components of the basal body assembly of flagellum share homology with those of the type III machinery which indicates that the two systems have a common evolutionary origin (Hueck, 1998). The type III secretion machine is highly conserved among the pathogens that possess them. Indeed electronmicrographs of the supramolecular structure of type III secretion machineries of *S. flexneri* and *S. typhimurium* reveal remarkable similarities between the two translocons (Kubori *et al.*, 1998) (Blocker *et al.*, 2001). Furthermore electron microscopy of the protein conduits of *S. flexneri*, *S. typhimurium*, and *Y. entercolitica* indicate that these three organisms fashion similar needle-like hydrophobic projections that cross or may pierce the eukaryotic plasma membrane (Blocker *et al.*, 2001) (Kubori *et al.*, 2000) (Hoiczyk and Blobel, 2001). Further evidence suggests that the secretion machines are interchangeable. For instance the *Y. pseudotuberculosis* type III apparatus recognized and translocated *P. aeruginosa* exoenzyme S toxin (Errington *et al.*, 2003), a type III substrate, into HeLa cells (Frithz-Lindsten *et al.*, 1997).

Electron microscopy of *S. typhimurium* revealed that the type III secretion structure has a base which begins at the bacterial inner membrane and extends to the outer membrane where it connects with a needle-like projection that protrudes from the bacterial surface. Complexes extracted from the membrane have a cylindrical symmetry. Moreover, the base structure contains two upper and two lower rings which anchor the needle-like projection to the cell envelope. The needle consists of a stiff straight tube, 80 nm long and 13 nm wide, and appears hollow (Kubori *et al.*, 1998). In addition to the needle complex all T3SSs have a group of highly conserved integral membrane proteins located at the base of the needle complex to facilitate passage of the secreted proteins through the bacterial inner membrane (Cornelis and Van, 2000).

Like the basal body assembly component of flagella, there is an ATPase associated with the needle complex

of the type III apparatus thought to drive secreted proteins through the machinery (Hueck, 1998) (Cornelis and Van, 2000). The catalytic β subunit of the flagella ATPase and the type III ATPase display a high level of amino acid sequence similarity. Recently type III-associated ATPase was found to be crucial for functionality of the type III machinery (Akeda and Galan, 2004). Three distinct domains of the protein were identified. The N-terminal end of the ATPase participates in membrane association, while the central portion of the protein is important for self-association. Finally the C-terminal domain contains the catalytic ATPase site.

The length and width of the T3SS needle complex varies among bacteria that produce it. For example in EPEC the needle extends between 75-260 nm with a diameter of 10-12 nm (Daniell *et al.*, 2001). In *Yersinia* the YscP protein appears to act as a molecular ruler to control the length of the needle that consist of polymerized YscF (Journet *et al.*, 2003). Amazingly, the length of the needle is dependent on the number of amino acid residues present within the regulatory protein YscP. It is believed that YscP positions itself by anchoring to the basal body with its other end attached to the growing tip of the needle and when the needle reaches the length of the regulator protein polymerization of YscF stops.

### Asymmetric localization of secretory machineries

There are many examples of individual proteins and large supramolecular complexes restricted to discrete locations within the cell. For instance, chemoreceptors of *Caulobacter* are distributed to the cell pole while proteins involved in cell division are restricted to the septum (Alley *et al.*, 1992) (Buddelmeijer and Beckwith, 2002) (Errington *et al.*, 2003). Recently it was revealed that the Sec machinery produced by *Streptococcus pyogenes* localize to discrete foci distal from the new and old poles (Rosch and Caparon, 2004). Similarly the type II apparatus of *Vibrio cholerae* is localized to the old pole of the cell (Scott *et al.*, 2001). The mechanism of restrictive positioning of the type II apparatus is unknown but preliminary data indicate that the M protein (EpsM) may play an important role. EpsM is distributed to the pole when expressed in *E. coli* in the absence of other type II proteins, unlike EpsL which disperses throughout the cell membrane. Yet, co-expression of EpsM with EpsL results in polar localization of EpsL (Scott *et al.*, 2001). Therefore EpsM may serve as nucleation factor for polar assembly of the *V. cholerae* type II secretion complex or a subcomplex thereof. Localization of the type II apparatus at the pole of the cell may be an advantageous method of concentrating the relatively low number of secretion complexes as a means to deliver secreted material exactly where it is needed without waste or dilution.

The coupling protein of the type IV secretion machinery produced by *A. tumefaciens* was also determined to localize at the pole of the cell (Kumar and Das, 2002). This data supports an earlier observation that *Agrobacterium* attaches to the plant cell in a polar manner (Llosa and O'Callaghan, 2004). It is not known whether other secretion machineries such as type I and III are maintained at the pole or localized to some discrete domain of the cell envelope but theoretically, directed secretion may offer the same possible survival advantage to other species of bacteria as well. For example the type III secretion apparatus has only been viewed following *in vitro* induction of secretion genes. Under these conditions the needle-like projections that form the type III apparatus appear to be indiscriminately placed along the periphery of the cell membrane. This observation begs the question of whether or not these machines would aggregate to one discrete site when legitimate induction occurs.

## CLOSING REMARKS

Bacterial protein secretion is an exciting and expanding field. Scrutiny of the current systems reveals basic repetitive themes used to translocate proteins from the cytoplasm and across lipid barriers. Pathogenic bacteria have devised systems to deliver poisons directly to their host and in some cases in expeditious and thrifty ways. A perfect example is autotransporters that exploit the Sec pathway and achieve translocation across the outer membrane without a multimolecular secretion apparatus. Yet equally fascinating is the type III system which has usurped the perfected design of the basal body assembly of flagella and turned it with a few important changes into an efficient delivery machine. Let's not forget the asymmetrically positioned type II and type IV systems that harbor ancestral genes to create vessels that span the cell envelope to carry effectors to the host. It is possible that additional and perhaps mysterious secretion systems are yet to be discovered. As each new and old system is studied, weaknesses are revealed which may become therapeutic targets for the new generation of antibiotic drugs.

CHAPTER

# 6

# Toxin receptors

*Yasuhiko Horiguchi and Eisuke Mekada*

## GENERAL NOTES ON BACTERIAL TOXIN RECEPTORS

The initial step in the intoxication process by bacterial toxins involves binding to target cells. This is made possible by the presence of specific receptors on the cell surface. Although the molecular nature of the receptors varies depending on the toxins involved, they all bind the toxins, then either transduce particular signals into the cell cytoplasm or are involved in the internalization of the toxins. Cell sensitivity to the toxin is largely determined by the existence of the receptors; therefore these latter provide a molecular basis for the toxins' target cell specificities. As a result, in order to understand toxin actions, molecular analysis of each toxin receptor becomes essential. However, to date, regardless of their substantial roles, only few receptors have been definitively identified (Table 6.1). This is probably because only a small number of receptors are present on the cell surface, and either identification of a particular toxin receptor requires laborious procedures or applicable methods are not known.

For a cellular substance to be accepted as a bacterial toxin receptor, two criteria must be at least satisfied. First, it must be demonstrated that the substance has a property of binding directly and specifically to the toxin. For this purpose, quantitative measurements of the binding must be made. For example, a direct binding assay with the toxin labeled with a radioisotopic or fluorescent probe can be done, and is more preferable than qualitative methods such as combinations of immunoprecipitation and immunoblotting. Indeed, the use of labeled toxins provides much more information about the binding. The Kd or Ka values obtained from the cell-free binding assay might be useful to compare toxin binding affinities to the toxin-susceptible cells. Whether the substance-toxin binding is saturable or unsaturable, this is determined by the direct assay, but it would also be helpful to distinguish the real receptor from the substance that non-specifically binds the toxin. The second criteria addresses cell sensitivity to the toxin. This must depend on the expression level of the substance. For instance, you might have to demonstrate that transfection with the substance cDNA confers toxin sensitivity to the parental toxin-resistant cells, if the putative receptor is a protein.

## HOW DO YOU IDENTIFY BACTERIAL TOXIN RECEPTORS?

Table 6.1 shows a list of bacterial toxin receptors identified to date. Although the process of identification and confirmation of bacterial toxin receptors is far from being simple and contains many episodes for each toxin, we will simply review here critical methods involved in receptor identification. Later on, we particularly provide a detailed description of some toxin receptors.

The cholera toxin receptor was suggested to be GM1 ganglioside in the early 1970s (van Heyningen *et al.*, 1971; Cuatrecasas, 1973; Holmgren, 1973). Attempts to search for the cholera toxin receptor started with findings that the toxins were inactivated by tissue extracts or cell membrane fractions, indicating that these preparations might contain a substance responsible for the

**TABLE 6.1** Bacterial toxin receptors

| Toxin | Receptor | Key method or episode | Key reference |
|---|---|---|---|
| Cholera toxin | GM1 ganglioside | Inhibition of toxic action | van Heyningen *et al.*(1971); Cuatrecasas (1973); Holmgren (1973) |
| Shiga toxin | Gb3 globoside | Inhibition of toxic action | Jacewicz *et al.* (1986) |
| Diphtheria toxin | HB-EGF / 14.5 kDa protein | Expression cloning / Purification | Naglich *et al.* (1992) / Mekada *et al.* (1988) |
| *Pseudomonas* exotoxin A | LDL receptor-related protein | Affinity purification | Thompson *et al.* (1991); Kounnas *et al.* (1992) |
| *E. coli* heat-stable toxin I(a) | Guanylyl cyclase C | PCR with guanylyl cyclase primers | Schulz *et al.* (1990) |
| *Botulinum* toxin type B | Synaptotagmin I and II | Purification | Nishiki *et al.* (1994); Dong *et al.* (2003) |
| Aerolysin | GPI-anchored proteins | Ligand overlay | Cowell *et al.* (1997); Nelson *et al.* (1997) |
| *Clostridium perfringens* enterotoxin | CPE-R / claudin | Expression cloning | Katahira *et al.* (1997a) |
| *Helicobacter pylori* VacA | RPTP α and β | Immunoprecipitation and purification | Yahiro *et al.* (1999); Yahiro *et al.* (2003) |
| *V. cholerae* El Tor hemolysin | Glycophorin B | Preparation of monoclonal antibody to erythrocyte membranes | Zhang *et al.* (1999) |
| Anthrax toxin | TEM8, CMG2 | Expression cloning | Bradley *et al.* (2001) |
| *Bordetella* adenylate cyclase toxin | CD11b / CD18 | Combinations of binding assays | Guermonprez *et al.* (2001) |
| *E. coli* cytotoxic necrotizing factor | Laminin receptor precursor | Yeast two-hybrid system | Chung *et al.* (2003) |

specific binding of the toxins. GM1 ganglioside was then found to inhibit the binding of cholera toxin to the cell membrane and to neutralize toxic action. Subsequently, many studies presented increasing supporting evidence for GM1 ganglioside as the cholera toxin receptor (Hollenberg *et al.*, 1974; Holmgren *et al.*, 1975; Moss *et al.*, 1976). Finally, crystallography of the cholera toxin/GM1 ganglioside complex was available in the 1990s, providing the molecular basis for the toxin-ganglioside interactions (Merritt *et al.*, 1994; Merritt *et al.*, 1998). Gb3 globoside, the Shiga toxin receptor, was also identified in a similar way (Keusch and Jacewicz, 1977; Jacewicz *et al.*, 1986; Acheson and Keusch, 1999). Studies of these toxin receptors indicate that searching for the inhibitory substance to the toxic effect from toxin-sensitive cells is an effective way to identify the toxin receptors. However, this is not sufficient to prove for the real receptor that a cellular substance merely inhibits toxic effects as mentioned above, and in some cases it may meet with a pseudo receptor as exemplified by the nucleotide-like molecules for diphtheria toxin receptor (see page 112 in this chapter).

Protein purification of toxin-binding substances extracted from detergent-solubilized membrane fractions using chromatography, combined with a cell-free binding assay using labeled bacterial toxins, provide a classical but reliable method to identify toxin receptors. Diphtheria toxin receptor and synaptotagmins for botulinum toxin type B were successfully purified from Vero cells and synaptosomal membranes, respectively (Mekada *et al.*, 1988; Mekada *et al.*, 1991; Nishiki *et al.*, 1993, Nishiki *et al.*, 1994). In order to use this method, the following conditions must be fulfilled: (i) binding affinity between toxins and receptors must be fairly high (Kd = $10^{-10} \sim 2 \times 10^{-9}$ M), (ii) rapid and quantitative measurements for toxin-receptor binding using solubilized membrane fractions must be applied, (iii) reasonable amounts of starting material for purification must be available. Recent progress in mass spectrometry (MS) would be quite valuable to identify the protein from partially purified fractions.

The use of expression cloning techniques would provide the most powerful way to identify toxin receptors and their cDNA cloning. In this case, a cDNA library produced by transcripts from toxin-susceptible cells is generally transfected to toxin-resistant (receptor-negative) recipient cells and cells that become toxin-sensitive (or receptor-positive cells by the binding assay with labeled toxin) are picked up. Following screening for receptor-positive cells, the cDNA encoding the receptor is isolated. Screening methods for receptor-positive clones are the key to good results. A replica assay that isolated toxin-sensitive clones was used for heparin-binding EGF-like growth factor (HB-EGF) just like in the case of the diphtheria toxin receptor (Naglich *et al.*, 1992). HB-EGF was later found to be identical to the 14.5 kDa protein of diphtheria toxin receptor that had been purified as mentioned above. Flow cytometry, which seems to be the currently most powerful method for receptor identification, was used

for anthrax toxin receptor (ATR/TEM8) and *Clostridium perfringens* enterotoxin receptor (CPE-R/claudin4) (Katahira *et al*., 1997a; Bradley *et al*., 2001).

Receptor-like protein-tyrosine phosphatases (RPTPs) for *Helicobacter pylori* VacA toxin were identified from sensitive cells by immunoprecipitation and isolated using affinity chromatography (Yahiro *et al*., 1997; Yahiro *et al*., 1999). In this case, the authors found that exposure of VacA to alkaline or acidic conditions increased its binding to the appropriate target cells, which later facilitated the isolation of the receptors.

The receptor for cytotoxic necrotizing factor 1 of *Escherichia coli* was identified using the yeast two-hybrid system. This system is frequently used for DNA cloning (Chung *et al*., 2003), although it may not be generally applicable to membrane proteins like toxin receptors.

*E. coli* heat-stable enterotoxin I (STI) receptor was identified by PCR screening. Since the 1970s, STI has been known to activate guanylate cyclase (Field *et al*., 1978; Hughes *et al*., 1978; Waldman *et al*., 1986). Although most mammalian tissues contain both soluble and particulate forms of guanylate cyclase, the enzyme is predominantly particulate in intestinal mucosa. Thus, particulate guanylate cyclases were thought to be the ST receptor candidates, whilst membrane-type guanylate cyclases known at earlier times were negated as candidates. In 1990, Schulz *et al*. looked for new clones of guanylate cyclases using PCR with degenerate oligonucleotide primers based on conserved sequences in both soluble and plasma membrane forms of the enzyme and template cDNA prepared from small intestinal mucosa, and finally they identified guanylate cyclase C (GC-C) as a STI receptor.

## EXAMPLES OF TOXIN RECEPTORS

### Diphtheria toxin receptor

#### *Diphtheria toxin*

Diphtheria toxin is produced as a single polypeptide chain of 58,348 Da with two disulfide bridges (Collier and Kandel, 1971; Gill and Pappenheimer, 1971). The native toxin is easily hydrolyzed by splitting a peptide bond between one of the disulfide bridges by mild treatment with trypsin-like proteases or furin (Tsuneoka *et al*., 1993) to yield a nicked toxin. On reduction of the disulfide bridges, the nicked toxin is split into two large peptides, fragment A (Mr = 21,167 Da) and fragment B (Mr = 37,199 Da). The toxicity of diphtheria toxin is due to the enzymatic activity of fragment A, catalyzing the transfer of an ADP-ribosyl moiety from NAD to elongation factor 2 (EF-2) (Honjo *et al*., 1968). EF-2 is a GTP-binding protein involved in protein synthesis in eukaryotic cells. ADP-ribosylated EF-2 is unable to mediate polypeptide chain elongation, resulting in inhibition of protein synthesis. Since fragment A alone is unable to penetrate the cell membrane, it cannot reach the cytosol of intact cells without the involvement of fragment B. Fragment B binds to the specific receptor of toxin-susceptible cell membranes (Uchida *et al*., 1972) and facilitates translocation of fragment A into the cytosol.

#### *Cell sensitivity to diphtheria toxin*

Diphtheria toxin is highly toxic to most animals, including rabbits, guinea pigs, and monkeys, as well as humans. The only mammals known to be resistant to the toxin are rats and mice. Cells derived from sensitive species are sensitive to the cytotoxic actions of diphtheria toxin, while cells from toxin-resistant species are quite resistant to its actions (Middlebrook and Dorland, 1977). The resistance of cells to diphtheria toxin is thought to be generally due to the binding and entry process (Yamaizumi *et al*., 1978). Although a number of cellular factors could influence toxin activity, cell sensitivity to diphtheria toxin is primarily determined by the presence of functional diphtheria toxin receptors (Umata *et al*., 2000).

#### *Identification of diphtheria toxin receptor protein*

The existence of a specific receptor for diphtheria toxin on the cell surface was suggested by competition experiments using CRM197, a non-toxic mutant of diphtheria toxin (Itelson and Gill, 1973). Subsequently, binding abilities of $^{125}$I-labeled diphtheria toxin to cultured cells were demonstrated (Middlebrook *et al*., 1978). However, it took about 10 years for the diphtheria toxin receptor to be identified at the protein level from detergent-treated cell fractions (Mekada *et al*., 1988). One difficulty that impeded the identification and purification of the specific receptor for diphtheria toxin from cell fractions was due to the existence of another diphtheria toxin-binding substance present in the membrane fractions (Mekada *et al*., 1988). This non-receptor diphtheria toxin-binding molecule, which contains a ribonucleotide structure, inhibited the binding of the toxin to its specific receptor. Therefore, this non-receptor diphtheria toxin-binding substance was initially mistaken for the real receptor.

A solution to the problem was obtained from binding assays with CRM197. CRM197 differs from the wild-type toxin in one amino acid residue of fragment A (Giannini *et al*., 1984). CRM197 does not bind nucleotides, the non-receptor diphtheria toxin-binding substances (Mekada *et al*., 1988) but binds to diphtheria

toxin receptor with an affinity similar to or greater than that of diphtheria toxin (Mekada and Uchida, 1985). A binding assay with $^{125}$I-labeled CRM197 enabled to demonstrate the specific binding to the diphtheria toxin receptor in a membrane preparation from Vero cells (Mekada *et al*., 1988) with a Kd value of 2.4 nM, which was quite similar to that obtained with intact Vero cells. Using a combination of several chromatographic steps, the diphtheria toxin receptor was purified in the presence of detergents (Mekada *et al*., 1991). The purified receptor essentially showed a single band of 14.5 kDa by SDS-PAGE. Evidence that the 14.5 kDa protein was the receptor, or at least a part of the receptor, was obtained by immunoprecipitation with diphtheria toxin and anti-diphtheria toxin antibody from partially purified receptor fractions or by blotting using $^{125}$I-CRM197 as a probe (Mekada *et al*., 1988). Although the 14.5 kDa protein was the major form isolated from Vero cell membrane lysates, other sizes of diphtheria toxin-binding molecules (ac 20 and 17 kDa) were detected in different fractions using CM-Sepharose ion-exchange chromatography (Mekada *et al*., 1991). The 14.5 kDa protein and the 17 and 20 kDa proteins were suggested to derive from a single precursor protein, as discussed below.

### *Cloning of the diphtheria toxin receptor gene*

cDNA encoding the diphtheria toxin receptor was isolated as a diphtheria toxin sensitivity gene by expression cloning (Naglich *et al*., 1992). Mouse L cells were transfected with a cDNA library obtained from monkey kidney (Vero) cells. Transfectants that were sensitive to diphtheria toxin were isolated using a replica plate assay (Naglich and Eidels, 1990). cDNA (pDTS) was recovered from the diphtheria toxin–sensitive transfectants. Mouse L cells transfected with this cDNA became sensitive to diphtheria toxin and displayed diphtheria toxin–binding molecules on the cell surface that had the characteristics of the diphtheria toxin receptor (Naglich *et al*., 1992). The predicted protein product of pDTS was 185 amino acids, showed a quite basic isoelectric point, and had characteristics of an integral membrane protein. These characteristics were consistent with the characteristics of the diphtheria toxin receptor protein isolated by chromatography (Mekada *et al*., 1991).

pDTS is identical to a known heparin-binding growth factor, HB-EGF (Naglich *et al*., 1992), initially identified by Higashiyama (Higashiyama *et al*., 1991). Further evidence that the product of pDTS was the diphtheria toxin receptor has been obtained from direct binding experiments with diphtheria toxin and a recombinant human HB-EGF (Iwamoto *et al*., 1994). $^{125}$I-diphtheria toxin bound to immobilized recombinant HB-EGF with an affinity similar to that of intact Vero cells (Kd of about 1 nM). These results clearly show that the diphtheria toxin receptor is HB-EGF.

### *Structure and function of the diphtheria toxin receptor*

Diphtheria toxin receptor/HB-EGF cDNA encodes a protein of 208 amino acids (Higashiyama *et al*., 1991; Naglich *et al*., 1992). This protein consists of a characteristic signal sequence of 23 amino acid residues, a presumed extracellular domain of 136 residues (24–159), a putative transmembrane domain of 25 residues (160–184), and a carboxyl terminal cytoplasmic domain of 24 residues (185–208). The mature protein, after cleavage of the signal peptide, seems to be comprised of 185 amino acids with a calculated molecular weight of 20,652 Da. The extracellular domain includes two characteristic features: (i) an EGF-like domain with six cysteine residues with highly conserved spacing and (ii) a heparin-binding domain with a highly basic stretch of amino acid residues upstream from the EGF-like domain.

Because HB-EGF is expressed in multiple tissues, i.e., in rats, mice, and humans, with a very similar tissue distribution (Abraham *et al*., 1993), the question arises as to why cells from rats and mice are resistant to diphtheria toxin. Transfection of human diphtheria toxin receptor/HB-EGF cDNA into mouse L cells confers sensitivity to diphtheria toxin, but transfection of mouse HB-EGF cDNA does not (Mitamura *et al*., 1995). These results indicate that mouse HB-EGF does not serve as a functional receptor for diphtheria toxin because of amino acid substitution. Transfection studies of a series of human/mouse HB-EGF chimeras indicated that the EGF-like domain of the human HB-EGF is essential for diphtheria toxin binding and diphtheria toxin sensitivity (Mitamura *et al*., 1995).

Results from human/mouse HB-EGF chimeras provide information on specific important amino acids for diphtheria toxin-diphtheria toxin receptor interactions. There are 10 amino acid differences between the EGF-like domain of human diphtheria toxin receptor/HB-EGF and that of mouse HB-EGF. Transfection experiments of human/mouse HB-EGF chimeras into mouse L cells revealed that the biggest effects were observed with E141H, and the second biggest effects were with F115Y and L127F (Mitamura *et al*., 1997). A computer model of the tertiary structure of the EGF-like domain of human diphtheria toxin receptor/HB-EGF, based on the tertiary structure of TGFα, predicted that three amino acid residues critical for diphtheria toxin-binding activity, Phe115, Leu127, and Glu141, are all located on the same face of the EGF-like domain, suggesting that this face of the diphtheria toxin receptor/proHB-EGF interacts with the receptor-binding

domain of diphtheria toxin. The crystal structure of diphtheria toxin-HB-EGF (Louie *et al*., 1997), which is quite consistent with the above model, provided a more defined description of its complex structure.

### *Molecules associated with the diphtheria toxin receptor and modulating receptor function*

*DRAP27/CD9*

DRAP27 (*D*iphtheria toxin *R*eceptor-*A*ssociated *P*rotein 27) was originally identified as the antigen of a monoclonal antibody that inhibits the binding of diphtheria toxin to intact Vero cells. Cloning of DRAP27 cDNA revealed that DRAP27 has 228 amino acids containing four putative transmembrane domains and that it is identical to the CD9 antigen (Mitamura *et al*., 1992). The role of DRAP27/CD9 in diphtheria toxin binding and diphtheria toxin sensitivity has been studied by transfecting DRAP27 cDNA into cells. DRAP27/CD9 alone had no particular function for enhancing the sensitivity to diphtheria toxin. However, when L cells were transfected with both DRAP27/CD9 and diphtheria toxin receptor cDNA, transfectants expressing both diphtheria toxin receptor and DRAP27 had a 15 times greater cell surface diphtheria toxin receptor number and were 20 times more sensitive to diphtheria toxin than stable L-cell transfectants expressing diphtheria toxin receptor alone, though the cell lines contained similar levels of diphtheria toxin receptor mRNA. Thus, it is clear that DRAP27/CD9 upregulates diphtheria toxin receptor number and diphtheria toxin sensitivity through protein-protein interaction, although the upregulation mechanism is still elusive.

*Heparin-like molecules*

Diphtheria toxin receptor/proHB-EGF shows high affinity to heparin. It associates with heparan sulfate proteoglycan at the heparin-binding domain (HBD). Diphtheria toxin receptor binds diphtheria toxin at the EGF-like domain, and this domain is sufficient to bind diphtheria toxin, while binding of heparin-like molecules to HBD is necessary for full binding activity of diphtheria toxin receptor to diphtheria toxin when assayed in intact cells (Shishido *et al*., 1995). ProHB-EGF mutants lacking HBD have higher affinity for diphtheria toxin than that of wild type proHB-EGF in the absence of heparin-like molecules. By adding heparin or heparan sulfate, diphtheria toxin binding was greatly increased in wild type proHB-EGF, but didn't increase a lot in proHB-EGF mutants lacking HBD (Takazaki *et al*., 2004). These results indicate that HBD is not necessary for binding to diphtheria toxin, but rather plays a role as a negative regulator for the binding of diphtheria toxin to the EGF-like domain of proHB-EGF. Heparin or heparan sulfate proteoglycans would cancel or neutralize the negative effect of HBD through binding to the HBD domain.

### *Physiological role of the diphtheria toxin receptor*

Diphtheria toxin receptor, i.e., HB-EGF, is cleaved upstream of the transmembrane domain by a cell-associated protease, and the extracellular domain is released into the medium as a soluble growth factor (Goishi *et al*., 1995). The secreted HB-EGF protein is also processed at multiple sites at the N-terminal portion (Nakagawa *et al*., 1996). Thus, multiple forms of HB-EGF with different molecular sizes are secreted. HB-EGF belongs to the EGF family of growth factors (Carpenter and Cohen, 1979). It binds to and gives a mitogenic signal through the EGF receptor and ErbB-4 (Elenius *et al*., 1997). The soluble form of HB-EGF is a potent mitogen and chemoattractant for a number of cell types, including vascular smooth muscle cells, fibroblasts, and keratinocytes (Higashiyama *et al*., 1993; Raab and Klagsbrun, 1997). HB-EGF has been implicated in a number of physiological and pathological processes, which include wound healing (Tokumaru *et al*., 2000), cardiac hypertrophy (Asakura *et al*., 2002), smooth muscle cell hyperplasia (Miyagawa *et al*., 1995), kidney collecting duct morphogenesis (Takemura *et al*., 2001), blastocyst implantation (Das *et al*., 1994), pulmonary hypertension (Lemjabbar and Basbaum, 2002), and oncogenic transformation (Fu *et al*., 1999). Recent studies on HB-EGF null mice ($HB^{del/del}$) revealed that HB-EGF is essential for normal heart function and $HB^{del/del}$ developed severe heart failure with grossly enlarged ventricular chambers and enlarged cardiac valves (Iwamoto *et al*., 2003).

Processing of the juxtamembrane domain of HB-EGF, so-called ectodomain shedding, is quite important for the function of HB-EGF (Yamazaki *et al*., 2003), and it is regulated by various extracellular stimuli and intracellular signaling (Izumi *et al*., 1998; Umata *et al*., 2001; Takenobu *et al*., 2003). Recent studies indicate that HB-EGF, especially in its soluble form, plays pivotal roles in tumor growth of cancer cells (Miyamoto *et al*., 2004). Thus, HB-EGF would be a potential target for cancer therapy.

## *Clostridium perfringens* enterotoxin (CPE) receptor

### Clostridium perfringens *enterotoxin*

CPE is a member of the pore-forming toxins, which destroy mammalian target cells by perturbing selective permeability of the plasma membrane. CPE is a single chain polypeptide that consists of 319 amino acids,

which is functionally separable into an N-terminal domain involved in pore formation and a C-terminal domain responsible for binding to target cells (Horiguchi *et al*., 1987; Hanna *et al*., 1991; Kokai-Kun *et al*., 1999). It is considered that after binding to target cells, large protein complexes comprised of CPE and cellular substances form in the cell membrane, leading to cell destruction.

### *CPE receptor*

The toxin does not affect erythrocytes, but a limited number of nucleated cell types to which CPE specifically binds (McDonel and McClane, 1979; Horiguchi *et al*., 1985), implying that the toxin utilizes a specific receptor, which is not ubiquitous in mammalian cells. Early studies demonstrated that pretreatment of rabbit intestinal cells (or their membranes) with proteases but not with neuraminidase, reduced or abolished CPE binding, indicating that the receptor has a protein moiety (McDonel, 1980; Wnek and McClane, 1986). Katahira *et al*. (1997), using expression cloning techniques, first reported the identification of the receptor (Katahira *et al*., 1997a). A cDNA encoding a 22 kDa protein was cloned from a cDNA library of CPE-sensitive Vero cells by screening transfected cells that bound to the C-terminal binding domain of the toxin. The nucleotide sequence of this gene revealed that the 22 kDa protein (designated CPE-R) consisting of 209 amino acids is highly hydrophobic, has four putative transmembrane domains, and shows homologies with the rat androgen withdrawal apoptosis protein RVP1 and the mouse oligodendrocyte specific protein (OSP). The CPE-R gene was found to be expressed only in the CPE-sensitive Vero, Hep3B, and Intestine 407 cells, but not in the CPE-resistant L929, K562, and JY cells. Moreover, transfection with the CPE-R gene conferred sensitivity to CPE-resistant L929 cells. These results clearly indicated that CPE-R was the functional receptor for CPE, although its physiological role remained unknown at that time. RVP1 was also evidenced to serve as another receptor for CPE (Katahira *et al*., 1997b).

### *Physiological function of CPE receptor*

Shortly after Katahira *et al*.'s report, it was found that CPE-R and its related genes constitute a novel multigene family, of which members are integral components of tight-junction strands at intercellular borders. Furuse *et al*. (1998) first identified two distinct components of tight junctions, which show similarities to CPE-R and RVP1, and designated them claudin-1 and claudin-2 (Furuse *et al*., 1998). Subsequently, database searches revealed the knowledge of six claudin-like proteins, including CPE-R and RVP1, and now, 24 members of the claudin family are known (Morita *et al*., 1999a; Morita *et al*., 1999b; Tsukita *et al*., 2001). Of these members, RVP1 and CPE-R were designated as claudin-3 and claudin-4, respectively. Furthermore, claudin-6, -7, -8, 14 were found to function as CPE-receptors with varied binding affinities (Table 6.2) (Fujita *et al*., 2000).

### *Structure and function*

Claudins commonly have four transmembrane domains and two extracellular loops with intracellular N- and C-termini. CPE recognizes the second extracellular loop of claudin-3 and probably other sensitive claudins (Fujita *et al*., 2000). However, neither the consensus sequence nor steric structure recognized by CPE has been defined in the second extracellular loop, which comprises fewer than 20 amino acids. On the other hand, the binding domain of CPE is limited to the C-terminal 30 amino acids (Hanna *et al*., 1991). In fact, the C-terminal fragment of CPE (C-CPE) bound to claudins on cells without any destructive effects with a Ka value equivalent to that of the full-length CPE (Horiguchi *et al*., 1987; Katahira *et al*., 1997a). Furthermore, it was found that C-CPE reversibly reduced the tight junction barrier of the epithelial layer made by MDCK I cells and degraded the network of tight junction strands, removing claudin-4/CPE-R from tight junctions (Sonoda *et al*., 1999). As a result, these observations provided conclusive evidence that claudins are, both structurally and functionally, involved in the construction of tight junctions.

### *Receptor-associating molecule*

Besides claudins, early attempts in the 1980s using affinity chromatography and immunoprecipitation methods demonstrated that 50–60 kDa and 70 kDa proteins could be isolated from CPE sensitive but not resistant cells (Wnek and McClane, 1983; Sugii and Horiguchi, 1988). These proteins were considered to be associated with the complex that forms after CPE binds to target cells (Wieckowski *et al*., 1994). The 70 kDa protein was identified as occludin, which is also an integral membrane protein localized at tight junctions (Singh *et al*., 2000). Occludin, however, endowed the CPE-resistant Rat-1/R12 fibroblasts with neither the sensitivity nor the ability to bind CPE.

## Botulinum neurotoxin receptor

### *Botulinum neurotoxin*

*Clostridium botulinum* neurotoxins (BoNTs) are known to cause muscle paralysis by blocking neurotransmitter release from nerve terminals at neuromuscular junctions. They can be classified into seven types from A to

**TABLE 6.2** Characteristic features and binding ability to CPE of claudins

| Claudin[a] | Distinctive characteristics[b] | Affinity to CPE (Ka)[c] |
|---|---|---|
| 1 | Present in high-resistance epithelia. | -[d] |
| 2 | Present in leaky epithelia. | - |
| 3 | Also known as RVP1. Present in the tighter segments of nephrons. | $4.6 \times 10^7\ M^{-1}$ |
| 4 | Present in the tighter segments of nephrons. | $7.9 \times 10^7\ M^{-1}$ |
| 5 | Alternative name for TMVCF, as it is frequently deleted in Velo cardio facial syndrome. Constitutes TJ strands in endothelial cells. | - |
| 6 | Present in embryonic epithelia. | $9.7 \times 10^7\ M^{-1}$ |
| 7 | Down-regulated in head and neck squamous cell carcinomas. | $8.8 \times 10^7\ M^{-1}$ |
| 8 | Present in the tighter segments of nephrons. | $1.0 \times 10^6\ M^{-1}$ |
| 10 | Not well characterized. | - |
| 11 | Also named OSP. Present in oligodendrocytes and Sertoli cells. | ND[e] |
| 14 | Expressed in the sensory epithelium of the organ of Corti. | $3.6 \times 10^6\ M^{-1}$ |
| 15 | Present in endothelial cells. | ND |
| 16 | Also known as paracelin-1. Critical for $Mg^{2+}$ and $Ca^{2+}$ resorption in the human thick ascending limb of Henle. | ND |
| 18 | Expressed in lung and stomach. | ND |

[a]Claudins 9, 12, 13, 17 and 19–24 still remain to be characterized and it is still unknown if they are CPE receptors.

[e]ND; Not determined

G on the basis of antigenic differences. All types of toxins are single chain polypeptides of ~150 kDa, which consist of an N-terminal light chain (approximately 50 kDa) and a C-terminal heavy chain (approximately 100 kDa). The heavy chain can be further segregated into an N-terminal ($H_N$) and a C-terminal ($H_C$). BoNTs bind to presynaptic membranes via the $H_C$ domain, and the light chain is intracellularly translocated and inhibits neurotransmitter release through its endopeptidase activities, which cleave the members of the synapse-specific proteins called SNAREs.

### *Identification of the receptor*

BoNTs specifically bind to cholinergic nerve terminals. Polysialogangliosides such as GD1a and GT1b, which are ubiquitously present in nerve tissues, were analyzed as receptor candidates, because they bound and inactivated BoNTs (Simpson and Rapport, 1971; Kitamura *et al*., 1979). However, the direct interaction between the toxin and the gangliosides hardly occurred under physiological conditions (Kozaki *et al*., 1984). Binding studies revealed that the toxin-binding molecules on the pre-synaptic membranes are different among toxin types (Kozaki, 1979; Black and Dolly, 1986), whereas ganglioside GT1b equally inactivates many types of BoNTs (Kozaki *et al*., 1984). Thus, whether the gangliosides are true receptors had remained uncertain.

Synaptotagmin, a synaptic vesicle membrane protein, was first isolated as a potential receptor from rat brain synaptosomes (Nishiki *et al*., 1993; Nishiki *et al*., 1994). BoNT type B bound to synaptotagmin isoforms I and II in the presence of gangliosides GT1b and GD1a with dissociation constants of 2.3 and 0.23 nM, respectively (Nishiki *et al*., 1996a). Synaptotagmin II binding to BoNT type B with high affinity is known to be heavily expressed in peripheral nerve cells, which is consistent with the fact that BoNTs act at neuromuscular junctions. Synaptotagmin, which resides in the synaptic vesicles, possesses a single transmembrane domain with short intravesicular N- and cytoplasmic C-termini. BoNT type B is believed to bind to the N-terminus of synaptotagmin through the $H_C$ domain that is also known to mediate the binding to gangliosides (Kamata *et al*., 1986; Kozaki *et al*., 1989). Ganglioside GT1b was found to be associated with the transmembrane domain of synaptotagmin probably via its ceramide moiety (Kozaki *et al*., 1998). Therefore, it is likely that the N-terminus of synaptotagmin and GT1b, which are associated within the cell membrane, cooperatively compose a recognition site for BoNT type B binding.

In 2003, Dong *et al*. proved that synaptotagmin is the functional receptor. In their study, Dong *et al*. used PC12 cells, which intrinsically express no synaptotagmin II and contain only low levels of gangliosides. They demonstrated that BoNT type B entered PC12 cells that had previously been loaded with gangliosides and cleaved intracellular synaptobrevin, a substrate for the toxin, but it did not intoxicate another

PC12 cell line that was lacking synaptotagmin I and II. Transfection of PC12 cells with the synaptotagmin II gene rendered the cells sensitive to the toxin even without ganglioside preloading.

Earlier studies demonstrated that intoxication of motoneurons by BoNTs emerged only after a certain duration of stimulation-induced muscle constrictions. Synaptotagmin provided a conceivable interpretation of this phenomenon. The intravesicular N-terminus of synaptotagmin is exposed to the extracellular milieu during exocytosis and recycling of synaptic vesicles (Matteoli *et al*., 1992; Nishiki *et al*., 1996b; Kozaki *et al*., 1998; Dong *et al*., 2003). In other words, synaptotagmins should appear *de novo* outside cells only when exocytosis (neurotransmitter release) occurs and synaptic vesicle membranes fuse with the plasma membrane; and then, the toxin bound to synaptotagmin should be internalized in concert with membrane recycling. In fact, it was shown that BoNT type B entered cells together with synaptotagmin in response to stimulation (Dong *et al*., 2003). Recently, it was reported that synaptotagmins I and II also serve as receptors for BoNT type G. Receptors for other types of BoNT are still unknown.

## *Helicobacter pylori* VacA toxin receptor

### *VacA toxin*

*Helicobacter pylori* vacuolating cytotoxin (VacA), which is known to cause characteristic vacuolation in toxin-sensitive cells, is synthesized as a 140 kDa precursor and is processed into the mature 95 kDa toxin during secretion. The mature toxin is further cleaved into an N-terminal 37 kDa fragment (p37) and a C-terminal 58 kDa fragment (p58), which both remain non-covalently associated. p58 is considered to conduct the binding and internalization steps in the toxic actions. The VacA gene shows variations in two distinct molecular regions; one resides in the signal sequence region (genotypes s1 and s2), and the other resides in the mid region of p58 (genotypes m1 and m2). Based on combinations of these genotypes, VacA can be classified into four types: s1/m1, s1/m2, s2/m1, and s2/m2, of which s1/m1 is the most toxic. In addition, it has been reported that m1 and m2 types of VacA show different specificities of target cells (Pagliaccia *et al*., 1998). Attempts to identify the VacA receptor have been conducted using m1-VacA.

### *VacA toxin receptor*

Two distinct proteins with 250 kDa and 140 kDa were first identified by immunoprecipitation as specific proteins associated with active VacA and subsequently isolated chiefly by lectin affinity chromatography. Partial amino acid sequences of the isolated proteins were consistent with those of receptor-like protein tyrosine phosphatase (RPTP) β and α, respectively (Yahiro *et al*., 1997; Yahiro *et al*., 1999; Yahiro *et al*., 2003). HL-60 cells that are originally resistant to VacA became sensitive during differentiation into macrophage or monocyte-like cells by stimulation with phorbol ester. This was accompanied with the expression of RPTPβ (de Bernard *et al*., 1998; Padilla *et al*., 2000). Furthermore, VacA resistant BHK-21 cells gained the ability to respond to the toxin after being transfected with RPTPβ cDNA (Padilla *et al*., 2000). RPTPα was isolated from G401 Wilms' human kidney tumor cells, which do not express RPTPβ. Inhibition of RPTPα expression by an antisense oligonucleotide reduced the levels of internalization and intoxication with VacA in G401 cells. Thus, it was proved that RPTPα and β are the functional receptors for VacA (Yahiro *et al*., 2003).

### *Structure and function*

There are four splicing variants of RPTPβ: the full- length transmembrane form RPTPβ-A, the short transmembrane form RPTPβ-B, and two soluble short forms called *phosphacans*. Among them, both the transmembrane proteins, RPTPβ-A and RPTPβ-B, serve as VacA receptors. RPTPs including RPTPα possess sugar moieties in their molecules. Because treatments of target cells with neuraminidase and of RPTPβ with neuraminidase or *O*-glycosidase diminished VacA binding, it becomes clear that the sugar moiety must be functioning as part of the receptors. Recently, the main region of RPTPβ-B that interacts with VacA was defined to five residues (QTTQP) at position 747–751, containing two threonines and potential *O*-glycosylation sites (Yahiro *et al*., 2004). This same region is commonly retained in RPTPβ-A. VacA caused gastric tissue damage leading to gastric ulcers in wild type mice but not in RPTPβ-deficient mice. At the cellular level, VacA caused detachment from the basement membrane in gastric epithelial cells in wild type mice but not in RPTPβ-deficient mice, although it caused the vacuolation in both types of cells. Pleiotrophin, an endogenous ligand for RPTPβ, also caused similar gastritis only in wild type mice. These results imply that: (i) VacA induces gastric damage through RPTPβ-dependent signaling pathways, (ii) pleiotrophin also acts as a stimulator, (iii) RPTPβ is not essential for the VacA-induced vacuolation in cells (Fujikawa *et al*., 2003). The binding region of RPTPβ for pleiotrophin is unlikely to be the same as that for VacA (Yahiro *et al*., 2004). Besides the vacuolating activity and induction of gastric cell damage, VacA is known to exert various biological activities, such as proinflammatory or immunosuppressive activities on T cells and apoptosis-inducing activity (Boncristiano *et al*., 2003; Gebert *et al*.,

2003; Sundrud *et al*., 2004). It remains to be determined whether RPTPs are involved in these VacA activities, although Boncristinano *et al*. (2003) implied that RPTPs are partly involved in the inhibition of T cell proliferation.

## Anthrax toxin receptor

### *Anthrax toxin*

Anthrax toxin is composed of three subunits: edema factor (EF), lethal factor (LF), and protective antigen (PA) (Leppla, 1995). EF is an adenylate cyclase, while LF is a metalloprotease specific for MAPK kinases. Although EF and LF are responsible for the toxicity of the anthrax toxin, these subunits cannot exert their effects in the absence of PA. PA is a receptor-binding protein that forms a pore in the endosomal membrane, enabling EF and LF to cross into the cytosol. The current model for cellular intoxication of anthrax toxin involves a multi-step mechanism. In the first step, the full-length 83 kDa form of PA (PA83) binds a host cell surface receptor. PA83 is cleaved by a furin-like protease on the cell surface, yielding the 63 kDa form of PA (PA63) (Molloy *et al*., 1992). PA63 then oligomerizes into a heptameric, receptor-bound prepore (Petosa *et al*., 1997). Oligomerized PA also binds LF and/or EF. The toxin/receptor complex is internalized by receptor-mediated endocytosis and delivered into an acidic endosomal compartment (Abrami *et al*., 2003). The low pH present inside the endosome induces a conformational change of the prepore, which leads to its insertion in the endosomal membrane and translocation of EF and LF into the cytoplasm (Blaustein *et al*., 1989).

### *Identification of anthrax toxin receptor*

Specific binding of PA to anthrax toxin was studied by using $^{125}$I-labeled PA (Singh *et al*., 1991). $^{125}$I-PA binds to specific cell surface receptors of CHO cells and mouse macrophages in a saturated manner with a single class of binding having a Kd of about 1 nM (Escuyer and Collier, 1991; Friedlander *et al*., 1993). Macrophages from different mouse strains vary in their sensitivity to anthrax toxin (PA plus LF), but show similar specific binding to PA, indicating that macrophage cell sensitivity to this toxin does not depend on the presence of functional anthrax toxin receptors, but is possibly due to the ubiquitous expression of the receptors (Friedlander *et al*., 1993).

Anthrax toxin receptor was identified by expression cloning using toxin-resistant mutant cells (Bradley *et al*., 2001). CHO-K1 cells are sensitive to anthrax toxin. To identify the anthrax toxin receptor, Bradley *et al*. (2001) first isolated receptor-deficient mutant cells by selecting for PA and LFN-DTA (a fusion protein composed of the N-terminal 255 amino acids of LF linked to the catalytic subunit of diphtheria toxin). The isolated mutant cells were defective in PA binding, suggesting that these cells lost expression of a putative PA receptor gene. Genetic complement analysis using a retrovirus-based cDNA library from human HeLa cells with a combination of selection of cells with a significant signal of PA binding detected by flow cytometry, identified a cDNA clone encoding the anthrax toxin receptor (ATR). Transfection of the ATR cDNA restored not only PA binding to CHO-R1.1 cells, but also sensitivity to LFN-DTA toxin in the presence of PA. Furthermore, ATR cDNA enhanced the binding of PA to parental CHO-K1 cells.

The cloned ATR is encoded by the tumor endothelial marker 8 (TEM8) gene, which is expressed in a wide variety of tissues. Although the physiological function of ATR/TEM8 is not yet known, this gene is suggested to have some roles in neovascularization. At least three different ATR/TEM8 protein isoforms have been described that are produced by alternative splicing of the TEM8 gene transcript, and two of the three isoforms (splice variants 1-2, or sv1-2) are suggested to function as ATRs (Scobie *et al*., 2003).

In addition to ATR/TEM8, capillary morphogenesis protein 2 (CMG2), originally known as a gene expressed in human placental tissues (Scobie *et al*., 2003), was also identified as a second PA receptor. Several different isoforms of CMG2 protein, which are generated by alternative splicing from CMG2 gene, are known; and at least CMG2$^{489}$, one isoform of the spliced variants, confers PA binding activity and sensitivity to LFN-DTA toxin in the presence of PA on CHO-R1.1 cells to a degree similar to that observed in ATR/TEM8. CMG2 gene, as well as ATR/TEM8 gene, is expressed in a variety of human tissues, suggesting that CMG2 protein is also involved in pathogenesis by anthrax toxin.

### *Structure and function*

The extracellular domains of ATR/TEM8 and CMG2 commonly contain a region that is highly related to von Willebrand factor type A domains (VWA domains), also called *integrin inserted domains* (I domains). The VWA/I domain of CMG2 is 60% identical to the VWA/I domain of ATR/TEM8. These domains are known to be important for protein-protein interactions and constitute ligand-binding sites for integrins. VWA/I domains frequently contain a metal ion–dependent adhesion site (MIDAS) motif. PA directly binds to the VWA/I domains of ATR/TEM8 and CMG2 in a metal ion–dependent manner (Bradley *et al*., 2001; Scobie *et al*., 2003).

Recently, the crystal structure of the single VWA domain of CMG2 (Lacy *et al*., 2004b) and the CMG2-PA complex structure (Lacy *et al*., 2004a; Santelli *et al*., 2004) were reported. The structure indicates that the binding surface of PA with CMG2 quite resembles that of collagen-integrin interaction, and also revealed the nature of interaction of PA with CMG2 at an atomic level, providing information for creating a new anthrax antitoxin.

## CONCLUSION

Although characterization of many bacterial toxin receptors is still not clarified, it is now clear that all bacterial toxin receptors identified to date play pivotal roles in host cell function, as well as intoxication by bacterial toxins. Membrane proteins that are ubiquitously present and essential for host cell membrane would be favorable for bacteria to exert their toxic actions to a large extent, and thus such membrane proteins must be particularly selected as toxin receptors. Identification and molecular characterization of their receptors are not only essential to understanding the intoxication mechanism of bacterial toxins, but also valuable for analyzing native functions of host cell proteins. Recent progress on analytical methods for dealing with small protein amounts seems to have eased the identification of toxin receptors. It is hoped that future efforts will identify receptors of most bacterial toxins.

CHAPTER

# 7

# Translocation of bacterial protein toxins into the cytosol

*Sjur Olsnes and Jørgen Wesche*

## INTRODUCTION AND BRIEF DESCRIPTION OF RELEVANT TOXINS

Bacterial protein toxins act either at the level of the cell surface or at targets in the cytosol. Superantigens and toxins containing lytic activity exert their action at the level of the cell surface and will not be discussed here. However, an increasing number of bacterial protein toxins are being demonstrated to have intracellular sites of action. This implies that the toxins must be able to cross cellular membranes. Most toxins do this by crossing membranes of intracellular organelles rather than penetrating through the plasma membrane.

Some toxins are equipped with their own translocation apparatus, whereas others must rely on cellular translocation processes that they exploit. This is most clearly evident in the case of immunotoxins. These constructs consist of an antibody that binds to target cells and a protein that is highly toxic once in the cytosol, but that is unable to translocate to the cytosol on its own. Recent research has shed some light on how these toxins and immunotoxins enter the cytosol. The toxins that will be particularly considered here are depicted schematically in Figure 7.1.

Diphtheria toxin is synthesized as a single chain protein with a signal sequence that is cleaved off when the toxin is excreted from the bacteria. The mature toxin is easily cleaved into two fragments by trypsin-like proteases, and the cleaved toxin represents the active form. It consists of an enzymatically active part, the A-fragment, which is linked by a disulfide bond to the B-fragment (Pappenheimer, Jr., 1977). The B-fragment consists of a receptor-binding domain (R) and a transmembrane domain (T), which can insert into the membrane and which plays a decisive role in the translocation of the A-fragment to the cytosol (Choe *et al.*, 1992). It resembles membrane-inserting domains in certain colicins and in the δ-toxin from *Bacillus thuringensis* (Li *et al.*, 1991). Once in the cytosol the A-fragment ADP-ribosylates a unique amino acid, diphthamide, in elongation factor 2, thereby inactivating the elongation factor and inhibiting protein synthesis (Collier, 1975; Van Ness *et al.*, 1980a; Van Ness *et al.*, 1980b).

*Pseudomonas aeruginosa* exotoxin A resembles in many respects diphtheria toxin. It has an enzymatically active part (domain III) that has the same activity as diphtheria toxin A-fragment and a region (domain II) that structurally reminds of the T-domain of diphtheria toxin and that is therefore believed to be involved in the translocation process (Wick *et al.*, 1990). It differs from diphtheria toxin and most other toxins in this group in that the enzymatically active domain of exotoxin A is located in the C-terminal part of the molecule. A disulfide-bridged cleavage site sensitive to furin is located in domain II, and it is believed that cleavage and reduction is required for translocation (Allured *et al.*, 1986). Domain I binds the toxin to cell surface receptors. The C-terminus of the toxin has a KDEL-like structure, suggesting that the toxin is transported to the endoplasmic reticulum, where it may be translocated to the cytosol.

The A–$B_5$ class of toxins comprises cholera toxin, *E. coli* heat-labile toxin, Shiga toxin, and Shiga-like toxins 1 and 2 (Merritt and Hol, 1995; Lencer and Tsai,

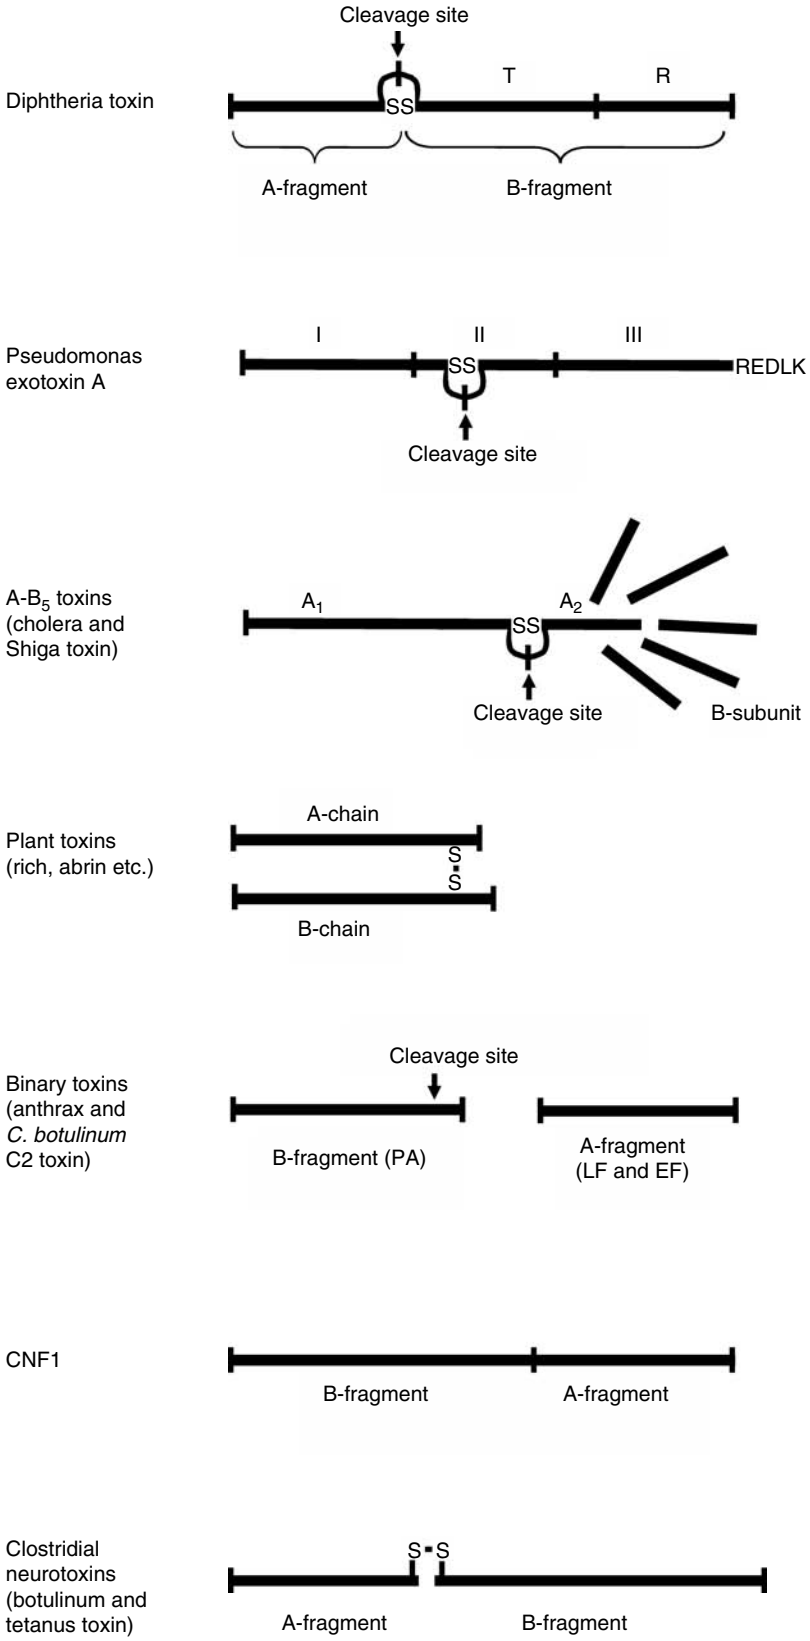

**FIGURE 7.1** Schematic structure of toxins. Details are discussed in the text.

2003). These toxins have a similar overall structure, but they have different functions. The toxins all consist of a pentameric B-subunit that is linked non-covalently to the C-terminal part of the A-subunit, which consists of a single polypeptide chain. The A-subunit contains in its C-terminal end a disulfide-bridged trypsin- and furin-sensitive loop, which is easily cleaved to yield the enzymatically active $A_1$-fragment and the small $A_2$-fragment that is associated with the B-subunit (Olsnes *et al*., 1981; Reisbig *et al*., 1981). The B-subunit of all toxins in this group binds to glycolipids. The enzymatically active A-subunits of cholera toxin and heat-labile *E. coli* toxin ADP-ribosylate and permanently activate the α-subunit of trimeric G-proteins, whereas the A-subunit of Shiga toxin and Shiga-like toxins inactivate ribosomes by removal of an adenine residue from the 28S RNA of the large ribosomal subunit, thereby inhibiting protein synthesis.

We will also discuss a group of plant toxins comprising ricin, abrin, modeccin, volkensin, and others that have properties similar to the bacterial toxins we are considering here (Olsnes *et al*., 1974). These toxins are synthesized as a continuous polypeptide chain, but prior to excretion they are cleaved in the vacuole of the plant cells to yield an enzymatically active A-chain and a receptor-binding B-chain held together by a disulfide bond (Figure 7.1). The B-chain has lectin properties and binds to surface glycoproteins and glycolipids with terminal galactose residues (Sandvig and Olsnes, 1979; Olsnes and Refsnes, 1978). The A-chain has the same enzymatic activity as the A-subunit of Shiga toxin (Endo *et al*., 1988).

The binary toxins are produced as two different proteins, one that binds to receptors at the cell's surface, and which is then cleaved to release a ~20 kDa fragment. In the case of anthrax toxin, and probably also other binary toxins, the remaining major part of the cleaved molecules forms heptamers that act as binding sites for an enzymatically active protein that is able to enter the cytosol. The *Clostridium botulinum* C2 toxin, *C. perfringens iota*-toxin, and *C. spiriforme* toxin are binary toxins that act by ADP-ribosylating the ATP-binding protein, actin. There are at least six mammalian actin isoforms, but *C. botulinum* C2 toxin ADP-ribosylates only the cytoplasmic form (Aktories *et al*., 1992; Aktories *et al*., 1986). Anthrax toxin is most studied among the binary toxins. In this case two different enzymatically active proteins, the edema factor and the lethal factor, can use the same binding subunit (called *PA* or *protective antigen*) to which they bind in a mutually exclusive manner. The lethal factor is a metalloprotease that cleaves MAP kinase kinase (Duesbery *et al*., 1998; Vitale *et al*., 1998). The edema factor is an adenylate cyclase that enters the cytosol where it is activated by calmodulin (Leppla, 1982), leading to elevation of the level of cAMP, thus interfering with the bacteriocidal capacity of the intoxicated cell.

Another invasive and calmodulin-activated adenylate cyclase (CyaA) is produced by *Bordetella pertussis* (Rogel *et al*., 1991). The 177 kD CyaA-protein can be divided into an N-terminal catalytic domain and a C-terminal hemolytic domain. Upon activation by calmodulin, CyaA elevates the level of cAMP in the cytosol.

An export protein from *Clostridium botulinum*, exoenzyme C3, is able to ADP-ribosylate the small G-protein Rho, which regulates actin polymerization and intracellular vesicular transport (Chardin *et al*., 1989). Similar enzymes are found in a wide variety of bacteria (Just *et al*., 1992a; Just *et al*., 1992b; Lencer *et al*., 2003) including *Staphylococcus aureus* (Inoue *et al*., 1991), although no bacterial substrate is known. Use of exoenzyme C3 has played an important role in the recent elucidation of the mechanism of action of certain microbial toxins, the *Clostridium difficile* toxins A and B (Just *et al*., 1995a) and the *E. coli* necrotizing toxin (CNF1) (Lemichez *et al*., 1997). When Rho had been pretreated with *C. difficile* toxins, it could no longer be ADP-ribosylated by exoenzyme C3, clearly indicating that the *C. difficile* toxin had modified Rho. This modification was later found to consist in transfer of glucose from the precursor UDP-Glc to a threonine residue in Rho and the related Rac and Cdc 42 (Just *et al*., 1995a; Just *et al*., 1995b). Lethal toxin from *C. sordellii* has the same activity, which leads to the disassembly of stress fibers in the toxin-treated cells (Popoff *et al*., 1996; Selzer *et al*., 1996). The toxins did not modify the more distantly related G-proteins ras, rab, and ARF. *C. novyi* toxin incorporates N-acetylglucosamine rather than glucose into rho (Just *et al*., 1996).

Cytotoxic necrotizing toxin (CNF1) from certain strains of *E. coli* is another toxin acting on Rho. The toxin consists of a single polypeptide chain (137 kD) with a putative N-terminal receptor-binding domain, a central hydrophobic domain, and a C-terminal catalytic domain (Lemichez *et al*., 1997). The toxin induces deamidation of a glutamine residue (Gln63) (Flatau *et al*., 1997; Schmidt *et al*., 1997), leading to permanent activation of Rho. As a result, there is a strong overactivity in actin polymerization and formation of multinucleated cells. Furthermore, the toxin induces phagocytosis in non-phagocytic cells, enabling toxigenic bacteria to enter and multiply in cells and to be transcytosed across epithelia. It is apparently part of the same strategy that the toxin inhibits apoptosis in the intoxicated cells (Fiorentini *et al*., 1997).

The neurotoxins tetanus toxin and botulinum toxins are not produced as export proteins, but rather as intracellular proteins that are released when the bacterium dies. The molecular action of these toxins has been elucidated in great detail in recent years. They are all metalloproteases that cleave proteins involved in exocytosis, particularly in the synapses (Schiavo *et al*., 1992; Montecucco and Schiavo, 1993). As a result, the synaptic transmission is paralyzed. Also, these toxins are formed as a single polypeptide chain, which is cleaved into an enzymatically active fragment and a fragment that is involved in binding and translocation. As in the case of diphtheria toxin, the two parts are disulfide-linked. Binding to different surface receptors is probably the reason that different neurons are affected in tetanus and botulism.

*Helicobacter pylori* produces a vacuolating toxin,VacA, which appears to be involved in the appearance of stomach ulcers. There are now clear indications that this toxin enters the cytosol. Thus, the vacuolation can be induced by intracellular expression of the toxin (Papini *et al*., 2001), it interacts with the intermediary filament protein, vimentin (de Bernard *et al*., 2000), and a 37 kD fragment of the toxin enters the mitochondria and induces release of cytochrome C and apoptosis of the cell (Boquet *et al*., 2003).

## BINDING TO CELL SURFACE RECEPTORS

All bacterial protein toxins must bind to cells in order to act. Since for obvious reasons the cells have not developed receptors for toxins, the toxins must employ cell surface structures that are designed for other purposes. Cells lacking the relevant receptors are resistant to the toxin. The surface molecules that the toxins use for binding may be hormone receptors, growth factor precursors, cell adhesion molecules, glycolipids, and other molecules. So far, there has not emerged any particular property that is common for toxin receptors. However, it is likely that the ability to transport the toxin to defined intracellular compartments will prove to be a common property.

Diphtheria toxin binds to the uncleaved precursor of a growth factor, namely that of heparin-binding, EGF-like growth factor (HB-EGF) (Naglich *et al*., 1992). All growth factors of the EGF family are formed as transmembrane proteins that are transported out of the cells and then cleaved to release the growth factor. Not all molecules are cleaved, and it is now clear that in many cases the uncleaved molecules act as growth factors in a juxtacrine manner by binding to EGF-receptors on adjacent cells (Raab and Klagsbrun, 1997; Takemura *et al*., 1997). Diphtheria toxin binds to the HB-EGF precursor present on most mammalian cells. Due to a few amino acids' difference, the HB-EGF precursor found in mouse and rat cells does not bind to the toxin, and cells from these animals are therefore resistant to diphtheria toxin (Hooper and Eidels, 1996). Transgenic mice expressing HB-EGF precursor from monkeys became sensitive to the toxin (Cha *et al*., 2003). By placing the gene behind an organ-specific promoter, selective deletion of the corresponding organ could be induced by intramuscular administration of diphtheria toxin (Saito *et al*., 2001; Akazawa *et al*., 2004).

The correct distance of the receptor-bound toxin to the membrane seems to be essential. Thus, when the distance was slightly increased by extending the juxtamembrane domain of the receptor by a few amino acids, it strongly reduced the ability of the receptor to facilitate translocation of A-fragment to the cytosol (Takahashi *et al*., 2001) in accordance with earlier studies (Lanzrein *et al*., 1996).

Two closely related cell adhesion molecules were recently shown to act as receptors for anthrax toxin (Bradley *et al*., 2001; Lacy *et al*., 2004; Scobie *et al*., 2003). Like the diphtheria toxin receptor, they are transmembrane proteins that pass the membrane once. Most of the extracellular part consists of a von Willebrand factor A domain that binds the protective antigen (PA) of the toxin. The affinity is very high in the high picomolar range and involves a $Mg^{2+}$-ion and a MIDAS motif (Lacy *et al*., 2004; Santelli *et al*., 2004). The structure of PA bound to the receptor has been solved (Lacy *et al*., 2004; Santelli *et al*., 2004; Bann and Hultgren, 2004).

Pseudomonas exotoxin A binds to a cell surface protein that binds to low-density lipoprotein and $\alpha_2$-macroglobulin (Kounnas *et al*., 1992).

Cholera toxin and *E. coli* heat-labile toxin bind to the ganglioside $Gm_1$ (van Heyningen, 1974), whereas Shiga toxin binds to neutral glycolipids. Shigella (or Shiga) toxin, the essentially identical Shiga-like toxin 1, and the slightly different Shiga-like toxin 2 bind to globoside $B_3$ (Ling *et al*., 1998), whereas the related Shiga-like 2e toxin binds to globoside $B_4$ (DeGrandis *et al*., 1989).

One of the botulinum toxins, toxin B, binds to the neuronal protein synaptotagmin (Nishiki *et al*., 1994). The receptors for the other botulinum toxins have not been identified.

The plant toxins ricin, abrin, and related toxins are rather unselective as they bind both to glycoproteins and glycolipids with terminal galactose residues (Meager *et al*., 1976; Hughes and Gardas, 1976; Olsnes *et al*., 1978). Therefore, it is not clear which molecules are the productive receptors as it is likely that

binding to most of the structures carrying terminal galactose will not result in translocation of the A-chain to the cytosol.

The *Helicobacter pylori* toxin, VacA, appears to bind to a GPI-anchored protein at the cell surface and is endocytosed by a mechanism not involving clathrin (Ricci *et al*., 2000).

The nature of the receptors for most protein toxins that enter the cytosol is not known.

## ENDOCYTOSIS

Since most toxins that act on components in the cytosol are translocated from intracellular organelles, the uptake mechanism usually starts with endocytosis. The uptake may follow the classical route from clathrin coated pits, but in several cases it appears to occur from other surface structures. These may include caveoli or other, so far uncharacterized, invaginations of the plasma membrane.

The first indication that endocytosis may be necessary for entry of toxins came from experiments in reticulocytes with the plant toxins, ricin and abrin (Olsnes *et al*., 1974). The ribosomes of reticulocytes are very sensitive to abrin and ricin, but in spite of this, protein synthesis in whole reticulocytes was not inhibited after incubation with high concentrations of these toxins. Both toxins were found to bind extensively to the surface of the reticulocytes, but there was no evidence for endocytic uptake. The exception is the invasive adenylate cyclase from *B. pertussis* that appears normally to enter through the surface membrane (Rogel and Hanski, 1992).

More definitive evidence was obtained with diphtheria toxin in nucleated cells in culture. It was found that when the cells were incubated with ammonium chloride or other weak bases that are able to penetrate cellular membranes and neutralize acidic compartments in the cells, the cells were protected from intoxication (Kim and Groman, 1965). This protection was overcome when the cells were briefly exposed to low pH (Draper and Simon, 1980; Sandvig and Olsnes, 1980). Moreover, in the latter case, the cells were more rapidly intoxicated than when the cells were incubated with toxin under normal conditions. These results indicated that the normal entry pathway for the toxin is from intracellular acidic compartments, and that when cells with surface-bound toxin are exposed to low pH, the conditions in endosomes are mimicked at the level of the surface membrane, and direct translocation is induced.

Later, similar data have been obtained with anthrax toxin (Koehler and Collier, 1991; Milne and Collier, 1993; Wesche *et al*., 1998), *Cl. botulinum* C2 toxin (Barth *et al*., 2000), and CNF1 (Contamin *et al*., 2000). In the case of other toxins, it has not been possible to induce entry from the cell surface by treating cells with low pH or other conditions, and it is therefore likely that in this case the entry mechanism is more complicated.

Considerable additional evidence has accumulated that endocytosis is required for the toxins to enter the cytosol. Thus, when endocytosis was blocked by depleting the cells for ATP, the cells were not able to take up toxins (Sandvig and Olsnes, 1982b). Other experiments pointing in the same direction were carried out by depleting cells for calcium (Sandvig and Olsnes, 1982a) or exposing them to slightly reduced pH, conditions that do not interfere with endocytosis. Under these conditions, the cells are still able to endocytose the toxins, but the toxins are not able to intoxicate the cells. Treatment with antibodies to inactivate toxin remaining at the cell surface and in the medium was then followed by incubation of the cells in normal medium to relieve the block. Under these conditions, the cells were intoxicated by toxin endocytosed during the block.

At temperatures below 18°C endocytosis is still active, but transport to the trans-Golgi and to late endosomes is blocked. At this temperature the cells were not intoxicated by ricin. The cells were, however, fully sensitive to diphtheria toxin under these conditions (Sandvig *et al*., 1984). Evidence has accumulated over time that transport to the trans-Golgi network is the important routing for many toxins. Further experiments showed that brefeldin A and ilimaquinone that lead to disintegration of the Golgi apparatus, which is transported back to the ER, protect against ricin and Shigella toxin (Nambiar and Wu, 1995; Yoshida *et al*., 1991a; Rapak *et al*., 1997). These drugs did not affect the toxicity of diphtheria toxin. Clearly, therefore, there is a difference in the entry mechanism of the two groups of toxins (Figure 7.2). However, a main conclusion from these data is that in all cases endocytic uptake is a prerequisite for entry to the cytosol.

When the uptake of ricin by endocytosis from coated pits was blocked by depleting the cells for potassium, the cells were still intoxicated by ricin at approximately the same rate as in control cells. This provided the first evidence that toxins can enter the cytosol by mechanisms bypassing endocytosis from coated pits (Moya *et al*., 1985). Later experiments showed that when endocytic uptake from coated pits was inhibited by other mechanisms, such as acidification of the cytosol (but not of the medium) and by exposing the cells to hyperosmolaric medium, the cells were also intoxicated by ricin, but not by diphtheria toxin (Sandvig *et al*., 1989).

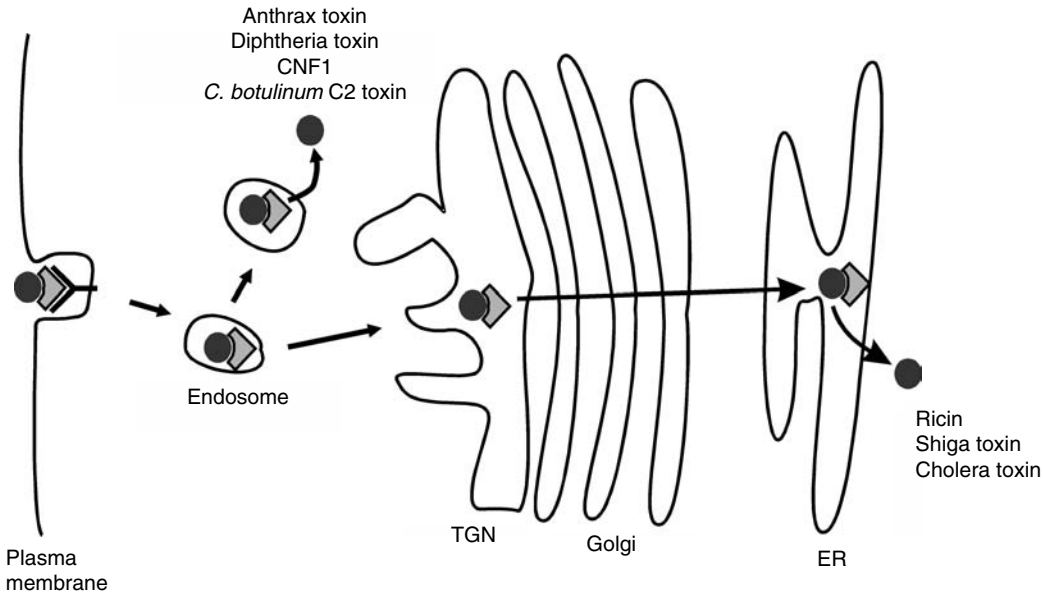

**FIGURE 7.2** Intracellular transport of toxins.

There is now considerable evidence that several toxins are endocytosed from structures different from the coated pits. It appears, however, that the toxin endocytosed by such an alternative pathway eventually ends up in the same endosomes as those taken up by the classical, clathrin-dependent pathway (van Deurs *et al*., 1989).

A more extensive description of endocytosis and vesicular transport of toxins is given in Chapter 8.

## RETROGRADE VESICULAR TRANSPORT

### Transport to the Golgi apparatus

As first observed with cholera toxin, a certain fraction of the endocytosed toxin is transported to the trans-Golgi network (Joseph *et al*., 1979). Later experiments demonstrated that this is also the case in a number of other toxins, such as Shiga toxin and ricin (Sandvig *et al*., 1992; Rapak *et al*., 1997). Furthermore, in the case of ricin it could be shown that the toxin is localized in the same compartment as newly synthesized export proteins. Thus, a cell line producing a monoclonal antibody against ricin was highly resistant to the toxin under conditions where the antibody was not able to inactivate the toxin at the cell exterior (Youle and Colombatti, 1987). More direct evidence was obtained in ultrastructural studies demonstrating that ricin imported from the medium met newly synthesized virus proteins in the trans-Golgi network (van Deurs *et al*., 1988). From here, it is then sorted to various locations in the cells, such as the endoplasmic reticulum, the lysosomes, or back to the cell surface. In polarized cells, the toxin may be transported to the opposite pole of the cells.

### Transport to the endoplasmic reticulum

A most interesting recent development in studies of toxin transport is the observation that a considerable part of the toxins that reach the Golgi apparatus is transported retrograde to the endoplasmic reticulum (ER) (Figure 7.2). The first suspicion that this may be the case came from structural observations with cholera toxin and the related *E. coli* heat-labile toxin. Both these toxins consist of a pentameric B-subunit that binds the toxins to gangliosides at the cell surface. The enzymatically active subunit, the A-subunit, contains in its C-terminal end the sequence KDEL (cholera toxin) and RDEL (heat-labile toxin). Since the only known function of this sequence is to bind to the KDEL receptor, it was suspected that this may indeed be involved in the intracellular routing of these two toxins (Chaudhary *et al*., 1990). Resident luminal ER proteins contain a C-terminal KDEL-sequence. In the ER where the pH is neutral, the proteins are not bound to the KDEL receptor, but under the slightly acidic conditions prevailing in the Golgi apparatus, the sequence will become bound to the receptor, which will then transport the proteins back to the ER where they are released. The KDEL receptor therefore has a function to retrieve ER luminal resident proteins that have escaped to the Golgi complex. Evidently, an external protein that contains this sequence might also

be transported to the ER if it has first reached the Golgi apparatus.

*Pseudomonas aeruginosa* exotoxin A contains a C-terminal sequence that resembles the KDEL sequence, namely REDLK. Experiments have shown that this sequence as such does not bind to the KDEL receptor, but if the C-terminal lysine is first removed by cellular exopeptidases, it binds, although not with high affinity. It was proposed that this sequence might direct the toxin to the ER (Chaudhary *et al*., 1990). In fact, removal of the REDLK sequence abolished the toxicity of the molecule, while replacing it with the sequence KDEL resulted in recovery of the toxicity. This strongly indicates that the transport to the ER is necessary for this toxin to act. It has, however, not been formally demonstrated that exotoxin A is really transported to the ER.

The first convincing evidence for transport of an external protein retrograde to the ER came with another toxin, Shiga toxin (Sandvig *et al*., 1992). This toxin has a structure that resembles that of cholera and heat-labile toxin, but it does not have a KDEL-related sequence. Also, this toxin binds to a glycolipid, and it had been known for some time that it is transported to the trans-Golgi region and possibly to the Golgi stacks. Treatment with butyric acid was found to sensitize some cells to the toxin, and upon analysis of butyric acid–treated cells that had been incubated with a conjugate of Shiga toxin and horseradish peroxidase, the conjugate was found in the ER, including the perinuclear space (Sandvig *et al*., 1992). Interestingly, the retrograde transport of Shiga toxin and cholera toxin was not inhibited by treatment with concanamycin that blocks the proton pump in intracellular vesicles, whereas the retrograde transport of furin and TGN38 was inhibited under these conditions (Schapiro *et al*., 1998).

Further evidence that toxins must pass the Golgi apparatus and the ER came from experiments with brefeldin A, which causes a disintegration of the Golgi apparatus. Treatment with this drug protected against intoxication of cells by ricin (Yoshida *et al*., 1991b). Furthermore, ricin containing signals for tyrosine sulfation and glycosylation modified accordingly after being added externally to the cells (Rapak *et al*., 1997).

## TRANSLOCATION TO THE CYTOSOL

### From the surface

So far only one bacterial toxin with an intracellular site of action has been demonstrated to be translocated from the cell surface, namely the invasive adenyl cyclase, CyaA, from *Bordetella pertussis*. This protein (177 kD) binds to, and apparently inserts into, membranes even at 4°C, as it cannot be removed by an alkaline carbonate wash. When the temperature is raised to 20°C or above, the toxin appears to translocate the enzymatically active part across the membrane. Calcium in the extracellular medium and an intact membrane potential are required for this process. Thus, when the cells were electrically depolarized, translocation did not occur. This raises the possibility that the enzymatically active part of the molecule is electrophorezed across the membrane, possibly through a pore. However, the electrical membrane potential affects the structure of all charged transmembrane molecules, and the role of the membrane potential could be an indirect one. It is interesting that translocation of fibroblast growth factors 1 and 2 also requires an intact membrane potential, in this case across the membrane of the endosomes (Malecki *et al*., 2002; Malecki *et al*., 2004). A 45 kD fragment of the *Bordetella pertussis* toxin carrying the enzymatic activity may subsequently be released into the cytosol (Rogel *et al*., 1992). Binding of calmodulin is required to activate the enzyme (Figure 7.3).

### From endosomes

Translocation from endosomes has been well characterized in two toxins, diphtheria toxin and anthrax toxin. In spite of their difference in primary structure and subunit composition, these two toxins are translocated by very similar mechanisms. Both toxins appear to be equipped with their own translocation devices. In the case of diphtheria toxin, this is part of the B-fragment, which is also involved in binding to receptors. The B-fragment contains a highly helical domain, the transmembrane or T-domain. At low pH as obtained in endosomes, this part of the toxin partially unfolds and inserts itself into the membrane forming an ion-conducting pore initiated by a hairpin of the hydrophobic helices 8 and 9 (Kaul *et al*., 1996). Hydrophobic photolabelling studies indicated that in addition to helices 8 and 9 that form the transmembrane hairpin, helices 1 and 5 also are inserted into the membrane, helix 1 in a transmembrane fashion (D'Silva and Lala, 1998; D'Silva and Lala, 2000). This brings the interfragment disulfide bond into the cytosol where it can be reduced to allow the A-fragment to be released into the cytosol (Figure 7.4). Hydrophobic and electrostatic interactions occur in a sequential manner in the process (Chenal *et al*., 2002; Ladokhin *et al*., 2004). The inserted T-domain may act as a membrane-inserted chaperone for the translocation of the A-fragment (Hammond *et al*., 2002; Rosconi *et al*., 2004). Although *in vitro* experiments with lipid films indicate that the toxin is able to

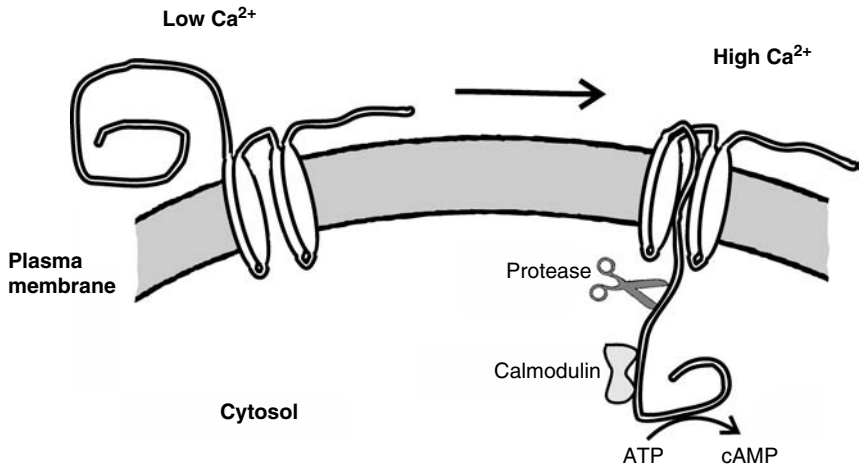

**FIGURE 7.3** Translocation of *Bordetella pertusssis* invasive adenyl cyclase.

translocate without assistance from other proteins (Senzel *et al*., 2000), in the *in vivo* situation additional proteins may increase the efficiency of translocation. Thus, recent data indicate that heat shock protein 90 and thioreductin reductase may be involved in the translocation process (Ratts *et al*., 2003).

Although cytotoxic necrotizing factor I from *E. coli* is endocytosed by a mechanism not involving clathrin, it appears to translocate to the cytosol in a similar way as diphtheria toxin (Contamin *et al*., 2000; Pei *et al*., 2001).

Anthrax toxin belongs to the group of binary toxins. One of the parts, the protective antigen (PA), binds to receptors at the cell surface and is then cleaved to release a 20 kD fragment (Petosa *et al*., 1997). The rest of the molecule forms heptamers at the level of the cell surface and at the same time generates a binding site for the other part of the toxin. This may be the edema factor or the lethal factor. Three molecules of either one can bind to each heptamer. The heptamer formed by the cleaved PA inserts into the membrane at low pH and forms ion-conducting channels in the membrane

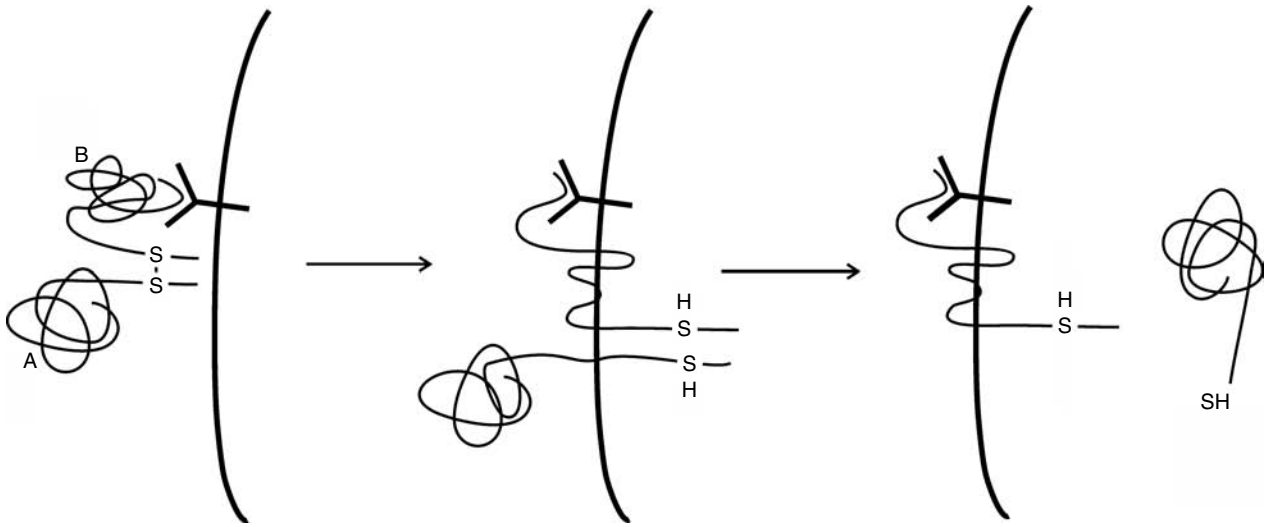

**FIGURE 7.4** Current model of translocation of diphtheria toxin. The toxin binds by its B-fragment to cell surface receptors and is endocytosed. Upon exposure to the low pH in endosomes, the helical T-domain is exposed and inserts into the membrane, pulling the C-terminal end of the A-fragment across the membrane. The disulfide bond is reduced upon exposure to the reducing conditions in the cytosol, and the remaining part of the A-fragment is translocated to the cytosol.

in a very similar way as diphtheria toxin. The enzymatically active part is translocated to the cytosol in the process (Figure 7.5). The heptameric PA appears to form a beta-barrel across the membrane, which could form the channel (Nassi *et al*., 2002). Certain mutations in PA that abolished the channel formation protected against toxicity, in spite of the fact that they did not impair binding of PA to the receptor (Sellman *et al*., 2001).

The C2 toxin from *Clostridium botulinum* is a binary toxin that resembles anthrax toxin but has another intracellular target: it ADP-ribosylates G-actin and induces depolymerization of actin. This toxin appears to enter by a mechanism similar to that of anthrax toxin (Blocker *et al*., 2003; Barth *et al*., 2000). Like anthrax toxin, it can carry passenger proteins into the cytosol (Haug *et al*., 2003b), and as in the case of diphtheria toxin, the chaperone Hsp90 is required for efficient translocation (Haug *et al*., 2003a).

In both the case of diphtheria toxin and anthrax toxin, it is necessary that the enzymatically active part is able to unfold during translocation. Thus, when disulfide-loops are introduced into the A-fragment of diphtheria toxin (it normally does not contain any), the translocation is blocked (Falnes *et al*., 1994). This is also the case if a ligand that confers tight folding is bound to a passenger protein that can otherwise be translocated along with the toxin (Wiedlocha *et al*., 1992). In the case of anthrax toxin, a fusion protein of diphtheria toxin A-fragment and the N-terminal part of anthrax toxin lethal factor ($LF_N$) can be translocated into the cytosol, but also here the translocation is blocked by the introduction of a disulfide bridge in the molecule (Arora and Leppla, 1994; Wesche *et al*., 1998).

The *Helicobacter pylori* toxin, VacA, requires low pH for activation, which is required for translocation to the cytosol (McClain *et al*., 2000). A chloride-permeable channel is formed in the process (McClain *et al*., 2003; Kim *et al*., 2004).

## From the ER

It now appears that an increasing number of toxins are found to be translocated from the ER. Although several toxins have been demonstrated to be transported retrograde to the ER (Lencer *et al*., 2003), it has been more difficult to demonstrate that the toxins are

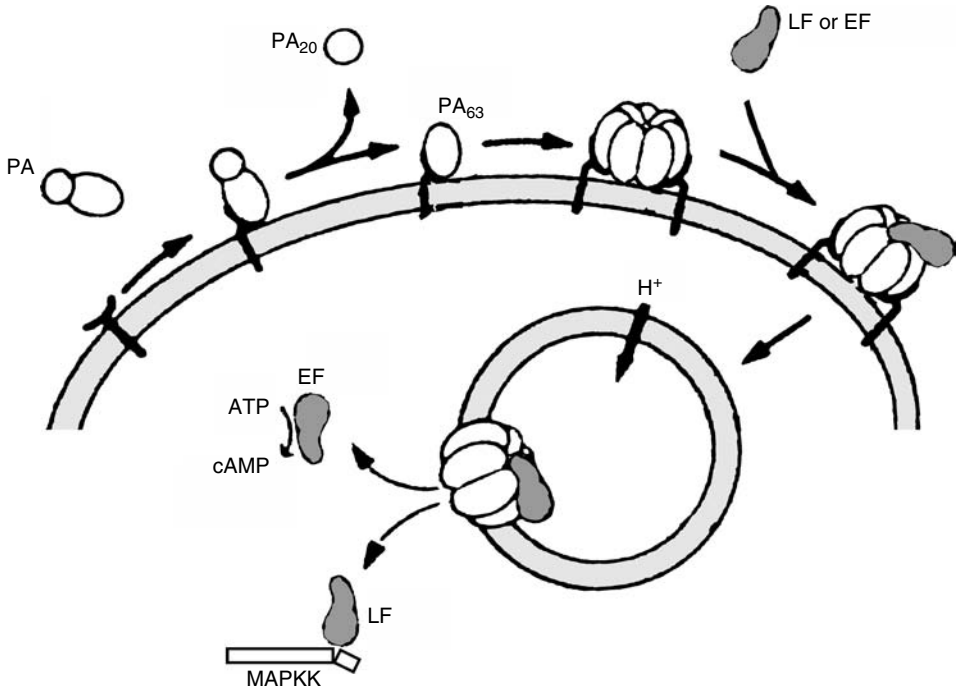

**FIGURE 7.5** Translocation of anthrax toxin. The protective antigen (PA) binds to cell surface receptors and a ~20 kD piece is cleaved off. The remaining part of the molecule aggregates with other cleaved PA molecules to form a heptamer, thereby generating binding sites for lethal factor (LF) and edema factor (EF). The complex is endocytosed. Upon acidification of the endosome, the heptamer inserts into the vesicle membrane and facilitates translocation of LF and EF to the cytosol (Petosa *et al*., 1997).

also translocated from this organelle. Certain plant toxins are very similar in structure and mechanism of action to bacterial toxins. One such plant toxin, ricin, acts on ribosomes in the same way as Shiga toxin, but it has a different B-subunit, which has lectin properties and binds to surface glycoproteins and glycolipids having terminal galactose residues (Olsnes *et al*., 1974). This toxin was the first to be shown to be transported retrograde from the cell surface to the trans-Golgi network (van Deurs *et al*., 1986; van Deurs *et al*., 1988). Some export proteins are sulfated on tyrosine and, since the sulfation occurs in the Golgi apparatus, a sulfation site was engineered into the C-terminal end of the toxin A-chain. By subsequently incubating the cells with labeled sulfate, those molecules that had been transported to the Golgi apparatus were selectively labeled. In other experiments where glycosylation sites were also engineered into the protein, it could be demonstrated that the labeled protein was partly glycosylated and that part of the A-chain molecules could be recovered from the cytosol (Rapak *et al*., 1997). Importantly, mainly the glycosylated form was found in the cytosol, indicating that only molecules that had been in the ER were translocated. It is therefore likely that the ER is the site of translocation. Calreticulin appears to be involved in the transport of ricin from the Golgi to the ER (Day *et al*., 2001).

This conclusion has become even more likely since it was found that misfolded export proteins are translocated retrograde from the ER to the cytosol where they become degraded by the proteasomes (Hiller *et al*., 1996; Knop *et al*., 1996; Werner *et al*., 1996). A membrane-associated ubiquitinating enzyme appears to be important for this process. It is conceivable that toxins such as ricin utilize this transport mechanism to penetrate the ER membrane. If that is so, the toxin must somehow avoid degradation by the proteasomes.

It was indeed found that ricin A-chain that had been glycosylated in the ER interacted with sec61p (Wesche *et al*., 1999). Evidence that this pathway is used for ricin and cholera toxin was also obtained (Simpson *et al*., 1999; Schmitz *et al*., 2000; Teter *et al*., 2002).

A yeast killer toxin, K28, also requires retrograde transport to the ER where it is translocated into the cytosol by a mechanism requiring Sec61 and luminal chaperones (Eisfeld *et al*., 2000). The internalized toxin irreversibly blocks DNA synthesis.

Very recently, evidence has appeared that retrograde translocation of misfolded proteins from the ER to the cytosol involves the transmembrane protein Derlin-1(Lilley and Ploegh, 2004; Ye *et al*., 2004). It will be interesting to see if this protein is also involved in the translocation of toxins.

## STABILITY OF TOXINS IN THE CYTOSOL

When wild type diphtheria toxin A-fragment was microinjected into cells, it proved to be exceptionally stable. The natural A-fragment has an N-terminal glycine residue that is stabilizing according to the N-end rule. However, even placing a destabilizing amino acid at the N-terminus of the A-fragment did not result in very rapid degradation. However, when a Flag-peptide was fused to the N-terminus, the N-terminal amino acid became very important for the stability (Falnes *et al*., 1998). When, in this case, a destabilizing amino acid was placed N-terminally, the toxic effect of the molecule was strongly reduced.

A survey of A-chains that are translocated to the cytosol revealed that there was not a strong tendency to avoid destabilizing amino acids at the N-terminal end. A possible reason for this is that a lysine residue that could serve as a target for ubiquitinylation is not present in a favorable distance from the N-terminus. When a lysine was inserted into ricin A-chain at a position favorable for ubiquitinylation, ricin was less toxic than the wild type toxin (Deeks *et al*., 2002). In fact, it appears that toxins that may be translocated from the ER and therefore exposed to the membrane-bound ubiquitinylating enzyme contain very few lysine residues, whereas diphtheria toxin, which is translocated from endosomes and therefore possibly less exposed to ubiquitinylation, contains a normal amount of lysines (Hazes and Read, 1997).

We found that ricin translocated to the cytosol accumulates to a larger extent in the presence of lactacystin that inhibits the proteasomes than in its absence (Wesche *et al*., 1999). Therefore, some degradation of the translocated ricin apparently takes place in the absence of the inhibitor. In accordance with this, the cells were also somewhat sensitized to ricin in the presence of lactacystin.

## TRANSLOCATION OF FUSION PROTEINS

It is an old concept that antibodies could be used to target toxins to cells of interest, such as cancer cells (Ehrlich, 1957; Olsnes, 2004). Originally, it was thought that it is sufficient that the antibody is efficient in targeting the molecule to the surface of the target cells. From our present knowledge, this is only part of the problem.

Immunotoxins may consist of an antibody linked to a whole toxin or only to its enzymatically active effector part. In the first case, the selectivity is usually low as the conjugate will bind to the toxin receptors in addition to

the target for the antibody. Higher selectivity is often obtained by linking only the effector moiety of the toxin to the antibody (Olsnes *et al*., 1989). However, in this case the conjugate does not have a translocation moiety, and it is dependent upon the translocation ability of the target cells. It is likely that in this case the conjugate must be transported to the ER for translocation to take place. This means that the antibody must be directed against a cell surface molecule that is able to direct the conjugate retrograde to the ER. So far no such protein has been described, whereas in the case of lipids such transport appears to take place. A number of natural toxins are, in fact, bound to cell surface lipids.

In the future design of immunotoxins, it will be advisable to look for molecules that are able to route the conjugate retrograde or to crosslink the receptor to another molecule that is able to direct the whole complex to the ER. A chimeric antibody reacting with both a cell-specific antigen and a molecule that is targeted to the ER could be able to carry out this task.

A more recent development in the field of toxin applications is to use toxins or their mutated, non-toxic counterparts to carry peptides into the cytosol for presentation by MHC class I molecules (Stenmark *et al*., 1991). There is a continuous breakdown of proteins in the cytosol, and some of the peptides produced by the proteasomes in this process are transported into the ER by the TAP transporters (Römisch, 1994) and become bound to newly synthesized MHC class 1 proteins. The complex, together with β2-microglobulin, is transported to the cell surface where it is presented to cytotoxic lymphocytes that recognize the complex if it contains a peptide not present in the normal complement of proteins. Foreign proteins that appear in the cytosol, such as viral proteins, and mutated autologous proteins, such as in cancer, are also broken down. Furthermore, when their peptides are presented at the cell surface, they are recognized as foreign, and the cell is destroyed before the virus can multiply or before the malignant cell can develop into a tumor. Exposure to a foreign peptide presented in this way leads to expansion of the relevant cytotoxic T-cell clone, i.e., an immunization effect.

It has been difficult to obtain a vaccination effect in the MHC class 1 system because the protein in question must be transported to the cytosol to be chopped up by the proteasomes into suitable pieces to bind to the MHC class 1 molecules. The property of protein toxins to enter the cytosol opened up the possibility using toxins as carrier molecules to transport passenger peptides and proteins into the cytosol (Stenmark *et al*., 1991; Wiedlocha *et al*., 1992; Klingenberg and Olsnes, 1996; de Haan and Hirst, 2002). The possibility of detoxifying the molecules without depriving them of their ability to be translocated could allow the development of a vaccine that does not have the potential side effects inherent in the use of attenuated viruses and injection of nucleic acids.

In attempts to test out the principle, various peptides that are known to be presented by MHC class 1 molecules were fused to the N-terminus of the A-fragment of diphtheria toxin. After binding the recombinant toxins to cells, it was possible to induce translocation of the fusion proteins into the cytosol in good yield (Stenmark *et al*., 1991). Attempts to demonstrate presentation by class 1 molecules were, however, unsuccessful.

Later, it was shown with anthrax toxin and with *Bordetella pertussis* invasive adenylate cyclase that peptides fused to the toxins are indeed able to induce a class 1 immune response in mice (Ballard *et al*., 1996; Ballard *et al*., 1998; Saron *et al*., 1997; Lu *et al*., 2000). This indicates, but does not prove; that the toxins transported the peptides to the cytosol by the toxin pathway. As mentioned previously, it now appears that proteins that are misfolded in the ER are translocated backwards into the cytosol where they are degraded by the proteasomes. Clearly, therefore, if a fusion protein is transported retrograde to the ER, it may be transported into the cytosol either as a conjugate with the toxin or after partial proteolytic degradation that could take place either at the level of endosomes in the Golgi apparatus or in the ER.

Whole proteins, such as acidic fibroblast growth factor (Wiedlocha *et al*., 1992), dihydrofolate reductase (Klingenberg *et al*., 1996), and a second A-fragment of diphtheria toxin (Madshus *et al*., 1992) can be translocated into cells by the toxin pathway. Unfortunately, most whole proteins that were fused to the toxin were not translocated (Wesche *et al*., 1998). Apparently, the reason for this is that the proteins must be able to unfold at low pH to follow the A-fragment across the membrane, and most proteins are not able to do this.

CHAPTER

# 8

# Intracellular trafficking of bacterial and plant protein toxins

*Christophe Lamaze and Ludger Johannes*

## INTRODUCTION

Intracellular trafficking is a very general but tightly regulated process used by a variety of molecules to cross the membranes of living cells. This process is therefore crucial to a large group of bacterial and plant toxins that need to be translocated to the cytosol where their intracellular targets are located. As most toxins use pre-existing transport pathways, the study of these pathways has contributed to the identification and understanding of several novel transport mechanisms in mammalian cells, including endocytosis and intracellular distribution pathways. Over the last 10 years, tremendous progress has been made in the characterization of multiple endocytic processes together with the intracellular distribution of endocytosed molecules.

In this chapter, we will address the molecular mechanisms used by selected toxins for their endocytosis and intracellular distribution in mammalian cells. Whether these toxins inhibit protein synthesis (diphtheria toxin (DTx), Shiga toxin and Shiga-like toxin (STx and SLTx), ricin, and *Pseudomonas aeruginosa* exotoxin A (PEx)) or cell signaling events (cholera toxin (CTx), the *Escherichia coli* heat-labile toxin (LTx), pertussis toxin (CyaA), and anthrax toxin), they all rely on endocytosis and intracellular transport to gain access to the cytosol where they exert their poisonous action.

## GENERAL CONSIDERATIONS

The toxins described here are also called *A-B toxins*, as they are composed of a catalytically active A-subunit covalently or non-covalently bound to the B-subunit. Only the B-subunit is necessary for the binding, uptake, and cellular trafficking of the holotoxin. Very low concentrations of these toxins are required to induce toxicity, and very few internalized molecules are sufficient to kill the cell. For instance, one ricin molecule can inactivate 2,000 ribosomes in one minute and one molecule of the DTx catalytic fragment A can kill a cell in two days (Yamaizumi *et al*., 1978). This characteristic must be considered when studying the endocytosis of toxins, as most inhibitors used to block known endocytic routes still allow the entry of a few molecules. This is particularly a problem for toxins that cannot be labeled with probes used to trace internalized cargos and that can only be detected via their cytotoxic effect.

## CELL SURFACE RECEPTORS

The first membrane step in endocytosis is the binding of exogenous molecules to a cell surface receptor. The identification of toxin receptors provides important information as many characteristics of toxin transport are determined by the nature and the specific localization of the receptor. For instance, ricin, produced by the plant *Ricinus communis*, binds to galactose residues present in many glycoproteins and glycolipids, and as a result can interact with multiple sites of the plasma membrane. Hence, ricin is internalized by every operating endocytic pathway available and serves as a marker of overall cell endocytic activity. Most toxins bind to more restricted receptor structures. The

receptors of some toxins have not yet been identified. This is true for cytotoxic necrotizing factor 1 (CNF1), a type III single-chain toxin molecule (Falbo *et al*., 1993) that is produced by uropathogenic *E. coli* strains (Cid *et al*., 1996). CNF1 induces ruffling of eukaryotic cell membranes, actin stress fiber formation, and spreading and multinucleation through the permanent activation of the small GTPase Rho. CNF1 binds tightly to a yet unidentified cell surface receptor. The first 190 amino-terminal residues of the single chain toxin are necessary for its binding to the cell surface (Fabbri *et al*., 1999).

Some toxins, such as STx, CTx, and closely related LTx, bind to lipids, whereas others bind to transmembrane protein receptors. In the latter group, *Pseudomonas* exotoxin A binds to the low-density lipoprotein receptor-related protein (LRP) via its domain IV (Kounnas *et al*., 1992). Like the LRP receptor, PEx is probably also endocytosed by the clathrin-coated pit pathway (Conner and Schmid, 2003). *Bordetella pertussis*, the agent responsible for whooping cough, secretes an adenylate cyclase toxin (CyaA) that is one of the major virulence factors of this organism. After cell invasion, CyaA activates endogenous calmodulin and increases cAMP production in a non-regulated manner. It was recently demonstrated that CyaA uses the alpha (M)beta(2) integrin (CD11b/CD18) as a cell receptor and that the increase in intracellular cAMP level following CyaA intoxication can be specifically inhibited by anti-CD11b monoclonal antibodies (Guermonprez *et al*., 2001). It was subsequently shown that the acylation of CyaA is required for the interaction of the toxin with cells expressing CD11b and that the main integrin interacting domain of CyaA is located in its glycine/aspartate-rich repeat region (El-Azami-El-Idrissi *et al*., 2003). The uptake mechanism used by CyaA is unknown, but it is likely that the integrin receptor and its bound toxin are also endocytosed through clathrin-coated pits, as is the case for most integrins. The entry pathway used by CyaA may not be important for its translocation, as CyaA reaches the cytosol directly from the plasma membrane (Rogel and Hanski, 1992).

Some toxins, such as the anthrax toxin, have developed more sophisticated ways of entering cells. The anthrax toxin is one of two virulence factors produced by *Bacillus anthracis* (Leppla, 1988). This toxin consists of three subunits: edema factor (EF), the lethal factor (LF), and the protective antigen (PA). These three subunits interact in a complex manner that conditions toxin entry and toxicity (Kurzchalia, 2003). PA is an 83 kD protein (PA83) that is required for the recognition and the cellular transport of subunits EF and LF. PA binds to a widely expressed transmembrane receptor of 368 amino acids termed ATR for Anthrax Toxin Receptor (Bradley *et al*., 2001). After binding to ATR, PA is cleaved at the cell surface by furin proteases, resulting in a 63 kD form of PA that remains bound to ATR. This cleavage is crucial as it confers two new properties that determine subsequent toxicity. First, PA63, unlike PA83, can oligomerize to form heptamers, a state required for their association with EF and LF at the cell surface (Cunningham *et al*., 2002; Mogridge *et al*., 2001; Singh *et al*., 1994). Second, PA63 is endocytosed together with EF and LF, whereas PA83 remains at the cell surface (Milne *et al*., 1994).

The binding of some toxins to the cell surface requires the expression of specific lipids. The best-characterized lipid-binding toxins are Shiga toxin (STx), produced by *Shigella dysenteriae*, and cholera toxins (CTx), produced by *Vibrio cholerae*, which respectively bind to cells expressing Gb3 and GM1. The heat-labile toxin (LTx), which is closely related to CTx and produced by some strains of *Escherichia coli*, also uses the glycolipid GM1 as a receptor. Type II LTx toxins also bind to the GD1a and GD1b glycosphingolipids. The binding of these pentameric toxins can result in the clustering of the glycolipids, and it has been shown that CTx binding can lead to the relocalization of GM1 to raft-type membrane microdomains (see below) (Harder *et al*., 1998; Spiegel *et al*., 1984). STx, which also has a pentameric B-subunit and binds to the glycolipid receptor Gb3, is also constitutively localized to this type of microdomain (Falguières *et al*., 2001; Katagiri *et al*., 1999; Kovbasnjuk *et al*., 2001). Interestingly, the proportion of Gb3-bound STx associated with lipid rafts differs from cell to cell and may be an important determinant for the intracellular targeting of the toxin (Falguières *et al*., 2001) (see below). As GM1 is found in both caveolae and lipid rafts, it was assumed that CTx was internalized by these structures. However, several groups have shown that CTx and STx can also be endocytosed by clathrin-coated pits (see below). How CTx and STx are recruited into clathrin-coated pits and the role of lipid clustering in this recruitment need to be determined to understand the trafficking of these toxins. Recent data have confirmed that STx can be efficiently endocytosed in cells devoid of functional clathrin-coated pits (Saint-Pol *et al*., 2004). The role and the importance of this alternative endocytic pathway in cell intoxication by STx have yet to be determined.

## MULTIPLE ENDOCYTIC PATHWAYS OPERATE IN MAMMALIAN CELLS

It was long assumed that endocytosis involving the formation of clathrin-coated pits and vesicles was the only

efficient process for the internalization of exogenous molecules bound to their specific transmembrane receptors. Several recent reviews have described the enormous progress that has been made in the last 10 years in the molecular understanding of the clathrin-dependent pathway (Brodsky *et al*., 2001; Owen *et al*., 2004; Rappoport *et al*., 2004). Nevertheless, it has been known for almost 20 years that some toxins can enter cells by means other than the well-described clathrin-dependent endocytosis (Montesano *et al*., 1982; Moya *et al*., 1985; Tran *et al*., 1987). Since these pioneering studies, our understanding of the molecular mechanisms involved in these so-called clathrin-independent endocytic pathways has not progressed much. Paradoxically, it is the recent progress in the understanding of clathrin-dependent endocytosis that has made the largest contribution to our understanding of clathrin-independent endocytosis (see Figure 8.1) (Johannes and Lamaze, 2002). There is no longer any doubt about the existence and the importance of these alternative pathways, which constitute a major portal of entry for many toxins. After a brief summary of the main characteristics of each of the known endocytic systems operating in mammalian cells, we will examine how different toxins

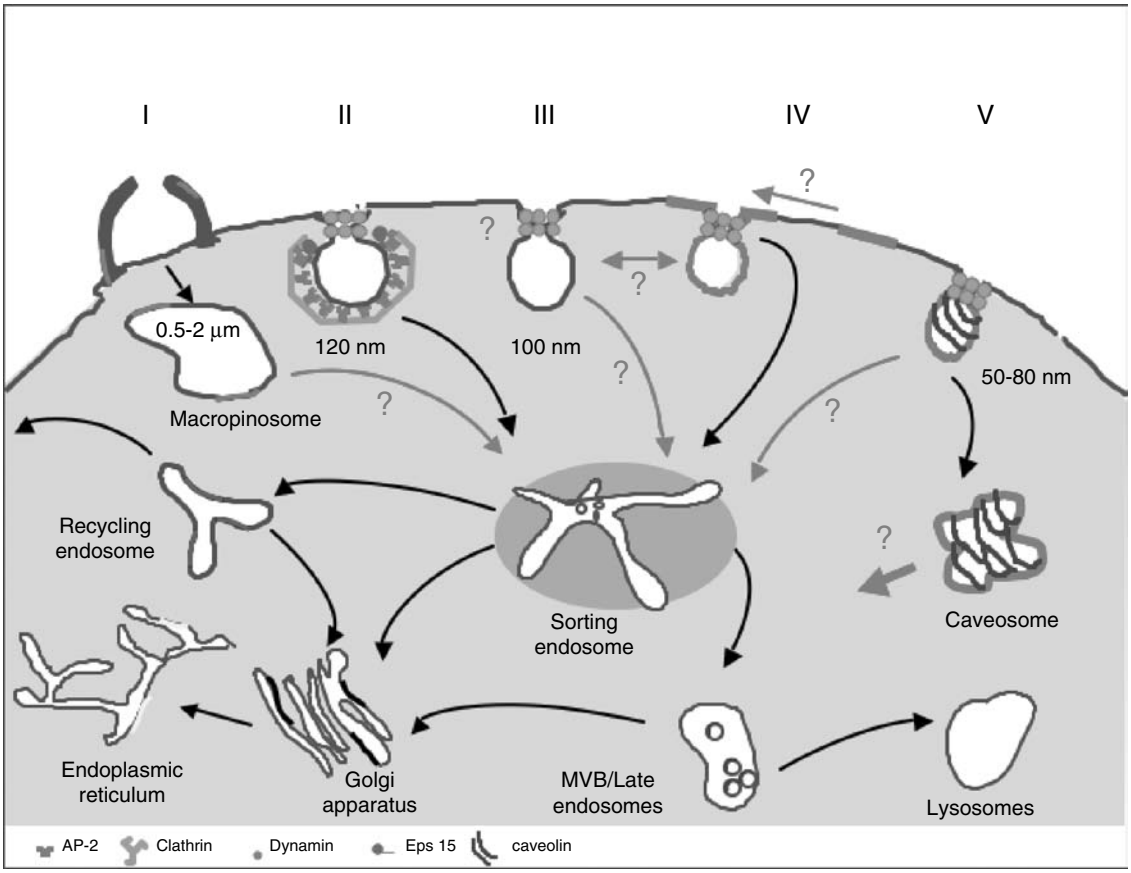

**FIGURE 8.1** Multiple endocytic pathways operate in mammalian cells. Besides the best-characterized clathrin-dependent endocytosis (II), several clathrin-independent endocytic pathways have been identified by molecular and morphological means and represent potential carriers for toxins delivery in the cell. Macropinocytosis (I) is a transient response to growth factors and mitogenic agents that contributes to fluid phase uptake through the formation of large vesicles of heterogeneous size. Non-coated invaginations (III) that pinch off to form smooth vesicles are commonly observed by conventional microscopy in different cell types and participate to fluid phase uptake. Certain lipid-based membrane microdomains including rafts (IV) and caveolae (V) are enriched in cholesterol and glycosphingolipids. Caveolin is an integral caveolar protein that gives a striated aspect to caveolae and allows us to distinguish them from other smooth invaginations. Caveolar endocytosis is mostly induced and can lead to the formation of "caveosomes" from which endocytosed molecules (SV40, CTx) could reach the endoplasmic reticulum and/or the nucleus. While it is not known whether lipid rafts tubulate or vesiculate to form smooth vesicles similar to (III), the vesicle budding GTPase dynamin is involved in clathrin-dependent endocytosis and some, but not all clathin-independent endocytosis. Black arrows represent established intracellular tracks whereas pathways with question marks have been less investigated (adapted from Johannes and Lamaze, 2002).

use these routes to enter cells. It should be noted, however, that most toxins can use several entry pathways and that endocytic plasticity is a trait common to many known toxins.

## CLATHRIN-DEPENDENT ENDOCYTOSIS

Clathrin-dependent endocytosis was first visualized in mosquito oocytes by electron microscopy 40 years ago (Roth and Porter, 1964). It is the oldest and the best-understood endocytic process in mammalian cells. Clathrin-dependent endocytosis is a constitutive process that begins with the concentration of high-affinity transmembrane receptors into specialized plasma membrane invaginations coated with clathrin (Brodsky *et al*., 2001; Owen *et al*., 2004; Rappoport *et al*., 2004). The coat proteins, clathrin and AP2, are the minimal machinery required to concentrate internalized molecules and to form a vesicle. The final step in clathrin-dependent endocytosis involves the dynamin GTPase, which is required for the release of cargo-loaded coated vesicles from the plasma membrane (Damke *et al*., 1994). Many other "accessory proteins" involved in the regulation of this process have been characterized in the last 10 years (Brodsky *et al*., 2001; Slepnev and De Camilli, 2000). Although it is classically thought that molecules internalized via clathrin-dependent endocytosis are either recycled to the plasma membrane or degraded via the late endosomal/lysosomal pathway, STx and CTx can be internalized through clathrin-coated pits and nevertheless escape the degradative pathway by going to the Golgi apparatus in a retrograde manner. These toxins can also use clathrin-independent endocytosis to enter the cells (see below). There are relatively few toxins that only undergo clathrin-dependent endocytosis. The best example is diphtheria toxin (DT), secreted by *Corynebacterium diphtheriae*. Morris *et al*. (1985) first showed that in the absence of functional coated pits, diphtheria toxin is unable to intoxicate Vero cells. Later work confirmed the entry of DTx by clathrin-mediated endocytosis and its trafficking into early endosomes where it translocates to its cytosolic target from acidic endosomes (Collier, 2001; Madshus *et al*., 1991; Simpson *et al*., 1998).

## CLATHRIN-INDEPENDENT PATHWAYS

The term *clathrin-independent endocytosis* includes a variety of endocytic mechanisms that are still poorly characterized at the molecular level and therefore are often described by negative properties. Classically, clathrin-independent endocytosis includes phagocytosis, macropinocytosis, and caveolar or non-caveolar lipid rafts (see Figure 8.1); (Johannes and Lamaze, 2002).

### Macropinocytosis and phagocytosis

Macropinocytosis is a ruffling-driven process that leads to the formation of large and irregularly sized endosomes in response to growth factors and other stimuli (Amyere *et al*., 2002). Macropinocytosis has never been shown to be involved in the entry of toxins *per se*, although it is likely that toxins such as ricin that bind to receptors present at most membrane sites (see above) are also present in macropinosomes together with general markers of endocytosis. Whether this entry can lead to a specific intracellular location or is associated with specific functions is not known. Macropinocytosis may play a more indirect role in the pathogenesis of toxin-secreting bacteria. For instance, toxins such as CNF1 secreted by *E. coli* activate Rho-GTPases, which in turn enhances macropinocytosis and therefore the uptake of pathogens (Steele-Mortimer *et al*., 2000). Phagocytosis, which allows the engulfment of solid particles by the cell, is not relevant to the entry of toxins and will not be discussed here.

### Caveolae

Although the role of caveolae in endocytosis is still debated, caveolae remain the best-characterized example of non-clathrin carriers present at the plasma membrane of many different cells. Their typical omega-like shape and their abundance in endothelial cells facilitated their identification. Indeed, they were identified in the early 1950s, almost 10 years before the discovery of clathrin-coated pits (Palade, 1953). These small (60 nm) plasma membrane invaginations are rich in cholesterol and sphingolipids, and represent a subset of lipid microdomains. Their particular lipid composition makes them sensitive to cholesterol depletion, a property shared with non-caveolar lipid rafts (see below) and to some extent with clathrin-coated pits (Rodal *et al*., 1999).

The structural and biological properties of caveolae are conferred by caveolin, a cholesterol-binding protein that distinguishes caveolae from other lipid microdomains. Caveolae have many functions, which have been extensively described in recent reviews. One of the most debated functions remains their contribution to clathrin-independent endocytosis (Nabi and Le, 2003; Parton and Richards, 2003; Pelkmans and Helenius, 2002). There are several reasons why the role

of caveolae in endocytosis is debated. First, in contrast with clathrin-coated pits, caveolin and morphologically detectable caveolae are not present in all cell types (Fra *et al*., 1994). Second, fluorescence recovery after photobleaching (FRAP) analysis of GFP-tagged caveolin has shown that caveolae are rather immobile structures at the plasma membrane (Thomsen *et al*., 2002), a property incompatible with an active role in constitutive endocytosis. However, recent studies using new approaches, such as expression of dominant negative mutants of caveolin or generation of caveolin-null mice, have provided new insight into the potential role of caveolae in endocytosis (Parton and Richards, 2003).

The complex role of caveolae in ligand uptake is best illustrated by the endocytosis of opportunistic ligands, such as viruses or toxins. Simian virus 40 (SV40) and CTx are the best-studied caveolar ligands, and both can be transported by caveolar endocytosis to caveosomes, a specialized subset of caveolin-1-positive endosomes with neutral pH (see below); (Pelkmans *et al*., 2001). CTx is a selective ligand for caveolar and non-caveolar lipid rafts, as shown by the sensitivity of its cytotoxicity to cholesterol-disrupting agents (Orlandi and Fishman, 1998; Wolf *et al*., 1998). Electron microscopy studies carried out in the early 1980s showed that gold-conjugated CTx bound to the GM1 glycolipid in smooth invaginations on the plasma membrane (Montesano *et al*., 1982; Tran *et al*., 1987). A few years later, it was shown that CTx did not bind uniformly in A431 cells and liver cells, and electron microscopy revealed the presence of caveolae. The presence of gold-conjugated CTx in early endosomes after warming the cells suggested that the toxin was internalized by caveolae (Parton, 1994). The finding that the dynamin GTPase, an actor of the clathrin-dependent machinery, was also associated with caveolae and required for their detachment further suggested that these organelles play a role in endocytic events (Henley *et al*., 1998; Oh *et al*., 1998). The endocytic potential of caveolae for toxins was also demonstrated by their ability to release CTx-loaded vesicles in a cell-free assay (Gilbert *et al*., 1999).

The fact that cells devoid of caveolae are still sensitive to the toxicity of CTx raised questions about the role of caveolae in CTx endocytosis and pathology (Nichols *et al*., 2001; Orlandi and Fishman, 1998; Torgersen *et al*., 2001). In the absence of caveolae, the internalization and toxicity of CTx relies on non-caveolar lipid microdomains because cholesterol depletion with methyl beta-cyclodextrin reversibly inhibits CT-induced chloride secretion and delays CTx endocytosis and toxicity (Wolf *et al*., 2002). Another study suggested a link between toxicity and sorting at the plasma membrane (Wolf *et al*., 1998). In this work, the authors compared the requirements for the toxicity of CTx and the closely related LTx enterotoxin from *E. coli*. Whereas CTx, which binds to GM1 in intestinal epithelial cells, was present in biochemically defined rafts, LTx, which binds to the glycolipid GD1a, was found in non-raft fractions. Although both toxins bear similar catalytic subunits, only raft-associated CTx was able to elicit a cAMP response. Whether this differential effect on toxicity is due to raft-dependent differences in trafficking or in signaling is not known (see below). Another layer of complexity is added by the possibility for CTx to be internalized by clathrin-coated pits in several cell types (Massol *et al*., 2004; Nichols, 2002; Shogomori and Futerman, 2001; Torgersen *et al*., 2001). The entry of CTx through clathrin-dependent endocytosis is consistent with the presence of GM1 in clathrin-coated pits (Parton, 1994). It should be pointed out that the natural distribution of the GM1 glycolipid is likely to be modified by the multivalence of CTx, as toxin-induced relocalization of GM1 to caveolar microdomains has been observed (Harder *et al*., 1998; Spiegel *et al*., 1984). Electron microscopy examination of cell sections after low-temperature embedding revealed a weaker concentration of GM1 in caveolae than in clathrin-coated pits. In contrast, CTx binding to GM1 induced the redistribution of GM1 to caveolae (Parton, 1994). These data were recently confirmed by fluorescence resonance energy transfer (FRET) on living cells, showing that CTx-induced GM1 clusters were excluded from clathrin-coated pits (Nichols, 2003).

Whereas these results question the role of clathrin-coated pits in the uptake of CTx, other studies point out some cell type specificities. For example, in hippocampal neurons, CTx bound to GM1 was found in lipid microdomains and Ctx endocytosis was blocked by inhibitors of clathrin-dependent endocytosis, whereas filipin and cyclodextrin, two compounds known to destabilize these microdomains, had no effect (Shogomori and Futerman, 2001). These authors proposed that CTx is internalized either through clathrin-coated pits after escaping from lipid rafts or directly after the diffusion of lipid rafts into clathrin-coated pits. This model was recently validated for the uptake of the anthrax toxin (see below). Finally, the endocytic "equipment" of the cell may affect toxin sorting at the plasma membrane. For example, CtxB is internalized via clathrin-independent endocytosis in cells with high caveolin-1 expression, whereas significant clathrin-dependent uptake occurs in cells with low caveolin-1 expression (Singh *et al*., 2003). This study also showed that fluorescent GM1, normally internalized by clathrin-independent endocytosis in HeLa cells with low caveolin-1 expression, is partially

internalized via the clathrin pathway in the presence of CTx. Accordingly, several studies have shown that caveolin-1 overexpression inhibits rather than stimulates clathrin-independent endocytosis (Le PU *et al*., 2002; Minshall *et al*., 2000; Sharma *et al*., 2004a). Likewise, the amount of GM1 present at the plasma membrane can determine the route by which CTx is endocytosed; CTx endocytosis is sensitive to cholesterol depletion when high levels of GM1 are expressed, whereas cholesterol depletion has a minor effect in cells expressing low levels of GM1 (Pang *et al*., 2004).

These results suggest that CTx can switch internalization pathways according to the number of caveolae and/or the amount of GM1 present at the plasma membrane. However, the role of this endocytic plasticity and, more particularly, of clathrin-dependent endocytosis in the toxicity of CTx remain to be determined. The complex relationship between CTx and endocytosis has not yet been resolved totally because Parton's group recently characterized a third pathway for the uptake of CTx that involves some new endocytic carriers other than clathrin-coated pits and caveolae (see below) (Kirkham *et al*., 2005).

STx, which, like CTx, relies on glycolipid binding for its uptake and toxicity, has also been shown to enter host cells through clathrin-independent endocytosis (Nichols *et al*., 2001; Puri *et al*., 2001; Saint-Pol *et al*., 2004) (see below). Although the Gb3 ceramide (CD77), the STx gycolipid receptor, has been found associated with Triton X-100-resistant membranes in HeLa cells (Falguières *et al*., 2001), it is not known whether these microdomains include caveolae and whether caveolae are involved in the uptake of STx.

## Caveolae-independent mechanisms

Caveolae are just one example of the cholesterol-rich microdomains found in the plasma membrane. There is an increasing amount of evidence supporting the raft hypothesis, i.e., the organization of the plasma membrane into sphingolipid- and cholesterol-enriched microdomains (Brown and London, 2000; Johannes and Lamaze, 2002; Sharma *et al*., 2002; Simons and Ikonen, 1997). A recent study has shown that microdomains of the raft type are very small (within the nanometer range) and highly dynamic structures that are capable of self-assembly for specific sorting of membrane proteins and glycolipids (Sharma *et al*., 2004b). Although the functional role of lipid-based membrane microcompartmentalization is currently a subject of intense debate (Munro, 2003) and much work is still needed to characterize these membrane structures, there is evidence suggesting a role for noncaveolar rafts in endocytosis (Johannes and Lamaze, 2002; Lamaze *et al*., 2001; Nabi and Le, 2003; Sharma *et al*., 2002). Due to their small size, it has been suggested that lipid rafts can be internalized by any endocytic vesicles.

This is best illustrated by the interleukin-2 receptor, which is also associated with lipid microdomains and is internalized in a clathrin- and caveolin-independent manner (Lamaze *et al*., 2001). This pathway still shares some mechanistic similarities with caveolar and clathrin-dependent endocytosis because IL-2 uptake requires the activity of the dynamin GTPase. A similar clathrin- and caveolae-independent endocytic pathway was recently described for the uptake of glycosylphosphatidylinositol (GPI)-anchored proteins through so-called GEECs (GPI-AP-enriched early endosomal compartments) (Sabharanjak *et al*., 2002). In this case, however, endocytosis of GFP-tagged GPI occurs via a dynamin-independent and CDC42-regulated pathway. Whether some toxins can also follow the interleukin-2 pathway is not yet known, but recent data have shown that CTx can enter cells through the GPI-AP pathway (see below). Another entry mechanism was recently characterized for the signaling and the internalization of immune receptors, including the T cell and the B cell receptors (BCR) (Crotzer *et al*., 2004; Dykstra *et al*., 2001; Stoddart *et al*., 2002). These authors suggested that BCR uptake occurs in different B cell lines only when clathrin is associated with rafts and is tyrosine phosphorylated by the Src kinase upon cross-linked BCR-induced association with lipid rafts.

The anthrax toxin is another example of a toxin that is taken up via clathrin-coated pits and lipid rafts. In this case, however, both pathways must be coordinated for the efficient entry of the toxin and intoxication of the host cell (Abrami *et al*., 2003; Kurzchalia, 2003). As described earlier, it is only after processing PA83, the so-called anthrax receptor (ATR) (Bradley *et al*., 2001), by furin family proteases that PA63 forms heptamers, allowing the entry of EF and LF (Cunningham *et al*., 2002; Petosa *et al*., 1997). Abrami and collaborators (Abrami *et al*., 2003) provided interesting new insight into the role of lipid rafts in the entry of the cleaved form of PA83. The major finding of this work is that ATR bound to heptameric PA63 but not to monomeric PA83 is associated with biochemically defined lipid rafts, i.e., detergent-resistant membranes. It appears that oligomerization of PA63 is essential, as artificial antibody-induced cross-linking of PA83 also leads to the association with lipid rafts. When cross-linked and associated with lipid rafts, the complex is internalized more efficiently than monomeric PA83. Although the association with lipid rafts is consistent with cholesterol-dependent entry, such as caveolae, the use of selective inhibitors of clathrin-dependent endocytosis

revealed that the PA63/EF/LF complex is internalized by clathrin-dependent endocytosis. In this context, the endocytic properties of anthrax toxin are similar to what was described for the B cell and the T cell receptors. As already mentioned, CTx may be taken up through a similar process in neuronal cells (Shogomori and Futerman, 2001). Whether ligand-induced oligomerization of anthrax or CTx also requires the activity of the src kinase, as described for these receptors, is not known. These examples reveal the tight interplay between lipid rafts and the clathrin machinery, and the complex nature of the endocytosis of toxins.

The observation that STx, which also binds raft-associated Gb3, can be internalized through clathrin-coated pits (Sandvig *et al*., 1989) raises the possibility that STx uptake can occur by one of the above-mentioned mechanisms. However, recent evidence does not support a model in which Gb3-bound STx is first associated with rafts and then internalized through clathrin-coated pits as described for the anthrax toxin. Indeed, a detailed analysis of the role of clathrin in STx internalization and intracellular transport has shown that STx is taken up normally in cells where clathrin function was inhibited (Saint-Pol *et al*., 2004). These data suggest that STx can enter cells by clathrin-dependent and/or -independent pathways. Whether clathrin-independent endocytosis operates in response to the inhibition of clathrin-dependent endocytosis, as shown for fluid phase markers in HeLa cells (Damke *et al*., 1995), or coexists with clathrin-dependent endocytosis is not known. Likewise, the contributions of each pathway in the overall uptake of STx and cell toxicity and the role of Gb3 binding in targeting each pathway have not yet been elucidated.

The endocytosis of STx appears to be independent from the dynamin GTPase (Lauvrak *et al*., 2004), a characteristic that distinguishes STx uptake from that of the IL-2 receptor and to a lesser extent from CTx internalization because CTx uptake is reduced by 50% in dynamin-inactivated cells (Torgersen *et al*., 2001). Most of the studies on clathrin-independent endocytosis used non-selective pharmacological inhibitors; this lack of selectivity has hampered the thorough molecular characterization of the alternate pathways (Johannes and Lamaze, 2002). Likewise, very few ultrastructural studies have addressed the morphological properties of these alternative pathways. Recently, however, Parton's group used quantitative light microscopy and a modified immunoelectron microscopic technique to characterize the entry pathway of CTx in primary embryonic fibroblasts (Kirkham *et al*., 2005). While this study showed that CTx can be internalized by clathrin-coated pits and caveolae, it indicated that CTx was rather trapped in caveolae, supporting the static role of caveolae previously demonstrated in some cell types (Thomsen *et al*., 2002). More importantly, this study revealed that 50% of CTx was efficiently transported through some uncoated tubular or ring-shaped structures also containing GPI-anchored proteins and fluid phase markers. Interestingly, the molecular characterization of this pathway revealed that the novel caveolae- and clathrin-independent tubular/ring-like carriers identified in these cells are indeed the same structures, GEECs, shown to be involved in the cdc42-dependent uptake of GPI-APs and fluid phase markers described earlier in this review (Sabharanjak *et al*., 2002). The particular role of this pathway in the cytotoxicity of CTx has not yet been documented. It will be interesting to determine whether STx, which shares many characteristics with CTx, including dynamin-independent entry and dynamin-dependent endosome to Golgi transport (Lauvrak *et al*., 2004), can also use this pathway.

About 50% of so-called fluid phase endocytosis would occur in the absence of functional clathrin-coated pits or in dynamin-inactivated cells (Cupers *et al*., 1994; Damke *et al*., 1995). It is likely that fluid phase endocytosis encompasses more examples of pinocytic uptake than the dynamin-independent pathways described above and that other, as yet uncharacterized, pinocytic pathways exist in mammalian cells. The uptake of the CNF1 toxin might occur via one of these uncharacterized pathways. Thus, in Hep-2 cells, the cytotoxicity of CNF1 is not blocked by filipin, a compound that reduces cholera toxin internalization by the caveolae-like mechanism (Contamin *et al*., 2000). Furthermore, Hep-2 cells, which contain proteins that inhibit the formation of clathrin-coated vesicles, are still sensitive to CNF1. After internalization by both clathrin- and caveolae-like-independent pathways, CNF1 is subsequently transferred to an endosomal compartment by a microtubule-dependent mechanism. CNF1 requires an acidic cell compartment to transfer its enzymatic activity into the cytosol in a manner similar to that required by diphtheria toxin. CNF1 is therefore the first bacterial toxin described that uses both a clathrin-independent endocytic mechanism and an acid-dependent membrane translocation step for delivery of the catalytic domain to the cytosol.

## INTRACELLULAR DISTRIBUTION PATHWAYS

Although numerous toxins, e.g., cholera and Shiga toxin, can enter cells by clathrin-dependent and independent mechanisms (see above), most of them are subsequently found in the transferrin receptor (TfR)-positive

"conventional" early endosome (EE). There are several subsequent sorting opportunities. Some toxins, such as ricin, recycle to the plasma membrane. Others, such as anthrax toxin, are efficiently targeted to the late endocytic pathway. Others, such as Shiga toxin, avoid recycling and degradation to reach other compartments in the cell using a recently discovered pathway termed the *retrograde route*. These different pathways are discussed in detail below (see also Figure 8.2).

## RECYCLING OF TOXINS TO THE PLASMA MEMBRANE

Proteins and lipids can recycle from endosomes back to the plasma membrane. Within the early endocytic pathway, two routes have been described using TfR as a prototypic recycling marker. In association with its receptor, some internalized Tf very rapidly returns to the plasma membrane with halftimes of around two minutes, depending on cell type. Another fraction remains associated with the cells longer and returns to the plasma membrane with halftimes of around 12 minutes. This slow recycling material is found in the pericentriolar region of many cells, often referred to as the *recycling endosome* (RE). As no general consensus currently exists on the terminology used to describe the early endocytic pathway, we will define the membrane structures that constitute the pathway.

The vacuolar organelles that result from the fusion of endocytic vesicles are often termed *early* or *sorting endosomes*. It is from these endosomes that recycling receptors return to the plasma membrane with very short halftimes (Mukherjee *et al*., 1997). Tubular membrane projections detach from these vacuoles, which, as part of their transformation process, start forming internal vesicles, the so-called multivesicular endosomes (Gruenberg and Stenmark, 2004). The tubular elements are often, but not always (for example, HeLa cells) (Lin *et al*., 2002), concentrated in the pericentriolar area, where they are called *RE*, due to the localization of recycling receptors to these structures. As mentioned above, recycling from RE is slower than recycling from peripheral early or sorting endosomes. There is some debate about whether the RE is an independent organelle. Considering: (i) that no single marker protein that can be used to distinguish RE from early or sorting endosomes has yet been described; (ii) that they recycle proteins to the plasma membrane in a similar way to early or sorting endosomes; (iii) and that it is likely that other sorting processes such as retrograde sorting to the TGN already start on early or sorting endosomes and continue on RE (see below), we prefer to consider the early endocytic membranes as one network and name them the *early/recycling endosomes* (EE/RE).

The mechanisms of sorting in the early endocytic pathway are still poorly understood. There is a general consensus that areas of high membrane-to-volume ratios, i.e., tubular structures, allow the retrieval of many receptors from vacuolar early or sorting endosomes that mature to become multivesicular late endosomes. Protein toxins are associated with membrane receptors, meaning they are prone to recycling. This is well documented for ricin (McIntosh *et al*., 1990). However, membrane association does not necessarily cause recycling. STx, for example, does not return to the plasma membrane (Mallard *et al*., 1998; Schapiro *et al*., 1998). How recycling is prevented is not yet known, but it is possible that association with raft type membrane microdomains is involved (see below).

## TOXIN TRAFFICKING TO LATE ENDOSOMES/ LYSOSOMES

A number of protein toxins use the endocytic pathway to reach a low pH environment that favors the translocation of their catalytic subunits to the cytosol. These toxins, such as diphtheria and anthrax toxins, are discussed in detail elsewhere in this book. A critical question is at what stage of the endocytic pathway these toxins cross membranes to release their catalytic chain into the cytosol. Several lines of evidence suggest that early endosomes are the site of translocation for the diphtheria toxin (Lemichez *et al*., 1997; Papini *et al*., 1993). Recent studies have shed new light on how endosomal subcompartmentalization can influence anthrax toxin translocation.

This work was made possible by the discovery of new elements of the endosomal sorting machinery that are involved in the formation of internal vesicles, the multivesicular endosomes (Gruenberg and Stenmark, 2004). One of these elements is the ALIX protein, which is involved in the regulation of the dynamics of late endosomal internal vesicles (Matsuo *et al*., 2004). The other element is a lipid, lysobisphosphatidic acid, antibodies to which also affect this process (Kobayashi *et al*., 1998). Interfering with ALIX or lysobisphosphatidic acid has distinct effects on the membrane translocation of diphtheria toxin and anthrax toxin, consistent with the following models (Abrami *et al*., 2004). Anthrax toxin is trapped in internal vesicles within multivesicular endosomes, and the catalytic lethal factor is transferred into the intravesicular lumen, the topology of which is that of the cytosol. Back-fusion of

the internal vesicles with the limiting membrane of multivesicular endosomes at late stages of the endocytic pathway leads to secretion of the lethal factor into the cytosol and allows it to access its cytosolic signaling targets. In contrast, diphtheria toxin is concentrated around the limiting membrane, and membrane translocation starting at the level of the early endosome enables direct transfer of the catalytic fragment to the cytosol.

## THE RETROGRADE ROUTE

Some protein toxins do not depend on endosomal acidification for their translocation to the cytosol. These include inhibitors of protein biosynthesis that modify ribosomal RNA, such as STx; the related verotoxins (or Shiga-like toxins); the plant toxin ricin; and *Pseudomonas* exotoxin (see Figure 8.2). They also include CTx, which induces ADP ribosylation of Gsα. These toxins escape from the endocytic pathway to be targeted to the endoplasmic reticulum (ER). Several studies have strongly suggested that it is from the ER that the catalytic subunits of these toxins are transferred to the cytosol (Simpson *et al*., 1999; Tsai *et al*., 2001; Wesche *et al*., 1999), using the cellular retrotranslocation or ERAD machinery (Tsai *et al*., 2002). After endocytosis, the retrograde route comprises two key steps: transport from endosomes to the TGN/Golgi apparatus and transport from the TGN/Golgi apparatus to the ER. The following sections will deal with each of these steps.

### Endosome-to-TGN transport

The first pathway to be described between the endocytic and the biosynthetic/secretory routes was the late endosome-to-TGN pathway followed by the mannose

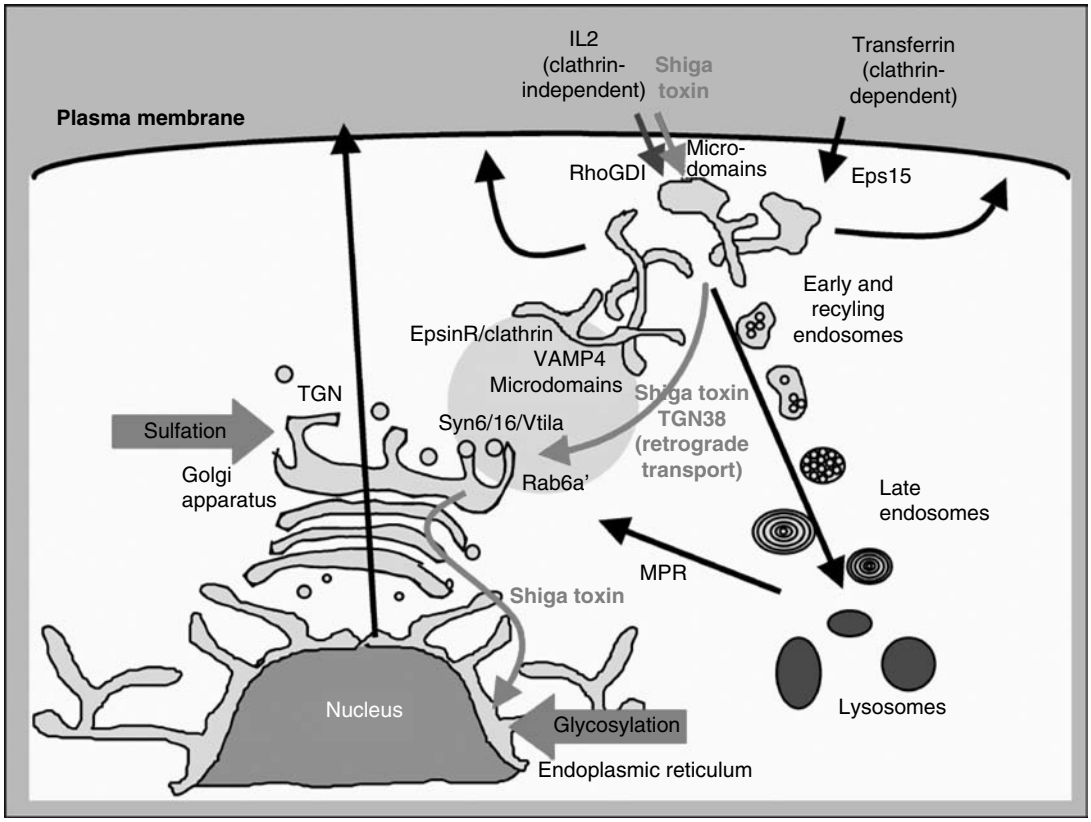

**FIGURE 8.2** Intracellular transport pathways of Shiga toxin. Black arrows indicate the classical transport pathways. Shiga toxin enters cells at least in part through clathrin-independent endocytosis. The gray circle represents the interface between early/recycling endosomes and the trans-Golgi network. Shiga toxin reaches this interface and is then transported to the Golgi apparatus via the retrograde pathway (gray arrow). The retrograde pathway is distinct from the well-known recycling pathway used by the mannose-6-phosphate receptor (MPR), even though recent evidence suggests that the MPR may also use the early/recycling endosomes-TGN interface. Shiga toxin is then transported from the Golgi apparatus to the endoplasmic reticulum (gray arrow). RhoGDI and Eps15 are specific inhibitors of the indicated endocytic pathways. Sulfation and glycosylation on corresponding B-subunit mutants are used to detect and quantify the arrival of the B-subunit in the trans-Golgi network and the endoplasmic reticulum, respectively. At the early endosome/TGN interface, selected molecular players are shown that have been directly or indirectly implicated in this transport step (See text for other retrograde sorting factors; adapted from Johannes, 2002).

6-phosphate receptor (see (Ghosh *et al*., 2003) (Figure 8.2). The molecular hallmarks of this pathway are the GTPase Rab9 (Lombardi *et al*., 1993) and the putative coat component TIP47 (Diaz and Pfeffer, 1998). To date, none of these has been shown to be involved in toxin transport (Lauvrak *et al*., 2002; Simpson *et al*., 1995), with the possible exception of CTx (Choudhury *et al*., 2002).

STx was particularly instrumental for the discovery of an alternative transport pathway between compartments of the early endocytic pathway and the TGN: the early/recycling endosome-to-TGN route (Johannes and Goud, 1998; Lord and Roberts, 1998; Sandvig *et al*., 2004) (Figure 8.2). In cells that are sensitive to STx-dependent inhibition of protein biosynthesis, it has been found that very little STx is recycled to the plasma membrane (Mallard *et al*., 1998; Schapiro *et al*., 1998) and that STx is absent from compartments of the late endocytic pathway (Mallard *et al*., 1998). Instead, the protein extensively overlaps with markers of early/recycling endosomes, such as the TfR. The toxin is then rapidly transferred from early/recycling endosomes to the TGN and the cisternae of the Golgi apparatus.

Molecular studies with quantitative methods, such as protein sulfation and glycosylation using engineered Shiga toxin B-subunit (STxB) variants (Johannes *et al*., 1997; for a review, see Mallard and Johannes, 2002), reconstitution approaches, and morphological tools have confirmed the existence of an EE/RE-to-TGN transport pathway (Figure 8.2). It has been shown that EE/RE-to-TGN transport involves a TGN-localized tSNARE complex composed of the heavy chain tSNARE syntaxin 16, the light chain tSNAREs Vti1a and syntaxin 6, and of two early/recycling endosomal vSNAREs, VAMP3/cellubrevin, and VAMP4 (Mallard *et al*., 2002). Both vSNAREs form independent complexes with the tSNAREs. A role for the trans-Golgi/TGN localized GTPase Rab6a' in retrograde transport was described in the same study. Upon expression of dominant negative Rab6a' mutants, STxB accumulates in the EE/RE. Rab6a' plays a predominant role in EE/RE-to-TGN transport, whereas other TGN or endosome-localized GTPases, such as Rab11 (Wilcke *et al*., 2000) and Rab9 (see above) appear to have, respectively, ill-defined or no functions.

The availability of quantitative and morphological STxB-based tools for the study of retrograde transport has allowed the biochemical dissection of EE/RE-to-TGN transport. In one study, another SNARE complex composed of syntaxin 5, GS15, GS28, and Ykt6 was found to be involved in STx transport from the EE/RE to the TGN (Tai *et al*., 2004). This is surprising given the function of syntaxin 5 in trafficking at the interface between the ER and the cis-Golgi (Dascher *et al*., 1994). However, other studies detected syntaxin 5 deep within Golgi stacks and in several SNARE complexes (Hay *et al*., 1998). These results suggest that syntaxin 5 functions in trafficking at several sites. They also show that trafficking at the EE/RE-TGN interface is more complex than initially anticipated, and that several molecular machineries may co-exist for the same transport intermediates, or that parallel pathways (the functions of which remain to be elucidated) exist.

The complexity of retrograde trafficking is further illustrated by considering molecular coats at the EE/RE-TGN interface. Clathrin was the first coat for which the function was addressed at this interface. Indeed, in addition to its well-established presence at the plasma membrane and the TGN, clathrin was found in endosomes (Stoorvogel *et al*., 1996). Cryo-electron microscopy demonstrated clathrin and the clathrin adaptor AP1 on the STxB-containing EE/RE (Mallard *et al*., 1998; Saint-Pol *et al*., 2004), and functional experiments confirmed a role for clathrin in STxB transport to the TGN (Lauvrak *et al*., 2004; Saint-Pol *et al*., 2004). Unexpectedly, interfering with AP1 function had no effect, even though several studies suggested a role for AP1 in retrograde transport (Folsch *et al*., 2001; Mallard *et al*., 1998; Meyer *et al*., 2000; Valdivia *et al*., 2002). Instead, the clathrin adaptor epsinR, a phosphatidylinositol 4-phosphate-binding protein, was found on the STxB-containing EE/RE and shown to be involved in retrograde sorting (Saint-Pol *et al*., 2004).

Another coat with functions at the EE/RE-TGN interface is the retromer. In yeast, this five-protein complex is involved in retrieval of receptors from the vacuole (Seaman *et al*., 1998). Recent studies on mammalian cells have suggested that this function is conserved at the EE/RE-TGN interface (Arighi *et al*., 2004; Seaman, 2004). Whether retromer is also involved in toxin trafficking and how clathrin and retromer operate in the same or parallel pathways remain to be elucidated.

Retrograde trafficking of STxB is also controlled by GPP130, a protein of unknown function (Natarajan and Linstedt, 2004), the GRIP domain protein Golgin-97 (Lu *et al*., 2004), and dynamin (Lauvrak *et al*., 2004).

Although studies on STxB led to the discovery of the first molecular players at the EE/RE-TGN interface, other toxins have also been used. For example, ricin has been used to study the role of dynamin (Llorente *et al*., 1998), cholesterol (Grimmer *et al*., 2000), calcium (Lauvrak *et al*., 2002), and protein kinase A (Birkeli *et al*., 2003). The problem with ricin as a cell biology tool is that only 5% of the cell-associated toxin is transported back to the TGN/Golgi apparatus (van Deurs *et al*., 1988), in association with one or several unidenti-

fied receptors. Thus, it is difficult to judge whether an inhibitory effect on retrograde transport, such as with dynamin, arises due to specific perturbation of retrograde transport-competent receptor trafficking at the plasma membrane or at any other step of the retrograde route.

Too little comparative information is currently available to determine whether the protein toxins that use the retrograde route (STx, CTx, ricin, etc.) depend on the same molecular machineries. The only molecular tools that have been applied to several toxins are dynamin, Rab9, and Rab11. Rab9 has no effect (see above). Rab11 and dynamin have similar effects on the retrograde sorting of STx and ricin (Iversen *et al*., 2001; Lauvrak *et al*., 2004; Llorente *et al*., 1998; Wilcke *et al*., 2000). As for Rab11, dominant negative or active mutants produced phenotypes that were relatively weak and difficult to interpret. Therefore, more studies are required to come to firm conclusions.

The retrograde route used to transport protein toxins between the EE/RE and the TGN is pre-existing and required for the trafficking of several cellular proteins. A detailed discussion of these examples would go beyond the scope of this review. The mannose 6-phosphate receptor, a shuttling protein required for the transport of mannose 6-phosphate-modified enzymes to lysosomes, uses this interface (see Saint-Pol *et al*., 2004 and references therein), in addition to the late endosome-to-TGN route. Several ubiquitous proteins with unknown functions have been mapped to the retrograde route: TGN38/46 (Ghosh *et al*., 1998; Mallard *et al*., 2002), GPP130, and GP73 (Natarajan and Linstedt, 2004). Upon insulin stimulation, the glucose transporter in adipocytes and muscle cells, Glut4, shuttles between an internal site and the plasma membrane, resulting in dynamic control of its activity; this internal site appears to be connected to the retrograde route (Shewan *et al*., 2003). Viruses (Bantel-Schaal *et al*., 2002) and viral proteins (Blot *et al*., 2003; Crump *et al*., 2004) have been described to reach the Golgi apparatus from the plasma membrane, possibly by EE/RE-to-TGN transport. Finally, infectious prion proteins might undergo retrograde transport to the ER (Beranger *et al*., 2002), followed by retrotranslocation to the cytosol (Ma and Lindquist, 2001).

Proteins are not the only determinants for retrograde transport. Indeed, CTx and STx are both associated with so-called membrane microdomains, or "rafts" (Harder *et al*., 1998; Katagiri *et al*., 1999), and in both cases, there is evidence suggesting a role for lateral lipid asymmetry in retrograde sorting. In the case of CTx, a related toxin, LTIIb, binds to the glycosphingolipid GD1a but not to GM1. In epithelial cells, CTx, but not LTIIb, is raft associated. This difference correlates with differences in their intracellular trafficking, CTx being able to enter the retrograde route, but not LTIIb (Fujinaga *et al*., 2003). Similar conclusions about the role of membrane microdomains in sorting at the EE/RE-TGN interface have been reached for STx based on the comparison of STx transport in different cell types. Unlike HeLa cells (Eiklid and Olsnes, 1980), monocytes and monocyte-derived cells, i.e., macrophages and dendritic cells, are resistant to STx (Ramegowda and Tesh, 1996; Tesh *et al*., 1994; van Setten *et al*., 1996). A correlation has been observed between this differential sensitivity to STx and the trafficking of the toxin in the respective cell types (Falguières *et al*., 2001). While STx follows the retrograde route in HeLa cells, no targeting to the TGN/Golgi or the ER can be detected in monocyte-derived cells. Interestingly, STx has been found in detergent-resistant membranes (DRMs) in HeLa cells, but not in monocyte-derived cells, suggesting that DRM association is required for retrograde sorting. Indeed, STx is associated with DRMs throughout its retrograde transport to the ER, and retrograde transport of STx is inhibited when microdomains are reversibly destabilized in HeLa cells. The mechanisms by which membrane microdomains contribute to the retrograde sorting of toxins remain to be determined.

Receptor heterogeneity has also been shown to be involved in retrograde transport of STx to the ER. The presence of Gb3 with C16 and C18 fatty acid chains was correlated with retrograde transport and intoxication of cells (Arab and Lingwood, 1998; Sandvig *et al*., 1996). However, this correlation has not yet been demonstrated directly. The ricin receptor involved in retrograde transport is still unknown. It does not seem to be a glycosphingolipid, however, as cells without glycosylceramide synthase activity are still normally sensitive to the toxin (Spilsberg *et al*., 2003).

## TGN/Golgi-to-ER transport

After reaching the TGN, protein toxins like STx, CTx, and ricin need to be targeted to the ER to reach the retrotranslocation machinery. The most direct evidence for this is based on experiments using the fungal metabolite brefeldin A, which redistributes Golgi markers into the ER, blocking anterograde and retrograde transport at the level of the biosynthetic/secretory pathway. In the presence of brefeldin A, cells are protected from STx (Donta *et al*., 1995), CTx (Nambiar *et al*., 1993), ricin, and *Pseudomonas* exotoxin (Yoshida *et al*., 1991). Quantitative measurements showed that this protection is due to the efficient blockage of retrograde transport (Mallard *et al*., 1998). However, cells are not totally protected by brefeldin A treatment,

indicating that at higher concentrations, toxins may escape from endosomes to the cytosol (Beaumelle *et al*., 1993).

Some proteins can follow the biosynthetic/secretory pathway in the opposite direction. This is the case for resident proteins of the ER that are retrieved from Golgi cisternae after escaping from their steady-state localization in the ER (Pelham, 1996). The retrieval signals are basic amino acids found at the C- or N-termini of type I or type II trans-membrane proteins, respectively, or the KDEL tetrapeptide at the C-terminus of luminal proteins. When retrieval signal-tagged resident ER proteins encounter sorting receptors in the intermediate compartment or in Golgi cisternae up to the TGN (Miesenbock and Rothman, 1995), their retrograde transport to the ER is induced. The retrograde sorting machinery at the Golgi-ER interface includes components of the COPI coat, which interact directly with retrieval signals, and mutation of which has been correlated with retrieval phenotypes (for a review, see Cosson and Letourneur, 1997).

With respect to toxins, two central questions arise. Do they cross the stacks of the Golgi apparatus en route to the ER: Is their retrograde transport dependent on the "classical" retrieval machinery involving the KDEL receptor and the COPI coat?

To date, no definite answer exists for the first question. Analysis of the retrograde transport of STx by immunofluorescence and immunoelectron microscopy revealed that the toxin first accumulates in the TGN and then very rapidly enters the Golgi stacks (Mallard *et al*., 1998), before becoming detectable in the ER (Kim *et al*., 1998). Furthermore, when membrane trafficking at the ER-Golgi interface is disrupted by using mutants of the gamma-tubulin and Golgi-binding protein GMAP210, STx accumulates in Golgi cisternae (Pernet-Gallay *et al*., 2002). These data are consistent with the notion that STx can reach the ER via Golgi cisternae. They do not exclude, however, the possibility that toxins might also be targeted directly from the TGN to the ER (Storrie *et al*., 2000).

The second question concerns the role of the KDEL-receptor/COPI machinery in retrograde TGN/Golgi-to-ER trafficking of toxins. Indeed, some toxins have KDEL signals, and there is evidence that their toxicity depends on these signals (Johannes and Goud, 1998). However, the observed effects were quite weak, and not consistent with the hypothesis that "conventional" retrieval signals play a critical role in toxin trafficking. This question was thus addressed more directly in a series of experiments on STx, CTx, PEx, and ricin.

STx does not carry a KDEL signal. Two approaches have been used to test whether the KDEL-receptor/COPI machinery was nevertheless involved in its trafficking to the ER. The first approach involved interfering with KDEL-receptor activity. This did not protect cells against STx (Jackson *et al*., 1999), and did not prevent STx from reaching the ER (Girod *et al*., 1999). It was suggested that the KDEL-receptor/COPI independent transport of STx to the ER involves the GTPase Rab6 (Girod *et al*., 1999; White *et al*., 1999), but a detailed molecular description of this route is still lacking. It is noteworthy that this transport step is also used by endogenous proteins. Indeed, if anterograde transport out of the ER is inhibited, Golgi markers accumulate in the ER, and this accumulation is not inhibited by interfering with KDEL-receptor/COPI function (Girod *et al*., 1999).

The second approach involved adding an ectopic KDEL retrieval signal to the C-terminus of STxB. Quantitative biochemical assays showed that this modification had no effect on retrograde transport of the protein to the ER (Johannes *et al*., 1997). The KDEL signal did, however, lead to an efficient retention of STxB in the ER. Thus, it appears that the minor effects of retrieval signals on protein toxin activities are explained, not by stimulating their retrograde transport as such, but by increasing the effective toxin concentration in the ER, thereby promotingretrotranslocation.

This proposal was addressed in a recent series of experiments on CTx and LTx. Both of these carry retrieval signals on their catalytic A-subunits, either the canonical KDEL signal in the case of CTx, or a variant (HDEL) in the case of LTx. In agreement with the abovementioned data on STxB and using similar quantitative biochemical tools, it was found that CTxB is transported to the ER with high efficiency, and independently of the presence of KDEL-bearing CTxA (Fujinaga *et al*., 2003). Mutating the retrieval signals on CTx or LTx poorly reduced toxicity (Lencer *et al*., 1995). Based on both the trafficking and toxicity data, it is clear that it is not the arrival in the ER that depends on the retrieval signals, but retention in this compartment and subsequent retrotranslocation. Such retention might be of particular importance in the case of CTx, as its A and B subunits dissociate before membrane translocation (Bacia *et al*., 2002; Bastiaens *et al*., 1996; Majoul *et al*., 1996), requiring retention of the non-membrane bound A-subunit from secretion by bulk flow.

This conclusion is further confirmed by the following observations. Impairment of COPI function using drugs had no effects on intoxication of cells by CTx (Chen *et al*., 2002a). However, morphological experiments have shown that microinjection of interfering anti-COPI or anti-KDEL receptor antibodies leads to the accumulation of CTxA in the Golgi apparatus (Majoul *et al*., 1998). Again, the most straightforward interpretation is to assume that arrival in the ER is not

impaired, explaining the efficient intoxication. However, once in the ER, CTx starts cycling between the ER and Golgi. When KDEL-bearing CTx encounters the KDEL receptor, which re-localizes to Golgi cisternae when COPI is dysfunctional, its localization is also shifted to this compartment.

The retrograde transport of ricin to the ER is COPI independent (Chen *et al*., 2003). Furthermore, toxins have been used to show that Golgi-to-ER transport is actin- (Duran *et al*., 2003; Luna *et al*., 2002; Valderrama *et al*., 2001) and calcium- (Chen *et al*., 2002b) dependent.

## NON-CONVENTIONAL ENDOSOMAL PATHWAYS

The sections above are based on the "conventional" model of the endocytic pathway being composed of early/recycling endosomes and late endosomes/lysosomes. Recent studies suggested that the complexity of structures may be higher than described by the "conventional" model, particularly at the level of the early endocytic pathway. The best-characterized example of these structures is the caveosome. This term was coined by the Helenius group studying the internalization of SV40 (Pelkmans *et al*., 2001). Following complex events at the plasma membrane involving actin remodeling (Pelkmans *et al*., 2002), SV40 is internalized into caveolin-positive membranes that are devoid of TfR and Rab5, two typical markers of the "conventional" early endosomes. Furthermore, these structures have a neutral pH, whereas early endosomes are acidic. After several hours, SV40 viruses leave caveosomes to enter the ER, using tubular transport intermediates.

Caveosomes also contain CTxB after co-internalization from the plasma membrane, as opposed to markers of clathrin-dependent endocytosis (e.g., Tf) and fluid phase markers (e.g., dextran). They may support the retrograde transport of CTx to the Golgi apparatus (Nichols, 2002; see below). No direct evidence in support of this hypothesis has been obtained, however, and follow-up studies showed that caveosomes and "conventional" EE communicate in an intricate manner (Pelkmans *et al*., 2004). Therefore, it remains possible that CTx can go in and out of caveosomes independently of trafficking to the TGN.

## CONCLUSION

The transport of bacterial and plant toxins in cells is of great interest both in fundamental science and in medicine. First, the understanding of these processes has provided important clues about endocytic mechanisms, such as the early suggestion of the existence of a clathrin-independent pathway (Montesano *et al*., 1982; Moya *et al*., 1985; Sandvig *et al*., 1987) or the retrograde transport of proteins across the Golgi apparatus (Johannes and Goud, 1998; Sandvig *et al*., 1992). The mechanisms that govern these different pathways are still poorly understood. It is highly probable that they carry unique and specific functions in the cell and that toxins have adapted to them so that they can be targeted to the right intracellular compartment. While most of the current knowledge was generated by using pharmacological inhibitors, which often lack specificity, new technologies such as live imaging and RNA interference will undoubtedly advance the molecular understanding of these pathways and the role they play in the pathology of toxins. The role of the different endocytic pathways in intracellular toxin trafficking remains obscure, and so far no clear correlation has been found between sorting at the plasma membrane and the ultimate fate of internalized molecules within the cell (Johannes and Lamaze, 2002).

The intracellular trafficking of toxins has also been used to convert them into targeting devices for therapeutic purposes. Indeed, toxins are specialized in the transport of protein moieties, i.e., their catalytic A-subunits, from the outside of cells into the cytosol. This type of transport is also the central theme of the cellular cross-presentation process observed with professional antigen presenting cells (Ackerman and Cresswell, 2004; Guermonprez and Amigorena, 2005), which leads to the presentation of antigens on MHC class I molecules, CD8+ T-cell priming, and immunity against viruses and cancer. Receptor-binding subunits of toxins are therefore being used to develop therapeutic vaccination strategies (Smith *et al*., 2002; Tartour *et al*., 2002). Recently, these strategies have mostly been based on two toxins that specifically target dendritic cells, the gatekeeper of cellular immunity: *Bordetella pertussis* adenylate cyclase toxin (Fayolle *et al*., 2004; Fayolle *et al*., 1999; Fayolle *et al*., 1996; Saron *et al*., 1997; Schlecht *et al*., 2004) and STxB (Haicheur *et al*., 2003; Haicheur *et al*., 2000; Lee *et al*., 1998; Smith *et al*., 2002). Other therapeutic approaches based on direct cancer cell targeting are currently being developed (Farkas-Himsley *et al*., 1995; Ishitoya *et al*., 2004). In conclusion, protein toxins may pay back some of the death toll that they still cause to humans.

CHAPTER

# 9

# Bacterial toxins and virulence factors targeting the actin cytoskeleton and intercellular junctions

*Michel R. Popoff and Bradley G. Stiles*

## INTRODUCTION

Actin is a highly conserved, versatile protein of ~43 kDa (monomeric form) found in eucaryotes throughout the biosphere, and it represents one of the most abundant proteins in all cells of multi-cellular organisms. In addition to the actin-like molecules found in plants and yeast, an ancient homologue of actin called *MreB* also exists in procaryotes such as non-spherical bacteria (Löwe *et al*., 2004). Although the role of MreB is not clearly defined, the molecule does share a remarkably similar conformation with eucaryotic actin. The filamentous forms of MreB may provide at least three functions for a procaryote that include: (i) a cytoskeleton-like structure that affords a distinct shape; (ii) segregation of plasmid as well as chromosomal DNA during mitosis; and (iii) cell polarity.

One focused aspect of this chapter, as well as the target of various bacterial toxins and secreted effector molecules, is eucaryotic actin, which assembles into organized filaments regulated by a variety of cytoskeletal proteins. Actin filaments can form a dynamic meshwork within a cell that extends throughout the cytosol (stress fibers) and underneath the plasma membrane (cortical actin), thus representing the main structure responsible for eucaryotic cell morphology. The actin-based cytoskeleton also controls many cellular functions critical for eucaryotic life including locomotion, endocytosis, exocytosis, trafficking of intracellular organelles, as well as maintenance of intercellular connections known as tight (TJs) and adherens (AJs) junctions. Since extracellular junctions are essential in building cell barriers, like the epithelia and endothelia that protect an organism from the environment as well as delineate internal compartments, pathogen manipulation of host cells via the actin cytoskeleton provides an effective means to breach a host's containment capabilities and gain access to essential nutrients from more appropriate niches throughout the body. Additionally, diversion of cytoskeletal processes provides a means for pathogens to avoid phagocytosis by macrophages. This "avoidance behavior" employed by a microbial invader circumvents a primary mechanism used by the host's immune system for clearing unwanted entities from the body.

One way that bacterial pathogens can obtain nutrients from a host and avoid the immune system is through potent protein toxins secreted into the environment. Certain Gram-positive and Gram-negative bacteria have evolved this method of manipulating the host via cell intoxication. Structurally, many bacterial toxins typically contain an "A" (enzymatic) and "B" (cell binding/translocation) domain located on one or more protein molecules. The "A-B" toxins act at a distance from the bacterium, and after binding to specific cell-surface receptors followed by internalization, these proteins can cause irreversibly profound cellular changes via various mechanisms. As described below, a large number of these bacterial toxins can modify the actin cytoskeleton by either direct interactions with

actin monomers or via altering Rho-GTPases, which then subsequently regulate actin polymerization. The main effects of these toxins upon a host include destabilization of epithelial and/or endothelial cell barriers, which leads to increased permeability and extensive tissue damage.

In addition to protein toxins secreted into the environment, certain Gram-negative pathogens have also evolved type-III secretion systems that require intimate contact with a target cell. The Gram-negative genera (i.e., *Erwinia*, *Escherichia*, *Pseudomonas*, *Ralstonia*, *Salmonella*, *Shigella*, *Vibrio*, *Yersinia*, and *Xanthomonas*) that possess type-III secretion systems are rather diverse and cause a myriad of diseases in plants as well as animals. Upon pathogen-cell contact that may be facilitated by lipid rafts, virulence factors are "injected" into the cytosol of a targeted cell, which then modulate various functions often involving the actin cytoskeleton.

Structurally, type-III secretion systems are composed of multi-protein complexes that form a "ringed-needle" protrusion called an *injectisome*. The transmembrane segment of this mechanism consists of a basal body similar to that anchoring flagella into the bacterial membrane. In fact, there are common proteins (based upon sequence analysis) found in the flagellar and type-III secretion systems, which suggests a common evolutionary link. The type-III secreted effector molecules generally possess two attributes for proper routing, which include: (i) an amphipathic, non-consensus sequence within the first 20 N-terminal residues; and (ii) a binding site for cytoplasmic chaperone molecules located within the first 140 N-terminal residues (Cornelis, 2002; Lee and Galan, 2004). Some invasive bacteria can translocate type-III secreted proteins that transiently reorganize the actin cytoskeleton, thus facilitating pathogen uptake into normally non-phagocytic cells. Once inside a targeted cell, invasive bacteria can sometimes further exploit the actin cytoskeleton for intra-/inter-cellular movement. Thus, these pathogens enter epithelial cells where they replicate away from the immune surveillance system and subsequently gain access to adjacent tissues, the bloodstream, and finally distal sites throughout a host. In other cases, bacteria use type-III effectors to disrupt the actin cytoskeleton of macrophages and avoid phagocytosis.

The following sections of this chapter delve into the mode of action and cellular effects elicited by various bacterial toxins, as well as type-III effectors, that reorganize the eucaryotic actin cytoskeleton (Figure 9.1). These processes employed by numerous pathogens ultimately play a major role in microbial survival, dissemination, and disease. It is evident that a better understanding of how pathogens interact with, and then exploit, the actin infrastructure of eucaryotes can provide promising means of abrogating, or even preventing, certain diseases in the future. For additional reading on this topic, several excellent reviews summarize quite nicely the manipulations of cellular functions by bacteria via toxins and other virulence factors (Herreros *et al*., 2001; Stebbins and Galan, 2001; Barbieri *et al*., 2002; Doye *et al*., 2002).

## ACTIN CYTOSKELETON AND REGULATION OF ACTIN POLYMERIZATION

The eucaryotic cytoskeleton is built upon three distinct, intercommunicating networks known as microfilaments (6 nm diameter), microtubules (23 nm diameter), and intermediate filaments (10 nm diameter) that are respectively composed of unique proteins like actin, tubulin, and various divergently evolved molecules such as keratin (acidic/basic), lamin, etc. Each filament/tubule type is the result of monomer assembly that constitutes a highly dynamic structure continuously assembled and disassembled in response to extracellular stimuli. The protein monomers and resultant filaments bind a large variety of other proteins, which enable the same filamentous strand to participate in unique functions throughout the cell.

Actin filaments can form stable, diverse structures such as the core of microvilli and contractile apparatus found in muscle cells. In non-muscle cells, the labile actin cytoskeleton forms a dense web underlying the plasma membrane (cortical actin) and is also found as long filaments called *stress fibers* that extend throughout the cytosol. Distinct subcompartments of cortical actin can be distinguished that correspond to different peripheral structures such as filopodia, focal adhesions, lamellipodia, microspikes, and ruffles. In most cells, the actin cytoskeleton is the main determinant of shape and participates in various functions. For example, in epithelial and endothelial cells, the actin structure helps maintain strong intercellular connections and adhesion to the underlying extracellular matrix, while macrophages and neutrophils use the actin-based network for movement, spreading, and phagocytosis (Pollard and Borisy, 2003). The actin cytoskeleton is implicated in many other processes such as cell division (cytokinesis), endocytosis, exocytosis, intracellular transport, membrane organization, and signal transduction. Clearly, actin is involved in many processes critical for eucaryotic life.

In non-muscle cells, actin is in a dynamic equilibrium between monomeric (G-actin) and polymeric or

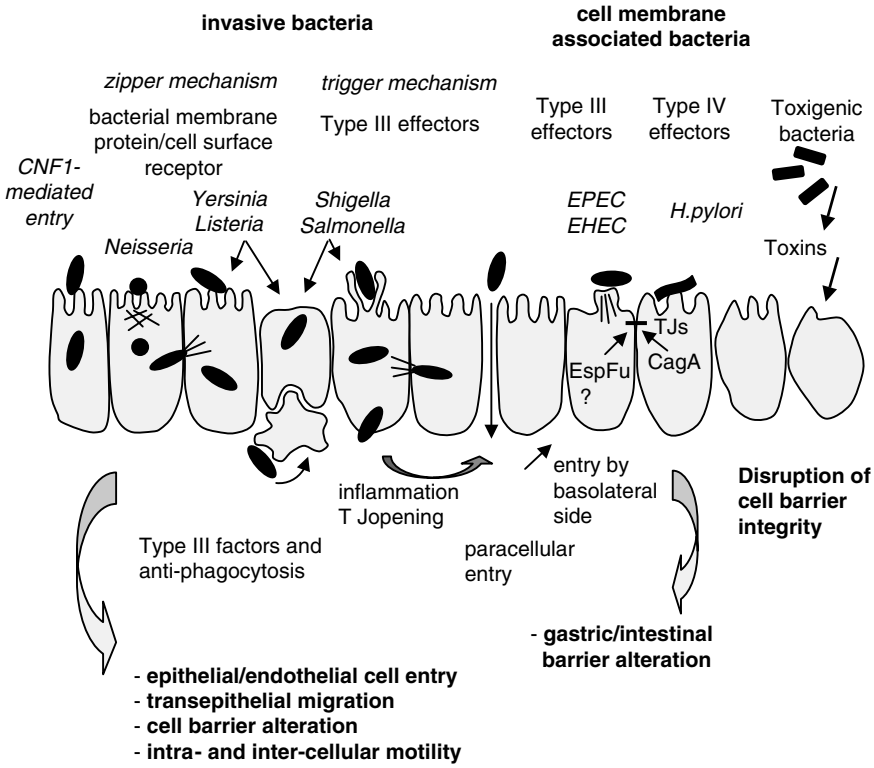

**FIGURE 9.1** Effects of toxins and type-III/IV secreted effectors from various bacteria upon the actin cytoskeleton and epithelial/endothelial cell barriers.

filamentous (F-actin) forms (Pollard *et al*., 2000), which involves a process regulated by various proteins such as profilin, ADF/cofilin, twinfilin, WASP/WAVE, Srv2/CAP, and verprolin/WIP (Figure 9.2). Structurally, actin monomers possess a globular structure with a central groove that binds tightly to an ATP molecule. The side chain of Ser14, and a "sensor loop" consisting of residues Pro70–Asn78 both play an important role in nucleotide binding and subsequent conformation of G-actin linked to either ATP or ADP. G-actin-ATP binds to the growing end of F-actin during polymerization, and ATP is hydrolyzed to ADP, which remains firmly trapped in the actin filament. Depolymerization of F-actin releases G-actin-ADP, which is not readily phosphorylated. Spontaneous dissociation of ADP from G-actin is very slow, but this process is markedly accelerated by the binding of actin monomers to profilin, another multifunctional protein found in all eucaryotes.

Actin filaments are polarized, preferentially polymerizing at the barbed or plus end, which then depolymerizes at the pointed or minus end. The polymerization rate is up to 10 times more evident at the barbed, versus pointed, end. Actin depolymerizing factor (ADF)/cofilin preferentially bind to ADP-bound forms of G-/F-actin (Paavilainen *et al*., 2004), thus increasing by twenty-five-fold the depolymerization rate at the pointed end via twisting of F-actin into a less thermodynamically stable form. This ultimately results in increased concentrations of G-actin-ADP, and then G-actin-ATP, that reach critical levels favorable for actin polymerization (Carlier, 1998; Cooper and Schafer, 2000).

The dynamics of actin monomers/filaments involve four principal stages that include: nucleation, elongation, monomer-polymer equilibrium, and treadmilling. Initiation of actin polymerization takes place by one of three independent mechanisms that include *de novo* nucleation of actin filaments by the actin-related protein (Arp2/3) complex or formins, uncapping of barbed filament ends, and severing of existing filaments to create new barbed ends (Higgs and Pollard, 2001; Suetsugu *et al*., 2002). At least three G-actin-ATP molecules must first associate with Arp2/3 to form a polymerization nucleus sufficient for subsequent F-actin assembly. This process is mainly governed by activated Cdc42 or Rac through WASP or WAVE proteins, respectively (Figure 9.2). From the nucleus, elongation takes place by addition of G-actin-ATP monomers to the barbed end of a nascent filament. Rapid growth at the barbed ends requires high concentrations (100 times the

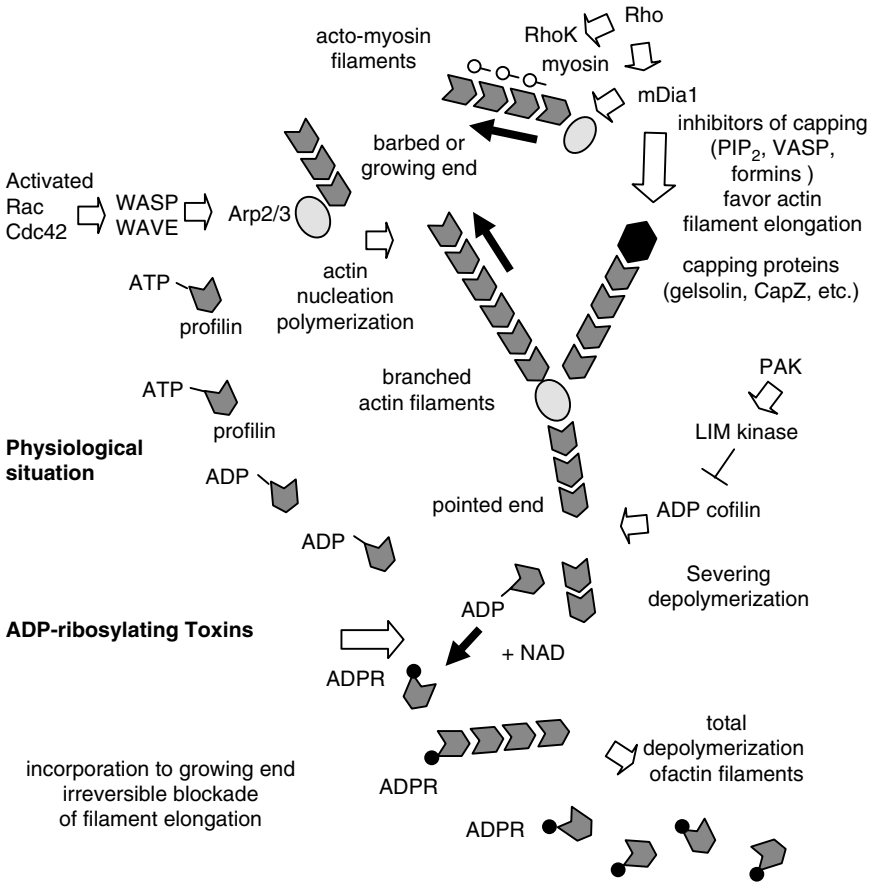

**FIGURE 9.2** Schematic representation of eucaryotic factors involved in actin nucleation and polymerization, as well as how ADP-ribosylating toxins inhibit actin polymerization by directly modifying actin monomers.

critical concentration necessary for polymerization) of polymerization-competent actin subunits. This results from several factors that include: (i) actin monomer-capping proteins, such as profilin, which recycle to ATP-actin and bind to barbed ends; (ii) barbed end capping proteins (i.e., gelsolin, CapZ), which quickly block polymerization of barbed ends and therefore concentrate available actin monomers to the few free barbed ends in response to a cellular or extracellular signal; and (iii) ADF/cofilin, which accelerate actin depolymerization, thus restoring the pool of ADP-actin monomers (Pollard and Borisy, 2003). Treadmilling is the continual process of adding and deleting actin monomers to the actin filament. The Arp2/3 complex also initiates actin polymerization from preexisting filaments leading to a branched actin network, since it remains attached to pointed ends and binds to the sides of actin filaments. Control of capping proteins at the barbed ends by inhibitory factors (i.e., $PIP_2$, VASP, formins) regulates actin filament polymerization. Another type of actin nucleator consists of the multidomain proteins called formins. These varying-sized molecules contain a highly conserved domain (FH2 or formin homology domain 2) that alone is sufficient to nucleate actin. In contrast to Arp2/3, formins generate straight filaments that bundle and associate with myosin to generate contractile structures such as stress fibers. Rho can activate the formin mDia1 and myosin through Rho-kinase (RhoK), thus leading to stress fiber formation (Zigmond, 2004).

Actin dynamics are regulated by numerous proteins in the cytosol that include: (i) actin monomer-binding proteins (i.e., thymosin β4, profilin); (ii) actin filament-binding proteins (i.e., gelsolin, CapG, CapZ ); (iii) actin filament-severing proteins; (iv) actin filament-bundling or cross-linking proteins (i.e., α-actinin, filamin, fimbrin, ABP120); and (v) actin depolymerizing proteins (i.e., ADF, cofilin) (Dos Remedios *et al*. 2002; Southwick and Purich, 2000). In addition, remodeling of the actin cytoskeleton in response to extracellular signals involves regulatory pathways encompassing small GTPases from the Rho family.

Rho proteins belong to the Ras superfamily, which are small (21–25 kDa) molecules that share structural homology and become activated only when bound to GTP. They are molecular switches that regulate various cellular processes including actin dynamics, endocytosis, gene transcription, cell-cycle progression, and differentiation. So far 20 members have been identified in the Rho-GTPase family (Burridge and Wennerberg, 2004), and the best-characterized molecules are Rho, Rac, and Cdc42, which respectively control the formation of stress fibers plus focal adhesions, membrane ruffling, and filopodia. Cycling between active and inactive forms of Rho-GTPases is regulated by at least three protein classes: (i) the guanine-nucleotide-exchange factors (GEFs), which promote exchange of bound GDP for GTP in response to an extracellular signal(s); (ii) the GTPase-activating proteins (GAPs), which enhance intrinsically low GTPase activity and thus inactivate Rho-GTPases; and (iii) the guanine-nucleotide-dissociation inhibitors (GDIs), which stabilize the GDP forms of Rho-GTPases in the cytosol (Van Aelst and Souza-Schorey, 1997; Bishop and Hall, 2000; Sah *et al*., 2000; Takai *et al*., 2001). Despite the evident diversity among GEF, GAP, and GDI molecules, each class shares a conserved mechanism of action (Vetter and Wittinghofer, 2001). Activated Rho-GTPases bind to membrane lipids via isoprenylated cysteines found in a Cys-Aliphatic residue-Aliphatic residue-X motif within the C-terminus, and then subsequently interact with their effectors. The conformational changes between GDP- and GTP-bound forms of Rho are localized within two surface loops, named *switch I* and *II*, which play an important role in GTP catalysis. Switch I of Rho-GTPases is the main region for interactions with effector molecules. Most Rac/Cdc42 effectors contain a conserved, GTPase-binding consensus site (CRIB), and many Rho effectors possess an N-terminal Rho effector homology domain (REM) composed of three leucine-zipper-like motifs. Effectors for Rho-GTPases often are Ser/Thr kinase, lipid kinase, lipase, or a scaffold protein (Bishop and Hall, 2000).

Bacteria have evolved various virulence factors, such as protein toxins and type-III secreted effectors, that can modulate the dynamic equilibrium of actin cytoskeletons via three routes: (i) modification of actin monomers leading to transient or permanent reorganization of the actin cytoskeleton that facilitates cell invasion, inhibition of phagocytosis, and/or alteration of cell barrier functions (Tables 9.1 and 9.2); (ii) regulation of Rho-GTPases by direct enzymatic modification or molecularly mimicking the eucaryotic regulatory proteins for Rho-GTPases (Tables 9.1, 9.2, and 9.3) and (iii) nucleation as well as formation of actin filaments promoting the intracellular mobility of bacteria and viruses (Table 9.3).

## BACTERIAL PROTEIN TOXINS TARGETING ACTIN

### *Bacillus* and *Clostridium* actin-ADP-ribosylating toxins

The actin-ADP-ribosylating toxins produced by *Bacillus* and *Clostridium* species share a common "A-B" structure consisting of two independent protein components not linked in solution by either covalent or non-covalent bonds (Table 9.1) (Barth *et al*., 2004). One protein represents a "B" component (~80–100 kDa) for cell-binding/membrane translocation, and the other is an enzymatic "A" component (~45 kDa). Three families can be distinguished among this binary toxin group. The Iota family includes *C. perfringens* iota toxin, *C. spiroforme* toxin, and a *C. difficile* toxin that differs from the large clostridal toxins designated as ToxA and ToxB. The C2 family corresponds to the C2 toxins produced by *C. botulinum* types C and D. These clostridial binary toxins are involved in necrotizing enteritis and diarrhea in animals, and occasionally are implicated in human diseases (Barth *et al*., 2004). The third family of bacterial ADP-ribosylating toxins that are likely specific for actin corresponds to the insecticidal binary toxins or vegetative insecticidal proteins (VIP) produced by *Bacillus cereus* and *Bacillus thuringiensis* (Han *et al*., 1999). Protein components within a family are highly related (80–85% identity among amino acid sequences), whereas the existing sequence identities between toxins from distinct families are noticeably less (29–40%). Protein components from the Iota family are immunologically cross-reactive and functionally complement each other to form chimeric toxins; however, this does not occur with either "A" or "B" component of C2 toxin (Popoff, 2000). Similar cross-reactivity and complementation experiments have not been reported for the VIP components with either the Iota or C2 family proteins.

The Iota and VIP family protein components are synthesized during exponential growth and contain a signal peptide, which facilitates secretion from the bacterium (Barth *et al*., 2004). In contrast, C2 toxin components lack a signal peptide, as they are produced during sporulation and subsequently released into the environment following sporangium lysis. All cell-binding components of these binary toxins are proteolytically activated via removal of a 20 kDa N-terminal peptide by different serine-type proteases (Barth *et al*., 2004). This in turn generates "activated" versions of the cell-binding component that form homoheptamers in

**TABLE 9.1** Secreted bacterial toxins that modulate the actin cytoskeleton

solution and/or on cell membranes. The enzymatic component (Ia) of iota toxin also requires the removal of 9 to 11 N-terminal residues for activity (Gibert *et al*., 2000), a unique process not yet elucidated for the other bacterial ADP-ribosyltransferases that target actin. To date, for the Iota, C2, and VIP family of toxins, it is unknown how many molecules of "A" bind to a heptameric form of "B." However, studies with closely related binary toxins produced by *Bacillus anthracis* (i.e., lethal and edema toxins) suggest a 3:7 mole ratio of A:B (Mogridge *et al*., 2002b).

The binding components of actin-ADP-ribosylating toxins share an overall sequence identity of 31–43% with the "B" component (protective antigen or PA) of *Bacillus anthracis* edema and lethal toxins. The PA crystal structure has been resolved at 2.1 angstroms and the molecule clearly possesses four distinct domains (Petosa *et al*., 1997). Following proteolysis and homoheptamer formation, the N-terminal domain (domain 1'; residues 1–249) of PA contains an exposed docking site for an enzymatic component (edema factor or lethal factor) (Cunningham *et al*., 2002). The edema and lethal factors share a common Val-Tyr-Tyr-Glu-Ile-Gly-Lys motif that is necessary for docking to PA. The C-terminal domain of PA (domain 4; residues 597–735) is involved in recognizing cell-surface protein receptors, recently

identified as tumor endothelium marker 8 and capillary morphogenesis gene 2 (Petosa *et al*., 1997; Bradley *et al*., 2001). Domain 3 (residues 488–596) is responsible for homoheptamer formation, which is subsequently important for effective docking of the edema and lethal factors to PA on the cell surface. Domain 2 (residues 250–487) contains long β-strands that form a classic "Greek key" motif that plays a central role in membrane insertion and channel formation. A flexible, amphipathic loop (amino acids 302–325) in PA forms a β-hairpin structure that within the PA heptamer collectively generates a β-barrel, which inserts into the membrane and facilitates translocation of partially unfolded enzymatic component(s) into the cytosol (Cunningham *et al*., 2002; Mogridge *et al*., 2002a; Mogridge *et al*., 2002b; Abrami *et al*., 2003).

The overall PA structure and domain organization are likely conserved among binding components of the actin-ADP-ribosylating toxins from other *Clostridium* and *Bacillus species*. Results generated by various techniques suggest that the C-terminus of each binding component from iota (Ib) and C2 (C2-II) toxins, corresponding to domain 4 of PA, is responsible for cell-surface recognition (Blöcker *et al*., 2000; Marvaud *et al*., 2001). Lower levels of a conserved amino acid sequence (less than 10% homology) between domains 4 of Ib and C2-II suggest that each toxin recognizes distinct receptors, which include a membrane protein for iota toxin (Stiles *et al*., 2000), and an Asn-linked glycan containing the α-D-mannoside-β1, 2-*N*-acetyglucosamine motif for C2 toxin (Eckhardt *et al*., 2000). The N-terminal region of either mature Ib or C2-II is required for Ia and C2-I docking, respectively (Barth *et al*., 1998; Marvaud *et al*., 2001). Similar work has not been done with the *C. difficile* and *C. spiroforme* binary toxins, or *Bacillus* VIP.

Crystal structures of the VIP (VIPII) and iota toxin (Ia) enzymatic components reveal two distinct, but related, structural domains that were probably derived by duplication of an ancestral gene (Figure 9.3). Each domain consists of a perpendicular packing of five mixed, β-sheet strands against a three stranded, antiparallel β-sheet flanked by four consecutive helices. The C-terminal domain, which shares homology with *C. botulinum* C3 ADP-ribosyltransferase specific for Rho-GTPases, encompasses the catalytic site; whereas the N-terminus interacts with heptameric forms of the binding component that subsequently facilitate enzyme entry into the cytosol (Han *et al*., 1999; Tsuge *et al*., 2003). The Ia segment encompassing amino acids 129–257 corresponds to a compact core within the N-domain and mediates docking with heptameric Ib (Marvaud *et al*., 2002); whereas the C2-I domain that binds to heptameric C2-II has been mapped to residues 1–87, which corresponds to the four α-helices located upstream from the N-domain core of VIPII (Barth *et al*., 2002).

## Mode of action

The proteolytically-activated binding components of *Bacillus* and *Clostridium* binary toxins are each ~80 kDa, or ~60 kDa for C2II as well as PA, and trigger internalization of enzymatic component(s) into cells by receptor mediated endocytosis (Barth *et al*., 2004). Mature binding components first recognize specific, cell-surface receptors, then subsequently form homoheptameric "B" structures and small ion permeable

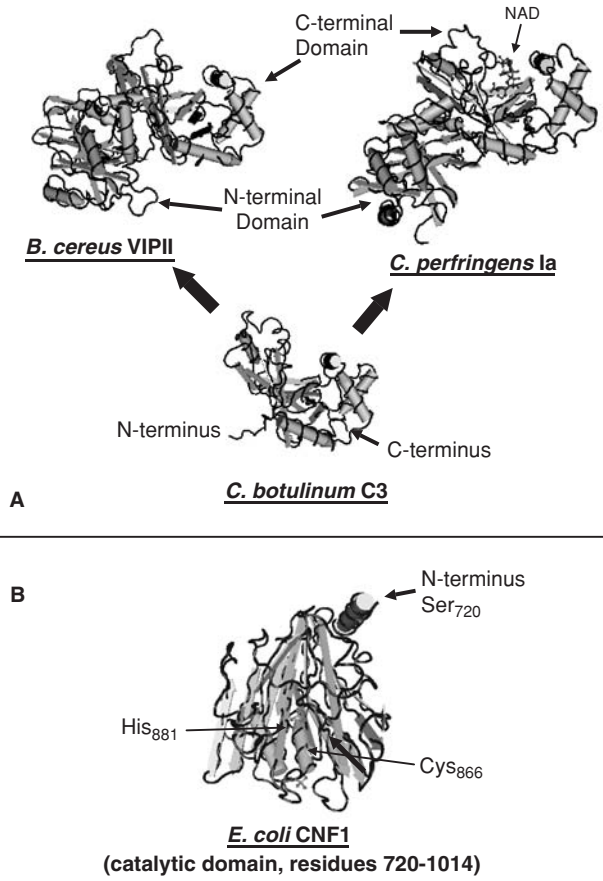

**FIGURE 9.3** Structures of the enzymatic components (VIPII and Ia) from actin ADP-ribosylating toxins, the Rho ADP-ribosylating enzyme C3 (A), and enzymatic domain of the Rho-deamidating toxin CNF (B). Enzymatic components of VIP and iota toxins each contain two similar domains that probably evolved from gene duplication. One domain (C-terminal) retains the enzymatic site that is highly related to the entire C3 molecule, which itself contains only an enzymatic domain devoid of any recognized cell-binding domain. In contrast, the deamidating domain of CNF is structurally unrelated to those of actin or Rho ADP-ribosylating toxins.

channels that facilitate enzyme transport into the cytosol via acidic endocytic vesicles (Schmid *et al*., 1994; Barth *et al*., 2000; Bachmeyer *et al*., 2001; Knapp *et al*., 2002). In contrast to PA, which is proteolytically activated either in solution by serine-type proteases or on the cell surface by furin or furin-like proteases via a unique Arg-Lys-Lys-Arg cleavage site, Ib and C2-II are exclusively processed in solution by serine-type proteases such as trypsin or alpha-chymotrypsin (Barth *et al*., 2004). After activation in solution, the PA, Ib, and C2-II molecules can also form homoheptamers that subsequently bind to cells. Proteolytically unprocessed Ib and C2-II also bind to cell-surface receptors, but they neither oligomerize nor mediate docking/entry of the enzymatic components into cells (Gibert *et al*., 2000; Stiles *et al*., 2000; Stiles *et al*., 2002).

Enzymatic components from the Iota toxin family can ADP-ribosylate all cellular and muscular isoforms of actin, whereas C2 toxin is more discriminating and only interacts with cytoplasmic and smooth muscle γ-actin. The ubiquitous nicotinamide adenine dinucleotide (NAD) molecule, commonly used by cells for normal reduction/oxidation reactions necessary for homeostasis, represents the source of ADP-ribose for specifically modifying actin monomers (G-actin), but not polymerized F-actin, at Arg177 (Vandekerckhove *et al*., 1987). Actin monomers complexed to gelsolin also represent an appropriate substrate for ADP-ribosylation by these bacterial enzymes. The targeted Arg177 residue is located at the actin-actin binding site, which is buried within an actin filament, and ADP-ribosylation on this part of G-actin prevents nucleation and subsequent polymerization. Moreover, ADP-ribosylated actin acts as a capping protein that binds to the barbed end of an actin filament, thus inhibiting further addition of unmodified actin monomers. Actin filaments depolymerize at the pointed end and the released actin monomers are immediately modified with ADP-ribose (Figure 9.2). In addition, ADP-ribosylation inhibits the intrinsic ATPase activity of actin. Microinjection of ADP-ribosylated actin monomers into cells induces the same effects (i.e., disassembly of actin filaments) as that seen after C2 or iota intoxication (Kiefer *et al*., 1996; Reuner *et al*., 1996; reviewed in Aktories, 2000). To date, the specific substrate(s) of VIPII within insect cells has not been determined experimentally, but the sequence and conformation are highly suggestive of an actin-modifying protein.

### Effects on cell barriers

The most prominent effects of clostridial ADP-ribosylating toxins include depolymerization of actin filaments and a subsequent increase in the G-actin pool. Intermediate filaments are also disorganized, unlike the microtubules, and the overall effects upon cells involve overt rounding and death (Aktories, 2000; Ohishi, 2000). For polarized monolayers of CaCo-2 cells, iota toxin can bind and then induce depolymerization of the actin cytoskeleton from either the apical or basolateral surfaces (Richard *et al*., 2002). The TJs and AJs are subsequently disorganized, resulting in decreased transepithelial resistance and increased paracellular permeability of small, as well as large, molecules that include $^{14}$C-mannitol and FITC dextrans ranging from 4.4 to 35 kDa (Figure 9.4) (Petit *et al*., 2001). Experimentally, C2 toxin is dermonecrotic like iota toxin and induces hemorrhagic enteritis in mice (Ohishi and Odagiri, 1984). In rabbit lungs, the C2 toxin also causes edema and alteration of endothelial cell membranes (Ermert *et al*., 1997). The massive edema and hypotonic shock observed in animals injected with C2 toxin probably results from deterioration of the vascular endothelium barrier (Aktories and Koch, 1995).

## TYPE-III SECRETION OF ACTIN ADP-RIBOSYLATING FACTORS

Non-typhoid strains of *Salmonella*, commonly associated with a major form of food poisoning that may include severe systemic infections, contain a 90 kb plasmid required for growth in macrophages and monocytes that harbors four *spv* (*Salmonella* plasmid virulence) genes (A, B, C, D) in an operon regulated by SpvR. Among these genes, *spvB* encodes a 65 kDa protein (SpvB) essential for virulence. Recombinant SpvB specifically ADP-ribosylates non-muscle actin (Table 9.2 and Figure 9.2), and is the first ADP-ribosyltransferase described as a virulence factor for any intracellular pathogen (Lesnick *et al*., 2001). The C-terminal domain of SpvB shares conserved residues and overall sequence homology with the ADP-ribosylating site of binary toxins produced by *Clostridium* (Iota and C2) or *Bacillus* (VIP, 25% with *B. cereus* VIPII), which specifically modify actin monomers. The Ser-Thr-Ser motif, flanked by a downstream Glu-X-Glu and upstream Arg, represents some of the common residues evident in ADP-ribosyltransferases from both Gram-negative and Gram-positive bacteria. CHO cells transfected with the *spvB* gene undergo actin filament destruction, and SpvB is crucial for virulence in a subcutaneous mouse model, as evidenced by mutant strains of *Salmonella typhimurium* lacking a functional *spvB* gene (Matsui *et al*., 2001). The N-terminal domain of SpvB is involved in secretion and shares 47% sequence homol-

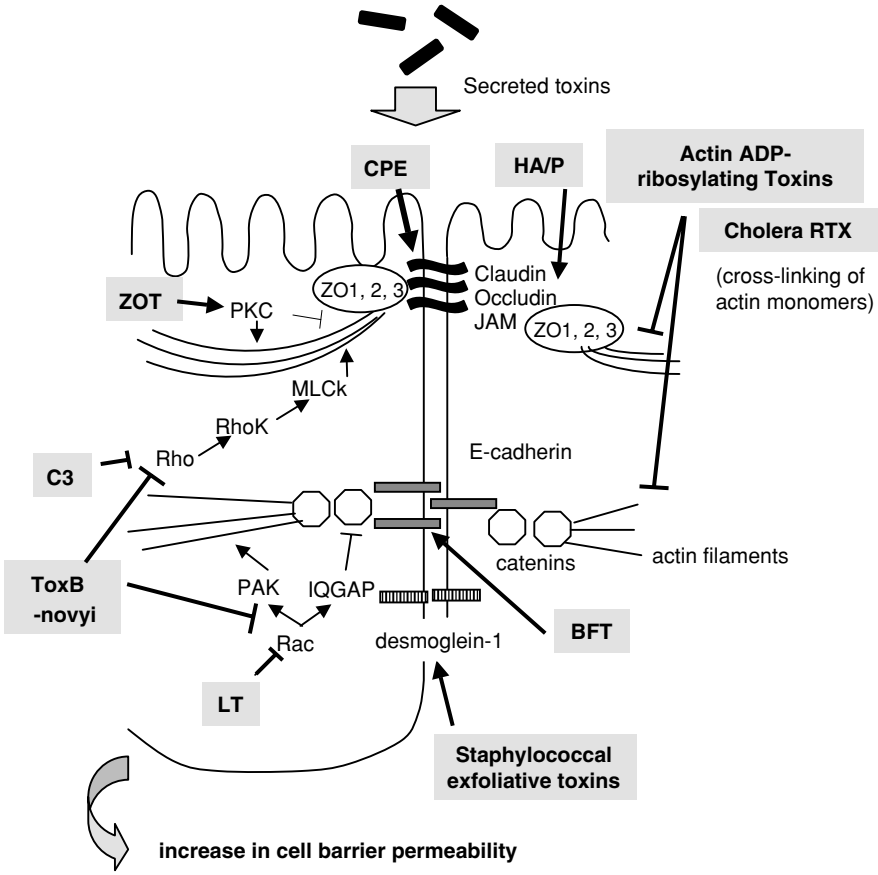

**FIGURE 9.4** Organization of the actin cytoskeleton and intercellular junctions, as well as toxins which modify the actin cytoskeleton and/or intercellular junction components. CPE, *C. perfringens* enterotoxin which binds to claudin(s) and incorporates occludin into a large complex (McClane, 2001); HA/P, haemagglutinin/protease from *V. cholerae* which degrades occludin and disturbs ZO-1 as well as actin filament organization (Wu *et al.*, 2000); ZOT, *V. cholerae* zonula occludin toxin which induces actin polymerization and ZO-1 disengagement from occludin as well as claudin (Wang *et al.*, 2000); RTX, *V. cholerae* repeats-in-toxin which cross-links actin monomers and causes depolymerization of actin filaments (Fullner and Mekalanos, 2000); BFT, *B. fragilis* enterotoxin which cleaves cadherin (Sears, 2001); staphylococcal exfoliative toxins which proteolytically cleaves desmoglein-1 (see chapter 56); LT, *C. sordellii* lethal toxin which glucosylates Rac leading to inactivation; ToxB, *C. difficile* toxin B which glucosylates Rho leading to inactivation; α-novyi, *C. novyi* toxin which transfers N-acetylglucosamine to Rac leading to inactivation (Schirmer and Aktories, 2004).

ogy with the insecticidal toxin TcaC produced by *Photorhabdus luminescens*, a motile Gram-negative bacillus of the Enterobacteriaceae family that also has a type-III secretion system and inhabits the gut of nematodes, which are themselves subsequently consumed by insects that become intoxicated by TcaC (Chattopadhyay *et al.*, 2004). To date, the exact mode of action for TcaC is unknown, but it may suppress phagocytosis by hemocytes via the actin cytoskeleton.

Like *Salmonella* SptP (described below), SpvB also reverses the effects of virulence factors that induce membrane ruffling and reorganization of the actin cytoskeleton for bacterial entry, thus permitting infected cells to regain their normal architecture after invasion. Although SpvB may be injected into host cells like SptP via a type-III secretion system, it has been shown that SpvB is secreted into growth medium by *Salmonella* mutants defective in type-III secretion (Gotoh *et al.*, 2003). The *spvB* gene is expressed 6 h after bacterial entry into epithelial cells or macrophages, and SpvB-dependent cytotoxicity/apoptosis is evident 10–12 h post infection (Lesnick *et al.*, 2001; Kurita *et al.*, 2003). In similar fashion, the fish pathogen *Aeromonas salmonicida* represents another member of the Enterobacteriaceae that produces an essential, type-III secreted virulence factor recently identified as a 50 kDa, ADP-ribosyltransferase designated as AexT (Burr *et al.*, 2003). Although the target substrate has not been clearly defined to date, AexT shares high sequence identity (60%) and epitopes with GAP ADP-ribosyltransferases, ExoS and ExoT, produced by *Pseudomonas aeruginosa*.

Finally, similar ADP-ribosyltransferase genes have recently been identified in the genome of *Menigococcus*

(NarE) and *Listeria monocytogenes* by a novel, computer-based approach based upon pattern recognition and predicted secondary structure (Masignani *et al*., 2004).

## TOXINS INACTIVATING RHO-GTPASES

### C3 and C3-like enzymes

Approximately 20 years ago, exoenzyme C3 was first identified from *Clostridium botulinum* types C and D as an ADP-ribosyltransferase specific for Rho protein (Aktories *et al*., 1987; Rubin *et al*., 1988). Two isoforms, C3bot1 and C3bot2, have subsequently been characterized and share 60% sequence identity. C3 and related C3-like molecules are ~25 kDa, basic (pI >9) proteins that are also produced by other Gram-positive bacteria, such as *Clostridium limosum* (C3lim), *B. cereus* (C3cer), and *Staphylococcus aureus* (Wilde *et al*., 2001). The C3 related enzyme produced by *S. aureus* is called *epithelial differentiation inhibitor* (EDIN), or C3stau, and consists of three isoforms (A, B, C) sharing ~35% sequence identity with the *C. botulinum* C3 molecule (Table 9.1). The EDIN-producing strains of *S. aureus* (~7.8% of all clinical isolates) are preferentially obtained from skin suppurations as well as other infection sites, versus only 3.7% of *S. aureus* isolated from healthy nasal carriers, thus suggesting that EDIN may be a virulence factor (Czech *et al*., 2001).

### Structure and enzymatic activity

C3 enzymes are secreted from bacteria into the extracellular milieu and possess a catalytic domain, but curiously lack binding and translocation domains that would permit targeted entry into cells. Crystallography data of C3 molecules from *S. aureus* and *C. botulinum* reveal a core structure containing five antiparallel β-strands packed against three-stranded antiparallel β-sheets that are flanked by four consecutive α-helices (Han *et al*., 2001; Evans *et al*., 2003). Interestingly, the C3 conformation is strikingly similar to the actin-specific, catalytic domains found in *B. cereus* VIPII and *C. perfringens* Ia (Figure 9.3) (Han *et al*., 1999; Tsuge *et al*., 2003).

Although there is no significant overall sequence homology with other ADP-ribosylating toxins, C3 retains the conserved NAD binding site and catalytic pocket consisting of an α-helix (α3; residues 83–93) bent over two antiparallel β-sheets that form a central cleft. The amino acids that have an essential role in ADP-ribosylation are conserved and consist of a hydrophobic segment containing the $_{174}$Ser-Thr-Ser$_{176}$ motif, flanked by Arg128 and Glu214 (Han *et al*., 2001). Additionally, Glu214 plays a pivotal role in catalysis of NAD and transfer of the ADP-ribose group onto Asn41 of Rho. C3 and the clostridial binary toxins differ from other ADP-ribosylating toxins by containing two adjacent protruding turns, designated as an ADP-Ribosylating toxin Turn-Turn (ARTT) motif consisting of Phe/Tyr-X-X-Gln/Glu-X-Glu involved in specific substrate recognition. However, the C3 and EDIN molecules that specifically modify Rho-GTPases contain a conserved Gln212 in turn 2, whereas the actin-ADP-ribosylating toxins have a Glu at this position (Han *et al*., 1999; Han *et al*., 2001). The ARTT-containing loop adopts a conformation upon NAD binding that permits transition of Gln212 from a buried, to a solvent-exposed, position. This indicates that C3 acts in three distinct steps that include NAD binding, Rho binding, and finally Rho ADP-ribosylation (Ménétrey *et al*., 2002). All C3 exoenzymes recognize RhoA, B, or C, and *S. aureus* EDIN also modifies RhoE (Wilde *et al*., 2001).

Rho-GDP is a preferred substrate for C3 (Habermann *et al*., 1991), as Rho-Asn41 is solvent accessible in the GDP structure (Wei *et al*., 1997). In contrast, the Asn41 residue of Rho found in a Rho-GDI complex is hidden and thus resistant to C3-mediated ADP-ribosylation (Bourmeyster *et al*., 1992). ADP-ribosylation of Rho-Asn41 by C3 does not impair GDP/GTP exchange, does not affect intrinsic GAP-stimulated GTPase activity, and does not impinge upon Rho interaction with its effectors (Ren *et al*., 1996; Sehr *et al*., 1998). However, ADP-ribosylation of Rho does block translocation to the membrane where it is required for activation and interactions with its effectors. Finally, ADP-ribosylated Rho can reassociate more efficiently with GDI than unmodified Rho, thus causing an accumulation of inactive Rho in the cytosol (Figure 9.5) (Fujihara *et al*., 1997; Ohishi, 2000).

### Effects on cell barriers

The enzymatic effects of C3 have been widely used to study the function of Rho, and the results from various groups implicate this GTPase in establishing, as well as maintaining, adhesive structures whose regulation may vary between cell types. For example, C3 induces cell rounding and destruction of actin filaments in epithelial and fibroblast cells, but there is little disorganization of cortical actin (Chardin *et al*., 1989). In polarized T84 cells, C3 profoundly alters the apical actin cytoskeleton, distribution of occludin, ZO-1 and claudin-1 found in TJs, as well as increases cell barrier permeability; however, there is no perturbation of the AJs (Nusrat *et al*., 1995; Walsh *et al*., 2001). C3 microinjected into MDCK cells causes the disappearance of

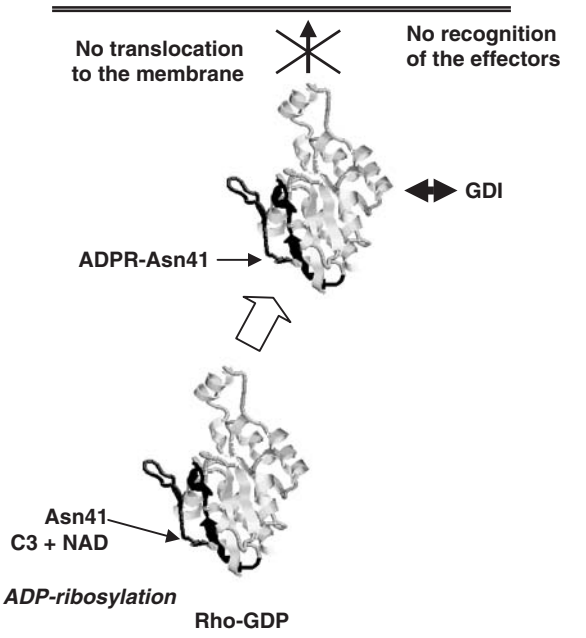

**FIGURE 9.5** Schematic mode of action for the Rho-inhibiting C3 enzyme via ADP-ribosylation.

actin filaments at cell-cell adhesion sites, as well as alters formation of TJs and AJs (Takaishi *et al*., 1997). In addition, C3 inhibits association of the ERM (ezrin, radixin, and moesin) family of proteins and vinculin with the plasma membrane, which is necessary for developing the basal edge and focal adhesions of cells (Kotani *et al*., 1997). Overall, this information indicates that Rho plays a central role in forming and maintaining TJs. Consistently, RhoK is a major downstream effector that controls TJ formation through monophosphorylation of the myosin light chain and contraction of the perijunctional actomyosin ring (Turner *et al*., 1997). However, as opposed to Rho inactivation by C3, inhibition of RhoK with Y27632 induces a redistribution of TJ molecules without completely abolishing the monolayer integrity (Walsh *et al*., 2001). Another mechanism independent of RhoK and the cytoskeleton could also be involved in TJ formation and phosphorylation of occludin, as measured by transepithelial electrical resistance (TER) (Hirase *et al*., 2001; Schneeberger and Lynch, 2004).

Effects of Rho on AJs, the latter structure being found underneath TJs and involved in cell-cell contact, gene expression, and cell differentiation via numerous (n >30) cadherin family proteins (Perrez-Moreno *et al*., 2003), depend upon the cell type and junctional maturity. For example, C3 disrupts E-cadherin staining of keratinocytes and MDCK cells, but not that in T84 or human umbilical endothelial cells (Nusrat *et al*., 1995; Braga *et al*., 1997; Takaishi *et al*., 1997; Braga *et al*., 1999). Integrin localization at cell-cell contact sites is not modified in keratinocytes treated with C3 (Braga *et al*., 1999). Other experiments show that C3 does not alter AJs in MDCK cells transfected with a dominant positive Rac, thus suggesting that AJs are mainly regulated by Rac (Takaishi *et al*., 1997). The Rho molecule probably controls E-cadherin intercellular junctions indirectly through rearranging the actin cytoskeleton (Fukata and Kaibuchi, 2001).

In contrast to epithelial cells, C3 disassembles actomyosin filaments and focal adhesions formed by endothelial cells, but it does not alter the intercellular junctions or endothelial permeability. In fact, C3 prevents the endothelial permeability induced by vasoactive agents like thrombin and histamine, thus indicating Rho involvement in this process. C3 also blocks the increased actomyosin contractility leading to cell retraction, intercellular gap formation, and the loss of TJs and AJs caused by thrombin as well as histamine (Figure 9.4) (Vouret-Craviari *et al*., 1998; Carbajal and Schaeffer, 1999; Wojciak-Stothard *et al*., 2001).

## CLOSTRIDIAL GLUCOSYLATING TOXINS

The glucosylating toxins produced by various clostridial species, also known as the large clostridial toxins, are 250–300 kDa single-chain proteins that include *C. difficile* toxins A (ToxA) and B (ToxB), *C. sordellii* lethal toxin (LT), and hemorrhagic toxin (HT), as well as *C. novyi* α toxin (α-novyi) (Table 9.1) (Schirmer and Aktories, 2004). Glucosylating toxins represent the main virulence factors of these *Clostridium* species, commonly involved in intestinal diseases and/or myonecrosis. *C. difficile* can cause pseudomembranous colitis and enteritis that often follow antibiotic treatment, which represents the most prevalent nosocomial form of diarrheal disease in hospitals (see chapter 22). *C. sordellii* and *C. novyi* both appear as common causative agents of gas gangrene in humans and animals. Additionally, *C. sordellii* is involved in hemorrhagic enteritis of cattle as well as enterotoxemia in sheep, and *C. novyi* can induce bovine hepatotoxemia (Songer, 1996).

The glucosylating toxins of *Clostridium* contain three functional domains. The C-terminus displays multiple repeated sequences that are homologous with peptide segments from streptococcal glucosyltransferases and recognize cell surface receptor(s). For example, the corresponding domain in ToxA recognizes a trisaccharide (Gal-α1-3Gal-β1-4GlcNac) motif, and a cell surface receptor found in rabbit ileal brush borders was subsequently

identified as the glycoprotein sucrase-isomaltase; however, this protein is not expressed in the human colon. Clearly, further work needs to be done to identify the receptor for ToxA that is pertinent in the human intestinal tract (Just *et al*., 2000). The central part of these toxins contains a hydrophobic segment that probably mediates translocation across a cell membrane (Pfeifer *et al*., 2003). An enzymatic site characterized by a Asp-X-Asp motif surrounded by hydrophobic regions, and the substrate recognition site, are both localized within the first 546 N-terminal residues of ToxB and 659 N-terminal residues of ToxA. ToxB and LT are highly related (76% amino acid sequence identity), but there is less identity (48–60%) evident with ToxA and α-novyi (Aepfelbacher *et al*., 2000).

## Mode of action

Large clostridial toxins enter cells by receptor-mediated endocytosis. The cytotoxic effects are blocked by inhibitors (i.e., monensin, bafilomycin A1, ammonium chloride) of endosomal and lysosomal acidification, a process that can be circumvented by an extracellular acidic pulse that facilitates direct toxin entry into the cytosol from the outer surface of the cell membrane (Qa'dan *et al*., 2000; Barth *et al*., 2001; Qa'dan *et al*., 2001). This indicates that the large clostridial toxins translocate from early endosomes following an acidification step. At low pH, ToxB and LT induce channel formation in cell membranes and artificial lipid bilayers, which correlates with a concomitant increase in hydrophobicity as determined by fluorescence methods (Qa'dan *et al*., 2000, 2001). This probably involves a conformational change and subsequent insertion of toxin into the membrane, possibly mediated by a hydrophobic peptide segment(s) located within the central domain. Although not clearly delineated, it is likely that a proteolytically derived N-terminal fragment containing the active site is translocated into the cytosol (Pfeifer *et al*., 2003).

Large clostridial toxins catalyze the glucosylation of 21 kDa G-proteins using UDP-glucose, with an exception being α–novyi, which utilizes UDP-*N*-acetylglucosamine as co-substrate. These enzymes transfer one molecule of glucose or *N*-acetylglucosamine to the hydroxyl group of an acceptor amino acid, such as Thr37 of Rho or Thr35 of Rac, Cdc42, and Ras proteins (Just *et al*., 1995; Böhmer *et al*., 1996). Rho complexed to GDI is not a substrate for glucosylation, and modified Rho does not bind to GDI (Genth *et al*., 1999). ToxA and ToxB glucosylate Rho, Rac, and Cdc42, whereas LT modifies Rac, Cdc42, and several Ras proteins (i.e., Ras, Rap, Ral). Some *C. difficile* and *C. sordellii* strains respectively produce variant ToxB or LT molecules that differ in activity towards specific substrates.

The conserved, glucosylated Thr37/35 residues are located on a loop within switch I of Rho-/Ras-GTPases and exposed only on the surface of GDP-bound GTPase (Figure 9.6). Therefore, GDP forms of GTPases represent a preferred substrate for glucosylating

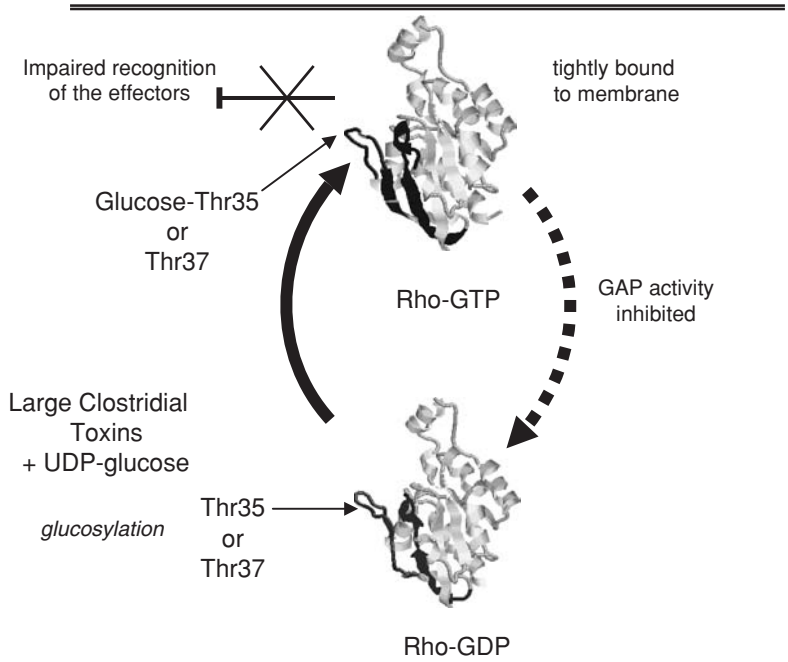

**FIGURE 9.6** Schematic mode of action for the large clostridial toxins that inhibit Rho-GTPases via glucosylation.

toxins. The Thr37/35 residues are involved in coordinating $Mg^{++}$ and subsequent binding of the β- and γ-phosphates of GTP. Nucleotide binding of glucosylated Ras by LT is not grossly altered, but the GEF activation of GDP forms is decreased (Essler *et al*., 1998). Glucosylation of Thr35 prevents recognition of the downstream effector, blocking the G-protein in an inactive form (Essler *et al*., 1998). Analysis of the crystal structure of Ras, modified by LT, shows that glucosylation prevents switching towards a GTP-bound conformation that exposes the effector loop necessary for interaction with an effector molecule like Raf (Vetter *et al*., 2000). Similar results were found with RhoA following glucosylation by ToxB (Sehr *et al*., 1998). In addition, glucosylation of the GTPase slightly reduces intrinsic GTPase activity and completely inhibits GAP-stimulated hydrolysis of GTP (Essler *et al*., 1998), leading to an accumulation of the GTP-bound form of Rho near the membrane where it binds to an unknown protein of ~70 kDa in a saturable, competitively inhibited manner. Glucosylated Rho does not cycle between a GDP- and GTP-bound form or the cytosol and membrane (Genth *et al*., 1999), and the crucial inactivation step of Ras-/Rho-GTPases by glucosylation consists of GTPase uncoupling from effector molecules.

## Effects on cell barriers

ToxB induces loss of actin stress fibers and reorganization of focal adhesions accompanied by cytoplasmic retraction and cell rounding, whereas long protrusions radiating around the cell yield a particular "actinomorphic" morphology (Ottlinger and Lin, 1988). ToxA and α-novyi cause similar cell alterations, but LT produces cell rounding without branched, membrane protrusions. In contrast to C3, large clostridial toxins modify more than one GTPase that renders more difficult the interpretation of cellular effects. Such effects could be linked to the simultaneous inhibition of several GTPase pathways and activities other than GTPase glucosylation attributed to the large clostridial toxins.

Alteration of the actin cytoskeleton is dependent upon intracellular UDP-glucosylation by *C. difficile* and *C. sordellii* toxins, since a cell line deficient in UDP-glucose is resistant to these toxins (Chaves-Olarte *et al*., 1996). Disruption of actin filaments by the *C. difficile* toxins results from Rho inactivation, subsequent diminishment of RhoK activity, and decreased phosphatidylinositol-bis-phosphate ($PIP_2$) levels as a consequence of reduced phosphatidylinositol 4-phosphate 5-kinase (PI4P5K) activity downstream of Rho and Rac. The actin cytoskeletal effects elicited by LT probably involve inhibition of the Rac-PI4P5K pathway.

ToxA and ToxB alter the barrier function of polarized intestinal cells such as CaCo-2 and T84 by increasing paracellular permeability (Hecht *et al*., 1988; Hecht *et al*., 1992; Johal *et al*., 2004). Concomitant with the permeability increase, ToxA and ToxB disrupt apical and basal actin filaments with a subsequent disorganization of the ultrastructure and component distribution (i.e., ZO-1, ZO-2, occludin, claudin) with TJs, whereas E-cadherin junctions do not evidently undergo any detectable alteration. ToxB decreases actin-ZO-1 association and disperses ZO-1 and occludin from lipid-rich membrane microdomains, without changing the occludin phosphorylation status (Nusrat *et al*., 1995; Chen *et al*., 2002). Since Rho plays an important role in TJ assembly, the effects of ToxB and ToxA on TJs presumably result from Rho glucosylation (Fig. 9.4) (Jou *et al*., 1998). However, ToxA induces protein kinase C (PKC) activation independently of GTPase modification, which could account for altered TJs and increased paracellular permeability (Chen *et al*., 2002). In addition, ToxA induces pro-inflammatory cytokine release, caspase activation, and apoptosis in T84 cells in a Rho-dependent manner, which altogether could contribute to mucosal damage (Brito *et al*., 2002).

*C. difficile* enteritis is characterized by a severe intestinal inflammation, which is toxin-mediated. ToxB and ToxA stimulate release of proinflammatory cytokines from monocytes. Indeed, ToxA increases interleukin (IL)-8 production and causes monocyte necrosis plus mucosal damage through p38MAP kinase activation (He *et al*., 2000). *In vivo*, ToxA is responsible for polymorphonuclear lymphocyte (PMNL) infiltration of the intestinal mucosa, and *in vitro* ToxA causes increased adherence, impaired migration, and reduced oxidative activity among PMNL (Brito *et al*., 2002; Pothoulakis and Lamont, 2001). Additionally, it has been shown recently that T84 cells increase IL-8 production and lose barrier function following ToxA exposure (Johal *et al*., 2004). *In vivo* mouse studies reveal that interferon-gamma and tumor necrosis factor alpha are involved in ToxA effects within the ileum (Ishida *et al*., 2004), while mice given a human intestinal xenograft and subsequently ToxB have an inflammatory response concomitant with a significantly increased expression of IL-8 (Savidge *et al*., 2003).

The LT of *C. sordellii*, which modifies Rac, Ras, Rap, and Ral, also alters permeability of intestinal cell monolayers via redistribution of E-cadherin, but not ZO-1 (Figure 9.4) (Richard *et al*., 1999). ToxB and LT also cause a redistribution of E-cadherin in endothelial cells, probably through Rac inactivation. Additionally, ToxB increases the permeability of both cultured endothelial cells and intact microvessels (Vouret-Craviari, 1999; Adamson *et al*., 2002; Waschke *et al*., 2004).

## TYPE-III VIRULENCE FACTORS WITH GAP ACTIVITY

### *Pseudomonas* exoenzymes

*Pseudomonas aeruginosa* is an opportunistic, nosocomial pathogen that produces several protein toxins called *exoenzymes* (Exo). ExoS, ExoT, ExoU, and ExoY are directly delivered into cells by a type-III secretion system (Table 9.2) (see Chapter 14) (Barbieri, 2000). In contrast, ExoA (~65 kDa) is a classic "A-B," single-chain toxin secreted from the bacterium into the environment and subsequently internalized into a targeted cell via receptor-mediated endocytosis after binding to an alpha-2 macroglobulin/low-density lipoprotein receptor. ExoA ADP-ribosylates elongation factor 2 via a post-translationally modified histidine called *diphthamide*, which subsequently inhibits cell protein synthesis. This intoxication process is similar to that employed by the diphtheria toxin of *Corynebacterium diphtheriae*. As evidenced by crystallography studies and subsequent biochemical analysis, ExoA consists of three domains that include: (i) N-terminal receptor binding region (residues 1–252 plus 365–404); (ii) central translocation region (residues 253–364); and (iii) C-terminal ADP-ribosyl transferase region (residues 405–613) (Pizza *et al*., 1999).

The type-III secreted ExoS molecule (~49 kDa) possesses two characterized activities (Barbieri, 2000). First, ExoS is an ADP-ribosyltransferase that recognizes several unrelated substrates like Ras, IgG2, apolipoprotein A1, as well as vimentin, and it curiously shares more sequence homology with vertebrate ADP-ribosyltransferases than those of procaryotic origin (Ganessan *et al*., 1999). The rather non-discriminating, ADP-ribosyltransferase activity of ExoS is stimulated by an ubiquitous eucaryotic protein (~28 kDa) called *factor-activating exoenzyme S* (FAS), which is a member of the conserved 14-3-3-protein family that is important in cell signaling among eucaryotes (Fu *et al*., 1993). ExoS ADP-ribosylates Ras at two residues, Arg41 and Arg128, that subsequently inhibits Ras-mediated signal transduction (Ganessan *et al*., 1999). The catalytic site on ExoS for ADP-ribosyltransferase activity is located within the C-terminal residues 234–453, with the 420–429 region being important for FAS interactions.

Additionally, ExoS has another activity localized within the N-terminus (residues 1–234), which ultimately disorganizes the actin cytoskeleton and induces cell rounding (Pederson *et al*., 2004). This latter domain of ExoS exerts a noncovalent, GAP activity towards Rho, Rac, and Cdc42 that stimulates the intrinsic GTPase activity of Rho proteins, with a slight preference for Rac. As recently discovered, ExoS activity is exerted in concert with Rho-GDI, which extracts activated Rho-GDP from the membrane and sequesters it in the cytosol (Sun and Barbieri, 2004). Amino acid sequence comparisons reveal that the arginine (Arg) finger, which stabilizes the transition state for GTP hydrolysis and is characteristic of Rho-/Ras-GAPs, is conserved within the N-terminus of ExoS (Ganessan *et al*., 1999). In addition, an Arg146Lys mutation within the Arg finger of ExoS abolishes GAP activity (Goehring *et al*., 1999). This finding further reveals that alteration of the actin filaments by ExoS is mediated by its GAP activity towards Rho, Rac, and Cdc42. The N-terminal domain of ExoS has an almost completely helical structure not related at the amino acid sequence and conformational levels to other Ras-/Rho-GAPs, although its mode of action is the same via insertion of an Arg finger within the catalytic site of Rho proteins (Figure 9.7) (Würtele *et al*., 2001). From a pathogenesis perspective, inactivation of Rho proteins by ExoS could inhibit phagocytosis of *P. aeruginosa* (Goehring *et al*., 1999).

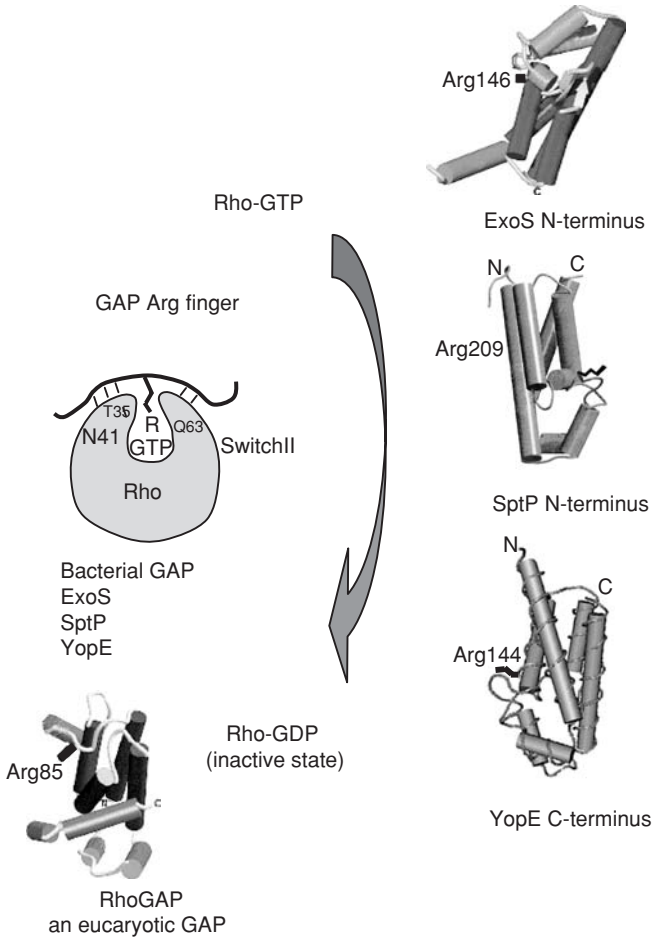

**FIGURE 9.7** Structural comparison of bacterial and eucaryotic GEF proteins, as well as schematic representation of the active Arg finger site.

Like ExoS, the type-III secreted ExoT molecule (~ 50 kDa) is also composed of two domains and shares 76% sequence homology. The N-terminal region of ExoT exerts GAP activity towards Rho, Rac, as well as Cdc42 (Krall *et al*., 2000), and the C-terminus possesses ADP-ribosyltransferase activity; however, this latter activity is only 0.2% of that evident in ExoS. ExoT plays an important role in inhibiting the healing process of damaged lung epithelial cells, and this property is localized within the C-terminus. As proposed for ExoS, the ExoT molecule also prevents phagocytosis by epithelial cells and macrophages (Garrity-Ryan *et al*., 2004).

## *Salmonella* secreted protein tyrosine phosphatase (SptP)

When internalized into cells, *Salmonella* can reverse the actin structures previously activated for bacterial entry, thus enabling the cell to regain its usual shape and intracellular organization. Sequential production by the bacterium, time of delivery into the targeted cell, and/or varying proteasome-dependent degradation patterns within the targeted cell of various virulence factors are probably involved in a coordinated effort upon the actin cytoskeleton that facilitates bacterial invasion and then restoration of the normal cell architecture. SptP represents the main virulence factor involved in the reversion process, and it is delivered into targeted cells by a type-III secretion system (Table 9.2). The N-terminal domain of the molecule is conformationally similar to other type-III secreted virulence factors like *Yersinia* YopE and *Pseudomonas* ExoS, sharing 22–29% amino acid sequence identity (Evdokimov *et al*., 2002). This region of SptP exerts a GAP activity towards Rac and Cdc42, but not Rho. SptP binds to Rac and Cdc42 in the GTP-bound form via SptP residues Thr213 (Switch I and II interface), Gln246 (Switch I interface), as well as Thr249 (Switch I and GDP interface) (Stebbins and Galan, 2000), which ultimately stimulates GTP hydrolysis. As mentioned before, all GAPs possess a conserved Arg that plays a pivotal role in enzyme activity. The Arg finger for SptP has been assigned to Arg209, as cells infected with a *Salmonella* strain producing an Arg209Ala mutant of SptP do not regain a normal actin cytoskeleton after infection. This confirms that SptP reverses the actin cytoskeleton rearrangement by its GAP activity towards Rac and Cdc42 (Fu and Galan, 1999). The C-terminal domain (residues 300–543) of SptP is related to *Yersinia* YopH (30% sequence identity) and several eucaryotic tyrosine phosphatases, with an active site localized to residues 479–489 as well as a phosphate-binding (P) loop motif (Iso/Val)-His-Cys-X-X-Gly-X-Gly-Arg-(Ser/Thr)-Gly typically found in phosphatases (Stebbins and Galan, 2000).

Analysis of a SptP-Rac1 crystal complex reveals that the SptP surface is highly complementary to that of the GTPase. SptP binds Rac exclusively through a four-helix bundle from the N-terminal GAP domain (residues 167–290) that recovers the nucleotide and interacts with both the Switch I (residues 30–41) as well as Switch II (residues 60–71) regions of the GTPase. Helices H3 (residues 207–221; particularly Thr213) and H5 (residues 244–248; particularly Gln246) are the main contact sites with Switch I, while H1 (residues 168–186) as well as H3 target Switch II. The Arg finger (Arg209) is located within helix H3 and inserts deeply into the active site of Rac1. Arg209 interacts with the β-phosphate of GTP and Switch I, thus constraining the Gln61 of Rac1 in a more catalytically favorable conformation for GTP hydrolysis. Although SptP possesses an overall different conformation versus that found in eucaryotic GAPs, its interaction domain with Rho-GTPases mimics that of host GAPs (Figure 9.7) (Stebbins and Galan, 2000). SptP is the smallest, yet one of the more active, Rho family GAPs that possesses unique characteristics involving: (i) location of the catalytic Arg209 on an α-helix, not on a loop, as found in eucaryotic GAPs; and (ii) interactions only with Switch I, Switch II, and the active site of Rac, which differs from eucaryotic GAPs that possess a larger interaction surface. Altogether, this outlines a minimal structure involved in GAP activity and argues for a convergent evolution of eucaryotic and bacterial GAPs. Binding to Rac does not conformationally change the C-terminal domain of SptP, which possesses a tyrosine phosphatase activity that plays an unknown role during intoxication. However, it is possible that the GAP domain targets tyrosine phosphatase to its relevant substrate(s) (Stebbins and Galan, 2000, 2001), which may ultimately down-regulate subsequent nuclear responses to Cdc42 and Rac stimulation (Galan, 2001). Additionally, both tyrosine phosphatase and GAP activities of SptP may reverse MAP kinase activation due to *Salmonella* infection by inhibiting Raf activation, and modifying vimentin involved in forming intermediate filaments as well as membrane ruffles important in bacterial entry (Murli *et al*., 2001; Lin *et al*., 2003).

## *Yersinia* outer protein (Yop) E

*Yersinia enterocolitica* and *Yersinia pseudotuberculosis* are Gram-negative, enteric pathogens that cause enteritis, lymphadenitis, extraintestinal abcesses, and septicemia. After ingestion, *Yersinia* penetrate intestinal lymphoid follicles (Peyer's patches) of the terminal ileum, colonize mesenteric lymph nodes, and then

may spread to other organs such as the spleen. Dissemination of *Yersinia* from the intestinal tract begins by entering M-cells via an invasin, a type-III secretion factor that is chromosomally encoded and interacts with β-integrin on the apical surface. Bacteria are then translocated through Peyer's patches and into lymph nodes by way of the M cells, finally multiplying extracellularly since they are resistant to phagocytosis. The main virulence strategy of *Yersinia* involves resistance to polymorphonuclear phagocytosis, which is based on type-III secreted proteins called Yops (Yop-E, -H, -M, -O, -P, and T) with various activities (Table 9.2) (Cornelis, 2002). The genes for Yops are localized on the pYV plasmid (~70 kb) found in *Y. enterocolitica* and *Y. pseudotuberculosis*, as well as an equivalent *Yersinia pestis* plasmid (pCD), and the resultant proteins are responsible for inhibiting phagocytosis, increasing release of proinflammatory cytokines (i.e., IL-12, tumor necrosis factor alpha), and inhibiting nitric oxide production from host cells (Cornelis, 2002; Brubaker, 2003; Monnazzi *et al*., 2004).

YopE (~24 kDa) is one of the most potent *Yersinia* factors responsible for resisting phagocytosis. Expression of GAP-active YopE by *Y. pseudotuberculosis* is an essential virulence factor in infection models with mice and HeLa cells, leading to loss of actin filaments, cell rounding, and inhibited bacterial uptake (Black and Bliska, 2000). YopE shares sequence similarity with the N-terminal domains of *Pseudomonas* ExoS and *Salmonella* SptP. Residues 1–50 of YopE are involved in type-III secretion from the bacterium into macrophages. The crystal structure of YopE GAP domain (residues 90–219) was recently resolved at 2.2 angstrom, thus revealing conformational similarity with ExoS and SptP (Evdokimov *et al*., 2002). In addition, the Arg finger motif is conserved in YopE and an Arg144Ala mutation yields an inactive protein; therefore, YopE acts as a GAP (Figure 9.7) (Black and Bliska, 2000; von Pawel-Rammingen *et al*., 2000). *In vitro* experiments show that YopE stimulates GTPase activity of Rho, Rac, and Cdc42, but not Ras (von Pawel-Rammingen *et al*., 2000). However, in primary human umbilical vein endothelial cells (HUVEC), YopE specifically inhibits Rac-, but not Rho- or Cdc42-, dependent actin structures. In addition, YopE only affects Rac activated via Cdc42 but not direct, Rac-1 induced ruffle formation following stimulation by sphingosine-1-phosphate (Andor *et al*., 2001). Thus, YopE inactivates Rho-GTPases by a GAP activity, thus leading to actin depolymerization and inhibition of phagocytosis. Specific inhibition of the Cdc42-dependent activation of Rac by YopE could block phagocytosis triggered by Fcγ-receptor, since it has been shown that an immunoglobulin receptor-dependent route of internalization is mediated by Cdc42 and Rac, whereas that used by the complement receptor is mediated by Rho (Caron and Hall, 1998).

## OTHER TYPE-III VIRULENCE FACTORS INACTIVATING RHO-GTPASES

### YopT, a cysteine-protease

YopT (~36 kDa) is a type-III cysteine protease that *in vitro* cleaves Rho-GTPases near the C-terminus, thus preventing their association to the membrane normally mediated via a C-terminal prenyl group and yielding irreversibly inactivated Rho-GTPases (Figure 9.8) (Shao *et al*., 2002). YopT disrupts actin filaments and induces cell rounding. When cells are infected with *Y. enterocolitica*, YopT localizes to cell membranes and selectively releases RhoA, but not Rac or Cdc42, from the membrane. RhoA accumulates in the cytosol uncoupled from Rho-GDI and can not activate downstream effectors. In macrophages, YopT disrupts the podosomal adhesion structure and phagocytic cup rich in actin filaments required for bacterial entry (Aepfelbacher *et al*., 2003).

### YopO/YpkA

YopO produced by *Y. enterocolitica* and the homologue YpkA (~80 kDa) from *Y. pseudotuberculosis* are type-III serine/threonine kinases that disrupt the actin cytoskeleton. These effectors directly interact with Rho and Rac independent of their phosphorylation status and GTP or GDP loading state of the GTPases (Table 9.2) (Barz *et al*., 2000; Nejedik *et al*., 2004). The exact mode of inactivation of Rho-GTPases by YopO and YpkA is still unknown.

### YopH

YopH (~50 kDa) is a potent phospho-tyrosine phosphatase that dephosphorylates focal adhesion proteins such as P130 CAS and P125FAK. The N-terminus (residues 1–130) and C-terminus (residues 206–488) are respectively responsible for substrate binding and catalysis (Smith *et al*., 2001).

## TOXINS ACTIVATING RHO-GTPASES

### Toxins that deamidate Rho-GTPases: *Escherichia* CNF and *Bordetella* DNT

The cytotoxic necrotizing factor (CNF) is produced by some pathogenic strains of *Escherichia coli* and consists of two variants, CNF1 and CNF2 (Table 9.1) (see

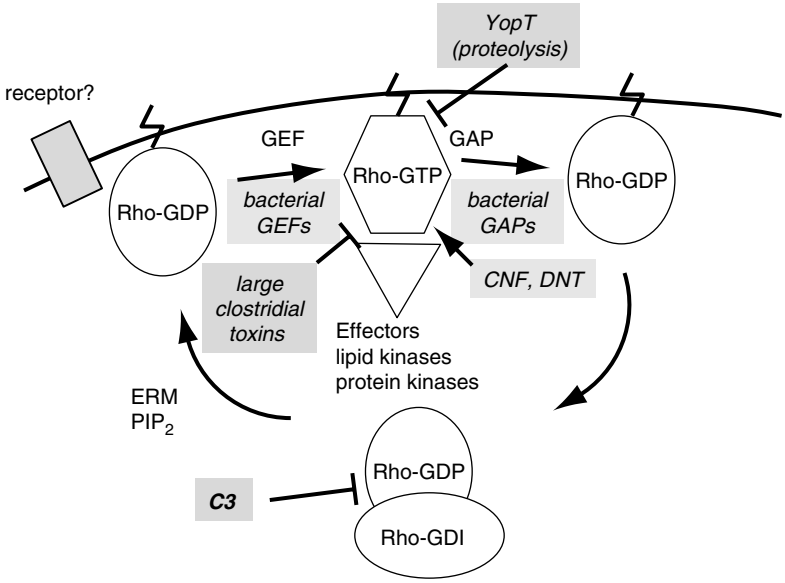

**FIGURE 9.8** Bacterial toxins and virulence factors that target Rho-GTPases. The C3 enzyme and large clostridial toxins enzymatically inactivate Rho-GTPases, whereas CNF/DNT enzymatically activate these targets. Type-III virulence factors from invasive bacteria mimic eucaryotic GEFs or GAPs.

Chapter 11). CNF1 is synthesized by human strains mainly isolated from urinary tract infections and neonatal meningitis, whereas CNF2 is primarily produced by strains of animal origin that are often involved in enteritis and septicemia of calves. Almost all uropathogenic isolates of *E. coli* that produce CNF1 (about 30% of all strains implicated in urinary infections) contain the alpha-hemolysin gene upstream of the *cnf1* gene. The *cnf1* gene is chromosomally located on a pathogenicity island between the alpha hemolysin operon and gene encoding Pap-related and/or S-fimbriae adhesins. The *cnf2* gene is harbored by the Vir plasmid (Bluetow *et al*., 2001).

*E. coli* CNF1 and CNF2 are highly related proteins (86% sequence identity) of ~ 110 kDa, and similar molecules are also produced by other Gram-negative bacilli such as *Bordetella* (i.e., dermonecrotic toxin or DNT; ~159 kDa) (Table 9.1), *Pasteurella* (i.e., *P. multocida* toxin or PMT; ~146 kDa), as well as *Y. pestis* and *Y. pseudotuberculosis* (i.e., cytotoxic necrotizing factor or $CNF_Y$; ~120 kDa) (Bluetow *et al*., 2001; Lockman *et al*., 2002). CNF1, and presumably CNF2, are released from *E. coli* into the local environment, bind to an unknown cell-surface receptor(s), and ultimately enter the cytosol via clathrin-independent endocytosis through late endosomes (Boquet, 2001).

Structurally, the CNF toxins contain three functional regions: (i) a N-terminal domain (amino acids 1–299) involved in binding to a cell surface receptor; (ii) a central domain (amino acids 299 to 720) containing two hydrophobic regions that likely enable translocation of toxin across the cell membrane; and (iii) the C-terminal catalytic domain (residues 720–1014) possessing deamidase activity. The C-terminal domain of CNF1 is unusually folded, since it forms a single compact domain containing a central β-sandwich resulting from two mixed β-sheets surrounded by helices and extensive loop regions. Residues Cys866 and His881, which are essential for catalytic activity, are located in a deep narrow pocket (Figure 9.3). This exclusive positioning of the active site likely dictates substrate specificity and supposes a conformational change for CNF1 and/or Rho to accommodate the switch II region containing the Gln63 target. Cys866 in its thiolate form is responsible for nucleophilic attack on the δ-carboxamide of RhoA Gln63 (Bluetow *et al*., 2001).

The first indication of CNF1 activity towards Rho protein came from an observed electrophoretic shift during SDS-PAGE, which was subsequently confirmed by microsequencing and mass spectrometry. CNF1 preferentially targets Rho and catalyzes deamidation of Gln63 to Glu, but Rac and Cdc42 are also modified at an equivalent residue (Gln61). GDI forms of the Rho-GTPases are not modified by CNF. Gln63 (Gln61) is located within switch II of the Rho-GTPases and has a pivotal role in intrinsic and GAP-stimulated GTPase activity. Deamidation of Gln63 (Gln61) into Glu impairs binding of a water molecule required for GTP hydrolysis (Fiorentini *et al*., 1997; Koch *et al*., 1997); therefore, CNF1 locks Rho-GTPases into a biologically

active form linked to GTP (Figure 9.9). Clearly, CNF2 and *Bordetella* DNT are related to CNF1 structurally, and they also share comparable mechanisms of action. However, DNT/CNF2 act preferentially as transglutaminases, whereas CNF1 is primarily a deamidase (Schmidt *et al*., 1999).

CNF1 and 2 are dermonecrotic upon intradermal injection in rabbits and guinea pigs, as well as lethal by intraperitoneal injection. In cultured cells, CNF1 converts Rho-GTPases into active forms that stimulate downstream signaling pathways leading to multinucleation, increased actin polymerization, reorganization of stress fibers, membrane ruffles, as well as increased phagocytic activity among human epithelial cells. The Rho-Glu63 and Rac-Glu61 forms activate PI4P5K, a subsequent increase of $PIP_2$ levels enhances actin polymerizaton, and activated RhoK stimulates bundling of the actomyosin filaments. The CNF cellular effects vary according to the cell type, which is a consequence of different cytosolic levels of Rho-GTPases. In fibroblasts, such as Vero cells, CNF1 induces formation of dense actin stress fibers and focal contact points, whereas in epithelial cells (Hep2), formation of lamellipodia and filopodia predominate. In both cell types, CNF1 leads to spreading that results from increased formation of actin filaments at the leading edge and anchorage of actomyosin filaments to focal contact points. This suggests that CNF1 activates first Cdc42 and Rac, then Rho, in epithelial cells, whereas the action upon fibroblasts is primarily mediated via Rho (Boquet, 2001). PMT from *P. multocida* also activates Rho and subsequently RhoK leading to actin stress fiber and focal adhesion formation by a yet undefined mechanism. This toxin induces additional cellular effects that include strong stimulation of DNA synthesis, proliferation, and stimulation of phospholipase C (Zywietz *et al*., 2001).

Activation of Rho-GTPases by CNF is only transient, since deamidated Rho-GTPases are ubiquitinated and rapidly degraded by the proteasome. This process favors bacterial internalization by epithelial cells that require Rho-GTPase activation for lamellipodia formation and phagocytosis, followed by down-regulation (Doye *et al*., 2002). In contrast to invasive bacteria, which use distinct activators and inhibitors of Rho-GTPases, CNF alone mediates both sequential activities.

The role of CNF in *E. coli* pathogenesis is still unclear. Various effects of CNF in host cells have been identified, which include stimulation of phagocytosis and bacterial uptake into cells, as well as protection against apoptosis. One of the primary CNF-induced perturbations involves modification of intestinal or urinary tract cell barriers. In intestinal cell monolayers, CNF1 decreases TER and enhances paracellular permeability from the basal to apical surface. Concomitantly, TJ proteins are redistributed in endosomal caveolar compartments, but microvillus F-actin and its binding

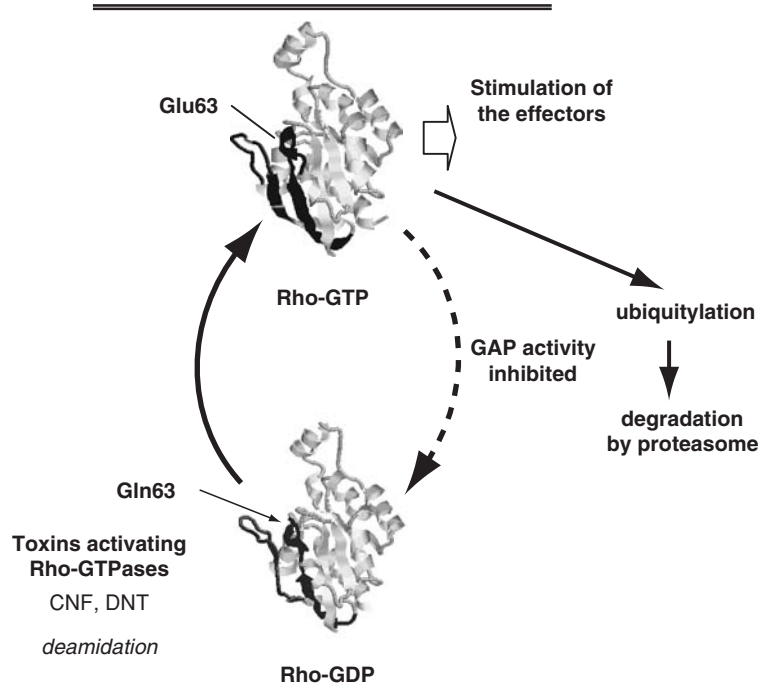

**FIGURE 9.9** Schematic mode of action for Rho-GTPase activating toxins that deamidate Gln63.

protein, villin, disappear. In contrast, AJs containing E-cadherin are preserved during CNF1 intoxication. CNF1-activation of RhoA predominantly mediates the aforementioned cellular effects, although Rac and Cdc42 are seemingly additional targets for CNF1. However, alteration of Rac and Cdc42 may result from an indirect perturbation in the delicate balance of Rho, Rac, and Cdc42 (Hopkins *et al*., 2002).

## VIRULENCE FACTORS WITH GEF ACTIVITY

### *Salmonella* outer protein (Sop) E

*Salmonella* can bind to cells via fimbriae, and then enter by a trigger mechanism consisting of large membrane ruffles that engulf the bacteria. The subsequent actin cytoskeleton and plasma membrane rearrangements are reminiscent of lamellipodia and filopodia induced by growth factors via Rho-GTPases. It was first found that Cdc42 and Rac were involved in *Salmonella*-dependent signaling, which triggers a cell structure rearrangement leading to bacterial internalization. Dominant negative mutants of Cdc42, but less so the Rac variants, inhibit *Salmonella* entry (Chen *et al*., 1996). It was then identified that a type-III secreted protein, called SopE (~25 kDa) interacts with Cdc42 and Rac (Table 9.2) (Hardt *et al*., 1998). Two isoforms exist, SopE and SopE2, which share 70% sequence identity, as well as activate Rho-GTPases like GEFs by catalyzing GDP-GTP exchange. *In vitro* experiments show that SopE exerts a GEF activity towards Rac1, Rac2, Cdc42, RhoG, and to a lesser extent RhoA, but there is no evident activity with RhoB, RhoC, Ran, H-Ras, and TC21 (Hardt *et al*., 1998). In contrast, SopE2 only interacts with Cdc42 and not Rac (Friebel *et al*., 2001). Microinjection of SopE in Cos cells stimulates actin cytoskeleton rearrangement and membrane ruffling similar to that induced by *Salmonella* infection (Hardt *et al*., 1998). SopE binds to switch I and II of Rho-GTPases like other Rho-GEFs, such as the eucaryotic Tiam (T-lymphoma invasion and metastasis)-1 protein (Buchwald *et al*., 2002), ultimately resulting in switch I and II rearrangement and nucleotide release. However, there are noticeable structural differences between SopE and other Rho-GEFs, as the former uses a loop containing the $_{166}$Gly-Ala-Gly-Ala$_{169}$ motif to reorient switches I and II, whereas the catalytic core of other Rho-GEFs consists of an α-helix containing a critical Lys at the active site (Figure 9.10) (Buchwald *et al*., 2002). SopE also acts as a GEF for Rab5, thereby mediating the recruitment of non-prenylated Rab5-GTP into phagosomes containing live *Salmonella*. This promotes phagosome fusion with early endosomes, thus avoiding terminal transport to lysosomes and destruction of the invading *Salmonella* (Mukherjee *et al*., 2001). In addition, activation of Cdc42 and Rac by SopE stimulates JNK and MAP kinase pathways, leading to transcriptional factor activation (Hardt *et al*., 1998). The activity of SopE1 and SopE2 is complemented by another type-III factor, called SopB or SigD, an inositol phosphatase that specifically dephosphorylates inositol (1,3,4,5,6)-pentakisphosphate (Ins1,3,4,5,6P$_5$), producing Ins(1,4,5,6)P$_4$ that acts as an indirect activator of Cdc42 (Zhou *et al*., 2001).

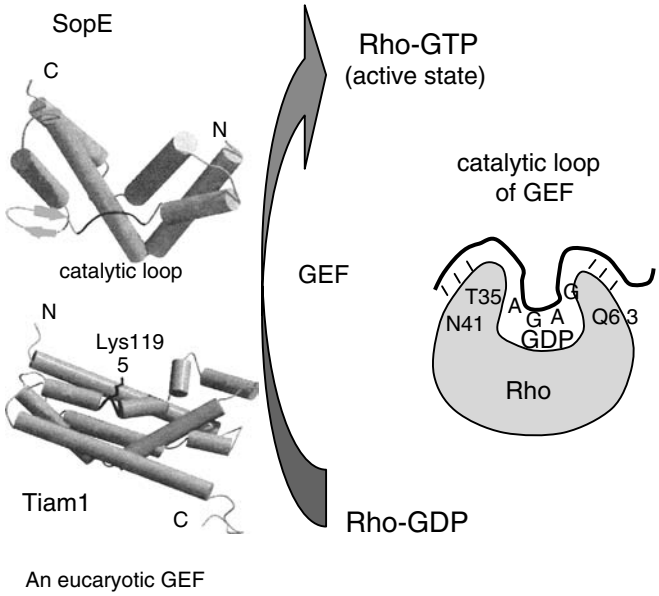

**FIGURE 9.10** Structural comparison of the bacterial GEF SopE (Cdc42/Rac specific) and an eucaryotic equivalent (Tiam1, a Rac GEF), as well as schematic representation of the active site.

## OTHER TOXINS MODIFYING ACTIN POLYMERIZATION

The zonula occludin toxin (ZOT, ~45 kDa) from *V. cholerae* serves a dual function involving phage protein assembly (N-terminus) and enterotoxin activity (C-terminus). The C-terminal part of ZOT is proteolytically cleaved, released, and interacts with a specific receptor that leads to actin polymerization in a PKCα-dependent manner, ZO-1-occludin as well as ZO-1-claudin disengagement, and finally increased cell barrier permeability. The ZOT molecule mimics an endogeneous modulator of TJs and intestinal permeability called zonulin (Wang *et al*., 2000).

*V. cholerae* also produces a RTX (repeats in toxin) toxin containing unusual repeats when compared to

the other RTX toxins. The central domain of cholera RTX cross-links G-actin into dimers, trimers, and higher multimers, thus inducing actin filament depolymerization, as well as subsequent loss of cell barrier function. Depletion of actin monomers, which disrupts the equilibrium between G- and F-actin, probably accounts for the depolymerization of actin filaments (Fullner *et al*., 2000; Fullner and Mekalanos, 2000).

## TOXINS TARGETING INTERCELLULAR JUNCTION MOLECULES

### *Bacteroides fragilis* enterotoxin (see Chapter 28)

*Bacteroides fragilis* enterotoxin (BFT or fragilysin) is a 20 kDa, single-chain protein produced as a 44 kDa protoxin which, upon activation by a serine-type protease, elicits fluid accumulation in ileal loops, as well as causes overt morphological changes in cultured intestinal and renal cells. The toxin is associated with diarrhea in animals and humans. BFT-induced effects on cells include rounding, increased size, and effacement of microvilli as well as apical junction complexes. BFT is a zinc-dependent protease possessing the consensus His-Glu-X-X-His motif, and it cleaves the extracellular domain of E-cadherin, which is primarily found in the zonula adherens that facilitate cell-cell adhesion (Table 9.1 and Figure 9.4). Experimental studies have led to a proposed two-step hypothesis for BFT intoxication, whereby the extracellular domain of E-cadherin is first cleaved by BFT, followed by intracellular degradation via an unidentified protease(s) (Sears, 2001). As a consequence, nuclear signaling and actin rearrangement occurs, which leads to the production of proinflammatory cytokines (Sanfilippo *et al*., 2000), diminished epithelial barrier function, and activation of ion transporters within the apical membrane. The cytotoxic effects of BFT are reversible, as cells adopt a normal morphology 2–3 days after toxin treatment (reviewed in Sears, 2001).

### C. *perfringens* enterotoxin (see Chapter 45)

*C. perfringens* enterotoxin (CPE) is a protein consisting of 319 amino acids (35.3 kDa) and is responsible for a major form of human food poisoning (Table 9.1) (McClane, 2001). It is synthesized by the bacterium during sporulation, lacks a signal peptide, and is released into the environment following sporangium lysis. CPE, like many other *C. perfringens* toxins, is proteolytically activated by serine-type proteases, which probably augment the natural intoxication process within the intestinal tract.

CPE is cytotoxic for Vero cells and intestinal epithelial cells that include CaCo-2, I407, and Hep3b. The first step during intoxication consists of CPE binding, through the 30 C-terminal residues, to membrane protein receptors present in CPE-sensitive cells. The receptors have been identified as claudin isoforms 3, 4, 6, 7, 8, and 14, representing essential components of TJs. CPE binding results in an initial small complex of 90–100 kDa in membranes. At this step, the toxin is largely accessible to antibodies and proteases such as pronase, indicating that it is exposed on the cell surface. Subsequently, a post-binding maturation occurs when CPE-intoxicated cells are incubated at 37°C, which consists of intermediate (135 kDa), and then large (160 or 200 kDa), complexes formed via the addition of other membrane proteins. Development of the large complex is dependent upon CPE residues 45–116, and once formed, it becomes significantly resistant to SDS and pronase treatment, which is likely due to complex insertion into the membrane. Occludin, a major structural protein of TJs, is part of the 200 kDa complex (Singh *et al*., 2000). The CPE large complex increases membrane permeability to small molecules (< 200 Da), possibly by pore formation induced by the 160 kDa complex. The loss of various small molecules (i.e., ions, amino acids, nucleotides, etc.) ultimately inhibits macromolecule synthesis and induces cytopathic effects leading to morphological changes, altered permeability for large molecules, and finally cell lysis. Additionally, the 200 kDa complex formed in polarized CaCo-2 cells removes occludin from TJs and increases paracellular permeability (Figure 9.4) (McClane, 2001; Singh *et al*., 2001). This mechanism for CPE intoxication is probably responsible for the intestinal fluid accumulation and epithelium desquamation observed *in vivo*. In the small intestine of experimental animals, CPE induces a desquamation particularly localized at the villi tips with a rapid loss of fluid and electrolytes. The ileum is the most CPE-sensitive segment of the intestinal tract, whereas little or no effects are in the colon. The histopathological changes elicited by CPE probably play a major role in the fluid and electrolyte perturbations (McClane and Rood, 2001).

## VIRULENCE FACTORS PROMOTING ACTIN NUCLEATION AND POLYMERIZATION

### *Listeria* ActA and *Shigella* IcsA

*Listeria monocytogenes, Shigella dysenteriae,* and *Rickettsia species* are intracellular pathogens that escape phagosomal

endosomes and move throughout the cytosol by using the actin machinery provided by the host's cell. Actin polymerization at one pole of the bacterium ensures intra-/inter-cellular movement, which is responsible for bacterial spreading throughout host tissues. *L. monocytogenes* and *S. flexneri* respectively synthesize surface proteins, ActA and IcsA, which are polar-anchored into the outer bacterial membrane and induce formation of a polarized actin tail that propels the bacterium (Table 9.3) (Cossart and Sansonetti, 2004).

ActA is a 610 amino acid protein consisting of a C-terminus (residues 395–584) anchored in a polar fashion to the outer bacterial membrane, a central domain containing four proline-rich repeats (residues 234–394), and an N-terminal part (residues 1–233) with two regions essential for actin polymerization. An acidic domain (residues 33–63) and residues ($Lys_{117}$-Lys-Arg-Arg-$Lys_{121}$) called the *T,* or tail, region play a key role in actin nucleation that likely occurs by binding and activating the Arp2/3 complex (Welch *et al*., 1998). The T region shares sequence homology with an active domain from the Wiskott-Aldrich-Syndrome protein (WASP) family, which contains WASP expressed exclusively in hematopoietic cells, and the most ubiquitous N-WASP especially enriched in the brain (Higgs and Pollard, 2001). The proline-rich domain, which binds the vasodilator-stimulated phosphoprotein (VASP) and subsequently profilin, has an accessory role in actin polymerization that dictates speed and direction of bacterial movement, as well as virulence (Auerbuch *et al*., 2003). VASP clearly increases the velocity of *Listeria* motility. VASP associated with ActA immobilized on bacteria or beads reduces the branching of actin filaments, and thus probably enhances bacterial motility by properly orienting actin filaments at the bacterial surface (Samarin *et al*., 2003; Sechi and Wehland, 2004). The mode of action of VASP is complex, as it enhances Arp2/3 complex-mediated nucleation of actin filaments, antagonizes the binding of capping proteins to barbed ends probably by an indirect competition facilitating filament elongation, and VASP also regulates actin filament branching (Sechi and Wehland, 2004).

ActA mimics N-WASP in nucleating actin monomers and promoting its polymerization into "comet-like" actin filaments via the Arp2/3 complex (Figure 9.11). WASP, N-WASP, and the related WAVE (or Scar) proteins contain a VCA domain (verprolin-homology (V), cofilin-homology (C) (Lys-Arg-Ser-Lys-Ala), and acidic consensus sequence (A) (Asp-Glu-Trp-Glu-Asp)) within the C-terminus, which is required for actin polymerization through Arp2/3 activation. The V, also known as the WASP homology 2 (WH2), domain is a G-actin binding site, while the CA domain recruits and activates Arp2/3 complex. Other regions of these molecules are involved in regulating VCA activity. WASP and N-WASP possess a N-terminal WH1 domain that binds WASP interacting protein (WIP), a basic region that binds $PIP_2$, a Cdc42-specific CRIB motif, and a proline-rich central region that recruits SH3 domains from various proteins that include profilin. The N- and C-termini of WASP naturally lead to an auto-inhibited conformation (Higgs and Pollard, 2001; Takenawa and Miki, 2001).

Cdc42-GTP, but not Cdc42-GDP, competes with the C-terminus for binding to the N-terminus; therefore, inducing a conformational change that enables the

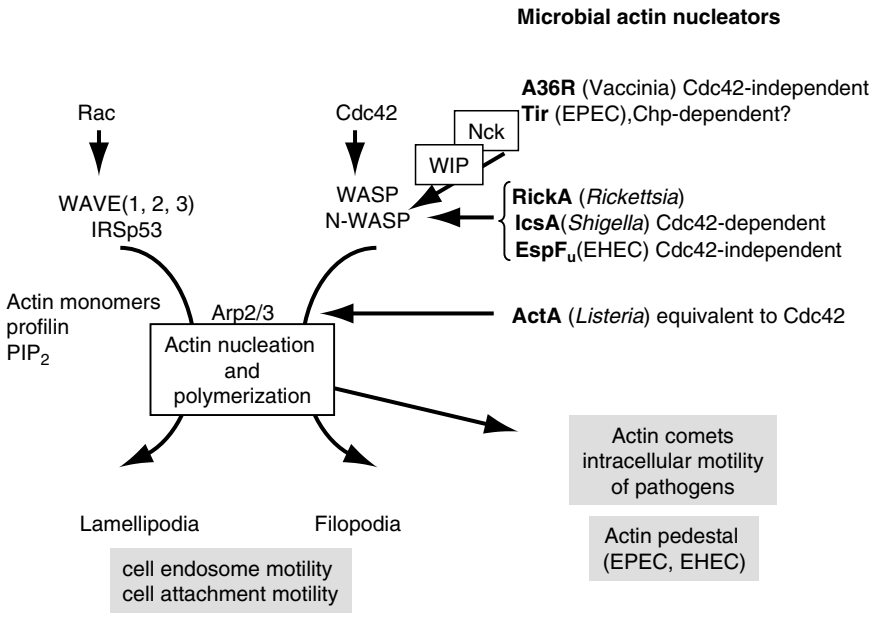

**FIGURE 9.11** The main eucaryotic and microbial virulence factors involved in actin nucleation.

VCA region to bind and activate the Arp2/3 complex, as well as facilitate interactions between actin monomers and profilin. The Arp2/3 complex recruits actin monomers and provides a nucleation site for actin polymerization as well as growth of nascent F-actin (Bishop and Hall, 2000; Carlier *et al*., 2003).

Like *Listeria,* the motility model for intracellular *Shigella* also involves a critical surface protein, IcsA, which promotes nucleation and polymerization of actin. IcsA is 120 kDa and has no sequence similarity with *Listeria* ActA (Cossart and Sansonetti, 2004). The molecule is inserted into the outer bacterial membrane through its C-terminus (37 kDa sized fragment) in a unipolar fashion, and binds to N-WASP, via glycine-rich repeats within the N-terminus (Sansonetti, 2002). IcsA mimics the eucaryotic Cdc42 by binding and activating N-WASP, which then recruits the Arp2/3 complex (Figure 9.11). This ternary structure triggers actin nucleation and filament elongation, which ultimately promotes bacterial movement throughout the cytoplasm of a host cell (Egile *et al*., 1999). IcsA also binds to vinculin, which interacts with VASP through a proline-rich central motif, which in turn recruits profilin via another proline-rich, repeat region. At the fast-growing end of actin filaments, profilin recruits actin monomers and $PIP_2$, thus enhancing actin polymerization (Loisel *et al*., 1999). However, although profilin is required for efficient *Shigella* motility and a vinculin-VASP complex is formed on intracellular *Shigella*, the recruitment of profilin seems independent of VASP (Ally *et al*., 2004). Additionally, Cdc42 facilitates the initiation of tail formation, but is seemingly dispensable thereafter (Suzuki *et al*., 2000).

*Rickettsia conorii*, which is responsible for tick/flea-borne spotted fever, also produces a surface protein called RickA (517 amino acids) that recruits and activates the Arp2/3 complex, thus inducing actin nucleation and subsequent polymerization (Figure 9.11) (Gouin *et al*., 2004). The activation process of Arp2/3 by RickA, although less efficient than that induced by *Listeria* ActA, leads to filopodia formation and bacterial locomotion.

Finally, it is noteworthy that many viruses also manipulate the host actin cytoskeleton to their advantage, such as vaccinia, which induces actin tail formation for intra-/inter-cellular motility (Cudmore *et al*., 1997). The cascade of events triggered by vaccinia virus seems to involve the following sequence: (i) the viral coat protein A36R is activated by a host Src kinase; (ii) recruitment of the adaptor protein Nck; (iii) binding of Nck to WIP-N-WASP complexes; (iv) and subsequent association with the Arp2/3 complex in a Cdc42-independent manner (Figure 9.11) (Frischknecht *et al*., 1999; Moreau *et al*., 2000).

## *Salmonella* invasion protein (Sip)A and SipC

Reorganization of the actin cytoskeleton involved in cell invasion by *Salmonella* requires an additional type-III secreted factor called SipA (Table 9.2) (Lilic

*et al*., 2003). *Salmonella* triggers rearrangement of the actin cytoskeleton and membrane ruffling at the bacterium-cell contact site, thus facilitating bacterial entry by means of several factors (Hayward and Koronakis, 2002). SipA (~74 kDa) molecularly mimics eucaryotic nebulin (600–900 kDa) by sharing common binding sites on actin, which are not evident on the procaryote equivalent MreB, that cross-link and ultimately stabilize F-actin strands (Galkin *et al*., 2002). Experiments show that a *Salmonella* mutant defective in SipA, but possessing other factors that stimulate actin polymerization, (i.e., SopE) induces a diffuse rearrangement of the actin cytoskeleton and is impaired in cell entry (Higashide *et al*., 2002). By competing with gelsolin and ADF/cofilin for binding sites on F-actin, SipA and specifically the C-terminal 238 residues can reduce concentrations of actin monomers below a critical level required for actin polymerization (Zhou *et al*., 1999). This action ultimately leads to increased stability of actin filaments and bacterial entry (Galan and Zhou, 2000). Additionally, SipA binds to fimbrin (or T-plastin), an actin binding protein that packages actin into very tight parallel bundles, which markedly increases F-actin stability (Galan and Zhou, 2000). Fimbrin is mainly localized to membrane ruffles and filopodia following Cdc42 activation. SipA probably acts in concert with SopE, which initially recruits actin filaments and fimbrin into membrane ruffles through Cdc42 activation. Subsequently, SipA reinforces and stabilizes actin filaments leading to a more efficient uptake of *Salmonella* (Zhou *et al*., 1999).

SipC (~45 kDa) is another secreted *Salmonella* type-III protein that directly nucleates and polymerizes actin, as well as cross-links F-actin strands, independent of cellular factors like Rho-GTPases; however, SipA stimulates SipC activity via an unknown mechanism. The N- and C-domains of SipC respectively provide F-actin bundling and actin-nucleating activity. Although SipC also associates with SipB, and this complex binds to lipid membranes, the precise role played by SipC is still elusive. The SipC-SipB complex could target cell membranes at the contact site with the bacterium, perhaps promoting actin condensation into filaments under the membrane of an invading *Salmonella* (Hayward and Koronakis, 1999).

## *Shigella* invasion plasmid antigen (Ipa)C

Invasion and colonization of the colonic epithelium by *Shigella* is a prerequisite step of shigellosis, which represents a severe form of diarrhea that can be fatal and is most commonly experienced by children in developing nations (Jennison and Verma, 2004). Like *Salmonella*, *Shigella* also induces at the contact point with a cell the formation of membrane extensions that raise and engulf the bacterium, thus facilitating internalization. As with many other Gram-negative pathogens, *Shigella* entry into cells depends upon injection of virulence factors through a type-III secretion apparatus (Tran Van Nhieu *et al*., 2000). Among the various virulence factors produced by *Shigella*, IpaC (~45 kDa) plays a key role in filopodia formation and is biochemically similar, but not identical, to *Salmonella* SipC. It was first found that *Shigella* entry requires an actin cytoskeleton rearrangement mediated by Cdc42 and Rac, while ezrin is recruited to the entry site by Rho (Tran Van Nhieu *et al*., 1999). Purified IpaC, when added to semi-permeabilized cells or microinjected into intact cells, promotes the formation of lamellipodia and filopodia. The C-terminal region of IpaC activates actin polymerization, which is a process inhibited by IpaC-specific monoclonal antibodies (Tran Van Nhieu *et al*., 1999). A central, hydrophobic, and highly immunogenic region is important for phospholipid interactions, while the N-terminus facilitates secretion from the bacterium as well as conversion of filopodia into lamellipodia. IpaC evidently interacts with Cdc42 by a novel mechanism, or acts upstream of the Rho-GTPases, possibly through Src kinases. It has been shown that Src tyrosine kinase activity is necessary for activating Cdc42 and Rac, but down-regulates Rho, during *Shigella* entry into cells (Tran Van Nhieu *et al*., 2000; Dumenil *et al*., 2000).

## Tyrosine kinase signaling and actin reorganization (enteropathogenic *E. coli*)

Various members of the Enterobacteriaceae family, such as the enteropathogenic *E. coli* (EPEC), enterohemorrhagic *E. coli* (EHEC), and *Citrobacter rodentium*, use the actin cytoskeleton machinery to specifically alter the intestinal mucosa via attaching/effacing lesions that are associated with disease pathology. These bacteria first adhere to the enterocyte membrane, transducing signals that lead to microvilli effacement and formation of an actin-rich bacterial adhesion structure, known as a "pedestal." EPEC and EHEC inject a 75 kDa, type-III-secreted Tir (translocated intimin receptor) that inserts into the host cell membrane and subsequently functions as a receptor for the bacterial, surface-exposed intimin (~97 kDa) (Table 9.2). The N- and C-termini of membrane-localized Tir are intracellular, but the intimin binding domain (residues 272–362) is extracellular and specifically interacts with the 181 C-terminal residues of intimin. In EPEC, Tir is phosphorylated at Tyr474 and binds to the adaptor protein Nck, which recruits and activates N-WASP as well as the Arp2/3 complex (Figure 9.11). This promotes

actin nucleation and polymerization required for pedestal formation. In contrast to EPEC, the EHEC Tir is not phosphorylated, thus suggesting that actin polymerization in the pedestal implicates another bacterial effector recently identified as *E. coli* secreted protein (Esp) $F_U$ (Campellone and Leong, 2003). Use of $EspF_U$ by EHEC strains circumvents the need for Tir phosphorylation and Nck, which are necessary for actin polymerization by EPEC strains. The association of EHEC Tir and $EspF_U$ leads to recruitment of N-WASP and actin assembly (Campellone *et al*., 2004). Tir-mediated polymerization of actin is independent of Cdc42 GTPase, but possibly dependent upon a Cdc42 homologue called Chp-GTPase, which is in contrast to the cytoskeletal effects induced by another EPEC effector known as the mitochondrial-associated protein (Map) (Kalman *et al*., 1999; Kenny *et al*., 2002). The EPEC Map has two distinct functions that include mitochondrial dysfunction involving loss of membrane potential and formation of Cdc42-dependent filopodia (Kenny *et al*., 2002). A combination of the Tir-induced signaling pathway that antagonizes filopodia formation, perhaps via GAP activity towards Cdc42, and signals triggered by Map can mediate a complex, coordinated bacterial invasion of epithelial cells (Jepson *et al*., 2003).

## BACTERIAL REORGANIZATION OF ACTIN AND PHYSIOPATHOLOGICAL EFFECTS

### Alteration of cell barriers

The first line of defense for any organism against infection is an intact epithelial cell barrier forming the skin and various mucosal surfaces of the respiratory, digestive, and uro-genital tracts, which also selectively controls passage of essential molecules with the external environment. The endothelia represent other internal cell barriers regulating solute exchange and leucocyte trafficking between blood and tissues. Over time, bacterial pathogens have developed different strategies to counteract these barriers.

Barrier cell function is mediated by intercellular junctions, which in epithelia are comprised of TJs, AJs, and desmosomes, while the endothelial equivalents include TJs, AJs, and gap junctions. In epithelia, intercellular junctions are well organized with TJs located at the apical surface and AJs along the basolateral surface between two adjacent cells. AJs play an important role in endothelia, whereas TJ organization varies along the vascular tree. Although TJs are well developed in endothelia of brain and large arteries, they are poorly organized in peripheral vessels such as venules.

TJs are protein complexes organized into parallel strands and contain integral transmembrane components, such as occludin, claudins, junctional adhesion molecules (JAM), as well as TJ plague proteins (i.e., ZO-1, ZO-2, ZO-3, cingulin). These proteins cross-link two adjacent cells by connecting integral TJ proteins to the actomyosin ring, as well as recruit cytosolic signaling molecules and many regulatory proteins. AJs consist of transmembrane cadherins, mainly vascular endothelium (VE)-cadherin, which form homophilic interactions within the intercellular space and are linked into the cytosol to actin filaments through α-, β-, and γ-catenins. The actin cytoskeleton and Rho-GTPases are important regulators of TJ and AJ function, which are controlled by a wide range of growth factors, cytokines, drugs, and hormones (Wojciak-Stothard and Ridley, 2003; Bazzoni and Dejana, 2004; Harhaj and Antonetti, 2004; Schneeberger and Lynch, 2004).

A common means of bacterial entry into an organism involves the digestive route. Many bacteria use the actin cytoskeleton to counteract the barrier function provided by the intestinal epithelium. Toxin secretion allows bacteria with neither type-III secretion nor invasive mechanisms to alter the intestinal barrier, gain access to essential nutrients, and invade internal tissues (Figure 9.1). Thereby, secreted toxins act at a distance from the infection site and produce severe as well as irreversible alteration of cell barriers. For example, clostridia have no adherent or invasive properties and only multiply in the intestinal content if the resident flora do not exert adverse effects. Only toxigenic strains ultimately interact with the intestinal mucosa and are responsible for gastro-intestinal diseases and enterotoxemia. Clostridia producing actin-ADP-ribosylating toxins cause a complete loss of actin filaments, cell morphology changes, and drastic alteration of TJs and AJs (Figure 9.4). Although a finely-tuned cooperation between Rho, Rac, and Cdc42 is required for cell barrier function, Rho has an important role in regulating TJ integrity mainly by controlling the apical actin ring contractility via RhoK (Wojciak-Stothard and Ridley, 2003). The toxins inactivating or activating Rho, but not other Rho-GTPases, alter epithelial barriers as well as cause necrotic lesions, and include: (i) *C. difficile* ToxA and ToxB involvement in pseudomembranous colitis; (ii) *C. sordellii* HT association with hemorrhagic enteritis; and (iii) *E. coli* CNFs role in hemolytic uremic syndrome (Figure 9.8). It is also the case for bacteria acting on the epithelium of the epidermis, like EDIN-producing *S. aureus* and skin suppurations (see above). Interestingly, Rho-GTPase-inactivating toxins from

clostridia involved in gangrene (i.e., *C. sordellii* LT, *C. novyi* α-toxin) mainly target Rac, and their preponderant effect upon the host is extensive edema. Gangrenous clostridia enter soft tissues via a tegument break, like a deep-penetrative wound, and upon growth in an anoxic environment these bacteria secrete toxins that act on endothelial cells and modify cell barrier permeability, where Rac-dependent AJs are predominant. Toxins like LT also cause muscle cell necrosis (Barbier *et al*., 2004), but additional necrotic toxins or extracellular hydrolytic enzymes (i.e., neuraminidases, phospholipases, proteases) are also produced by these bacteria. Moreover, toxins disrupting actin filaments via direct interaction with actin monomers (i.e., clostridial actin-ADP-ribosylating toxins, *V. cholerae* RTX) or increasing actin polymerization (*V. cholerae* ZOT) alter intercellular junctions and cell barrier permeability (Figure 9.4).

Another mechanism for altering cell barrier function consists of a direct toxin interaction with intercellular junction components. CPE binds and removes claudin-3 and -4, resulting in disintegration of TJ strands and increased permeability. BFT has a proteolytic activity towards E-cadherin. A *V. cholerae* hemagglutinin/protease (HA/P) specifically degrades occludin, resulting in the breakdown of TJ function (Wu *et al*., 2000). Summarized modes of action of bacterial toxins interfering with cell barrier function are shown in Figure 9.4.

## Cell invasion and transmigration through cell barriers

Other pathogens undergo more complex interactions with epithelial or endothelial cells that include hijacking the regulation of actin polymerization through bacterial surface proteins or effectors directly injected into target cells. Instead of secreting toxins that diffuse and indiscriminately disrupt all the cells from a monolayer, these pathogens restrict their activity to the cells to which they adhere. By this way, invasive bacteria induce their phagocytosis into normally non-phagocytic cells, and other bacteria remain adherent to the membrane leading to intimate interactions with a host cell.

Invasive bacteria escape host defenses once inside epithelial or endothelial cells, by two main types of entry mechanisms. The trigger mechanism used by *Salmonella* and *Shigella* consists of bacteria-cell contact through a type-III system, injection of virulence factors into the cytosol, drastic rearrangement of the cortical actin cytoskeleton, formation of ruffles and a phagocytic cup, internalization of bacteria into vacuoles, and subsequent restoration of the normal actin architecture (Table 9.2). *Salmonella* entry, the best characterized to date for any microorganism, is based on type-III-effectors like SopE and SptPs which respectively mimic eucaryotic GEFs and GAPs to manipulate the actin machinery. Although procaryotic GEFs and GAPs share no significant relatedness at the structural level with their eucaryotic counterparts, they retain a similar enzymatic site, suggesting a convergent evolution between pathogen and host. Additional type-III factors, like ADP-ribosylating proteins (SpvB) and an actin nucleator (SipC), are also involved in *Salmonella* pathogenensis.

*Shigella* uses a different set of type-III effectors, which also successively trigger actin polymerization (IpaC) and depolymerization (IpaA) via a more complex signaling pathway than regulating the Rho-GTPases cycle. IpaA binds to vinculin, but its mode of action remains unknown. *Shigella* enters the intestinal mucosa through M cells, which then initiates an inflammatory response, transmigration of neutrophils, opening of TJs, and enhances access to the basolateral surface of epithelial cells where the bacteria bind to integrins via IpaB/C.

In contrast, *Listeria* and *Yersinia* enter epithelial cells by a zipper mechanism, respectively mediated by the bacterial membrane proteins, invasin and internalin, which interact with cell surface receptors and activate a signaling cascade leading to a moderate rearrangement of the actin cytoskeleton for bacterial internalization (Table 9.3). Although this process is incompletely understood, it does involve Rac and Arp2/3 (Cossart and Sansonetti, 2004). *Neisseria* also uses a zipper mechanism to enter epithelial and endothelial cells triggered by adhesion mediated by type IV pili, bacterial surface proteins (i.e., Opa, Opc), and host cell receptor (CD46), which ultimately leads to activation of Src family tyrosine kinase (Table 9.3). In endothelial cells, type IV pilus-mediated adhesion is associated with recruitment of ERM proteins, activation of Rho and Cdc42, as well as actin rearrangement leading to microvilli formation, bacterial internalization, and subsequent bacterial transcytosis (reviewed in Nassif *et al*., 2002; Plant and Jonsson, 2003).

Unlike many of the other type-III transmitted effector molecules described in this chapter, CNF1 produced by uropathogenic *E. coli* enters epithelial cells by a mechanism different than the type-III secretion system. For ultimately enhancing phagocytosis, CNF1 ensures the transient stimulation of actin polymerization that leads to the formation of phagocytic vesicles, followed by down-regulation of the actin cytoskeleton (see above). CNF1 also causes a redistribution of TJ molecules and alters epithelium permeability (Hopkins *et al*., 2002). Although CNF1 activates Rho-GTPases in contrast to *C. difficile* ToxA and ToxB, both types of toxins increase the cell barrier permeability,

and this information suggests that a finely-tuned balance is required for cell barrier function. *Pasteurella* PMT, which is related to CNF1, also increases endothelial permeability by activating Rho, RhoK, and myosin light chain phosphorylation by an undefined pathway (Essler *et al*., 1998). Other pathogens intimately interact with the epithelial cell surface without invading cells, but their survival depends upon modifying the actin cytoskeleton and altering cell barrier integrity.

*Helicobacter pylori* adheres to gastric epithelial cells and injects a cytotoxic-associated antigen (CagA) protein through a type IV secretion system (Table 9.2). CagA is phosphorylated by a Src family kinase and binds to ZO-1 as well as JAM, leading to disruption of epithelial barrier function via a not yet defined mechanism (Amieva *et al*., 2003). Another unidentified type IV effector activates Rac as well as Cdc42, thus increasing epithelial cell motility and contributing to gastric carcinogenesis (Naumann and Crabtree, 2004).

EPEC and EHEC also intimately attach to intestinal cells, thus inducing loss of microvilli and generating attaching-effacing lesions, but these bacteria are poor invaders of host cells (see above). In addition, these entero-pathogens alter the intestinal barrier function. EPEC infection causes type-III-mediated phosphorylation of myosin light chain kinase, resulting in increased contraction of the actomyosin ring, as well as dephosphorylation and redistribution of occludin (Simonovic *et al*., 2000). In EHEC, the type-III-Esp$F_U$ that is not involved in attaching-effacing lesions can facilitate redistribution of occludin and increased cell barrier permeability (Table 9.2) (McNamara *et al*., 2001).

Finally, various *Chlamydia* species represent obligatory intracellular procaryotes that possess a distinct, biphasic development cycle. As pathogens, they are quite successful and cause prevalent forms of sexually transmitted disease as well as blindness throughout the world. These microorganisms employ a type-III secretion system to gain entry into cells, following the binding of elementary bodies to eucaryotic surfaces via lipid rafts (Fields *et al*., 2003; Stuart *et al*., 2003). Overall, little is known about chlamydial type-III secretion and effector molecules relative to other microorganisms; however, activation of Cdc42 and Rac are important for the infection process, unlike Rho (Subtil *et al*., 2004). Recently, the CT456 molecule has been identified as a type-III secreted effector that recruits actin to the elementary body-cell contact site for uptake (Table 9.2) (Clifton *et al*., 2004).

## Antiphagocytosis

When pathogens overcome the body's primary line of defense, represented by the tegument or epithelial barrier, they encounter macrophages, dendritic cells, and polynuclear lymphocytes that recruit additional cellular help towards the infection site via cytokines and chemokines. Additionally, stimulation of host innate immunity occurs through pattern recognition receptors on professional phagocytes that target specific pathogen associated molecular patterns (PAMPs), such as lipopolysaccharide, lipoteichoic acid, and CpG motifs. To overcome this swarming, inflammatory approach for protecting the host, some bacteria have developed strategies that prevent phagocytosis based upon manipulating the host's actin cytoskeleton (Figure 9.11). The best characterized examples of microorganisms that prevent phagocytosis have been derived from studies with *P. aeruginosa* and *Yersinia* species.

*P. aeruginosa* is a common environmental bacterium with opportunistic, pathogenic tendencies. This bacterium normally exploits an immunocompromised host, subsequently causing various maladies linked to the skin of burn patients, lungs (cystic fibrosis), urinary tract, surgical wounds, and ulcerative keratitis. Virulence factors associated with *P. aeruginosa* infections include antibiotic resistance, pili, flagella, and elastase, which all contribute in different ways to successful invasion as well as dissemination. In addition, during an infection, this microorganism secretes various type-III effectors, which play different roles that include the inhibition of phagocytosis and wound healing. In particular, *Pseudomonas* ExoS down-regulates actin polymerization in macrophages through a GAP activity towards Rho-GTPases and ADP-ribosylation of other targets.

Foodborne pathogens like *Y. enterocolitica* and *Y. pseudotuberculosis* can cross the intestinal epithelium through M cells, thus reaching the lymphoid tissues within Peyer's patches. This process induces a recruitment of phagocytic cells that includes polymorphonuclear leucocytes and monocytes with subsequent formation of microabcesses. The host inflammatory response does restrict *Yersinia* invasion; however, this bacterium can resist phagocytosis and disseminates to the mesenteric lymph nodes, liver, and spleen. When passed through M cells, *Yersinia* produces various virulence factors that afford a microbial defense towards innate immunity and subsequent extracellular multiplication in lymphoid tissues. Among the important virulence factors, *Yersinia* secretes a set of type-III proteins (i.e., YopE, YopH, YopT, and YpkA/YopO) that have a negative impact upon cytoskeletal dynamics and resist phagocytosis. YopE, YopT, and YpkA/YopO act on Rho-GTPases via different mechanisms. YopE has GAP activity, while YopT also inactivates the same targets via cysteine protease activity. YpkA/YopO

binds to actin and Rho-GTPases, but its mode of action is still unclear; whereas YopH is a phospho-tyrosine phosphatase acting on the focal adhesion protein P130 (Cornelis, 2002). It is noteworthy that for a more efficient antiphagocytic effect, these bacteria down-regulate the actin cytoskeleton by simultaneously inactivating pivotal targets necessary for actin polymerization along with several effectors possessing different mechanisms of action.

### Intracellular motility

Another strategy for pathogen escape from host defenses consists of intracellular replication, movement, avoidance of degradation mechanisms (i.e., lysosomes), as well as eluding engulfment by professional phagocytes. *Salmonella* survive in macrophages through type-III effectors that enable survival in an intracellular compartment sheltered from the NADPH oxidase-dependent respiratory burst and ensuing oxygen radicals. Other intracellular bacteria, like *Listeria*, can lyse the intracellular vacuole membranes through a cholesterol-dependent, pore-forming toxin called listeriolysin O, phosphatidylinositol-phospholipase C, and phosphatidycholine-phospholipase C; whereas, IpaA molecule serves the same function for *Shigella*. The bacteria can then replicate in the cytosol, thus avoiding trafficking/destruction to the lysosomes. To colonize host tissues, these pathogens use actin dynamics similar to the processes occurring at the leading edge of a moving eucaryotic cell, thus propelling themselves within the cytosol and into adjacent cells. It is interesting to note that *Shigella*, which are strictly adapted to humans and monkeys, as well as an environmental opportunistic pathogen, like *Listeria*, both exploit related actin-based cellular mechanisms to enter cells and disseminate intracellularly. The *Rickettsia* and vaccinia virus also possess a similar mode of intracellular, actin-based motility. Certain bacterial or viral membrane proteins, which mimic a eucaryotic counterpart, play a key role in triggering host actin nucleation as well as polymerization at one pole of the pathogen and include: *Listeria* ActA, *Shigella* IcsA, *Rickettsia* RickA, and vaccinia virus A36R (Table 9.3 and Figure 9.11).

## CONCLUSION

Actin supports numerous fundamental processes needed for eucaryotic life, and many actin-based mechanisms are involved in procaryotic interactions with eucaryotic cells, which thus forms the basis of various bacterial and viral infections/intoxications. From the pathogen's perspective, an ability to manipulate the host is desirable for obtaining additional nutrients, avoiding the immune system, and ultimately disseminating to a new host. Relative to eucaryotes, many procaryotes contain at most a "rudimentary" form of an actin cytoskeleton, but various microbial pathogens have cleverly evolved ways of exploiting the host actin machinery for their own objectives by producing toxins or virulence factors that interfere with actin regulation. Among the numerous partners responsible for actin regulation, procaryotic toxins and virulence factors act at two levels that involve actin monomers and Rho-GTPases. Various toxins enzymatically modify actin monomers that prevent further polymerization, while in contrast several procaryotic surface proteins act as nucleating factors permitting intra-/inter-cellular motility of pathogens. Rho-GTPases also represent either a direct target of various toxins and type-III secreted factors or an indirect target regulated via GEFs as well as GAPs and modulated by equivalent procaryotic factors. Rho-GTPases play a key role in regulating actin polymerization, since they amplify signals through an effector cascade and then direct them towards a particular pool of actin that facilitates a coordinated cell function like endocytosis/phagocytosis. Toxins that directly target actin molecules rapidly disrupt the entire actin cytoskeleton, which is concomitant with a brutal and drastic rupture of cell barrier integrity. In contrast, toxins and virulence factors acting on Rho-GTPases modulate specific cellular functions, thus allowing pathogens to alter certain intercellular junctions or to cross through cell barriers and escape host mechanisms of defense (phagocytosis in non-killer cells, intra-/inter-cellular motility, and antiphagosytosis directed towards macrophages and polynuclear cells). How have procaryotes evolved such factors that mimic eucaryotic molecules for actin regulation? Structure analysis shows that procaryotes synthesize original molecules that differ from their eucaryotic partners, yet there is a retention of conserved active motifs. Although the basis of this coevolution and their selective pressure remains largely unknown, it is apparent that such molecular mimicry leads to pathogen "success." As time progresses, there is no doubt that additional pathogens and novel methods by which they exploit the eucaryotic actin system will be discovered by various laboratories throughout the world. Now, how can we use all this knowledge to strike back?

CHAPTER

# 10

# Bacterial toxins and mitochondria

*Antoine Galmiche and Patrice Boquet*

## INTRODUCTION

Although mitochondria have been known for a long time to be important organelles in the energetics of eukaryotic cells, their contribution to some aspects of cell regulation was only discovered during the last decade. In particular, the observation that mitochondria play a critical role in programmed cell death initiated a new interest in their study. During the past five years, a number of reports have documented that some protein toxins and virulence factors produced and secreted by bacteria can target mitochondria of their host cell, shedding new light on the interaction between bacteria and eukaryotic cells. Here, we'll discuss the structure and functions of mitochondria, and we'll review the current state of knowledge regarding bacterial toxins and factors that act on mitochondria.

## STRUCTURE AND BIOGENESIS OF MITOCHONDRIA

Mitochondria are membrane organelles present in all animal cells. Although mitochondria are usually described as rod- or balloon-shaped organelles, their morphological appearance can vary catly from one cell type to the other. Modern imagery techniques showed that, rather than being present as isolated organelles in the cytoplasm, mitochondria form an intracellular reticulum (reviewed in Yaffe *et al*., 1999). They are formed by two membranes, a mitochondrial outer membrane (MOM) and a mitochondrial inner membrane (MIM), containing numerous inner folds. Both membranes delineate an intermembrane space and the mitochondrial matrix. The infoldings of the MIM delineate the mitochondrial cristae, which can be visualized by electron microscopy as tubules and vesicles, in the matrix or in continuity with the intermembrane space. The functional consequences of this sophisticated organization are currently poorly understood.

Mitochondria are motile structures that associate with the cell cytoskeleton, particularly microtubules (Yaffe *et al*., 1999). Like all other membrane organelles, mitochondria are constantly remodeled by fission and fusion processes (Yaffe, 1999). Mitofusins, the vertebrate homologues of the product of the Drosophila protein *fuzzy onion*, a GTPase located in the outer mitochondrial membrane, mediate mitochondrial fusion. Their action is counterbalanced by Dynamin-related proteins (Drp), which catalyze mitochondrial fission events. Thus, the shape of mitochondria and their topological organization are kept under permanent control.

The two mitochondrial membranes have different physical properties and compositions. The MIM contains large amounts of the lipid cardiolipin, and is virtually impermeable to all solutes. The MIM contains the proteins of the respiratory chain and forms the major barrier between the mitochondrial matrix and the cytosol. It plays a paramount role in the cell energetics and metabolism, according to mechanisms that we will mention later. A voltage gradient (expressed as a transmembrane potential $\Delta\Phi m$, in mV) exists across the MIM. This gradient is an important parameter of mitochondrial physiology. It is commonly determined by measuring the uptake of small lipophilic, positively charged dyes endowed with fluorescence properties. The properties of the MOM are less well understood. The MOM was long assumed to be freely permeable to solutes of small size, thanks to the presence of a protein,

the mitochondrial porin (also known as the *Voltage-Dependent Anion Channel*, or VDAC). This view is now challenged, and recent studies suggest that the MOM forms a regulated barrier between the intermembrane space of mitochondria and the cytosol.

An important particularity of mitochondria is the fact that these organelles possess their own genome, consisting in a circular DNA of approx. 16.5 kb, and residing inside the matrix. This DNA is the most evident stigma of the bacterial origin of mitochondria (Gray *et al*., 1999; Dyall *et al*., 2004). According to the now widely accepted endosymbiotic hypothesis, mitochondria are the remnant of an α-proteobacterium that would have once colonized an early eukaryote. Phylogenetic analysis of the mitochondrial genome revealed that members of the rickettsial subdivision of the α-Proteobacteria, a group of obligate intracellular parasites that includes genera such as *Rickettsia*, *Anaplasma*, and *Ehrlichia*, are the closest known eubacterial relatives of mitochondria (Gray *et al*., 1999; Dyall *et al*., 2004). During evolution, the proteobacteria and the eukaryotic cells probably evolved in a concerted fashion: a dramatic process of gene reduction occurred. Important parts of the mitochondrial genome were lost, and others became integrated into the cell nucleus. During this process, mitochondria became *bona fide* organelles (Gray *et al*., 1999; Dyall *et al*., 2004).

In mammals, mitochondria contain the enzymes required for the transcription and the replication of this genome. In addition, the mitochondrial genome contains 13 mRNAs encoding essential subunits of respiratory complexes. Most mitochondrial proteins are encoded by genes that are carried by the nuclear genome. These proteins are synthesized in the cytosol and imported by a specialized protein import machinery formed by protein complexes present in the outer membrane (TOM, for *Translocase of the Outer Membrane*) and in the inner membrane (TIM, for *Translocase of the Inner Membrane*) (review in Wiedemann *et al*., 2004) (see Figure 10.1).

Although these common principles of mitochondrial physiology apply to all tissues, mitochondria from varied tissues have unique properties, as the analysis of their protein contents reveals (Mootha *et al*., 2003). Furthermore, they are functionally heterogenous in a single cell, a phenomenon called *heteroplasmia*.

## MITOCHONDRIA: ORGANELLES DEDICATED TO THE LIFE AND DEATH OF THE CELL

Mitochondria are essential organelles in the regulation of the cell metabolism and energetics. In normal conditions, they are the main producer of the central cellular energy carrier, adenosine triphosphate (ATP). In the mitochondria, this ATP is regenerated from adenosine diphosphate (ADP) in a process called oxidative phosphorylation (see Figure 10.2). But the impact of mitochondria extends beyond the production of energy. Mitochondria regulate many aspects of cellular signaling and metabolic pathways. For example, mitochondria regulate the Ca2+ metabolism. Mitochondria can eventually be observed in close connections with the endoplasmic reticulum (ER) (Rizzuto *et al*., 1998), an organization that could allow them to accumulate Ca2+. The storage and release of Ca2+ from mitochondria affects both the release of this ion from the ER and its entry across the plasma membrane (Rizzuto *et al*., 2004). Very recently it was reported that the intracellular local calcium concentration controlled mitochondrial movement on microtubules, probably by modulating the activity of a myosin (myosin Va) (Yi *et al*., 2004). Mitochondria also play a role in the metabolism of some amino acids and certain lipids: for example, specialized mitochondria play a key role in steroidogenesis in the cells of the adrenal cortex (Jefcoate, 2002). The metabolism of iron is another important aspect of mitochondrial physiology. Mitochondria are the major site of synthesis of the heme and of iron-sulfur (Fe/S) clusters (Lill *et al*., 1999).

The contribution of mitochondria to the control of cellular metabolism has been known for a relatively long time, but a new interest in this organelle came only recently with the observation of its key role in the regulation of apoptosis (reviewed in Kroemer and Reed, 2000). Apoptosis, and by extension most forms of cell death, were found to be tightly programmed events. In many circumstances, apoptosis was observed to be initiated by the release of cytochrome c from the mitochondria into the cytosol (Liu *et al*., 1996). Following this initial seminal observation, it was observed that mitochondria host many other factors whose release into the cytosol can induce apoptosis: beside cytochrome c, these other factors are the flavoprotein AIF, Smac/Diablo, the serine-protease HtrA2/Omi, and a nuclease, endonuclease G (reviewed in Newmeyer and Ferguson-Miller, 2003) (see Figure 10.3). Whereas cytochrome c is normally only present in the mitochondrial intermembrane space, its cytosolic release initiates the assembly of a large protein complex called the *apoptosome*. This complex is responsible for the activation of apoptotic proteases of the caspase family, thereby resulting in the execution of the apoptotic program and the appearance of the typical morphological changes that characterize apoptosis. An increased permeability of the MOM therefore seems to be the main event in the course of apoptosis induction.

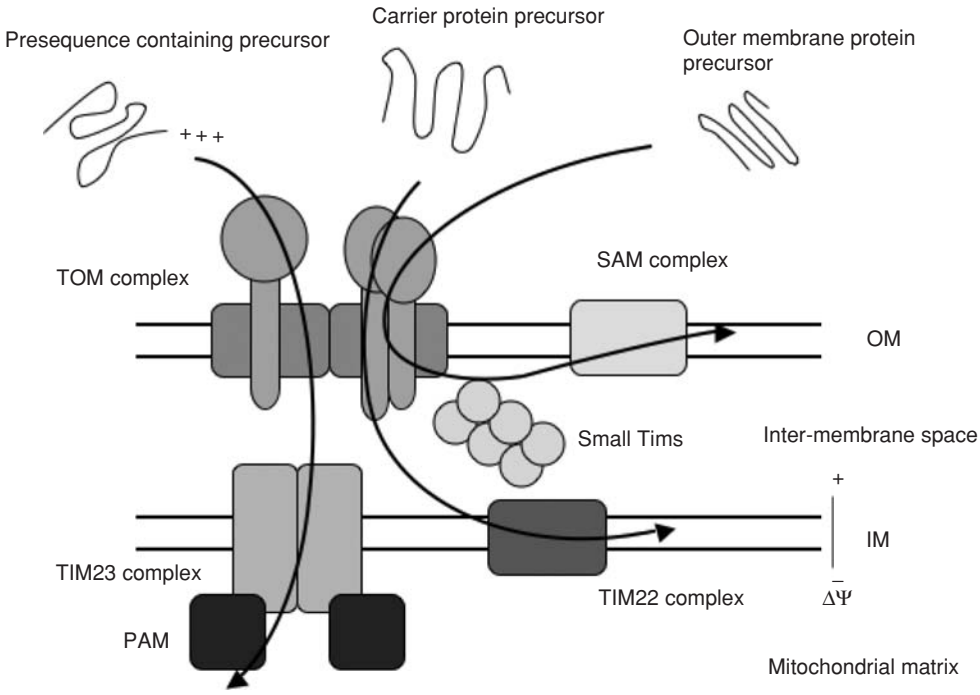

**FIGURE 10.1** Protein import into mitochondria (adapted from Wiedemann *et al*., 2004).

Most mitochondrial proteins are synthesized in the cytosol of the cell before their import into mitochondria. These proteins are often synthesized as precursors containing an amino-terminal signal sequence, usually composed of 20 to 60 residues forming an amphipathic α-helix. Other mitochondrial proteins contain internal targeting signals (in particular, this is the case for hydrophobic precursor proteins destined to the inner membrane, like the ADP/ATP carrier). Cytoplasmic chaperones guide precursor proteins to receptors on the surface of mitochondria. There, preproteins encounter the mitochondrial protein import machinery.

The mitochondrial protein import machinery is formed by protein complexes present in the outer membrane (TOM, for *Translocase of the Outer Membrane*) and in the inner membrane (TIM, for *Translocase of the Inner Membrane*). The TOM complex is the central entry gate for practically all mitochondrial proteins (Wiedemann *et al*., 2004). It includes receptors for the mitochondrial presequence (proteins Tom20 and Tom22) or for proteins with internal targeting information (Tom70), and a protein conducting channel formed by the protein Tom40.

Upon passing through the TOM complex, the precursor proteins can follow one of three major pathways (Wiedemann *et al*., 2004): i) the proteins of the MOM, like the mitochondrial porin (also called VDAC, *Voltage Dependent Anion Channel*), use a protein complex called the SAM (*Sorting and Assembly Machinery*) for their folding and membrane insertion. ii) the preproteins that contain a presequence are transferred to the TIM complex. The preprotein-translocase Tim23, in cooperation with the matrix heat shock protein mtHsp70 actively imports the protein inside the mitochondrial matrix. iii) the preproteins that contain internal targeting signals, like the ADP/ATP carrier, follow a different pathway for their insertion. The TIM22 complex, with the aid of the small Tim proteins, is responsible for insertion of proteins with internal targeting signals into the inner membrane.

As we mentioned earlier, the MOM is normally only permeable to solutes of small size (reviewed in Kroemer and Reed, 2000). How apoptogenic stimuli are converted into changes in the permeability of the MOM is still controversial, but different models have been proposed to account for these changes: they either implicate the formation of pores, the complete rupture of the MOM, or even mitochondrial fission events (Newmeyer and Ferguson-Miller, 2003). Depending on the nature of the apoptotic stimuli that the cell receives, these events might happen in a separate or sequential fashion through mechanisms that are yet unclear. The proteins of the Bcl-2 family play a role in the regulation of these events (reviewed in Cory and Adams, 2002). In mammals, there are at least 20 members of this family of proteins. These proteins share at least one conserved Bcl-2 homology (BH) domain among the four that Bcl-2 contains (BH1–BH4). Members of the Bcl-2 family can be classified into different subtypes, the most evident classification being based on their opposing functions, either as pro-survival or pro-apoptotic member.

i) The pro-survival family. Bcl-2 and Bcl-XL are the best-characterized members of this family. Bcl-XL is predominantly located in the MOM, whereas Bcl-2 has a broader membrane distribution, including the ER and nuclear envelope (Kaufman *et al*., 2003). The members of the pro-survival family of Bcl-2 proteins are able to directly bind and counteract the effect of the pro-apoptotic family members.

ii) The pro-apoptotic family. This family can be further separated into a BH3-only subfamily (Bad, Bid, Bim, Bmf, Noxa, Puma) and the Bax subfamily (Bax

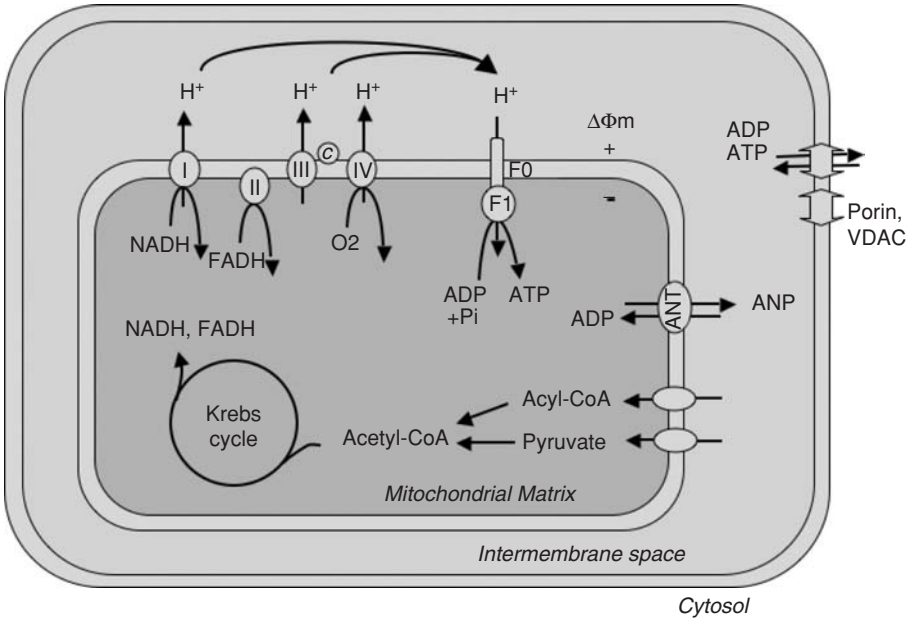

**FIGURE 10.2** Respiration and ATP synthesis in mitochondria

The mitochondria regenerate the cell energy by a process known as *oxidative phosphorylation*. Mitochondria use pyruvate, the end product of glycolysis, and fatty acids to regenerate energy. Pyruvate and acyl chains are actively imported into the mitochondrial matrix. There, they are metabolized into acetyl-CoA and oxidized through a cycle of reactions known as the *tricarboxylic acid cycle*, or Krebs cycle. The high-energy electrons that are extracted during these reactions are transferred to the carriers NAD (Nicotinamide Adenosine Dinucleotide) and FAD (Flavin Adenosine Dinucleotide). The reduced factors NADH and FADH serve as shuttles for these high-energy electrons: they transfer them to the respiratory chain. The mitochondrial respiratory chain is composed of four large enzyme complexes embedded in the inner membrane of the mitochondria. These complexes are the NADH-CoQ reductase (complex I), the succinate-CoQ reductase (complex II), ubiquinol-cytochrome *c* reductase (complex III), and the cytochrome c oxidase (complex IV). The respiratory complexes transfer electrons to each other, and finally to their final acceptor, the oxygen molecule. The coupling of electron transfer to ATP synthesis is indirect, via the constitution of aNH+ electrochemical gradient: the transfer of electrons along the respiratory chain is coupled to the expulsion of protons out of the mitochondrial matrix, across the inner membrane. In this way, respiration creates both a membrane potential ($\Delta\Phi m$) and a pH gradient ($\Delta pH$). These pH and electrical gradients form a proton motive force that the mitochondria uses to synthesize ATP. An enzyme, the F0F1-ATP synthase (also called complex V of the respiratory chain), couples the reentry of protons into the mitochondrial matrix with the chemical conversion of ADP into ATP. This ATP synthase is composed of a F0 portion, crossing the MIM, and connected to a globular, F1 portion, in the mitochondrial matrix. Proton reentry into the matrix, through the associated F0 subunit of ATP synthase induces the rotation of the F1 subunit, and this rotation is coupled to the synthesis of ATP. The F1 portion therefore functions as a genuine rotary molecular motor (Itoh *et al*., 2004; Diez *et al*., 2004). Following its mitochondrial synthesis, ATP is transported across the MIM by the protein ANT (Adenine Nucleotide Translocator). The porin, or VDAC, transports ATP across the MOM.

and Bak) (reviewed in Cory and Adams, 2002). Genetic evidence supports the role of the Bax proteins subfamily as core components of the apoptotic machinery; indeed, Bax/Bak double knock-out cells are resistant to most apoptotic stimuli (Wei *et al*., 2001). On the other hand, the members of the BH3-only subfamily function upstream of Bax/Bak (Zong *et al*., 2001; Cheng *et al*., 2001). A current hypothesis holds that the BH3-only proteins constitute cellular sentinels, and that they are able to activate the Bax/Bak system in response to a variety of death-inducing stimuli. In a living cell, they are normally kept in check by different mechanisms, including sequestration at the subcellular level (interaction with the cell cytoskeleton in the case of Bim and Bmf), post-translational modifications (phosphorylation in the case of Bad, proteolytic processing in the case of Bid), or regulation at the transcriptional level (Noxa and Puma) (review in Cory and Adams, 2002). During apoptosis, protein efflux from mitochondria might be a consequence of local reorganization of the lipids in the MOM, and this process could be driven by the pro-apoptotic protein Bax. Kuwana *et al*. (2002) have reported the use of a cell-free assay using purified components to reconstitute the permeabilization of the MOM by the protein Bax *in vitro*; in this system, Bax added to liposomes mimicking the composition of the MOM rendered them permeable to large-molecular-weight dextran molecules. This process occurred in the

absence of any intrinsic mitochondrial proteins, but required the presence of the mitochondrial lipid cardiolipin (Kuwana *et al*., 2002). In addition to the reorganization of the lipids of mitochondrial membranes, the proteins of the Bcl-2 family might contribute to apoptosis through the changes of mitochondrial shape, especially the mitochondrial fragmentation that are noticed during apoptosis (Karbowski *et al*., 2002, 2004).

Other events take place in the mitochondria of dying cells. A phenomenon known as the *mitochondria-permeability transition* (MPT) is often observed. It is caused by the opening of a pore formed at points of contact of the MOM with the MIM. This pore results in a drop in mitochondrial inner membrane polarity and in the swelling of the mitochondrial matrix. Although its exact role and its molecular composition remain unclear (Kokoszka *et al*., 2004), this pore could cause the complete rupture of the MOM and its non-selective permeabilization (review in Kroemer and Reed, 2000).

Mitochondria are also an important source of reactive oxygen species (ROS). This aspect is worth pointing out because the production of ROS could in some instances participate in cell death. In the normal setting, oxydative phosphorylation produces limited amounts of ROS. An increased production of ROS is often observed at an advanced stage of the apoptotic execution, as a consequence of the cleavage of components of the respiratory chain by caspases (Ricci *et al*., 2004). Clearly, many different events take place in the mitochondria of dying cells, and it is not currently possible to establish a complete causality between them.

## BACTERIAL TOXINS AND VIRULENCE FACTORS TARGETING MITOCHONDRIA

Following a couple of initial reports of bacterial toxins and virulence factors targeting mitochondria, there has been a surge in the number of similar observations. In Table 10.1, we have attempted to list the currently known toxin proteins for which mitochondrial targeting properties were established. This list is not closed, and it is likely to expand as more investigators

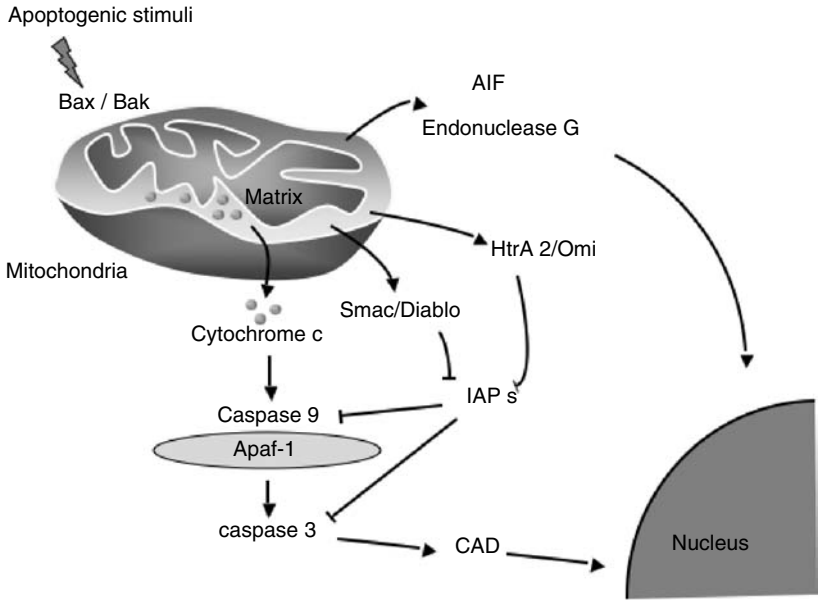

**FIGURE 10.3** Mitochondria and apoptosis

An increased permeability of the MOM occurs early in the course of apoptosis. Apoptogenic stimuli could induce this permeabilization of the MOM through the formation of pores in the MOM, or through its complete rupture. Multiple proteins of the intermembrane space are released into the cytosol. Cytochrome c triggers the formation of the apoptosome, a large protein complex that activates the initiator Caspase-9. Other proteins released from the intermembrane space also contribute to Caspase activation: the Serine-protease HtrA2/Omi and the factor Smac/Diablo that relieve the inhibitory effect of a family of anti-apoptotic factors: the IAPs, that are normally present in the cytosol. The activated Caspase cascade causes the cleavage of multiple cellular substrates. The protein CAD (Caspase-Activated DNAse) is activated and translocates to the nucleus, resulting in the characteristic oligonucleosomal DNA fragmentation observed in apoptotic cells. Other mitochondrial factors can initiate apoptosis through Caspase-independent mechanisms: AIF and endonuclease G can directly translocate from the mitochondria to the nucleus.

now become aware of the existence of mitochondrial targeting by bacterial pathogens. At this point, however, some first conclusions can be drawn.

i) Toxins and virulence factors targeting mitochondria are produced by many microbes. In addition, a single microbe produces several toxins or virulence factors that can act on mitochondria (for example, EPECs produce at least three factors: Tir, MAP, and EspF, that can eventually target mitochondria). Targeting mitochondria seems to be a common event in the bacterial world.
ii) Although the mitochondrial tropism of some of the factors listed in Table 10.1 is now well accepted, for none of these factors do we have a complete understanding of the mode of action inside mitochondria. During our recent investigation of the mode of action of the vacuolating cytotoxin VacA produced by the bacteria *Helicobacter pylori*, we observed that VacA is localized to the MIM following its mitochondrial import (Galmiche *et al*., 2000). There, it is currently unclear whether VacA can form an ion-conducting channel or carry an enzymatic activity (Whillhite and Blanke, 2004). On the other hand, the factor PorB produced by *Neisseria gonorrhoae* inserts into the MOM of infected cells (Müller *et al*., 2002). Although both VacA and PorB are apparently able to induce the apoptosis of infected cells, the mechanisms involved might be quite different.
iii) Another point that remains unclear is the *in vivo* role played by mitochondrial targeting. The production of mitochondrially-acting toxins does not evidently correlate with the microbial lifestyle or the type of infection produced. Considering the many roles played by mitochondria in the cell metabolism, in cell death and regulation, various microbes might exploit mitochondria for different purposes. Mitochondrially-acting toxins of bacterial pathogens are probably "multipurpose tools." It is likely that these purposes will need to be investigated both in an infection- and cell type-specific fashion. Although many reports show that apoptosis regulation is an important consequence of mitochondrial targeting, it is likely that bacterial pathogens could get other benefits from mitochondrially-acting toxins (i.e., inhibition of cells of the immune system, mobilization of the iron from eukaryotic cells). This remains however to to be established.
iv) It is currently unclear how these various toxins and virulence factors reach mitochondria. AB toxins and virulence factors that are injected into cytosol via needle-like, type III secretion (TTSS) (Hueck *et al*., 1998) could gain access to mitochondria after a cytosolic transit step. Alternatively, vesicle-mediated traffic might exist between cellular plasma/endosomes membranes and the mitochondria (Zhang *et al*., 2004).

In the following paragraphs, we'll briefly describe toxins and virulence factors recently documented to target mitochondria.

## The *Neisseriae gonorrhoeae* and *Nesseriae meningitidis* porins PorB

*Neisseriae meningitidis* and *Neisseria gonorrhoeae*, two Gram-negative bacteria, are responsible respectively for meningitis and the sexually transmitted disease gonorrhea. *Neisseria* adhere to and invade epithelial and endothelial cells. Different virulence factors modulate the interactions and cross-talk of these bacteria with host cells, among these type IV pili, Opa proteins, and porins. Meningococcal porin B (MW: 33 kDa) and gonococcal porin B (37 kDa) are β-barrel-structures proteins sharing 70% amino acid sequence homology. In the outer bacterial membrane, they assemble as trimers and form membrane channels implicated in the transport of ions and solutes.

The *N. gonorrhoeae* PorB has been shown to induce cell apoptosis during *N. gonorrhoeae* infection of epithelial cells and macrophages or when added as a purified protein to cultured epithelial cells (Müller *et al*., 1999). During infection, when the bacteria is tightly attached on the host cell surface, PorB translocates from the bacterial outer membrane to the cell plasma membrane (Weel and van Putten, 1991). There, it forms voltage-dependent channels regulated in their ion gating activity and selectivity by ATP and GTP nucleotides (Rudel *et al*., 1996). Properties of *N. Gonorrhoeae* PorB resemble thus the VDAC (Rudel *et al*., 1996). This prompted Müller *et al*. (2000) to examine whether apoptosis induced by PorB was due to a mitochondrial activity of the bacterial porin. Treatment of Jurkat T cells, monocytes, or epithelial cells with purified PorB induced a loss of the $\Delta\Phi$m and the release of cytochrome c from mitochondria (Müller *et al*., 2000). Expression of anti-apoptotic members of the Bcl-2 family, such as Bcl-2 and Bcl-XL, prevented PorB-induced cytochrome c release and apoptosis, showing that gonoccocal PorB induces apoptosis through the intrinsic pathway (Müller *et al*., 2000). Targeting of PorB to mitochondria was subsequently demonstrated by cell fractionation and immunofluorescence studies (Müller *et al*., 2000). The cellular pathway that PorB uses to be transported from the bacterial surface to mitochondria is unknown. The deorganization of actin filaments or microtubules does not prevent PorB from reaching mitochondria, leading to the conclusion that endocytosis and endosome trafficking are probably not implicated in the transport of the porin from the cell surface to mitochondria (Müller *et al*., 2000). No signal sequence or linear determinant responsible for mitochondrial import could be identified in the sequence of PorB (Müller *et al*, 2002). Mitochondrial insertion of PorB into the MOM was found to require the protein import machinery of this organelle, including the Tom20 receptor and the general import pore (Müller *et al*., 2002).

How does *N. gonorrhoeae* PorB provoke cytochrome c release from mitochondria? Following its intracellular expression into HeLa cells, it was observed that *N. gonorrhoeae* PorB localizes to the MOM and forms oligomers (Müller *et al*., 2002). These authors reported that the gonococcal PorB could interact with the ANT, but not with the VDAC (Müller *et al*., 2002). As a consequence, they proposed that PorB might induce apoptosis through the induction of the MPT.

*Neisseria meningitidis* PorB, like *N. gonorrhoeae* PorB, was also found to target mitochondria (Massari *et al*., 2000; Massari *et al*., 2003a). In contrast to its homologue in *N. gonorrhoeae*, PorB produced in *N. meningitidis* was not toxic for cells. No apoptosis could be detected when HeLa or Jurkat cells were exposed for 24 h to doses as high as 100 μg/ml of purified *N. meningitidis* PorB (Massari *et al*., 2000; Massari *et al*., 2003a). No modification of the $\Delta\Phi$m, swelling of mitochondria, or release of cytochrome c could be observed in these conditions (Massari *et al*., 2000; Massari *et al*., 2003a). Moreover, *N. meningitidis* PorB afforded protection, like Bcl-XL or Bcl-2, against a proapoptotic stimulation induced by staurosporine (Massari *et al*., 2000; Massari *et al* 2003a). In cells treated with *N. meningitidis* PorB, the porin was shown to co-immunoprecipitate with the mitochondrial VDAC, but not ANT (Massari *et al*., 2000). From these data, it was hypothetized that the *N. meningitidis* PorB, by interacting with VDAC, might this time prevent the occurrence of the MPT, perhaps in a fashion similar to Bcl-2 or Bcl-XL, resulting in an increased cell survival (Massari *et al*., 2000; Massari *et al*., 2003b).

How can two highly homologous proteins induce opposing effects on cell apoptosis? It has been argued that, rather than a difference between the structure of the two porins, the methods used by Müller *et al*. (2000) or Massari *et al*. (2000) to purify PorB (in particular the detergent concentration) or to perform the intoxication were probably responsible for the opposing porin activities on mitochondria (Massari *et al*., 2000; Massari *et al*., 2003b). In view of these conflicting results, it is currently difficult to propose an *in vivo* role for *Neisserial* PorB action on host mitochondria.

## The *Helicobacter pylori* VacA cytotoxin

*Helicobacter pylori* is a Gram-negative bacterium that infects 50% of the world population. *H. pylori* is determinant in the pathogenesis of peptic ulcer, chronic gastritis, gastric carcinoma, and the lymphoma deriving from the mucosa-associated lymphoid tissue (reviewed in Blaser and Atherthon, 2004). Several virulence factors are associated with *H. pylori,* in particular the vacuolating cytotoxin VacA. We will only briefly describe here this molecule, since this cytotoxin is reviewed in detail in another chapter of this book.

VacA has initially been identified by its ability to induce large vacuoles in cultured cells (reviewed in Papini *et al*., 2001). Cell vacuolation by VacA requires the presence of weak bases, such as ammonium chloride, and develops selectively from late endosomes (Papini *et al*., 2001). In its mature form, VacA has a molecular weight of 87 kDa. Once released from the bacteria, the cytotoxin is cleaved into two subunits of 34 kDa (the N-terminal fragment p34) and 58 kDa (the C-terminal fragment p58) that remain associated by non-covalent interactions (Papini *et al*., 2001). VacA binds host cells on one or several receptor(s) putatively identified as receptor tyrosine phosphatase α (RPTPα) (Yahiro *et al*., 2003)

and VacA localizes in lipid rafts (Ricci *et al*., 2000; Schraw *et al*., 2001; Patel *et al*., 2001; Gauthier *et al*., 2004). Full activity of VacA requires GPI-anchored proteins (Ricci *et al*., 2000; Kuo and Wang, 2003; Gauthier *et al*., 2004). In the membrane bilayer, the cytotoxin hexamerises and forms channels that are selective for anions on the cell surface (Papini *et al*., 2001). These channels are pinocytosed by an actin-dependent mechanism, which does not require clathrin or dynamin (Ricci *et al*., 2000; Gauthier *et al*., 2004). Once in the late endosomes, VacA channels increase the permeability of this membrane organelle to anions. This facilitates the function of the V-ATPase, the proton pump that is responsible for the acidification of intracellular compartments. This leads to an accumulation of osmotically active species that results in the swelling of these compartments (Gauthier *et al*., 2004). Beside its vacuolating activity, VacA also induces apoptosis in cultured cells (Kuck *et al*., 2001; Cover *et al*., 2003). The mechanism by which the cytotoxin induces cell apoptosis was first shown by expressing the p34 or the p58 cytotoxin fragments fused with the Green Fluorescent Protein (GFP) into epithelial cells: using this strategy, we observed that GFP-p34, but not GFP-p58, colocalized with mitochondria (Galmiche *et al*., 2000) (see Figure 10.4). It was subsequently demonstrated that VacA and its p34 fragment (but not p58) were imported *in vitro* into isolated mitochondria (Galmiche *et al*., 2000). It was shown that VacA and the p34 fragment were imported into the MIM or the matrix compartment of mitochondria (Galmiche *et al*., 2000). At the same time, we noticed that the intracellular expression of the p34 fragment or the full length VacA in HEp-2 cells could induce cytochrome c release and a subsequent activation of the effector caspase-3 (Galmiche *et al*., 2000). HEp-2 cells incubated with the purified native toxin for a prolonged period of time (24 h) also exhibited a release of cytochrome c, indicating that VacA is indeed targeting mitochondria when it is applied outside of cells (Galmiche *et al*., 2000). From these observations, it was concluded that VacA resembles an AB toxin in which the A (p34) moiety target mitochondria, whereas the B subunit (p58) allows the binding of the cytotoxin to host cells and the penetration of the active subunit into the cytosol. Our observations clarified a previous report indicating that VacA could induce mitochondrial damages in human gastric cells (producing a drop in $\Delta\Phi$m, an inhibition of the cell oxygen consumption, and an ATP depletion) (Kimura *et al*., 1999). These data were subsequently confirmed and extended by other groups showing (i) that incubation of purified VacA with HeLa or gastric AZ-521 cells induces the release of cytochrome c into the cytosol (Willhite *et al*., 2003; Nakayama *et al*., 2004), (ii) that VacA incubated with gastric AZ-21 or Hela cells induces a decrease in $\Delta\Phi$m (Nakayama *et al*., 2004; Willhite and Blanke, 2004), and (iii) that fluorescently labeled VacA applied to Hela cells localizes to mitochondria (Willhite and Blanke, 2004). Like *Neisseriae* PorB, VacA does not contain any linear targeting sequence responsible for mitochondrial targeting; residues spread over the all p34 moiety are important (Galmiche *et al*., 2000).

We are now focusing our investigation on the mode of action of VacA inside the mitochondria. Two modes of action have been proposed. A first model holds that the ability of VacA to form anionic channels in lipidic membranes is required for the mitochondrial cytotoxin activity (Willhite *et al*., 2003; Willhite and Blanke, 2004). Such an anionic channel, assembled in the MIM, would result in the collapse of the $\Delta\Phi$m and the release of cytochrome c. This model is supported by the protective effect of pharmacological blockers of VacA-dependent chloride transport on the mitochondrial toxicity of VacA (Willhite and Blanke, 2004). In addition, a mutant of VacA defective in its anionic channel

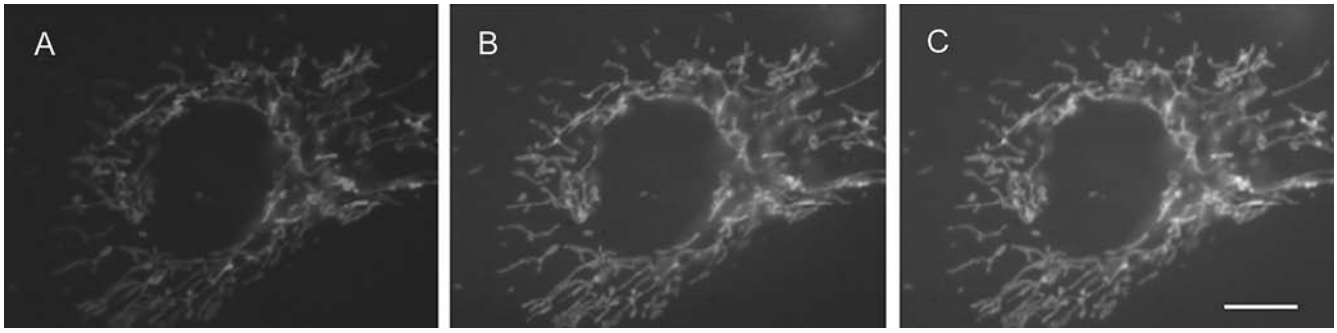

**FIGURE 10.4.** The vacuolating cytotoxin VacA of *Helicobacter pylori* targets mitochondria

Human umbilical vein epithelial cells (HUVEC) were co-transfected with the construct DsRed-mito, allowing the live visualization of mitochondria (panel A), and the amino-terminal part of the cytotoxin VacA of *Helicobacter pylori*, the protein p34 fused to GFP (panel B). A nearly total overlap of the two stainings was observed (see the overlay presented in panel C). Bar : 10 µm.

formation because of a 22 amino acid residues deletion (Δ6-27 VacA) is still targeted to mitochondria, albeit unable to modify the ΔΦm (Vinion-Dubiel *et al*., 1999; Willhite and Blanke, 2004). The model of a VacA channel-mediating toxicity is however challenged by the observation that VacA-induced vacuolation and effects on mitochondria are dissociable events: the intracellular expression of p34 induces cytochrome c release and cell death without any vacuolation (Galmiche *et al*., 2000). In fact, the p34, albeit unable to oligomerize and thus to form channels (Papini *et al*., 2001), has the same toxic activity as the whole VacA molecule on mitochondria (Galmiche *et al*., 2000). While it remains possible that p34 alone could oligomerize and create a channel in the MIM, we would like to propose an alternative model for the mode of action of VacA, where p34 might be endowed with an enzymatic activity that modifies one or several mitochondrial target molecule(s).

An interesting issue is the mechanism by which VacA, upon binding to its cell surface receptor, is transferred to mitochondria. We proposed the following model. The ability of VacA to induce the swelling of endosomes might have been exploited to rupture these compartments, thereby releasing the cytotoxin or the p34 fragment in the cytosol and allowing it to reach mitochondria. That model is derived from the cellular mechanism by which DNAs can be transfected into cells using charged polyplexes molecules, such as polyethylene imines (PEIs). PEIs are known to induce endosome swelling by provoking, like VacA, an influx of chloride ions into these compartments and are used as drugs to increase DNA transfections (Sonawane *et al*. 2003). Swelling is followed by the rupture of a small population of endosomes and the release of transfectant DNAs (Sonawane *et al*. 2003). That VacA uses such a mechanism might be supported by the observation that apoptosis of gastric AGS cells induced by VacA is promoted by the weak base ammonium chloride, required for VacA-induced late endosome swelling (Cover *et al*., 2003).

We have recently suggested that VacA, being produced by *H. pylori* in the gastric mucosa, could target the cells of the epithelium, and, in particular, parietal cells. This cell type produces chlorhydric acid, and is one of the cell types richest in mitochondria in the organism. We have proposed that VacA intoxication of these cells could reduce the gastric acid secretion and help *Helicobacter pylori* colonize the gastric mucosa, either through apoptosis induction or by "de-energizing" these cells (Boquet *et al*., 2003). In the long term, apoptosis induction inside the gastric epithelium could play a distinct pathogenic role. Continuous apoptosis induction might promote the appearance of a pre-malignant state, known as *atrophic gastritis* (Shirin and Moss, 1998).

## Enteropathogenic *Escherichia coli* (EPEC) Map, Tir and Espf virulence factors

Enteropathogenic *Escherichia coli* is a major cause of diarrhea in young children in developing countries (reviewed in Nataro and Kaper, 1998). EPEC infect the intestinal epithelium. While these bacteria remain extracellular, they induce a characteristic modification of the cell cytoskeleton that causes the formation of a pedestal made of filamentous actin. At this level, the bacteria strongly adhere to the eukaryotic host via the afimbrial adhesin intimin. EPEC induce host epithelial cell apoptosis (Abul-Milh *et al*., 2001). To produce these effects, EPEC inject, by a TTSS, the protein Tir (the receptor for intimin but also an inducer of actin polymerization) (Kenny *et al*., 1997). Other bacterial proteins appear to be co-injected by TTSS into the host cell together with Tir including, Map and EspF. Map, Tir, and EspF have been shown to be targeted to mitochondria (Kenny and Jepson, 2000; Malish *et al*., 2003; Nougayrede and Donnenberg, 2004; Nagai *et al*., 2004).

The mitochondrial associated protein (Map) (also known as *Orf19*) contains an N-terminal mitochondrial amino acid sequence and targets mitochondria where it induces a drop of the ΔΦm (Kenny and Jepson, 2000). However, it is yet not clear whether Map induces cell apoptosis (Kenny and Jepson, 2000). Independently of its activity on mitochondria, Map also interferes with the actin cytoskeleton via the GTPase Cdc42, and it plays a role with Tir in the bacterial cell invasion (Jepson *et al*., 2003).

The intimin receptor Tir when expressed by transfection into cells localizes to mitochondria and induces apoptosis of transfected cells (Malish *et al*., 2003). However, localization of Tir into mitochondria of EPEC-infected cells has not been observed (Malish *et al*., 2003). Tir, being the receptor for intimin, contains a membrane-spanning domain, which might also incorporate, upon expression into cells, into the mitochondrial MOM.

EspF has been shown to induce intestinal epithelium tight junctions opening, contributing to diarrhea caused by EPEC (McNamara *et al*., 2001). EspF contains a consensus mitochondrial targeting N-terminal sequence (Nougayrede and Donnenberg, 2004; Nagai *et al*., 2004) and colocalizes with mitochondria in EPEC infected cells (Nougayrede and Donnenberg, 2004; Nagai *et al*., 2004). EspF was shown to modify the ΔΦm, to induce cytochrome c leading to activation of the executioner caspase 3 causing cell death (Nougayrede and Donnenberg, 2004; Nagai *et al*., 2004). Importantly, the

ability of EspF to target mitochondria was linked to the bacterial pathogenesis and colonization in an animal model of infection (Nagai *et al*., 2004).

## *Staphylococcus aureus* α-toxin

*Staphylococcus aureus* is a frequent pathogen for human and animals and represents an important concern in nosocomial infections. Patients with severe *S. aureus* sepsis and undergoing multiple organ failure exhibit lymphocyte apoptosis, which might account for the depletion of immune cells favoring bacterial spread. *S. aureus* secretes many virulence factors among these pore-forming toxins (for more details see chapters on pore-forming toxins in this book). It was recently shown that the pore-forming α-toxin of *S. aureus* is a major mediator of lymphocyte apoptosis induced by this bacterium (Bantel *et al*., 2001). The α-toxin induced the release of cytochrome c from Jurkat T cells or primary T lymphocytes together with activation of the executionner caspase 3 (Bantel *et al*., 2001). Release of cytochrome c could also be induced directly on isolated mitochondria by the toxin (Bantel *et al*., 2001). Furthermore, it was demonstrated that the release of cytochrome c was under the control of the anti-apoptotic factor Bcl-2 (Bantel *et al*., 2001). These observations led to the conclusion that α-toxin acted selectively on the mitochondrial pathway of apoptosis to induce cell death (Bantel *et al*., 2001). However, in this report, it was not demonstrated that the α-toxin localized into mitochondria in toxin-treated cells. These conclusions were subsequently slightly modified by observations showing that primary lymphocytes, in contrast to Jurkat cells, were able to produce TNF-α upon α-toxin incubation (Haslinger *et al*., 2003). TNF-α by stimulating the caspase-8 pathway of apoptosis could induce cell death independently from the mitochondrial pathway (Haslinger *et al*., 2003). In addition, it was shown that *S. aureus* α-toxin could provoke the cell death of Jurkat T or MCF-7 breast carcinoma cells in a necrotic-like manner by a caspase-independent mechanism (Essmann *et al*., 2003). Therefore, it is not yet clear which cell death pathway *S. aureus* α-toxin manipulates during an infectious process *in vivo*.

## *Salmonella* SipB

The facultative intracellular pathogen *Salmonella* triggers programmed cell death in macrophages (reviewed in Hueffer and Galàn, 2004). This programmed cell death is essentially mediated by the protein SipB, a factor that is encoded in the pathogenicity island SPI-1 of *Salmonella* (SPI-1 for *Salmonella* Pathogenicity Island-1). This pathogenicity island encodes a TTSS that secretes SipB and allows it to reach the plasma membrane of the cells that are infected by *Salmonella*.

SipB essentially induces the apoptosis of the host macrophage in a caspase-1 dependent fashion (Hersch *et al*., 1999), but caspase-1-independent mechanisms also exist (Hueffer and Galan, 2004). A recent work suggests that a mitochondrial action of SipB could explain this caspase-1-independent pro-apoptotic effect (Hernandez *et al*., 2003). This conclusion was reached using intracellular expression of SipB in cells that are resistant to caspase-1 activation by *Salmonella* (primary macrophages from caspase-1 knock-out mice and epithelial cells): in the epithelial cell line COS, expression of SipB induced the formation of multilamelar structures that resembled autophagic structures and contained endoplasmic reticulum and mitochondrial markers (Hernandez *et al*., 2003). In caspase-1-deficient macrophages infected with *Salmonella*, SipB localized to mitochondria, and these organelles displayed swelling and disparition of cristae. Finally, an increase in the formation of autophagosomes was noticed, and a form of cell death occurred that could not be prevented by the pharmacological inhibition of the caspases (Hernandez *et al*., 2003). Based on these observations, it was proposed that SipB might target the mitochondria of its host cells and induce cell death with autophagy as an essential morphological feature (Hernandez *et al*., 2003). In this respect, autophagy is a common finding in some forms of caspase-independent cell death (Locksin and Zakeri, 2002).

The molecular details of SipB mode of action on mitochondria are unknown, but Hernandez *et al*. (2003) have extended their conclusions with a model based on SipB ability to promote the membrane fusion of liposomes mimicking the composition of the bacterial and cellular membranes, especially those containing the lipid cardiolipin, an abundant component of mitochondrial membranes (Hayward *et al*., 2000). They proposed that, following its localization to mitochondria, SipB would exert its membrane fusion activity in a fashion reminiscent of the protein mitofusin and induce the appearance of the observed multilamellar structures (Hernandez *et al*., 2003). Although appealing, this model remains largely unproven, and more work will be required to clarify the mitochondrial effect of SipB.

## Large clostridial cytotoxins

The high-molecular-weight cytotoxins (MW 250–300 kDa) produced by the anaerobic bacteria *Clostridium sordelli* (lethal (LT) and hemorragic (HT) toxins), *C. difficile* (toxin A (CdtA) and B (CdtB)) and *C. novyi*

(α toxin) have been grouped under the term of large clostridial cytotoxins (LCCs) (Eichel-Streiber *et al*., 1996). LCCs are described in detail in other chapters of this book, and we will outline only briefly their main features. All these cytotoxins affect the organization of the host cell actin cytoskeleton (reviewed in Eichel-Streiber *et al*., 1996). The LCCs, CdtA, CdtB, and HT all exhibit glucosyltransferase activity and modify small GTPases of the Rho family on threonine 35/37 of their effector loop (reviewed in Boquet and Lemichez, 2003b). The *C. sordellii* LT toxin isolated from strain IP-82 glucosylates the GTPases Ras, Rap, and Ral (reviewed in Boquet and Lemichez, 2003b).

CdtB was first shown to induce apoptosis of intestinal crypt cells (Fiorentini *et al*., 1998). Later, CdtA was described to localize to mitochondria and to induce early mitochondrial damages, including cytochrome c release, ATP depletion, reactive oxygen production, and cell apoptosis (He *et al*., 2000, 2002). Interestingly, it was shown that CdtA could induce leakage of cytochrome c from isolated mitochondria (He *et al*., 2000). Effects of CdtA on mitochondria appeared to be independent from the activity of the cytotoxin on the actin cytoskeleton via the Rho GTPases (He *et al*., 2000). More recently, the LT toxin from *C. sordellii* strain IP82 was shown to localize to mitochondria and to induce cytochrome c release leading to apoptosis by the mitochondrial pathway in HL 60 cells (Petit *et al*., 2003). LT enzymatic activity on small GTPases did not appear to play a role in inducing cell apoptosis (Petit *et al*., 2003). However, the toxin activity on the Ral GTPase to provoke cell death could not be totally excluded (Petit *et al*., 2003). Indeed, LT toxin from *C. sordellii* strain 9048 that exhibits the same spectrum of small GTPases modifications as LT-IP82, except that it does not glucosylate the Ral GTPase, was not able to induce cell death on HL 60 (Petit *et al*., 2003). Interestingly, it has been shown very recently that the 18 N-terminal residues of LT contains a phophatidylserine binding site required for the full glucosylation of the membrane-attached Rac GTPase (Mesmin *et al*., 2004). It might be possible that LT may exhibit also some affinity for lipids of MOM, thereby allowing alteration of the mitochondrial MPT. CdtB is highly homologous to *C. sordellii* LT toxin (88% of homology at the amino acid sequence and both toxins cross-react immunologically). Recently, it was observed that purified or recombinant CdtB added to isolated mitochondria were each able to alter the MIM $\Delta\Phi m$ (Fiorentini and Matarese, 2004). In contrast to *C. sordellii* LT, CdtB does not exhibit an affinity for lipids at the level of its N-terminal amino acids (Mesmin *et al*., 2004). It remains to be demonstrated whether CdtA, CdtB, and LT act on mitochondria by similar or different molecular mechanisms.

## WHY DO BACTERIAL TOXINS AND VIRULENCE FACTORS TARGET MITOCHONDRIA ?

Is mitochondrial targeting an event of frequent occurrence for bacterial proteins, and toxins in particular? A recent computer-based survey of the proteins present in the genome of. *E.coli* showed that up to 5% of the proteins encoded have sequence features that could serve as mitochondrial targeting information (Luccatini *et al*., 2004). An explanation for this frequent "predisposition" is likely to be found in the phylogenetic origin of mitochondria (Dyall *et al*., 2004). The study of the topogenesis of β-barrel membrane proteins of the MOM and the outer membrane of bacteria recently strikingly illustrated one consequence: the conservation of protein transport mechanisms between bacteria and human mitochondria (Paschen *et al*., 2003). In line with this observation, the recent study of the mitochondrial import of *Neisseria* PorB revealed that this porin shares its mitochondrial import pathway with its cousin, the mitochondrial porin/VDAC (Müller *et al*., 2002). A complete discussion of the consequences of this conservation is clearly beyond the scope of this review, but we would like to suggest that, in the context of bacterial pathogenesis, evolution might have favored mitochondrial targeting because of the many similarities that exist between mitochondria and Gram-negative bacteria.

## CONCLUSION

The study of mitochondrial targeting by bacterial virulence factors is a developing field. Because mitochondria are organelles that probably originated from bacteria, evolution could have favored the constitution of virulence factors interfering with these organelles. Studies on mitochondria, first reduced as providers of energy, show that these organelles play important roles in the regulation of cell homeostasis. Regulatory mechanisms of the cellular homeostasis have been constantly exploited by virulence factors of pathogens. Deciphering the activities of those factors will undoubtly lead to the discovery of important new concepts in cell biology.

## ACKNOWLEDGMENTS

We would like to thank Nils Gauthier (INSERM U 627, Nice, France) for his contribution to Fig. 10.4, Carla Fiorentini and Paola Matarese (Istituto Superiore di

Sanità, Roma, Italy) for their communication of unpublished results, and Ulrike Rapp-Galmiche (Max Planck Institut für Infektions, Berlin, Germany) for reviewing the manuscript.

# Toxins activating Rho GTPases and exploiting the cellular ubiquitin/proteasome machineries

*Michel Gauthier, Gilles Flatau, Patrice Boquet, and Emmanuel Lemichez*

## INTRODUCTION

One of the most fascinating aspects of bacterial factors modifying Rho GTPases follows from the findings that, in addition to Rho inactivating factors, we have identified a growing family of activating factors. These factors are either toxins or factors directly injected into cells by cell-bound bacteria. The diversity and multiplicity of bacterial factors activating Rho proteins clearly highlight their importance for bacteria in establishing a tight relationship with their host. Toxins activating Rho proteins are closely related to each other. They share a high level of sequence homology and molecular mechanism of action. These bacterial factors were termed "toxins" to refer to their mechanism of penetration into cells. Progress made on the knowledge of their mechanism of action now raises questions on the nature of these bacterial factors, which likely represent bacterial factors for persistence in the host. Supporting this notion are the recent discoveries concerning the cellular mechanism of action of the CNF1 toxin. It catalyzes the permanent activation of Rho GTPases by post-translational modification. In cells, it has been recently established that Rho proteins, upon activation by CNF1, are rapidly ubiquitinylated and conveyed to the proteasomal machinery for proteolysis. This counterintuitive mechanism of action results in a moderate activation of Rho proteins. Host cells respond to the activation of Rho proteins by producing a large array of immunomodulators. Based on these findings it is likely that, while Rho protein activation allows bacterial internalization into cells, a decrease in the level of Rho protein activation lowers the host inflammatory responses.

## THE FAMILY OF RHO GTPASE–ACTIVATING TOXINS

To date, bacterial toxins activating Rho proteins have been isolated exclusively from human and animal pathogenic Gram-negative bacteria. These bacterial products were first purified based on their dermonecrotic (or necrotizing) activity when injected subcutaneously and at high doses in guinea pigs, mice, or rabbits (Caprioli *et al*., 1983; Horiguchi *et al*., 1989). Cloning and sequence analysis of these factors revealed their organization similarity to other known toxins (Falbo *et al*., 1993; Horiguchi, 2001). This toxin family encompasses different toxins found in either species belonging to *Bordetella* (dermonecrotic toxins, DNTs) or *Escherichia* and *Yersinia* species (cytotoxic necrotizing factors, CNF1, CNF2, or CNFy).

CNF1 is a chromosomally encoded protein of 1,014 amino acids with a predicted molecular mass 113.7 kDa. It is found in 30% of uropathogenic *E. coli* isolates (Landraud *et al*., 2000). CNF2, isolated from calves' and piglets' pathogenic *E. coli*, is a 110 kDa protein that shares about 90% identity with CNF1 (De Rycke *et al*.,

1999). More recently, Lockman and coworkers have described a CNF-related toxin in *Yersinia pseudotuberculosis,* namely CNFy, which bears 65.1% sequence identity with CNF1 (Lockman *et al*., 2002). Finally, the dermonecrotic toxins (DNTs) have been isolated from *Bordetella pertussis, B. parapertussis,* and *B. bronchiseptica* (Horiguchi, 2001). The DNT genes of *B. pertussis* and *B. bronchiseptica* were found to be more than 99% identical (Walker and Weiss, 1994; Pullinger *et al*., 1996). DNT of *B. bronchiseptica* is a protein of 1,464 amino acids, which shares sequence homologies with CNFs restricted to its catalytic domain (Lemichez *et al*., 1997; Horiguchi, 2001).

The *cnf1* gene is located within the pathogenicity island (PAI) PAI-II of the J96 UPEC strain, where it lies between the *hly* and *prs* operons (Swenson *et al*., 1996). At the difference with *cnf1* and *cnfy*, which are chromosomally encoded, *cnf*2 is located on a plasmid (Oswald and De Rycke, 1990; De Rycke *et al*., 1999). The genetic link between genes encoding CNF1 and α-hemolysin toxin reflects a co-regulation in their transcription (Landraud *et al*., 2003). In the *E. coli* J96 strain, transcription of *cnf1* is initiated from the *hly* promoter and requires the RfaH antiterminator factor activity (Landraud *et al*., 2003). RfaH binds to a specific nucleotide sequence found in the *hly* promoter (*ops/JUMP start*), where it interacts with the RNA polymerase and confers to the enzyme an antiterminator activity (Santangelo and Roberts, 2002). It is established that the α-hemolysin operon *hlyCABD* is transcribed in a single mRNA under the positive control of RfaH (Leeds and Welch, 1996). The transcription of the *cnf1* gene likely results from the formation of a polycistronic *hlyCABDcnf1* mRNA (Landraud *et al*., 2003).

## CNF1 AND DNT STRUCTURE/FUNCTION RELATIONSHIP

### Organization of CNF1 and DNT toxins in functional domains

CNF1 and DNT toxins are synthesized as unique polypeptides, which are organized in three functional domains (Figure 11.1) (Lemichez *et al*., 1997; Kashimoto *et al*., 1999). The amino-terminal parts of both toxins contain the cell receptor-binding domain (Lemichez *et al*., 1997; Kashimoto *et al*., 1999). The cell-binding domain of CNF1 has been delineated to the first 190 amino-terminal residues, whereas for DNT it is comprised in the first 53 amino-terminal residues (Fabbri *et al*., 1999; Matsuzawa *et al*., 2004). CNF1 binds tightly to its receptor, with a Kd as low as $2.10^{-11}$ M on HEp-2 cells (Contamin *et al*., 2000). The receptor-binding domain of CNF1 is followed by a domain containing two hydrophobic helices. Based on homologies to diphtheria toxin (DT), it has been hypothesized that this part of CNF1 might correspond to a membrane-anchoring domain, allowing the initiation of the translocation of catalytic domain into the cell cytosol (Figure 11.1) (Lemichez *et al*., 1997). In the case of DT, negatively-charged residues located between the two hydrophobic helices TH8–9 are protonated at acidic pH (O'Keefe *et al*., 1992). This allows the insertion of TH8–9 into the lipid bilayer (Wang *et al*., 1997). This event likely initiates the translocation of the catalytic domain. Mutagenesis analysis of the inter-region of the CNF1 hydrophobic helices has confirmed the analogy between both toxins (Pei *et al*., 2001). Finally, the most carboxy-terminal part of CNF1 and DNT contains the enzymatic domain. The catalytic domain of CNF1 has been crystallized (Buetow *et al*., 2001). The CNF1 deamidase domain form a narrow (15×30 $Å^2$) and deep pocket of about 10 Å, in which is located the catalytic triad corresponding to residues V833, C866, and H881. Consistently, mutations C866S and H881A abolished the toxin enzymatic activity (Schmidt *et al*., 1998). The tight structure of this pocket likely ensures a restriction of the accessibility of the glutamine 63 of the switch-II region (residues 59–78) of RhoA and thus confers the specificity of modification of Rho proteins by CNF1 (Flatau *et al*., 2000; Buetow *et al*., 2001). Other determinants, such as the flexible loops lining the entrance of the pocket of catalytic domain of CNF1, may confer the specificity of Rho protein recognition. Consistently, it has been observed that deletion of loop-8 (residues 964–970) and loop-9 (residues 996–1003) dramatically abolished the deamidation activity of the catalytic domain of CNF1, whereas this activity showed a significant increase upon deletion of loop-2 (residues 790–795). These results suggest that whereas loops -8 and -9 might be directly involved in RhoA recognition and/or binding, loop-2 might have to rearrange during RhoA binding (Buetow and Ghosh, 2003). Modelization of the catalytic domain of DNT suggests that, in contrast to that of CNF1, the pocket contains a negative charge that may attract positively charged primary amines (Buetow *et al*., 2001). This difference likely accounts for the transglutaminase activity of DNT (Buetow *et al*., 2001).

### CNF1 and DNT translocation into the cell cytosol

Despite their close organization, CNF1 and DNT toxins have evolved two different mechanisms to inject their catalytic domain into cells (Figure 11.2). CNF1 binds to a cell surface receptor, which was identified as

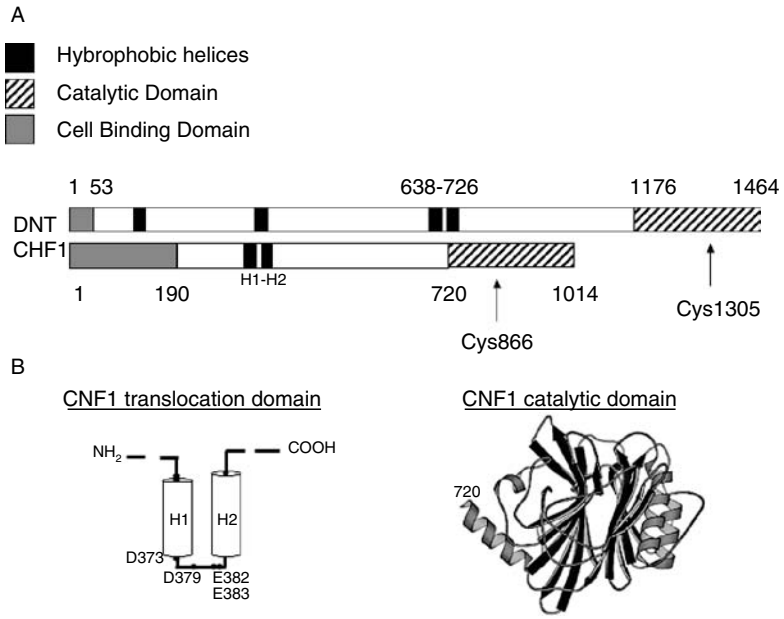

**FIGURE 11.1** Organization of CNF1 and DNT toxins in functional domains. A. Schematic representation of the organization of CNF1 and DNT toxins. B. CNF1 translocation domain: this shows a representation of the two helices of CNF1, which probably act by anchoring the toxin into the lipid bilayer at acidic pH to initiate the translocation of the catalytic domain into the cell cytosol (Pei *et al.*, 2001). CNF1 catalytic domain: this shows a representation of the structure of the catalytic domain of CNF1 (residues 720-1014) (Buetow *et al.*, 2001).

the 67 kDa laminin receptor (Chung *et al.*, 2003; Kim *et al.*, 2004). It remains to be determined whether this cellular receptor actually represents the high affinity receptor to CNF1. In contrast to CNF1, no DNT receptor has been isolated to date. The binding of both toxins to a cell surface receptor allows their internalization into endocytic vesicles at low rate. CNF1 enters endocytic vesicles by a non-clathrin endocytosis (independent of Eps15, dynamin, or intersectin-Src homology 3) (Contamin *et al.*, 2000). Following its entry into endocytic vesicles, CNF1 reaches late endosomal compartments. The acidic conditions found in late endosomes allow the transfer of the catalytic domain to the cytosol (Contamin *et al.*, 2000; Pei *et al.*, 2001). It remains to be determined which part of the molecule reaches the cytosol. At the difference with other known bacterial toxins, DNT intoxicates cells by an original mechanism, independent of endosome acidification (bafilomycin A1 insensitive) and of its transfer to the endoplasmic reticulum (brefeldin A insensitive) (Matsuzawa *et al.*, 2004). DNT enters endocytic compartments by a dynamin-dependent endocytosis, where the amino-terminal domain (residues 1–53) is likely cleaved by furin. It is thought that cleavage of the last 53 amino acid residues might unmask hydrophobic helices of the toxin and thus initiate the translocation of the catalytic domain into the cytosol (Matsuzawa *et al.*, 2002).

## CNF1 and DNT-catalyzed deamidation/transglutamination of Rho proteins

Following the initial discovery that CNF1 intoxication of cells resulted in a massive reorganization of the actin cytoskeleton (Fiorentini *et al.*, 1988) and that both CNF1 and DNT induced a mobility shift of RhoA on SDS-PAGE (Fiorentini *et al.*, 1994; Oswald *et al.*, 1994; Horiguchi *et al.*, 1995) , it was hypothesized that these toxins might catalyze a direct post-translational modification of Rho (Fiorentini *et al.*, 1995; Horiguchi *et al.*, 1995). Soon after, it was discovered through different approaches that CNF1 catalyzes the deamidation of the glutamine 63 of RhoA into a glutamic acid (Flatau *et al.*, 1997; Schmidt *et al.*, 1997). At the difference with CNF1, the DNT toxin preferentially produced the transglutamination of RhoA (Figure 11.3) (Schmidt *et al.*, 1998; Masuda *et al.*, 2000). Both biochemical reactions are similar except that deamidation uses $H_20$ as acceptor molecules instead of amine molecules used for transglutamination. The Rho sequence determinants responsible for CNF1 recognition and modification were identified by constructing chimeric molecules between RhoA and Ha-Ras, a more distant small GTPase not modified by CNF1. The specificity of deamidation is conferred by the residues R68 and L72 of RhoA (Lerm *et al.*, 1999a). These residues are found at this position specifically in members of the Rho

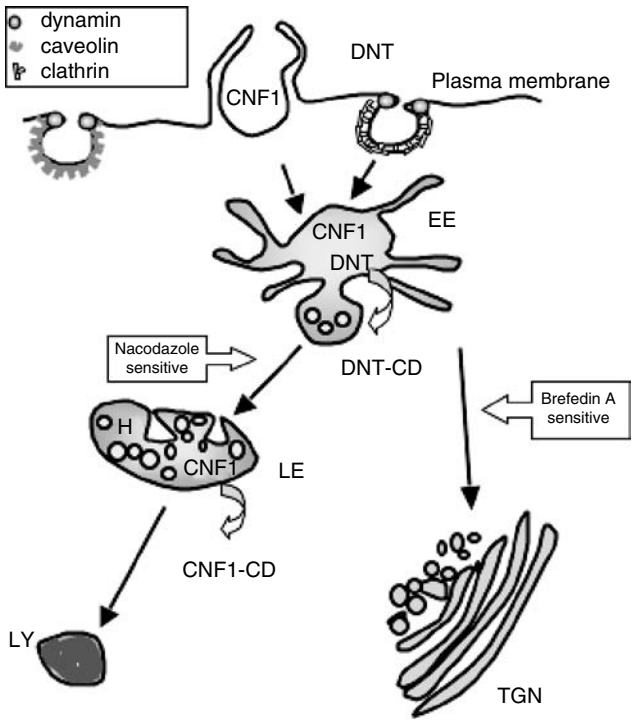

**FIGURE 11.2** CNF1 and DNT penetration into host cells. CNF1 and DNT cell intoxication depicting the endosomal compartments EE (early endosome), LE (late endosome), LY (lysosome), and TGN (trans-Golgi network). CNF1 binds to a cell surface receptor. This carrier protein allows the toxin to reach endosomal compartments by a pathway, which is blocked neither with filipin (caveolae-like) nor by dominant negative mutants of Eps15, dynamin, or intersectin-Src homology 3 (clathrin-coated-vesicles). Cell internalization of the toxin is followed by its reaching to a late endosomal compartment. The acidic conditions of the late endosome allow the transfer of the catalytic domain of the toxin into the cytosol (noted CNF1-CD). Intoxication of cells by DNT, at the difference with CNF1, does not require endosomal acidic conditions (Bafilomycin A1 insensitive). The transfer of the catalytic domain (DNT-CD) likely occurs in an early endosomal compartment, which reaching is independent from actin cytoskeleton (Cytochalasin D insensitive), the microtubules (Nocodazole insensitive), or a retrograde transfer to the reticulum (Brefeldin A insensitive).

subfamily such as RhoA, Rac1, and Cdc42 (Lerm *et al*., 1999a). Consequently, Rac1 and Cdc42 are also deamidated by CNF1 *in vivo* (Lerm *et al*., 1999b).

The glutamine-63 of RhoA modified by CNF1 is a critical amino-acid conserved in all known proteins of the Ras superfamily (Takai *et al*., 2001). This glutamine residue had long been identified as a hot spot of oncogenic mutations in HRas. Its mutation is responsible for impairing the HRas GTPase activity (Der *et al*., 1986). Similarly, the CNF1-catalyzed deamidation of the glutamine 63 of RhoA was indeed found to block its GTPase activity, thereby conferring Rho permanent activation (Flatau *et al*., 1997; Schmidt *et al*., 1997).

## *In vivo* molecular activity of CNF1 and DNT

Studying the extent of Rho protein activation in a model of bladder epithelial cells in order to determine the specificity of Rho activation by CNF1, it was observed that cell intoxication resulted in a transient (instead of permanent) activation of Rho proteins (Doye *et al*., 2002). In this cellular model, CNF1 produced a maximal activation of Rac and Cdc42 isoforms (Doye *et al*., 2002). The transient activation of Rac was directly correlated to the proteasomal degradation of the form activated by CNF1 (Figure 11.2) (Doye *et al*., 2002; Lerm *et al*., 2002). Prior to degradation by the proteasome, cellular proteins are epitope-tagged by conjugation with a polyubiquitin string (Finley *et al*., 2004). Proteasomal degradation of endogenous Rac was found to follow the classical formation of a K48-polyubiquitin chain (Doye *et al*., 2002). Rac sensitivity to ubiquitin-mediated proteasomal degradation correlated with the strength of its activation (Doye *et al*., 2002; Boyer and Lemichez, 2004). In addition it was shown that Rac activation by the GEF domain of Dbl also resulted in a significant increase of Rac ubiquitinylation sensitivity (Doye *et al*., 2002). These results suggested that ubiquitinylation of Rho proteins might correspond to a yet unraveled regulation of these proteins that CNF1 may have hijacked. This idea is now sustained by the finding that the Smad ubiquitinylation-related factor 1 (Smurf1) bears an ubiquitin ligase activity on RhoA (Wang *et al*., 2003). It has been hypothesized that Rho ubiquitinylation might occur during mislocalized activation of RhoA, especially in membrane ruffles where activated RhoA might have antagonized the activity of Rac (Wang *et al*., 2003).

Recent findings suggest a more complex relationship between Rho protein activation and their ubiquitin-mediated proteasomal degradation. For instance, it has been reported that DNT activates but does not produced the proteasomal degradation of Rac in HeLa cells (Pop *et al*., 2004). These discrepancies probably reflect differences in the efficiencies of cell intoxication by CNF1 and DNT toxins. In fact, the proteasomal degradation of Rac can be detected when the kinetic of deamidation/degradation is higher than its kinetic of synthesis. For instance, a 24-hour cell intoxication by CNF1 produces a cellular depletion of Rac clearly visible at concentrations higher than $10^{-10}$ M (Munro *et al*., 2004). In addition, it has also been reported that CNFy specifically activates RhoA in HeLa cells, whereas it impairs the GTPase activity of RhoA, Rac1, and Cdc42 *in vitro* (Hoffmann *et al*., 2004). These reports, together with other findings showing that Rac is activated without being degraded in HEp-2 cells, raise open questions (Doye *et al*., 2002). For instance, these differences

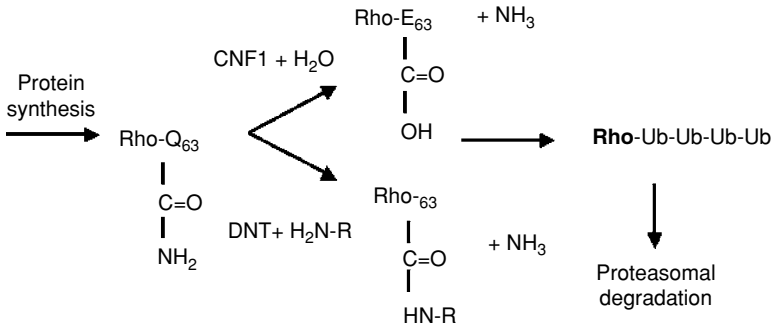

**FIGURE 11.3** Enzymatic activity of Rho GTPase, activating toxins. CNF1, 2, and CNFy have a deamidase activity responsible for the post-translational mutation of the glutamine 63 of RhoA and its equivalent 61 in Rac and Cdc42 into a glutamic acid. This mutation impairs the intrinsic GTPase activity of Rho proteins, resulting in their permanent activation. The activation of Rho proteins sensitizes them to the ubiquitin-mediated proteasomal degradation (Doye *et al.*, 2002). Similarly, DNT catalyzes the transglutamination of the glutamine 63 of RhoA (61 in Rac and Cdc42). The effects of CNF1 on Rho proteins result from different kinetics and are a direct consequence of the toxin concentration. If the reaction of deamidation and ubiquitin-mediated proteasomal degradation is higher to that of Rho protein synthesis, it produces a robust and transient activation of Rho proteins resulting from the cellular depletion of Rho proteins. This effect occurs at high concentrations of CNF1. In contrast, at lower concentrations of CNF1, the deamidation and ubiquitin-mediated proteasomal degradation of Rho proteins allow their moderate activation without visible cellular depletion.

might be attributed to the cell type specificity. One possibility could be that CNF1 specifically triggers Rho, Rac, and Cdc42 ubiquitin-mediated degradation in epithelial bladder and endothelial cells (Doye *et al.*, 2002; Munro *et al.*, 2004). These observations may account for the findings that CNF1 is preferentially encountered in *E. coli* strains responsible for urinary or meningitis infections. A more trivial explanation would be that some cancer cell lines might have a lower activity of ubiquitinylation of one (or more) Rho protein isoform(s). This would raise important questions concerning a possible relationship between ubiquitinylation of Rho proteins and cancer.

## CELLULAR EFFECTS OF RHO ACTIVATION/DEGRADATION BY BACTERIAL TOXINS

### Biological activities of Rho proteins

Rho proteins have turned out to be a major subject of research for both microbiologists and cell biologists since their first description as targets of *C. botulinum* C3 exoenzyme and as master transducers of the regulation of the actin cytoskeleton by growth factors (Chardin *et al.*, 1989; Ridley and Hall, 1992; Ridley *et al.*, 1992; Ridley and Hall, 2004). To date, we know at least 20 bacterial virulence factors and toxins modifying Rho proteins (Boquet and Lemichez, 2003). Rho proteins belong to the Ras superfamily of small GTPases (Takai *et al.*, 2001; Burridge and Wennerberg, 2004). Upon GTP binding, Rho protein members associate with and activate specific effectors (Burridge and Wennerberg, 2004). These interaction specificities allow, for instance, Cdc42 and Rac1 to regulate actin filament assembly producing membrane filopodia or ruffles, respectively (Burridge and Wennerberg, 2004). In contrast, RhoA and RhoC control both the bundling of actin filaments and their contraction through the regulation of the activity of myosin (Burridge and Wennerberg, 2004). Studies made on the cross-talk between bacterial virulence and Rho proteins have highlighted the importance of these cellular proteins in controlling and organizing the cellular defenses against pathogenic bacteria (Boquet and Lemichez, 2003). Through their regulatory properties of actin filament polymerization, organization, and contractility, Rho proteins control a large array of cell processes requiring cell shaping and membrane dynamics (Etienne-Manneville and Hall, 2002). For instance, Rho proteins control the cohesion of cells either between each other or at the contact with the cellular matrix (Etienne-Manneville and Hall, 2002). This aspect is of importance for pathogenic bacteria, of which penetration into host cells is frequently limited due to the basolateral localization of their cell-internalization receptors (Cossart and Sansonetti, 2004). Rho proteins also participate in the control of cell cycle progression and apoptosis (Sahai and Marshall, 2002). This last aspect is also closely related to pathogen requirements. For instance, it is thought that apoptosis inhibition in target cells may favor bacterial persistence at the epithelium surface, whereas apotosis

may favor bacterial spreading inside tissues (Mulvey *et al*., 1998). Rho proteins also regulate cell motility and differentiation (Etienne-Manneville and Hall, 2002). These aspects are of particular interest in relationship to cellular effectors of the immune response. For instance, macrophage chemotactism up to the site of bacterial infection is under the control of the actin cytoskeleton machinery, as is the phagocytosis bacteria by macrophages (Caron and Hall, 1998).

## Biological activities of CNF1 and DNT toxins

Whether DNTs and CNFs play similar roles in the bacterial pathology, with respect to *Bordetella* and *Escherichia* productive strains, remains to be investigated. DNT studies in animal models have clearly highlighted the importance of this toxin in turbinate atrophy and pneumonia pathology (Magyar *et al*., 2000; Brockmeier *et al*., 2002), whereas studies carried on CNF1 have rather investigated its effects on cellular models. Major progress has been made in our knowledge of molecular mechanism of invasive factors of Gram-negative bacteria (Cossart and Sansonetti, 2004). Importantly, all these bacterial cell-invasion strategies have in common the activation of a family of cellular regulators expressed in all cells, namely the Rho GTPases. In that respect, the CNF1 toxin represents an interesting model. CNF1 produces a counterintuitive mechanism consisting of Rho protein activation responsible for sensitizing them to ubiquitin-mediated proteasomal degradation (Figure 11.2) (Doye *et al*., 2002). These observations raise the question of the importance of both Rho protein activation and degradation in bacterial virulence. It has been shown that activation of Rho proteins is necessary to induce the CNF1-triggered internalization of bacteria by epithelial and endothelial cells (Falzano *et al*., 1993; Doye *et al*., 2002; Kim *et al*., 2004). Interestingly, the reaching of a low level of Rho protein activation due to equilibrium between activation and degradation was shown to confer higher invasive properties to pathogenic bacteria (Figure 11.4). Similar requirements were also found to confer intercellular junction dismantling and epithelial cell motility inside monolayers (Doye *et al*., 2002). Urinary tract infections (UTIs) have long been considered as acute and often self-limiting infections caused by non-invasive *E. coli*. Nevertheless, growing evidence suggests that UPECs are individuals capable of colonizing the bladder mucosa by a process requiring the coordinate action of different virulence factors (Anderson *et al*., 2004). At first, bacteria attach to bladder epithelial cells through adhesins, preventing them from miction clearing. Persistence of bacteria probably also requires to escape host defenses, comprising innate effectors such as the membrane attack complex of the complement system and immune-cell effectors. New evidence suggests that protection of UPECs against host defenses may be achieved by limiting the impact of host innate responses, for instance, by invading cells (Schilling *et al*., 2001). In fact, intracellular invasion of epithelial cells may not only protect UPECs against host defenses but may also allow bacteria to replicate and/or persist into host cells (Mulvey *et al*., 1998; Svanborg *et al*., 1999). Further studies will have to clarify whether CNF1 is a major determinant of recurrent cystitis, which might then be due to formation of UPECs reservoir in epithelial cells during infection.

Studying the cell response to intoxication by CNF1 revealed that intoxication interferes with classical signaling pathways, such as the c-Jun N-terminal kinase and NF-κB pathways, leading to gene regulation (Lerm *et al*., 1999b; Boyer *et al*., 2004; Munro *et al*., 2004). Consequently, high levels of cell intoxication by CNF1 trigger a gene response consisting of a selective activation of about 0.19% of the 33,000 genes probed on DNA arrays (Munro *et al*., 2004). The 10 most CNF1-activated genes formed a coherent family of inflammatory mediators aiming at leukocyte recruitment and activation (Figure 11.4). These results are in agreement with a possible effect of CNF1 in the development of UPECs infection, which results in an acute inflammatory disease. Induction by CNF1 of membrane metalloproteases and syndecan family products may contribute to the recruitment of leukocytes to the site of infection. Other identified inflammatory regulators, such as PLAU-urokinase (for lumen arteries restriction), as well as Prostaglandin G/H synthesis enzymes, may complete the task of leukocytes recruitment and activation to the site of bacterial infection. Production of GRO-family and MIP-3α chemokines may participate in recruiting lymphocytes and antigen presenting dendritic cells, respectively. CNF1-intoxicated cells also produce innate-defense effectors, comprising complement factor-3 for pathogen phagocytosis, and factor-9 (a component of the cytolytic membrane attack complex), as well as GliPR, a plant pathogen related-1 protein homologue. Finally, the transcriptome of CNF1-intoxicated HUVECs appears to share many similarities with known TNFα-regulated genes, among them TRAF1, cIAP2, and A20.

Interestingly, the transcriptome analysis of cells intoxicated by CNF1 points to Rac/Cdc42 activation being responsible for the production of inflammatory mediators (Munro *et al*., 2004). For instance IL8, MCP-1, and MIP-3α were found to be were expressed as a function of the levels of activated-Cdc42 or Rac (Munro *et al*., 2004). These findings are consistent with other studies showing that Rac and Cdc42 are engaged in Toll-like receptors (TLRs) signal transduction (Arbibe

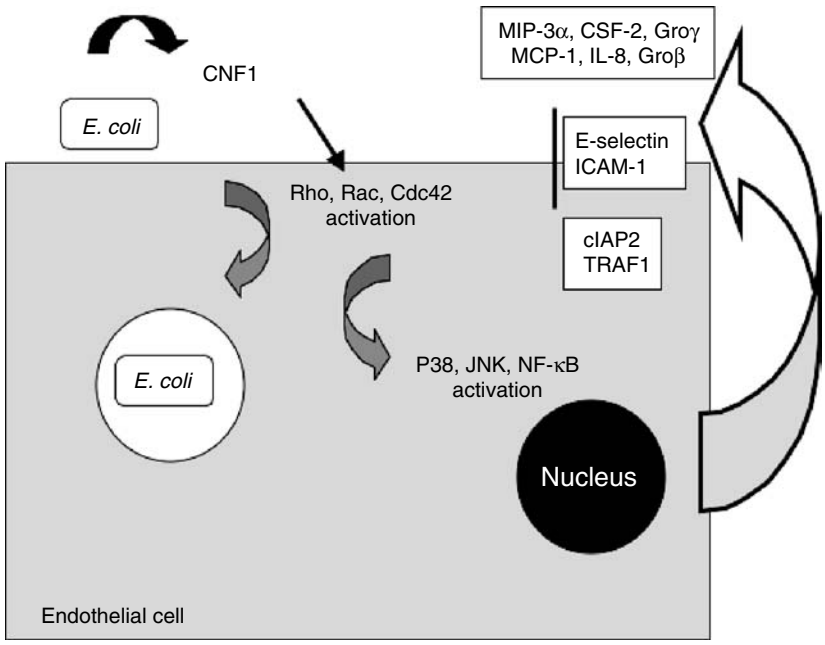

**FIGURE 11.4** Relationship between *E. coli* producing CNF1 and the host cell genetic response. The intoxication of human umbilical vein endothelial cells HUVECs by CNF1 results in the activation of p38 and c-Jun kinases, as well as I-κB degradation for NF-κB activation. While CNF1 allows the internalization of *E. coli* into HUVECs, the activation of these signaling pathways engages a genetic program aimed at leukocytes' recruitment and activation. Here are depicted the 10 most CNF1-activated genes (Munro *et al*., 2004). Induction of inflammatory mediators for leukocytes' attraction and activation: MIP-3α, CSF-2, Groγ, MCP-1, IL-8, Groβ could be correlated to the production of the leukocyte cell-binding receptors E-Selectin and ICAM-1. Cell response to CNF1 also included TRAF1 (TNF-receptor associated protein-1) and cIAP2 (mammalian inhibitor of apoptosis protein-1 homologue C), two modulators of the TNF-α receptor signaling.

*et al*., 2000). Collectively, these results indicate that bacteria have evolved virulence systems aimed at producing a moderate activation of Rho proteins to delay and/or mit the cellular alarm program of the host, while invading cells. The moderate activation of Rho proteins, for bacterial internalization into cells, may thus be beneficial during early stages of the bacterial infection, prior to substantive bacterial growth and a resulting acute inflammatory reaction (Janssens and Beyaert, 2003; Anderson *et al*., 2004). During the acute phase of the inflammatory reaction, CNF1 may also play a role by acting directly on inflammatory cells or protecting cells from apoptosis (Fiorentini *et al*., 1997; Capo *et al*., 1998; Hofman *et al*., 2000; Malorni *et al*., 2003).

## ACKNOWLEDGMENTS

We are grateful to all members of our laboratory. We apologize to our colleagues whose excellent work could not be cited because of the lack of space. Our laboratory is funded by the French National Institute of Health and Medical Research (INSERM).

# Molecular, functional, and evolutionary aspects of ADP-ribosylating toxins

*Vega Masignani, Mariagrazia Pizza, and Rino Rappuoli*

## INTRODUCTION

The mono-ADP-ribosylation reaction is an enzymatic activity that was initially discovered and studied at the molecular level in bacterial toxins. For a while this reaction was believed to be a peculiarity of bacteria and no role was known for it on normal metabolism of eukaryotic cells. Recently, many enzymes with ADP-ribosylating activity have been discovered in eukaryotic cells. Examples are mammalian ART1-5 and the rodent RT6. This growing family of enzymes shows that ADP-ribosylation is also an enzymatic reaction with an important role in the posttranslational modification of the eukaryotic cells.

ADP-ribosylating toxins are a variety of bacterial proteins with totally unrelated structures that have in common only one feature: they contain an enzyme with ADP-ribosyltransferase activity. The toxins with this activity are shown in Figure 12.1. The enzymatic moiety, which is represented by the black "A" domain in Figure 12.1, is responsible for the toxic effect. This domain is contained in a protein of approximately 20–25 kDa, but in some cases the size can be greater. Based on their overall structure the toxins can be divided into A/B toxins, binary toxins, or A/only toxins. A/B and binary toxins are molecules released by bacteria in the extracellular environment. The A domain contains the enzymatic toxic activity, while the B domain is a non-toxic part that functions as a carrier or delivery system for the A domain: it binds the receptor on the surface of eukaryotic cells and helps its translocation within the cell.

As shown in Figure 12.1, the A/B toxins are the best studied, and we know the three-dimensional structure of most of them. In some cases, the B domain can be divided into the B (cell binding) and T (membrane translocation domain).

The binary toxins have a similar organization; however, in this case the A and B domains are separately secreted on the culture supernatant. The B domain binds to the receptor on the surface of the target of the eukaryotic cells and only then is able to bind the A domain and help its translocation into the cytosol. Toxins with this structure are the C2 toxin of *Clostridium botulinum* and the related toxins shown in Figure 12.1.

The A/only toxins are those toxins constituted uniquely by the A domain with the enzymatic activity. A typical example of this type of toxin is the Exoenzyme S of *Pseudomonas aeruginosa* that is directly injected by bacteria into eukaryotic cells by a specialized secretion system. Other toxins with this structure have a still unknown mechanism of cell entry (Exoenzyme C3 of *C. botulinum*).

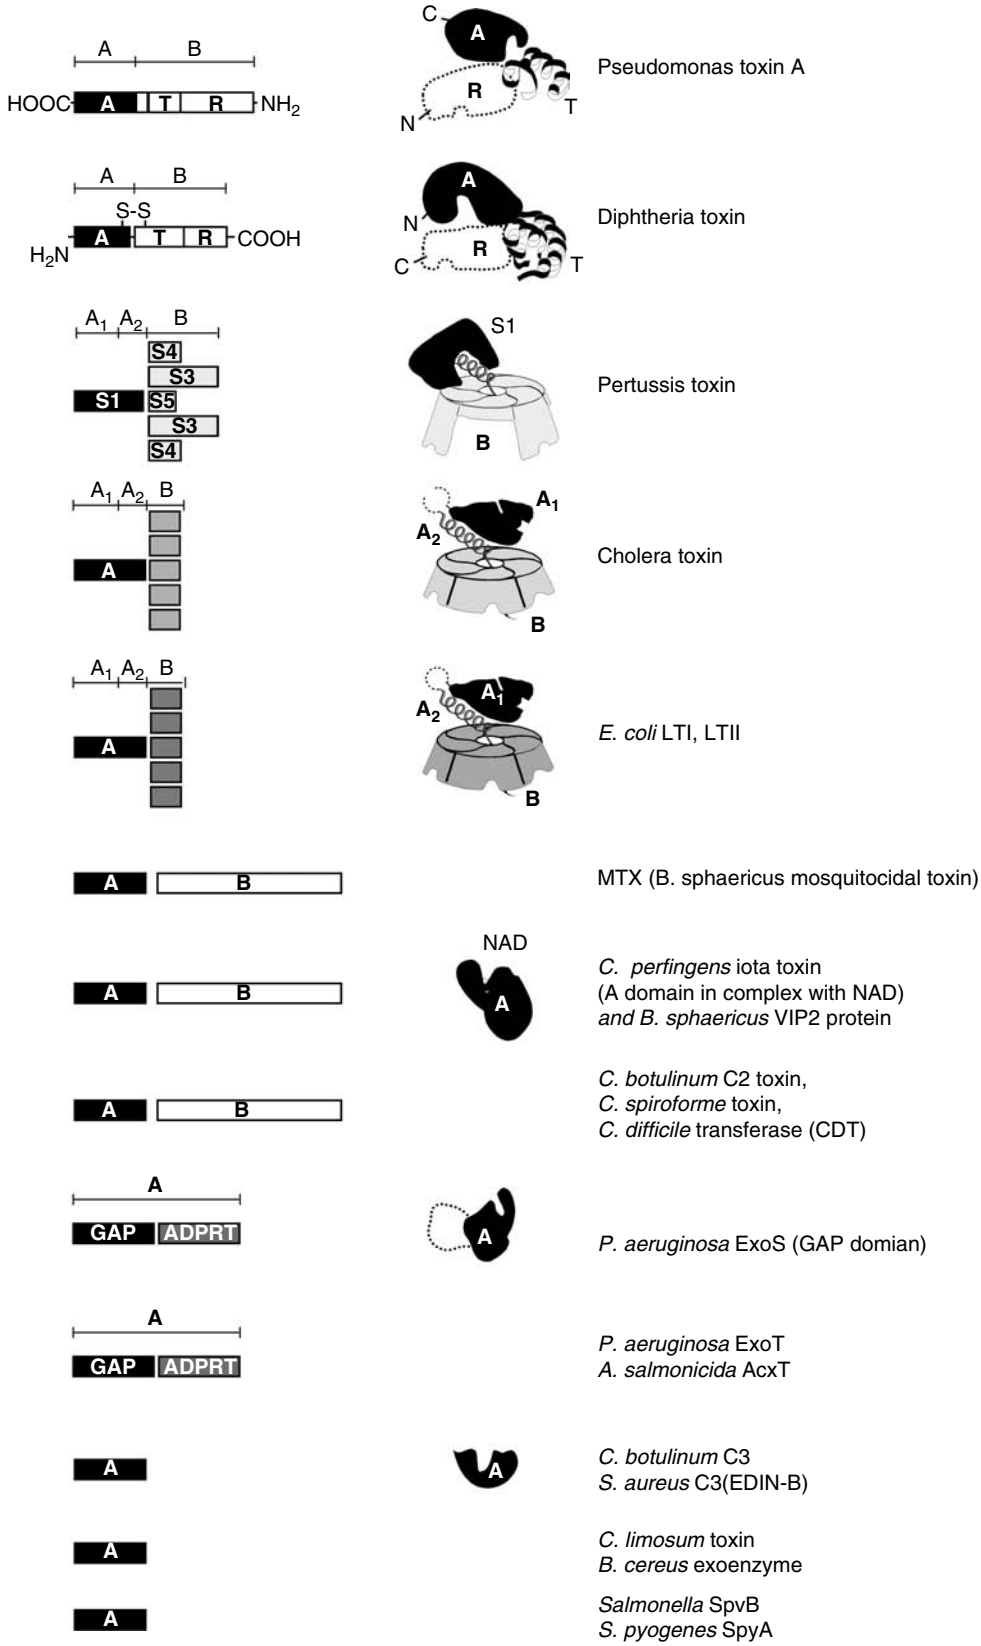

**FIGURE 12.1** Structural organization of bacterial ADP-ribosylating toxins. The enzymically active, toxic moiety (A) is black. The carrier domain(B), when present, is white (left). When crystallographic data are available, a schematic representation of the quaternary structures of the domains is reported (right).

## THE ENZYMATIC REACTION AND THE SUBSTRATES

Two types of ADP-ribosylation reactions are known to occur in nature: poly- and mono-ADP-ribosylation (Ueda and Hayaishis 1985; Althaus and Richter 1987). Poly-ADP-ribosylation occurs mostly in the nucleus of eukaryotic cells where histones and other nuclear proteins are posttranslationally modified first by the covalent attachment of an ADP-ribose group to the carboxyl group of the C-terminal amino acid, and then by the elongation of the ADP-ribose chain through the addition of further ADP-ribose groups. Here, we are interested in mono-ADP-ribosylation, an enzymatic reaction that is mediated by bacterial toxins, phage, and *Escherichia coli* proteins, and a growing family of cytoplasmic and membrane-associated eukaryotic enzymes.

Mono-ADP-ribosyltransferases are produced by bacteriophages, bacteria, and vertebrates (Corda and Di Girolamo, 2003). They bind NAD and transfer the ADP-ribose group to a specific target protein that, following the posttranslational modification, usually changes its function dramatically. The ADP-ribose group is transferred to a nitrogen atom in the side chain of amino acids such as diphthamide, arginine, asparagine, or cysteine, according to the reaction shown in Figure 12.2. Recently, pierisin-1, a novel factor able to ADP-ribosylate DNA, has been discovered in the cabbage butterfly (Kanazawa *et al.*, 2001). Pierisin-1 acts by transferring an ADP-ribosyl group to DNA at N-2 of guanine base and induces apoptosis in mammalian cells accompanied by a release of cytochrome c (Watanabe *et al.*, 2002).

Interestingly, with the exception of actin and of the RNA polymerase, which is the substrate of viral ADP-ribosyltransferases, all the eukaryotic proteins that are ADP-ribosylated by bacterial toxins belong to a quite restricted family: they are GTP-binding proteins (G-proteins). These proteins are molecular switches involved in a variety of cell functions, including cell proliferation, tissue differentiation, signal transduction, protein synthesis, protein translocation, vesicular trafficking, and cytoskeleton structure. These proteins consist of two parts: a common core structure involved in GTP binding, and one or more different domains that act as effectors, or are involved in the interactions with the molecules regulated by these molecular switches (Figure 12.3) (Kjeldgaard *et al.*, 1996). G-proteins have four regions of sequence homology (named Σ1–Σ4 in Figure 12.3) and a structurally conserved core that binds GTP. This domain is the core of the molecular switch that is in the "on" conformation when GTP-bound. Hydrolysis of GTP to GDP causes a conformational change of an α-helix in this core structure that turns the switch in the "off" conformation (Hamm and Gilchrist, 1996; Gilchrist *et al.*, 1998; Sunhara *et al* 1997; Vaughan, 1998; Ji *et al.*, 1998; Gether and Kobilka, 1998; Lefkowitz, 1998). The GTP-binding proteins are divided into four groups: the Ras-like G-proteins, the heterotrimeric G-proteins, the translation factors, and tubulins. Tubulins do not contain the conserved core and are not substrates of ADP-ribosylation. All other groups of G-proteins have one or more components that are substrates of ADP-ribosyltransferases. One question that remains unanswered is whether ADP-ribosylating toxins derive from a common ancestor that recognized the common core structure of G-proteins, or whether during evolution they have independently selected G-proteins as targets many times just because they regulate very important cellular circuits and, therefore, are ideal targets for molecules that intend to intoxicate cells or tissues. The mechanism by which ADP-ribosylating toxins recognize different substrates has so far been open to discussion. However, a recent work reports the identification of several regions that cooperatively define the substrate specificity by exposing a different electrostatic potential at the site of molecular interface (Sun *et al.*, 2004).

The eukaryotic proteins that are mono-ADP-ribosylated by bacterial toxins are the following:

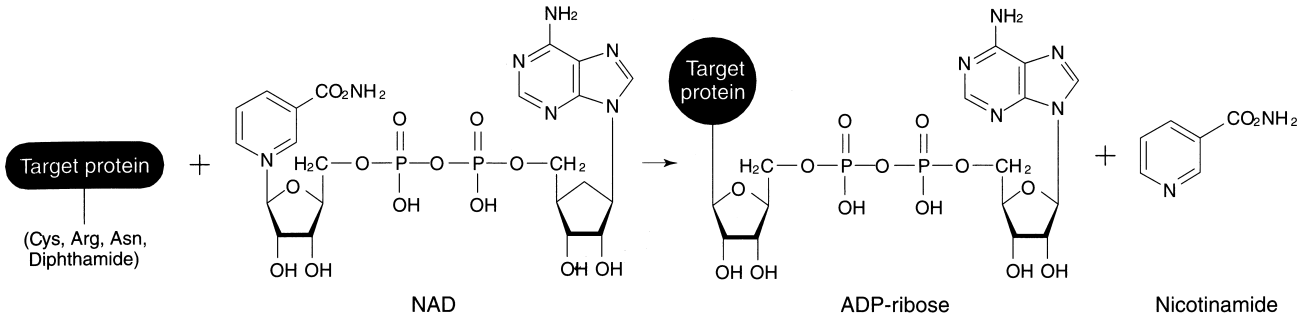

**FIGURE 12.2** Mechanism of the mono-ADP-ribosylation reaction catalyzed by ADP-ribosyltransferases: an ADP-ribose moiety is transferred to a specific target protein and a nicotinamide group is released. Following the post-translational modification the target protein changes its properties.

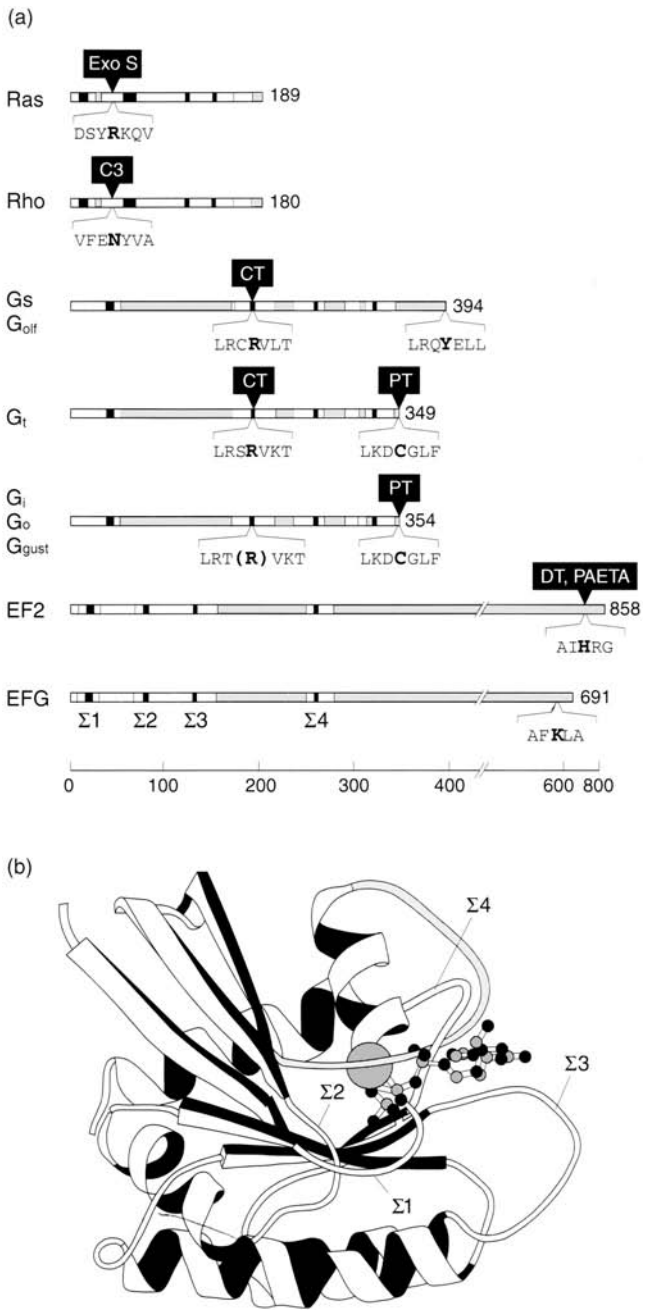

**FIGURE 12.3** (a) schematic representation of GTP-binding proteins. The Σ1–Σ4 are the regions that form the core of the GTP-binding domain. They are present in all G-proteins. In the figure they are indicated by black boxes. The amino acids that are ADP-ribosylated by each toxin are indicated in bold. (b) Three-dimensional structure of the GTP-binding domain common to all G-proteins and formed by the homologous regions Σ1–Σ4.

## Elongation factor 2 (EF2)

Eukaryotic EF2 is a protein of 95,700 Da, which is involved in protein synthesis (Kohno *et al.*, 1986). It contains a posttranscriptionally modified histidine residue (diphthamide 715) (Van Ness *et al.*, 1980a, b), which is ADP-ribosylated by diphtheria toxin DT and Pseudomonas exotoxin A (PAETA) (Honjo *et al.*, 1968; Gill *et al.*, 1969). Following ADP-ribosylation, EF2 is unable to carry out protein synthesis, and this causes rapid cell death. The region containing diphthamide 715 is very close to the anticodon recognition domain of EF2. This suggests that ADP-ribosylation interferes with EF2 binding to the tRNA. The homologous bacterial EFG contains a Lysine in this position, and therefore it is not a substrate for these toxins (see Figure 12.3) (Kohno *et al.*, 1986). Recently, the factor responsible for the first step of the posttranslational modification of EF-2 at $His^{715}$ that yields diphtamide has been identified (Liu and Leppla, 2003). This gene (DESR1) is present in mammalian cells and an analog has also been identified in yeast. Conversely, bacteria, which do not express DESR1, are resistant to diphtheria and pseudomonas toxins. In evolution, the first organisms containing an EF2 that is susceptible to DT and PAETA are the archebacteria.

## Heterotrimeric G-proteins

Heterotrimeric G-proteins are involved in transduction of signals from surface-exposed receptors to intracellular effectors. They generally consist of an α subunit containing the GTP-binding domain and the intrinsic GTPase activity and the βγ subunit complex, containing two protein chains. In the "off " position, the α subunit binds ADP and is found in a membrane-bound complex together with the β and γ subunits. A positive signal from the receptor will cause the exchange of the GDP with GTP. The GTP-bound form of α dissociates from the βγ complex and interacts with a downstream effector molecule, thus transducing an extracellular event in a change of the intracellular chemical environment. They usually regulate the activity of enzymes such as adenylate cyclase, phospholipase C, and cyclic GMP-phosphodiesterase, which release secondary messengers into the cytoplasm as a response to external stimuli (Stryer and Bourne, 1986; Neer and Clapham, 1988). Adenyl cyclase, for instance, is regulated by two GTP-binding proteins: $G_s$ and $G_i$. $G_s$ receives signals from stimulatory receptors located on the surface of eukaryotic cells and stimulates the activity of adenyl cyclase. $G_i$, on the other hand, receives signals from the inhibitory receptors and inhibits the adenyl cyclase activity

(Gilman, 1984). In addition to $G_s$ and $G_i$, the family of heterotrimeric G proteins contains $G_o$, $G_t$, $G_g$, $G_{olf}$, and many other less characterized proteins with similar function. As shown in Figure 12.3, cholera toxin ADP-ribosylates Arg201 of the α subunit of $G_s$, $G_{olf}$, $G_t$. The corresponding Arg residues in $G_i$ and $G_o$ are ADP-ribosylated only when they are activated by the receptor. Arg201 is located in the core region that is involved in binding GTP. ADP-ribosylation has therefore a direct consequence on the enzymatic activity: it slows down GTP hydrolysis, thus keeping $G_s$ in a permanent "on" position. Pertussis toxin ADP-ribosylates Cys352 of the α subunit of $G_i$, $G_o$, $G_{gust}$, $G_t$, and other G proteins, but is unable to ADP-ribosylate $G_s$ and $G_{olf}$ that have a Tyrosine instead of a Cysteine in this position. This carboxyterminal region of Gα is involved in interaction with the receptor, and therefore ADP-ribosylation causes receptor uncoupling. ADP-ribosylation of G proteins by cholera and pertussis toxins causes a variety of effects in different tissues. In the case of adenyl cyclase, treatment with cholera toxin causes constitutive activation of the enzyme and accumulation of the second messenger cAMP, while treatment with pertussis toxin uncouples $G_i$ from its receptor so that it becomes unable to inactivate adenyl cyclase.

## Ras, Rho, and the small GTP-binding proteins

The Ras proteins are a large family of membrane-associated, GTP-binding proteins of approximately 21 kDa. They function in transmembrane signaling systems that control a variety of cellular processes including growth, proliferation, and differentiation of cells. The human Ras family consists of three highly homologous members: N-, K-, and K-Ras. They contain a "CAAX" carboxyterminal box that can be modified by the addition of a farnesyl lipid moiety, thus increasing their hydrophobicity. In the active conformation, the GTP-bound Ras interacts with the GTPase activating proteins (GAPs) effector molecules that turn it off by stimulating GTP hydrolysis. Many Ras proteins are known to be protooncogenes, requiring a single amino acid change to turn them into oncogenes. The mutations that are mostly found in tumors are in position 12 in Σ1 and in position 61 in Σ3. The oncogenic proteins exhibit a low GTPase activity following interaction with GAP, and therefore are blocked mostly in the "on" position.

Rho (Ras homology) are a subgroup of the Ras family GTPases containing several members including RhoA, B, C, D, E, and G, Rac1, 2, and 3, Cdc42, etc. Like Ras they contain the "CAAX" carboxyterminal box and can be posttranslationally modified. However, while Ras is only plasma membrane-associated, Rho can be found in a variety of locations, including the cytoplasm (RhoA and C, Rac1 and 2), the endosomes (RhoB), or the Golgi and endoplasmic reticulum (Cdc42). Rho proteins are controlled by three groups of regulatory proteins. Guanine nucleotide exchange factors (GEFs) induce activation of Rho by facilitating the GDP/GTP exchange, GTPase-activating proteins (GAPs) stimulate the hydrolysis of GTP thus turning off Rho proteins, while Guanine dissociation inhibitors (GDIs) keep Rho in the inactive form. Rho, Rac, and Cdc42 are involved in the regulation of the actin cytoskeleton. Rho induces formation of focal adhesion and actin stress fibers. Rac is involved in lamellopodia formation and induces adhesion complexes. Cdc42 induces the formation of microspikes. In summary, the Rho family of GTPases are involved in focal adhesion, integrin function, cell movement, and cell division. Ras is ADP-ribosylated at Arg41 by the Exoenzyme S of *P. aeruginosa*, while Rho is modified at Asn41 by the C3 enzyme of *C. botulinum* and *C. limosum*, by the *Staphylococcus aureus* EDIN protein, and by the VIP2 of *Bacillus cereus*. ADP-ribosylation causes inactivation of Ras and Rho, inability to stimulate actin polymerization with consequent loss of cell shape and cell rounding.

## Actin

Actin, a polypetide of 375 amino acid residues, is an ATP-binding protein that, in addition to contraction of muscle cells, in non-muscle cells controls the shape and the spatial organization of the cells, the cell movement, endo- and exocytosis, vesicle transport, cell contact, and mitosis. Microfilaments, which are the major structure of the cytoskeleton, are filamentous structures of 7–9 nm diameter, composed by polymerized actin. Rapid changes in cell shape are based on the ability of microfilaments to polymerize and depolymerize. Several bacterial toxins ADP-ribosylate monomeric actin at Arg 177. This Arg is located at the contact site between actin monomers, and therefore it can be modified in monomeric G actin, but it is not available for ADP-ribosylation in polymerized actin. Once ADP-ribosylated, monomeric actin is unable to make contacts with the other actin monomers, and therefore it cannot polymerize. As a consequence, toxin-treated cells are not able to build microfilaments and their cytoskeletal structure is rapidly destroyed. The toxins that ADP-ribosylate actin are *C. botulinum* C2 toxin, *Clostridium perfringens* iota toxin, *Salmonella enterica* SpvB toxin, and the ADP-ribosylating toxins of *Clostridium spiroforme* and *Clostridium difficile*.

## CELL ENTRY

Since the target proteins of ADP-ribosylating toxins are all located in the cytosol or in the inner face of the cytoplasmic membrane, the toxins need to cross the cell membrane in order to reach their intracellular targets. This is done mainly in two ways: (i) receptor-mediated endocytosis (see Figure 12.4, paths 1 and 2); or, (ii) direct injection of the toxin from the bacterium into the cytosol of the eukaryotic cell by a type III secretion system (see Figure 12.4, path 3).

### Receptor-mediated endocytosis

Receptor-mediated endocytosis is used by soluble toxins with an A/B structure and by binary toxins where the A and B domains are physically separated. The toxins with this structure are released by bacteria in the culture supernatant and bind to the surface of eukaryotic cells by their B domain, which contains a receptor-binding site. Following binding, the A/B toxins are internalized and located in membrane-bound vesicles (early endosomes). In the case of binary toxins, the B domain binds first to the cell receptor and then captures the A domain to the cell surface. The binding components of C2 toxin and iota toxin have been shown to form heptamers in solution (Barth *et al.*, 2000; Blocker *et al.*, 2001). In the case of C2, once formed, the heptamers insert as pores into the lipid bilayer and mediate the translocation of the active subunit into the cytosol (Blocker *et al.*, 2003). Furthermore, the host cell chaperone Hsp90 has recently been shown to be essential in the second step of translocation of C2I and iota toxin from endosomes into the cytosol (Haug *et al.*, 2004). Following internalization, two quite different pathways are used by different toxins to translocate their A domain into the cytosol. The two pathways have been best studied for diphtheria and cholera toxin, respectively. Diphtheria toxin A domain crosses the membrane early after internalization (see Figure 12.4, path 1). As soon as the pH of the endosomes decreases to 5.5 units, the B domain changes conformation and exposes hydrophobic α-helices that are not soluble any longer in water and therefore penetrate the lipid bilayer of the membrane. This initiates a process that favors the translocation of the A subunit across the membrane and also involves the action of a cytosolic translocation factor (TFC) complex. (See the paragraph on diphtheria toxin for a more detailed description of this process.)

The toxins known to cross the membrane by a mechanism similar to diphtheria toxin are botulinum and tetanus toxins.

Conversely, cholera toxin has a much more complicated intracellular route before it reaches the cytoplasm (Figure 12.4, path 2). Following internalization in early endosomes, it undergoes a retrograde transport back to the Golgi apparatus, across it until it reaches the endoplasmic reticulum (ER). The routing of the A subunit to this pathway is believed to be medi-

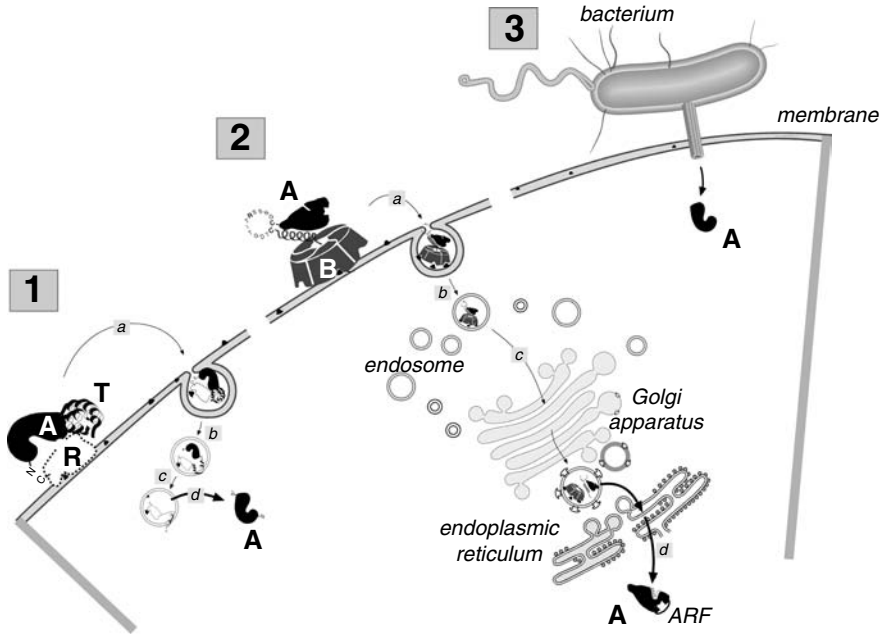

**FIGURE 12.4** Schematic representation of the three strategies used by ADP-ribosylating toxins to enter into cells.

ated by an amino acid motif (KDEL), which is similar to the endoplasmic reticulum retention domain of eukaryotic proteins. Once in the ER, the misfolded catalytic toxin subunit uses a retro-translocation path to finally reach the cytosolic compartment, where it rapidly refolds, avoids the proteasome, and induces toxicity (Lencer and Tsai, 2003).

The toxins that follow the intracellular route of cholera toxin are: Shiga toxin, the related verotoxin, pertussis toxin, *E. coli* heat-labile enterotoxin, and Pseudomonas exotoxin A (Johannes and Goud, 1998).

### Direct transfer of toxins from bacteria to eukaryotic cells

Some bacteria have evolved sophisticated transport systems to transfer their weapons directly into eukaryotic cells. The most famous are the type III and type IV secretion systems of Gram-negative bacteria. In these cases, the transmembrane machinery of flagella and conjugative pili, respectively, were evolved into contact-dependent delivery systems able to translocate macromolecules into eukaryotic cells. The toxins translocated by these mechanisms do not need a B domain since they are directly injected into eukaryotic cells (Figure 12.4, path 3). ADP-ribosylating toxins known to be injected into cells by a type III secretion system are Exoenzyme S and its homologue ExoT of *P. aeruginosa* (Sundin *et al.*, 2004). This is made by a single polypeptide chain containing the enzymatically active portion in the carboxyterminal region and a part recognized by the secretion system in the aminoterminal domain. Furthermore, the ADP-ribosyltransferase AexT produced by the fish pathogen *Aeromonas salmonicida* has also been shown to be secreted by a type III secretion system (Burr *et al.*, 2003).

A further example of a toxin secreted by specialized systems is pertussis toxin (PT). This protein is exported via a two-step process. In the first step, the individual subunits are secreted into the periplasm by a Sec-dependent mechanism. Upon assembling of the components to reconstitute the holotoxin, pertussis toxin traverses the outer membrane with the assistance of the type IV *Ptl* secretion system (Weiss *et al.*, 1993; Farizo *et al.*, 2000).

## BACTERIAL TOXINS

### Toxins acting on protein synthesis

#### *Diphtheria toxin*

Diphtheria toxin is a protein molecule, of 58,350 Da, that is released into the supernatant by toxinogenic *Corynebacterium diphtheriae* strains (Pappenheimer, 1977; Collier, 1982). The toxin is synthesized as a single polypeptide chain that, after mild trypsin treatment and reduction of a disulfide bond, can be divided into two functionally different moieties: fragment A and fragment B of 21,150 and 37,200 Da, respectively (Pappenheimer, 1977) (Figure 12.5A). The molecule contains four cysteines and two disulfide bridges: the first one joins Cys-186 to Cys-201 and links fragment A to fragment B, whereas the other is contained within fragment B and joins Cys-461 to Cys-471. The determination of the three-dimensional structure of the molecule (Choe *et al.*, 1992; Bennett *et al.*, 1994) has shown that the toxin can be divided into three separate domains: the C (catalytic) domain, corresponding to fragment A; the T (transmembrane or translocation) domain, composed of nine α-helices (TH1–TH9) (Figure 12.5C); and the carboxyterminal R (receptor-binding) domain.

Fragment A is a $NAD^+$ -binding enzyme that catalyzes the transfer of the ADP-ribosyl group to a posttranslationally modified histidine residue (diphthamide) present in the cytoplasmic elongation factor 2 (EF-2) of eukaryotic cells (Brown and Bodley, 1979; Van Ness *et al.*, 1980a). The EF-2-ADP-ribose complex is inactive, and therefore diphtheria toxin causes inhibition of protein synthesis and cell death. It has been shown that *in vitro* a single molecule of fragment A is enough to kill one eukaryotic cell (Yamaizumi *et al.*, 1978). This observation correlates well with the *in vivo* studies that show that, on a weight basis, diphtheria toxin is one of the most potent bacterial toxins, the minimal lethal dose of which is below 0.1 $\mu$g/kg of body weight (Pappenheimer, 1984).

Although the entire lethal activity of diphtheria toxin is located in fragment A, fragment B is required for receptor-binding and for translocation of fragment A across the cell membrane. The COOH-terminal domain involved in receptor-binding (R) and the NH2-terminal hydrophobic domain (T), involved in the interaction with the cell membrane, mediate this process. The receptor is the heparin-binding, EGF-like growth factor precursor (Naglich *et al.*, 1992; Hooper and Eidels, 1995; Brown *et al.*, 1993; Iwamoto *et al.*, 1994) that is present on most animal cells. Murine cells contain amino acid changes in the receptor that make rodents insensitive to diphtheria toxin (Mitamura *et al.*, 1995; Brooke *et al.*, 1998). Following receptor-binding, DT is internalized by receptor-mediated endocytosis. When the pH of the endosomes decreases below pH 5.5, fragment B undergoes a conformational change that exposes the hydrophobic regions of the T domain, allowing interaction with the endosomal membrane and translocation of denaturated fragment A from the endosome into the cytoplasm (Sandvig and Olsnes,

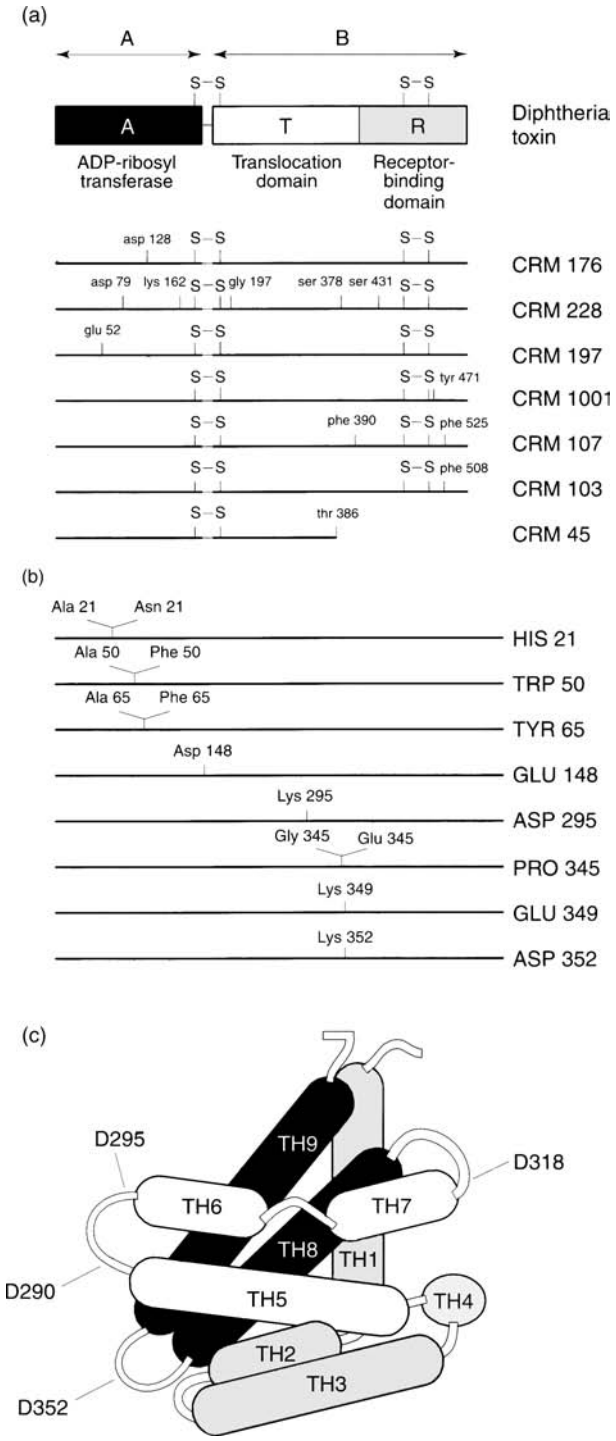

**FIGURE 12.5** Diphtheria toxin: (a) structure of the toxin and mutant CRMs obtained by random chemical mutagenesis; (b) mutants obtained by site-directed mutagenesis; (c) three-dimensional structure of the seven α-helices that form the hydrophilic T domain. The position of the mutations described in this region are shown.

1981; Cieplak *et al*., 1987; Neville and Hudson 1986; Papini *et al*., 1987a; Papini *et al*., 1987b). Therefore, whereas fragment A is very stable over a wide range of pH, temperature, and denaturing agents (it can be boiled, treated with urea, or various detergents without affecting its enzymatic activity), fragment B is very sensitive to low pH and is unstable in many buffers. According to a recent model, the A subunit of DT is able to cross the endosomal membrane making use of a metastable transmembrane domain, which has also been identified (Wolff *et al*., 2004). Although much is known on the mechanisms of receptor-binding and receptor-mediated endocytosis of native DT, little is known about the precise mechanisms that drive the translocation of the active subunit across endosomal membranes. Unfolding of the A domain before translocation was initially demonstrated by Wiedlocha *et al.*, (1992) and by Falnes *et al.*, (1994). Ratts and colleagues (2003) have shown that *in vitro*, a cytosolic translocation factor (CTF) complex, composed of Hsp90 and thioredoxin reductase, is essential for the translocation and cytoplasmic release of the A domain from early endosomes. Another activity described for DT is apoptosis of target cells. This activity is apparently mediated by the A fragment, but is not linked to the enzymatic activity. In fact, apoptosis has also been described for cross-reacting material (CRM197), an enzymatically inactive, nontoxic mutant of DT (described below). Whether apoptosis plays a role in toxicity *in vivo* is unclear; however, it cannot be a major role because the mutants, which are active in apoptosis but enzymatically inactive, are non-toxic *in vitro* and *in vivo*.

The diphtheria toxin gene is carried by a family of closely related bacteriophages (corynebacteriophages) that are able to integrate into the bacterial chromosome and convert non-toxinogenic, non-virulent *C. diphtheriae* strains into toxinogenic, highly virulent species (Freeman, 1951; Uchida *et al*., 1971). Lysogenic *C. diphtheriae* strains produce diphtheria toxin only when the medium is depleted of iron. The iron regulation of DT synthesis was discovered by A.M. Pappenheimer (1938) and is today well understood at the molecular level. The region upstream of the DT gene contains a sequence that is bound by an iron-binding repressor that dissociates from DNA only in the absence of iron (Qiu *et al*., 1995; Ding *at al*., 1996; Pohl *et al*., 1998; White *et al.*, 1998).

The best-known toxinogenic corynephages are βtox+ (Costa *et al*., 1981), isolated in 1950 during an outbreak of diphtheria in Canada, and ωtox+, isolated from the hypertoxinogenic PW8 strain (Rappuoli *et al*., 1983a). The process of integration of corynephage DNA into the bacterial chromosome closely resembles the mechanism of lysogenization described by Campbell (1962)

for bacteriophages: the phage DNA contains a locus called *phage attachment site* (*att*P), which is homologous to a sequence in the bacterial chromosome (bacterial attachment site or *att*B). Following site-specific recombination between these two sites, the phage DNA becomes stably integrated into the bacterial chromosome. Unlike *E. coli,* the chromosome of *C. diphtheriae* contains two primary attachment sites (attBl and attB2) (Rappuoli *et al*., 1983b; Rappuoli and Ratti, 1984). This allows the stable integration of two copies of corynephage DNA into the bacterial chromosome (Rappuoli *et al*., 1983b). Because each phage carries one copy of the *tox* gene, double lysogens produce twice the toxin produced by monolysogens. This property has been very important for obtaining strains hyperproducing CRM197, a nontoxic form of diphtheria toxin, that is used as a carrier for *Haemophilus influenzae* type B (Anderson *et al*., 1987; Egan *et al*., 1995; Rothbrock *et al*., 1995) and for meningococcal (Costantino *et al*., 1992) conjugate vaccines, and has been proposed as a new vaccine against diphtheria (Rappuoli, 1983).

The gene coding for diphtheria toxin is contained within an 1850 base pair (bp) *EcoRI-HindlII* DNA fragment, which has been cloned and entirely sequenced from phages ßtox+ and ωtox+ (Greenfield *et al*., 1983; Ratti *et al*., 1983). The sequences of the two *tox* genes obtained from phages isolated more than 50 years apart are identical, showing the remarkable conservation of the diphtheria toxin molecule. With the determination of the x-ray structure of DT in complex with its substrate NAD, DT was the first toxin for which structure-function relationships were elucidated, and it has been a model for all the other toxins (Bell and Eisenberg, 1997).

### *Mutants of diphtheria toxin*

Most of the functional and structural properties of DT were initially deduced from the analysis of a number of non-toxic DT mutants (cross-reacting materials of CRMs), encoded by corynephages that had been mutagenized by nitroguanidine (Uchida *et al*., 1971, Uchida *et al*., 1973a, b, c; Laird and Groman, 1976). The analysis of the properties of these mutants and the sequence of their genes was the first tool to map the functional domains of diphtheria toxin, and to identify some of the amino acids that play an important role in the enzymatic activity of fragment A, the receptor-binding domain of fragment B, and the translocation of fragment A across the eukaryotic cell membrane. The most relevant diphtheria toxin mutants are described below and reported in Figure 12.5a.

CRM 176 contains a Gly-128 to aspartic acid mutation that reduces the enzymatic activity of fragment A by a factor of 10 (Comanducci *et al*., 1987). CRM 228 contains two mutations in fragment A and three in fragment B, which result in inactive A and B fragments (Kaczorek *et al*., 1983). The mutation Gly79 → Asp has been later shown to be golely responsible for the lack of enzymatic activity of fragment A (Johnson and Nicholls, 1994a).

CRM 197 contains a single Glycine to Glutamic acid change in position 52 that makes the fragment A unable to bind NAD+ and, therefore, enzymatically inactive (Giannini *et al*., 1984; Pappenheimer *et al*., 1972). Being enzymatically inactive, and therefore non-toxic, but otherwise identical with diphtheria toxin, CRM 197 has been proposed as a natural candidate to develop a new vaccine against diphtheria. However, some subtle structural differences between diphtheria toxin and CRM 197 have been detected (Bigio *et al*., 1987), making this mutant more susceptible to proteases and less immunogenic than diphtheria toxoid (Pappenheimer *et al*., 1972). After stabilization with formalin, CRM 197 becomes immunogenic and able to induce protective antibody titers against diphtheria (Porro *et al*., 1980); however, its potency per μg of protein is still slightly lower than that of diphtheria toxoid. However, both DT and its nontoxic mutant CRM197 have found wide application as carrier molecules for glycoconjugate vaccines.

CRM 1001 has an enzymatically active fragment A and a fragment B that binds the toxin receptors, but is unable to translocate fragment A across the eukaryotic cell membrane. The nucleotide sequence of its gene has shown that Cys-471 has been replaced by Tyrosine, thus inhibiting the formation of the disulfide bridge between Cys-461 and Cys-471 (Dell'Arciprete *et al*., 1988).

CRM 103 and CRM 107 are two mutants that are unable to bind the receptors on the surface of eukaryotic cells (Laird and Groman, 1976; Greenfield *et al*., 1987). Sequence analysis has shown that both molecules contain mutations in the R domain. In CRM 103, Ser-508 has been changed to Phenylalanine, whereas in CRM 107 both Leu-390 and Ser-525 have been replaced by a Phenylalanine. CRM 45 is a shorter molecule prematurely terminated because of a nonsense mutation that introduces a stop codon at position 387; therefore, CRM 45 lacks entirely the R domain and is unable to bind the toxin receptors (Giannini *et al*., 1984).

The characterization of the structure-function relationships, initially performed using the above mutants produced by nitrosoguanidine mutagenesis, has made great progress by studying mutant proteins constructed through site-directed mutagenesis, and containing amino acid changes in those positions that the crystal structure and biochemical studies had suggested to be important. Among the mutations produced by site-directed mutagenesis, the most relevant are described below and shown in Figure 12.5.

Histidine 21, initially identified as important for catalysis by biochemical methods (Papini *et al*., 1989), was later confirmed to be so important that it cannot be substituted with other amino acids without abolishing the enzymatic activity. Some activity was only maintained when His was replaced by Asn (Johnson *et al*., 1994b; Blanke *et al*., 1994a).

Substitution of Tryptophan 50 with Alanine decreased ADP-ribosyltransferase by $10^5$-fold, while substitution with Phenylalanine had only minimal effects, suggesting an important role for an aromatic residue in this position for NAD affinity (Wilson *et al*., 1994).

Tyrosine 65 was initially identified as important for binding the nicotinamide ring by photolabeling studies (Papini *et al*., 1991), and later confirmed to be relevant by mutagenesis studies. Alanine substitution caused a 350-fold decrease of enzymatic activity, while Phenylalanine substitution caused only a small decrease (Blanke *et al*., 1994b).

Glutamic acid 148 was also initially identified as being near the catalytic site by photoaffinity labeling (Carroll *et al*., 1985), and was later shown to be so important for catalysis that it could not be substituted even with the closely related Aspartic acid (Tweten *et al*., 1985).

Asp 295, which is located in the hairpin loop between the α-helices TH5 and TH6 of the T domain, was shown to be important for membrane interaction of fragment B, because its substitution with a Lysine residue caused reduction of toxicity (Silverman *et al*., 1994). Finally, several amino acids, located between α-helices TH8 and TH9, were also found to be very important for DT translocation across the endosomal membrane. Substitution of Proline 345 with Glycine or Glutamic acid caused 99% reduction of toxicity (Johnson *et al*., 1993). Substitution of Glutamic acid 349, or Aspartic acid 352 with Lysine, caused more than 100-fold reduction of toxicity (Silverman *et al*., 1994).

The information deriving from biochemical, structural, and mutagenesis studies has increased our knowledge about the way the catalytic and translocation domains work. The present understanding is described below.

The active site (Figure 12.11) is formed by an α-helix bent over a β-strand, which forms the ceiling and the floor of the NAD-binding cavity, respectively. Within the cavity, Tyrosine 52 and Tyrosine 65 are parallel and between their aromatic rings there is just enough space to allow the entrance of the nicotinamide ring of NAD, which is then held firmly sandwiched between the two Tyrosines. At each side of the NAD-binding cavity, there are two amino acids that are essential for catalysis: His 21 and Glu 148.

His 21 is likely to be involved in positioning the NAD into the cavity, so that it is available for the nucleophilic attack of the substrate. Glu 148 is likely to be involved in interaction with the incoming substrate molecule. The structure of the active site shown in Figure 12.11 is conserved in all ADP-ribosylating enzymes known to date (Domenighini *et al*., 1991; Domenighini *et al.,* 1994; Domenighini *et al*., 1995a).

The T domain (Figure 12.5C) is formed by nine α-helices arranged in three layers. The internal one contains helices TH8 and TH9 that are hydrophobic and amphipathic, respectively. The intermediate one contains helices TH5, TH6, and TH7, which form a second hydrophobic shell. Finally, the external layer contains helices TH1, TH2, and TH3, which are rich in charged residues and help in maintaining the T domain and the toxin in a soluble form at neutral pH. When the pH decreases within the endosomes during toxin internalization, the charged residues located at the hairpin between two hydrophobic α-helices, such as Glu 295, Glu 349, and Asp 352, lose their charge, thus making the entire structure hydrophobic. This triggers the interaction of the T domain with the membrane and the consequent translocation of the A domain in the cytoplasmic site.

The genetic organization of DT, with the region encoding for the receptor-binding domain at the 3'-end of the gene, has allowed the development of a number of hybrid toxins in which the receptor-binding domain has been replaced by interleukin 2, or by the melanocyte hormone MSH (Murphy *et al*., 1986; Williams *et al.,* 1987; Bacha *et al*., 1988). These new molecules kill activated T cells and MSH receptor-bearing cells, respectively. They might find therapeutic applications for the treatment of allograft rejection and melanomas.

### *Pseudomonas exotoxin A*

*Pseudomonas* exotoxin A (PAETA) is secreted in the culture medium as a single polypeptide chain of 613 amino acids of which the sequence and the three-dimensional structure at 3 Å of resolution is known (Gray *et al*., 1984; Allured *et al*., 1986). According to X-ray crystallography studies, the molecule can be divided into three domains (Hwang *et al*., 1987; Siegall *et al*., 1989; Pastan and FitzGerald, 1989). Domain I is composed of two non-contiguous regions: Ia comprising amino acids 1–252 and Ib composed of amino acids 365–404.

Domain II is composed of amino acids 253–364, while domain III comprises amino acids 405–613 (see Figures 12.1 and 12.6). Four disulphide bridges are present, two located in domain Ia, one in domain Ib, and one in domain II. Genetic studies, based mainly on the expression of mutated forms of the PAETA gene in *E. coli*, have shown that the deletion of domain Ia results in non-toxic, enzymatically active molecules

that cannot bind the cells. A similar result can be obtained by mutating Lys57 to Glu (Jinno *et al*., 1988). Deletions in domain II result in molecules that bind to the cells and that are enzymatically active but not toxic. A similar result can be obtained by mutagenizing Arg276, Arg279, and Arg230 (Jinno *et al*., 1989) or by converting Cys265 and Cys268 to other amino acids, thus changing the structure of domain II (Siegall *et al*., 1989). Deletions or mutations in domain III result in enzymatically inactive molecules (Siegall *et al*., 1989).

Based on these observations, it can be concluded that the three domains observed in the X-ray structure correspond exactly to three functional domains involved in cell recognition (domain I), membrane translocation (domain II), and ADP-ribosylation of elongation factor 2 (domain III). To become active, the PAETA toxin requires an intracellular, furin-mediated proteolytic cleavage to generate a 37 kDa C-terminal fragment that is then translocated to the cytoplasm to reach the EF2 target (Chiron *et al.*, 1997). By using a fluorescence resonance energy transfer approach, the mechanism of interaction between PAETA and its substrate EF has been studied, showing that the binding is strongly dependent on the pH. Furthermore, the finding that EF-2 bound to GDP or GTP is still recognized by PAETA shows how adaptable this toxin is in ADP-ribosylating its substrate (Armstrong *et al.*, 2002). In particular, mutational analysis affecting the last five residues at the carboxy-terminus of the enzymatic domain resulted in complete loss of cytotoxicity; this segment (Arg-Glu-Asp-Leu-Lys, REDLK) closely resembles the KDEL motif that is a well-defined endoplasmic reticulum retention sequence and that has also been found at the C-terminus of other ADP-ribosyltransferases, such as cholera toxin and heat-labile enterotoxin of *E. coli* (Chaudhary *et al.*, 1990). It has been postulated that the sequence REDLK may be a recognition signal required for entry of the ADP-ribosylation domain of PAETA into the cytosol.

PAETA can be described as a typical bacterial toxin with an A-B structure, having a mechanism of action identical to diphtheria toxin. Similarly to DT, PAETA has also been shown to induce apoptosis in human mast cells by a caspase-3 and -8 mediated mechanism (Jenkins *et al.*, 2004). Although identical in function, DT and PAETA have an opposite structural organization: the enzymatically active domain is at the C-terminus of PAETA and at the N-terminus of DT. While the B domains of DT and PAETA do not have any structural similarity, the enzymes share a common structure of the catalytic site (see Figure 12.11 for details) (Brandhuber *et al*., 1988; Carroll and Collier, 1988). The structure of this site, well-described by X-ray crystallography, has been further corroborated by functional studies, which have identified amino acids playing a key role in enzymatic activity. Glu553 was initially shown to be at the catalytic site, because it was the only amino acid photoaffinity-labeled by NAD+ (Carroll and Collier, 1987). Later it was shown that substitution of Glu553 with any amino acid, including Asp, decreased the enzymatic activity by a factor of 1,000 (Douglas and Collier, 1990), and that deletion of Glu553 completely abolished the toxicity of PAETA. Similarly, iodination of Tyr481, which is also at the catalytic site, was shown to abolish enzymatic activity (Brandhuber *et al*., 1988). Other amino acids that, although not located at the catalytic site, have been shown to be essential for enzymatic activity are His 426 and residues 405–408 (Galloway *et al*., 1989). His 426 has been proposed to be necessary for the interaction between PAETA and EF2.

The well-defined structural divisions in separated domains make PAETA an ideal candidate for the development of chimeric toxins by replacing the gene parts encoding for domain I with others encoding for cell-binding domains with different specificities. So far, nucleotides encoding domain I have been replaced by sequences encoding interleukin 2, interleukin 6, interleukin 4, and T cell antigen CD4. In all instances, expression of these genes in *E. coli* has given new toxins, which specifically kill the cells bearing the receptor recognized by the new domain I. Such molecules are promising candidates for the treatment of arthritis and

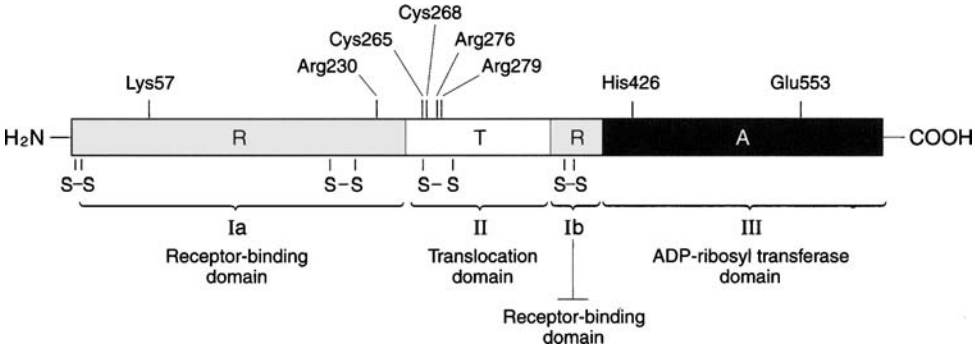

**FIGURE 12.6** Domain organization of *Pseudomonas aeruginosa* exotoxin A (PAETA). The enzymic domain (A) is shown in black, while the receptor-binding (R, Ia and Ib) and the translocation (T) domains are colored grey and white, respectively. The more relevant mutants affecting either cell binding or enzymic activity are reported in the upper portion of the figure. Disulfide bridges are also shown.

allograft rejection (PAETA-IL2), AIDS (PAETA-CD4), and other diseases (Chaudhary *et al*., 1987; Chaudhary *et al*., 1988; Siegall *et al*., 1988; Lorberboum-Galski *et al*., 1988; Ogata *et al*., 1989; Baldwin *et al*., 1996; Mori *et al*., 1997; Zimmermann *et al*., 1997; Essand *et al*., 1998).

## Toxins acting on signal transduction

### *Acting on large G proteins*

*Pertussis toxin*

Pertussis toxin (PT) is a protein of 105,000 Da released into the extracellular medium by *Bordetella pertussis*, the etiological agent of whooping cough. PT is a complex bacterial toxin composed of five different subunits that have been named S1 (21 220 Da), S2 (21 920 Da), S3 (21 860 Da), S4 (12 060 Da), and S5 (11 770), according to their electrophoretic mobility (Tamura *et al*., 1982; Sekura *et al*., 1985). Exposure of PT to 2 M urea disassembles the PT into the monomer A (subunit S1) and the oligomer B (which comprises the subunits S2, S3, S4, and S5). Upon exposure to 5 M urea, the B oligomer can be dissociated into two dimers: dimer 1 (comprising S2 and S4) and dimer 2 (comprising S3 and S4), and the monomer S5 (see Figure 12.1). With 8 M urea, PT dissociates into five monomeric subunits (Tamura *et al*., 1982).

As in the case of the other ADP-ribosylating toxins, the B oligomer of PT binds unidentified glycoconjugate receptors on the surface of eukaryotic cells and allows the toxic subunit S1 to reach its intracellular target proteins. In Chinese hamster ovary (CHO) cells, the PT receptor has been shown to be a 165-kDa glycoprotein, which binds the PT B oligomer through a branched mannose structure containing sialic acid. Dimers S2–S4 and S3–S4 are also able to bind the same receptor (Witvliet *et al*., 1989; Stein *et al*., 1994a).

S1 ADP-ribosylates the Cys353 of the α subunit of protein $G_i$, and the corresponding cysteine in $G_o$, and transducin (see Figure 12.3) (Katada *et al*., 1983; West *et al*., 1985). Gsα, which contains a Tyr in place of the Cys residue, is not ADP-ribosylated by PT. ADP-ribosylation of the above G proteins causes alteration in the response of eukaryotic cells to exogenous stimuli and results in a variety of phenotypes. *In vivo*, the most relevant consequences of PT intoxication are leukocytosis, histamine sensitization, increased insulin production with consequent hypoglycemia, and potentiation of anaphylaxis (Sekura *et al*., 1985). Although its direct role in the severe coughing disease has long been uncertain, data from a recent study indicate that PT plays an early role in the colonization by *B. pertussis* and that its enzymatic activity is required for full colonization (Carbonetti *et al.*, 2003). *In vitro*, PT has a number of different activities, the most relevant of which is the change in cell morphology in CHO cells, a phenotype which is able to detect as little as 10 pg of active PT (Hewlett *et al*., 1983). Further *in vitro* activities are hemagglutination, T-cell mitogenicity, inhibition of migration of peritoneal macrophages, enhancement of receptor-mediated accumulation of cAMP, and many others (Sekura *et al*., 1985). In contrast to the other bacterial toxins where all the activities are mediated by the enzymatically active subunit, in the case of PT several biological activities are due to the B oligomer (Tamura *et al*., 1983). In fact, the B subunit of pertussis toxin is a polyclonal mitogen for T cells. *In vitro* the effect requires at least 0.3 μg of pertussis toxin or of its B subunit. The effect has not been observed *in vivo*, possibly because the dose required for activity is never achieved. It also has hemagglutination activity. *In vitro*, the effect requires 0.3 μg/ml of wild-type PT, or of its B subunit. In addition, the B oligomer is able to induce signal transduction through inositole phosphate pathway. The numerous *in vitro* and *in vivo* activities of PT are listed in Table 12.1. As shown in the table, the toxic activities are all abolished when the active site is inactivated by site-directed mutagenesis, such as mutant PT-9K/129G. On the other hand, the non-toxic biological activities that are mediated by the receptor-binding site present in the B oligomer are all maintained, even in the absence of ADP-ribosyltransferase activity.

The genes encoding for the five subunits of pertussis toxin are clustered in a fragment of DNA of 3,200 base pairs, organized in an operon structure and in the following order: S1, S2, S5, S4, and S3 (Nicosia *et al*., 1986; Locht and Keith, 1986). Each of the five subunits are co-translationally exported into the periplasmic space where the holotoxin is assembled. The release of the toxin into the extracellular medium requires the products of the *ptl* locus, an operon containing 11 genes, which is homologous to the *tra* operon of *E. coli* and the VirB operon of *Agrobacterium tumefaciens*. The *ptl* operon is located downstream from the PT operon, is transcribed by the PT promoter, and codes for a type IV secretion system (Weiss *et al*., 1993; Covacci and Rappuoli, 1993; Ricci *et al*., 1996; Farizo *et al*., 2000). The *Ptl* secretion machinery mediates the translocation of the PT holotoxin across the outer membrane. However, recent data provide evidence that the S1 subunit localizes to the outer membrane prior to assembly with the B oligomer and independently from the *Ptl* system. Therefore, the membrane-bound S1 may serve as a nucleation site for assembly with the B oligomer and for subsequent interaction with *Ptl* proteins (Farizo *et al*, 2002).

The amino acid sequence of subunit S1 shows a significant homology with the A1 promoter of cholera and *E. coli* LT toxins (see Figure 12.10) (Nicosia *et al*.,

**TABLE 12.1** Toxic and non-toxic properties of PT and PT–9K/129G mutant

[a]No effect was observed at the highest dose reported used in the assay.

1986; Locht and Keith, 1986). The crystal structure of the toxin (Figure 12.11) has revealed a structural similarity to the catalytic subunits of the other ADP-ribosylating toxins and a structure of the B subunit that resembles that of cholera toxin organized around a central cavity composed by the α-helices of each subunit (Stein *et al*., 1994b).

### *Mutants of pertussis toxin*

The role of many amino acids of the S1 subunit has been tested by site-directed mutagenesis initially performed to produce non-toxic mutants of PT to be used as vaccines. The minimal region still enzymatically active contains amino acids 4–179 (Pizza *et al*., 1988; Cieplak *et al*., 1988; Barbieri and Cortina, 1988). Within this region, many amino acids have been changed by site-directed mutagenesis (Figure 12.7; Barbieri and Cortina, 1988; Pizza *et al*., 1988; Burnette *et al*., 1988; Black *et al*., 1988; Kaslow *et al*., 1989; Locht *et al*., 1989; Lobet *et al*., 1989). Arg9, Asp11, Arg13, Trp26, His35, Phe50, Glu129, and Tyr 130 were found to be essential for enzymatic activity. In fact, their replacement with other amino acids reduced the activity of recombinant S1 molecules to levels equal or below 1%. Most of these amino acids could be replaced without altering the overall structure of the recombinant S1 molecule, which was still recognized by toxin-neutralizing monoclonal antibodies specific for a conformational epitope. In addition to the amino acids described previously, Cys41 was shown to be close to the active site since its alkylation decreased enzymatic activity (Kaslow *et al*., 1989). By photoaffinity labeling with NAD+, Glu129 was shown to be equivalent to Glu148 of DT and Glu553 of PAETA (Barbieri *et al*., 1989). When the above amino acid changes were introduced either alone or in combination into the PT operon in the *B. pertussis* chromosome, a number of mutant PT molecules were obtained; most of them had a polyacrylamide gel electrophoretic pattern indistinguishable from the wild-type PT and a reduced toxicity. Some mutants were

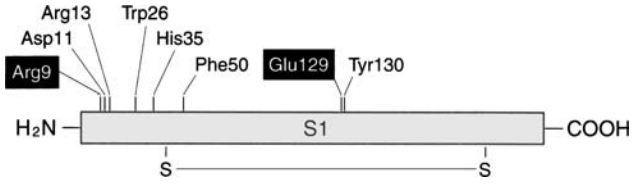

**FIGURE 12.7** Toxic subunit $S_1$ of the pertussis toxin (PT) and illustration of some of the residues that have been mutagenized. In particular, double substitution of Arg9 and Glu129 (black boxed) produces the most well-known mutant that has been used for the construction of an acellular vaccine against pertussis.

unable to assemble the S1 subunit and released into the extracellular medium only the B oligomer. These mutants contain mutations in any of the two cysteines, in regions homologous to cholera toxin (8D/9G, 50E, 88E/89S), or contain three amino acid changes as in mutant 13L/26I/129G. The above mutations are believed to alter the structure of the S1 subunit and prevent its assembly into the holotoxin (Pizza *et al*., 1990). In general, the molecules containing single amino acid mutations had a toxicity reduced from 4- to 1000-fold, but none of them was completely non-toxic. The mutant that has become most famous contains two amino acid substitutions: Arg 9 → Lys and Glu 129 → Gly (PT-9K/129G). This mutant has a structure indistinguishable from wild-type, but is completely free of any toxicity (see Table 12.1). It has been used for the construction of a vaccine against pertussis that has been extensively tested in clinical trials and shown to induce protection from disease. The vaccine containing this mutant is presently licensed in several countries (Pizza *et al*., 1989; Rappuoli 1997).

Mutants in the B oligomer have also been constructed. The most relevant is the one containing deletion of Asn105 in S2 and Lys105 in S3, which resulted in drastic reduciton of binding (Lobet *et al*., 1993).

*Cholera toxin and* Escherichia coli *enterotoxin*

Cholera toxin (CT) and *E. coli* heat-labile enterotoxin (LT) are AB toxins sharing high homology (95% identity) in their primary structure (Dallas and Falkow, 1980; Spicer *et al*., 1981) and super-imposable tertiary structures (Sixma, 1991). Both toxins are composed of a pentameric B oligomer that binds the receptor(s) on the surface of eukaryotic cells and an enzymatically active A subunit that is responsible for the toxicity (Holmgren, 1981; Moss and Vaughan, 1988) (see Figure 12.1). Both the A and B subunits of CT and LT are synthesized intracellularly as precursor proteins that, after removal of the leader peptide and translocation across the cytoplasmic membrane, assemble in the periplasmic space to form the final $AB_5$ complex. While *V. cholerae* exports the CT toxin into the culture medium, LT remains associated to the outer membrane bound to LPS (Horstman and Kuehn, 2002). The A subunit is composed of a globular structure linked to the B oligomer by a trypsin-sensitive loop and a long α-helix whose carboxyterminus enters into the central cavity of the B oligomer, thus anchoring the A subunit to the B pentamer (Sixma, 1991). Following protease cleavage of the loop, the A subunit is divided into the globular (enzymatically active) $A_1$ and the carboxy-terminal $A_2$ fragments that remain linked by a disulfide bridge between the $A_1$-cys187 and the $A_2$-cys199. Proteolytic cleavage of the loop and reduction of the disulfide bridge are both necessary in order to generate the enzymatic activity (Gill and Rappaport, 1979). The loop is intact when the molecules are produced in *E. coli*, while it is already cleaved when molecules are produced in *Vibrio cholerae*, which produces a specific protease to cleave this loop. The $A_1$ subunit contains the ADP-ribosylating activity and transfers the ADP-ribose group to the stimulatory α subunit of Gs. Once this G protein is ADP-ribosylated, the adenylate cyclase is permanently activated, causing abnormal intracellular accumulation of cAMP (Field *at al*., 1989a; Field *et al*., 1989b). While cAMP accumulation is believed to be responsible for the toxicity of CT and LT, we cannot exclude a contribution of interactions with less well-characterized G proteins to the toxicity.

The active site of the A subunit has a structure similar to all enzymes with mono-ADP-ribosylating activity (see Figure 12.11; Domenighini *et al*., 1994; Domenighini and Rappuoli, 1996). The catalytic site is formed by a cavity with a β-strand (the floor of the cavity) followed by an α-helix (the ceiling of the cavity) that contains two amino acids that are essential for catalysis: these are Arg7 (Burnette *et al*., 1991; Lobet *et al*., 1991) and Glu110–Glu112 (Tsuji *et al*., 1990; Tsuji *et al*., 1991). A peculiar feature of CT and LT is that the basal ADP-ribosyltransferase activity is enhanced by interaction with 20-kDa guanine-nucleotide binding proteins, known as ADP-ribosylation factors or ARFs (Tsai *et al*., 1988).

ARF proteins are known not only to function as activators of CT and LT, but also to play a crucial role in vesicular membrane trafficking in both endocytic and exocytic pathways, maintenance of organelle integrity, and assembly of coat proteins in eukaryotic cells. The most abundant and the best known ARFs family members are class I ARF, which are involved in the endoplasmic reticulum (ER)-Golgi and intra-Golgi transport. Like all GTP-binding proteins, ARF can bind GDP or GTP. The GDP-bound form is present in the cytosol. Initiation of vesicles' formation occurs when a Golgi membrane enzyme interacts with the ARF-GDP complex and catalyzes the release of GDP and the binding of GTP. The ARF-GTP form mediates the assembly of cytosolic coat proteins (coatomers) to Golgi membranes, inducing budding of the transported vescicles, (Donaldson and Klausner, 1994; Moss and Vaughan, 1995; Boman and Kahn, 1995). Therefore, we can see the A1 fragment as having at least two independent functions: enzymatic activity and ARF binding. The enzymatic activity takes place within the eukaryotic cells and can be measured *in vitro*; whether ARF activates CT and LT in the eukaryotic cells remains unknown. While the region of LT and CT carrying the catalytic site is well-characterized, so far we have no

idea of where the ARF binding site is localized on the A1 subunit. However, it is known that both trypsinization and reduction of the A subunit are needed for expression of a functional ARF binding site (Moss *et al.*, 1993), and in a study on non-toxic derivatives of LT it has been shown that the two sites (catalytic and ARF binding) are independent and located on different regions of the A1 domain (Stevens *et al.*, 1999). The B oligomer is a pentameric molecule of 55 kDa, containing five identical polypeptide monomers. The structure is compact, resistant to trypsin, and requires boiling in the presence of sodium dodecyl sulfate to be dissociated. The five subunits are arranged in a cylinder-like structure with a central cavity that on one side exposes five symmetrical cavities that are responsible for binding to the eukaryotic cell receptor (Sixma *et al.*, 1991; Sixma *et al.*, 1993). The receptor binding site is specific for a variety of galactose-containing molecules and shows a different fine specificity between LT and CT. CT binds mostly to the ganglioside GM1 that is believed to be the major toxin receptor (Holmgren, 1973), while LT binds not only to GM1 but also to other glycosphingolipids (Teneberg *et al.*, 1994), to glycoprotein receptors present in the intestine of rabbits and humans (Holmgren *et al.*, 1982; Holmgren *et al.*, 1985; Griffiths *et al.*, 1986), to polyglycosilceramides (PCGs) (Karlsson *et al.*, 1996), and to paragloboside (Teneberg *et al.*, 1994). Furthermore, the two variants of LT, human LT (hLT) and porcine LT (pLT) that differ only by four amino acids (Domenighini *et al.*, 1995b), are identical in their binding to glycoproteins and PCGs, but different in binding to paragloboside. Only pLT and not hLT is able to bind paragloboside, and the reason seems to be due to the differences in the residue in position 13, which is an Arg in pLT and an His in hLT (Karlsson *et al.*, 1996). The different receptor-binding activities of the molecules may be significant for the qualitatively different immunological properties exhibited by LT and CT. The B oligomer can be produced in great quantities from *E. coli* transformed with the B subunit gene under the control of a strong promoter (Lebens *et al.*, 1993). The monomeric subunits are individually secreted into the periplasmic space where they are assembled into the pentameric structure (Hofstra and Witholt 1985). CTB and LTB are systemic and mucosal immunogens, and this property is dependent by the binding to the GM1 receptor. In addition, they are strong inhibitors of T cell activation and are able to induce apoptosis of $CD8^+$ T cells and, to a lesser extent, of $CD4^+$ T cells (Truitt *et al.*, 1998). On the basis of results of different studies, we have summarized in Figure 12.4 the sequence of events that take place during cell intoxication (Bastiaens *et al.*, 1996; Majoul *et al.*, 1996).

The holotoxin binds the receptor located on the eukaryotic cell membrane (Figure 12.4, stage 2). It is internalized into vesicles that, instead of taking the usual endocytic pathway leading to lysosomes, are transported retrogradally to the Golgi compartment (Figure 12.4, stages 2b and 2c). At this stage, the toxin is still in the $AB_5$ form. In the ER, the A1-chain of the CT unfolds and enters the cytosol by a process termed retro-translocation. Upon entering the cytosol, the A1-chain rapidly refolds, binds ARF (Figure 12.4, stage 2d) and induces toxicity by ADP-ribosylating the α subunit of $G_s$ located on the plasma membrane (Lencer and Tsai, 2003). The B subunits persist in the Golgi and are subsequently degraded.

***Mutants of cholera and Escherichia coli enterotoxin***

In order to study the structure-function of CT and LT and to find molecules that are non-toxic but still active as mucosal adjuvants and immunogens, more than 50 different site-directed mutants have been produced (Okamoto *et al.*, 1988; Tsuji *et al.*, 1990; Tsuji *et al.*, 1991; Burnette *et al.*, 1991; Lobet *et al.*, 1991;Lycke *et al.*, 1992; Pizza *et al.*, 1994a; Pizza *et al.*, 1994b; Fontana *et al.*, 1995; Douce *et al.*, 1995; de Haan *et al.*, 1996; Yamamoto *et al.*, 1997; Guidry *et al.*, 1998; Jobling and Holmes, 2001; O'Neal *et al.*, 2004). The most important ones are reported in Figure 12.4. Among these, the ones that have been best studied are LTK63, LTK97, and LTK7, for which the three-dimensional structure has been determined (Merritt *et al.*, 1995; van den Akker *et al.*, 1995; van den Akker *et al.*, 1997). One of the most interesting mutants is LTK97, where the Val → Lys mutation does not change at all the three-dimensional structure of the molecule but introduces a salt bridge between the charged amino group of Lysine 97 and the carboxylate of the glutamic acid 112, thus making it unavailable for further interactions. The observation that a simple hydrogen bond inactivates the enzymatic activity suggests an important role of the negative charge of the Glutamic acid in the enzymatic activity. Other interesting mutants are LTK63 and CTK63 (containing a serine-to-lysine substitution in position 63 of the A subunit). These holotoxoids have no detectable enzymatic activity and no toxicity *in vitro* or *in vivo*, even when huge amounts of them are used (Giannelli *et al.*, 1997; Giuliani *et al.*, 1998). Therefore, we can consider them as complete knock-outs of enzymatic activity but otherwise indistinguishable from wild-type. In fact, many other biological properties measured to date are maintained intact, including receptor and ARF-binding (Stevens *et al.*, 1998). The X-ray structure of LTK63 has shown complete identity to the wild-type LT across the entire molecule, with the exception of the active site, where the bulky side chain of Lys63 fills the catalytic

cavity, thus making it unsuitable for the enzymatic activity (see Figure 12.8, panel C) (van den Akker *et al.*, 1997). LTK63 is an excellent mucosal adjuvant although the activity is reproducibly reduced in comparison to LT (Partidos *et al.*, 1996; Di Tommaso *et al.*, 1996; Douce *et al.*, 1997; Ghiara *et al.*, 1997; Marchetti *et al.*, 1998; Giuliani *et al.*, 1998) while CTK63 is a less active mucosal adjuvant (Douce *et al.*, 1997; Pizza *et al.*, 2001).

A second class of mutant molecules contains LTR72 (containing an alanine-to-arginine substitution in position 72 of the A subunit) and CTS106 (containing a proline-to-serine substitution in position 106 of the A subunit). These mutants have approximately 1% of the wild-type ADP-ribosylating activity, have a toxicity *in vitro* in Y1 cells reduced by a factor of $10^4$–$10^5$ and a toxicity *in vivo* in the rabbit ileal loop reduced by

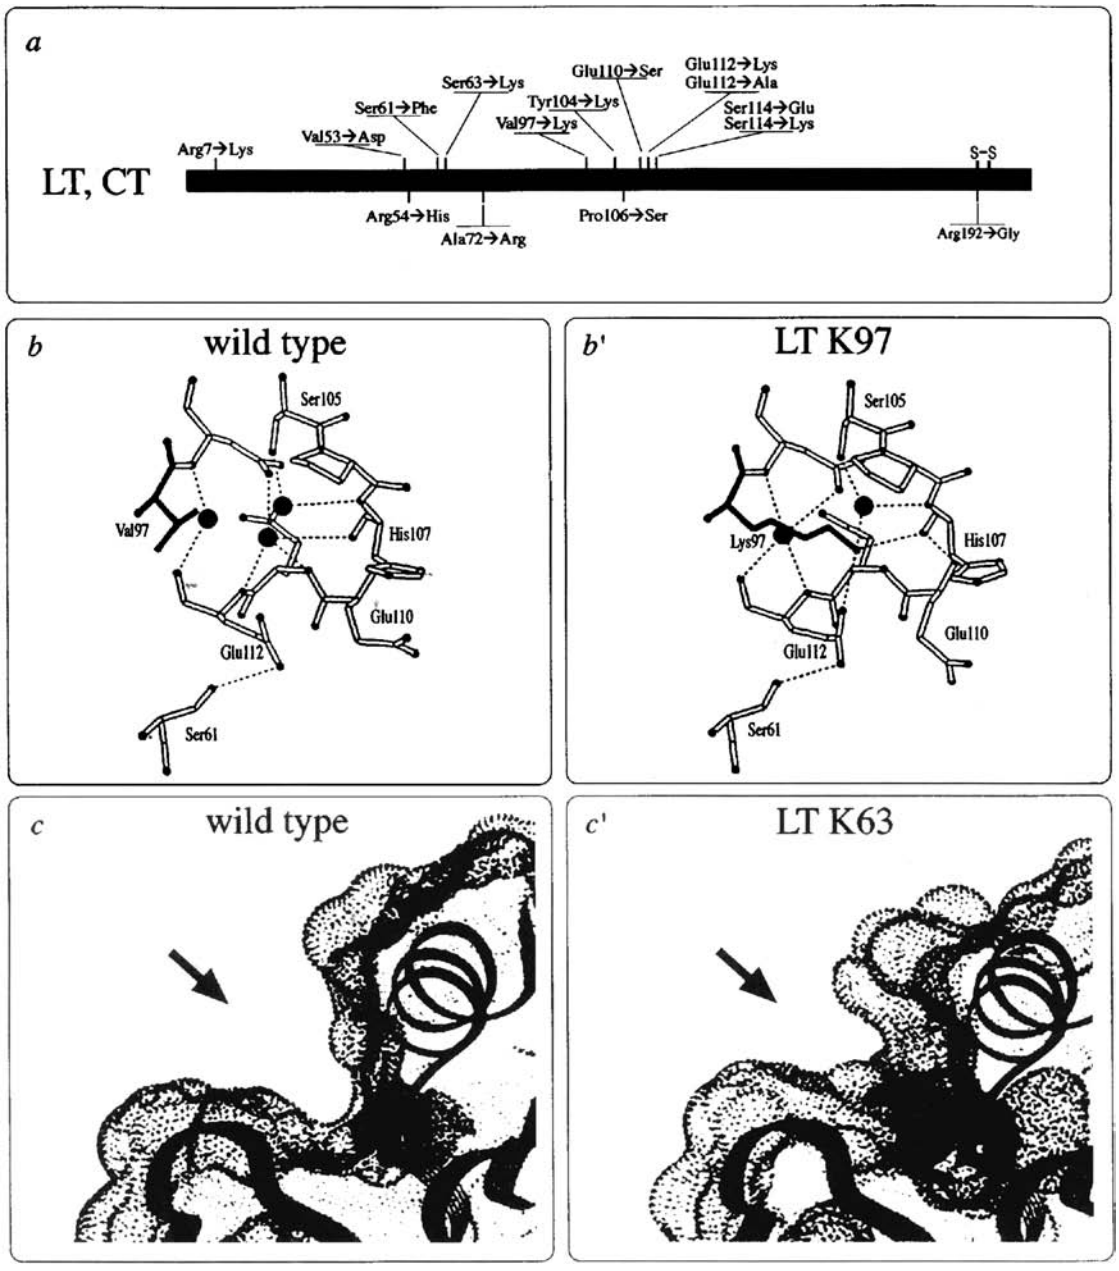

**FIGURE 12.8** (a) Schematic representation of LT–CT toxins, where the most relevant site-directed mutations are reported. Two of them are illustrated in more detail in (b) and (c). (b) Structure of the wild-type LT and of the mutant LT K97 (b′). Glu112 is involved in one hydrogen bond in the native structure and in two in the mutant. (c) Three-dimensional structure of the enzymic cavity of the wild-type LT and (c′) of the mutant LT K63. The arrows show how this single mutation can affect the dimensions of the pocket and thus the entrance of the NAD molecule.

25–100 fold (Figure 12.9). Both LTR72 and CTS106 are excellent mucosal adjuvants, being as effective as LT and CT, respectively (Douce *et al.*, 1997; Giuliani *et al.*, 1998; Pizza *et al.*, 2001).

Mutants in the protease sensitive loop have been also constructed with the aim of making the loop insensitive to proteases, and therefore the toxin not susceptible to the activation process that is necessary for enzymatic activity and toxicity. Among the many mutants constructed, LTG192 is the best characterized. In this LT mutant, the arginine in position 192 is replaced by a glycine (Grant *et al.*, 1994; Dickinson and Clements 1995; Giannelli *et al.*, 1997). *In vitro* the mutant is completely resistant to trypsin treatment. *In vivo*, proteases different than trypsin may partially cleave the loop and activate the toxin because toxicity is detectable. The toxicity observed in Y1 cells is approximately $10^3$ times lower than that of wild-type toxin during the first 8 hours of incubation and becomes only 5–10 times lower than wild-type following longer incubation (Giannelli *et al.*, 1997). In practice, this molecule takes longer to be activated but delivers approximately the same total enzymatic activity as wild-type. The difference is that the delivery of the active toxin is diluted over a longer period of time. *In vivo*, in the rabbit ileal loop, almost no difference in toxicity is observed between LTG192 and wild-type LT (Figure 12.9) (Giannelli *et al.*, 1997). Ongoing human trials are expected to establish the safety profile of these molecules (Vaccine Weekly, 1995).

Mutant derivatives of LTB have also been constructed. Those that are defective in receptor binding (for example LTB/D33, containing a glycine-to-aspartic acid substitution in position 33) were found to be almost completely non-immunogenic at mucosal surfaces, suggesting that an intact receptor-binding site is necessary both for binding and the immunogenicity associated with the molecule (Nashar *et al.*, 1996). Other studies with a non-receptor–binding mutant of LT (LTD33) have confirmed that receptor binding is necessary also for adjuvanticity (Guidry *et al.*, 1997). Interestingly, non-binding LTB mutants have also been shown to lose other immune-modulating activities, including their ability to induce apoptosis of CD4+ and CD8+ cells (Nashar *et al.*, 1996; Truitt *et al.*, 1998).

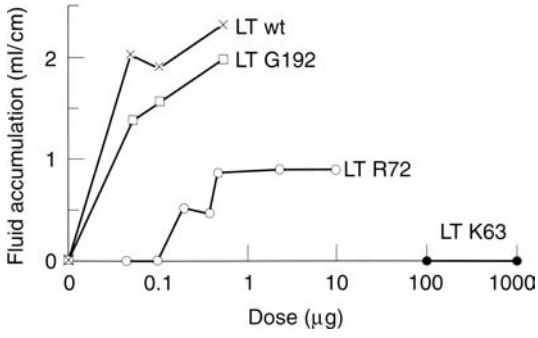

**FIGURE 12.9** Toxicity in the rabbit ileal loop of wild-type LT and of the most important mutants.

## Binary toxins and toxins that are directly delivered to the cytoplasm of eukaryotic cells

### Clostridium botulinum *C2 and iota-like toxins*

*C. botulinum* C2 toxin is a member of a family of "binary" cytotoxins that ADP-ribosylate monomeric G-actin at an Arginine in position 177 (Vandekerckhove *et al.*, 1988). Being the Arginine at contact site between actin monomers, the binding of the ADP-ribose makes actin unable to polymerize (Aktories *et al.*, 1986). *C. botulinum* toxin C2 is an extremely toxic agent, which induces hypotension, increase in intestinal secretion, vascular permeability, and hemorrhaging in the lungs. C2 is composed of two separate molecules, the 50 kDa enzymatically active toxin (C2I) and a receptor-binding component (C2II) of 75 kDa, (Aktories and Wagner 1992). The organization of C2 resembles closely that of the EF, LF, and PA of *Bacillus anthracis*. Like PA, C2II is activated by proteolytic cleavage and forms ring-shaped heptameric pores on the membrane of host cells by a pH-mediated process. Following C2II oligomerization and binding to the host cell receptor, the toxic moiety binds to the heptameric pore and is translocated across the membrane (Blocker *et al*, 2003). Toxins related to C2 are *C. perfringens* iota toxin (Perelle *et al*., 1995), the mosquitocidal toxin (MTX) produced by *Bacillus sphaericus* (Schirmer *et al*., 2002), the *C. spiriforme* toxin (Stiles and Wilkins, 1986), the ADP-ribosyltransferase (CDT) produced by *C. difficile* (Popoff *et al*., 1988; Gulke *et al*., 2001), and the vegetative insecticidal protein VIP2 of *Bacillus cereus* (Han *et al*., 1999). The level of primary sequence homology detected among the enzymatic and binding components of this class of ADP-ribosylating toxin ranges from 32 to 80% identity, the binding domains being the better conserved.

The iota toxin is a binary toxin produced by *Clostridium perfringens* type E, which has been implicated in fatal calf, lamb, and guinea pig enterotoxemias. Structurally, it has two independent domains: Ia, which is the ADP-ribosyltransferase, and Ib, which is involved in the binding and internalization of the toxin by the cell (Marvaud *et al*., 2001). The crystallization of the C2-I component in complex with its substrate NADH has recently been achieved (Tsuge *et al*., 2003), showing a close relationship of iota toxin with insecticidal protein VIP2 of *Bacillus cereus*, whose structure is also available (Han *et al*., 1999).

*Pseudomonas aeruginosa ExoenzymeS and related proteins*

Some toxins do not have a receptor-binding component and a translocation domain and are directly injected by bacteria into the cytoplasm of eukaryotic cells. In this case, bacteria intoxicate individual eukaryotic cells by using a contact-dependent secretion system to inject or deliver toxic proteins into the cytoplasm of eukaryotic cells. ExoS of *P. aeruginosa* and its homologue ExoT have been shown to reach the cytoplasm of eukaryotic cells by delivery through a specialized type III secretion system (Frithz-Lindsten *et al.*, 1997; Sundin *et al.*, 2004). For convenience, we also include here the C3 toxin of *Clostridium botulinum* for which a receptor-binding and translocation domain is not known.

The exoenzyme S is a 49 kDa bifunctional type-III cytotoxin of *Pseudomonas aeruginosa*. The N-terminal 233 residues comprise the Rho GTPase-activating protein (Rho GAP) domain, while residues 234–453 comprise the ADP-ribosyltransferase domain. The GTPase activating domain (GAP) of ExoS has been crystallized (Wurtele *et al.*, 2001). ExoS ADP-ribosylates the small G protein Ras at position 41 (Ganesan *et al.*, 1998). In order to become enzymatically active, ExoS requires the interaction with a cytoplasmic factor named FAS or 14.3.3 (Coburn *et al.*, 1991). The toxin is injected into eukaryotic cells by a type III secretion system (Frithz-Lindsten *et al.*, 1997). When cells are transfected with the *exoS* gene under the control of an eukaryotic cell promoter, collapse of the cytoskeleton and a change of the cell morphology that results in the rounding up of the cells are observed. Recent data suggest that *in vivo*, ExoS may contribute to the establishment of *P. aeruginosa* infections by inhibiting wound healing and tissue regeneration by ADP-ribosylating Ras and therefore inhibiting the cellular motility and angiogenesis required for wound healing. Through the inhibition of tissue regeneration and wound healing, ExoS may play a pivotal role in chronic disease by maintaining sites of colonization (Barbieri, 2000).

ExoT is 75% homologous to ExoS; however, when compared with ExoS, it exhibits highly reduced ADP-ribosylating activity, but still exhibits GAP (GTPase activating protein) activity on RhoA GTPase *in vitro* (Sundin *et al.*, 2001). More recent data have suggested that ExoT ADP-ribosylates Crk-I and Crk-II (CT10-regulator of kinase) that play an essential role in integrin-mediated phagocytosis and focal adhesion (Sun and Barbieri, 2003). ADP-ribosyltransferase activity of ExoT mediates changes in cell morphology, which correlate to disruption of the actin microfilaments of the infected cells (Sundin *et al.*, 2004).

Finally, another protein belonging to the group of ExoS-related toxins is exoenzyme T (AexT) of *Aeromonas salmonicida*, a fish pathogen implicated in furunculosis. The amino acid sequence of AexT closely resembles those of ExoS and ExoT, and antibodies directed against AexT cross-react with ExoS and ExoT. Expression of AexT occurs specifically during infection of the host and causes cell damage, suggesting that this novel ADP-ribosyltransferase is a key virulence determinant of *A. salmonicida* (Braun *et al.*, 2002). Similarly to *P. aeruginosa*, *A. salmonicida* also encodes a type III secretion system, which is utilized for AexT export across the membrane and into the cytosol of eukaryotic cells (Burr *et al.*, 2003).

Clostridium botulinum *exoenzyme C3 and related proteins*

Exoenzyme C3 is a protein of 211 amino acids that is produced by *C. botulinum* (Aktories *et al.*, 1989; Chardin *et al.*, 1989) and that *in vitro* ADP-ribosylates the small regulatory protein Rho at Asparagine 41 (Sekine *et al.*, 1989), thus inactivating its function. If the protein is microinjected into cells or the cells are transfected with the C3 gene under an eukaryotic promoter, this causes disruption of actin stress fibers, rounding of the cells, and formation of arborescent protrusions (Hill *et al.*, 1995). However, for the moment, we do not know whether C3 alone is able to enter cells and intoxicate them because no mechanism of cell entry has been found.

Other members of this family of C3-related exoenzymes have been isolated from Gram-positive bacteria, such as certain strains of *Staphylococcus aureus* (Sugai *et al.*, 1992), *Clostridium limosum* (Just *et al.*, 1992), and *Bacillus cereus* (Just *et al.*, 1995). Whereas *C. botulinum* C3 and *C. limosum* exoenzyme are about 70% homologous and immunologically related, the epidermal cell differentiation inhibitor (EDIN) produced by *S. aureus* is only 35% homologous with C3 and shows no immunological cross-reactivity. However, crystal data recently obtained for *S. aureus* C3 exotoxin (EDIN-B) have disclosed a very similar structure (Evans *et al.*, 2003). *Bacillus cereus* exoenzyme exhibits the same substrate specificity as the other C3-like transferases; nevertheless, some differences can be observed for this toxin, such as the higher molecular weight (28 kDa) and, more importantly, the lack of immunological relationship to any other member of this family (Just *et al.*, 1995).

## Novel bacterial ADP-ribosylating toxins detected by genome-mining

With the advent of the Genomic Era, identification of bacterial factors possibly involved in virulence can be easily approached using computer-based techniques. In fact, given the vast amount of information that we now possess on toxins—including sequence data—and thanks to the growing number of sequenced bacterial

genomes, it is possible to proceed by homology criteria in order to predict novel members of important classes of bacterial toxins. Several examples exist where computer-based methodologies have been instrumental to the identification of novel potential bacterial toxins in sequenced genomes.

In the specific case of mono-ADP-ribosyltransferases (mADPRTs), these proteins display limited overall conservation at the primary structure level; however, the catalytic subunits show remarkable similarity within the enzymatic cavity where they are significantly well-conserved.

Given their importance in the virulence of related microorganisms, a series of studies have been directed towards the computer-based identification of novel ADP-ribosylating toxins by sequence-homology criteria in finished and unfinished genomes.

One of these works used sequence information and a database search to predict the ADP-ribosyltransferase activity of SpvB, a previously known virulence factor produced by *Salmonella* strains (Otto *et al*., 2001). Sequence analysis revealed that SpvB is composed of two domains, of which the C-terminus contains features characteristic of ADP-ribosylating factors like VIP2 and iota toxin. SpvB uses actin as a substrate and depolimerizes actin filaments when expressed in CHO cells. Its cytotoxicity is required for intracellular proliferation of *Salmonella* and represents the first ADP-ribosylating enzyme acting as a virulence factor for an intracellular pathogen.

In a subsequent paper, Pallen and colleagues (Pallen *et al*., 2001) reported the use of specialized homology search methods for the identification of novel putative ADP-ribosyltransferases encoded by diverse Gram-positive and Gram-negative bacterial species. All these predicted ADPRT belong to the group of CT-like enzymes and lack a predicted translocation domain (Table 12.2). Despite the absence of experimental data for most of them, sequence data indicate a possible role of these proteins in the pathogenesis of the corresponding microorganisms.

So far, only one of these predicted toxins, produced by *Streptococcus pyogenes* (SpyA), has been investigated to prove its ADP-ribosyltransferase activity and to assess its capability of entering eukaryotic cells.

SpyA is a protein of 250 amino acids, which shares good sequence homology to *C. botulinum* C3 exotoxin and to *S. aureus* EDIN. The recombinant protein has NAD-glycohydrolase and ADP-ribosyltransferase activities *in vitro* and modifies Arginine residues. *In vivo*, SpyA modifies numerous cytoskeletal proteins, such as vimentin, tropomyosin, and actin, therefore suggesting its direct involvement in cytoskeleton disruption and host colonization (Coye and Collins, 2004).

Very recently, a new protein has been added to the list of ADP-ribosyltransferases detected by computer analysis (Masignani *et al*., 2003). This novel factor has been identified by means of primary and secondary structure analysis in the genomic sequence of a virulent isolate of *Neisseria meningitidis* and has been named NarE (Neisseria ADP-ribosylating enzyme). As predicted by "in silico" studies, biochemical analysis has demonstrated that NarE is capable of transferring an ADP-ribose moiety to a synthetic substrate.

**TABLE 12.2** New ADP-ribosyltransferases detected by genome analysis

| Species | ADPRT | Length (aa) | Leader peptide | Features | Reference |
|---|---|---|---|---|---|
| *Bacillus halodurans* | BH3531 | 490 | no | Similar to phage structures | Pallen *et al.*, 2001 |
| *Burkholderia cepacia* | ART1-ART5 | 886–1283 | no | Detected on unfinished genome | Pallen *et al.*, 2001 |
| *Clostridium acetobutylicum* | ART_CLOAB | 388 | no | ART domain at the C-terminus | Pallen *et al.*, 2001 |
| *Enterococcus faecalis* | ART1_ENTFA | 487 | no | Similar to phage protein | Pallen *et al.*, 2001 |
| | ART2_ENTFA | 423 | no | Similar to phage protein | Pallen *et al.*, 2001 |
| *Mycobacterium avium* | ART_MYCAV | 180 | no | ART domain only | Pallen *et al.*, 2001 |
| *Mycoplasma pneumoniae* | YD72_MYCPN | 591 | yes | Similar to PT S1 | Pallen *et al.*, 2001 |
| *Pseudomonas syringae* | ART1-ART5 | 182–300 | no | ART domain mostly | Pallen *et al.*, 2001 |
| *Salmonella typhi* | TOXA_TYPHi | 242 | yes | Similar to PT S1 | Pallen *et al.*, 2001 |
| *Streptomyces coelicolor* | SCO5461 | 219 | yes | Secreted protein | Pallen *et al.*, 2001 |
| *Vibrio parahemolyticus* | TH3996 | 275 | no | none | Pallen *et al.*, 2001 |
| *Salmonella spp* | SpvB | 591 | yes | ADP-ribosylating activity shown | Otto *et al.*, 2001 |
| *Streptococcus pyogenes* | SpyA | 250 | yes | Similar to EDIN, ADP-ribosylating activity shown | Coye and Collins, 2004 |
| *Neisseria meningitidis B* | NarE | 145 | no | Secreted in the periplasm, ADP-ribosylating activity shown | Masignani *et al.*, 2003 |

## EUKARYOTIC MONO-ADP-RIBOSYLTRANSFERASES

Eukaryotic mono-ADP-ribosyltransferases (ARTs) are ectoenzymes produced by vertebrates, but absent in lower eukaryotes, like yeast, worms, flies, and mustard weed. Recent database searches and structure prediction methodologies have confirmed the presence of a limited number of ARTs in human and mouse genomes (Glowacki *et al*., 2002). Despite their limited primary sequence homology, their deduced amino acid sequences have similarities to those of viral and bacterial toxin enzymes in the region of the active site cleft, which is consistent with a common mechanism of NAD-binding and ADP-ribose transfer (Domenighini and Rappuolis 1996). Common substrate recognition domains have not yet been identified (Han and Tainer, 2002).

In vertebrates, this posttranslational protein modification can be used to control important endogenous physiological functions, such as the induction of long-term potentiation in the brain, terminal muscle cell differentiation, and the cytotoxic activity of killer T cells (McMahon *et al.*, 1993; Zolkiewska and Moss, 1993; Schumann *et al.*, 1994; Wang *et al.*, 1994). More recently, since ARTs are expressed preferentially in cells of the immune system, their possible involvement in the immune response has also been proposed (Paone *et al*., 2002).

The first vertebrate ribosyltransferases were purified and sequenced from chicken bone marrow and from rabbit and human skeletal muscle, and their specific target proteins have been identified. The majority of eukaryotic enzymes are arginine-specific transferases; nonetheless, ADP-ribosylation of cysteines was reported in bovine and human erythrocytes and platelet membranes (Saxty and van Heyningen, 1995; Tanuma *et al.*, 1988).

The family of mammalian enzymes consists of five proteins (ART1–5), which share extensive similarities in their gene structure and amino acid sequence (Okazaki and Moss, 1998). ART1–ART4 are all glycosylphosphatidylinositol (GPI)-anchored membrane proteins, with an extracellular catalytic domain, whereas ART5 possesses an N-terminal signal sequence that directs its secretion.

The rabbit ART1 is a 36kDa protein and its deduced amino acid sequence possesses hydrophobic amino- and carboxy-terminal signal peptides that are characteristic of GPI-linked proteins. There is roughly 75% of sequence identity among ART1 muscle enzymes isolated from humans, rats, and rabbits, this feature being consistent with considerable conservation across species. Like CT and LT, the muscle transferases specifically use the guanidino group of arginine as an ADP-ribose acceptor. The α7 integrin has been shown to be the target protein for cell surface mono-ADP-ribosylation in muscle cells. The ART1 enzymes have significant amino acid sequence identity to the RT6 (ART2) family of rodent T cell differentiation and activation antigens (Takada *et al.*, 1995). Rat and mouse ART2 sequences are roughly 80% identical, while in humans and chimpanzees, the ART2 genes contain three premature stop codons and thus appear not to be expressed. Recent studies suggest that ART2 may trigger T cell apoptosis (Liu *et al*., 2001). ART3 and ART4 were cloned from human testis and spleen, respectively, and they possess several regions of sequence similarity with ART1.

An ART5 cDNA was cloned from Yac-1 murine lymphoma cells, and its deduced amino acid sequence has similarities to other ART proteins in regions believed to be involved in catalytic activity.

Other mammalian ADP-ribosyltransferases have been purified from rat brain and adrenal medulla (Fujita *et al.*, 1995). These enzymes have been shown to modify, to different degrees, β/γ-actin, smooth muscle γ-actin, $G_s$, $G_i$, and $G_0$. The *in vitro* modification of brain and adrenal G proteins suggests potential mechanisms for cell signaling, similar to those observed with the bacterial toxins.

Previous studies have shown that the bacterial ADP-ribosyltransferases share three separate regions of similarity in their amino acid sequences, which seem to be also present in vertebrate ART enzymes. Alignment of these domains highlights conserved residues within the catalytic sites of the mammalian and bacterial toxin ADP-ribosyltransferases (Okazaki and Moss, 1994; Figure 12.11).

Recently, the three-dimensional structure of ART2 from rats has been solved (Mueller-Dieckmann *et al*., 2002). Detailed analysis reveals that, apart from the catalytic cleft, which is maintained among all ADP-ribosyltransferases, the global fold of ART2 is more closely related to VIP2 and C3 exoenzymes than to other bacterial ADP-ribosylating toxins.

Moreover, the deduced amino acid sequences of human poly(ADP-ribose) polymerases (PARPs) and perhaps ART3 appear to have regions of similarity that align with DT and PAETA; to support this observation, crystal structure of the chicken PARP (Ruf *et al.*, 1996) and mutagenesis of human PARP (Marsischky *et al.*, 1995) demonstrated that Glu 988, which is essential for ADP-ribose chain elongation, is positioned in a cleft similar to that found in bacterial toxins.

These data are consistent with the hypothesis that several of the bacterial toxins and vertebrate transferases possess a common mechanism of NAD binding and ADP-ribose transfer, and that differences observed

in the three-dimensional structures may reflect differences in substrate proteins.

## A COMMON STRUCTURE OF THE CATALYTIC SITE

Enzymes with ADP-ribosylating activity include toxins organized in an AB structure such as PAETA, CT, LT, toxins directly injected into eukaryotic cells such as ExoS and ExoT, phage-encoded proteins, and the ART family of proteins found in eukaryotic cells.

The analysis of the sequences of ADP-ribosylating enzymes known to date shows that all enzymes can be divided into two groups (Figure 12.10): the DT-like group, mainly composed of DT, PAETA, and human poly-ADP-ribosylpolymerases (PARPs), and the CT-like group comprising CT, LT, PT, C2, and C3 exoenzymes, MTX, ExoS, other bacterial ADP-ribosyltransferases, and eukaryotic ART enzymes. The obvious question is whether all these enzymes that perform the same reaction on different substrates have something in common.

While some homology is present within the CT family, overall no significant and extended sequence similarity can be detected to justify the observed common mechanism of catalysis. Nevertheless, biochemical experiments of photoaffinity labeling and studies of site-directed mutagenesis had previously demonstrated that all the toxins possessed a catalytic glutamic acid so important for enzymatic activity that not even a conservative substitution with an aspartic acid could be tolerated without loss or drastic decrease of toxicity. The structural identity of the active site was later confirmed by the crystal structure of several enzymes and computer modeling studies. This is formed by a β-strand followed by a slanted α-helix that has a different length in the various toxins. The β-strand and the α-helix represent, respectively, the lower and upper face of the cavity in which the nicotinamide ring of NAD enters and is anchored during the enzymatic reaction (Figure 12.11). The three-dimensional structure recently obtained for the *C. botulinum* C3 exoenzyme has shown that this toxin, although preserving the ADP-ribosyltransferase activity, lacks the elongated alpha helix, which generally constitutes the ceiling of the active site cleft in the ADP-ribosylating toxins crystallized so far. Seemingly, this feature does not impair the ability of C3 either to accommodate the NAD substrate or to carry out the enzymatic reaction (Han *et al*., 2001).

**FIGURE 12.10** Sequence alignment of protein segments containing Regions 1, 2, and 3 of known ADP-ribosylating enzymes. The two groups of homology (DT-like and CT-like groups) are distinguished. Catalytic residues of Regions 1 and 3 and most relevant and conserved residues of Region 2 are in bold, and extended consensus sequences detected in the three regions are shaded. Predicted and observed secondary structure folding is indicated for each region: Region 1 and 3 are β-strands (arrows), while Region 2 is characterized by a short coil, followed by a β-strand and by a α-helix. PARP, human poly-ADP-ribosylpolymerases.

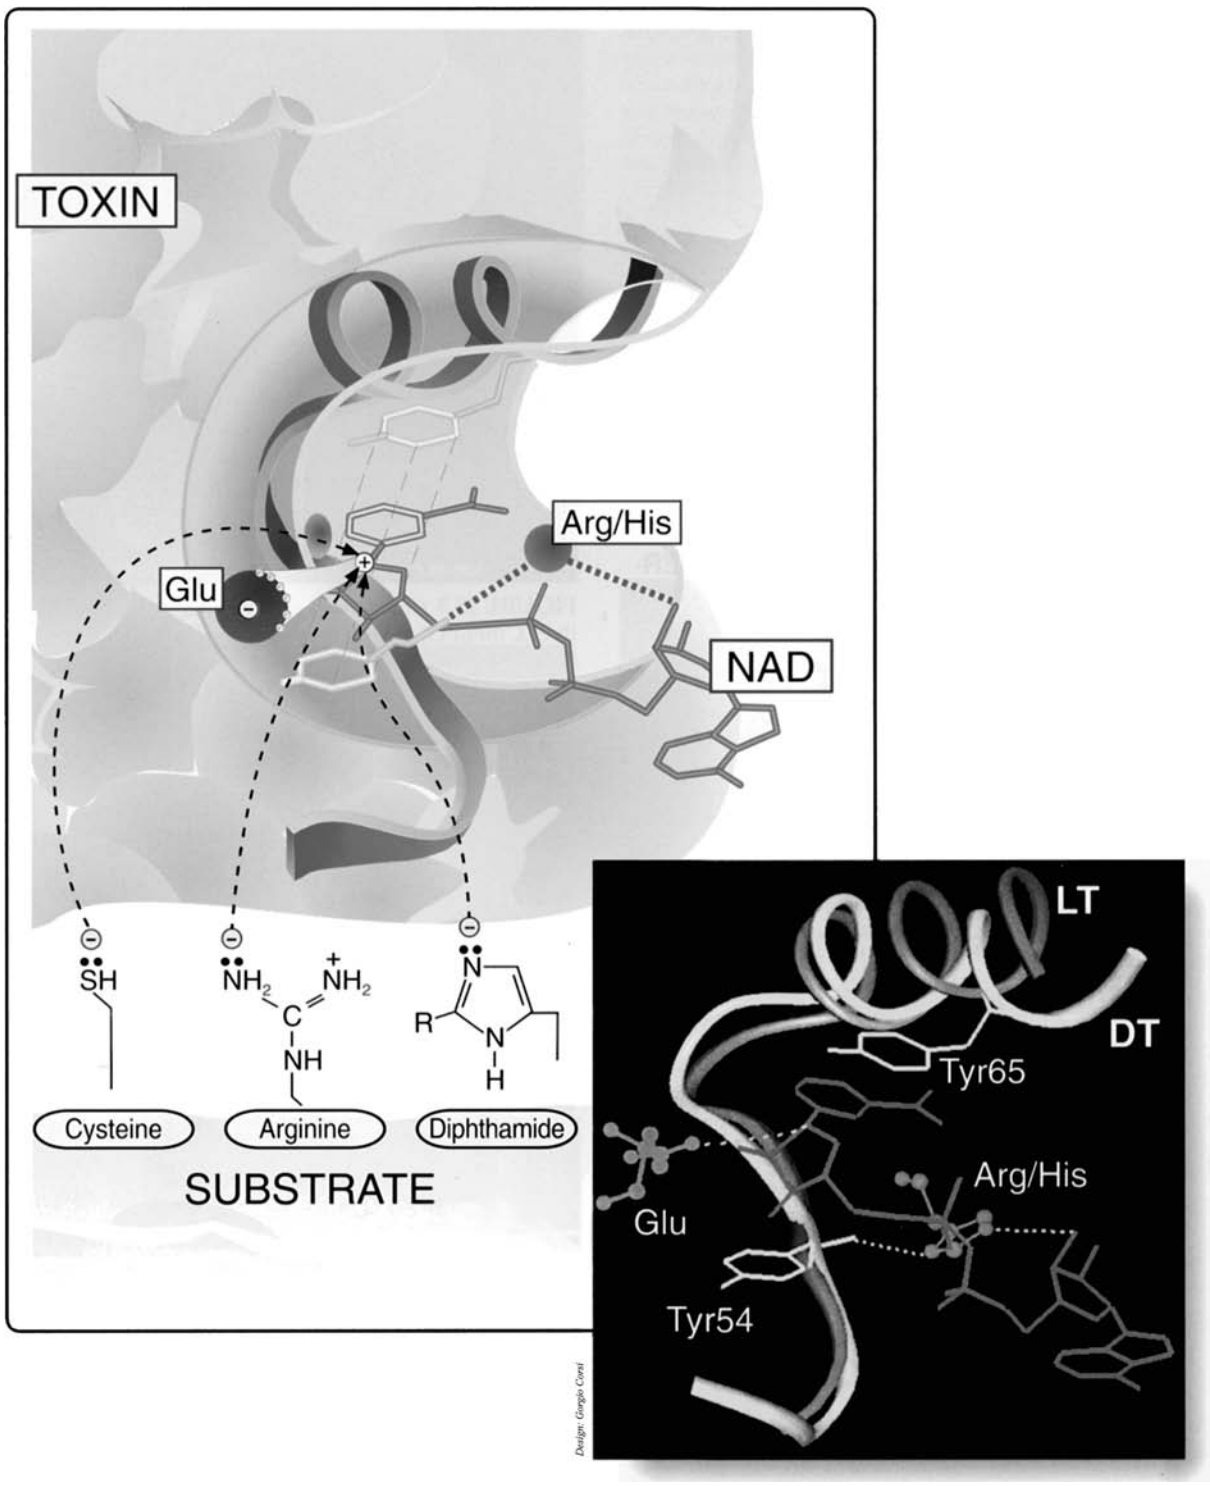

**FIGURE 12.11** Catalytic site of ADP-ribosylating toxins. Upper panel: a schematic representation of a possible common mechanism of catalysis is illustrated: the NAD molecule is docked inside the cavity by means of stacking interactions provided by the two aromatic rings that protrude from the scaffold of the $\beta$–$\alpha$ structure. The catalytic glutamic acid and its possible interactions with the acceptor residues of the various substrates are also reported. The Arg–His residue provides stabilizing interactions with the backbone of the cavity and seems also to be responsible for the correct positioning of NAD inside the pocket. Lower panel: superimposition of the backbones of the three-dimensional structures of the $\beta$–$\alpha$ motif of DT and LT. The NAD molecule has been introduced inside the cavity as it is folded in the complex with the DT structure (Bell and Eisenberg, 1997). The essential amino acids together with their main interactions are again reported.

Although all the toxins share a similar folding in the region of the catalytic domain, at the amino acidic level, the only residues that appear to be conserved among all representatives of the DT and CT subgroups are a glutamic acid and an histidine or an arginine; X-ray data have shown that they are carried by two independent β-strands and retain an equivalent spatial position and orientation in all the enzymes. The knowledge of the structure of the active site and of the amino acids that form it allowed us to go back to the primary sequences and find similarities that had been previously disregarded.

Briefly, all the mentioned toxins share three common features, namely the cavity formed by the β-α structure and the two catalytic residues (identified by numbers 2, 1, and 3 respectively in Figure 12.10). A closer look at these regions shows that the β-α structure (region 2) has very little or no amino acid sequence homology; however, it is identified by an ...S-X-S... motif in most of the enzymes of the CT group and by an ...Y-$(X)_{10}$-Y... in the DT group. The glutamic acid shown in Figure 12.10, (region 3) (namely Glu 148 of DT, Glu 553 of PAETA, Glu 112 of CT and LT, Glu 129 of PT, Glu 214 of C3 exoenzyme, etc.) is characterized by a Glu/Gln-X-Glu in the CT group. The other conserved amino acid (region 1) is an Arg in the CT group and a His in the DT group (His 21 of DT, His 440 of PAETA, Arg 7 of CT, Arg 9 of PT, Arg91 in C3, etc.). This region is usually identified by the Aro-Arg/His motif (region 1). The essential role of the amino acids in regions 1 and 3 and of the structure of the cavity in region 2 has been confirmed experimentally by site-directed mutagenesis. In the case of DT, it has been established that the carboxylate group of the side chain of Glu 148 lies near the nicotinamide ring of NAD, at a distance of 4 Å from the N-glycosidic bond. Extending this observation to all the toxins, the more likely explanation in terms of enzymatic activity is that the essential glutamic acid could play a role in stabilizing a chemical intermediate of NAD by forming a hydrogen bond with the O2′ hydroxyl group of the nicotinamide ribose (Han *et al.*, 1999). Although several models have been proposed to explain the possible function of the conserved histidine/arginine, it seems now widely accepted that this residue does not play a direct role in catalysis; very likely, it has the function of maintaining the integrity of the active-site pocket upon formation of structurally stabilizing hydrogen bonds.

The other reported block of homology is the domain β-α, which includes a number of amino acids that, while maintaining the same secondary structure in both DT and CT families, still strongly differ in terms of sequence. This region corresponds to the core of the active site cleft, which is devoted to the docking of NAD. The difference detected in terms of primary structure between the two subgroups suggests that the toxins may adopt a diverse mechanism of binding. The consensus sequence generated for the DT group is characterized by two conserved tyrosines spaced by 10 amino acids, and respectively located on the middle portion of the β-strand and on the internal face of the α-helix. Tyr 54 and Tyr 65 of DT, and Tyr 470 and Tyr 481 of PAETA have been shown to play a very important role in catalysis, since they anchor the nicotinamide ring creating a π pile of three aromatic rings that strengthen the overall binding of NAD and stabilize the complex. In PT, a similar role is likely to be played by Tyr 59 and Tyr 63, which have a similar spatial orientation and distance from each other. This observation is supported by the fact that in CT and LT, where the stacking interactions produced by the two tyrosines are lacking, the affinity for NAD is 1000-fold lower. In the case of the CT group, the box β-α is centered on a conserved core region characterized by the consensus Ser-Thr-Ser that is observed and predicted to fold in a β-strand that represents the floor of the cavity. No conclusive information is available to define the precise role of these small, polar residues in catalysis, but experiments of site-directed mutagenesis confirm that they are extremely important in maintaining the cavity available for NAD entrance and docking. Substitutions of Ser 61 and Ser 63 of LT with Phe and Lys, respectively, have been shown to produce non-toxic mutants.

Another amino acid that has been proposed as being important in catalysis is His 35 of PT, which is located near the beginning of the β-strand that forms the floor of the cavity in a position equivalent to that of His 44 of LT and CT; a functional homologue His is also present in MTX, but absent in DT and PAETA.

In the three-dimensional structure, this residue appears to be sufficiently close to the oxygen atom of the ribose ring of NAD to interact with it and increase the electrophilicity of the adjacent anomeric carbon atom. The absence of an equivalent residue in DT and PAETA again supports the idea that the two groups of toxins perform the same enzymatic activity in a slightly different fashion.

An additional feature that is common to all ADP-ribosylating toxins is the need for a conformational rearrangement in order to achieve enzymatic activity. In the native structure, the NAD binding site of LT and CT is obstructed by a loop comprising amino acids 47–56, which needs to be displaced in order to obtain a functional NAD-binding cavity. A functionally homologous region is also present in PT where the loop comprises residues 199–207. In the case of DT, where the crystallographic data of the complex are available, the observation

that the active site loop consisting of amino acids 39–46 changes structure upon NAD binding suggests that these residues may be important for the recognition of the ADP-ribose acceptor substrate, EF-2.

This proposal is supported by at least two lines of evidence: first, DT and PAETA have a high degree of sequence similarity in this loop region with a number of identical or highly conservative substitutions supporting the idea that these residues have some essential function; second, antibodies raised against a peptide corresponding to this loop sequence were able to block the catalytic domain of DT from catalyzing the ADP-ribosylation of EF-2.

The crystallographic data of the DT-NAD complex and the presence of common features within all ADP-ribosylating toxins allow us to speculate on a possible common mechanism of catalysis (Bell and Eisenberg, 1997).

The best hypothesis is that NAD enters the cavity upon displacement of the mobile loop, which is then made available for the recognition of the substrate; NAD is subsequently docked at the bottom of the pocket where a small residue (the conserved serine in the β-α box of the CT-group, the threonine 56 of DT, and the alanine 472 of PAETA) is required to allow good positioning. The nicotinamide moiety of NAD is then blocked in a suitable position by means of stacking interactions provided by a couple of aromatic rings (Tyr 54 and Tyr 65 of DT, Tyr 470 and Tyr 481 of PAETA, and possibly Tyr 59 and Tyr 63 of PT, respectively). In this context, the conserved arginine/histidine might display its key role in maintaining the correct shape of the active site pocket via hydrogen bonds formed with the backbone of the structure and possibly with one of the ribose moiety.

The enzymatic reaction is then catalyzed by the essential glutamic acid, which is likely to stabilize a positively charged oxocarbonium intermediate of NAD, in order to favor its subsequent interaction with the nucleophilic residue of the incoming substrate (Figure 12.11).

While a possible mechanism of reaction has been proposed, so far the residues implicated in substrate recognition have not been clearly mapped for any of the known ADPRTs. However, sequence alignment highlights the fact that all known Arg-specific ADP-ribosyltransferases contain a glutamic acid two residues upstream of the catalytic Glu (Figure 12.10). Mutation of this residue to glutamine has been shown to convert arginine-specific ADPRT activity into NAD-glycohydrolase activity in case of *C. botulinum* C2 toxin (Barth *et al*., 1998), *C. perfringens* iota toxin (Radke *et al*., 1999), and *Pseudomonas* exoenzyme S (Nagahama *et al*., 2000). On the other hand, all Rho-specific C3-like toxins display a Gln residue in this position, thus implying that this Gln may be required for Rho substrate recognition (Han *et al*., 2001).

Structural and mutagenesis studies of the NAD binding core of a binary toxin have identified an ARTT motif (ADP-ribosylating turn-turn motif) that is implicated in substrate specificity and recognition, and represents a general recognition region for most ADP-ribosylating enzymes (Han and Tainer, 2002). However, the ARTT motif seems to be only one of the several factors that determine substrate specificity. Very recently, in a study based on ExoS and ExoT in which the residues involved in substrate recognition were mapped, the authors proposed a model in which the substrate specificity is determined by the electrostatic potential in the enzyme-substrate interface (Sun *et al*., 2004).

CHAPTER

# 13

# Diphtheria toxin

*Diana Marra Oram and Randall K. Holmes*

## INTRODUCTION

Diphtheria is a serious respiratory disease characterized by the formation of a pseudomembrane consisting of necrotic tissue and bacteria. *Corynebacterium diphtheriae*, visualized in 1883 by Klebs in stained samples from pseudomembranes, was isolated in 1884 by Loeffler and shown to be the cause of diphtheria. In causing respiratory diphtheria, *C. diphtheriae* colonizes the mucosus membranes of the upper respiratory tract and secretes diphtheria toxin. *C. diphtheriae* is rarely found outside of the local area of infection, but diphtheria toxin is absorbed into the circulatory system and disseminated. Many cell types are susceptible to killing by diphtheria toxin, but the primary systemic effects occur in the heart and peripheral nerves. The major clinical manifestations of diphtheria are attributable to the action of diphtheria toxin.

Diphtheria is easily transmitted from person to person and was a leading cause of infectious disease morbidity and mortality until the early 1900s. The discovery that treatment of diphtheria toxin with formaldehyde converted it to a nontoxic form (toxoid) that can still induce the formation of toxin-neutralizing antibodies provided the basis for widespread immunization against diphtheria (Ramon Jr., 1923), and immunization with toxoid has made diphtheria a rare disease in countries with high levels of medical care (Holmes, 2005). Outbreaks of diphtheria can still occur when immunity levels within a population decline. In 1990 a large outbreak of diphtheria began in Russia and quickly spread to the newly independent states of the former Soviet Union, resulting in over 150,000 cases by the mid 1990s. The outbreak was controlled by a massive immunization campaign, but not before it had resulted in more than 4,000 deaths. Small but significant outbreaks of diphtheria have also occurred in the USA, Australia, and western Europe in the last 40 years (Chen *et al*., 1985; Dittmann *et al*., 2000; Gilbert, 1997; Harnisch *et al*., 1989; Rappuoli *et al*., 1988). These outbreaks as well as recent reports that the majority of the adult population in Europe and the United States lacks adequate immunity to diphtheria has resulted in renewed interest in *C. diphtheriae*.

Diphtheria toxin was discovered in the late 1800s (Roux and Yersin, 1888) and is one of the most extensively studied bacterial toxins. In 1957 two groups reported that low concentrations of diphtheria toxin were lethal for many cell lines (Lennox and Kaplan, 1957; Placido Sousa and Evans, 1957). In 1959, Strauss and Hendee reported that the first effect of diphtheria toxin on HeLa cells was a cessation of protein synthesis at approximately one and a half hours after exposure, and other toxic effects on respiration, nucleic acid synthesis, and cellular morphology were not observed until much longer after exposure to diphtheria toxin (Strauss and Hendee, 1959). The minimal lethal dose of diphtheria toxin for humans and highly susceptible animals is below 0.1 μg per kg of body weight (Pappenheimer, 1984), and delivery of a single molecule of diphtheria toxin fragment A (the portion of the molecule containing the catalytic activity) to the cytosol is sufficient to kill a eukaryotic cell (Yamaizumi *et al*., 1978). Later, it was definitively established, by several groups, that diphtheria toxin is a specific inhibitor of eukaryotic protein synthesis.

Diphtheria toxin was the first A-B type toxin to be characterized, and it serves as the prototype for this large group of protein toxins, which includes among others, cholera toxin, *Escherichia coli* heat-labile

enterotoxin, *Pseudomonas aeruginosa* exotoxin A, tetanus and botulinum neurotoxins, and Shiga toxin. A-B type toxins have two functionally distinct components: A, the moiety representing the catalytic (toxic) function and B, the moiety representing the receptor binding function. The A and B components of A-B type toxins can be represented either by separate polypeptide subunits or by different domains of the same polypeptide, as is the case for diphtheria toxin. In *Corynebacterium diphtheriae*, diphtheria toxin is secreted from the bacterial cells as a 535 amino acid proenzyme that must be cleaved into the A fragment and the B fragment in order for its toxicity to be expressed.

## GENETICS AND REGULATION OF DIPHTHERIA TOXIN PRODUCTION

Diphtheria toxin production by *C. diphtheriae* is controlled by bacteriophage conversion (Barksdale and Pappenheimer, 1954; Freeman, 1951; Groman, 1953). Analysis of recombination between the toxin-positive corynephage β and the toxin-negative corynephage γ demonstrated that the $tox^+$ and $tox^-$ markers segregated as alleles of a unique genetic locus (Holmes and Barksdale, 1969). The *tox* locus, which represents the structural gene for diphtheria toxin (Uchida *et al*., 1971), is present in the genomes of several corynephages (Barksdale and Arden, 1974; Holmes and Barksdale, 1970). Expression of *tox* is not regulated coordinately with other corynephage genes (Gill *et al*., 1972; Matsuda and Barksdale, 1966), but production of diphtheria toxin is affected by the composition of the growth medium (Mueller, 1940; Mueller and Miller, 1941; Pappenheimer and Johnson, 1936). The component of the medium that has the largest and best studied effect on production of diphtheria toxin is iron.

Many bacterial pathogens respond to the severely limited availability of free iron in the host by expressing virulence factors (including toxins) (Cornelissen, 2003; Litwin and Calderwood, 1993; Rodriguez and Smith, 2003). Production of diphtheria toxin by toxinogenic *C. diphtheriae* is stringently repressed by high concentrations of iron in the extracellular environment *in vivo* and *in vitro*. An *in vitro* system provided the first evidence that a *C. diphtheriae* encoded product was responsible for this repression. In a transcription/translation system from *E. coli*, DNA from a $tox^+$ corynephage directed the synthesis of diphtheria toxin as well as other phage encoded proteins. Addition of *C. diphtheriae* extracts to this *in vitro* system resulted in inhibition of diphtheria toxin production, but it did not affect synthesis of the other phage proteins (Murphy *et al*., 1974). Several mutants of the corynephage were isolated that interfered with the ability of iron to repress diphtheria toxin production (Murphy *et al*., 1976; Uchida *et al*., 1977; Welkos and Holmes, 1981a; Welkos and Holmes, 1981b). In addition, mutations in the chromosome of *C. diphtheriae* that affected the ability of iron to repress diphtheria toxin productions were isolated (Kanei *et al*., 1977). These and other studies supported the hypothesis that a chromosomally encoded diphtheria toxin repressor existed and that it used iron as a co-repressor.

The cloning of the structural gene for diphtheria toxin *tox* occurred in the 1980s and led to the characterization of the contiguous upstream regulatory sequences (Greenfield *et al*., 1983; Kaczorek *et al*., 1983; Ratti *et al*., 1983). The promoter P-tox, at which transcription of *tox* initiates, was located and characterized shortly thereafter (Boyd and Murphy, 1988; Leong and Murphy, 1985). Finally in the early 1990s, the chromosomally encoded diphtheria toxin repressor DtxR was cloned (Boyd *et al*., 1990; Schmitt and Holmes, 1991). The physiologic role of DtxR is similar to that of the ferric uptake regulator Fur, which was previously found in several Gram-negative bacterial species. Fur and DtxR are now recognized as the prototypes for two different groups of iron-dependent bacterial repressor proteins.

The iron bound form of DtxR binds a DNA sequence that overlaps P-tox and prevents initiation of transcription. Thus, DtxR is an iron-dependent transcriptional repressor. The function and structure of DtxR have been extensively characterized (Feese *et al*., 2001; Holmes, 2000). In addition to *tox,* DtxR regulates several chromosomally encoded genes (Kunkle and Schmitt, 2003; Lee *et al*., 1997; Qian *et al*., 2002; Schmitt and Holmes, 1991; Schmitt and Holmes, 1994). Many DtxR regulated genes encode products that are involved in iron utilization and acquisition. Analysis of the DNA sequences bound by DtxR at different promoters has identified a 19 basepair consensus palindrome at the core of the DtxR binding site (Schmitt and Holmes, 1994; Tao and Murphy, 1994). Structurally, DtxR binds DNA as a dimer, and each DtxR monomer contains two metal binding sites. There are several specific contact sites between the DtxR dimer and the DNA (Chen *et al*., 2000; Pohl *et al*., 1999; White *et al*., 1998; Wisedchaisri *et al*., 2004).

Although $Fe^{2+}$ is the primary metal ion that acts as co-repressor *in vivo*, DtxR is capable of binding several divalent metals *in vitro*, including cadmium, cobalt, manganese, nickel, and zinc (Schmitt and Holmes, 1993; Schmitt *et al*., 1992; Tao *et al*., 1992; Tao and Murphy, 1992). DtxR-like regulator proteins have been identified in a wide variety of bacterial species where

they regulate gene expression in response to divalent metals (Feese *et al*., 2001; Guedon *et al*., 2003; Oram *et al*., 2004; Rodriguez and Smith, 2003). Interestingly, IdeR, the DtxR homologue in Mycobacterial species, has been shown to act as both a repressor and as an activator of transcription (Rodriguez and Smith, 2003). The characterization of the roles of DtxR-like regulators in virulence of bacterial pathogens, including Mycobacterial species, is of interest to a wide variety of researchers concerned with combating infectious disease.

## STRUCTURE OF DIPHTHERIA TOXIN

Diphtheria toxin is synthesized and, following removal of a signal sequence, is secreted by *C. diphtheriae* as a single polypeptide (Figure 13.1). The mature secreted toxin is 535 amino acid residues in length and has a molecular mass of approximately 58 kDa. The secreted holotoxin is a proenzyme that must be both cleaved and reduced in order for toxicity to be expressed. The holotoxin contains four cysteines that participate in two disulfide bonds: the first between Cys186 and Cys201 and the second between Cys461 and Cys471. *In vivo*, the proenzyme is cleaved, after binding its cellular receptor, by members of the furin family of cell-associated proteases (Gordon *et al*., 1995), and *in vitro* treatment of toxin with typsin and reduction of the "nicked" toxin produces two polypeptide fragments designated A and B. The amino terminal fragment A (molecular mass, about 21 kDa) is the catalytically active portion of toxin that mediates the intracellular action. The carboxyl terminal fragment B (molecular mass, about 37 kDa) contains the receptor binding and translocation portions of the toxin. Diphtheria toxin was the first described example of an A-B toxin, in which the catalytic and receptor-binding functions are positioned on separate polypeptides or on separate domains within a protein.

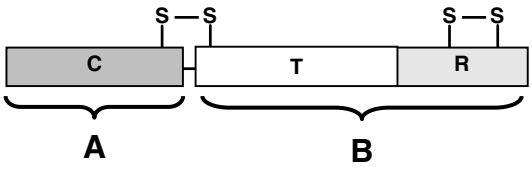

**FIGURE 13.1** Secondary structure of diphtheria toxin. The A and B fragments are labeled. The amino terminal catalytic domain (C) is shown in dark gray, the translocation domain (T) is shown in white, and the carboxyl terminal receptor binding (R) domain is shown in light gray. The Cys to Cys disulfide bonds are shown as S-S.

The first crystal structure of diphtheria toxin was reported in 1992 (Choe *et al*., 1992). The form crystallized was a dimer that was generated by freezing the toxin under certain conditions. The dimer is non-toxic but dissociates slowly at neutral pH to yield a toxic monomer. The structure of monomeric diphtheria toxin was solved shortly thereafter and revealed that the configurations of the individual domains were virtually identical to their counterparts in the dimer structure (Bennett and Eisenberg, 1994). Diphtheria toxin has three discrete domains C, T, and R, corresponding to the three major functions of the toxin: catalysis, translocation, and receptor-binding, respectively. The C domain corresponds to the A fragment and the T and R domains are contained within the B fragment.

The catalytic C domain of diphtheria toxin includes eight β strands and seven α helices, and the active site of the enzyme is formed by an α helix bent over a β strand. The catalytic activity of the C domain transfers the adenosine diphosphate ribose (ADP-ribose) moiety from nicotinamide adenine dinucleotide (NAD) to a modified hisitidine residue (diphthamide) in elongation factor 2 (EF-2), thereby inactivating protein synthesis in intoxicated cells (Collier, 1967; Honjo *et al*., 1968). The C domain binds NAD *in vivo*, but the first structures of diphtheria toxin included ApUp, an endogenous dinucleotide that is found in many toxin preparations occupying the active site cleft of the C domain. ApUp binds with high affinity and apparently acts as an NAD analog. Within the active site cavity, Tyr54 and Tyr65 are parallel with just enough space between their aromatic rings to allow entrance of the nicotinamide ring of NAD. His21 and Glu148, which are required for catalysis, are positioned on either side of the binding cavity. In addition, the crystal structure of dimeric diphtheria toxin in complex with NAD was solved in 1996, making it the first crystal structure of an ADP-ribosyltransferase in complex with NAD. In this structure, the carboxylate group of Glu148 was in proximity to the scissile, N-glycosidic bond of NAD (Bell and Eisenberg, 1996; Bell *et al*., 1997). This arrangement is consistent with the known requirement of Glu148 for ADP-ribosylation by diphtheria toxin. The structure of the active site appears to be conserved in all ADP-ribosylating enzymes (Domenighini *et al*., 1991, 1994).

The structure of the T domain of diphtheria toxin is organized in three layers of α helices. The outer layer contains three helices that are rich in charged residues and help maintain the T domain and diphtheria toxin in a soluble form at neutral pH. The middle layer contains three helices that form a hydrophobic shell, and the internal layer includes hydrophobic and amphipathic helices. At neutral pH, a central

hydrophobic helical hairpin is hidden from the solvent by the outer helices, and acidic pH induces a conformational change that results in a molten state with exposure of the hydrophobic parts of the central layer of helices, promoting interaction with membranes (Zhan *et al*., 1994). A Glu349Lys mutation, which blocks translocation, lies in an interhelix loop between the helices in that innermost helical hairpin. A positively charged Lys at this position would be expected to block insertion of this hairpin into the membrane, supporting a model in which the innermost helical hairpin represents a membrane-insertion motif that functions in translocation. Several recent results support this model (D'Silva and Lala, 2000; Kachel *et al*., 1998; Oh *et al*., 1999b; Ren *et al*., 1999b).

The R domain of diphtheria toxin is a globular domain that consists exclusively of β-sheets. The domain includes two β-sheets, each consisting of four β-strands. There is some evidence that the R domain may interact with membranes during its translocation (mediated by the T domain). Portions of the R domain are protected by membranes from external proteases, and the structure of the domain changes during interaction with membranes (Quertenmont *et al*., 1999). Within the R domain, Lys516 and Phe530 have a role in recognition of the receptor on the target cell (Shen *et al*., 1994). Overall, the structure of the diphtheria toxin R domain has similarities to the variable domain of immunoglobulins.

## DIPHTHERIA TOXIN RECEPTOR

The first step in intoxication of eukaryotic cells by diphtheria toxin is the binding of the toxin to a specific cellular receptor. The gene that encodes the receptor for diphtheria toxin was first cloned as a cDNA from toxin sensitive monkey Vero cells and was able to confer toxin sensitivity to the normally toxin-resistant mouse L-M(TK-) cell line (Naglich *et al*., 1992a). The cDNA encoded a protein with a predicted amino acid sequence that was identical to that of the heparin-binding epidermal growth factor precursor (pro-HB-EGF). The heparin-binding epidermal growth factor (HB-EGF) is a member of the EGF family, and it is derived through a proteolytic cleavage of the surface-exposed, membrane-bound pro-HB-EGF (Higashiyama *et al*., 1991). Although pro-HB-EGF is cleaved to release soluble HB-EGF, a significant amount of pro-HB-EGF remains on the cell surface where it functions as a growth factor (Higashiyama *et al*., 1995) and serves as a receptor for diphtheria toxin (Iwamoto *et al*., 1994; Naglich *et al*., 1992a).

On the cell surface, pro-HB-EGF forms a complex with several other membrane proteins, including heparin sulfate proteoglycans and CD9 (Iwamoto *et al*., 1991; Shishido *et al*., 1995), both of which are known to enhance the ability of the receptor to bind diphtheria toxin. The effects of heparin-like molecules, including heparin sulfate proteoglycans, and CD9 on the binding of diphtheria toxin are additive, suggesting that they influence binding by different mechanisms. Heparin-like molecules bind to the heparin-binding domain of pro-HB-EGF, causing a change in the conformation of the domain that increases the affinity of the receptor for diphtheria toxin (Shishido *et al*., 1995). The precise mechanism by which CD9 promotes pro-HB-EGF binding to diphtheria toxin has not been determined, but direct protein to protein contact between the two molecules is required and regions of CD9 essential for this contact have been identified (Hasuwa *et al*., 2001; Nakamura *et al*., 2000; Ryu *et al*., 2000).

Most mammalian species are sensitive to the effects of diphtheria toxin, but mice and rats are highly resistant to diphtheria toxin. The resistance of these species to the action of diphtheria toxin is caused by the lack of a functional receptor on cell surfaces (Cha *et al*., 1998). Recently, several authors have used the natural resistance of mice to diphtheria toxin as a tool to study the roles of specific cell types in development and disease. The first transgenic mice expressing a functional receptor for diphtheria toxin were described in 2001 (Saito *et al*., 2001). These mice expressed human pro-HB-EGF under control of a hepatocyte-specific promoter. The injection of diphtheria toxin resulted in rapid and severe hepatitis, thus providing a useful model for disease. This hepatitis model was the first description of "toxin receptor-mediated cell knockout" in which the expression of the diphtheria toxin receptor permits the expressing cell type to be specifically eliminated through the administration of diphtheria toxin without affecting other cells. Since 2001 other lines of "toxin receptor-mediated cell knockout" mice have been engineered and used successfully to study the functions of cell types other than liver cells, including dendritic cells and cardiomyocytes (Akazawa *et al*., 2004; Jung *et al*., 2002). This technology provides a powerful tool for researchers wanting to precisely and specifically eliminate any mouse cell type that can be engineered to express human pro-HB-EGF, at any time during pre- or postnatal development, through the administration of diphtheria toxin.

In addition to transgenic mice expressing the diphtheria toxin receptor in specific cell types, a line of mice expressing the receptor in most cell types has been engineered (Cha *et al*., 2003). In these mice the expression of human pro-HB-EGF is under control of a

cytomegalovirus promoter that is activated postnatally, since embryonic overexpression of pro-HB-EGF in all mouse cells proved to be fatal. The transgenic mice expressing pro-HB-EGF are sensitive to diphtheria toxin at a concentration of 0.1 μg per kg, which is similar to that of sensitive species such as guinea pigs (Collier, 1975). These mice were used to test the ability of a soluble receptor-based, toxin-binding peptide (Cha *et al*., 2002) to protect against the action of diphtheria toxin, and they can be used to test any potential antidote for diphtheria toxin.

## INTERNALIZATION AND TRANSLOCATION OF DIPHTHERIA TOXIN

After binding to pro-HB-EGF on the surface of a susceptible cell, diphtheria toxin is internalized in a process termed *receptor-mediated endocytosis*. Specifically, diphtheria toxin enters cells by clathrin-mediated endocytosis (Moya *et al*., 1985; Simpson *et al*., 1998), and it has been visualized in clathrin-coated pits (Morris *et al*., 1985). In confirmation of this mechanism of entry, lowering the intracellular potassium level, which inhibits pit formation and clathrin-mediated endocytosis, protects cells from the effects of diphtheria toxin (Moya *et al*., 1985; Sandvig *et al*., 1985). In addition, the cytoplasmic domain of pro-HB-EGF has a tyrosine-containing sequence (Naglich *et al*., 1992b), which may serve to anchor the receptor in clathrin-coated pits and ensure that diphtheria toxin enters the cell via clathrin-dependent endocytosis.

Although the precise molecular mechanism by which diphtheria toxin translocates across the endosomal membrane and is released into the cytoplasm is an area of active investigation, several steps in the process have been characterized. The translocation of diphtheria toxin across membranes can be observed in cell-free systems, suggesting that the toxin alone has the ability to penetrate and transverse lipid bilayers (Jiang *et al*., 1991; Oh *et al*., 1999a; Umata and Mekada, 1998). In addition, it has been demonstrated that translocation of diphtheria toxin from the lumen of early endosomes to the external milieu requires the addition of a cytosolic translocation factor complex that includes heat shock protein 90 and thioredocin reductase (Ratts *et al*., 2003). The proposed role of the cytosolic translocation factor complex is to aid in release and refolding of the C domain of diphtheria toxin after translocation from early endosomes. Several lines of evidence support the theory that the catalytic C domain (in the A fragment) of diphtheria toxin is denatured prior to translocation (Donovan *et al*., 1981; Falnes *et al*., 1994; Kagan *et al*., 1981; Wiedlocha *et al*., 1992). Interestingly, a direct interaction between the C domain and lipid membranes has recently been demonstrated (Wolff *et al*., 2004).

The T domain of diphtheria toxin has a critical role in translocation of the toxin. It is a largely α helical domain, and it has a hydrophobic carboxyl terminal portion that has the ability to insert into and form pores within both biological and model membranes under conditions of low pH (Kagan *et al*., 1981; Papini *et al*., 1988; Sandvig and Olsnes, 1988; Sharpe and London, 1999). The T domain of diphtheria toxin can also assist the translocation of some heterologous proteins across lipid bilayers at low pH (Ren *et al*., 1999a). Following endocytosis, the low pH of the endosomes induces a conformational change that results in diphtheria toxin dissociating from pro-HB-EGF (Brooke *et al*., 1998) and interacting with the endosomal membrane (Sandvig and Olsnes, 1980). The interaction of the T domain with lipid membranes is an area of active research as a model for trafficking across membranes. Hydrophobic helices 8 and 9 of the T domain form a transmembrane helical hairpin (Moskaug *et al*., 1991; Oh *et al*., 1999b; Quertenmont *et al*., 1996), and a second transmembrane hairpin is predicted to be formed by helices 5, 6, and 7, although there is less supporting evidence for this structure than that for the transmembrane helical hairpin formed by helices 8 and 9. Recent evidence suggests that helices 5, 6, and 7 may form stable but nonclassical inserted segments in lipid bilayers (Rosconi *et al*., 2004). Further details of toxin translocation and intracellular trafficking can be found in chapters 7 and 8.

## ACTIVITY OF DIPHTHERIA TOXIN AND INTRACELLULAR TARGET

Diphtheria toxin kills cells by inhibiting eukaryotic protein synthesis, and its mechanism of action has been extensively characterized. This potent toxin inactivates elongation factor (EF-2) required for protein synthesis (Collier, 1967). Specifically, diphtheria toxin transfers the ADP-ribose moiety of NAD to EF-2 (first demonstrated using radiolabeled NAD) (Honjo *et al*., 1968). Diphtheria toxin was the first member to be identified of a group of bacterial protein toxins that act by ADP-ribosylation of a target protein. The ADP-ribosylation activity of diphtheria toxin is determined completely by the A fragment, and no portion of the B fragment is required for catalytic activity.

The intracellular toxicity of the A fragment of diphtheria toxin is preserved even when it is produced

independently from the B fragment. Therefore, tissue-specific intracellular expression of the diphtheria toxin A fragment can be used to kill particular cell types. This method has been used extensively to study eukaryotic development. Briefly, the coding sequence for the A fragment of diphtheria toxin is placed under the transcriptional control of a tissue-specific eukaryotic promoter and the resulting promoter-gene fusion is integrated into embryonic cells. As the organism develops, the tissue specific promoter is activated, and expression of the diphtheria toxin A fragment results in death of all cells in which the tissue-specific promoter is active. Using this method, the developmental roles of several cell types have been determined, including those involved in development of the eye, pancreas, kidney, and roof plate in mice (Breitman *et al*., 1987; Lee *et al*., 2000; Palmiter *et al*., 1987; Pentz *et al*., 2004). This method is applicable to a wide variety of plants, animals, and insects, including *Drosophila*, rainbow trout, and *Arabidopsis* (Han *et al*., 2000; Kalb *et al*., 1993; Tsugeki and Fedoroff, 1999; Uzbekova *et al*., 2003). In some cases, production of wild-type A fragment results in lethality early in development so mutant forms of the A fragment that are less active, and therefore less toxic, than wild-type have been used to kill cells slower and later in development. Characterization of the active site of the A fragment provided the basis for the development of less toxic forms of diphtheria toxin.

The amino acids that make up the active site of the A fragment have been characterized using several methods. There is only one amino acid residue, Glu148, that is completely conserved within the family of ADP-ribosyltransferase toxins. Glu148 is essential for the ADP ribosylation activity of the A fragement, and it is positioned near the NAD binding pocket in the crystal structure (Carroll and Collier, 1984; Choe *et al*., 1992; Tweten *et al*., 1985). His21 is also required for catalytic activity, and it is important for NAD binding (Papini *et al*., 1990; Papini *et al*., 1989). Another amino acid residue, Tyr65, was initially identified by biochemical studies as important for binding NAD (Papini *et al*., 1991), and site-directed mutations have confirmed its importance in catalysis (Blanke *et al*., 1994). In addition, Tyr50 is required for full enzymatic activity. A substitution of Try50 with Ala drastically decreased the enzymatic activity (105-fold), but a substitution of Phe had a very small effect. This suggests a role for an aromatic residue at position 50 (Wilson *et al*., 1994).

The intracellular target of ADP ribosylation by diphtheria toxin, EF-2, mediates the translocation step in peptide chain elongation by promoting transfer of peptidyl tRNA from the A to the P site of the ribosome. The amino acid residue of EF-2 that is ADP-ribosylated by diphtheria toxin is a posttranslationally modified histidine called *diphthamide*. The diphthamide residue is unique to EF-2 from eukaryotes and Archea and is not found in any other protein (Bodley *et al*., 1984; Collier, 2001). Synthesis of diphthamide is a complex process that requires the participation of at least seven different gene products (Liu and Leppla, 2003; Liu *et al*., 2004; Mattheakis *et al*., 1993; Schultz *et al*., 1998). The retention of the diphthamide biosynthesis pathway by eukaryotes and Archea implies a significant function of diphthamide apart from its inactivation by diphtheria toxin, although mutant cell lines that cannot produce diphthamide remain viable and are resistant to diphtheria toxin (Phan *et al*., 1993). It has been suggested that ADP ribosylation of diphthamide in EF-2 may occur as a regulatory event in normal cellular physiology (Fendrick *et al*., 1992), but evidence for the precise physiological role of diphthamide in eukaryotes remains elusive.

## DIPHTHERIA TOXIN AS A VACCINE COMPONENT

In addition to the use of the diphtheria toxid for universal immunization against diphtheria, non-toxic mutants of diphtheria toxin have been used as a component of vaccines designed to elicit immune responses to antigens from a variety of bacterial pathogens. The non-toxic diphtheria toxin molecules increase both the cell-mediated and humoral immune responses to some specific antigens that elicit poor immune responses when administered alone. The most common non-toxic diphtheria toxin mutants used to enhance immune responses are CRM197 (Uchida *et al*., 1973), which contains a single amino acid change in the catalytic portion of the molecule (Giannini *et al*., 1984), and CRM9, which has a single amino acid change in the B fragment that lowers its affinity for the receptor (Hu and Holmes, 1987). CRM9 conjugate vaccines are being developed against diseases caused by *Shigella* and *Moraxella* species (Jiao *et al*., 2002; Passwell *et al*., 2003). CRM197 conjugate vaccines directed against many different bacterial antigens including *Haemophilus influenzae* type b capsular antigen, as well as meningococcal, pneumococcal, mycobacterial, and streptococcal antigens, have already been proven to be safe and effective (Baker *et al*., 2004; Baraldo *et al*., 2004; Klugman *et al*., 2003; Mawas *et al*., 2004; Mazzantini *et al*., 2004). In addition, new vaccines based on CRM197 and directed against diphtheria are also being developed (McNeela *et al*., 2004; Rydell and Sjoholm, 2004). Further information about the ability of bacterial toxins to affect the immune response can be found in Section V, Chapters 54 and 61.

## POTENTIAL MEDICAL USES OF THE DIPHTHERIA TOXIN R DOMAIN AND THE CELLULAR RECEPTOR

Patients with diphtheria are treated with equine diphtheria antitoxin, which neutralizes unbound diphtheria toxin. This treatment can result in serum sickness, an immune complex disease, so a better treatment for diphtheria patients would be desirable. One approach to developing a new treatment is based on preventing diphtheria toxin binding to its cognate receptor pro-HB-EGF. While the soluble form of HB-EGF will bind diphtheria toxin and block its binding to pro-HB-EGF (Hooper and Eidels, 1995), soluble HB-EGF is likely to have side effects based on its growth factor activity. The careful characterization of the region of pro-HB-EGF required for binding of diphtheria toxin has laid the groundwork for the development of a receptor-blocking–based antidote for diphtheria. The region of pro-HB-EGF required for binding of toxin was identified by expressing chimeric fusions between the murine pro-HB-EGF receptor, which does not bind diphtheria toxin, and either human or monkey receptors, both of which bind diphtheria toxin (Hooper and Eidels, 1995; Hooper and Eidels, 1996; Mitamura *et al*., 1995). These studies localized the toxin binding region to an extracellular portion of the protein within the EGF domain. In addition, several specific amino acid residues, including Phe115, Leu127; His135, and Glu141, were identified as being critical for toxin binding (Cha *et al*., 1998; Hooper and Eidels, 1996; Mitamura *et al*., 1997). Recently, a recombinant truncated form of HB-EGF that blocks binding of diphtheria toxin but has 100-fold lower mitogenic activity than full-length HB-EGF was described (Cha *et al*., 2002). Further refinement of this receptor-blocking recombinant protein may lead to a new treatment for diphtheria without the possible side effects of serum sickness.

Since the catalytic activity of fragment A is not required for binding of diphtheria toxin to cognate receptor pro-HB-EGF, some non-toxic mutants of diphtheria toxin can bind the receptor with an affinity equal to that of wild-type toxin. The non-toxic mutant form of diphtheria toxin CRM197 (Uchida *et al*., 1973) has been studied extensively for its ability to act as a carrier in conjugate vaccines (discussed previously), and it is now being used to block the signaling activity of the receptor. The ability of the non-toxic CRM197 to bind the pro-HB-EGF receptor and inhibit this receptor's mitogenic activity (Mitamura *et al*., 1995) has provided the basis for the development of new methods to treat some forms of cancer. In some cancers, including ovarian cancer, pro-HB-EGF is overexpressed and shed. In such cancers, blocking the ability of pro-HB-EGF to signal using CRM197 has shown some promise as a therapy (Buzzi *et al*., 2004; Miyamoto *et al*., 2004). This area of research is likely to grow as the precise effects of pro-HB-EGF up-regulation on cancer development and spread are elucidated.

## USES OF THE DIPHTHERIA TOXIN C AND T DOMAINS IN TREATMENT OF DISEASE

The high potency of diphtheria toxin is advantageous to researchers who want to eliminate specific cell types efficiently. If the receptor-binding R domain of diphtheria toxin is replaced with another protein domain capable of recognizing specific cell surface expressed molecules, the catalytic C domain and the translocation T domain can be delivered specifically to cells that display such molecules. There are currently two types of molecules that have been fused to the C and T domains of diphtheria toxin with the goal of facilitating the delivery of the catalytically active portion of the toxin to specific cell types.

First, the C and T domains of diphtheria toxin have been fused to antibodies that recognize cell surface epitopes, and such constructs are called *immunotoxins*. Recombinant immunotoxins are antibody-toxin chimeric molecules that kill cells by binding to a surface antigen and delivering the toxin portion to the cell cytosol. Diphtheria toxin based immunotoxins are in development for use against several forms of leukemia and other cancers (FitzGerald *et al*., 2004; Frankel *et al*., 2001). Second, the C and T domains of diphtheria toxin have been fused to growth factors and cytokines that bind to specific cell surface receptors. The fusion proteins have included granulocyte macrophage-colony stimulating factor and IL-3, whose receptors are overexpressed on many acute myeloid leukemias, and IL-2, whose receptor is expressed by many lymphoma and leukemia cells (Hogge *et al*., 2004; Walker and Dang, 2004). The use of protein toxins in tumor therapy is discussed in more detail in Section V, Chapter 60.

## CONCLUSION

Years of studying the structure and function of diphtheria toxin and its receptor have made diphtheria toxin one of the best characterized bacterial protein toxins. The modular A-B structure of the toxin is amenable to manipulations that separate the catalytic domain from the translocation and receptor binding portions. In addition, the mechanism of ADP-ribosylation used by diphtheria toxin to modify its cellular target has provided a model for the action of other

ADP-ribosylating enzymes. All of this information is now being used for applications in a wide variety of biological science areas, including eukaryotic cell biology, developmental biology, signal transduction, protein translation, and cancer research.

Even though diphtheria toxin is well characterized, there are several important aspects of its action that merit further investigation. Two of these are the mechanism of translocation of the toxin across cellular membranes and the precise sequence of events that lead from toxic effects on particular cells, tissues, and organs to the death of the affected human or animal. In addition, the physiologic role of the target of diphtheria toxin, the diphthamide residue of EF-2, remains to be elucidated. The structure and function of diphtheria toxin, and uses of the toxin as a molecular tool to examine other biological problems, continue to be vigorous and productive areas of research more than 100 years after the discovery of diphtheria toxin.

CHAPTER

# 14

# *Pseudomonas aeruginosa* toxins

*Anthony W. Maresso, Dara W. Frank, and Joseph T. Barbieri*

## INTRODUCTION

Bacterial pathogens subvert host responses through multiple and diverse mechanisms, while eukaryotic organisms utilize innate and acquired immunity to prevent bacterial pathogens from establishing infections. A successful pathogen must initially permeate a network of barrier-forming cells, down-regulate or eliminate an innate and directed adaptive immune response, replicate, and then damage the host. Each bacterial pathogen damages the host by unique molecular mechanisms. *Pseudomonas aeruginosa* is a ubiquitous Gram-negative bacterium that has adapted to grow in diverse environments, from soil and water reservoirs to the mammalian lung. *P. aeruginosa* is an opportunistic pathogen that utilizes surface and secreted virulence factors, including a potent exotoxin and four type III secreted cytotoxins. The structural, molecular, and functional properties of these toxins will be discussed in this chapter.

*P. aeruginosa* is responsible for 16% of nosocomial pneumonia cases, 12% of hospital-acquired urinary tract infections, 8% of surgical wound infections, and 10% of bloodstream infections (Van Delden and Iglewski, 1998). *P. aeruginosa* is pathogenic to individuals who suffer from immune system complications, such as neutropenics and burn victims, or genetic disorders such as cystic fibrosis (CF) (Adams *et al*., 1998). Intrinsic resistance to antibiotics makes *P. aeruginosa* difficult to eradicate (Finland, 1972; Mendelson *et al*., 1994; Kazama *et al*., 1998). Cell surface and secreted virulence factors include endotoxin, fimbriae, flagella, proteases, phospholipases, iron siderophores, and alginate (Barbieri, 2000). Cytotoxins include exotoxin A (ETA), a classic AB exotoxin, and four type III cytotoxins, ExoS, ExoT, ExoY, and ExoU (Figure, 1 & Table 14.1). Each cytotoxin contributes uniquely to the pathogenic potential of *P. aeruginosa*.

### Exotoxin A

*P. aeruginosa* produces three ADP-ribosyltransferases: ETA, ExoS, and ExoT. Both ETA and ExoS contribute to pathogenesis, since strains of *P. aeruginosa* that are deleted for the genes encoding these proteins are less toxic than parental strains (Nicas *et al*., 1985; Nicas and Iglewski, 1985). ExoT has been linked to an anti-internalization activity of *P. aeruginosa* (Garrity-Ryan *et al*., 2000).

#### *Identification and AB structure-function properties of ETA*

Shortly after the determination that diphtheria toxin ADP-ribosylated elongation factor-2 (EF-2), ETA was isolated from the culture supernatant of *P. aeruginosa* and also shown to ADP-ribosylate EF-2 (Iglewski *et al*., 1977). ETA was initially cloned from the chromosome of *P. aeruginosa* strain PA103 and determined to encode a 638 amino acid protein that included a 30 amino acid N-terminal signal sequence (Gray *et al*., 1984). Unlike diphtheria toxin, which encoded an N-terminal catalytic domain, the catalytic domain of ETA was located in the C terminus (Figure 14.2) (Hwang *et al*., 1987). Unexpectedly, diphtheria toxin and ETA shared little primary amino acid homology. Subsequent studies showed that this is a general property of bacterial ADP-ribosylating exotoxins (bAREs). Despite having conserved structural active sites, these toxins share limited overall conservation of structure within the catalytic domain and possess a limited number of

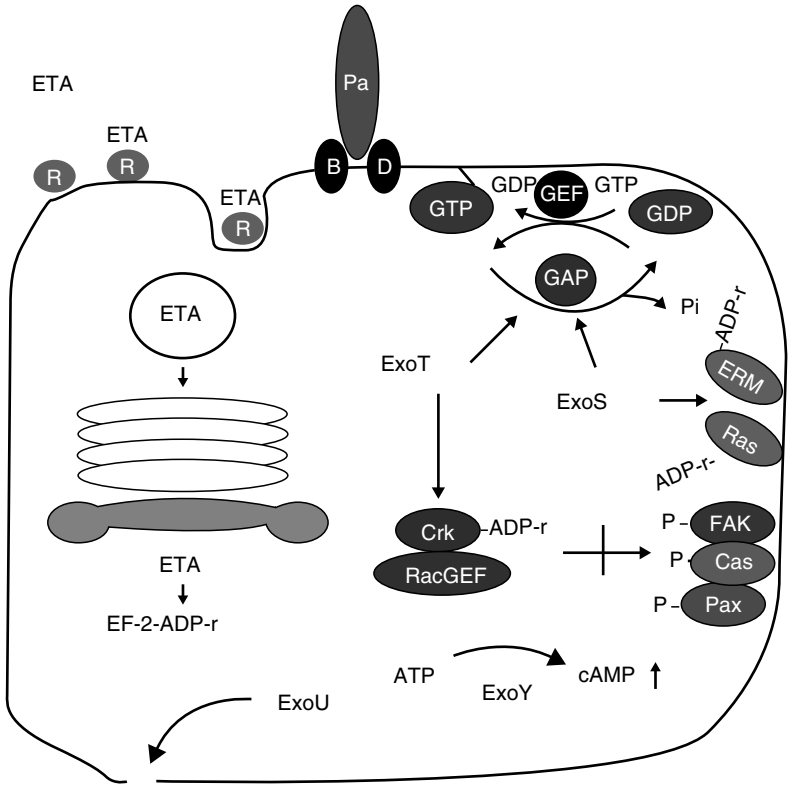

**FIGURE 14.1** *P. aeruginosa* translocates five toxins into eukaryotic cells. ETA is an AB exotoxin that is internalized via receptor-mediated endocytosis and transported to the ER. Upon release into the cytosol, ETA ADP-ribosylates EF-2. ExoS, ExoT, ExoY, and ExoU are type III delivered toxins that possess unique enzymatic activities. ExoS is poly-ADP-ribosylation specific and ADP-ribosylates numerous host proteins, including small molecular weight GTPases and the ERM proteins. ExoT ADP-ribosylates CrkI/II. The RhoGAP domain of ExoS and ExoT inactivate Rho, Rac, and Cdc42. The adenylyl cyclase activity of ExoY leads to supra-physiological levels of cAMP. ExoU is the most potent type III cytotoxin of *P. aeruginosa* that acts as a phospholipase.

**TABLE 14.1** Properties of *P. aeruginosa* toxins

| Toxin | Mw, pI, AA[a] | Enzymatic activity | Substrates[b] | Co-factor | Delivery | Other domains[c] |
|---|---|---|---|---|---|---|
| ETA | 68, 5.4, 638 | ADP-r | EF2 | No | receptor-mediated endocytosis | Leader sequence (1–30)<br>Receptor binding (1–252)<br>Translocation (253–364) |
| ExoS | 49, 5.5, 453 | ADP-r, GAP | ADP-r (GTPase, ERM), GAP (GTPase) | Yes (Fas) | type III | Secretion (1–15)<br>Chaperone (15–50)<br>MLD (51–77) |
| ExoT | 52, 5.5, 456 | ADP-r, GAP | ADP-r (Crk I/II), GAP (GTPase) | Yes (Fas) | type III | Secretion (1–15)<br>Chaperone (15–50)<br>MLD (51–77) |
| ExoY | 42, 5.4, 378 | Adenylate cyclase | NA | Yes (unknown) | type III | Secretion (1–15)<br>Chaperone (15–50) |
| ExoU | 74, 5.7, 687 | Phospholipase | Neutral/ Phospholipids | Yes (unknown) | type III | Secretion (1–15)<br>Chaperone (15–50) |

[a]Mw is in kDa, AA refers to the number of amino acids.
[b]ExoS ADP-ribosyltransferase can also modify vimentin(Coburn *et al.*, 1989a), apolipoprotein 1A, IgG (Knight and Barbieri, 1997), and the artificial substrate soybean trypsin inhibitor (SBTI) (Liu *et al.*, 1996).
[c]The secretion signal of ExoT, ExoY, ExoU, and the chaperone binding domain of ExoS, ExoT, and ExoY, and ExoU are inferred by analogy to *Yersinia* cytotoxins. The MLD of ExoT is inferred by analogy to ExoS.

conserved residues that are involved in catalysis. bAREs have AB structure-function properties; the A domain comprises the ADP-ribosyltransferase activity, while the B domain includes the receptor binding domain and the translocation domain, which delivers the A domain into eukaryotic cells (Figures 14.1 and 14.2). The three domains of ETA are discrete structures with an N-terminal receptor binding domain, an internal translocation domain, and C-terminal ADP-ribosyltransferase domain (Figure 14.2) (Allured *et al*., 1986).

### *Entry and intoxication of eukaryotic cells by ETA*

ETA expression is regulated by several factors, including iron (Carty *et al*., 2003). ETA is secreted from *P. aeruginosa* into the surrounding environment by the type II secretion pathway, which requires cleavage of an N-terminal signal sequence for export (McVay and Hamood, 1995). ETA binds the low-density lipoprotein receptor-related (LRP) protein on the surface of sensitive eukaryotic cells (Kounnas *et al*., 1992) and is internalized via receptor-mediated endocytosis. Like diphtheria toxin, ETA is activated by proteolytic processing and disulfide bond reduction. Furin, or a furin-like enzyme, cleaves ETA on the cell surface or after entry into the endosome on the C-terminal side of RQPR (amino acids 276–279 of ETA) (Chiron *et al*., 1994; Inocencio *et al*., 1994) and after disulfide bond reduction to generate a 37 kDa catalytic A domain (Ogata *et al*., 1990; Ogata *et al*., 1992). ETA possesses a C-terminal signal sequence, REDLK, which is functionally analogous to the eukaryotic KDEL sequence (Chaudhary *et al*., 1990). Upon cleavage of the C-terminal lysine, ETA retrograde traffics from the early endosome to the endoplasmic reticulum (ER). Similar to cholera toxin (Feng *et al*., 2004), the A domain of ETA is secreted from the lumen of the ER into the cytosol by the Sec63, a complex that eliminates improperly folded proteins from the lumen of the ER (Willer *et al*., 2003). The A domain ADP-ribosylates EF-2, blocking mRNA translocation within the ribosome complex, inhibiting eukaryotic cell protein synthesis (Lee and Iglewski, 1984).

Although the A domains of diphtheria toxin and ETA possess limited primary amino acid homology, the toxins share a common reaction mechanism that utilizes a conserved catalytic glutamic acid. Like Glu-149 of diphtheria toxin (Carroll *et al*., 1985), Glu-553 of ETA is necessary for ADP-ribosyltransferase activity (Carroll and Collier, 1987; Douglas and Collier, 1990).

## TYPE III SECRETION IN *P. AERUGINOSA*

*P. aeruginosa* delivers four cytotoxins directly into the host cell by the type III secretion system (Frank, 1997). The secretion and translocation of the *Pseudomonas* type III cytotoxins is analogous to the type III secretion system in *Yersinia* (Cornelis, 2002b). The genes encoding

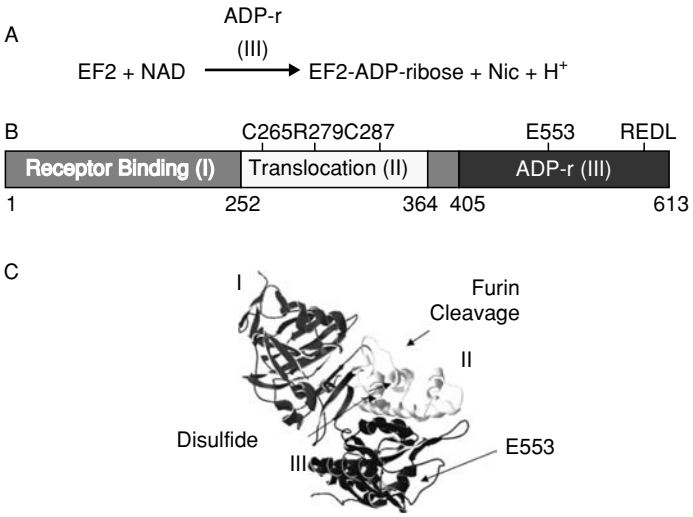

**FIGURE 14.2** Enzymatic activity, domain organization, and structure of ETA. A-B ETA is an AB exotoxin with three functional domains: an N-terminal receptor binding domain (1–252), an internal translocation domain (252–346), and a C-terminal ADP-ribosyltransferase domain (405–613). Glu-553 is a catalytic residue required for ADP-r activity. Cys-265 and Cys-287 form a disulfide bond that is reduced following proteolysis at Arg-279. **C** The crystal structure of ETA showing the three-dimensional arrangement of the domains (PDB, 1IKQ) (Wedekind *et al*., 2001).

the type III secretion system are clustered on the *P. aeruginosa* chromosome and designated *psc*, *pcr*, *exs*, and *pop*. *Psc* and *pcr* encode components of the type III secretion apparatus and *exs* are transcriptional regulators of the system (Frank, 1997). The type III apparatus is composed of 20 or more proteins with a diverse range of functions, which includes an ATPase (PscN) that provides energy for translocation and chaperones that maintain translocation competent conformation of the effectors in the cytoplasm of the bacterium. In addition to the type III apparatus, three proteins, PopB, PopD, and PcrV, provide passage of the type III cytotoxins across the eukaryotic membrane. Conservation of function between PopB, PopD, and PcrV and their *Yersinia* homologies underscore the conservation function of the type III apparatus of the two pathogens (Frithz-Lindsten *et al*., 1998; Broms *et al*., 2003).

## ExoS and ExoT

### *Identification of exoenzyme S*

The earliest studies of ExoS were performed on a protein complex that was termed e*xoenzyme S*. Exoenzyme S was initially identified as a second ADP-ribosyltransferase of *P. aeruginosa*, based upon the ability to ADP-ribosylate proteins that were distinct from EF-2, the preferred target for ADP-ribosylation by ETA (Iglewski *et al*., 1978). Exoenzyme S ADP-ribosylated many cellular proteins and was considered a broad specificity ADP-ribosyltransferase (Coburn *et al*., 1989b). exoenzyme S was purified from the spent culture media of *P. aeruginosa* strain 388 as an aggregate composed of two proteins with molecular masses of 53 kDa and 49 kDa. The 49-kDa form of ExoS possessed ADP-ribosyltransferase activity, while the 53-kDa form of exoenzyme S lacked detectable ADP-ribosyltransferase activity (Nicas and Iglewski, 1984). The genes encoding the 49-kDa and 53-kDa proteins were subsequently cloned and designated ExoS for the 49-kDa protein and ExoT for the 53-kDa protein (Kulich *et al*., 1994). Subsequent studies determined that while ExoS was a polysubstrate-specific ADP-ribosyltransferase, ExoT ADP-ribosylated a limited subset of mammalian proteins, including the Crk proteins (Sun and Barbieri, 2003). FASTA alignment predicts that the ExoS ADP-ribosyltransferase domain is more similar to eukaryotic ADP-ribosyltransferases than bacterial ADP-ribosyltransferases (Ganesan *et al*., 1999a), which is consistent with the broad substrate specificity observed for some eukaryotic ADP-ribosyltransferases (Okazaki and Moss, 1996).

ExoS (453 amino acids) and ExoT (457 amino acids) are bifunctional cytotoxins that possess linear functional domains. The N terminus encodes the type III recognition sequence and the chaperone binding domain; residues 51–77 comprise a membrane localization domain (MLD) that targets type III delivered ExoS and ExoT within the mammalian cell; residues ~96–219 comprise a Rho GAP domain, and the C-terminal ~220 residues comprise the ADP-ribosyltransferase domain.

### *Membrane localization domain (MLD)*

During early studies, ExoS purified from the culture supernatants of *P. aeruginosa* as an aggregate of >300 kDa (Kulich *et al*., 1993). This was consistent with a domain within ExoS that mediated self-association. Further studies identified a hydrophobic stretch of amino acids between residues 51–72 (subsequently termed the *membrane localization domain*, MLD) of ExoS that was responsible for the aggregative properties and for the localization of ExoS to a membrane fraction after delivery into mammalian cells. Corroborative studies showed that MLD targeted ExoS to a Golgi-ER-like region inside mammalian cells (Pederson *et al*., 2002). Deletion of the MLD resulted in the loss of ExoS aggregation and the homogenous purification of the toxin in *E. coli* (Maresso and Barbieri, 2002), suggesting that the MLD was also responsible for the self-association. Deletion of the MLD also facilitated the study of ExoS-specific conformers, a charge heterogeneity of ExoS observed by 2D-electrophoresis thought to be related to the ability to transverse lipid bilayers upon type III translocation (Maresso *et al*., 2003). The MLD targeted ExoS to Ras, ExoS that lacked the MLD modified Ras inefficiently *in vivo,* but not *in vitro* (Riese and Barbieri, 2002). A leucine-rich motif within the MLD was responsible for targeting ExoS to the Golgi-ER region of mammalian cells (Zhang and JTB, submitted).

### *RhoGAP Domain of ExoS and ExoT*

The RhoGAP domains of ExoS and ExoT are functionally identical. An early indication that ExoS possessed a second catalytic activity was predicted from the determination that mutated ExoS that lacked ADP-ribosyltransferase activity retained partial capacity to stimulate the reorganization of the actin cytoskeleton (Frithz-Lindsten *et al*., 1997). Subsequent studies showed that a peptide comprising the N-terminal 234 amino acids of ExoS stimulated the reorganization of the actin cytoskeleton (Pederson and Barbieri, 1998). This morphological change was reversed by CNF1, a known activator of Rho, implicating the inactivation of the Rho pathway (Pederson *et al*., 1999). *In vitro* studies identified ExoS(1-234) as a Rho GTPase Activating Protein or (GAP) that facilitated the inactivation of Rho, Rac, and Cdc42 by hydrolyzing the γ–phosphate from GTP-bound Rho (Figure 14.3). Similar to the

mammalian RhoGAPs, ExoS RhoGAP utilized a catalytic arginine (Arg-146) to stimulate GAP activity (Figure 14.3) (Goehring *et al*., 1999). The GAP domain of ExoS has little structural homology to the mammalian p50RhoGAP, but utilizes a similar mechanism to stimulate GTPase activity. The p50RhoGAP inserts a catalytic arginine into the active site of the Rho GTPase to indirectly stabilize a catalytic $H_2O$ in the transition state of the GAP reaction (Wurtele *et al*., 2001), while ExoS RhoGAP inserts the primary chain carboxyl group of Gly141 to indirectly stabilize the catalytic $H_2O$. In cultured cells, Rho, Rac, and Cdc42 were inactivated by type III delivered ExoS Rho GAP (Krall *et al*., 2002), promoting deregulation of the actin cytoskeleton, actin stress fiber formation, and cell rounding. YopE, the *Yersinia* homologue to the RhoGAP domain of ExoS, prevented phagocytosis of *Yersinia* (Black and Bliska, 2000), supporting a role for the inactivation of the Rho GTPases in the down-regulation of phagocytosis.

ExoT was a GAP for Cdc42, Rac, and Rho *in vitro* and elicited cell rounding *in vivo*, presumably through the same mechanism as ExoS (Krall *et al*., 2000; Pederson *et al*., 2002). Arg-149 (Figure 14.3B) is required for the Rho GAP activity of ExoT. The Rho GAP activity of ExoT prevents phagocytosis of *P. aeruginosa* (Garrity-Ryan *et al*., 2000).

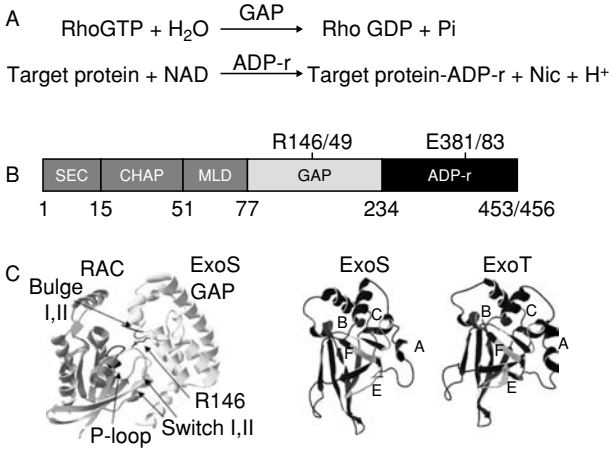

**FIGURE 14.3** Enzymatic activity, domain organization, and structures of ExoS and ExoT. (A-B) ExoS/T Rho GAP activity (96-234) act to stimulate the hydrolysis of the terminal phosphate from GTP bound Rho GTPases to make RhoGDP, thus inactivating the Rho pathway. ExoS/T ADP-ribosyltransferase activity (ExoS/ExoT) (235-453/456) covalently attaches and ADP-ribose moiety from NAD onto target substrates. (C) Left panel: The co-crystal of the complex between the Rho GAP domain of ExoS (right) and Rac (left), showing the catalytic arginine (146) inserting into the active site of Rac (PDB, 1HE1) (Wurtele *et al*., 2001). Bulge one and two regions, important in coordinating Arg-146, are shown. The P-loop, important for nucleotide binding, and the switch I and II regions, important in the intrinsic GTPase reaction of Rac, are indicated. Right panel: Modeled three-dimensional structures of ExoS and ExoT (Sun, *et al*., 2004).

### *ADP-ribosyltransferase domain of ExoS*

The ADP-ribosyltransferase domain lies within the C-terminal 220 amino acids of ExoS (Knight *et al*., 1995). ExoS is a biglutamic acid transferase; Glu-379 contributes to the transfer of ADP-ribose to target proteins, while Glu-381 is required for catalysis (Liu *et al*., 1996; Radke *et al*., 1999). Mutation of Glu-381 to aspartic acid-reduced catalysis ~2000-fold (Liu *et al*., 1996).

The first substrate of ExoS was vimentin, an actin cytoskeleton-associated protein (Coburn *et al*., 1989a). Subsequently, ExoS was shown to ADP-ribosylate numerous mammalian proteins, including several small-molecular-weight monomeric GTPases and itself (Coburn and Gill, 1991; Riese *et al*., 2002). Ras is the most extensively characterized substrate of ExoS. Ras regulates several cellular signal transduction pathways that are involved in differentiation, growth, and survival (Wiesmuller and Wittinghofer, 1994). ExoS ADP-ribosylates Ras at two arginines. Arg-41 is the preferred site and Arg-123 is the secondary site for ADP-ribosylation. Arg-41 and Arg-123 lie on distinct surfaces of Ras, indicating that ExoS can bind Ras in multiple conformations (Ganesan *et al*., 1998). ADP-ribosylation at Arg-41 blocks the association of Ras with its cognate *G*uanine *E*xchange *F*actor (GEF), preventing the activation of Ras (Ganesan *et al*., 1999b). Type III delivered ExoS ADP-ribosylates Ras in cultured cells (McGuffie *et al*., 1998; Henriksson *et al*., 2002; Riese and Barbieri, 2002), suggesting a functional role for Ras ADP-ribosylation *in vivo*.

ExoS also ADP-ribosylates Rap (Riese *et al*., 2001), RalA (Fraylick *et al*., 2002), Rac, Rab, and Cdc42 (Henriksson *et al*., 2002). Like Ras, ADP-ribosylation uncouples the interaction Rap with its cognate GEF, C3G (Riese *et al*., 2001), suggesting that ExoS uses a common inhibition mechanism to modulate host signal transduction pathways. Recently, ExoS has been shown to ADP-ribosylate the ezrin/radixin/moesin (ERM) proteins with high affinity both *in vitro* and during infection (Maresso *et al*., 2004). ERMs are regulators of Rho activation and are bridges between the actin cytoskeleton and receptor complexes. Inhibition of ERM function could lead to a loss of actin-rich structures, such as microvilli or down-regulation of the Rho signaling pathway (Mangeat *et al*., 1999).

### *ADP-ribosyltransferase domain of ExoT*

ExoT was originally proposed to be a precursor of ExoS. ExoT and ExoS were subsequently shown to be encoded by separate genes. ExoT ADP-ribosylated several substrates of ExoS at ~0.2% of the rate of ExoS

and appeared to encode a defective enzyme (Liu *et al*., 1997), despite sharing 76% primary amino acid homology with ExoS. The limited ADP-ribosyltransferase activity of ExoT required two glutamic acids, Glu-383 and Glu-385 (Figure 14.3B). Recent studies showed that ExoT elicited morphological changes to cultured cells, distinct from ExoS (Sun and Barbieri, 2003) and independent of Ras signal transduction (Sundin *et al*., 2001). ExoT was then implicated in the inhibition of lung epithelial wound repair (Geiser *et al*., 2001), and ExoT mutated for GAP activity retained anti-internalization activity (Garrity-Ryan *et al*., 2000), suggesting the ADP-ribosyltransferase domain had an unidentified function. These observations stimulated a more detailed characterization of the ADP-ribosyltransferase activity, which led to the determination that ExoT efficiently ADP-ribosylated the Crk proteins (Sun and Barbieri, 2003). Crk proteins contain SH2 and SH3 domains and are adaptors at focal adhesion sites, promoting cytoskeleton dynamics through the integrin pathway. Upon stimulation of the integrin receptors, Src kinase phosphorylates paxillin, focal adhesion kinase, and p130Cas within the focal adhesion complex. Paxillin-P and p130Cas-P bind the Crk SH2 domain, while the Crk SH3 domain binds to downstream exchange factors, the Rac GEF, DOCK180, and the Rap GEF, C3G (Tanaka *et al*., 1994). ADP-ribosylation of Crk I and Crk II may inhibit upstream interactions with Paxillin-P and p130Cas-P or downstream interactions with C3G or DOCK180, which may be a mechanism of *P. aeruginosa* ExoT-mediated anti-phagocytic action.

### *Substrate recognition by ExoS and ExoT ADP-r domains*

One of the intriguing questions in *P. aeruginosa* toxin biology is why both ExoS and ExoT ADP-ribosylate such diverse sets of host proteins. Diphtheria toxin, *E. coli* heat-labile enterotoxin, ETA, Pertussis toxin, and C3 exoenzyme have overall structural homology within the NAD binding cleft (Han *et al*., 2001). The C3 structure, which ADP-ribosylates Rho GTPases (Chardin *et al*., 1989; Mohr *et al*., 1992), has two adjacent turns within the NAD binding cleft that are predicted to be important for substrate recognition (Aktories *et al*., 1995). The first turn coordinates Phe-209 to interact with a hydrophobic stretch in the active site of Rho, while the second turn orients Gln-212 to hydrogen bond with Asn-41 of Rho for the nucleophilic attack on the NAD-ribose. This reaction mechanism was supported by mutations in Tyr-175 (Phe-209 of C2) of C3stau, which reduced ADP-ribosyltransferase activity (Wilde *et al*., 2002). The structures of ADP-ribosylating toxins Iota (Tsuge *et al*., 2003) and Vip2 (Han *et al*., 1999) define an ADP-ribosylating toxin-turn turn (ARTT) motif for substrate recognition.

Molecular modeling of the ADP-ribosyltransferase domains of ExoS and ExoT defined several regions that contribute to substrate recognition. Three loops surrounding the site of NAD binding defined ExoS substrate specificity, while an α-helix adjacent to the site of NAD binding defined the ExoT substrate specificity (Figure 14.3). Thus, although the overall shape of the active sites between ExoS and ExoT were similar (Figure 14.3C), the electrostatic potential appears to define substrate recognition with the polysubstrate specific ExoS being a mixture of acidic, basic, and neutral residues, while the Crk specific ExoT contains only an acidic surface (Sun *et al*., 2004).

## ExoY

### *ExoY, an adenylyl cyclase secreted directly into eukaryotic cells*

Comparison of extracellular protein profiles from parental and type III secretory mutants combined with the availability of genomic sequence facilitated the identification of a 42-kDa protein (378 amino acids), termed ExoY (Yahr *et al*., 1997; Yahr *et al*., 1998). The coordinate regulation of ExoY synthesis with other type III proteins, its extracellular localization, and the absence of a signal peptide sequence indicated ExoY as type III secreted protein (Yahr *et al*., 1998). ExoY contains two conserved regions (Regions I and II) that align with the adenylyl cyclases from *Bordetella pertussis* (CyaA) and *Bacillus anthracis* (edema factor, EF) (Escuyer *et al*., 1988; Mock *et al*., 1988). Region I, an ATP/GTP binding A motif, is postulated to be a contact point for the α-phosphate of the bound nucleotide (Glaser *et al*., 1991). Region II is common to various nucleotide-binding proteins and mediates interaction between the β and γ phosphates (Glaser *et al*., 1991). CyaA and EF both possess an additional region of homology (Region III) and a calmodulin binding site, which is absent in ExoY (Yahr *et al*., 1998). These data indicate that ExoY is a bacterial adenylyl cyclase delivered directly into eukaryotic cells by the type III secretion system of *P. aeruginosa*.

### *Enzymatic activity of ExoY*

Adenylyl cyclase activity of ExoY was demonstrated *in vitro* using a recombinant protein and HPLC separation of reaction products. The formation of cAMP from ATP was sensitive to phosphodiesterase

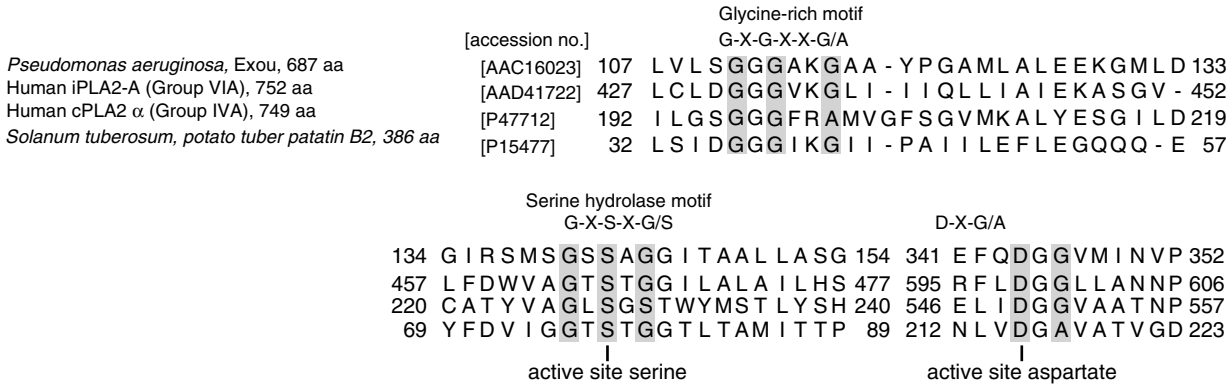

**FIGURE 14.4** Enzymatic activity and domain organization of ExoU. The alignment of ExoU (amino acids 107–133, 134–154, and 341–352) with the patatin-like phospholipase $A_2$ domains of human $iPLA_2$ (Group VIA), 752 aa; human $cPLA_2$ (Group IVA), 749 aa; and potato tuber patatin B2, 396 aa. Conserved amino acid residues among listed proteins are shaded and the catalytic amino acids are labeled.

inhibitors. Mutagenesis of conserved amino acid residues predicted to be involved in ATP binding (K81M, K88I, Region I and D212N, D214N, Region II) abolished *in vitro* adenylyl cyclase activity of ExoY. Substitution of GTP for ATP did not result in the formation of cGMP. Unlike CyaA and EF, calmodulin did not stimulate ExoY adenylyl cyclase activity, which is consistent with the absence of a calmodulin-binding domain in ExoY. The basal adenylyl cyclase activity of ExoY, however, was stimulated approximately 500-fold by a cytosolic extract of an epithelial cell line, Chinese hamster ovary (CHO) cells. The eukaryotic cofactor appears to be heat labile, but has not yet been identified.

### *Biological consequences of ExoY intoxication*

*In vivo*, ExoY is delivered into cultured cells by the type III secretion system (Yahr *et al*., 1998; Sawa *et al*., 1999). Mutations in proteins involved in type III translocation or secretion inhibit ExoY intoxication. Type III delivered ExoY intoxicates CHO cells by increasing intracellular cAMP, which correlates with a rounded cell morphology. Treatment of CHO cells with pertussis toxin or heat-labile enterotoxin also induces intracellular cAMP synthesis, but results in a different morphological change characterized as clustering. The differential changes in the cytoskeletal architecture may be related to the localization of ExoY relative to other toxins or to effects on endogenous mammalian adenylyl cyclases. In pulmonary microvascular endothelial cells (PMVEC), synthesis of cAMP increases tight junction complexes at cell-to-cell borders and prevents intercellular gap formation that occurs during inflammatory processes. This phenomenon is due to membrane-associated adenylyl cyclases that increase cAMP concentrations in plasma membrane microdomains. The pool of cAMP synthesized by ExoY that is injected during infection appears distinct from the endogenous pool of cAMP associated with the barrier function of endothelial cells (Sayner *et al*., 2004). Evidence to support this model includes the predominant cytoplasmic localization of ExoY during infection of PMVEC and the insensitivity of the ExoY-mediated cAMP pool to *in vivo* phosphodiesterase activity. In perfused lungs, ExoY expression correlates to increased endothelial permeability (Sayner *et al*., 2004). These data indicate that unlike the membrane-associated pools of cAMP that protect barrier function, injection and expression of cytoplasmically localized ExoY disrupts cytoskeletal components to result in intercellular gaps. Further, the insensitivity of cytoplasmic cAMP to phosphodiesterase regulation augments the longevity of the biologic response. Thus, expression of ExoY *in vivo* may increase fluid accumulation in tissues and worsen inflammation.

## ExoU

### *Differential phenotypes suggest that another cytotoxin is associated with the type III secretory system, the discovery of ExoU*

When administered to animals or in tissue culture infections, *P. aeruginosa* demonstrates observable variations in cytotoxicity and virulence. This property was used to identify ExoU, a potent phospholipase that is injected into target cells by the type III system. The original observation leading to the discovery of ExoU

showed that some strains of *P. aeruginosa* caused an acute cytotoxic response and cleared cultured cells within a few hours of infection (Fleiszig *et al*., 1997). The toxic activity was linked to the type III system due to its dependence on the transcriptional activator, ExsA, but was unrelated to ExoS, ExoY, or ExoT expression (Finck-Barbancon *et al*., 1997; Fleiszig *et al*., 1997; Yahr *et al*., 1998). All the strains that induced the acute cytotoxic response secreted a 72–74 kDa protein after growth in calcium-limited medium, a condition that induces type III secretion in *P. aeruginosa* (Finck-Barbancon *et al*., 1997). Transposon mutagenesis identified strains that possessed a specific chromosomal insertion within *exoU* (Finck-Barbancon *et al*., 1997; Kang *et al*., 1997; Hauser *et al*., 1998). Transposon mutants and strains specifically engineered to delete *exoU* no longer caused acute cytotoxicity and were complemented for this phenotype when *exoU* was provided in *trans*.

### *The mechanism of action of ExoU*

Determining the mechanism of action of ExoU was difficult. Transfection experiments suggested that minimal expression of ExoU caused cell death (Finck-Barbancon and Frank, 2001). When different subclones were used in co-transfection studies, several regions of ExoU appeared to be required but not sufficient for cytotoxicity. Controlled expression of ExoU in *Saccharomyces cerevisiae*, however, provided a genetically tractable model system with commercially available immunological reagents to accurately determine the biological events preceding cell death (Sato *et al*., 2003). These experiments revealed that ExoU was responsible for a vacuolar fragmentation phenotype. In addition, ExoU appeared to be affecting other organelles, as immunofluorescent signal intensity increased for markers located in mitochondria, late Golgi, and endosomes (Sato *et al*., 2003). Various inhibitors were tested to determine if ExoU cytotoxicity could be suppressed (Phillips *et al*., 2003; Sato *et al*., 2003). These studies indicated that irreversible inhibitors of calcium-independent ($iPLA_2$) and cytosolic ($cPLA_2$) phopholipase $A_2$ prevented cytotoxicity and allowed immunologic detection of full-length ExoU. The range of biologic effects and the specificity of the inhibitors indicated that ExoU likely possessed phospholipase activity.

ExoU aligns with patatin, a soluble storage protein of potato tubers, human $cPLA_2$, $iPLA_2$, as well as a number of bacterial encoded enzymes (Sato and Frank, 2004). The alignment of ExoU with patatin, $cPLA_2$, and $iPLA_2$ identified serine 142 and aspartate 344 as potential catalytic amino acids. Site-specific mutagenesis of S142 and D344 to alanine suppresses toxicity, supporting

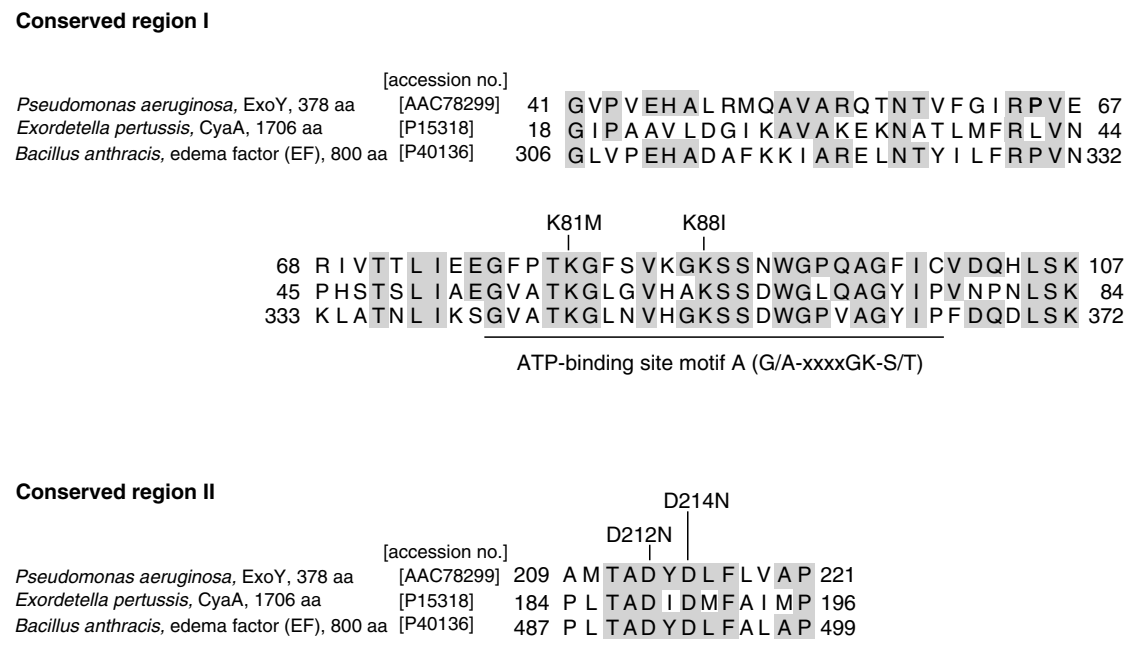

**FIGURE 14.5** Enzymatic activity and domain organization of ExoY. PILEUP alignment of the conserved regions I and II within ExoY, the adenylate cylase toxin from *Bordetella pertussis* (CyaA), and the edema factor from *Bacillus anthracis* (EF) adenylate cyclases are shown. Residues within CyaA and EF that are homologous to ExoY are shaded. Position of the ATP-binding site motif is shown.

the prediction that ExoU belongs to the family of enzymes utilizing a catalytic dyad (Phillips *et al*., 2003; Sato *et al*., 2003). These data suggest that the amino-terminal half of ExoU contains the catalytic domain. The catalytic domain of $cPLA_2$ is composed of the serine-aspartate dyad and a flexible lid that requires interfacial activation to access phospholipid substrates (Nalefski *et al*., 1994). ExoU, however, does not appear to possess a calcium-dependent lipid-binding domain. It is also unclear whether ExoU contains a flexible lid or requires interfacial activation.

A host protein also appears to activate phospholipase activity of ExoU. While *in vivo* expression of ExoU is detectable in yeast and mammalian cells by measuring the changes in phospholipid profiles upon induction (Phillips *et al*., 2003; Sato *et al*., 2003; Sato and Frank, 2004; Sato *et al*., 2005), the activity of purified recombinant protein was detectable only in the presence of crude yeast or mammalian cell extracts (Sato *et al*., 2003; Sato and Frank, 2004). These data indicate that similar to ExoS, ExoT, and ExoY, a cofactor is required for ExoU phospholipase activity. The cofactor appears to be limited to eukaryotic extracts, as prokaryotic lysates do not activate ExoU. ExoU will hydrolyze liposomes that simulate bacterial membranes, indicating that the apparent specificity of ExoU for eukaryotic membranes is related to the presence of the cofactor. Biochemically, the cofactor is susceptible to heat denaturation and to proteases, implicating that part of this activity is due to a protein or a protein complex (Sato *et al*., 2005).

### Mammalian proteins are cofactors for the *Pseudomonas* type III cytotoxins

Each of the four type III cytotoxins of *P. aeruginosa* utilize a mammalian protein to stimulate their activity. ExoS and ExoT ADP-ribosyltransferase activity is dependent on a eukaryotic cofactor termed factor activating ExoS (FAS) (Coburn *et al*., 1991). FAS is a member of the 14-3-3 family of ubiquitous proteins (Fu *et al*., 1993), which have diverse functions ranging from being scaffolds for signal transduction cascades to apoptosis. The exact mechanism by which ExoS is activated by FAS is unknown, but appears to be allosteric in action (Knight and Barbieri, 1999). The interaction site of FAS and ExoS is through an amphiphatic region on FAS (Masters *et al*., 1999) and a DALDA sequence at the C terminus of ExoS (Hallberg, 2002), which may mimic a negative charge normally present on eukaryotic proteins that bind FAS. ExoU (Sato *et al*., 2003) and ExoY (Yahr *et al*., 1998) activities are also stimulated by the addition of a mammalian cell lysate, implying that like ExoS and ExoT, they utilize a mammalian protein to activate their intrinsic catalytic activity. The utilization of eukaryotic cofactors by the *Pseudomonas* type III cytotoxins implies the importance of the posttranslational regulation of these enzyme activities. This may be related to the fact that these cytotoxins are synthesized and maintained in the cytosol of the *Pseudomonas*, presumably in full-length, catalytically active forms prior to secretion through the type III secretion apparatus.

## DISCUSSION

#### *Role of* Pseudomonas *cytotoxins in pathogenesis*

ETA and the type III cytotoxins play complementary roles toward establishing and maintaining *P. aeruginosa* within the host and ultimately harming the host. Whereas ETA acts at a distance from the site of infection, type III cytotoxins are delivered into host cells by direct contact-mediated injection into the host cell and therefore act locally to the site of infection. ETA is secreted into the extracellular environment (McVay and Hamood, 1995) and transported throughout the host to target tissues and organs. ETA binds to the mammalian cell through the alpha 2-macroglobulin receptor/low-density lipoprotein receptor-related protein, which internalizes ETA via receptor-mediated endocytosis (Kounnas *et al*., 1992). Since the receptor is widely distributed and numerous organs and tissues can be harmed, ETA provides *P. aeruginosa* an advantage by compromising host functions that are beyond the site of colonization. The production of ETA as a proenzyme that is activated at the cell surface by furin (Inocencio *et al*., 1994) provides a mechanism to stabilize the toxin during transport throughout the cell. In contrast, the direct injection of the type III cytotoxins into a host cell provides the immediate ability to compromise macrophages and neutrophils that respond to the initial colonization of the host by *P. aeruginosa*.

#### *Multiple catalytic activities of ExoS and ExoT, analogous to the type III cytotoxins of* Yersinia *and* Salmonella

The discovery that ExoS and ExoT are bifunctional enzymes, as opposed to the more typical situation where a toxin encodes a single enzymatic activity, raises an interesting issue about their role in *P. aeruginosa* pathogenesis, including the coordination, potency, and specificity in the modulation of host cell physiology.

*Coordination: Salmonella* invades mammalian cells by modulating the cell cytoskeleton through the sequential action of two type III cytotoxins. Initially, SopE activates Rho GTPases to promote invasion (Galan, 2001) and subsequently, SptP inactivates Rho GTPases to

reverse actin reorganization required for uptake (Galan, 2001). The two opposing activities are temporally modulated to allow *Salmonella* to effectively invade a mammalian cell where differential stability of the two proteins within the cell allows the invasion phenotype (Kubori and Galan, 2003). In contrast, the expression of two independent catalytic activities within ExoS and ExoT imply the importance of a coordinated expression of Rho GAP and ADP-ribosylation at a similar stage of the infection.

*Potency: Yersinia* utilize multiple cytotoxins to dampen the host immune response to infection, which coordinately inactivate actin organization and downregulate host immune response (Cornelis, 2002a). Although the deletion of one *Yersinia* type III cytotoxin often yields only a limited effect on pathogenesis, deletion of multiple cytotoxins with similar or unique functions can have profound effects on virulence (Logsdon and Mecsas, 2003). Thus, the effective inactivation of host defense mechanisms requires multiple bacterial virulence factors. This may parallel the type III cytotoxins of *P. aeruginosa*, where the expression of RhoGAP and ADP-ribosyltransferase activities function in concert to efficiently inactivate one or more signal transduction pathways. Support of this concept comes from the recent finding that ExoS ADP-ribosylates the ERM proteins during an infection (Maresso and Barbieri, in press). ERM proteins modulate Rho activation by facilitating the removal of Rho GDI from inactive Rho GTPases and potentially complementing RhoGAP activity. Likewise, the recent determination that ExoT ADP-ribosylates the Crk proteins (Sun and Barbieri, 2003) provides a second mechanism for the inactivation of Rac signaling that can augment Rho GAP activity. Inactivation from two different upstream mechanisms would provide potent and efficient inactivation of Rho signal transduction.

*Specificity*: Another role for bifunctionality may be related with the wide range of environments that *P. aeruginosa* inhabits, from soil to a mammalian host. To adapt to this wide range of conditions, *P. aeruginosa* may need multiple, overlapping adaptive mechanisms where the RhoGAP or ADP-ribosyltransferase activities may not have evolved to function within the same environmental niche.

### *Covalent versus non-covalent modification of host cell proteins; analogous, but unique to* **Salmonella**

The discovery of bacterial GAPs, GEFs, and adenylyl cyclases add another dimension to toxin biology: modulation of host cell physiology by non-covalent mechanisms. The acquisition of a non-covalent enzymatic activity by a bacterial pathogen to modulate host cell physiology may allow a framework to modulate the infectious cycle. This strategy is also illustrated in *Salmonella*, with SopE and SptP. In contrast, covalent modifications are permanent, unless a host enzyme can remove the modification. Thus, non-covalent modifications allow the bacterium to temporally control the extent and timing of host cell modification.

## CONCLUSION

Since the initial discoveries of ETA and exoenzyme S, progress has been made in characterizing cytotoxins of *P. aeruginosa*. Their analysis has led to insights into not only toxin biology and virulence mechanisms by pathogenic bacteria, but also the physiology of the mammalian cell. Understanding the function of *P. aeruginosa* cytotoxins may also lead to therapies to control the pathogenesis of this unique and versatile microorganism. Advances in understanding the action of ETA have also led to the development of therapies to cure specific cancers through immunotherapy (FitzGerald *et al*., 2004), while characterization of the type III secretion system may lead to novel strategies for early detection (Banwart *et al*., 2002) and therapies (Frank *et al*., 2002) to control *P. aeruginosa* infections.

CHAPTER

# 15

# *Vibrio cholerae* and *Escherichia coli* thermolabile enterotoxin

*Timothy R. Hirst and Jocelyne M. D'Souza*

## INTRODUCTION

Historical accounts of cholera-like disease date back to the times of Hippocrates and Buddha (Barua, 1991), and today the devastating impact of cholera is still evident in developing countries. Cholera toxin (Ctx) from *Vibrio cholerae*, and subsequently the closely related heat-labile enterotoxins (Etx) from certain toxigenic strains of *Escherichia coli* were among the earliest bacterial toxins to be characterized. In the past 25 years there has been a growing appreciation that the cholera toxin family of thermolabile enterotoxins has provided an inspirational insight into some of the great themes of microbial pathogenicity. For example, studies on the biogenesis of Ctx in *V. cholerae* have provided important insights into the mechanisms of gene regulation and protein secretion in bacteria, and resulted in Ctx being a paradigm of virulence factor expression. Studies on the interaction of Ctx and Etx in epithelial cells have illuminated the mechanisms by which the toxins cause severe, and at times, life-threatening disease. Moreover, they have provided considerable insight into the cellular events associated with vesicular movement and targeting, a central feature of eukaryotic cell biology.

A scant survey of the number of papers citing cholera toxin that are listed by PubMed reveals that number will soon pass 10,000. This startlingly high number reflects the magnitude of research into these molecules, as well as the widespread use of cholera toxin as a biochemical reagent to elevate cAMP in mammalian cells, and to its ever growing use as a vaccine adjuvant. Such applications and uses of cholera toxin and *E. coli* thermolabile enterotoxins are not covered in this chapter; it instead focuses on the remarkable "life and times" of these toxins, from the genetics of toxin expression, assembly, and secretion in the bacteria, to their interaction, uptake, and action in disease.

## CHOLERA AND RELATED ENTEROPATHIES

Robert Koch, the great German bacteriologist, established that a "comma-bacillus," now called *V. cholerae* serogroup O1, was the causative agent of Asiatic cholera (Koch, 1884). The organism, which is transmitted in contaminated water, colonizes the surface of the small bowel and induces the production of copious quantities of watery diarrhea. The rapid spread of the organism and its capacity to reduce a previously healthy individual to the point of death in as little as 6–8 hours made cholera a disease to be feared. However, with the widespread introduction of fluid and electrolyte replacement therapies (intravenous or oral), the mortality rate can be reduced to less than 1%.

Nonetheless, the devastating impact of cholera is all too evident, as seen in the Rwandan refugee camps in 1994 when an estimated 600,000 cases of cholera occurred over a three-week period, including 45,000 deaths (Waldman, 1998). The worldwide incidence of cholera is difficult to evaluate, although it has been estimated that there are approximately 8 million cases per annum, including 124,000 deaths (Black, 1986). In

1992, a new serogroup of *V. cholerae* emerged that caused a large number of cholera cases and deaths in India and Bangladesh alone during the first three months of 1993 (Albert *et al.*, 1993; Sack *et al.*, 1996). The strain did not react with antibodies against the O1-antigen or any of the other 137 non-O1 serogroups and has been designated O139. Although *V. cholerae* O139 produces a different O-antigen, it shares many pathogenic features with *V. cholerae* O1 (biotype El Tor), including production of Ctx (Nakashima *et al.*, 1995).

In 1956, S.N. De noted that the common gut bacterium *E. coli* was also capable of producing a cholera-like disease (De *et al.*, 1956). By the early 1970s, it was clear that enterotoxigenic *E. coli* (ETEC) were of global significance as agents of diarrheal disease in both humans and domestic animals. ETEC have a worldwide distribution, but their significance as human pathogens is most evident in developing countries, where it has been estimated that approximately 20% of all acute (life-threatening) diarrheal cases in children under 5 years of age are due to ETEC (Evans *et al.*, 1977; Black *et al.*, 1980; Agbonlahor and Odugbemi, 1982; de Mol *et al.*, 1983; Echeverria *et al.*, 1985; Steffen, 1986). The secretory diarrhea produced by ETEC is due to its ability to produce either an oligomeric heat-labile enterotoxin (Etx) that is structurally and functionally homologous to Ctx (see below) or a heat-stable enterotoxin (ST) or both (Nataro and Kaper, 1998).

## STRUCTURE OF CHOLERA TOXIN AND RELATED ENTEROTOXINS

Purification and structural analysis of cholera toxin (Ctx) from sterile culture filtrates of *V. cholerae* was first attempted in 1966 (Finkelstein *et al.*, 1966), but it was not until the successful crystallization and X-ray analyses of Ctx almost 30 years later that the toxin arrangement of six non-covalently associated subunits was confirmed (Zhang *et al.*, 1995). Ctx is now well-characterized as a hexameric protein toxin comprised of a single A-subunit (240 amino acids with a molecular weight of 27,500 Da) arranged on a toroidal ring of five B-subunits (103 amino acids each with a molecular weight of 11,800 Da). When Ctx was analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) under non-reducing conditions, the A-subunit migrated as a single polypeptide with an apparent electrophoretic mobility of *about* 28,000 Da, but under reducing conditions, separated into two polypeptides, A1 ($M_r$ = ~22,000) and A2 ($M_r$ = ~5500), corresponding to the N-terminal and C-terminal fragments of the A-subunit, respectively (Gill, 1975).

### Primary sequence

The primary amino acid sequences of the A- and B-subunits of Etx derived from ETEC strains isolated from humans (hEtx), pigs (pEtx), chickens (cEtx), and Ctx (derived from classical and *El Tor* strains of *V. cholerae* O1 and *V. cholerae* O139) have been deduced (Dallas and Falkow, 1980; Gennaro *et al.*, 1982; Spicer and Noble, 1982; Dallas, 1983; Gennaro and Greenaway, 1983; Lockman and Kaper, 1983; Mekalanos *et al.*, 1983; Yamamoto *et al.*, 1984; Yamamoto *et al.*, 1987; Leong *et al.*, 1985; Takao *et al.*, 1985; Sanchez and Holmgren, 1989; Brickman *et al.*, 1990; Dams *et al.*, 1991; Inoue *et al.*, 1993).

Figure 15.1 shows a comparison of the complete amino acid sequences of the A- and B-subunits of Ctx from the classical *V. cholerae* O1 strain 569B and those of hEtx from an *E. coli* strain, H74-114, of human origin (Leong *et al.*, 1985; Dams *et al.*, 1991). From the sequence, it was apparent that both the A- and B-subunits of Ctx and Etx are synthesized as longer precursors with amino-terminal signal sequence extensions of 18 and 21 amino acids, respectively (denoted by negative numbers in Figure 15.1). Such signal sequences are involved in targeting precursors to the cytoplasmic membrane and are cleaved off during translocation to yield a mature polypeptide.

The mature A-subunits of Ctx (CtxA) and Etx (EtxA), shown in Figure 15.1, are 240 amino acids in length and share considerable sequence identity (82.1%). Similarly, the mature B-subunits (CtxB and EtxB) are comprised of 103 amino acids and share 83.5% identity. The only region where there is little homology between Etx and Ctx is between amino acid residues 190 and 212 of the A-subunits, where the sequence identity is 34.8%. This region contains an exposed disulfide bond between two cysteine residues at positions 187–199. The loop can be easily "nicked" by exogenous proteases, thereby cleaving the A-subunit to its A1/A2 polypeptides and activating the toxin. Commercially available preparations of Ctx contain A-subunits that have already undergone proteolytic nicking, with the cleavage occurring between residues 193 and 193 (Xia *et al.*, 1984). In contrast, Etx purified from *E. coli* is unnicked, although the A-subunit can be easily cleaved by exogenously added trypsin, yielding A1 and A2 polypeptides similar to those of Ctx (Clements and Finkelstein, 1979; Clements *et al.*, 1980). Nicking of the polypeptide chain and reduction of the disulfide bond occurs over 20Å away from the proposed Ctx/Etx active site (van den Akker *et al.*, 1995), suggesting that several key residues distant from the active side might be crucial for the activation pathway. Structural studies of A-subunit mutants of Ctx and Etx have provided insight on the activation and catalytic activity of toxins.

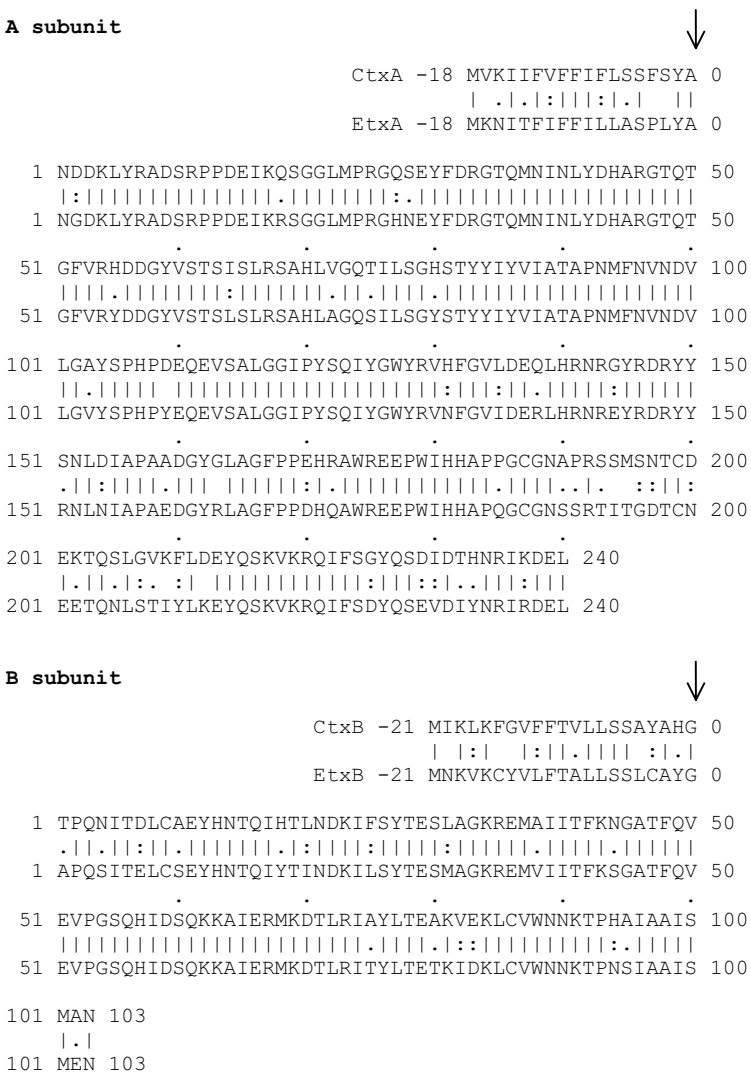

**FIGURE 15.1** Primary amino acid sequence alignments of the A- and B-subunits of cholera toxin and *E. coli* heat-labile enterotoxin. Cholera toxin sequences are from the classical biotype *V. cholerae* O1 strain 569B (Dams *et al.*, 1991); heat-labile enterotoxin sequences are derived from *E. coli* strain H74-114 of human origin (Leong *et al.*, 1985). Amino acids comprising the signal sequences of A- and B-subunits are denoted by negative numbers. The arrows indicate the positions of cleavage between the signal sequences and the mature polypeptides.

Mutagenesis experiments and crystal structure analysis of active Ctx mutants suggest that disorder in the activation loop is necessary and sufficient for toxin activity. This activation loop disorder causes an increase in flexibility of the A-subunit, exposing the active site residues upon substrate binding, thereby rendering the toxin active (O'Neal *et al.*, 2004).

The primary sequences of B-subunits of Ctx and Etx reveal a number of other distinctive features. First, there is a pair of conserved cysteine residues (at positions 9 and 86), which were subsequently shown to form a single intramolecular disulfide bridge (Hardy *et al.*, 1988; Sixma *et al.*, 1991), the formation of which is essential for toxin assembly (see below). Second, they have a high content of charged resides, which for each B-subunit of Ctx includes 3 Asp, 7 Glu, 9 Lys, and 3 Arg residues (Figure 15.1). Third, each B-subunit possesses a single conserved tryptophan residue (at position 88), which forms the floor of the B-subunit's receptor binding function.

Analyses of a variety of ctx genes from different strains of *V. cholerae* have revealed a small number of amino acid differences in the B-subunit sequences compared with that shown in Figure 15.1, and also in the subunits of Etx from human and porcine origin (Tables 15.1 and 15.2). These minor differences have no known effect on the overall 3D structure of the toxin, but they do appear to give rise to significant novel antigenic specificities, and they may influence subtle differences in the receptor binding activities of the toxins.

## Quaternary structure

The successful determination of the X-ray structure of porcine heat-labile enterotoxin from *E. coli* by W.G.J Hol and co-workers in 1991 provided an exquisite

insight into the tertiary and quaternary structure of this toxin family (Sixma *et al.*, 1991; Sixma *et al.*, 1993).

This revealed that the A1-fragment had a single-domain structure with a triangular shape, with one side abutting a 23 residue alpha-helix formed by the A2-polypeptide (Figure 15.2). The C-terminal segment of the A2-polypeptide was also revealed to extend downwards into the central pore of the doughnut-shaped ring of five B-subunits (Figure 15.2). Each B-subunit in the pentameric structure is folded into two three-stranded anti-parallel beta-sheets (with one sheet on each side of the monomer facing an adjacent B-subunit) and a large central helix positioned at the wall of the central pore, with the five helices (one from each subunit) forming a pentagonal helix barrel. This forms a pore, 30Å long, with a diameter ranging from ~11Å near the surface at which the A-subunit is positioned to ~15Å on the lower surface. The three-stranded anti-parallel beta-sheets on each side of the B-subunit interact directly with the beta-sheets of the adjacent B-subunits (via multiple hydrogen bonds)—a feature that contributes to the remarkable stability of the B-pentamer. The B-subunit receptor binding site is found on the lower convoluted surface, with each B-monomer possessing a single receptor-site (Hol, 1995; Sixma *et al.*, 1992).

The structural fold of EtxB has also been found in other proteins: staphylococcal nuclease, the anticodon

**FIGURE 15.2** Ribbon diagram of the crystal structure of the porcine variant of the *E. coli* heat-labile enterotoxin. The A-subunit (comprised of the A1- and A2-fragments) forms a triangular-shaped structure; the long α-helix of the A2-fragment is clearly visible to the right-hand side. The B-subunits form a pentameric ring with a central pore in which the C-terminal portion of the A2-fragment is situated. The GM1-receptor binding sites in the B-pentamer are located on the lower convoluted side of the molecule.

[c]The amino acid sequences of the A- and B-subunits of cEtx from chicken ETEC isolate were found to be identical to those of strain H10407 (Inoue *et al.*, 1993).

binding domain of asp-tRNA synthase, which binds oligonucleotides, and verotoxin B-subunit pentamer, which binds a different glycolipid receptor, Gb3 (Arnone *et al.*, 1971; Murzin, 1993; Sixma *et al.*, 1993). The similarity of the B-subunits of Etx (and Ctx) to these other oligosaccharide and oligonucleotide binding proteins has led to the coining of the term "OB-fold" for proteins that possess this overall structure, even though they do not share any homology to their primary sequences.

The porcine variant of Etx used in the crystallographic determination was purified from a recombinant *E. coli* K-12 strain and, as a consequence, the A-subunit was unnicked. The residues 189–195 corresponding to the exposed loop and nicking site between the A1- and A2-polpeptides were not revealed in the electron density map, presumably because of the flexibility of this region. Likewise, the three amino-terminal and four carboxy-terminal amino acids of the A-subunit were not visible within the refined structure.

The subsequent X-ray crystallographic determination of the Ctx structure by Westbrook and co-workers revealed a molecule with a similar overall fold to that of pEtx. The only region of major structural dissimilarity was found in the A2-segment from residue 227, which in Ctx appears to enter the central pore of the B pentamer as an alpha-helix rather than as an extended chain (Zhang *et al.*, 1995). In addition, the last four residues (KDEL) were clearly visibly in the electron density of Ctx and may reflect the more compact structure of the CtxA2- when compared with the EtxA2-fragment. However, a recent determination of the Ctx crystal structure has revealed an elongated conformation of the CtxA2-fragment (O'Neal *et al.*, 2004) in contrast to the helical-type tail proposed by the original published structure of wild-type Ctx (Zhang *et al.*, 1995). The KDEL sequence is disordered in the new Ctx structures, and the observed elongated tail conformation positions this sequence to extend into solvent at the exit of the $B_5$ pore, thus facilitating its proposed interaction with the KDEL receptor (O'Neal *et al.*, 2004).

The A1-polypeptide (amino acids 1–194) contains the enzyme active site capable of ADP-ribosylation (for a fuller description see below). When the crystal structure of Etx was compared with that of another ADP-ribosylating toxin, exotoxin A (ETA) from *Pseudomonas aeruginosa*, it was apparent that 44 residues in the A1-polypeptide could be superimposed with residues in the enzymic domain of ETA (Sixma *et al.*, 1993). Of these, only three amino acids were identical: Tyr 6, Ala 69, and Glu 102 in Etx, with the latter corresponding to the active site residue Glu 533 of ETA.

## BIOGENESIS OF CHOLERA TOXIN AND RELATED ENTEROTOXINS

### Toxin gene organization

One of the important discoveries in cholera research in the past few years was made by Waldor and Mekalanos, who found that the structural genes *ctxA* and *ctxB* encoding the A- and B-subunits of Ctx are located on a single-stranded filamentous phage, CTXΦ (Waldor and Mekalanos, 1996).

The *ctxAB* genes are organized as an operon located near one end of the phage genome (Figure 15.3). The phage contains two regions, a 4.6-kb central "core" and a 2.4-kb repetitive sequence "RS2." The core region of the CTXΦ is composed of the Ctx operon (*ctxAB*) and four additional genes, namely *zot* (encoding the zonula occludes toxin), *ace* (encoding the accessory cholera enterotoxin), *cep* (encoding a core-encoded pilin), and *orfU* (encoding the M13 gene III homologue), all of which have homology to gene sequences from the filamentous bacteriophage M13 (Mekalanos, 1983; Mekalanos *et al.*, 1983; Goldberg and Mekalanos, 1986; Fasano *et al.*, 1991; Baudry *et al.*, 1992; Pearson *et al.*, 1993; Trucksis *et al.*, 1993; Waldor *et al.*, 1997). These genes along with *psh* (from RS2) are required for phage packaging and morphogenesis.

Toxigenic *V. cholerae* also contain a 2.7-kb CTXΦ-related element "RS1" adjacent to the CTX prophage. The DNA sequences of RS1 and RS2 are almost identical, and both encode proteins required for replication (RstA), integration (RstB), and regulatory gene expression (RstR) (Waldor *et al.*, 1997). In addition, RS1 encodes a novel protein, RstC, an antirepressor that promotes the expression of CTXΦ genes, resulting in the transmission of CTXΦ and production of Ctx (Davis *et al.*, 2002). RS1 was recently shown to be a "satellite" phage of CTXΦ capable of propagating horizontally as a filamentous phage (Davis *et al.*, 2002; Faruque *et al.*, 2002).

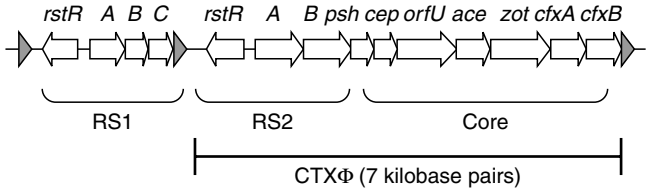

**FIGURE 15.3** Schematic representation of the genetic organization of the CTX DNA element. The 7.0-kb CTXΦ element is comprised of a 2.5-kb repetitive element (RS2) and a 4.6-kb central core region. A 2.7-kb CTX-related element (RS1) is adjacent to the CTXΦ. The open reading frames are shown as arrows, and gray triangles represent the *attRSI* sites (adapted from Boyd and Waldor, 1999).

The CTXΦ genome also encodes the functions necessary for a site-specific integration system, and can integrate into the *V. cholerae* chromosome at a unique 17-bp attachment site, *attRS* (Pearson *et al.*, 1993). CTXΦ can undergo excision from the chromosome and replicate as a plasmid yielding single-stranded phage DNA (Waldor and Mekalanos, 1996). Recently, it was shown that CTXΦ integration is dependent on two chromosomally-encoded tyrosine recombinases, XerC and XerD, since deletion of either *xerC* or *xerD* in *V. cholerae* abolished CTXΦ integration (Huber and Waldor, 2002). *In vitro* studies have indicated that a more complex XerC/D recombinase binding site is required for CTXΦ integration, and integration probably requires additional host-encoded factors (McLeod and Waldor, 2004).

Several filamentous bacteriophages use pili as receptors for infection of host bacterial cells. In *V. cholerae*, a type IV toxin co-regulated pilus (termed TCP) necessary for bacterial colonization of the human intestines has also been found to be the functional receptor for the CTXΦ (Waldor and Mekalanos, 1996). The TCP-encoding genes are clustered on the vibrio pathogenicity island (VPI) (Karaolis *et al.*, 1998) and expression of TCP is optimal under conditions found in the intestine, suggesting that the CTXΦ may have evolved to be a highly efficient transmissible agent within the gastrointestinal environment.

## Enterotoxin operon structure

In contrast to the location of the *ctx* genes on a lysogenic phage, the genes specifying the production of Etx are found on large naturally occurring plasmids, called *ENT,* present in enterotoxinogenic strains of *E. coli* (Gyles *et al.*, 1977). These plasmids have been shown to be transmissible by conjugation, and often known to possess additional genes for drug resistance and colonization antigens (Smith and Linggood, 1971; Gyles *et al.*, 1977). Since the *E. coli* Etx genes were plasmid borne, Falkow and co-workers were able to use the emerging techniques of genetic engineering in the mid-1970s to isolate and clone the Etx genes from an ENT plasmid derived from an ETEC strain of porcine origin (So *et al.*, 1978).

The genes encoding the A- and B-subunits of Etx have been variously designated by early investigators as either *eltA/eltB* or *toxA/toxB*, with the use of subscripts H or P in some cases to denote the origin of the gene as arising from a human or porcine strain of *E. coli*. Because of these disparities in nomenclature, the authors have chosen to use a general mnemonic, *etxA* and *etxB*, for the genes encoding the A- and B-subunits of the *E. coli* heat-labile enterotoxin, irrespective of the source of the ETEC infection.

The *etx* genes from a porcine isolate (P307) and two human isolates (H10407 and H74-114) have been sequenced (Dallas and Falkow, 1980; Spicer and Noble, 1982; Yamamoto and Yokota, 1982; Yamamoto and Yokota, 1983; Yamamoto *et al.*, 1984; Yamamoto *et al.*, 1987; Leong *et al.*, 1985; Webb and Hirst, unpublished). This revealed that *etxA* and *etxB* genes overlapped one another by four nucleotides, and upon sequencing the *ctxA* and *ctxB* genes, an identical 4-bp overlap was also found (Mekalanos, 1983; Lockman and Kaper, 1983). A consensus promoter sequence for RNA polymerase binding is located upstream of *etxA*, whereas no such sequence is found in the nucleotides proximal to *etxB* (Dallas and Falkow, 1979; Dallas *et al.*, 1979). Upstream of the single promoter site proximal to the *ctxA* gene is a series of three to eight tandemly repeated copies of a TTTTGAT motif, involved in ToxR-mediated activation of Ctx expression (see below) (Mekalanos *et al.*, 1983; Miller and Mekalanos, 1984; Miller *et al.*, 1987).

## Regulation of toxin expression

Several genes required for the virulence of *V. cholerae*, including Ctx gene expression, are under the control of the ToxR protein. This is a 32.5-kDa integral cytoplasmic membrane binding protein that influences the transcription of the *ctx* operon in response to changes in several environmental factors, including aeration, osmolarity, pH, temperature, and the availability of several amino acids (DiRita, 1992; Miller and Mekalanos, 1988; Mekalanos, 1992). ToxR is essential for virulence, and increases the transcription of the *ctxAB* promoter by binding to the TTTTGAT repeat motif found upstream of the -35 region (Miller *et al.*, 1987).

ToxR function depends on its interaction with an integral membrane protein ToxS, encoded downstream of *toxR* (Miller *et al.*, 1989). It is thought that ToxS may stabilize ToxR as a homodimer in the membrane, facilitating attainment of an activated state (Miller *et al.*, 1989; DiRita and Mekalanos, 1991). In a *toxR* mutant strain of *V. cholerae*, no Ctx expression occurs; however, constitutive expression of ToxT, an AraC-like transcriptional activator, overcomes this defect, suggesting that ToxT as well as ToxR may modulate the activity of the *ctx* promoter (DiRita, 1992; DiRita *et al.*, 1996). *V. cholerae* strains with a *toxT* mutation were avirulent and unable to express Ctx or TCP (Champion *et al.*, 1997), signifying that *toxT* activation is essential for virulence.

A second two-component regulatory complex comprising of TcpPH is also involved in mediating activation of *toxT* and works in a similar manner to the ToxRS system. TcpP is essential for TCP production, and activity of TcpP is enhanced by TcpH (Figure 15.4). It has been suggested that both ToxRS and TcpPH are

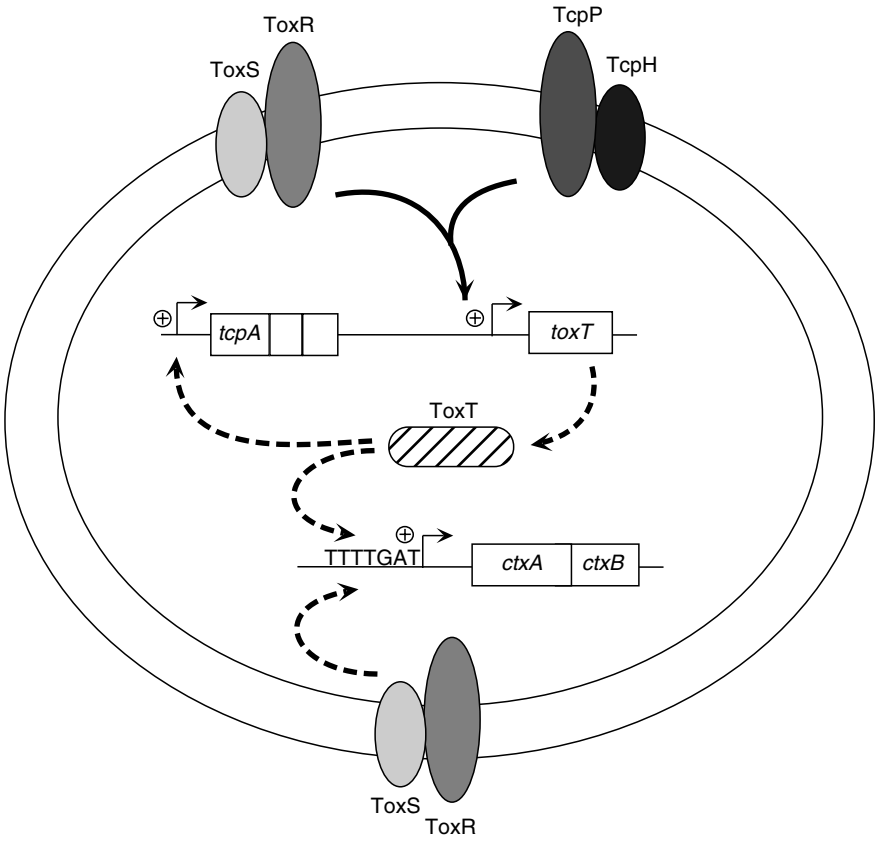

**FIGURE 15.4** Model for activation of *ctxAB* transcription. ToxR, ToxS, TcpP, and TcpH are inner membrane proteins that activate *toxT* transcription from the toxT promoter. ToxT protein then activates transcription of the *tcpA* promoter, producing more ToxT. ToxT also activates other virulence genes, such as *ctxA* and *ctxB*. ToxR can also directly activate the *ctxAB* promoter by interaction with an upstream septamer sequence $(TTTTGAT)_n$ (adapted from Yu and DiRita, 1999).

required for optimal expression of ToxT in *V. cholerae* (Hase and Mekalanos, 1998); however, the exact mechanism that TcpP and ToxR utilize for full activation of *toxT* is poorly understood.

Recently, two additional activators, AphA and AphB, were identified as regulators of the ToxR virulence cascade (Skorupski and Taylor, 1999; Kovacikova and Skorupski, 1999) and thought to interact directly with each other resulting in *tcpPH* activation (Kovacikova *et al.*, 2004). Another two-component bacterial signal transduction system, VieSAB, was identified as a positive regulator of *ctxAB* (Lee *et al.*, 2001) and may modulate *ctxAB* expression through influencing transcription of *toxT* (Tischler *et al.*, 2002). In addition, the histone-like nucleoid-associated protein (termed H-NS) has been shown to repress several genes within the ToxR virulence regulon, including the *toxT, tcpA*, and *ctx* promoters (Nye *et al.*, 2000; Nye and Taylor, 2003). Such ongoing extensive studies of this complex regulatory system will provide further insight into the nature of toxin expression and the initiation of the virulence cascade that leads to such a potent and devastating infection.

The expression of *E. coli* heat-labile enterotoxin is influenced by growth temperatures, with an approximated fourfold elevation in Etx production at 37˚C compared to 30˚C (Hirst and Uhlin, unpublished observations). While this could be due to an influence on any one of the multiple steps in toxin biogenesis, it is thought that this is mediated at the level of *etx* mRNA transcription as a result of changes in the local topology of DNA caused by H-NS.

## Translational control of subunit stoichiometry

Translation of the polycistronic *ctx* or *etx* mRNAs that arise from transcriptional initiation upstream of the *ctxA* or *etxA* cistrons is the start of events that lead to the synthesis of the A- and B-subunits.

Initially, the subunits are produced as precursor polypeptides (preA- and preB-) that then undergo export across the cytoplasmic membrane (see below). Since the subunit structure of the assembled toxins is 1A:5B-subunits, this implies that the synthesis of the A- and B-subunits may be stoichiometrically controlled in some way. A careful examination of the relative levels of A- and B-subunit synthesis in *E. coli* expressing either porcine or human Etx indicated that one to two A-subunits are synthesized per five B-subunits (Hofstra and Witholt, 1984; Hirst and Hardy, unpublished observations). The

molecular mechanisms responsible for this have, as yet, not been comprehensively investigated.

The fact that both subunits are expressed from a polycistronic mRNA means that the relative levels of A- and B-subunit synthesis must be governed by events that occur after transcriptional initiation. The most likely explanation is that differences in the efficiency of the Shine-Dalgarno (SD) sequences just upstream of the start codons of the A- and B-cistrons influence translational initiation, although other explanations, such as the presence of local stable secondary mRNA structures interfering with or promoting ribosomal recognition of the SD sequence or ribosome movement along the mRNA, cannot be excluded. An analysis of the SD sequences upstream of the initiation codons of the A- and B-subunits of Ctx and Etx revealed clear differences in the number of nucleotides of the A- and B-cistrons that share complementarity with the SD consensus sequence (5′-AGGAGG-3′), which would be consistent with the higher level of B subunit synthesis being due to the presence of a more efficient ribosome-binding site adjacent to the B-subunit cistron.

## Toxin export across cytoplasmic membrane

Protein export across the cytoplasmic membranes of bacteria, especially in *E. coli*, has been extensively investigated over the past 30 years. Protein translocation is dependent on both distinct structural properties of exported proteins, such as the presence of the amino-terminal signal peptides, and a highly efficient translocation machinery that not only delivers exported proteins to the membrane but also achieves their translocation across it.

Our current perception of how the A- and B-subunits of Etx and Ctx cross the cytoplasmic membranes of *E. coli* and *V. cholerae* is based primarily on an understanding of protein export in general, in laboratory strains of *E. coli* K–12. The precise molecular mechanism by which polypeptides translocate across the cytoplasmic membrane remains to be elucidated, but based on current concepts, it seems most likely the polypeptide is threaded like a "string of beads" through a Sec translocation channel in an energy-dependent process requiring both ATP and proton motive force (pmf).

The signal peptides present at the amino-termini of the precursor A- and B-subunits of Ctx/Etx are 18 and 21 amino acids long, respectively (Figure 15.1). A comparison of the signal peptides encoded by the *ctx* and *etx* genes and between *etx* genes of human and porcine origin shows that the signal sequences are less well conserved than the mature sequences (Figure 15.1) (Mekalanos *et al.*, 1983; Yamamoto *et al.*, 1987; Dams *et al.*, 1991). This is not too unexpected, since there is considerable sequence diversity among signal peptides in general, even though they perform a conserved function (Randall and Hardy, 1989).

To date, eight Sec proteins are known to be involved in the targeting and translocation of precursor proteins across bacterial cytoplasmic membranes (Driessen *et al.*, 1998). These are SecA (a translocation ATPase), SecB (a molecular chaperone), SecE, G, and Y (which form a trimeric membrane), SecD, F, and the largely uncharacterized YajC (also located in the cytoplamic membrane, although SecD and SecF have large periplasmic loops) and LepB (leader peptidase II—responsible for cleaving off the signal peptide from the precursor molecule). Similar proteins have been identified in other Gram-negative and Gram-positive bacterial species (Pugsley, 1993; Simonen and Palva, 1993), although as yet, the respective homologues in the *Vibrionaceae*, including *V. cholerae*, have not been characterized.

Protein export is an energy-dependent process, requiring both ATP and pmf (Driessen *et al.*, 1998; Geller, 1991). Early studies on the biogenesis of Etx in *E. coli* showed that in the presence of uncouplers of pmf, unprocessed precursor B-subunits accumulated (Palva *et al.*, 1981). The ATP requirement for export across the cytoplasmic membrane is presumed to be due solely to the activity of SecA. It is now accepted that ATP and pmf function at different stages of the translocation process, with ATP playing an essential role in the early events of precursor insertion and translocation, while pmf completes the process. However, the exact function of pmf in translocation remains to be precisely determined, especially in light of the findings that different precursors appear to require different levels of pmf for efficient export (Daniels *et al.*, 1981; Driessen and Wickner, 1991; Driessen, 1992).

The last step in the export of the toxin subunits across the cytoplasmic membrane of both *E. coli* and *V. cholerae* involves their release from the translocation channel into the aqueous environment of the periplasm. This step coincides with the important events of subunit folding and the acquisition of tertiary structure. Interactions between secondary structural elements are likely to begin as soon as the amino-terminal portion of the polypeptide emerges from the translocation channel, and will lead to the formation of loosely packed tertiary domains. If the polypeptide is exported co-translationally, it is conceivable that a significant degree of folding may have occurred on the periplasmic face of the cytoplasmic membrane, before the carboxy-terminal portion of

the polypeptide has been synthesized. The release of polypeptides from the membrane may, in fact, be dependent on the acquisition of a soluble tertiary-like structure, since parameters, such as low temperature (which slows down folding) or the use of truncated proteins that do not fold correctly, can result in the failure to release the polypeptide from the membrane (Ito and Beckwith, 1981; Koshland and Botstein, 1982; Hengge and Boos, 1985; Minsky *et al.*, 1986; Fitts *et al.*, 1987; Sandkvist *et al.*, 1987; Sandkvist *et al.*, 1990).

Pulse-chase experiments, using [35S]-methionine, have been used to follow the kinetics of toxin subunit export and release into the periplasm of *E. coli* and *V. cholerae* (Hirst *et al.*, 1983; Hofstra and Witholt *et al.*, 1988). This revealed that, in common with other proteins, export of the B-subunits of porcine and human Etx was very fast: release was complete within 10 s. In contract, Hofstra and Witholt (1984) showed that release of mature A-subunits occurred much more slowly, with up to a third remaining membrane-associated 3 min after the initiation of the pulse-chase. Given that these studies used a recombinant plasmid, EWD299, which produced porcine EtxA- and EtxB-subunits in a molar ratio of approximately 2:5, it is conceivable that if A-subunits are expelled from the translocase but fail to associate with B-subunits, they may then irreversibly re-associate with the membrane. This certainly occurs for mutant B-subunits with minor deletions or substitutions at their carboxy-termini or mutations in the Cys-residues, which prevent correct assembly (Sandkvist *et al.*, 1990; Hardy and Hedges, 1996).

## Toxin folding and assembly

The folding and assembly of the A- and B-subunits to form a final toxin structure clearly represent key molecular processes in toxin biogenesis. While the events of folding and assembly can be thought of as distinct processes, it is perhaps more appropriate to view them as a pathway of events involving both intra- and inter-molecular protein interactions.

During assembly, the intramolecular interactions that give rise to tertiary structure in the individual toxin subunits will create interfaces that will allow specific intermolecular interactions that ultimately lead to stable quaternary complexes. The nature of the interactions between B-subunits, and between the A and B-subunits, affords the possibility that these associations may affect late folding events. It is also important to consider that the folded B-subunit monomer contains two surfaces that extensively pack against adjacent B-subunits in the assembled toxin (Figure 15.2) (Sixma *et al.*, 1993). Since these surfaces are particularly hydrophobic, it is possible that the folded monomer may require "shielding" by chaperone-like proteins to prevent them from aggregating or non-specifically associating with the membrane.

The A- and B-subunit polypeptides of Ctx and Etx undoubtedly begin to fold as soon as they emerge from the translocase channel, although it is not yet clear to what extent they achieve a folded tertiary structure before being fully released into the periplasm. Recently, it was demonstrated that the formation of the disulfide bond in the B-subunit was critically dependent on a periplasmic enzyme, DsbA (Peek and Taylor, 1992; Yu *et al.*, 1992). The periplasmic location of this enzyme suggests that this late step in folding of the B-subunit occurs in the periplasm. Furthermore, it has been shown by pulse-chase experiments that the release of toxin subunits into the periplasm precedes the appearance of assembled oligomers (Hirst *et al.*, 1983; Hofstra and Witholt, 1984; Hirst and Holmgren, 1987b). As a result of these observations, it has been proposed that toxin assembly occurs largely within the periplasmic compartment of the bacterial envelope, although the possibility remains that certain subunit-subunit interactions may start at the membrane (Hirst and Leece, 1991).

In common with many other exported and secreted polypeptides, the A- and B-subunits of Etx and Ctx possess cysteine residues that must oxidize to form specific intrachain disulfide bonds during folding. Each of the toxin subunits possesses a single disulfide bond, between Cys 187 and Cys 199 in the A-subunit and between Cys 9 and Cys 86 in each B-subunit (Sixma *et al.*, 1993). The importance of the formation of disulfide binds in toxin biogenesis was first demonstrated by the use of the sulfhydryl reducing reagent dithiothreitol (DTT), which immediately stopped the assembly of new EtxB-pentamers in an EtxB-producing strain of *E. coli*, although it had no effect on the pentamers that had already assembled. The subsequent demonstration that substitution of Cys 9 or Cys 86 by Ser in the B-subunit of Ctx and Etx (Jobling and Holmes, 1991; Hardy and Hedges, 1996) abolished B-subunit assembly into stable oligomers confirmed that disulfide bond formation in the B-subunit is an essential step in toxin biogenesis.

It is now known that the formation of disulfide binds in the enterotoxin molecule is catalyzed by a periplasmic thiol-disulfide oxidoreductase (Yu *et al.*, 1992; Bardwell, 1994; Missiakas and Raina, 1997). Genes encoding analogous enzymes responsible for disulfide bond formation (*dsbA*) have been identified in *E. coli*, *V. cholerae*, and *Haemophilus influenzae* (where the mnemonic *ppfA*, *tcpG*, and *por* have also been used) (Bardwell *et al.*, 1991;

Kamitani *et al.*, 1992; Peek and Taylor, 1992; Tomb, 1992; Yu *et al.*, 1992).

The *cis-trans* isomerization of peptidylprolyl bonds is recognized to be a slow, rate-limiting step in the refolding of proteins *in vitro* (Jaenicke, 1987; Jaenicke, 1991; Lang *et al.*, 1987). Peptidylprolyl *cis-trans* isomerases are located in the cytoplasm and the periplasm of bacteria and are thought to accelerate *cis-trans* prolyl isomerization *in vivo* (Liu and Walsh, 1990; Hayano *et al.*, 1991; Missiakas and Raina, 1997; Dartigalongue and Raina, 1998). Equilibrium is established between the *cis* and the *trans* states of the monomeric EtxB under denaturing conditions, resulting in the generation of assembly-competent (*cis*) and assembly-incompetent (*trans*) forms (Cheesman *et al.*, 2004). Each B-subunit contains a single *cis*-proline residue at position 93 (P93) and a single tryptophan residue at position 88 (W88) revealed by X-ray crystallography. Recently, mutagenesis of the P93 to a glycine or an alanine residue revealed minor differences in their biophysical and biochemical properties, but major changes in the kinetics of pentamer disassembly and reassembly, relative to wild-type protein. These substitutions resulted in a *cis* peptide bond between amino acids 92 and 93, suggesting that the adoption of the *cis* conformation is a prerequisite for efficient production and secretion of these recombinant proteins (Cheesman *et al.*, 2004).

The precise pathway of subunit interactions and the identity of assembly intermediates that lead to the formation of an $AB_5$ holotoxin complex are not yet known. The B-subunits of Ctx and Etx readily assemble in the periplasm (in the absence of concomitant A-subunit synthesis) to form stable pentamers (Hirst *et al.*, 1984). This should not be taken to imply that assembly involved the formation of the B-pentamer before association with the A-subunit, since there is compelling evidence that the A-subunit interacts with B-subunits before pentamerization is complete.

Although the exact pathway of B-subunit pentamerization is not known, it has been speculated that a preferred pathway might involve the initial dimerization of two B-subunit monomers, followed by incorporation of a further monomer, and culmination in the association of a further dimer to form a stable pentameric structure (Hirst *et al.*, 1995). A kinetic simulation of the pathway of CtxB pentamerization has recently been modeled based on monitoring changes in Trp-fluorescence during assembly *in vitro* (Lesieur *et al.*, 2002).

The association of the A- and B-subunits to form an $AB_5$ holotoxin adds another level of complexity to the assembly process. The crystal structure of the holotoxin gives a picture of the final outcome of these interactions. The major contacts between the A- and B-subunits are clustered towards the C-terminal portion of the A2-polypeptide, which is inserted into the central pore of the B-pentamer where there are five salt-bridge interactions (Sixma *et al.*, 1993) (Figure 15.2). Within the central pore, there are surprisingly few specific contacts: just two regions of hydrophobic contact at each end of the pore and three salt bridges between three adjacently positioned B-subunits (Sixma *et al.*, 1993).

*In vivo* studies on Etx assembly in *E. coli* have revealed that the rate at which B-subunits attain a pentameric structure in the periplasm is increased by roughly fourfold when the A-subunit is co-expressed (Hardy *et al.*, 1988). This has been interpreted to mean that the A-subunit stabilizes an intermediate in B-subunit assembly. Although several pathways for A-/B-subunit assembly can be envisaged, it seems plausible to hypothesize that assembly of the A- and B-subunits proceeds via the formation of an $AB_3$ intermediate. Indeed, it may be the stabilization of the B-trimer by the A-subunit that leads to the enhancement in the rate of B-subunit pentamerization observed by Hardy *et al.* (1988). If the generation of the $AB_3$ intermediate is part of the normal pathway of toxin assembly, then its subsequent association with a preformed B-dimer would form the holotoxin complex.

## Toxin secretion across OM

*V. cholerae* has a distinct secretory apparatus capable of translocating fully folded and assembled proteins across its outer membrane, including Ctx. Studies on the export and secretion of the A- and B-subunits of Ctx from strains engineered to express one or the other of the subunit toxins led to the conclusion that the assembled B-pentamer contains all of the necessary structural determinants to permit secretion across the *V. cholerae* outer membrane (Hirst *et al.*, 1984; Hirst and Holmgren, 1987a). Subsequently, Sandkvist and colleagues showed that Ctx is secreted via the extracellular protein secretion (Eps) system, a type II secretion pathway (Sandkvist, 2001b), previously referred to as the main terminal branch of the general secretion pathway (GPS) (Pugsley *et al.*, 1997). The extracellular localization of proteins transiting two membranes occurs via a two-step mechanism; first, the Sec machinery translocates unfolded proteins through the inner membrane into the periplasm, where folding and posttranslational modification take place, and second, the subsequent translocation of the folded protein through the outer membrane is mediated by Eps proteins (Sandkvist *et al.*, 1999; Sandkvist *et al.*, 2000; Russel, 1998) (Figure 15.5).

The genetic organization of type II secretion systems is highly conserved among Gram-negative bacterial

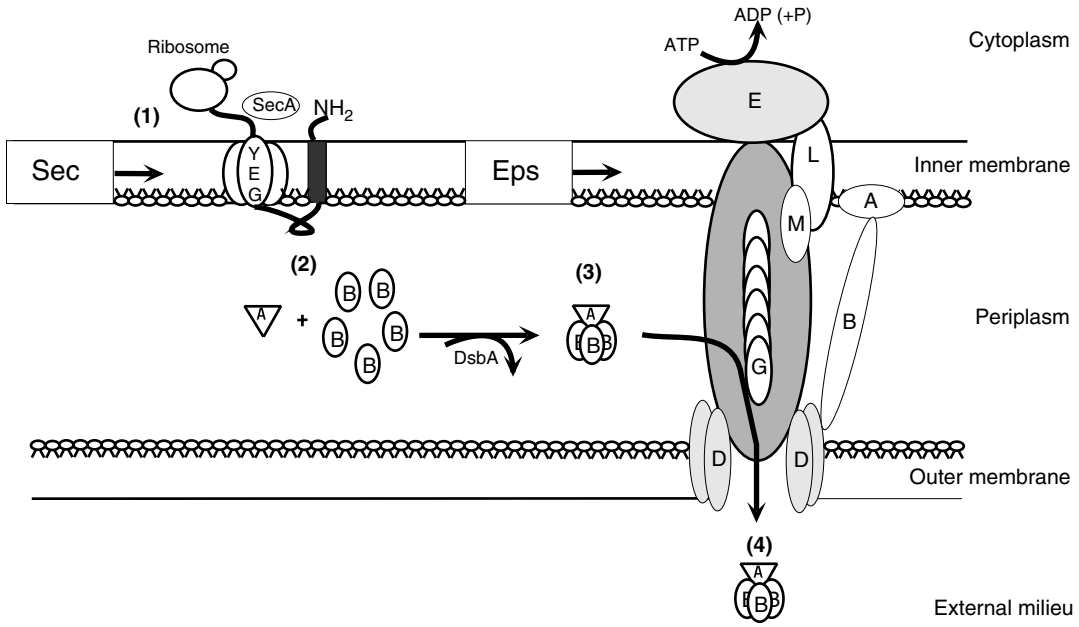

**FIGURE 15.5** Schematic model of the pathway of toxin biogenesis in *E. coli* (steps 1–3 only) and in *V. cholerae* (steps 1–4). Step (1), precursor A- and B-subunits are exported across the cytoplasmic membrane via a Sec-dependent {58}pathway involving SecA, SecE, SecY, and EcG (SecD, SecF, YajC not shown), followed by their cleavage by LepB (not shown) to yield mature A- and B-subunits that are released into the periplasm. Step (2), folding of the mature subunits is mediated both by intramolecular interactions within the polypeptide chain and by intermolecular interactions with factors that may facilitate or catalyze folding events, such as DsbA and peptidyl prolyl cis-trans isomerase. Step (3), holotoxin assembly occurs to give rise to an $AB_5$ structure. Step (4) the $AB_5$ complex engages with the type II secretion apparatus via specific recognition of $B_5$, and is secreted across the outer membrane via the Eps-secretion machinery. The function of the various Eps proteins is still to be resolved, but it is speculated that EpsG-K may form a retractable pilus that participates like a piston in pumping the toxin through the secretion pore, comprised of EpsD. It is likely that the secretion pore is gated to prevent the non-specific loss of resident proteins or the influx of low molecular mass solutes. Energy in the form of ATP and pmf is required for holotoxin translocation across the outer membrane. (adapted from Sandkvist, 2001a)

species including *V. cholerae*. The genes are organized in a single operon (see Sandkvist, 2001a for a comprehensive review of known type II secretion pathway genes). To date, 15 *eps* genes have been identified in *V. cholerae* essential for type II secretion, with the gene products designated by letters A through O. Since the function and interaction of all the proteins in the type II secretion system have been reviewed (Sandkvist, 2001a; Sandkvist, 2001b), it will not be discussed in great detail. These EPS proteins are thought to form a large multiprotein complex that spans across the periplasmic compartment and enables the translocation of proteins through the outer membrane. EpsL and EpsM are thought to be responsible for opening and closing the secretion pore (Sandkvist *et al.*, 1999), while EpsD present in the outer membrane mediates both Ctx and CTXΦ secretion (Davis *et al.*, 2000). Subsets of these *eps* genes (*epsD*, *epsE*, *epsF*, and *epsO*) are homologous to the genes required for assembly and export of type IV pili, and other *eps* genes (*epsG epsH*, *epsI*, *epsJ*, and *epsK*) encode proteins similar to type IV prepilin subunits. It has been suggested that these *eps* gene products represent a subset of the type II secretion system with the capability of forming a pilus-like structure (Sandkvist, 2001a). The structure of some EPS proteins from *V. cholerae* has been elucidated, including EpsE (Robien *et al.*, 2003), EpsM (Abendroth *et al.*, 2004b), and EpsL (Abendroth *et al.*, 2004a), and it has provided insight into the functional aspect of these proteins. However, much remains to be done to fully comprehend the sophisticated mechanism by which these toxins are secreted.

Although the exact mechanism by which Ctx is secreted still remains unknown, different models for pilus-mediated secretion have been proposed. Recent studies have shown that type IV pili can forcefully retract (Merz *et al.*, 2000) with subunits assembling into filaments prior to translocation (Wolfgang *et al.*, 2000). This suggests that type II secretion pilus may act as a piston, pushing secreted proteins through a gated pore (Sandkvist, 2001a). A source of energy in the form of proton-motive force or ATP hydrolysis is essential, and may be required for opening of the secretion pore or assembly of the secretion apparatus (Figure 15.5).

Studies on *Aeromonas hydrophilia* have revealed that ATP hydrolysis by ExeA is necessary for aerolysin secretion (Pugsley *et al.*, 1997) and two homologues of *exeA* have been found in *V. cholerae* (Hillary and Hirst, unpublished observations). It is speculated that EpsE, which is an ATP binding protein, plays an important role in linking ATP hydrolysis to the process of toxin secretion (Sandkvist *et al.*, 1995; Sandkvist, 2001a). However, the role of energy and how this is coupled to the secretory event still needs to be explored. Once released from the microorganism, either by secretion or by non-specific lysis, the toxin is free to interact with the epithelium of the gut and initiates the events that lead to toxin-mediated diarrhea.

## ACTION OF CHOLERA TOXIN AND RELATED ENTEROTOXINS IN MEDIATING DIARRHEA

Ctx and Etx exert their diarrheagenic action by subverting the normal physiological processes of gut epithelial cells. To do so, the toxins must bind to and enter the cells of the gut epithelium.

### Cell surface receptor binding

The B-subunit moiety of Ctx and Etx are lectins that enable them to bind to cell surface receptors (refer to de Haan and Hirst, 2004 for a recent review). The principal receptor for Ctx is GM1-ganglioside (Gal(β1-3)GalNAc (β1-4)[NeuAc(α2-3)]Gal (β1-40)Glc(β1-1)ceramide), a glycosphingolipid found ubiquitously on the surface of eukaryotic cells (Van Heyningen *et al.*, 1971; Cuatrecasas, 1973; Holmgren, 1973). The X-ray structure of CtxB bound to the pentasaccharide moiety of GM1 revealed that each B-subunit has a GM1 binding pocket (Merritt *et al.*, 1994; Merritt *et al.*, 1998). Upon receptor binding, a flexible loop comprising amino acids 51–58 becomes more ordered, stabilizing the toxin-GM1 complex (Merritt *et al.*, 1994).

High-affinity interaction between CtxB and the pentasaccharide moiety of GM1 is due to hydrogen bond interactions with the terminal Gal and sialic acid (NeuAc) residues, and to a more limited extent with GalNAc of GM1. This results in an exceptionally high affinity with reported dissociation constants of ($K_{D'S}$) of 7.3 x $10^{-10}$M for CtxB and 5.7 x $10^{-10}$M for EtxB (Kuziemko *et al.*, 1996). In addition to GM1, CtxB is reported to bind with lower affinity to other receptors, such as GD1b, GQ1b, GD1a, GT1b, and GM2 (Fukuta *et al.*, 1988; Angstrom *et al.*, 1994; Kuziemko *et al.*, 1996; Lauer *et al.*, 2002). EtxB displays a more promiscuous receptor-binding activity and in addition to binding to the gangliosides above, also interacts with asialo-GM1, non-ganglioside glycolipid receptors, lactosylceramide, and certain galactoproteins (Orlandi *et al.*, 1994; Teneberg *et al.*, 1994; Karlsson *et al.*, 1996; Backstrom *et al.*, 1997). The significance of these differential binding specificities on the toxicity properties of Ctx and Etx has yet to be fully evaluated.

Studies on the enterotoxicity of a GM1-binding mutant of Etx, Etx(G33D), which contains a Gly33 to Asp substitution in the B-subunit, confirmed that GM1 binding is essential for toxin action (Tsuji *et al.*, 1985; Jobling and Holmes, 1991; Guidry *et al.*, 1997; Nashar *et al.*, 1998). However, GM1 binding alone may not be sufficient to ensure full expression of toxicity, since a mutational analysis of the 51–58 loop revealed that substitution of His57 to Ala resulted in a mutant B-subunit that retained its GM1-binding properties, but its capacity to induce electrogenic chloride secretion in model epithelia was ablated (Aman *et al.*, 2001; Rodighiero *et al.*, 2002; Fraser *et al.*, 2003).

Recently, Etx bound to lipopolysaccharide on the bacterial surface was shown to be able to bind to GM1, a finding that may suggest the toxin is able to mediate the delivery of associated somatic antigens or other virulence determinants at the same time as the toxin enters enterocytes (Horstman and Kuehn, 2002; Horstman *et al.*, 2004). Moreover, an immunofluorescence analysis of the interaction of ETEC vesicles with intestinal epithelial cells has suggested that toxin-containing vesicles may be the primary means of entry of active Etx into host cells (Kesty *et al.*, 2004).

### Uptake and trafficking of toxin

The use of polarized human colonic epithelial T84 cells (Lencer *et al.*, 1992) has greatly facilitated studies of Ctx and Etx toxin action, since toxicity can be readily monitored as the induction of electrogenic $Cl^-$ secretion. GM1 ganglioside is clustered in detergent insoluble glycosphingolipid-rich membrane microdomains (DIGs), which play a significant role in receptor-mediated endocytosis and signal transduction. The binding of Ctx to GM1 ganglioside within DIGs is a critical step in the targeting of the toxin into intracellular compartments (Wolf *et al.*, 1998; Wolf *et al.*, 2002; Orlandi and Fishman, 1998). An early study showed that cholesterol derivatives of GM1 were more effective receptors for Ctx action than native GM1 or phospholipid derivatives of GM1 (Pacuszka and Fishman, 1991) and treatment of T84-cells with cholesterol-depleting drugs such as filipin or β-cyclodextrin reversibly inhibited Ctx-induced $Cl^-$ secretion (Orlandi and Fishman, 1998; Wolf *et al.*, 1998;

Wolf *et al.*, 2002). Several other studies have also suggested that cholesterol may be involved in the recruitment of lipid raft constituents that interact with and facilitate the internalization of Ctx-GM1 complexes in a clathrin-independent manner (Torgersen *et al.*, 2001; Nichols, 2002). The disruption of the actin cytoskeleton by drugs such as Cyto-D resulted in intact lipid rafts but loss of cytoskeleton-dependent lipid raft functions (Badizadegan *et al.*, 2004), suggesting that the actin cytoskeleton also plays a role in trafficking of Ctx.

Once Ctx is internalized in endocytic vesicles (AE), the toxin trafficks to the trans-Golgi network (TGN) and then enters the endoplasmic reticulum (ER) (Figure 15.6) (Sandvig *et al.*, 1994; Nichols and Lippincott-Schwartz, 2001; Lencer and Tsai, 2003). The presence of a KDEL motif at the C-terminus of CtxA (RDEL in EtxA), although not essential for toxicity, increases the efficiency of retrograde trafficking into the ER (Lencer *et al.*, 1995). A well-characterized pathway of retrograde transport is via COPI-coated vesicles (Cosson and Letourneur, 1997). This large cytosolic protein complex forms a coat around vesicles budding from the Golgi, and utilizes a GTP-switch mechanism for coating and uncoating (Barlowe, 2000). Conversely, anterograde transport into the Golgi from the ER, termed *COPII*, is mediated by a distinct coated vesicle and also employs a similar coating mechanism (Barlowe, 2000). The retrograde cargo of COPI vesicles includes ER-resident proteins that carry a C-terminal KDEL-motif and interact with the abundantly expressed KDEL receptor (or Erd2p) (Munro and Pelham, 1987; Pelham, 1988; Tang *et al.*, 1993; Griffiths *et al.*, 1994; Orci *et al.*, 1994; Majoul *et al.*, 1998). The active domains of a number of bacterial toxins, such as the A-subunit of Ctx, contain a C-terminal KDEL sequence, and it is likely that retrograde transport of these toxins through the ER involve COPI-coated vesicles. Studies have shown that the movement of Ctx A-subunits into the ER was blocked by microinjection of antibodies specific for subunits of the COPI coat (Majoul *et al.*, 1998). Moreover, trafficking of Ctx depends on the p24 family proteins that are sites for COPI coatomer binding (Stamnes *et al.*, 1995), further confirming the involvement of these vesicles in the trafficking of Ctx.

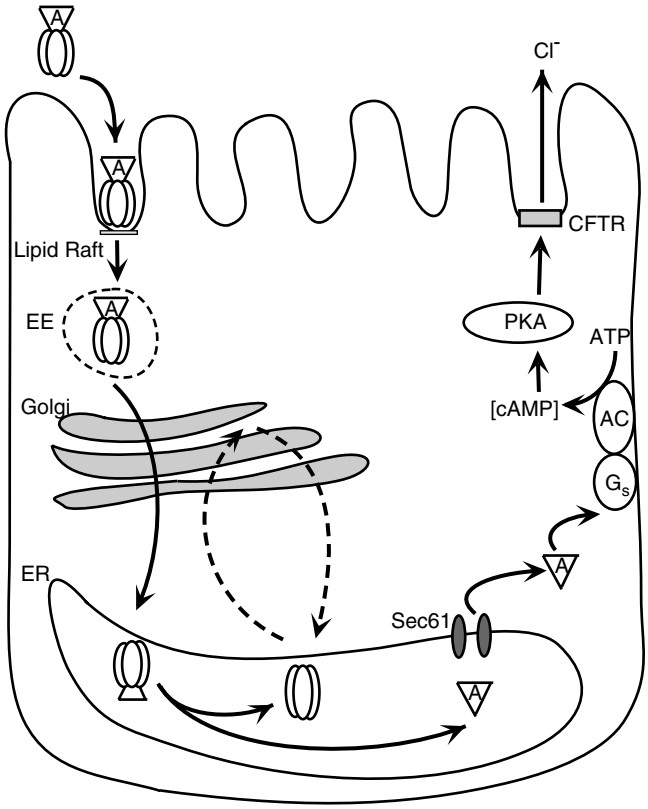

**FIGURE 15.6** Schematic model of toxin uptake and action in polarized epithelia. The cholera toxin (CT) binds to GM1 and enters via a lipid raft. After endocytosis, the CT may move from the early endosome (EE) directly to the Golgi and then to the endoplasmic reticulum (ER). In the ER, the A1 fragment unfolds and dissociates from the B-pentamer, and is then translocated to the cytosol through the protein conducting channel. As the A1 fragment moves into the cytosol, it avoids ubiquitination, and rapidly folds into and exzymatically active state enabling it to ADP ribosylate the GTP binding protein, Gs. Activated Gs stimulates the adenylate cyclase complex (AC), leading to a concomitant rise in cyclic AMP (cAMP). This in turn causes activation of protein kinase A (PKA), which phosphorylates the major chloride channel, (CFTR), resulting in a CT secretory response, the primary event responsible for causing diarrhea.

Although these COPI vesicles are thought to be involved in Ctx trafficking, there has been some evidence suggesting the contrary. It was found that CtxB and EtxB alone were able to traffic to the various Golgi cisternae and do not appear to require the KDEL sequence (Parton, 1994; Sandvig *et al.*, 1994; Sandvig *et al.*, 1996). Furthermore, a mutation or replacement of KDEL in Ctx (or RDEL in Etx) resulted in a delay, but not complete inhibition of toxin-induced $Cl^-$ secretion and trafficking to the basolateral membrane (Lencer *et al.*, 1995; Cieplak *et al.*, 1995) and recently, treatment of Vero cells with a drug that interacts with COPI coatomer inhibited binding to Golgi membranes and subsequently failed to inhibit Ctx trafficking to the ER (Chen *et al.*, 2002). These findings suggest that Ctx may be transported in COPI-coated vesicles without necessarily binding to the KDEL receptor. Alternative trafficking routes for Ctx may possibly exist, as studies on Shiga toxin (which does not have a KDEL sequence) were found to utilize a COPI-independent retrograde pathway controlled by a small G protein, Rab6 (Girod *et al.*, 1999; White *et al.*, 1999). Furthermore, Ctx-induced toxicity was unaffected despite the inhibition of multiple endocytic pathways for Ctx trafficking into

the ER, suggesting that an additional retrograde trafficking pathway may exist (Massol *et al.*, 2004).

It has been speculated that the A1 fragment dissociates from the A2-B pentamer complex in the ER through the action of protein disulfide isomerase (PDI), which has both a thiol-disulphide oxidoreductase activity and a capacity to act as an unfoldase (Tsai *et al.*, 2001). PDI catalyzes reduction of the disulphide bridge between Cys-187 in the A1 fragment and Cys-199 in the A2 fragment, and forms a transient intermediate adduct with the A1 fragment that must then be oxidized in order for the A1 fragment to be released and translocated across the ER membrane. Recently, the ER oxidase Ero1 was found to be responsible for inducing release of the A1 fragment by mediating oxidation of the carboxy-terminal disulfide bond in PDI (Tsai and Rapoport, 2002). The complex of PDI and unfolded toxin is targeted to the luminal side of the ER for translocation across the membrane, since the A1 fragment alone does not have a high affinity for the ER (Tsai and Rapoport, 2002).

The subsequent translocation of the unfolded A1 fragment into the cell cytosol is thought to occur via direct association with the Sec61p secretion channel found in the ER membrane (Hazes and Read, 1997; Schmitz *et al.*, 2000). The Sec61p protein complex is involved in the transport of newly synthesized proteins from the cytosol into the ER, as well as transport of misfolded proteins from the ER for proteasomal degradation in the cytosol (Kopito, 1997; Matlack *et al.*, 1998). It would appear that the toxin takes advantage of this protein quality control machinery of cells for handling misfolded proteins, known as *ER-associated degradation* (ERAD), to achieve its translocation to the cytosol (Werner *et al.*, 1996; Teter and Holmes, 2002; Tsai and Rapoport, 2002). However, once translocated into the cytsol, the A1 fragment does not undergo proteasomal degradation since the A1 chain has a paucity of lysines, which are sites of ubiquitination and proteasomal targeting (London and Luongo, 1989; Hazes and Read, 1997). Recent findings have revealed that the A1 fragment may undergo some ubquitin-independent degradation, presumably by other cytosolic proteases (Teter *et al.*, 2002).

Once translocated, the A1 fragment interacts with ADP-ribosylation factors (ARFs) (Moss *et al.*, 1993) that influence its catalytic activity and may serve to efficiently target the A1 fragment to the plasma membrane-associated G-proteins that are the primary target of the A1 fragment. ARFs are members of a highly conserved multigene family of small GTP binding proteins and interact with several other proteins involved with membrane trafficking (Moss and Vaughan, 1995). ARF proteins were originally identified as cofactors in Ctx-catalyzed ADP-ribosylation of G-proteins (Kahn and Gilman, 1986), but since then have been shown to be widely expressed in most mammalian tissues (Tsuchiya *et al.*, 1991). It has been found that ARFs do not interact with native Ctx; instead, they only interact after nicking and reduction of CtxA has occurred, leading to the exposure of an ARF-binding site on the A1 fragment of Ctx (Moss *et al.*, 1993). ARF6, the most divergent member of the ARF family, appears to function in the peripheral plasma membrane (D'Souza-Schorey *et al.*, 1995; Radhakrishna *et al.*, 1996) and utilizes the GTP cycle to regulate the membrane traffic pathway (Radhakrishna and Donaldson, 1997). The functional interaction between the A1 fragment and human ARF6 is essential for maximal toxicity of Ctx (Jobling and Holmes, 2000). Critical residues in the A1 fragment involved in this intricate interaction have been identified, and lead to exposure of four aromatic residues thought to create an initial ARF interaction motif (Jobling and Holmes, 2000).

Bacterial exotoxins utilize a common mechanism to ADP-ribosylate specific host proteins, and the A1 fragment of Ctx is known to irreversibly ADP-ribosylate a trimeric GTP-binding protein $G_{s\alpha}$. The formation of an A1 fragment-ARF-$G_{s\alpha}$ complex is involved in the transfer of the ADP-ribose moiety of $NAD^+$ to Arg201 in $G_{s\alpha}$ (Gill, 1975; Moss *et al.*, 1976; Van Dop *et al.*, 1984; Bourne *et al.*, 1991), causing an inversion of stereochemical configuration in the N-ribosidic bond and release of nicotinamide. This ADP-ribosylation reaction results in the inhibition of the intrinsic GTPase property of $G_{s\alpha}$ (Hepler and Gilman, 1992), thus enabling $G_{s\alpha}$ to bind GTP and activate adenylate cyclase. This leads to the continuous stimulation of the adenylate cyclase complex and a concomitant massive elevation of intracellular cAMP levels.

The high levels of cAMP cause the activation of protein kinase A (PKA), which phosphorylates the major chloride channel identified in intestinal epithelial cells, namely, the cystic fibrosis transmembrane conductance regulator (CFTR), resulting in active chloride secretion (Field *et al.*, 1989; Burch *et al.*, 1988; Cheng *et al.*, 1991; Denning *et al.*, 1992; Picciotto *et al.*, 1992) (Figure 15.6). In addition to activation of the apically located chloride channel, the basolaterally located Na/K/2Cl co-transporter is also inhibited (McRoberts *et al.*, 1985; Halm *et al.*, 1988; Matthews *et al.*, 1992) and the $Cl^-$ secretory response is amplified by the release of prostaglandins (PGs) (Kimberg *et al.*, 1971; Speelman *et al.*, 1985; Burch *et al.*, 1988; Peterson and Ochoa, 1989; Thielman *et al.*, 1997). The inhibition of micro-tubule organization and a remodelling or dissociation of actin filaments in intestinal epithelial cells results in apical membrane recruitment of the CFTR (Shapiro *et al.*,

1991; Tousson *et al.*, 1996), and a widening of tight junctions further contributes to the loss of electrolytes (Field *et al.*, 1972; Powell, 1974). The resultant net increase in electrogenic $Cl^-$ secretion and inhibition of $Na^+$ absorption leads to osmotic movement of a large quantity of water into the intestinal lumen and results in severe secretory diarrhea. With appropriate intravenous fluid and electrolyte replacement therapy, the most severely affected cholera patients have been known to purge in excess of 80 litres of diarrhea. Most cases of *E. coli*-mediated diarrhea are less severe, and may be attributable to a whole range of parameters that influences the relative pathogencity of ETEC versus *V. cholerae*.

Interestingly, a comparison of the relative toxicity of Ctx and Etx in polarized human epithelial (T84) cells has revealed that Ctx is the more potent of the two toxins. The underlying structural basis for this difference in toxicity was determined by engineering a set of mutant and hybrid Ctx/Etx toxins (Rodighiero *et al.*, 1999). This revealed that the differential toxicity of Ctx and Etx was not due to differences in the A-subunit C terminal KDEL targeting motif (RDEL in Etx), since a KDEL to RDEL substitution had no effect on Ctx activity. Moreover, it could not be attributed to either the enzymically active A1 fragment, since hybrid toxins in which the A1 fragment of Ctx was substituted for that of Etx had exactly the same potency as that of authentic Ctx, or the B-subunit, since the replacement of the B subunit in Ctx for that of Etx caused no alteration in toxicity. Remarkably, the difference in toxicity could be mapped to the 10 amino acid segment of the A2-fragment that penetrates the central pore of the B-subunit pentamer. This region is responsible for maintaining A-/B-subunit interaction. A comparison of the *in vitro* stability of two hybrid toxins, differing only in this 10 amino acid segment, revealed that the Ctx A2 segment conferred a greater stability to the interaction between the A- and B-subunits than the corresponding segment from Etx A2. This suggests that the reason for the relative potency of Ctx compared with Etx stems from the increased ability of the A2-fragment of Ctx to maintain holotoxin stability during uptake and transport into intestinal epithelia. These findings highlight the importance of a region in the toxin that has hitherto been generally overlooked, and provides a possible contributory explanation for the difference in severity of cholera and traveller's diarrheal disease, respectively.

## CONCLUSION

Cholera toxin and related enterotoxins from *E. coli* continue to be a source of considerable fascination. While much is now known about the biogenesis of these toxins, the precise molecular basis by which the toxins are translocated across the bacterial outer membrane remains a challenging area for future investigation. The increasing insights being gained into the uptake and trafficking of the molecules in mammalian cells is also shedding light on aspects of eukaryotic cell biology. These toxins will therefore remain excellent models for investigating important cellular processes in both prokaryotic and eukaryotic systems.

## ACKNOWLEDGMENTS

We wish to thank the many colleagues and collaborators who have contributed to the many achievements documented in this review, particularly Lolke de Haan, Wayne Lencer, Simon Hardy, Jan Holmgren, Toufic Nashar, Neil Williams, Jun Yu, Chiara Rodighiero, Abu Tholib Aman, Sylvia Fraser, Jenny Rivett, and Arron Hearn. This was supported by a Research Development Grant from the University of Sydney.

# *Bordetella* protein toxins

*Jiri Masin, Peter Sebo, and Camille Locht*

## INTRODUCTION

The genus *Bordetella* comprises several species, three of which, *Bordetella pertussis, Bordetella parapertussis*, and *Bordetella bronchiseptica,* are important pathogens of mammalian hosts. *Bordetella avium* is a bird pathogen, whereas the remaining *Bordetella* species are rarely isolated from clinical specimens, although some of them may be opportunistic pathogens. The best-studied species are *B. pertussis*, *B. bronchiseptica*, and *B. parapertussis*, and their genome sequences are known (Parkhill *et al.*, 2003). *B. pertussis* is the causative agent of whooping cough, and *B. parapertussis* causes a milder whooping cough–like syndrome in humans. *B. bronchiseptica* is essentially a swine and dog pathogen and causes atrophic rhinitis in pigs, often associated with a co-infection by *Pasteurella multocida*. However, *B. bronchiseptica* is also relatively frequently isolated from patients suffering from acquired immunodeficiency, whereas *B. pertussis* is rarely found in immuno-compromised individuals.

The pathogenic potential of the *Bordetella* species relies on multiple factors, including several adhesins and toxins (Locht, 1999). Genomic studies have revealed an even more complex array of different virulence factors (Locht *et al.*, 2001), most of which are under the control of a two-component transcriptional regulatory system named BvgA/S. In addition to three major protein toxins, *Bordetella* produces non-protein toxins, such as endotoxin or lipopolysaccharide and tracheal cytotoxin. These toxins may sometimes act in synergy with the protein toxins. The three major protein toxins are pertussis toxin, adenylate cyclase, and dermonecrotic toxin, and they are the subject of this review.

## PERTUSSIS TOXIN

Pertussis toxin (PTX) is the most complex soluble bacterial exo-protein known to date. It is composed of five different subunits, named S1 through S5, according to their decreasing molecular weights. The subunits are arranged in a hexameric structure with the following stoechiometry : 1S1:1S2:1S3:2S4:1S5 (Tamura *et al.*, 1982). PTX is a member of the A-$B_5$ class of toxins, in which the A moiety expresses enzymatic activity, whereas the B moiety is responsible for the binding of the toxin to the target-cell receptors. The crystal structure of PTX has revealed that the B oligomer, composed of subunits S2 through S5, forms a triangular base on top of which the A protomer, composed of the S1 subunit, is anchored via its C-terminal end that extends into the pore of a central barrel formed by the B oligomer subunits (Stein *et al.*, 1994a). The toxin is actively secreted by *B. pertussis* (Weiss *et al.*, 1993) and plays an essential role in the pathogenesis of whooping cough (Pittman, 1984). As a major virulence factor, it is also a protective antigen and an important component of pertussis vaccines (Decker and Edwards, 1988).

### Biogenesis of PTX

The five PTX subunits are encoded by contiguous cistrons within a single polycistronic operon (Locht and Keith, 1986; Nicosia *et al.*, 1986), whose expression

is regulated by the BvgA/S system. The individual subunits are produced as pre-proteins containing cleavable signal peptides, and therefore cross the inner membrane of the bacterium most likely via a Sec-dependent pathway. Although the signal peptides show typical features of the substrates for leader peptidase I, their cleavage by the *Escherichia coli* leader peptidase I is very inefficient. Co-expression of the *B. pertussis lep* gene in *E. coli* substantially increases the maturation of PTX subunits, although the overall topology of the *B. pertussis* leader peptidase I is very similar to that of the *E. coli* enzyme (Smith *et al.*, 2000). However, not all *B. pertussis* pre-proteins require *B. pertussis*-specific leader peptidase I, as examplified by the *B. pertussis* porin protein, whose signal peptide is efficiently cleaved by the *E. coli* enzyme (Antoine and Locht, unpublished). The molecular details of this specificity remain to be investigated.

Once the individual subunits have reached the periplasmic space, and their signal peptides have been removed, the holotoxin is assembled prior to secretion through the outer membrane. A key step in toxin assembly is the correct disulphide bond formation. S1 contains 2 cysteines, whereas S4 and S5 each contain 4 cysteines and S2 and S3 each contain 6 cysteines (Locht and Keith, 1986; Nicosia *et al.*, 1986). All the cysteines are involved in intra-chain disulphide bonds (Stein *et al.*, 1994a). The disulphide formation is important for the toxin biogenesis, as the alteration of either cysteine in S1 prevents this subunit from assembling with the B oligomer (Antoine and Locht, 1990). The proper disulphide formation requires the action of the *B. pertussis* protein disulphide isomerases DsbA and DsbB. Mutations in either *dsbA* or *dsbB* result in decreased levels of S1 and S2, indicating that both enzymes are required (Stenson and Weiss, 2002). However, mutations in *dsbC*, coding for a third disulphide isomerase, have apparently no effect on the assembly of the toxin, although they impair its secretion, suggesting DsbC acts on a component that is specifically required for PTX secretion.

Full assembly of the holotoxin is important for efficient secretion, and strains engineered to produce only S1 or only the B oligomer show a defect in secretion (Farizo *et al.*, 2000). However, in some constructs, fully functional B oligomer can be assembled and secreted in the absence of S1 (Antoine and Locht, 1990), indicating that the presence of S1 is not an absolute prerequisite for B oligomer secretion. In contrast, S1 alone cannot be secreted in the absence of the B oligomer, suggesting that the secretion determinants are located within the B oligomer, although the presence of S1 may certainly enhance the secretion efficiency. Certain mutations in the S1 subunit gene have a strong deleterious effect on secretion, in particular the area around Arg-57 (Craig-Mylius *et al.*, 2000), suggesting that this region of S1 plays a role in the secretion of PTX. In the absence of the B oligomer, S1 most likely partitions to the outer membrane, perhaps via its C-terminal, hydrophobic domain. This may be the site of assembly with the B oligomer prior to secretion through the outer membrane (Farizo *et al.*, 2002).

The molecular steps in holotoxin assembly are still poorly understood. Single subunits in mutant strains that do not produce the other subunits are rapidly degraded. Certain combinations of subunits appear to mutually stabilize each other (Burns *et al.*, 2004). For example, the stability of the S2 subunit is greatly enhanced by the presence of S4 and vice versa, which is consistent with the S2-S4 dimer formation revealed by the crystal structure of the holotoxin. It is also possible that subassemblies of the S2-S4 dimer with the S1 subunit are formed in the absence of S3 and S5. The S2-S4 dimer has not been found to be secreted in *B. pertussis*, whereas the addition of S1 to this dimer can result in some secretion.

The transport of PTX through the outer membrane of *B. pertussis* relies on a type IV secretion system composed of nine different proteins, named PtlA through PtlI (Weiss *et al.*, 1993; Farizo *et al.*, 1996). These proteins are homologous to those of type IV secretion systems from other bacteria, including *Agrobacterium tumefaciens*, *Bartonella tribocorum*, *Brucella suis*, *Helicobacter pylori*, *Legionella pneumophila*, and *Rickettsia prowasekii* (Baron *et al.*, 2002). In all cases, these systems mediate secretion of proteins or protein-DNA complexes, which most often constitute virulence factors. The *ptl* genes lie directly downstream of the five structural PTX genes (Weiss *et al.*, 1993), and their expression depends on the *ptx* promoter (Kotob *et al.*, 1995). The *ptl* genes form together with the *ptx* genes most likely a single polycistronic operon (Baker *et al.*, 1995; Antoine *et al.*, 1996). Nevertheless, the Ptl proteins appear to be produced at lower levels than the PTX subunits, as investigated by translational fusions of the *phoA* gene with various *ptx* and *ptl* genes (Cheung *et al.*, 2004). The production of certain Ptl proteins appears to be a limiting step in the secretion of PTX. During exponential growth, the bacteria have been estimated to secrete three toxin molecules/min/bacterial cell (Rambow-Larsen and Weiss, 2004), and subunits have been found to accumulate within the periplasmic space, both as individual subunits and assembled into holotoxin. Subunit accumulation occurs throughout exponential growth even though the levels of certain Ptl proteins increase between 30 to 1,000 molecules per cell. Thus, secretion

rather than toxin production or assembly may be rate limiting. Curiously, in the absence of the Ptl proteins, some subunit combinations, such as the S2-S4 dimer in the presence of S1, can be secreted (Burns *et al.*, 2004), although the secretion of the holotoxin strongly depends on the presence of the Ptl proteins. Ptl-independent secretion has also been observed for strains producing only the S1 subunit without any of the B oligomer subunits (Farizo *et al.*, 2000).

The Ptl proteins are thought to form a complex spanning both the inner and the outer membranes (Johnson and Burns, 1994), and all of them (at least PtlA–H) appear to be needed for the toxin secretion, as investigated by mutations in each individual *ptl* gene (Craig-Mylius and Weiss, 1999). Some of the mutations introduced in *trans* into wild-type *ptl*$^+$ strains resulted in a dominant negative secretion phenotype, confirming that at least PtlC to PtlH are part of a multimeric complex. The role of certain individual Ptl proteins in the secretion of PTX has been investigated. A key step in PTX secretion is obviously its ability to cross the peptidoglycan layer, and PtlE has been shown to express peptidogycanase activity (Rambow-Larsen and Weiss, 2002). This 276-residue long protein contains active site similarities with other glycohydrolases, and alanine substitutions at this site have been shown to strongly diminish the peptidoglycanase activity of recombinant PtlE. The same substitutions in natural PtlE also abolish secretion of PTX by *B. pertussis*, strongly suggesting that PtlE is the peptidoglycanase required for the toxin to cross the peptidoglycan layer.

PTX secretion also most likely requires energy. Two of the Ptl proteins, PtlC and PtlH, contain putative ATP-binding sites and might thus provide the energy necessary for toxin secretion. Both proteins have been shown to be necessary for secretion (Kotob and Burns, 1997; Cook *et al.*, 1999), and in both cases, the putative ATP-binding sites are essential for function. For both, a dominant negative phenotype is observed when mutant alleles are co-expressed with the wild type allele, suggesting that both function as multimers or are part of the secretion complex. However, the reason of this redundancy is not known, and it is not clear what the relative contribution of PtlC and PtlH is in energy supply and toxin secretion.

The functional role of the other Ptl proteins is not yet known, but some of them might perhaps be inferred by analogy to the *A. tumefaciens* VirB system. PtlF shows features of outer membrane proteins, but it may also be associated with the inner membrane, like its VirB9 homologue. In non-reducing conditions, PtlF and PtlI migrate as a complex during sodium dodecyl sulfate-polyacrylamide gel electrophoresis, indicating that PtlI binds to PtlF by disulphide bond formation (Farizo *et al.*, 1996). The proper disulphide bond formation between PtlI and PtlF might depend on DsbC, as mutations in the *dsbC* gene affect secretion without affecting toxin assembly (Stenson and Weiss, 2002).

## Structure-function relationship

The molecular events of PTX action can be divided into four major steps: (i) target-cell receptor binding, (ii) intracellular trafficking, (iii) membrane translocation of the enzymatically active S1 subunit, and (iv) expression of ADP-ribosytransferase activity of S1.

Binding of the toxin to its target-cell receptors occurs via the B oligomer. Virtually all eukaryotic cells display PTX receptors at their surface, although the nature of these receptors may vary from cell type to cell type. The toxin receptors identified so far are all glyco-conjugates, generally sialoglycoproteins (Armstrong *et al.*, 1988), although certain peptides can mimic the glycosidic moiety of the receptors (Bogdan *et al.*, 2003), suggesting that glycosylation may not necessarily be an absolute requirement. On the other hand, other glyco-conjugates, such as the glycolipid $G_{D1a}$, may also serve as PTX receptors (Hausman and Burns, 1993). Receptor proteins of sizes between 43 kDa and 200 kDa have been identified (Rogers *et al.*, 1990; El Baya *et al.*, 1995), depending on the cell type. Various treatments of the sugar moieties of the receptor glycoproteins have indicated the importance of the terminal sialyl groups in PTX binding (Brennan *et al.*, 1988).

The broad range specificity of PTX receptor binding may explain the wide range of biological activities expressed by the toxin and may be the consequence of its particularly complex quaternary structure. The crystal structure of the oligosaccharide-bound form of PTX revealed the presence of at least two distinct carbohydrate-binding sites (Stein *et al.*, 1994b). One of them involves the S2 subunit and one involves S3. The two subunits display approximately 70% amino acid sequence identity (Locht and Keith, 1986; Nicosia *et al.*, 1986). Each one of these subunits dimerizes with S4, and the receptor-binding units are probably constituted by the S2/S4 and the S3/S4 dimers. Although both dimers are able to bind to sialo-carbohydrates in essentially the same manner, they nevertheless differ in their receptor specificity. For example, dimer S2/S4 is able to bind to haptoglobin, whereas dimer S3/S4 binds to glycoproteins at the surface of Chinese hamster ovary cells (Lobet *et al.*, 1993). The C-terminal half of S2 and of S3 adopt a fold similar to that found in the B subunits of other carbohydrate-binding toxins, and the sialyl group of the oligosaccharide bound to PTX is within hydro-

gen-bonding distance of the polar and charged groups of Tyr-102, Ser-104, and Arg-125 in both S2 and S3 (Stein *et al.*, 1994b). Site-specific alterations of the residues in that region abolish receptor binding of PTX (Lobet *et al.*, 1993; Loosmore *et al.*, 1993). Interestingly, deletion of Asn-105 in S2 affects haptoglobin binding of the toxin, while keeping its ability to bind to CHO cells intact, whereas the deletion of Lys-105 in S3 has the inverse effect (Lobet *et al.*, 1993), indicating that these residues contribute to receptor-binding specificity. Other regions, in particular in the N-terminal domain of these subunits, may also be involved in receptor recognition (Saukkonen *et al.*, 1992).

Upon binding to its receptors, the toxin enters the target cells by receptor-mediated endocytosis. This does probably not require a conformational change of the toxin (Shigeta, 1994). Several lines of evidence suggest that the toxin follows the retrograde transport system involving the Golgi apparatus and possibly the endoplasmic reticulum (ER) (Xu and Barbieri, 1995; El Baya *et al.*, 1997). The addition of $NH_4Cl$ or chloroquine to the target cells inhibits PTX action, suggesting that a pH-sensitive step is involved in toxin trafficking. However, membrane translocation of PTX does not appear to depend on a pH gradient (Hausman and Bruns, 1992), suggesting that the translocation step does not occur in acidified endosomes. Much of the toxin may actually travel back to the cell surface (Xu and Barbieri, 1995). The compartment where toxin translocation occurs is not yet known.

The PTX domains involved in toxin translocation also have not yet conclusively been determined. Unlike diphtheria toxin and *Pseudomonas aeruginosa* exotoxin A, PTX does not contain a well-defined translocation domain in its B moiety. The fact that S1 is able to bind to phospholipid bilayers (Hausman and Burns, 1992) suggests that the S1 subunit may directly interact with the membrane and mediate its own membrane translocation. The B oligomer may thus perhaps not be essential for the membrane translocation step *per se*. This hypothesis is supported by results obtained from cell transfection experiments (Veithen *et al.*, 2000; Castro *et al.*, 2001) showing that when the S1 subunit gene is expressed in CHO cells with a signal-peptide coding sequence, the subunit is targeted to the ER. The matured S1 then travels back to the cytosol and expresses its enzymatic activity, which results in a toxic phenotype of the CHO cells in the absence of the B oligomer. Consistent with these data, Hazes and Read (1997) have proposed a model in which S1 dissociates from the B oligomer in the ER and translocates without further help from the B oligomer. This model is based on the crystal structure of the PTX-ATP complex (Hazes *et al.*, 1996). The negative charges of the triphosphate moiety of ATP displace the C-terminal, negatively charged residues of S1 from the B-oligomer pore, resulting in a destabilization of the S1-B oligomer interactions and ultimately the release of S1 from the B oligomer. Since, in addition to the cytosol, the ER is the only subcellular compartment where ATP can be found, Haze and Read (1997) suggest that the release of S1 from the B oligomer occurs in the ER. Furthermore, this compartment also contains protein disulphide isomerases that may help to reduce the intramolecular disulphide bond of S1, which is necessary for the expression of the enzymatic activity.

Cytosolic, reduced S1 catalyzes the transfer of the ADP-ribose moiety of NAD onto acceptor substrate proteins. The acceptor substrates are the α subunits of a class of signal-transducing G proteins (Katada and Ui, 1982). In particular, PTX ADP-ribosylates Cys-351 of Gi/o, located near the C-terminus of their α subunits. ADP-ribosylation of this residue results in uncoupling of the G protein from its cognate receptor and disruption of signal transduction. Although Cys-351 of Giα is the natural acceptor substrate of PTX, the toxin can also hydrolyze NAD in a reaction referred to as the NAD-glycohydrolase reaction. This amounts to the transfer of ADP-ribose to a water molecule.

The enzymatic mechanism of PTX has been extensively studied (Locht and Antoine, 1995). Catalytic residues have been identified, as well as the residues or regions involved in NAD binding and in acceptor substrate binding (Locht *et al.*, 2000). The C-proximal portion of S1 is involved in the interaction with Gα (Locht *et al.*, 1990; Cortina *et al.*, 1991), and the region around Trp-26 and Arg-9 appears to be involved in NAD binding (Cortina and Barbieri, 1989). The two catalytic residues that have been identified by the role they play in the velocity of the reaction are His-35 (Antoine and Locht, 1994) and Glu-129 (Antoine *et al.*, 1993). Both residues are within hydrogen-bonding distance from each other (Stein *et al.*, 1994a), and Glu-129 is strictly conserved among all ADP-ribosyltransferases investigated so far (Pallen *et al.*, 2001). We have proposed that Glu-129 weakens the N-glycosidic bond linking ADP-ribose to the nicotinamide ring by stabilizing or promoting the formation of an oxacarbenium-like intermediate. This may occur through ionization of the nicotonamide ribose diol, which would result in intramolecular electrostatic stabilization of the intermediate. The existence of an oxacarbenium-like ribose ring at the transition state has been demonstrated by isotope effect characterization of the transition state in the PTX-catalyzed NAD-glycohydrolase reaction (Scheuring and Schramm, 1997). Recently, analogs of NAD that resemble their oxacarbenium ion transition

states have been shown to inhibit the NAD-glycohydrolase reaction catalyzed by PTX (Zhou *et al.*, 2004). His-35 probably increases the nucleophilicity of the acceptor substrate to enhance its attack of the weakened N-glycosidic bond, ultimately resulting in the transfer of ADP-ribose onto the acceptor substrate, probably by an SN2-type mechanism. $D_2O$ kinetic isotope effects are consistent with the activation of the acceptor cysteine through deprotonation prior to the nucleophilic attack (Scheuring and Schramm, 1997b). His-35 is less well conserved among the ADP-ribosyltransferases, as the acceptor substrates of these enzymes vary.

## Role of PTX in pathogenesis and protection against whooping cough

PTX expresses a wide variety of different biological activities. They include the induction of morphological changes of target cells, of exocrine secretion, of the stimulation of lipolysis, the activation of pancreatic islet cells, histamine sensitization, the induction of lymphocytosis, and many others. Therefore, PTX was originally given different names, such as islet-activating protein, histamine sensitization factor, and lymphocytosis promoting factor. It was only in the early 1980s through the work of Munoz on very pure, crystallin PTX that all these different activities were related to a single molecule, named *pertussigen* by Munoz (Munoz, 1985), and now known as PTX. Most of the biological activities of PTX *rely* on its ADP-ribosyltransferase activity. However, a few, such as hemagglutination and mitogenicity, are independent of the ADP-transfer reactions, but depend on certain target-cell receptor-binding properties of PTX (Lobet *et al.*, 1993; Loosemore *et al.*, 1993).

Some of the biological activities of PTX are hallmarks of whooping cough, which has led to the proposal that pertussis is essentially a toxin-mediated disease, similar to tetanus and diphtheria (Pittman, 1984). However, through genomic studies, it has now become clear that the pathogenic mechanisms of pertussis are far more complicated than initially assumed, and that many additional virulence factors contribute to the pathogenesis of the disease (Locht *et al.*, 2001).

Nevertheless, PTX plays a key role in the pathogenesis. A PTX-deficient mutant strain is severely impaired in its ability to cause lethal infections in infant mouse models and is cleared more rapidly that an isogenic PTX-producing strain, although in the initial phases, the colonization profiles do not differ significantly between the two strains (Goodwin and Weiss, 1990). In adult mice, PTX-deficient strains induce much less lung pathology than PTX-producing strains, although both types of strains are able to colonize adult mouse lungs equally well.

Interestingly, intranasal infection with PTX-deficient strains induces a stronger antibody response to other *B. pertussis* antigens, such as filamentous hemagglutinin, than infection with PTX-producing strains, indicating that PTX has immunosuppressive functions *in vivo*. These functions depend on the ADP-ribosyltransferase activity. One reason for the immunosuppressive function of PTX may lie in its ability to reduce HLA-DR surface expression in infected monocytes (Shumilla *et al.*, 2004). In addition, PTX has been shown to inhibit the ability of monocytes to internalize bacteria, suggesting that the inhibition of monocyte phagocytosis by PTX may represent an immune evasion mechanism of *B. pertussis* (Schaeffer and Weiss, 2001). However, these observations are in contrast to previously described adjuvant activities of PTX. These contrasting observations may be due to differences in the route and time of administration of PTX, relative to the target antigen, as well as the amount of PTX used in the different studies.

Such apparent paradoxical effects have also been observed in experimental autoimmune disease models, where PTX has been found to have enhancing and inhibitory effects, depending on its time of administration. Also, the administration of high doses of PTX led to strongly increased cytokine responses, enhanced adaptive Th1 immunity, and disease, whereas low doses of PTX suppressed experimental autoimmune uveoretinitis (Agarwal *et al.*, 2002). The inhibitory effect appeared to be due to the ADP-ribosyltransferase activity, whereas disease induction and enhancement of delayed-type hypersensitivity was independent of enzyme activity of PTX and largely due to the B oligomer of the toxin (Su *et al.*, 2003). The immune enhancing effects of PTX probably result from PTX-mediated stimulation of dendritic cells, as injection of dendritic cells stimulated *in vitro* with PTX is able to substitute for PTX injection to promote experimental autoimmune uveitis (Hou *et al.*, 2003), suggesting that PTX promotes the maturation of dendritic cells. PTX-mediated maturation of dendritic cells has been shown, but, strangely, this activity appeared to depend on the ADP-ribosyltransferase of PTX and could even be mimicked by cAMP analogs, showing that the PTX-mediated maturation of dendritic cells is cAMP-mediated (Bagley *et al.*, 2002). The activation of antigen-presenting cells by PTX has been shown to result in antigen-specific clonal expansion of both $CD4^+$ and $CD8^+$ T cells, as well as in substantially elevated levels of IL-5 and IFN-γ (Shive *et al.*, 2000). Elegant studies using Gi2α knockout mice have further suggested that Gi2α protein-mediated signaling is involved at least in the induction of Th1 type

responses to antigens co-administered with PTX (He *et al.*, 2000). These observations are at odds with the above described ADP-ribosyltransfer-independent adjuvant activities of PTX, and in contrast with a report describing that maturation of myeloid dendritic cells and the induction of IL-12 and TNF-α by PTX does not require its enzymatic activity (Tonon *et al.*, 2002). The reasons for this controversy are currently not known, although it should be noted that in the latter studies very high concentrations of PTX were used.

In addition to its action on immune cells, PTX action on epithelial cells may also be critical for the regulation of inflammatory reactions in the respiratory tract of *B. pertussis*-infected subjects. When human respiratory epithelial cells are infected with PTX-deficient mutants, higher levels of ICAM-1 mRNA are induced than when they are infected with PTX-producing strains, and purified PTX suppresses the *B. pertussis*-induced up-regulation of ICAM-1 (Ishibashi and Nishiwawa, 2002). These observations suggest that PTX may decrease immune responses by down-regulating surface expression of adhesion molecules on epithelial cells, thereby limiting immune cell recruitment at the site of infection.

Given the important role of PTX in the pathogenesis of pertussis and because of its immunomodulatory properties, this molecule can be used for several potential applications. An interesting application may result from the ability of the toxin to inhibit tumor cell motility both *in vitro* and *in vivo*. It has therefore been proposed as a therapeutic agent against certain forms of cancer, such as bladder cancer, and initial phase I studies in humans have shown that intravesical instillation of PTX is safe and well tolerated in dosages at least up to 72 mg (Otto *et al.*, 1999).

Probably the most widely used application of PTX is its inclusion as a protective antigen in vaccines against whooping cough. PTX has long been recognized as a protective antigen in animal models. In fact, vaccination with PTX alone is sufficient to fully protect mice against intracerebral challenge with virulent *B. pertussis* (Sato *et al.*, 1991). Therefore, PTX has been included in all the acellular vaccines currently available, although these vaccines vary substantially with respect to the inclusion of other antigens, such as filamentous hemagglutinin, pertactin, and the fimbriae (Decker and Edwards, 2000). It has even been suggested that detoxified PTX can be used alone without any of the other *B. pertussis* antigens to develop efficacious vaccines against whooping cough (Taranger *et al.*, 2001). On the other hand, it may also be possible to develop efficacious vaccines in the absence of PTX, as infection with a PTX-deficient strain is able to fully protect mice against subsequent challenge with a virulent strain (Mielcarek *et al.*, 1998).

## ADENYLATE CYCLASE TOXIN

The adenylate cyclase (ACT, AC-Hly, or CyaA) is the only known enzyme toxin capable of directly penetrating target cells across the cytoplasmic membrane and of reaching the cytosol without the need for endocytosis (Gordon *et al.*, 1988; Bellalou *et al.*, 1990; Schlecht *et al.*, 2004). This mode of entry into cells by self-supported membrane translocation is accomplished by a single CyaA polypeptide of 1706 residues (Figure 16.1). The toxin molecule consists of an N-terminal ~400 residue-long adenylate cyclase enzyme (AC) domain that is linked to a characteristic RTX hemolysin (Hly) moiety of ~1300 residues (Glaser *et al.*, 1988a). The Hly portion serves both for the secretion of CyaA out of the bacteria (Glaser *et al.*, 1988b) and for toxin binding to the $\alpha_M\beta_2$ integrin receptor (CD11b/CD18, CR3, or Mac-1) of myeloid phagocytic cells (Guermonprez *et al.*, 2001; El-Azami-El-Idrissi *et al.*, 2003) and delivery (injection) into the target cells (Bellalou *et al.*, 1990).

The toxin was discovered in 1975 by Hewlett *et al.* (1976) as an extracytoplasmic AC enzyme activity present in *B. pertussis* culture media. Wolff *et al.* (1980) found in 1980 that the activity of the AC enzyme was enhanced by several orders of magnitude following interaction with eukaryotic calmodulin. Confer and Eaton (1982) then showed that CyaA can penetrate phagocytic cells and provokes their impotence by elevating intracellular levels of cAMP, a key cellular "second messenger" signaling molecule. Finally, Weiss *et al.* (1986) demonstrated in 1986 that the toxin plays a key role in *Bordetella* virulence, by showing that *cyaA::Tn5* mutants unable to produce CyaA exhibit a substantially higher $LD_{50}$ in the infant mice model of intranasal *B. pertussis* infection than wild-type strains. The toxin was subsequently found to play a particularly important role in the early stages of *Bordetella* colonization of the host respiratory tract (Goodwin and Weiss, 1990; Khelef *et al.*, 1992) and, in contrast to PTX, CyaA is produced also by *B. parapertussis* and *B. bronchiseptica* (Parkhill *et al.*, 2003).

### Biogenesis of CyaA

CyaA belongs to the steadily growing family of RTX (*R*epeat-in-*T*o*X*in) proteins of Gram-negative bacteria that are secreted through the type I pathway and harbor the calcium-binding aspartate and glycine-rich G-G-X-G-X-D repeats (Welch, 2001). The toxin is encoded

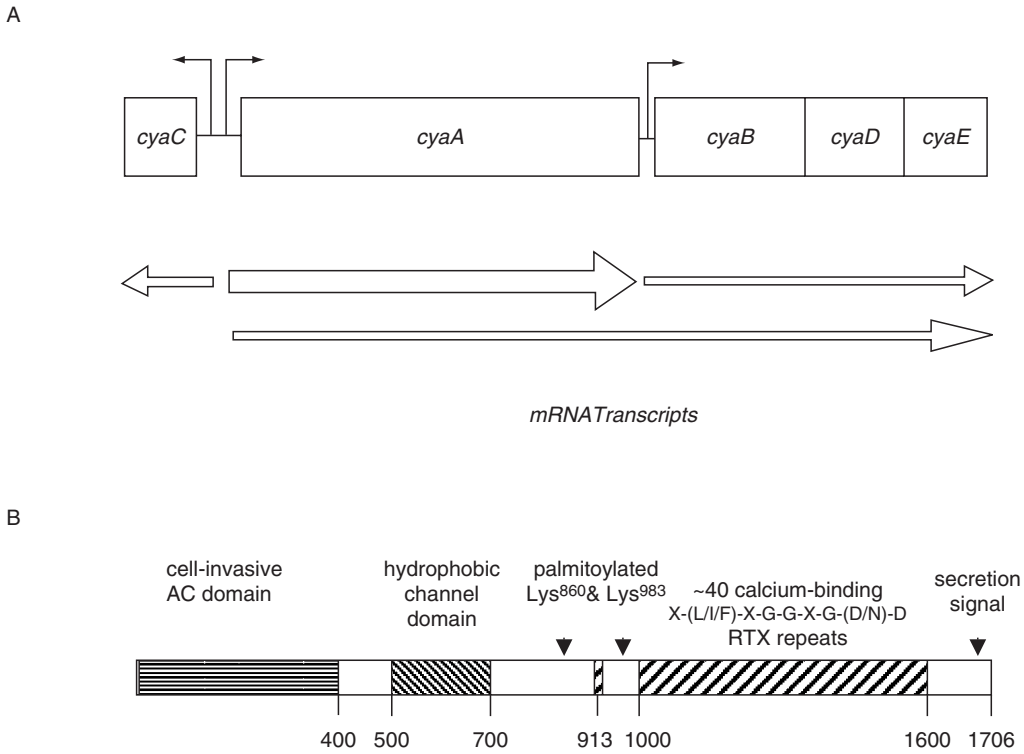

**FIGURE 16.1** (A) Organization of the *cya* locus of *Bordetella pertussis*. The *cyaABDE* genes (Glaser *et al.*, 1988a) form an operon transcribed from a BvgA/S-regulated promoter located 115 bp upstream from the translational start codon of the protoxin (proCyaA) gene *cyaA*. The transcript is partially terminated 3′ to the *cyaA*, with some read-through into the downstream genes resulting in full-length *cyaABDE* transcripts. The *cyaBDE* genes coding for the components of a the type I secretion apparatus are constitutively transcribed at a lower level from a BvgA/S-independent promoter located in the intergenic *cyaA-cyaB* region (Laoide and Ullmann, 1990). The *cyaC* gene is transcribed in the opposite direction and encodes the 22-kDa CyaC protein responsible for the posttranslational fatty-acyl modification of proCyaA (Barry *et al.*, 1991).
(B) Organization of the CyaA toxin molecule. CyaA consists of an N-terminal ~400 residue-long, cell-invasive, and CaM-activated AC domain (Wolff *et al.*, 1980; Confer and Eaton, 1982; Glaser *et al.*, 1989) and of a ~1300 residue-long RTX hemolysin/cytolysin (Hly) moiety (Glaser *et al.*, 1988a; Sakamoto *et al.*, 1992). The Hly portion contains (i) between residues 500 to 700 a hydrophobic channel-forming domain (Benz*et al.*, 1994); (ii) between residues 800 to 1,000 a domain where the activation by posttranslational palmitoylation of $Lys^{860}$ and $Lys^{983}$ takes place (Hackett *et al.* 1994, 1995); (iii) between residues 1,000 to 1,600 an RTX domain containing the characteristic repeats formed by X-(L/I/F)-X-G-G-X-G-(N/D)-D nonapeptides into which up to 40 calcium atoms bind with low-affinity (Rose *et al.*, 1995) and a C-terminal secretion signal (Sebo and Ladant, 1993).

by the *cya* locus (Figure 16.1A), and its production is under control of the BvgA/S system (Scarlato *et al.*, 1991). Of the five *cya* genes in the locus, the *cyaABDE* genes are grouped within an operon (Glaser *et al.*, 1988a; Laoide and Ullmann, 1990), while the *cyaC* gene is transcribed in an opposite direction. It encodes the 22-kDa CyaC protein, an acyltransferase that catalyzes the posttranslational fatty-acyl modification converting proCyaA to the mature and biologically active CyaA (Barry *et al.*, 1991). The *cyaABDE* operon starts by the structural *cyaA* gene, followed by three genes encoding the inner membrane ATP-ase (CyaB), the membrane fusion protein (CyaD), and the outer membrane channel component (CyaE) of a typical type I protein secretion system (Glaser *et al.*, 1988b). The toxin is likely to be secreted by a mechanism identical to that used for secretion of the RTX α-hemolysin (HlyA) of *E. coli* through the HlyBD/TolC apparatus (Koronakis *et al.*, 2004). By analogy, CyaB would operate as an ABC family transporter that recognizes the secretion signal located within the last 74 residues of CyaA (Sebo and Ladant, 1993) and drives secretion of an unfolded CyaA polypeptide through a tightly packed trimeric CyaBDE "channel-tunnel" conduit, directly from bacterial cytoplasm into the external medium, without passage of CyaA through the periplasmic compartment (Koronakis *et al.*, 2004). In many *Bordetella* isolates, the protein remains attached to the bacterial surface following secretion, due to an interaction with the filamentous hemaglutinin (Zaretzky *et al.*, 2002). However, most of the cell-attached CyaA appears to be aggregated and unable to act as a "contact weapon"

since only the newly secreted CyaA is capable of penetrating target cells and raising intracellular cAMP levels (Gray *et al.*, 2004).

## The RTX hemolysin moiety of CyaA

The RTX hemolysin (Hly) moiety of CyaA (~1300 carboxy-proximal residues) is functionally independent and is itself capable of forming small cation-selective membrane channels of a diameter between 0.6 to 0.8 nm (Sakamoto *et al.*, 1992; Benz *et al.*, 1994). These channels can permeabilize target cell membranes and provoke colloid-osmotic lysis of erythrocytes, accounting for the hemolytic halo of *Bordetella* colonies on blood agar plates (Weiss *et al.*, 1984). However, compared to typical hemolysins of the RTX family, the specific hemolytic activity of CyaA is low (Bellalou *et al.*, 1990; Ehrmann *et al.*, 1991), suggesting that the main role of the Hly moiety is not hemolysis *per se*, but rather supporting delivery of the AC domain into target cells (Rogel *et al.*, 1991; Rogel and Hanski, 1992).

The RTX Hly of CyaA consists itself of several functional subdomains (Iwaki *et al.*, 1995; Rose *et al.*, 1995). It contains (i) a hydrophobic channel-forming domain comprising residues 500 to 700 (Benz *et al.*, 1994); (ii) an activation domain between residues 800 and 1000, where the posttranslational palmitoylation of CyaA occurs (Hackett *et al.*, 1994; Hackett *et al.*, 1995); and (iii) a typical calcium-binding RTX domain, harboring the more-or-less conserved nonapeptide repeats of a consensus sequence X-(L/I/F)-X-G-G-X-G-(N/D)-D, which form numerous (aproximedtely 40) calcium-binding sites (Rose *et al.*, 1995; Rhodes *et al.*, 2001). Cooperation and structural integrity of all domains of the Hly moiety appear to be critical for membrane insertion and translocation of the AC domain into the target cell cytosol (Bellalou *et al.*, 1990; Iwaki *et al.*, 1995). The main segment of CyaA required for binding to the CD11b/CD18 integrin receptor has been recently located in the glycine-rich repeat region between residues 1166 to 1281 of CyaA (El-Azami-El-Idrissi *et al.*, 2003).

## The cell-invasive adenylate cyclase enzyme domain of CyaA

Following penetration into target cells, the AC domain binds intracellular calmodulin (CaM) in a 1:1 stoichiometry, and its enzymatic activity is increased by >1000-fold, reaching the extremely high catalytic power of $k_{cat}$ ~2000 $s^{-1}$. This appears to be about three orders of magnitude higher than the activity of endogenous cellular adenylate cyclases (Ladant, 1988; Glaser *et al.*, 1989). Upon limited proteolysis of the AC-CaM complex with trypsin, two functional subdomains of the catalytic AC domain could be defined as T25 and T18 fragments that are still able to assemble with CaM into a fully active ternary complex (Ladant, 1988). By using residue modification and mutagenesis, the AC catalytic site was located within the T25 subdomain (residues 1–224), while the main CaM-binding domain was located on the T18 (residues 225–399) fragment (Glaser *et al.*, 1989; Ladant *et al.*, 1989). Amino acid substitutions of $Trp^{242}$ have yielded AC enzymes with a full catalytic activity and up to 1000-fold reduced affinity for CaM (Glaser *et al.*, 1989; Ladant *et al.*, 1989). The hydrophobic side of the α-helical region situated around $Trp^{242}$ is the major site of the AC domain interaction with CaM, supporting the conclusion that the secondary rather than the primary structure of the binding site is important for interaction with CaM (Bouhss *et al.*, 1993). However, AC appears to make contact with CaM at multiple sites, as a 71 residue-long peptide, comprising residues 196 to 267 of CyaA and overlapping with the carboxyl terminus of T25 and the amino terminus of T18, is needed to recover 90% of the binding energy of the AC-CaM complex (Bouhss *et al.*, 1993).

The *Bordetella* AC domain was found to share three short homologous protein segments (I to III) with edema factor (EF) of *Bacillus anthracis*, the other known CaM-dependent bacterial AC enzyme (Glaser *et al.*, 1991). This similarity allowed investigators to pinpoint several residues that are critical for the catalytic activity of AC. $Lys^{58}$ and $Lys^{65}$ within segment I (residues 54–77) were found to be part of the AC catalytic site, and their replacements result in an important decrease, or total loss, of enzyme activity (Glaser *et al.*, 1989). In addition, $His^{63}$ in segment I has been identified as the general acid/base catalyst in a predicted charge-relay system proposed to be involved in the reaction mechanism of adenylyl cyclization (Munier *et al.*, 1992). In segment II (residues 184–196), $Asp^{188}$ and $Asp^{190}$ appear to be required for binding of the $Mg^{2+}$-ATP complex (Glaser *et al.*, 1991). Finally, substitutions of $His^{298}$ and $Glu^{301}$ in segment III (residues 294–314) also affect the nucleotide binding properties of AC, albeit to a lesser degree (Glaser *et al.*, 1991). The original conclusion, that $His^{298}$ and $Glu^{301}$ are involved in the mechanism of AC activation by CaM, may need to be revised, given that the corresponding segment of *B. anthracis* EF (residues $Asn^{583}$, $Glu^{588}$, and $Asp^{590}$) clearly appears to be involved in catalysis (Drum *et al.*, 2002). In general, however, the recent structural work on EF suggests that mutagenesis of AC yielded a fairly accurate identification of the essential catalytic residues of CyaA, with $His^{63}$ of CyaA corresponding well to $His^{351}$ that serves as a general catalytic base in EF (Drum *et al.*, 2002). The

studies on EF revealed a novel reaction mechanism for the CaM-activated bacterial AC, which differs from the two-metal-ion catalytic mechanism of mammalian enzymes. However, it remains to be determined whether AC of CyaA uses a similar reaction mechanism as EF, since the AC and EF enzymes exhibit substantial differences in CaM binding and activation, and the entire helical domain of EF is missing in the AC enzyme (Shen *et al.*, 2002). The ~10,000-fold activation factor of AC upon CaM binding is higher than that of EF, and AC exhibits an about 100-fold higher affinity for CaM than EF. The $K_d$ of AC for CaM ranges between ~20 nM and ~2 nM at physiological concentrations of intracellular $Ca^{2+}$ and CaM (50 nM to 10 fM) and is decreased to about ~0.2 nM at 0.1 mM free $Ca^{2+}$ concentrations (Ladant *et al.*, 1992; Shen *et al.*, 2002).

## Role of $Ca^{2+}$ ions in toxin activity of CyaA

Calcium ions are required for CyaA binding to the $\alpha_M\beta_2$ integrin receptor (CD11b/CD18) on myeloid cells (Guermonprez *et al.*, 2001), and the toxin activity of CyaA strictly requires exposure of the protein to physiological (>0.3 mM) concentrations of free calcium ions (Hanski and Farfel, 1985; Hewlett *et al.*, 1991). CyaA harbors numerous (about 40) calcium binding sites, and already a seemingly "irreversible" loading of a small number of $Ca^{2+}$ binding sites (about 5) allows the toxin to interact with membranes and to express hemolytic activity (Rogel and Hanski, 1992; Rose *et al.*, 1995). The precise location of these high-affinity binding sites within the Hly moiety of CyaA remains unknown, while the low-affinity ($K_d$ >0.3 mM) $Ca^{2+}$ binding sites (~35-40) have been located within the 700 C-terminal residues of CyaA (Rose *et al.*, 1995; Rhodes *et al.*, 2001). By analogy with the structure of the RTX moiety of the alkaline protease of *Pseudomonas* (Baumann *et al.*, 1993), the calcium atoms are expected to bind to CyaA within the turns connecting adjacent anti-parallel beta strands formed by the X-(L/I/F)-X-G-G-X-G-(N/D)-D nonapeptides of the RTX domain. Calcium ions bind to CyaA in an extremely cooperative manner, and the channel-forming activity of CyaA is enhanced by ~50-fold upon a minimal (15%) increase of the free $Ca^{2+}$ concentration from 0.6 to only 0.8 mM (Knapp *et al.*, 2003). This suggests that following secretion from the calcium-poor bacterial cytoplasm into the body fluids containing millimolar concentrations of calcium, the $Ca^{2+}$ ions cooperatively bind to CyaA at numerous sites in parallel. This would account for the massive structural differences between the calcium-free and calcium-loaded CyaA molecules that have been observed earlier by negative staining electron microscopy (Hewlett *et al.*, 1991). Such "toggle-like" switching of the CyaA protein from an "off" to the "on" conformation would then support toxin penetration into target cell membranes, formation of CyaA channels, and delivery of the AC domain into cell cytosol.

## Posttranslational activation of CyaA by fatty-acylation

Similar to the other cytolytic RTX toxins, the capacity of CyaA to bind to and penetrate cellular membranes depends on activation by posttranslational modifications (Rogel *et al.*, 1989). For CyaA this is mediated by the co-expressed accessory protein CyaC (Barry *et al.*, 1991; Sebo *et al.*, 1991), which catalyzes covalent palmitoylation of the ε-amino groups of $Lys^{860}$ and $Lys^{983}$ in the conserved RTX acylation sites of CyaA (Hackett *et al.*, 1994; Hackett *et al.*, 1995).

Acylation of CyaA is required for the high-affinity ("irreversible") binding of CyaA to the CD11b/CD18 integrin receptor (El-Azami-El-Idrissi *et al.*, 2003). Interestingly, acylation also determines the capacity of CyaA to induce protective immunity against *Bordetella* infection (Betsou *et al.*, 1993), suggesting that acylation alters the overall conformation of CyaA. Native CyaA extracted from the *B. pertussis* strain 338 is acylated at the single $Lys^{983}$ residue (Hackett *et al.*, 1994), and single acylation of only $Lys^{983}$ appears to be necessary and sufficient for toxin activity on the so far examined target cell types. Furthermore, acylation of $Lys^{983}$ is sufficient for CyaA penetration of membranes of cells lacking CD11b/CD18, such as sheep erythrocytes (Basar *et al.*, 2001). However, recombinant CyaA produced in *E. coli*, or CyaA overproduced by a recombinant *B. pertussis* strain 18323/pBN, have both been found to be acylated on both conserved lysine residues, raising a question about the biological significance of the second acylation of CyaA (Havlicek *et al.*, 2001). Recently, we found that acylation of either $Lys^{860}$ or $Lys^{983}$ individually confers the full capacity of CyaA to tightly associate with CD11b/CD18-expressing cells. Moreover, CyaA acylated only on $Lys^{860}$ still exhibited a fairly high cytotoxic activity towards murine monocytic cells expressing $CD11b^+$ (Masin *et al.*, unpublished). This suggests that acylation of the two lysine residues is partially redundant in function, and it remains unclear whether acylation of both lysines is required for toxin activity on some as yet unknown targets.

Unexpectedly, acylation of CyaA is not essential for toxin interaction with lipid membranes, since the non-acylated proCyaA is even more active in penetrating and disrupting liposomes than acylated CyaA (Masin

*et al.*, 2004). However, the acyl residues attached to CyaA appear to play a role in modulating the protein-protein interactions that underlie toxin oligomerization and formation of the CyaA channels. This is suggested by the observation that acylation of recombinant CyaA by the C16:1 palmitoyl residues causes a highly selective decrease of the channel-forming (oligomerization) capacity of recombinant CyaA, as compared to the *B. pertussis* CyaA acylated by C16:0 palmitoyl chains, while both proteins exhibit an equal capacity to penetrate cellular membranes and to translocate the AC domain into cells (Benz *et al.*, 1994; Hackett *et al.*, 1995; Havlicek *et al.*, 2001). A structural role of acylation in promoting formation of toxin channels is also consistent with the observation that the high cation selectivity of the CyaA channel strongly depends on neutralization of the positive charge of $Lys^{983}$ by fatty-acylation (Masin *et al.*, unpublished). This indicates that acylated $Lys^{983}$ may be located at the mouth or within the CyaA channel.

## Membrane interaction and penetration of CyaA into cells

The CD11b/CD18 integrin is the high-affinity receptor for CyaA on myeloid phagocytic cells (Guermonprez *et al.*, 2001), which appear to be the physiologically most relevant cellular targets of the toxin (Harvill *et al.*, 1999). However, CyaA can also penetrate and intoxicate a variety of other cell types lacking CD11b/CD18, such as mammalian erythrocytes (Hanski, 1989; Bellalou *et al.*, 1990). Several reports have shown that CyaA is unique among the enzymatically active toxins in its capacity to cross directly the cytoplasmic membrane of cells and to reach their cytosol without the need for endocytosis. Intoxication of cells occurs instantaneously upon exposure to CyaA (Gentile *et al.*, 1988), and inhibitors of the known endocytosis mechanisms block only the CD18-dependent trafficking of CyaA for endosomal degradation and not the accumulation of intracellular cAMP (Gordon *et al.*, 1988; Guermonprez *et al.*, 1999), or the AC domain-mediated delivery of foreign epitopes into cell cytosol (Schlecht *et al.*, 2004).

Translocation, but not the mere insertion of CyaA into the cytoplasmic membrane of cells, appears to be driven by membrane potential (Otero *et al.*, 1995). However, the path of translocation of the ~40 kDa AC domain of CyaA across the lipid bilayer remains poorly defined. The AC does not seem to enter cells through the CyaA hemolysin channel, which has a diameter of only 0.6 to 0.8 nm and is thus too small for the passage of even a fully unfolded AC (Benz *et al.*, 1994). Formation of hemolytic CyaA channels is not a prerequisite for AC domain translocation into cells, as clearly shown by comparisons of CyaA activities on human and sheep erythrocytes and/or by comparison of activities between recombinant and native CyaA (Betsou *et al.*, 1993; Hackett *et al.*, 1995; Gray *et al.*, 1998). Moreover, translocation of the AC domain can be dissociated from the formation of the cation-selective CyaA channels by amino acid substitutions in the predicted membrane segments of CyaA (Osickova *et al.*, 1999). Mutant forms of recombinant CyaA have recently been generated, which exhibit an about twenty-fold lower channel-forming activity than native CyaA, while both forms of the protein are equally capable of translocating the AC domain into the cytososol of $CD11b^+$ monocytic cells (Basler, Masin, and Sebo, unpublished). Altogether, the available data allow us to propose a model of CyaA action in which two different and more-or-less mutually exclusive toxin conformers co-exist and insert into the target-cell membrane in parallel (Figure 16.2). One of these forms gives rise to a translocation precursor delivering the AC domain across the cytoplasmic membrane, while the other form inserts as a channel precursor and oligomerizes within the membrane to form the CyaA channel. However, the possibility still remains that CyaA interacts with the cellular membrane as a very stable dimer, since this would be indistinguishable from a monomer in the toxin activity versus concentration plots. The capacity of CyaA to form functional oligomers is also suggested by the rather efficient functional complementation of pairs of individually inactive toxin molecules carrying non-overlapping deletions (Iwaki *et al.*, 1995; Bejerano *et al.*, 1999).

## Physiological consequences of CyaA interactions with target cells

The role of CyaA in the interaction of *Bordetella* with the cells of the respiratory epithelia and in the modulation of the host immune response through induction of proinflammatory cytokine secretion remains poorly explored. Inflammation is observed in lungs of patients who died of whooping cough, and infection of human bronchial epithelial cells with *B. pertussis* upregulates mRNA expression of a number of genes encoding proinflammatory cytokines and induces IL-6 and IL-8 secretion (Belcher *et al.*, 2000). Recent work suggests that the CyaA activity may account for the induction of IL-6 in tracheal epithelia colonized by *B. pertussis* (Bassinet *et al.*, 2004). CyaA contributes to numerous pathological effects seen in the murine model of lung infection, such as efficient pulmonary colonization, induction of histopathological lesions in the lungs, recruitment of inflammatory leukocytes, and

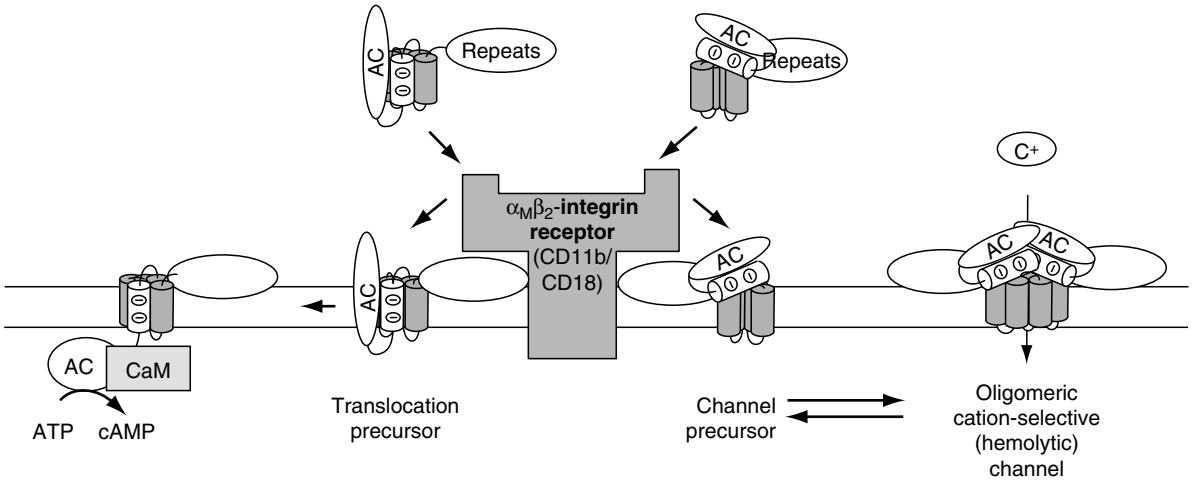

**FIGURE 16.2** Model of CyaA action on target cell membranes. The sum of currently available data suggests that following binding to the CD11b/CD18 receptor, CyaA inserts into the cell membrane in two different and more or less mutually exclusive conformations, one giving rise to a translocation precursor delivering the AC domain across the cytoplasmic membrane and the other inserting as a channel precursor and oligomerizing within the membrane to form the CyaA channel (Osickova *et al.*, 1999). The model is substantiated by a series of observations. Only about 50% of cell-associated AC activity is found translocated across a membrane into a trypsin-inaccessible compartment (Masin *et al.*, 2004). Different types of acylation differently affect only the hemolytic (channel-forming) activity of CyaA without affecting its capacity to deliver the AC domain across the membrane (Hackett *et al.*, 1995). Furthermore, amino acid substitutions can be generated in the channel domain that dissociate the AC delivery and channel-forming activities of CyaA (Osickova *et al.*, 1999) and can shift the balance between channel-forming and AC translocation activities of the toxin in both directions (Basler *et al.* unpublished).

induction of lethality (Weiss *et al.*, 1984; Gueirard *et al.*, 1998). In a physiologically relevant model of natural infection of mice by *B. bronchiseptica*, a mutant strain defective in CyaA production has been found to be completely avirulent in B and T cell deficient mice, while remaining fully virulent in neutropenic mice (Harvill *et al.*, 1999). This strongly suggests that myeloid phagocytic cells, and especially neutrophiles, are the primary *in vivo* targets of *B. bronchiseptica* CyaA and most likely also of the *B. pertussis* AC toxin (Weingart *et al.*, 2000). Indeed, CyaA-mediated intoxication has been found to inhibit signaling resulting from engagement of Fc receptors by opsonizing antibodies, thereby inhibiting phagocytosis of *B. pertussis* cells by neutrophils (Weingart and Weiss, 2000). CyaA activity further causes loss of chemotactic and oxidative burst capacities required for bactericidal activity of leukocytes (Friedman *et al.*, 1987). Moreover, the toxin can induce macrophage apoptosis (Khelef *et al.*, 1993; Khelef and Guiso, 1995) by a mechanism involving disruption of the membrane potential in mitochondria (Bachelet *et al.*, 2002).

## AC as a marker enzyme tool

The fact, that Gram-negative bacteria generally do not express CaM homologues and that in the absence of CaM the AC domain exhibits only residual enzyme activity allowed for the use of the AC domain as a reporter enzyme for tracing protein translocation into the eukaryotic cell cytosol (Sory and Cornelis, 1994). The AC reporter protein is fused to a bacterial test protein, such as a *Yersinia* Yop protein. While the hybrid protein exhibits very low AC activity in the bacterial cell and/or culture supernatants, once it is injected via the Yop effector domain into a eukaryotic host cell, the AC enzyme is activated by >1000-fold by the host CaM and catalyzes rapid conversion of ATP to cAMP. This can be easily assayed as intracellular cAMP accumulation that is proportional to the amount of injected AC fusion protein. This approach has become a standard technique to investigate mechanisms of protein translocation into eukaryotic host cells by the type III secretion apparatus.

A second application of AC activity makes use of the fact that the residual activity in the absence of CaM requires the physical interaction of the T25 and T18 fragments of the AC domain, which can be exploited to develop a bacterial two-hybrid system for detection of protein-protein interactions (Karimova *et al.*, 1998). When the T25 and T18 fragments are individually fused to peptides or proteins that are able to bind to each other, the interaction of the chimeric polypeptides yields a functional complementation of the T25 and

T18 fragments and the restoration of the residual capacity of the enzyme to convert intracellular ATP to cAMP. This, in turn, can be monitored in a rather sensitive manner by using *E. coli* lacking the endogenous adenylate cyclase activity as indicator strains for the two hybrid screening, as even very low levels of cAMP produced by the reconstituted AC enzyme still allow for the transcription of the genes involved in lactose and maltose catabolism in *E. coli*. Hence, this property offers a convenient detection system of functional interactions between proteins expressed in the two-hybrid screens on indicator plates or by the positive selection for growth of bacterial colonies in minimal media containing maltose as the unique carbon source (Dautin *et al.*, 2002).

### CyaA as a novel antigen delivery tool to induce specific T cell responses

The capacity of genetically detoxified CyaA to penetrate with high efficiency the professional antigen-presenting cells expressing CD11b/CD18 ($CD11b^{high}$) allowed for the development of CyaA into a tool for antigen delivery and induction of specific T cell responses against viruses and tumors (El-Azami-El-Idrissi *et al.*, 2002; Simsova *et al.*, 2004). Advantage can be taken of the capacity of the AC domain to accommodate foreign antigenic polypetides of up to 200 residues in length without losing cell invasiveness (Gmira *et al.*, 2001). Genetically detoxified hybrid CyaA toxoids can be used for highly efficient *in vivo* delivery of foreign $CD8^+$ and $CD4^+$ T cell epitopes or entire antigens into the MHC class I- and class II-dependent antigen-presentation pathways in parallel (Fayolle *et al.*, 2001; Schlecht *et al.*, 2004; Vordermeier *et al.*, 2004). In this manner strong $T_{h1}$-polarized and epitope-specific $CD4^+$ and $CD8^+$ CTL responses can be simultaneously induced for effective prophylactic vaccination against viruses (Saron *et al.*, 1997) or immunotherapy of tumors (Fayolle *et al.*, 1999; Dadaglio *et al.*, 2003). Phase I/II clinical trials in humans aiming at exploring this application of CyaA are currently in preparation.

## DERMONECROTIC TOXIN

In contrast to the other *Bordetella* protein toxins, dermonecrotic toxin (DNT) is an intracellular toxin (Cowell *et al.*, 1979). In fact, DNT was originally named endotoxin (Bordet and Gengou, 1909). It has also been called heat-labile toxin, because of its complete inactivation after 60 minutes. at 56°C (Livey and Wardlaw, 1984). The term DNT is due to the characteristic skin lesions that the toxin produces when injected into animals (Bordet and Gengou, 1909). Although its role in the pathogenesis is far from being clear, it is a very potent toxin, as an intravenous inoculation of very low doses of DNT is lethal for mice (Kume *et al.*, 1986).

### Structure-function relationship of DNT

DNT is produced by *B. pertussis, B. parapertussis*, and *B. bronchiseptica* (Parkhill *et al.*, 2003), and the degree of sequence similarities between the three proteins is very high (approximately 99% sequence identity). Its gene is also present in the *B. avium* genome, but the sequence of the *B. avium* DNT shows much divergence from the other three DNT sequences. The *B. pertussis* and the *B. bronchiseptica* DNT each contain 1,451 amino acids and have a predicted molecular mass of 159 kDa (Pullinger *et al.*, 1996; Walker and Weiss, 1994). The three-dimensional structure of DNT has not been determined, but based on the primary structure, the protein can be divided into two principal domains. The N-terminal domain constitutes the receptor-binding region, and the C-terminal domain expresses enzymatic activity. As such, DNT is thus a member of the A-B toxin family.

Within the N-terminal domain of DNT, a fragment consisting of the N-terminal 54 amino acid residues has been shown to inhibit the intoxication of cells by full-length DNT (Matsuzawa *et al.*, 2002). This 54 residues-long fragment is able to bind to the surface of target cells, and this binding can be inhibited by a monoclonal antibody that is able to neutralize the effects of DNT when mixed with the toxin. This antibody is not able to neutralize the toxin activity when microinjected into the target cells, indicating that it interferes with toxin binding. These observations indicate that the extreme N-terminal portion of DNT is crucial for receptor binding. Interestingly, the 54 residue-long peptide does not bind to DNT-resistant cells, indicating that DNT-sensitive cells contain on their surface a specific receptor for the toxin. This receptor remains to be identified.

The C-terminal, catalytic domain of DNT shares sequence similarities with the *E. coli* cytotoxic necrotizing factor (CNF) (Walker and Weiss, 1994). Both toxins cause deamidation of glutamine 63 in Rho (Horiguchi *et al.*, 1997; Flatau *et al.*, 1997). In the presence of primary amines, DNT also catalyzes the transglutamination of Rho. This catalytic activity is expressed by a fragment covering residues 1136–1451 of DNT (Schmidt *et al.*, 1999), the region that is highly homologous to the catalytic domain of CNF1. The three dimensional structure of the CNF1 catalytic domain has been determined at a 1.83 Å resolution (Buetow *et al.*, 2001) and was found to contain a Cys-His-main chain oxygen catalytic triad. This triad is highly conserved

among the homologous proteins, suggesting that they all express their enzymatic activity by the same mechanism. The catalytic cysteine of CNF1 is located at the base of a deep pocket. This position would be expected to restrict the access to potential substrates, thereby explaining the high specificity of these toxins. Whereas the catalytic pocket of CNF1 is electrostatically nondescript, the DNT pocket carries a net negative charge that may attract positively charged primary amines. This structural difference may account for the differences in enzymatic activities between the two toxins, since CNF1 is preferentially a deamidase, whereas DNT is preferentially a transglutaminase, replacing the side chain of amide of the glutamine by a primary amine rather than by a hydroxyl (Smidt *et al*., 1999). Site-directed alterations of the conserved Cys-1292 in DNT abolish both the deamidase and transglutaminase activities of DNT.

## Molecular mechanisms of DNT action

DNT is produced by *Bordetella* as a single polypeptide chain. However, upon binding to its target cell receptor, it can undergo proteolytic cleavage, which separates the N-terminal fragment from the catalytic domain. The mammalian endoprotease furin has been shown to cleave DNT specifically at the C-terminal site of Arg-44 (Matsuzawa *et al*., 2004). This cleavage appears to be necessary for the expression of toxin activity, as mutant toxins that are insensitive to furin have no toxic effect. Conversely, an *in vitro* nicked form of the toxin is more potent than the intact form, indicating that nicking by furin is a prerequisite for toxin action. The nicked toxin part lacking the first 44 amino acid residues is then able to dissociate from the receptor-binding domain and to cross the lipid bilayer to gain access to the cytosol, where the catalytic domain is able to express its enzyme activity. The translocation step of DNT relies on amino acid residues 45–166, which include a putative transmembrane domain. Translocation does not require acidification of endosomes, nor retrograde vesicular transport. However, the toxin appears to be internalized by dynamin-dependent endocytosis.

Once the toxin has reached the cytoplasm of the target cells, its enzymatic domain catalyzes the deamidation of the small GTPases Rho (Horiguchi *et al*., 1997), Rac, and Cdc42 (Masuda *et al*., 2002). Upon deamidation Rho, Rac, and Cdc42 lose their GTP-hydrolyzing, but not their GTP-binding, activities. Reduced GTP hydrolysis results in prolonged activation of these small GTP-binding proteins, which in their activated states interact with their respective effectors. This, in turn, results in ultrastructural rearrangements of the cytoskeleton, leading to morphological changes, such as the formation of lamellipodia and filopodia, accompanied by the assembly of actin stress fibers and focal adhesions (Horiguchi *et al*., 1995).

In addition to Rho, Rac, and Cdc42 deamidation, DNT also catalyzes cross-linking of Rho, Rac, and Cdc42 with ubiquitous polyamines (Masuda *et al*., 2000). Polyamination occurs at the same residues as deamidation and also results in reduced GTP-hydrolase activity, without affecting GTP binding. Interestingly, polyaminated Rho, even in its GDP-bound form, interacts more effectively with its effector ROCK than deamidated Rho in the GTP-bound form, indicating that polyamination of Rho transduces signals to its effector ROCK in a GTP-independent manner.

The DNT-catalyzed modification of Rho also induces the proliferation of cytoplasmic membrane organelles, such as the Golgi apparatus, the endoplasmic reticulum, and the mitochondria, as well as the formation of plasmalemmal calveolae (Senda *et al*., 1997). The focal adhesion phenotype may be related to the stimulation of tyrosine phosphorylation of focal adhesion kinase and paxillin upon modification of Rho (Lacerda *et al*., 1997).

## Role of DNT in pathogenesis

One of the principal target cells for DNT is the osteoblast. Upon treatment with DNT, osteoblasts undergo a transition from a spindle-shaped, stretched morphology to spherical or block forms (Horiguchi *et al*., 1991). In addition, they lose their extensions and form small blebs on their surface, although they remain viable and continue to proliferate. Alkaline phosphatase activity and the accumulation of type I collagen are reduced in treated cells compared to control cells, suggesting that DNT impairs the ability of osteoblasts to differentiate, and that thereby the toxin acts on osteogenesis.

The pathology induced by DNT has best been studied in pigs infected with *B. bronchiseptica*, where the toxin has been shown to induce ultrastructural changes in the nasal turbinate bones (Silvera *et al*., 1982), leading to the development of atrophic rhinitis. The use of *B. bronchiseptica* strains differing in their ability to produce DNT in a neonatal swine infection model has indicated that only strains that synthesize high levels of DNT are able to produce nasal and lung lesions (Roop *et al*., 1987). These lesions vary from moderate to severe, establishing a direct correlation between the level of toxin production and the ability of *B. bronchiseptica* to induce nasal and lung lesions. In fact, mutant derivatives of virulent strains that lack DNT do not induce clinical manifestations, but have been

shown to induce protective immunity. DNT-deficient strains may, therefore, be considered as live vaccine candidates against atrophic rhinitis (Nagano *et al*., 1988).

The role of the *B. bronchiseptica* DNT in the pathogenesis of respiratory disease in swine has more recently been firmly established by the use of isogenic strains only differing in the production of DNT (Brockmeier *et al*., 2002). Compared to the wild-type strain, the DNT-deficient mutant was found to slightly less well colonize the upper respiratory tract of one-week-old piglets. The colonization ability of the lower respiratory tract was not affected by the lack of DNT. In addition to the slight difference in upper respiratory tract colonization, the mutant strain did not induce turbinate atrophy or pneumonia in the piglets, whereas turbinate atrophy and bronchopneumonia were found in most piglets infected with the parent strain. Similar observations have been made in the mouse model after infection with either the wild-type or the isogenic mutant strain (Magyar *et al*., 2000).

The role, if any, of DNT in whooping cough is less well understood. *B. pertussis* strains lacking DNT are as virulent in infant mice as the wild-type parent strain (Weiss and Goodwin, 1989), and different human isolates from whooping cough patients may vary in their ability to produce the toxin. There is apparently no correlation between the level of DNT production and the infectivity of *B. pertussis* in humans. In fact, most clinical isolates appear not to produce DNT, suggesting that this toxin does not play a major role in the virulence of *B. pertussis* in humans (Gueirard and Guiso, 1993).

# The Shiga toxins: properties and action on cells

*Kirsten Sandvig*

## INTRODUCTION

Shiga and Shiga-like toxins (Stxs) are produced by bacteria able to cause infectious disease (Karmali, 2004b; Karmali, 2004a; O'Loughlin and Robins-Browne, 2001). These protein toxins belong to the group of A-B toxins (Figure 17.1) (Lingwood, 1999; Sandvig, 2001; Sandvig and van Deurs, 2002; Lingwood, 2003). The binding part (B) of Shiga toxins consists of a pentamer that recognizes specific glycosphingolipids at the cell surface; most of these toxins bind to globotriasoylceramide (Gb3). After binding, the toxin is endocytosed and transported retrogradely to the Golgi apparatus and the endoplasmic reticulum (ER) (Sandvig *et al.*, 1992) from where the enzymatically active moiety (A or A1) is translocated to the cytosol (Figure 17.2). After entry into the cytosol, the toxin inactivates ribosomes by removing one adenine from the 28S RNA (Endo *et al.*, 1988), and thereby it inhibits protein synthesis. During entry into cells, the A-chain is cleaved by the cellular enzyme furin into the small A2 fragment and the enzymatically active part, the A1 fragment (Garred *et al.*, 1995b). The Shiga toxins can in some cells induce synthesis of cytokines (Foster and Tesh, 2002; Lee *et al.*, 2002), and the toxins are able to cause apoptosis (Yoshida *et al.*, 2002; Smith *et al.*, 2003). In most cells, apoptosis seems to be caused by ribotoxic stress (Smith *et al.*, 2003). Furthermore, binding of these toxins can induce signaling cascades that may contribute to the entry and the effects observed (Sandvig *et al.*, 2004).

Contaminated water and food are major sources of infection with bacteria producing Shiga toxins (Kumar *et al.*, 2004b; Karmali, 2004a). Although cattle and other animals (Urdahl *et al.*, 2004a) serve as a natural reservoir of Stx-producing *Escherichia coli* (STEC), not only beef but also contaminated seafood, vegetables, and fruits give rise to infections (Kumar *et al.*, 2004b; Karmali, 2004a; Kumar *et al.*, 2004a). Furthermore, also person-to-person transmission can easily occur since the infectious dose of *Escherichia coli* is very low (Karmali, 2004a). Infection with bacteria producing Shiga-like toxins is a threat to human health even in industrialized countries. Diarrhea caused by these bacteria can be followed by hemolytic uremic syndrome (HUS), which is characterized by acute renal failure, thrombocytopenia, and microangiopathic hemolytic anemia (Karmali, 2004a). HUS can also be a complication to urinary tract infection by Shiga toxin producing *E. coli* (Karmali, 2004a). Especially children are at risk of getting kidney failure after such infections. Of infected persons, 5–10% will develop HUS, and 5% of these will die from the disease. The reader is referred to earlier reviews (Andreoli *et al.*, 2002; Siegler, 2003; Paton and Paton, 1998) when it comes to the development and characteristics of this disease where toxic effects are observed in the kidney endothelial cells as well as in other cell types. Studies so far reveal that although the Shiga toxins are related, their effects differ, and the outcome of an infection with bacteria producing one or more of these toxins is dependent on the type of toxin produced. Increased understanding of the mode of action of Shiga toxins is important both to

prevent and to cure toxin-induced disease (Karmali, 2004a; Karmali, 2004b). Importantly, Shiga toxins can also be used as tools in medicine and biology (Sandvig and van Deurs, 2002; Smith *et al.*, 2002b; Kim *et al.*, 1998; Facchini and Lingwood, 2001). This chapter will describe the various aspects of the Shiga toxins and their interactions with cells.

## THE SHIGA TOXINS AND THE BACTERIA THAT PRODUCE THEM

As shown in Figure 17.1, Shiga toxin, which is produced by *Shigella dysenteriae*, consists of a ring of five identical B-chains (the B-moiety), which is noncovalently associated with the A-chain of the toxin. The B-chains of Shiga toxin each have a molecular mass of 7,691, and each B-chain has been found to have three binding sites for Gb3. However, these are not equal in their ability to bind the receptor. As described below, the ability of one toxin molecule to bind multiple glycosphingolipid molecules is likely to be important not only for its strong binding to the cell surface but also for entry into the cells. The intact A-chain of Shiga toxin has a mass of 32,225, and importantly, it contains a loop formed by a disulfide bond involving the two cysteines in position 242 and 261. In this loop area, there is the sequence Arg-X-X-Arg that is the minimal recognizable motif for the cellular enzyme furin, which seems to be responsible for cleavage of the A-chain into the active A1-part and the inactive A2-peptide (Garred *et al.*, 1995b). In Shiga toxin, the active site of A1 is blocked by a methionine residue found in A2 (Fraser *et al.*, 1994). When cells without furin are transfected with this enzyme, they obtain the ability to cleave the toxin, and they do also become sensitized to Shiga toxin. Amino acid changes that involve removal of one of the arginines in the loop, or deletion of the loop, make the molecule resistant to cleavage by furin and reduce the effect of Shiga toxin on cells (Garred *et al.*, 1995a). Furin-induced cleavage of Shiga toxin occurs most efficiently at low pH (Garred *et al.*, 1995b), and since furin recycles between the cell surface and the endosomes, cleavage of the toxin can occur at an

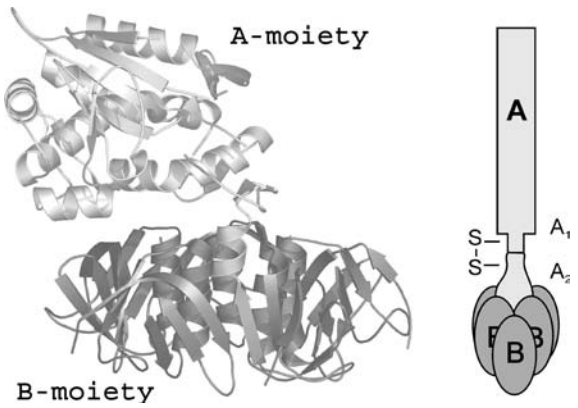

**FIGURE 17.1** Structure of Shiga toxin; chrystallographic and schematic (PDB protein data bank 1DMO). The binding moiety consists of the five small B fragment that are responsible for binding to glycosphingolipids (Gb3) at the cell surface. The A fragment can be cleaved by the cellular enzyme furin to A1 and A2, and the enzymatic activity resides in the A1 fragment.

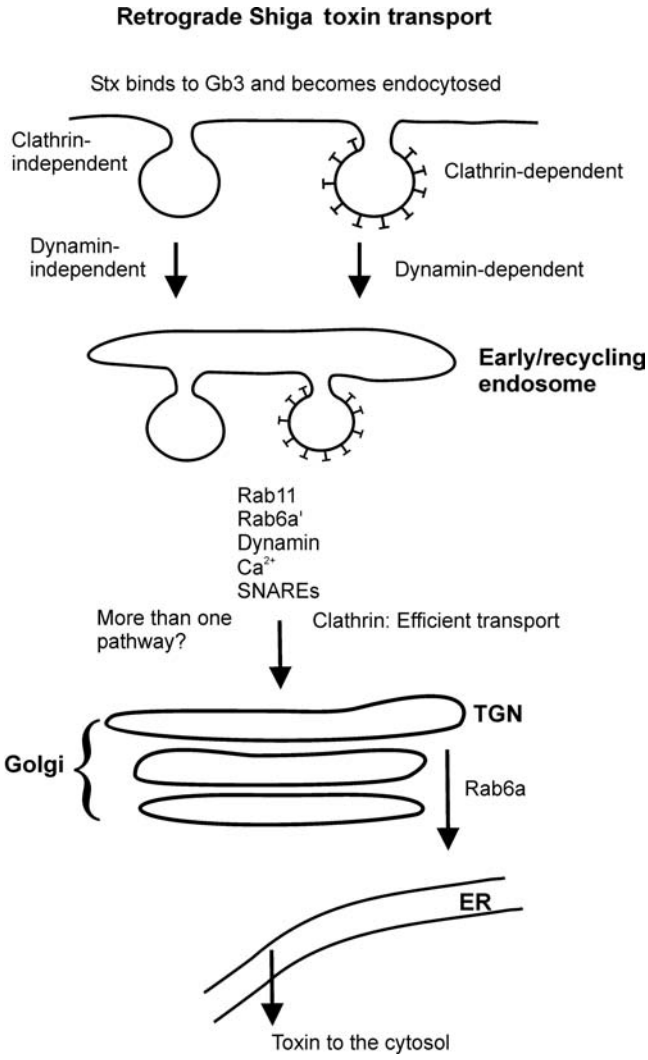

**FIGURE 17.2** Entry of Shiga toxin into cells. After endocytic uptake either from clathrin-coated pits or by clathrin-independent endocytosis, the toxin is transported to the Golgi apparatus by a process that can be dependent on clathrin, dynamin, and two different SNARE-complexes, as discussed in the text. After retrograde transport to the endoplasmic reticulum, at least the enzymatically active A1 fragment is transferred to the cytosol where it inactivates the ribosomes and thereby inhibits protein synthesis. This may then induce apoptosis (see main text).

optimal rate shortly after it is endocytosed. It should be noted that furin activates not only Shiga toxin but also other toxins such as diphtheria and anthrax toxin (Gordon and Leppla, 1994). However, the conditions for optimal cleavage differ and the location of toxin processing in the cell is therefore likely to be toxin-dependent. Thus, cleavage of anthrax occurs already at the cell surface (Klimpel *et al.*, 1992). After cleavage of Shiga toxin with furin, the internal disulfide bond in the A-chain will function to keep the two parts of the A-chain together and in association with the B-chain that can mediate retrograde transport of the enzymatically active part to the Golgi apparatus and the ER. If the disulfide is deleted by mutation of one of the cysteines (C242S), the A1-moiety of the A-chain is released from the rest of the molecule after cleavage with furin (Garred *et al.*, 1997). Even in cells without furin, there is a certain toxicity and cleavage of the A-chain. However, the toxicity is seen after longer times, and the cleavage occurs at a later stage of the intracellular journey of Shiga toxin since it (in contrast to furin-induced cleavage) is abolished by brefeldin A that disrupts the Golgi apparatus. Interestingly, inhibitors of the cytosolic enzyme calpain can reduce this processing, and one may therefore speculate as to whether the cleavage occurs after translocation of the intact A-chain to the cytosol (Garred *et al.*, 1995a). Different studies of Shiga toxin and Shiga-like toxins, as well as of the plant toxin ricin, reveal that there are two areas with sequence homology in the A-chains that are important for the enzymatic activity. For the A-chain of Shiga toxin, a change of glutamic acid in position 167 to aspartic acid was found to reduce the toxic effect of the molecule by a factor of 1,000 (Acheson and Keusch, 1999).

A number of Shiga-like toxins (Stxs) are produced by *Escherichia coli* and also other bacteria, such as *Aeromonas hydrophila, A. cavia, Citrobacter freundii*, and *Enterobacter cloacae,* have been reported to secrete similar toxins (Schmidt, 2001; Paton and Paton, 1998; Schmidt *et al.*, 1993). Furthermore, the fact that free Shiga toxin bacteriophages can be isolated from sewage (Muniesa *et al.*, 2004) might suggest that other bacteria can be toxin producers also. It should be noted that these toxins are also called *verotoxins* (VT) due to their strong toxic effect on Vero cells (names such as VT1 and VT2 are still commonly used). In contrast to Shiga toxin that is chromosomally encoded, the Stxs are encoded by prophages in *E. coli*, and they may therefore be transferred to other bacteria. Shiga-like toxin 1 (Stx1) is almost identical to Shiga toxin; there is only one amino acid that differs. However, although the differences are not large, some variants of Stx1 have been found and characterized (Paton *et al.*, 1995; Ohmura-Hoshino *et al.*, 2003; Suzuki *et al.*, 2004). In contrast, Shiga-like toxin 2 (Stx2) consists of several subgroups: Stx2, Stx2c (Schmitt *et al.*, 1991), 2d (Pierard *et al.*, 1998), 2e (Weinstein *et al.*, 1988), and 2f (Schmidt *et al.*, 2000). The toxins are not neutralized by antiserum to Shiga toxin, and the homology is around 60%. Interestingly, some bacteria produce more than one toxin variant. A number of different Shiga toxin types are produced in humans after infection. For instance, studies of 677 Shiga-toxin–producing *E. coli* revealed that they produced six different types of toxin (Stx1, Stx1c, Stx2, Stx2c, Stx2d, and Stx2e) (Beutin *et al.*, 2004). As mentioned, most of the Shiga-like toxins bind Gb3. A special case is Stx2e, secreted by bacteria that mostly infect pigs, since it binds to Gb4. Mutations of the B-chain affecting the binding specificity have been performed (Acheson and Keusch, 1999). Recent structural studies of Stx2 (Fraser *et al.*, 2004) reveal important differences between Stx and Stx2. For instance, in contrast to Stx (Fraser *et al.*, 1994), the active site of Stx2 is accessible in the crystal structure, the carboxyl termini of the A subunits of the two toxins differ in structure, and one of the receptor-binding domains in the B-pentamer differs in conformation. These differences are likely to be related to the fact that the toxins are far from identical in their interaction with cells and in development of disease.

## DETECTION OF SHIGA AND SHIGA-LIKE TOXINS

Detection of Stx-producing bacteria and of Stx can be performed by different methods, including enzyme-linked immunosorbent assays (ELISA), cytotoxicity assays, and polymerase chain reaction (PCR) (Pulz *et al.*, 2003; Shimada *et al.*, 1999; Kumar *et al.*, 2004a). Also, flow cytometry detection of Shiga toxins bound to polymorphonuclear leukocytes was reported to be a rapid, simple, and sensitive method to detect circulating Shiga toxin and to diagnose STEC infections (Tazzari *et al.*, 2004). For a historical overview of Stx discovery and purification, the reader is referred to Acheson and Keusch (Acheson and Keusch, 1999).

## BINDING OF TOXIN TO CELL SURFACE RECEPTORS

Binding of Stxs to cell surface receptors is a complex and, in general, a necessary first step for intoxication. However, binding to specific receptors does not always lead to a subsequent toxic effect (see below). As described above, the Stxs (with the exception of Stx 2e) bind to the sequence Gal α1-4 Gal-Glu of Gb3, but the

interaction with the carbohydrates is toxin-specific (Binnington *et al.*, 2002; Lingwood and Mylvaganam, 2003). This has been demonstrated by removal of hydroxyl-groups from the carbohydrates. Although mutational analysis of the Gb3-binding sites of the toxin B-chain suggests that all three binding sites of the B-chain play a role (Soltyk *et al.*, 2002), the interaction of the three sites with Gb3 is not identical. The role of one of these sites (site 3) in Stx 1B may be to orient the molecule at the cell surface. Not only the carbohydrate part of Gb3 but also the fatty acid in the receptor (Gb3) is important for binding (Binnington *et al.*, 2002). The length, the degree of unsaturation, and the hydroxylation of the fatty acid can determine the toxin binding. Importantly, the binding of the different Stxs are not affected to the same extent by a change in fatty acid composition, indicating that differences in effects on cells seen with various Stxs can be due to the interaction with the receptor and the location of Gb3 in the membrane. Gb3 with long saturated fatty acids is localized in lipid domains, in contrast to Gb3 with more unsaturated fatty acid, and intoxication and entry of Stxs into cells have been reported to be dependent on Gb3 composition and the presence of the receptor in rafts (Falguieres *et al.*, 2001; Kovbasnjuk *et al.*, 2001a). Not only the direct interaction of Stx with Gb3 is important for the binding. Interestingly, also the phospholipids in the surrounding membrane play a role (Arab and Lingwood, 1998; Arab and Lingwood, 1996), and the receptor-bound toxin itself has been reported to interact with surface proteins (Shimizu *et al.*, 2003). Such interactions could of course influence the location of the toxin-receptor complex, and the interactions could facilitate uptake of the toxin by specific endocytic pathways. Thus, although more Stx1 than Stx2 binds to human renal endothelial cells, these cells are more sensitive to Stx2 (Louise and Obrig, 1995). The possibility exists that Stx2 binds to receptors that are more prone to be internalized and transported to the right destination.

It should be mentioned that although glycolipids provide high-affinity binding sites for Stxs, the interactions with proteins at the cell surface of polymorphonuclear lymphocytes (PMNs) might play an important role in disease (te Loo *et al.*, 2000). Since this interaction is weaker than the one between Stx and glycolipids, these cells could function to bring the toxin from the site of infection to the kidney where the toxin would become associated with glycolipid receptors on kidney cells (te Loo *et al.*, 2000). The ability of kidney cells to bind Stx might be a function of age (Chark *et al.*, 2004) and could explain the larger susceptibility of children to get kidney failure. However, the interaction of Stx with different cell types seems to play a role in the development of disease. The recent finding that Stx binds to activated blood platelets (Ghosh *et al.*, 2004) may be important for the pathogenesis of HUS. However, the symptoms seen in connection with HUS can be caused by a combination of factors affecting cells. For instance, Shiga-like toxins might increase hemin-induced toxicity in renal tubular epithelial cells due to an inhibition of the cellular response to excess heme (Bitzan *et al.*, 2004).

The synthesis of Gb3 can, in certain cell types, be regulated by cytokines (for instance TNF-α and interleukin-1), by bacterial lipopolysaccharide (LPS), as well as by chemical substances such as butyric acid and increased levels of cAMP (Sandvig *et al.*, 2004; Lingwood, 1999). Since Stx in itself can induce synthesis of cytokines (see below), the toxin can to some extent regulate its own binding and effect on cells. The fact that quite high concentrations of butyric acid can be found in the intestine might be important for effects of Stx (McIntyre *et al.*, 1993; Fishman, 1982; Agarwal and Schimmel, 1989). It should be noted that the increased binding of Shiga toxin seen after treatment with butyric acid is not only due to an increased binding, it is also due to a change in the glycolipid composition of the cells facilitating transport of the toxin in the direction of the Golgi apparatus (Sandvig *et al.*, 1992; Sandvig *et al.*, 1996; Sandvig *et al.*, 1994). The induced production of Gb3 usually takes some time; a more rapid increase in exposure of Gb3 was recently reported to occur after treatment of endothelial cells with sphingomyelinase (Obrig *et al.*, 2003). Thus, a number of factors are important for the interaction of Stxs with surface receptors on cells.

Although action of Stx usually is dependent on interaction of the toxin with surface receptors, recent data suggest that the toxin might also have alternative ways to exert biological activity (Ferens *et al.*, 2004). Interestingly, the toxin was found to inhibit replication of bovine leukemia virus in a culture of bovine peripheral blood mononuclear cells, probably by entering directly through the permeabilized membrane of these cells (Ferens *et al.*, 2004).

## ENDOCYTIC UPTAKE OF SHIGA TOXIN

After binding of Shiga toxin to Gb3, the toxin-receptor complex is endocytosed. The uptake can occur by different endocytic pathways (Figure 17.2), and the fraction of toxin endocytosed by a given pathway is cell-type dependent and can be changed by the growth conditions (Lauvrak *et al.*, 2004; Khine *et al.*, 2004). In HeLa cells, the toxin can induce its own entry from clathrin-coated pits by a so far unknown mechanism

(Sandvig *et al.*, 1991; Sandvig *et al.*, 1989). Shiga toxin was the first lipid-binding toxin found to be internalized from clathrin-coated pits. More recently, it has been found that in some cells also cholera toxin can enter in a clathrin-dependent manner (Torgersen *et al.*, 2001; Shogomori and Futerman, 2001; Lencer and Tsai, 2003). It is possible that interactions with other surface molecules might play a role (Shimizu *et al.*, 2003). Along this line, it has been demonstrated that the glycosylphosphatidyl-anchored prion protein can enter from clathrin-coated pits due to an interaction of its protein part with other molecules at the external side of the membrane (Shyng *et al.*, 1995; Sunyach *et al.*, 2003).

As mentioned above, Stx can be internalized by different endocytic mechanisms (Nichols, 2002; Sandvig *et al.*, 2002; Lauvrak *et al.*, 2004; Lingwood, 1999; Khine *et al.*, 2004). Interestingly, when clathrin-dependent toxin uptake is blocked by expression of a dominant negative mutant of dynamin, which will inhibit uptake both from clathrin-coated pits and from caveolae, Stx is still endocytosed (Lauvrak *et al.*, 2004). Also when antisense to clathrin-heavy chain is expressed in BHK cells leading to an inhibition of clathrin function (Iversen *et al.*, 2003), Shiga toxin is taken in by endocytosis. In both cases, the uptake is reduced by about 50%. This does not necessarily reflect the fraction of toxin normally taken in by clathrin-independent endocytosis, since it has previously been shown that reduction of uptake from clathrin-coated pits by expression of mutant dynamin can up-regulate clathrin-independent endocytosis (Damke *et al.*, 1995). In some of the studies cited above, the uptake of Stx B-chain and not intact Stx was studied. Whether this makes a difference has not been reported, but could indeed be the case. Thus, at this point, one should be careful in making conclusions on the behavior of the intact toxin from studies of the B-chain. However, it is in agreement with studies of intact toxin (Lauvrak *et al.*, 2004) that similar investigations employing vector-based RNAi against clathrin heavy chain were shown to reduce also the rate of uptake of Stx-B chain (Saint-Pol *et al.*, 2004).

One can apparently regulate the fraction of toxin taken in by clathrin-dependent versus clathrin-independent endocytosis even in one and the same cell (Lauvrak *et al.*, 2004). When BHK cells are treated with butyric acid, they are sensitized to Stx, and a larger fraction seems to be internalized by clathrin-dependent endocytosis. As described below, clathrin also seems to play an important role for endosome to Golgi transport under these conditions. The Stx-receptor complex can be present in lipid rafts at the cell surface (Falguieres *et al.*, 2001). To what extent this is important for endocytosis of the toxin is not known, but one could imagine that it might affect the pathway used. As discussed below, raft association seems to be important for intracellular sorting of the toxin.

## TRANSPORT OF STX BETWEEN ENDOSOMES AND THE GOLGI APPARATUS

A critical step for intoxication with Stx is transport from endosomes to the Golgi apparatus (Figure 17.2) (Sannerud *et al.*, 2003; Sandvig and van Deurs, 2002). There are different lines of evidence indicating that Stx in sensitive cells is sorted directly from early and not via late endosomes to the Golgi apparatus (Mallard *et al.*, 1998; Sandvig *et al.*, 2002). Rab9-dependent transport from late endosomes to Golgi apparatus has been well characterized in the case of the mannose-6-phosphate receptor (Lombardi *et al.*, 1993; Riederer *et al.*, 1994), and we therefore produced cells with inducible synthesis of dominant negative mutant Rab 9 (Sandvig *et al.*, 2002). Upon induction of this mutant Rab9, there was a strong inhibition of Golgi transport of the mannose-6-phosphate receptor, whereas there was no effect on toxicity of Shiga toxin or on the Golgi transport of the related plant toxin ricin. Also, microscopical studies had already indicated that the Stx B-chain was transported from early endosomes to the Golgi, possibly via the perinuclear recycling compartment. In this compartment, the toxin could be seen in membrane areas coated with clathrin and containing AP1 (Mallard *et al.*, 1998). More recent studies have revealed a requirement for the clathrin adaptor epsin R, whereas AP1 does not seem to be required (Saint-Pol *et al.*, 2004). These results are in agreement with our data showing that clathrin is required for efficient endosome to Golgi transport (Lauvrak *et al.*, 2004). In cells sensitized to Stx with butyric acid, there is a strong inhibition of Stx transport to the Golgi apparatus upon induction of antisense to clathrin heavy chain. Interestingly, without sensitization to Stx by butyric acid, there is a smaller difference upon reduction of clathrin function and also a lower extent of protection against the toxin. These findings seem to reconcile some of the previous reports on the role/lack of role for clathrin in endosome to Golgi transport of Stx. In addition to clathrin, dynamin is important for this transport step (Lauvrak *et al.*, 2004), and it has been reported that also Rab11 and Rab6A′ are involved at this point (Sannerud *et al.*, 2003). Furthermore, SNAREs involved in this transport step (endosome to Golgi) have been characterized: the v-SNAREs VAMP3 and VAMP4 and the t-SNARES syntaxin 6, syntaxin 16, and Vti1A are important for this transport (Sannerud *et al.*, 2003; Johannes and Goud, 2000) and recently a second complex consisting of the

SNAREs syntaxin 5, GS28, Ykt6, and GS15 was found to be involved in endosome to Golgi transport of the StxB-chain (Tai *et al.*, 2004). When antibodies to these components were added to an *in vitro* system, the sulfation (a Golgi modification) of a modified StxB-chain was inhibited. The authors of this article suggest that there might be parallel pathways, employing different SNARE-complexes, operating between endosomes and the Golgi apparatus. Importantly, the level of cytosolic $Ca^{2+}$ plays a role in endosome to Golgi transport. Increasing levels of $Ca^{2+}$ will increase transport of Stx-B to Golgi by a factor of two in MDCK II cells (Lauvrak *et al.*, 2002), and it has been reported that decrease of the cytosolic $Ca^{2+}$ by a chelating agent that binds this ion decreased Shiga toxin transport to the Golgi (Chen *et al.*, 2002). However, in MDCK cells, increased levels of $Ca^{2+}$ have a much stronger effect on the transport of ricin (Lauvrak *et al.*, 2002) that presumably also is transported from early endosomes, supporting the idea that there could be multiple pathways or transport from different subdomains of endosomes. Interestingly, cholesterol is, as first shown for ricin (Grimmer *et al.*, 2000), also required for endosome to Golgi transport of Shiga toxin (Falguieres *et al.*, 2001). The exact role of cholesterol is, however, not known. Lipid rafts containing the toxin receptors may play a role in concentrating the receptors for transport in the direction of the Golgi apparatus, or such domains or cholesterol in itself could recruit cytosolic proteins of importance for vesicle formation or docking. Interesting in this context is the finding that glycolipids are not required for the retrograde transport of the plant toxin ricin (Spilsberg *et al.*, 2003).

## RETROGRADE STX TRANSPORT TO THE ER AND TRANSLOCATION OF THE A-CHAIN TO THE CYTOSOL

How does retrograde Stx transport occur? Stx does not have a KDEL sequence that could mediate retrograde transport by binding to the KDEL-receptor in COP I-coated vesicles (Calderwood *et al.*, 1987; Kozlov *et al.*, 1987). In agreement with this, saturation of KDEL receptors by lysozyme-KDEL expression did not protect cells against Stx1, whereas it did protect against *Pseudomonas* exotoxin A (Jackson *et al.*, 1999), which is believed to be transported retrogradely by exploiting the KDEL-system. However, different possibilities for retrograde transport exist, and Stx seems to use a Rab6A, COP I-independent route on its way to the ER and the cytosol (Figure 17.2) (White *et al.*, 1999; Girod *et al.*, 1999; Ghosh *et al.*, 2004). Studies of retrograde transport are complicated by the fact that the cells may use alternative pathways leading to the ER when one interferes with the normal routing. This was demonstrated to be the case in CHO cells where the Golgi was vesiculated by incubating cells with a temperature-sensitive ε-COP at the non-permissive temperature (Llorente *et al.*, 2003). At the non-permissive temperature the Golgi apparatus was vesiculated, and there seemed to be induction of a direct route between endosomes and the ER, a transport circumventing the Golgi vesicles. To investigate this compensatory routing, we used a modified form of the protein toxin ricin, a form that could be both sulfated by the sulfotransferase of the Golgi and glycosylated by ER-enzymes. Although Stx may be transported all the way to the ER in lipid rafts, it is not known whether the raft location is a requirement for TGN to ER transport (Ghosh *et al.*, 2004). Not surprisingly, actin may be important for retrograde transport (Luna *et al.*, 2002; Duran *et al.*, 2003). However, although actin seems to be required, too much actin and a strong network can actually inhibit the retrograde transport (Luna *et al.*, 2002; Duran *et al.*, 2003).

When Stx arrives in the ER, cells containing furin have already cleaved and activated the A-chain so it now consists of A1 connected to A2 by a disulfide bond (Garred *et al.*, 1995b). What happens to Stx is not known, but in analogy with cholera toxin that also has a disulfide bond which needs to be cleaved and where it has been shown that the ER-enzyme protein disulfide isomerase is involved in release of A1 from the rest of the molecule (Tsai *et al.*, 2001; Tsai and Rapoport, 2002), one might guess that this happens also in the case of Shiga toxin. However, this still has to be demonstrated. Also, it is not known how Stx is translocated from the ER to the cytosol, but again, in analogy with other toxins (Wesche *et al.*, 1999; Simpson *et al.*, 1999; Schmitz *et al.*, 2000), the Sec61-complex may be involved. This is the protein complex that is responsible for translocation of newly synthesized proteins from the cytosol to the ER, and this complex has been reported to be responsible for transfer of misfolded proteins from the ER to the cytosol where they are then subsequently degraded (Romisch, 1999). The Sec61-complex has, for instance, been found to interact with ricin (Wesche *et al.*, 1999; Simpson *et al.*, 1999) and with cholera toxin (Schmitz *et al.*, 2000). It should be noted that two recent publications (Ye *et al.*, 2004; Lilley and Ploegh, 2004) describe a new ER tranlocator, Derlin-1, responsible for transport of some proteins from the ER to the cytosol. Whether this protein might play a role in toxin transport remains to be investigated.

An important question that needs to be answered is: Which parts of Stx can enter the cytosol from the ER?

An enzymatically active part (presumably intact A1) is known to enter the cytosol since protein synthesis is inhibited, but can the whole A be translocated? The results obtained with Stx-mutants without the furin recognition site suggest that this is the case since these mutant molecules are cleaved by the cytosolic enzyme calpain (Garred *et al.*, 1995a). What about the B-chain? Could it also be translocated from the ER? It has been suggested that this is the case since epitopes orginally bound to the B-chain can be presented by MHC class I (Smith *et al.*, 2002b). However, there might be other explanation's for this presentation the epitope could for instance be transferred to the MHC class I in the ER (Smith *et al.*, 2002a). Also, it has been demonstrated that expression of the B-chain in the cytosol of cells leads to apoptosis (Nakagawa *et al.*, 1999), similarly as seen after addition of toxin to cells. However, these phenomena may be unrelated, and it is possible that B-chain production is toxic to cells. Thus, these questions still need clarification.

## TRANSPORT OF STX ACROSS EPITHELIAL CELLS

An important step in disease caused by Stx-producing bacteria is the transfer of the toxin across polarized epithelial cell layers. This can occur by transcytosis, a term that implies that the toxin is taken up into vesicles on one side of the cell layer and released again on the other side of the epithelial layer. Transcytosis of Stx1 and Stx2 has been demonstrated (Hurley *et al.*, 1999), and importantly the two toxins differ when it comes to how their transport is regulated. Disruption of microtubules with colchicine reduced the transport of Stx1 but not that of Stx2, whereas monensin (an ionophore that will increase the pH of acidic endosomes) decreased transport of both of them. Surprisingly, addition of Stx2 did not block transport of Stx1 (Hurley *et al.*, 1999). Whether differences between these two toxins at this stage contribute to the fact that Stx2 seems to be more potent in causing disease is not known. In polarized Caco-2 cells, the internalization of the Stx1 B-subunit was found to be dependent on lipid rafts (Kovbasnjuk *et al.*, 2001b). However, whether this is a general phenomenon for polarized epithelial cells and whether the same applies to Stx2 has not yet been investigated.

The toxins might also cross the epithelial cell layer by a paracellular route. Studies of the epithelial cell line T84 revealed that Stx-producing bacteria could induce synthesis of interleukin 8 and transmigration of polymorphonuclear leukocytes (Hurley *et al.*, 2001). This movement of leukocytes increased paracellular permeability to Stx (Hurley *et al.*, 2001), and would thereby increase the chance of HUS development. Another cell type that might play a role in disease caused by Stx-producing bacteria is the macrophage. If the epithelial cell barrier is disrupted, then macrophages can engulf the bacteria. Importantly, even when the bacteria are taken up and killed by the macrophages, these cells secrete toxin to the surroundings (Shimada *et al.*, 1999).

## INDUCTION OF CYTOKINE PRODUCTION

Stxs are able to induce production of cytokines such as interleukin 1, 6, and 8 after interacting with different types of cells (Cameron *et al.*, 2003; Smith *et al.*, 2003; Lee *et al.*, 2002; Thorpe *et al.*, 2001; Zoja *et al.*, 2002; Matussek *et al.*, 2003). In most cases, production of the interleukins and other peptides seems to be due to the stress caused by toxin-induced inactivation of the ribosomes (Thorpe *et al.*, 1999; Yamasaki *et al.*, 1999). This idea is supported by the following results: The protein toxin ricin has a similar effect as Stx on the intestinal epithelial cell HCT-8; both toxins induce secretion of interleukin-8 (Thorpe *et al.*, 1999), suggesting that the response is not due to the ability of Stx to selectively interact with Gb3. Also, a non-toxic mutant of Stx does not induce cytokine production (Yamasaki *et al.*, 1999). Interestingly, chemokine mRNAs can both be induced and stabilized by addition of Stx to cells (Thorpe *et al.*, 2001).

Toxin-induced activation of various protein kinases seems crucial for the production and release of cytokines. For instance, inhibition of MAP kinase (mitogen activated protein kinase) p38 resulted in reduced release of interleukin 8 (Thorpe *et al.*, 1999). Furthermore, there is evidence for involvement of other MAP kinases, such as JNK (Smith *et al.*, 2003). In monocytes, p38 and the kinase ERK seem to be involved in Stx-induced production of tumor necrosis factor α (TNFα) and granulocyte-macrophage colony-stimulated factor (GM-CSF) (Cameron *et al.*, 2003; Foster and Tesh, 2002). Quite recently, it was reported that Stx1 could induce release of adenine by a direct effect on DNA (Brigotti *et al.*, 2002), suggesting that the toxin can use different strategies to attack cells. Thus, the possibility exists that the ability of the toxin to change transcription could be related to the direct effect on nuclear DNA (Brigotti *et al.*, 2002).

There is evidence that the toxin-induced release of various active polypeptides is important for the development of disease after infection with Stx-producing bacteria. For instance, in response to Stx-induced

release of chemokines, neutrophiles may be recruited to the gut (the site of infection), and the intestinal barrier could become affected (Thorpe *et al.*, 2001). As discussed already, an important effect of some of the released active proteins is that they can induce synthesis of Gb3, the receptor for Stx, on other cell types and thereby make them sensitive to the toxin (Sandvig *et al.*, 2004).

The finding that Stx2 seems to be more potent than Stx1 in inducing HUS could be related to differences in the ability of these toxins to regulate cytokine production (Siegler *et al.*, 2003; Matussek *et al.*, 2003). Importantly, studies with cDNA arrays revealed that Stx2 produced by *E. coli* O157:7 isolated from a patient with HUS had the ability to up-regulate one-third of cytokine genes in renal tubular cells (Lee *et al.*, 2002), and it was suggested that these changes are associated with the renal injury seen in HUS. Studies in baboons (Siegler *et al.*, 2003) have actually demonstrated a difference in cytokine response after administration of Stx2 and Stx1. In that model, some of the changes associated with HUS were only observed with Stx2.

## TOXIN-INDUCED APOPTOSIS

Shiga toxins are known to induce apoptosis in several cell types, but the mechanisms involved seem to be cell-type dependent (Cherla *et al.*, 2003). At least in some cell types, the apoptosis mediated by Stx is induced after entry of the A-chain into the cytosol since disruption of the Golgi apparatus by the drug brefeldin A protects the cells not only against inhibition of protein synthesis but also against Stx-induced apoptosis (Yoshida *et al.*, 2002; Kojio *et al.*, 2000; Fujii *et al.*, 2003). Some of the stress-induced kinases, such as JNK and the MAP kinase p38, are reported to be involved in apoptosis since an inhibition of these kinases protected cells against this process (Smith *et al.*, 2003). Furthermore, Stx-induced apoptosis can be mediated by activation of caspases (Tetaud *et al.*, 2003; Smith *et al.*, 2003; Cherla *et al.*, 2003), but also caspase-independent, toxin-induced apoptosis has been reported (Cherla *et al.*, 2003). Inhibition of synthesis of the antiapoptotic protein MCl-1 (a Bcl-2 family member) may be involved in Stx-induced apoptosis in human dermal microvascular endothelial cells, and inhibition of protein degradation in these cells by addition of lactacystin prevented the toxin-induced apoptosis (Erwert *et al.*, 2003). Furthermore, overexpression of Bcl-2 in Hep-2 cells protected against apoptosis caused by Stx1 and Stx2 (Jones *et al.*, 2000). How the toxin-induced inactivation of ribosomes leads to activation of kinases and caspases is not known.

Cells can also undergo apoptosis in response to the B-chain only (Mori *et al.*, 2000; Tetaud *et al.*, 2003), suggesting that in some cases signaling caused by the receptor-bound B moiety is sufficient to induce apoptosis. A rapid activation of the tyrosine kinase Syk and the Src family kinase Lyn was observed in Ramos cells (Mori *et al.*, 2000). Interstingly, Stx and antibodies to Gb3 both induce apoptosis in Burkitt's lymphoma cells (Tetaud *et al.*, 2003), but different mechanisms are involved: Only the toxin-induced process was dependent on caspases (Tetaud *et al.*, 2003). Also, in the human renal tubular endothelial cells (ACHN), Stx rapidly activated the Scr kinase family member Yes (Katagiri *et al.*, 1999). Interestingly, in ACHN cells the Stx B subunit is sufficient to induce a cytoskeletal remodeling, which is dependent on Src kinases and Rho-associated kinase (Takenouchi *et al.*, 2004). A redistribution of a number of proteins including ezrin, CD44, vimentin, actin, and tubulin was demonstrated (Takenouchi *et al.*, 2004). However, the consequences of these changes need to be clarified. During disease caused by Stx-secreting bacteria, multiple factors are likely to contibute. Importantly, an apoptotic response can be increased by simultaneous exposure of cells to Stx, LPS (lipopolysacharide), and cytokines (Cherla *et al.*, 2003; Pijpers *et al.*, 2001).

## PROTECTION AGAINST SHIGA TOXINS

Both Shiga toxin produced by *Shigella dysenteriae* and Stxs produced by other bacteria can get into the bloodstream of the infected person and cause HUS. The Stxs also cause hemorrhagic colitis, although the role for Shiga toxin in Shigellosis is unclear (Acheson and Keusch, 1999). In contrast to Stx-secreting *E. coli*, *Shigella dysenteriae* invades the epithelial cells of the gut. Protection against the toxin by neutralizing it in the intestine and/or after transport to the blood is attempted in various ways. Immunization has been tried for some time (Acheson and Keusch, 1999), and more recently Stx-liposome conjugates are being investigated for effectiveness in vaccination (Uchida, 2003). New types of therapies are developed based on the detailed knowledge about the toxin-receptor interactions. Soluble receptor-based compounds able to bind Stxs after passage into the circulation or in the gut have been designed (Mulvey *et al.*, 2003; Karmali, 2004b; Watanabe *et al.*, 2004). Slight modification of these compounds can even change the specificity when it comes

to binding the different toxins (Mulvey *et al.*, 2003). Another approach to protect against the Stxs is to use bacteria that have been engineered to express Stx-binding molecules at the surface, thereby making these bacteria able to bind Stx and prevent spread to the circulation (Paton *et al.*, 2000). Interestingly, naturally occurring *E. coli* can produce LPS able to neutralize Stx2, and such bacteria might be used as probiotics (Gamage *et al.*, 2004). Improved technology and increased knowledge about the action of Stx are providing us with new tools to prevent and treat disease caused by toxin-producing bacteria.

## EXPLOITATION OF SHIGA TOXIN IN MEDICINE

Several protein toxins are used in construction of hybrid molecules (including immunotoxins), where a foreign binding part directs the hybrid molecule to the cell one wants to kill. For instance, both diphteria toxin and ricin conjugates directed against cancer cells have been prepared (Frankel *et al.*, 2002; Frankel *et al.*, 2000; Kreitman, 2003; Sinha, 2003; Thorburn *et al.*, 2004). In the case of Stxs, a similar approach might be used. However, it has also been suggested that Stx can be used against some forms of cancer without any modification (Siegler *et al.*, 2003; Arab *et al.*, 1999; Salhia *et al.*, 2002). Also, non-toxic derivatives of Stx were recently shown to possess adjuvant activity for mucosal immunity (Ohmura-Hoshino *et al.*, 2004).

Importantly, protein toxins can be used to obtain presentation of epitopes by MHC class I (Moron *et al.*, 2004; Smith *et al.*, 2002b). Parts of the toxin or inactivate mutant forms of the toxin with an extension containing the epitope to be presented are then incubated with cells, and the epitope is released from the modified toxin and presented by MHC class I (Moron *et al.*, 2004; Smith *et al.*, 2002b). In the case of Stx, epitopes have been added both to the A- and to the B-chain, and they are subsequently presented by MHC class I (Lee *et al.*, 1998; Haicheur *et al.*, 2000; Noakes *et al.*, 1999). Another possibility would be to add proteins with a biological function either to the A- or B-chain in order to obtain transport to the cytosol, as has been observed for other protein toxins (Wiedlocha *et al.*, 1994; Aullo *et al.*, 1993).

## CONCLUSION

The number of Shiga toxins that are discovered and characterized has been increasing, and our knowledge about the action of these toxins on single cells as well as in the whole organism is expanding. However, future research is required to obtain a complete understanding of the complex mechanism of action of these toxins and to develop new strategies to prevent and cure disease caused by the members of the Shiga toxin family. The exploitation of these fascinating toxins as vehicles in medicine, as well as probes to study general questions in cell biology, can be expected to lead to new discoveries.

## ACKNOWLEDGMENTS

CHAPTER

# 18

# *Bacillus anthracis* toxins

*Stephen H. Leppla*

## INTRODUCTION

Anthrax was recognized for many centuries as a serious disease of animals and man, one that inflicted great losses in agricultural economies and caused significant disease in humans. Thus, anthrax was a major concern to the pioneers of microbiology, and its study by Pasteur, Koch, Mechnikoff, and others led to the establishment of many basic principles of infectious disease study. Regrettably, anthrax has regained a prominent role in infectious disease research following its use as a bioterrorism weapon in the United States in 2001 (Lane *et al*., 2001).

In domestic livestock and wild animals, symptoms of infection by *Bacillus anthracis* are rarely evident until the animal becomes lethargic several hours before death. Necropsy shows extensive edema in many tissues and concentrations of bacteria in blood that may exceed $10^8$ $mL^{-1}$ (Turnbull, 1990). Most human cases arise from contact with infected animals or spores present in animal products (wool, leather, bone meal), and begin as cutaneous infection. This is easily treated with antibiotics if correctly diagnosed. The less frequent but more dangerous gastrointestinal and respiratory forms of anthrax show a rapid progression and must be recognized early to be successfully treated (Inglesby *et al*., 2002).

The virulence of *B. anthracis* for animals and man depends on the production of two recognized virulence factors, the gamma-linked poly-D-glutamic acid capsule, and the three-component protein exotoxin (Smith *et al*., 1955; Keppie *et al*., 1963). The capsule appears to protect bacteria from phagocytosis, and therefore plays an essential role during establishment of an infection. Recent work suggests that release of capsular material from the bacteria may also contribute to pathogenesis (Makino *et al*., 2002). The protein exotoxin may also help to establish an infection by incapacitating phagocytes (Keppie *et al*., 1963; Wade *et al*., 1985; O'Brien *et al*., 1985), but its more obvious role is to cause the extensive tissue edema that appears to be a principal cause of death. It is generally accepted that the pathological effects causing death in infected animals result largely from the toxin (Smith and Stoner, 1967). A number of recent reviews have discussed the toxin and its role in pathogenesis (Turnbull, 1996; Dixon *et al*., 1999; Duesbery and Vande Woude, 1999; Little and Ivins, 1999; Leppla, 2000; Turnbull, 2002; Ascenzi *et al*., 2002; Mock and Mignot, 2003; Collier and Young, 2003; Mourez, 2004). A recent monograph includes six additional review chapters on anthrax (Koehler, 2002b).

Virulent strains of *B. anthracis* contain two large plasmids, pXO1 and pXO2. The genes coding for toxin are contained on pXO1 (Mikesell *et al*., 1983; Thorne, 1985), and the genes for capsule are on pXO2 (Uchida *et al*., 1985; Green *et al*., 1985). Virulence requires the presence of both plasmids. Thus, strains lacking plasmid pXO1 do not produce toxin and are essentially avirulent in most animals (Ivins *et al*., 1986; Uchida *et al*., 1986), but do retain some virulence for mice (Welkos *et al*., 1993). Strains lacking pXO2 are at least $10^5$-fold less virulent than wild-type (Ivins *et al*., 1986; Welkos and Friedlander, 1988). Although it is possible that these plasmids code for other materials that contribute to virulence, none that have a large role have been identified. Complete DNA sequences have been obtained for the plasmids and for the chromosomal DNAs of several strains (Read *et al*., 2003).

The anthrax toxins described in this chapter are studied both because they are the principal virulence determinants of *B. anthracis* and because they constitute a useful model for study of interactions of protein ligands with eucaryotic cells. A unique feature is that the three toxin proteins are individually non-toxic. These proteins are designated protective antigen (PA), lethal factor (LF), and edema factor (EF). Toxic activity is obtained only when the proteins are administered in pairwise combinations. The combination of PA with LF, which causes rapid death of certain animal species when injected intravenously, is designated lethal toxin (LT). The combination of PA with EF, which causes edema when injected intradermally, is designated edema toxin (ET).

Work in recent years, to be detailed in this chapter, shows that PA binds to receptors on eucaryotic cells (Bradley *et al*., 2001; Scobie *et al*., 2003) and mediates the internalization of LF and EF to the cytosol (Figure 18.1). EF is an adenylate cyclase; it converts ATP to unphysiologically high concentrations of cAMP that cause metabolic perturbations (Leppla, 1982; Leppla, 1984). LF is a metalloprotease that cleaves mitogen activated protein kinase kinases (MEKs, also MKKs) (Vitale *et al*., 1998; Duesbery *et al*., 1998). The anthrax toxins can be viewed as fitting the A/B model described by Gill (1978), where the A moiety is a catalytic polypeptide (i.e., enzyme), and the B moiety is the receptor binding region and also usually contains a subdomain that facilities membrane translocation. In the case of anthrax toxin, the PA protein serves as the B moiety, whereas LF and EF are alternate A moieties. Anthrax toxin is unusual in that the A and B moieties are separate gene products and proteins. Several other toxins are now known that have separate protein components. Most similar to anthrax toxins are a group of related clostridial toxins. In those toxins, the receptor recognition protein that resembles PA is activated by proteolysis and then binds and promotes the internalization of an actin ADP-ribosylating protein (Barth *et al*., 2004).

Some confusion may arise from use of the designation PA for a component of a toxin. Before discovery of the toxin, it was shown that culture supernatants of *B. anthracis* could immunize animals against infection (Gladstone, 1948). Only after the toxin was discovered did it become clear that the "protective antigen" in the culture supernates was a component of the toxin. PA remains the principal and essential immunogen in both killed and live anthrax vaccines (Hambleton *et al*., 1984; Ivins and Welkos, 1988). Therefore, study of anthrax toxin has direct application to development of improved vaccines, a subject not covered in depth here.

## THE GENETICS OF TOXIN AND VIRULENCE

### Plasmids pXO1 and pXO2

The possibility that the genes for the dominant *B. anthracis* virulence factors might be extrachromosomal was suggested by the work of Louis Pasteur and Max Sterne, who each isolated variants of *B. anthracis* having reduced virulence. After some initial difficulties, plasmids associated with toxin and capsule were discovered (Mikesell *et al*., 1983; Uchida *et al*., 1985; Green

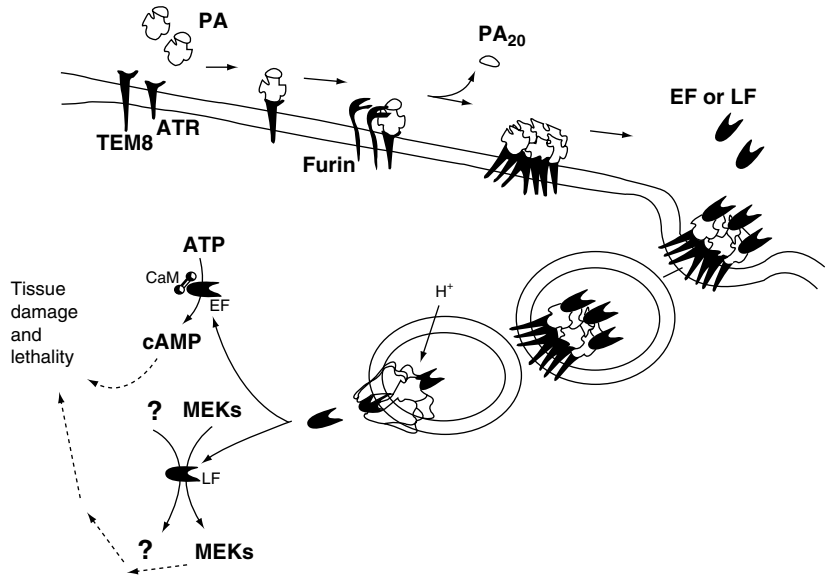

**FIGURE 18.1** Binding and internalization of anthrax toxin. Toxin components and cellular proteins that interact during LF and EF internalization are described in the text. CaM is calmodulin, and MEKs refers collectively to is mitogen activated protein kinase kinases.

*et al*., 1985). Special care is required in isolating these plasmids because their large size makes them easily sheared. Both these large plasmids have been sequenced. Plasmid pXO1 is 181.6 kb (Okinaka *et al*., 1999) and pXO2 is 96.2 kb (Pannucci *et al*., 2002). The replication origin of pXO2 is known to be similar to that of pAMβ1 (Tinsley *et al*., 2004), while that of pXO1 remains unknown.

The *B. anthracis* plasmids can each be selectively cured, pXO1 by repeated passage at 42°C, and pXO2 by growth in novobiocin. Comparison of plasmid-cured variants proved that pXO1 is needed for production of toxin and pXO2 for production of capsule (Thorne, 1985). Conjugal transfer of pXO1 to plasmid-cured strains of *B. anthracis* confirmed that all the genes necessary for toxin production are contained on the plasmid (Thorne, 1985; Heemskerk and Thorne, 1990). These results explain the properties and the efficacy of the anthrax vaccines developed by Louis Pasteur and Max Sterne. It is now well established that *B. anthracis* strains must produce PA in order to induce protective immunity (Ivins and Welkos, 1988). Elimination of the pXO1 plasmid yields an avirulent strain, but one that does not induce immunity. In retrospect, it is evident that Louis Pasteur's attenuation of the virulence of *B. anthracis* cultures by growth at 42°C was due to partial curing of plasmid pXO1. The cultures he used to successfully immunize sheep probably contained a small number of virulent ($pXO1^+$, $pXO2^+$) bacteria with a larger number of avirulent ($pXO1^-$, $pXO2^+$) bacteria, with their efficacy due to the former, which would induce antibodies to PA. While effective, these vaccines could cause infection if the fraction of virulent organisms was too high. Max Sterne's important contribution was to analyze carefully the rare, spontaneous non-capsulated variants appearing on agar plates, and to show that they were greatly reduced in virulence (Sterne, 1937). These variants, now known to have lost the pXO2 plasmid, are effective animal vaccines and do not revert to virulence. The ($pXO1^+$, $pXO2^-$) "Sterne" strain continues in use today as the preferred veterinary vaccine and as a convenient strain for laboratory studies because of its relative safety.

## Genes specifying toxin structure and expression

The recognition that anthrax toxin was encoded on pXO1 facilitated the cloning and sequencing of the genes encoding PA (*pagA*), LF (*lef*), and EF (*cya*) (Vodkin and Leppla, 1983; Robertson and Leppla, 1986; Tippetts and Robertson, 1988). Each of the genes has a G+C content of about 30% (Table 18.1), similar to that of the *B. anthracis* genomic DNA (35% G+C). Upstream of the ATG start codons in each of the genes is an appropriately located ribosome binding site, AAAGGAG for the PA and LF genes, and AAAGGAGGT for the EF gene. Each of the three proteins contains a typical bacillus signal peptide of 29–33 amino acids, with cleavage occurring after an Ala or Gly. Following the stop codon of the PA gene is an inverted repeat that may act as a transcriptional stop; no similar structures are present in the LF or EF regions.

Production of both capsule (Meynell and Meynell, 1964) and PA (Gladstone, 1948) by *B. anthracis* is dependent on addition of bicarbonate or $CO_2$. Early studies showed that stimulation of PA synthesis by bicarbonate requires the presence of a gene located on pXO1 (Bartkus and Leppla, 1989). This gene, *atxA*, was mapped by transposon mutagenesis and cloned and sequenced (Uchida *et al*., 1993; Koehler *et al*., 1994). The product of the *atxA* gene, a protein of 56 kDa, increases by at least 10-fold the transcription from a start site, P1, located at bp -58 relative to the start codon. Constitutive, low-level transcription initiates at another site, P2, at bp -26. Both these start sites are located in a potential 58-bp stem-loop structure (Welkos *et al*., 1988). Disruption of the *atxA* gene and complementation with an *atxA*-expressing plasmid proved that this regulator is needed for transcription of all three toxin genes, and it follows that *B. anthracis* strains lacking *atxA* are less virulent for mice (Uchida *et al*., 1993; Dai *et al*., 1995). A region of 111 bp upstream of the *pag* coding sequence is required for AtxA action, but no evidence is available suggesting that AtxA itself binds there (Dai *et al*., 1995) and no common sequences can be identified in the regions upstream of *pag*, *cya*, and *lef* to which

transcriptional regulators might bind. More recent studies with microarrays showed that AtxA is a key global regulator of many plasmid and chromosomal genes (Bourgogne *et al*., 2003; Mignot *et al*., 2004). The regulation of capsule biosynthesis by *atxA* requires the presence of either of two additional regulators, *acpA* and *acpB*, encoded on pXO2, and having limited sequence similarity to *atxA* (Drysdale *et al*., 2004).

## Toxin gene sequence homologies and variations

PA is similar to toxins produced by some pathogenic *Clostridia* and *Bacillus* species (Barth *et al*., 2004). All these homologues are binary toxins, like the anthrax toxins, but the second, catalytic component has ADP-ribosylation activity. The PA homologues are listed in Table 18.2, and the properties of the proteins are discussed in a later section. The most recent and novel addition to this list of proteins are two identified in an unusual *Bacillus cereus* strain, G9241, that contains a plasmid closely similar to pXO1 (Hoffmaster *et al*., 2004). This plasmid encodes proteins having high sequence identify to those in *B. anthracis* (99.7, 99, and 96% amino acid identity to PA, LF, and EF, respectively). A second large plasmid in the same strain, pBC218, contains additional PA and LF homologues resembling the *B. cereus* binary toxins mentioned above. It is not yet known whether these toxins are active. Comparison of these proteins may provide new insights into PA structure and function. This finding reminds us that *B. anthracis* and *B. cereus* are closely related and may represent the visible and more prominent parts of a genetic continuum.

Within the *B. anthracis* species, there is very little sequence variation between toxin genes of different isolates. Only three amino acid residues were found to vary among 26 sequenced PA genes (Price *et al*., 1999). It is of interest that the variable residues 536 and 571 are adjacent and on the surface of the protein, suggesting that these residues may be part of an epitope recognized by the immune system of animals and therefore under selective pressure to mutate to escape antibody neutralization.

The EF gene, *cya* (Escuyer *et al*., 1988;Robertson *et al*., 1988), has homology to several other adenylate cyclase genes of pathogenic bacteria (Ahuja *et al*., 2004), the best studied being that encoding the "invasive" adenylate cyclase of *Bordetella pertussis* (Glaser *et al*., 1988; Hanski and Coote, 1991). The homology to the *B. pertussis* cyclase occurs only in the regions known to comprise the catalytic domain. More recently, adenylate cyclases that may contribute to pathogenesis have been identified in *Pseudomonas aeruginosa* (Yahr *et al*., 1998) and in *Yersinia* species (Parkhill *et al*., 2001). The EF gene also has strong homology to the LF gene in the amino terminal region that is now recognized as involved in binding to PA. Beyond residue 250, LF has a very limited sequence homology to other metalloproteases.

## Role of the toxin in virulence

A number of tools are now available for performing genetic modifications to *B. anthracis* (Thorne, 1993; Koehler, 2002a). These include transduction and conjugation (Battisti *et al*., 1985; Heemskerk and Thorne, 1990) and transformation by electroporation (Bartkus and Leppla, 1989). The elegant methods developed for use of Tn*917* in *Bacillus subtilis* have been adapted to *B. anthracis* (Heemskerk and Thorne, 1990). Methods for gene disruptions are also available (Dai *et al*., 1995). A conjugational transfer system was used to transfer a mutated PA gene into the Sterne strain, replacing the resident PA gene (Cataldi *et al*., 1990). The latter

**TABLE 18.2** Protein neighbors of PA

method was employed to produce strains expressing every combination of the three components (Table 18.3). The only strain that retained some virulence was RP9, which makes PA and LF (Pezard *et al*., 1991; Pezard *et al*., 1993). This suggests that LF is the more important virulence factor, whereas EF provides a smaller contribution. However, this analysis needs to be repeated in a strain having pXO2 in addition to pXO1 because of the interaction of regulatory genes on the two plasmids (Bourgogne *et al*., 2003).

## THE PROTEINS

### Production of toxin from *B. anthracis* and *B. subtilis*

Study of the anthrax toxin proteins has been facilitated by the relative ease with which they can be prepared in milligram amounts. Extensive work in the period 1940–1965 led to development of synthetic media that support good production of PA for use in vaccines (Puziss *et al*., 1963; Haines *et al*., 1965). Key ingredients of synthetic media are bicarbonate (Gladstone, 1946) to activate toxin gene transcription (Bartkus and Leppla, 1989) and a buffering system that maintains the pH above 7.0 (Strange and Thorne, 1958). Later work led to development of a completely synthetic medium, designated R (Ristroph and Ivins, 1983), which was subsequently modified further (Leppla, 1988; Leppla, 1991a). Growth of 50-L fermentor batches typically yielded 500 mg PA, 100 mg LF, and 40 mg EF.

For production of individual toxin proteins and mutated variants of them, the PA gene and upstream sequences were cloned into the staphylococcal vector pUB110, which is a high copy number plasmid in bacilli. The resulting vectors, pPA101 and pPA102, expressed PA at 20–40 mg/L from *Bacillus subtilis*, but the PA was rapidly destroyed by extracellular proteases (Ivins and Welkos, 1986). Expression from pPA101 in *B. subtilis* WB600, a strain in which six extracellular proteases are inactivated, improved yields of intact PA (Miller *et al*., 1998), but degradation of PA in the WB600 cultures remained a problem compared to the situation in *B. anthracis* culture supernatants, which are quite low in secreted proteases. In the most extensive studies with the pPA102 plasmid, use of a sporulation deficient *B. anthracis* strain grown in a rich medium under optimized fermentor conditions yielded PA at 20–30 mg/L (Farchaus *et al*., 1998).

A further improvement for production of PA and LF in *B. anthracis* came with creation of the shuttle vector pYS5, constructed from pPA102 and a pBR322-derived plasmid (Singh *et al*., 1989). This vector lacks the *atxA* regulator gene, causing transcription from the normally used PA promoter to be low, and yields in RM medium are minimal. However, in a rich medium (FA) under optimal conditions, PA is produced at 50–100 mg/L. In this case, transcription may originate from other promoters. The pYS5 vector has been used successfully in the author's lab and by others to produce PA and many PA mutants. Efficient production of LF has been achieved in a similar expression vector containing the PA promoter and signal peptide (Park and Leppla, 2000). A comparable vector for EF production has proved less effective. In general, these findings emphasize the advantages of producing a protein in its original host, where there has been natural selection to adapt the toxin to the host's secretion apparatus and to resist the host's proteases.

### Production of toxin components and fusion proteins in *E. coli*

For production of native and mutated anthrax toxin proteins, many laboratories have used *E. coli* expression systems. T7-based vectors that include signal peptides were found to successfully secrete PA and PA mutant proteins to the *E. coli* periplasm with

**TABLE 18.3** Virulence properties of modified *B. anthracis* strains

| Strain name | Parental strain | Plasmid content | Proteins produced | $LD_{50}$ for mice |
|---|---|---|---|---|
| 7702 | - | pXO1 | PA, LF, EF | $10^6$ |
| 7700 | 7702 | -(cured) | | $>10^9$ |
| RP8 | 7702 | pXO1 pagΔ322 | LF, EF | $>10^9$ |
| RP9 | 7702 | pXO1 cyaΔ303 | PA, LF | $10^7$ |
| RP10 | 7702 | pXO1 lefΔ238 | PA, EF | $>10^9$ |
| RP4 | RP9 | pXO1 cyaΔ303 pagΔ652 | LF | $>10^9$ |
| RP31 | RP10 | pXO1 lefΔ238 pagΔ652 | EF | $>10^9$ |
| RP42 | RP10 | pXO1 lefΔ238 cyaΔ303 | PA | $>10^9$ |

Toxin genes were inactivated by insertion of erythromycin or kanamycin resistance genes (Cataldi *et al.*, 1990; Pezard *et al.*, 1991; Pezard *et al.*, 1993). Swiss mice were injected subcutaneously with spore suspensions and lethality monitored.

yields after purification of 0.5 mg/L (Sharma *et al*., 1996; Benson *et al*., 1998). A T5-based vector was used to produce LF with an N-terminal, 6-His sequence, which enabled convenient affinity purification at yields of 1.5 mg/L (Gupta *et al*., 1998). With PA and LF, use of synthetic genes having codon usage suitable for *E. coli* has improved yields to high levels (Laird *et al*., 2004). Fusion proteins in which LF residues 1–254 (LFn) are attached to other polypeptides have been made in several standard *E. coli* expression systems (Arora and Leppla, 1993; Ballard *et al*., 1996). Initial EF expression work produced a protein lacking the N-terminal 261 aa that was expressed at 2% of total protein in *E. coli*, purified to homogeneity, and used in characterizations of the catalytic properties (Labruyere *et al*., 1990). More recently, full-size EF has been produced from *E. coli* in good yields (Kumar *et al*., 2001; Soelaiman *et al*., 2003; Cooksey *et al*., 2004).

## Toxin purification

The toxin proteins collectively, or the recombinant PA and LF proteins individually, constitute more than 50% of the protein present in *B. anthracis* culture supernatants grown in the R or FA media noted above. This makes purification of the PA and LF proteins relatively easy once the proteins have been protected from proteases and concentrated. Recovery from culture supernatants has been done by hydrophobic "salting out" onto agarose resins (Leppla, 1991a), but other methods can also be used. Effective purification steps include chromatography on anion exchange resins or hydroxyapatite. Detailed protocols for purification from *B. anthracis* are available (Quinn *et al*., 1988; Leppla, 1988; Leppla, 1991a; Farchaus *et al*., 1998; Park and Leppla, 2000; Ramirez *et al*., 2002). Methods used for purification of the toxin proteins from *E. coli* have been more diverse. However, because the proteins lack disulfide bonds, they can be refolded from inclusion bodies in good yields. *E. coli* expression systems have the disadvantage that the products need to be analyzed for endotoxin contamination.

## Structural features common to the three toxin components

All three of the anthrax toxin proteins are similar in size and charge (Table 18.1). Especially notable is that all three proteins lack cysteine. This has proved advantageous for structure function analyses, because any cysteine added by mutagenesis for subsequent chemical modification is unique (Nassi *et al*., 2002; Mourez *et al*., 2003). It was noted some years ago that extracellular bacterial proteins generally have a low cysteine content (Pollack and Richmond, 1962), and this generalization appears to hold for a number of other secreted bacterial toxins. Perhaps most striking is the absence of cysteines in the *B. pertussis* adenylate cyclase, a protein of 1706 residues (Glaser *et al*., 1988).

## Overview of toxin binding and internalization by cells

Data on toxin structure combined with studies on interaction with cells to be discussed below has led to a model of toxin uptake depicted in Figure 18.1 (Petosa *et al*., 1997; Moayeri and Leppla, 2004). PA binds to cell surface receptors and is cleaved by cell surface proteases, principally furin, with release of the 20-kDa N-terminal fragment. PA63 then oligomerizes and also binds LF or EF. The complex is internalized by endocytosis, and acidification of the vesicle causes insertion of the PA63 heptamer into the endosomal membrane to produce a channel through which LF or EF translocate to the cytosol. Details of the individual steps are discussed in later sections.

## PA structure and function

### *PA crystal structure*

The structure of PA was solved by X-ray diffraction (Petosa *et al*., 1997). PA is a long, flat protein that is rich in β-sheet structure (Figure 18.2). Four domains are distinguished that correspond to functional regions previously defined by analysis of large fragments produced by trypsin and chymotrypsin. Domain 1 (aa 1-258) contains two tightly bound calcium ions and a large flexible loop (aa 162–175) that includes the sequence $_{164}$RKKR$_{167}$ that is cleaved during proteolytic activation. Domain 2 (aa 259–487) contains several very long β strands and forms the core of the membrane-inserted channel. It also has a large flexible loop (aa 303–319) implicated in oligomer formation and membrane insertion. Domain 3 (aa 488–595) has no clearly defined function. Domain 4 is loosely associated with the other three domains and is involved in receptor binding.

### *PA proteolytic activation, nicking, oligomerization, and binding of LF and EF*

The two flexible loops mentioned above contain sites uniquely sensitive to proteolytic cleavage, as was recognized even before the aa sequence was known. The sequence $_{164}$RKKR$_{167}$ is extremely sensitive to cleavage by trypsin, clostripain, and other proteases that recognize basic residues. PA in solution at 1 mg mL$^{-1}$ is completely cleaved in 30 minutes when treated with 0.1 μg mL$^{-1}$ of trypsin (Leppla *et al*., 1988; Singh *et al*., 1989).

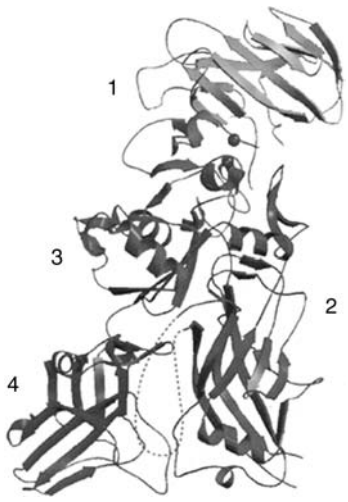

**FIGURE 18.2** Structures of anthrax toxin protective antigen (PA). PA domains 1–4 are indicated.

The fragments of 20 and 63 kilodaltons (designated PA20 and PA63, respectively) do not easily dissociate. However, at pH 7.5, concentrated solutions of the nicked PA incubated for several hours form a precipitate, which can be shown by SDS gel electrophoresis to contain PA63. Chromatography of trypsin-treated PA on the MonoQ anion exchange resin (Pharmacia) at pH 9.0 yields an early peak of PA20 and a later peak containing PA63. PA63 purified on MonoQ resin remains soluble indefinitely if kept at pH 9.0. Analysis by nondenaturing gel electrophoresis and gel filtration chromatography showed this material to be a large oligomer of the 63-kDa peptide (Leppla *et al*., 1988; Singh *et al*., 1994). This oligomer is extremely stable. By transmission electron microscopy after negative staining, the oligomer was shown to be a heptamer (Milne *et al*., 1994). This species was crystallized and its structure determined by X-ray diffraction, which confirmed the heptameric nature of the oligomer (Petosa *et al*., 1997). More recently, a higher resolution structure of the heptamer bound to receptor was determined (Lacy *et al*., 2004a). This showed that the loop including residues 303–309 stabilizes the heptamer by closely associating with neighboring PA63 monomers in the heptamer.

The functional importance of the trypsin-sensitive site at residues 164–167 became evident when it was noted that PA incubated with cells becomes nicked at this site (Leppla *et al*., 1988). Only PA63 remains bound to cells; PA20 can be detected in the supernate if this is concentrated before analysis. PA cleavage on cells occurs at 4°C, a condition in which PA is retained on the cell surface. A PA mutant in which the $_{164}$RKKR$_{167}$ sequence is deleted is not cleaved on the surface of cells and is non-toxic (Singh *et al*., 1989). The implication that PA63 is the active species needed for delivery of LF or EF was proven directly by showing that purified, heptameric PA63 is toxic to macrophages when combined with LF. Finally, PA incubated with cells at 37°C and allowed to internalize forms oligomers that are stable to heating in SDS (Milne *et al*., 1994; Liu and Leppla, 2002). This occurs because acidification of endosomes causes the oligomer to insert into membranes to form a second, stable type of heptamer (to be discussed later).

A detailed analysis of PA residues 164–167 showed that cleavage by cellular proteases requires the minimum sequence RxxR (Klimpel *et al*., 1992). This result, combined with inhibitor studies, proved that the cellular protease that most rapidly activates PA is furin. This finding was consistent with evidence that a number of other bacterial toxins require proteolytic activation by furin (Gordon *et al*., 1995; Gordon *et al*., 1997). The strict requirement that PA be proteolytically cleaved on the cell surface has been exploited in the design of toxins dependent on other proteases, as will be discussed later.

The other site that is uniquely sensitive to protease is the large loop in domain 2, aa 303–319. Cleavage in this region occurs in *B. anthracis* culture supernates, probably due to the action of a metalloprotease of the thermolysin type. Cleavage at the same site is obtained with 1 μg mL$^{-1}$ of chymotrypsin or thermolysin. This cleavage occurs at the pair of Phe residues, aa 313–314 in the sequence SFFDI (Novak *et al*., 1992). Deletion of the pair of Phe completely inactivates PA (Singh *et al*., 1994). The deleted mutant PA binds to cells, becomes nicked, and internalizes LF to endosomes, but fails to tranlocate LF to the cytosol (Novak *et al*., 1992; Singh *et al*., 1994). PA proteins mutated at this site have served as valuable controls when determining whether action of PA variants requires access to the cytosol. Receptor binding studies using radiolabeled PA that was nicked at residues 313–314 showed that only the C-terminal 47-kDa fragment was retained on cells. This result showed that the cell recognition domain is entirely contained in the 47-kDa fragment, residues 315–735.

The PA63 heptamer binds tightly to LF, as can be demonstrated by several methods, including sedimentation equilibrium and gel electrophoresis. On nondenaturing 5% polyacrylamide gels run at pH 8.5, PA63 moves as a sharp band, much slower than PA. In mixtures of PA63 and LF, several very closely spaced bands migrating even more slowly than PA63 are seen. These contain oligomeric PA63 with increasing

numbers of bound LF molecules (Singh *et al*., 1999). Although the author's initial studies were interpreted as showing that a PA63 heptamer can bind seven LF molecules, strong evidence against this came from mutagenesis studies showing both that the LF/EF binding site spans two adjacent PA63 monomers (Mogridge *et al*., 2002b) and that the large footprint of LF/EF on the heptamer precludes simultaneous use of two adjacent binding sites (Cunningham *et al*., 2002; Mogridge *et al*., 2002a). It follows that a maximum of three LF/EF molecules can bind to the heptamer. However, in recent cryo-electron microscopy analyses, only a single LF was observed bound to the PA63 heptamer (Ren *et al*., 2004), indicating that the stoichiometry question deserves continuing study.

### *Functional sites of PA defined by mutagenesis*

*Domain 1*

Removal of residues 1–167 (domain 1a) by proteolytic activation and formation of the heptameric PA63 leaves a surface (domain 1b) to which LF and EF bind. Two groups have used mutagenesis to identify PA residues involved in LF binding. Nine residues on the surface that is thought to interact with LF were altered, and four of them (aa 202, 203, 205, and 207) were found to be essential (Chauhan and Bhatnagar, 2002). A more extensive mutagenesis study agreed that aa 205 and 207 are required for LF binding, and implicated five additional residues (Cunningham *et al*., 2002). More importantly, by introducing certain of the mutations into separate monomers that could only form dimers, the residues involved in the adjacent monomer's subsites of the LF binding site were identified.

*Domain 2*

The crystal structure shows that residues 259–487 form the central core of the heptameric PA channel. Recognition that the large loop including aa 303–319 had alternating hydrophilic and hydrophobic residues led to the proposal that its insertion into the membrane would produce a β barrel (Figure 18.3) like that seen in the structure of staphylococcal alpha-hemolysin (Petosa *et al*., 1997). Extensive mutagenesis of residues 302–325 confirmed that the hydrophobic side chains interact with lipid while the hydrophilic residues are accessible to solvent, as expected if the structure followed the example of the alpha-hemolysin structure (Benson *et al*., 1998). Subsequent studies extended this analysis and suggested that the β barrel involved the entire region from aa 275 to 352 (Nassi *et al*., 2002), implying that a major rearrangement of the heptamer takes place upon membrane insertion, and that the β barrel extends beyond the bilayer.

The requirement for oligomerization implies that dominant negative mutant proteins can exist, ones in which mutations within a single monomer could inactivate an entire heptamer. A systematic mutagenesis study of the entire PA63 region was designed to identify candidate dominant negative mutants (Mourez *et al*., 2003). At least 33 residues in the entire PA63 sequence were found to be essential for toxicity. A more targeted search for dominant negative mutants identified several having that behavior (Sellman *et al*., 2001; Singh *et al*., 2001). By definition, such mutants are able to form the heptameric prepore, but this fails to convert to a functional protein-conducting channel. In theory, one could also expect that mutation of key residues lining the lumen of the channel may also yield dominant negative proteins, but none have yet been reported.

Systematic mutagenesis of domain 2 also identified several residues within the extended β barrel region that were required for toxicity (Mourez *et al*., 2003). Of particular interest are residues 337, 342, and 346, which were later shown to participate in binding of the prepore heptamer to the cellular receptor (Santelli *et al*., 2004; Lacy *et al*., 2004a), as will be discussed later.

*Domain 3*

Systematic mutagenesis studies (Mogridge *et al*., 2001; Mourez *et al*., 2003) identified very few residues in domain 3 (aa 488–595) that are essential for activity. An E515C mutant was inactive but an E515A mutant retained activity. The loops containing aa 483–486 and 510–518 interact with the adjacent monomer in the

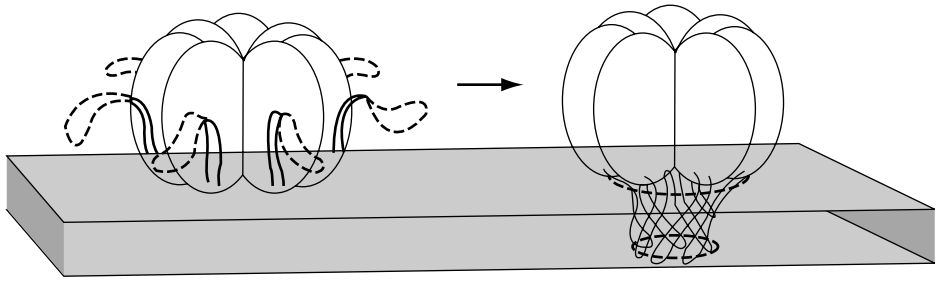

**FIGURE 18.3** Model for insertion of amphipathic hairpins to produce β barrel channel. The heptameric PA63 is shown with the flexible loop containing residues 300–325, shown as a dotted line.

heptamer prepore structure (Lacy *et al*., 2004a), and substitutions in these loops had modest effects on function. However, evidence to date suggests that the principal role of domain 3 is to stabilize the heptamer. It can be noted that the only residues (aa 536 and 571) that vary among the natural *B. anthracis* PA isolates (see above) are located in domain 3. If these residues are a target of neutralizing antibodies, as suggested above, then those antibodies might neutralize by blocking heptamer formation.

*Domain 4*

The C-terminal domain 4 of PA was initially implicated in receptor binding by analysis of mutants truncated to varying extents (Singh *et al*., 1991). Later studies suggested that the effect of these truncations was indirect, perhaps by causing changes to the folding of domain 4. Codon-based mutagenesis was used to identify important residues in the two solvent-exposed loops of domain 4 that were predicted to interact with the cellular receptor (Varughese *et al*., 1999; Brossier *et al*., 1999). Substitution of N657 or N682 had the largest effects in decreasing PA binding to receptor. Further mutagenesis of the small loop containing residues 679–693 showed that this region contains four residues for which single alanine substitutions decreased toxicity more than 10-fold (Rosovitz *et al*., 2003). The D683 residue was shown to be critical, which was later explained by its interaction with the divalent metal ion in the receptor, as discussed later. The systematic mutagenesis study referenced above (Mourez *et al*., 2003) identified residues 656, 657, 665, 682, 683, and 687 as important for PA activity.

### *Functional sites of PA defined by monoclonal antibodies*

Mouse monoclonal antibodies to PA were assigned by competition to at least 23 different epitopes (Little *et al*., 1988). However, very few of these antibodies neutralized the toxin. Three antibodies, including 14B7 and 3B6, react with a region that overlaps with the receptor-binding domain. Thus, 14B7 blocks binding of radiolabeled PA to cells and neutralizes toxicity when mixed with PA prior to addition to cells. Detailed mapping with alanine mutants in the domain 4 small loop showed that the sets of residues involved in binding to receptor and to 14B7 overlapped, but were not identical (Rosovitz *et al*., 2003). A number of companies have recently developed human antibodies to PA as therapeutic agents, and several of these appear to react with domain 4 (Sawada-Hirai *et al*., 2004).

Monoclonal antibodies may also act by blocking proteolytic activation of PA or oligomerization of PA63. An example of the former is provided by a mouse antibody to PA, which appears to prevent furin cleavage (Brossier *et al*., 2004). Well-characterized examples of antibodies that block heptamerization have not yet been reported.

The model for interaction of PA63 with LF predicts that neutralizing monoclonal antibodies could also act by blocking LF and EF binding to PA63. One antibody obtained by immunization with PA63 does have this property. Antibody 1G3 is unique because it reacts with PA63 but not with PA, it blocks LF binding to PA63, and it neutralizes toxin even when added at amounts far below those of PA (Little *et al*., 1996). This high potency occurs because 1G3 reacts only with the PA63 generated by activation of receptor-bound PA and not with the intact PA that is not bound to cells. The 1G3 antibody is also the only one of the mouse monoclonal antibodies tested that was able to delay the time to death of guinea pigs challenged with virulent *B. anthracis* (Little *et al*., 1997). A human antibody reacting to this same LF binding site was selected by panning of a phage-displayed antibody library on PA63, while adding soluble PA to block binding to other epitopes (Wild *et al*., 2003). This antibody neutralized toxin at less than molar ratios, like the mouse 1G3 antibody, and it protected rats from toxin challenge.

Surprisingly, none of the more than 35 monoclonal antibodies obtained by immunization with PA was reactive with PA20. Cleavage of PA on the surface of cells may release PA20 as a peptide that is too small to efficiently induce antibody. Monoclonal antibodies to PA20 were later obtained by immunizing mice with purified PA20 (unpublished work of Little and Leppla).

### *Conservation of functional sites within neighbors of PA*

The proteins having homology to PA are listed in Table 18.2. The high degree of similarity of these proteins argues that all are derived from a common ancestor. It is expected that these proteins all share the same structural design as PA. All six proteins have perfect conservation of the five Asp and Glu residues in PA whose side chain carboxyl groups chelate the two calcium ions (Figure 18.4). While several of these proteins are known to require proteolytic activation, none have a fully furin-susceptible cleavage site. The *C. spiroforme* toxin has a minimum furin site, RSAR, and several of the other proteins have basic residues in the putative cleavage region. Perhaps the four clostridial toxins, because they are produced by anaerobic pathogens that grow in restricted spaces, have evolved to depend on activation by proteases of the producing bacteria.

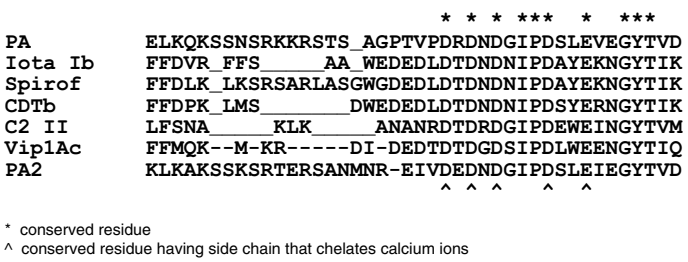

**FIGURE 18.4** Sequences of PA family members in the region containing the protease activation and calcium binding sites. Protein designations correspond to those in Table 18.2. Vip1Ac is vegetative insecticidal protein 1 of *B. thuringiensis*. PA2 is the protein encoded by plasmid pBC218 of *B. cereus* G9241.

Sequence similarity of the proteins decreases greatly in the regions corresponding to PA domain 4, suggesting that the toxins have diverged from a common ancestor so as to acquire specificity for cellular receptors in different target organisms. Little is known about the cellular receptors for these toxins. The C2 toxin receptor appears to require asparagine-linked carbohydrates, but no protein component has been identified. Progress in understanding these toxins would be greatly aided by identifying their cellular receptors.

## EF structure and function

### *EF structure*

EF was the last of the three toxin components to have its structure solved, and initially only the structure of the catalytic domain was reported (Drum *et al.*, 2002). Comparison of the LF and EF sequences showed that the N-terminal regions of approximately 250 residues have substantial homology, consistent with their common ability to bind to PA63. The EF region following residue 250 has homology to the *B. pertussis* cyclase and is an active enzyme when expressed as a recombinant protein (Labruyere *et al.*, 1991). Adenylate cyclase activity absolutely requires the presence of calmodulin (Leppla, 1984), and the basis for this was evident in the intimate association of the two proteins and the large changes induced in the EF structure upon calmodulin binding (Drum *et al.*, 2002). In particular, the C-terminal largely helical domain (aa 660–800) undergoes major rearrangements when associated with calmodulin. Three other regions, termed switches A, B, and C, are rearranged in the EF-calmodulin complex so as to form the catalytic site. The structure of the calmodulin in the complex is unusual in that the C-terminal domain has two bound calcium ions, as it does in its interactions with other proteins, whereas the N-terminal domain, which has a similar overall structure, is altered by its strong association with EF so that it does not bind calcium. Extensive mutagenesis and NMR studies suggested a model in which the N-terminal calmodulin domain associates weakly with EF and brings the C-terminal domain close to EF. Binding of calcium ions to the C-terminal domain gives it the ability to associate strongly with the other EF domains and stabilize the rearranged, catalytically active EF species (Shen *et al.*, 2002; Ulmer *et al.*, 2003). These studies also identified the active site residues involved in catalysis and characterized the complex role of calcium in EF activation.

Information about the structure of EF was also deduced from a set of monoclonal antibodies (Little *et al.*, 1994). Cleavage in formic acid produced the three fragments of 18, 53, and 17 kDa expected from cleavage at Asp-Pro bonds, and these were used to map the antibodies. The two antibodies that blocked binding of EF to PA on cells reacted with the N-terminal 18-kDa fragment, consistent with its role in binding to PA. Several other antibodies inhibited adenylate cyclase activity.

### *EF catalytic activity*

After initial reports on the catalytic properties of EF (Leppla, 1982; Leppla, 1984; Labruyere *et al.*, 1991), there was a period of inactivity, only recently ended. This is surprising because the enzyme is highly active and therefore has considerable potential as a pharmacological tool for transiently increasing cAMP concentrations in eucaryotic cells. EF has high catalytic activity, with a $V_{max}$ = 1.2 mmol cAMP/min/mg protein (Leppla, 1984), corresponding to a turnover number of 1000–2000 molecules per second. The Km for ATP in the presence of $Mg^{2+}$ is 0.16 mM. Similar values have been reported in more recent studies (Shen *et al.*, 2002). The enzyme activity is very sensitive to $Ca^{2+}$, showing optimum activity at 1–100 μM (depending on assay conditions) and inhibition at higher concentrations. $Mn^{2+}$ can substitute for $Ca^{2+}$ in activation of calmodulin and does not cause inhibition, so its use is convenient in routine assays to make the assay insensitive to variations in free $Ca^{2+}$.

The enzyme activity of EF has an absolute requirement for calmodulin. In the presence of 50 μM $Ca^{2+}$, the concentration of calmodulin giving half-maximal activity is 2.0 nM. When the $Ca^{2+}$ is chelated by excess EGTA, calmodulin still can activate EF, but 5 μM is needed to get equivalent activity. Thus, calmodulin can

activate EF even when it contains no bound $Ca^{2+}$. The *B. anthracis* cyclase differs from the *B. pertussis* enzyme in that fragments of the protein have no activity in the absence of calmodulin. This is consistent with the observation that *E. coli* strains expressing EF but not calmodulin produced no detectable cAMP and do not have any adenylate cyclase activity (Mock *et al.*, 1988), in spite of the probable presence of breakdown fragments of the EF protein.

The availability of the crystal structure of EF has enabled a detailed analysis of the catalytic process (Guo *et al.*, 2004; Shen *et al.*, 2004). A structure of EF bound to cAMP and pyrophosphate was used to propose that catalysis involves a key histidine residue and two divalent ions. It was also shown that the reverse synthetic reaction to produce ATP can proceed at the same rate as the forward reaction, suggesting that EF might have value for synthesis of ATP analogs from modified cAMP compounds. In the structure obtained for the complete EF protein, the structure of the N-terminal PA-binding domain was shown to be very similar to the structure of the corresponding LF domain, as was expected from their similarity in sequence and function (Shen *et al.*, 2004).

## LF structure and function

### *LF structure*

Although biochemical analyses had provided an overview of the functional domains, solving the crystal structure of LF provided the information needed to greatly accelerate study of its function (Pannifer *et al.*, 2001). The structure showed that the N-terminal domain I, aa 1–262, is an entirely separate domain having no interactions with the rest of the protein. This is consistent with its role in binding to the PA heptamer. Mutagenesis of surface residues conserved between LF and EF identified a local surface region formed by two sequences (aa 182–188 and aa 223–236) in which seven different single alanine substitutions greatly reduced binding to PA (Lacy *et al.*, 2002). The same mutations introduced into a corresponding EF construct produced very similar effects on binding. Other studies have identified additional residues that are important for LF activity, but in these cases, it was possible that the mutations altered folding of the domain (Quinn *et al.*, 1991; Gupta *et al.*, 2001; Kumar *et al.*, 2001).

Domain 2, containing residues 263–297 and 385–550, has limited sequence similarity but high structural homology to ADP-ribosylating toxins such as C2 and Vip, the same toxins in which the second, cell-binding component resembles PA (Table 18.2). This domain does not retain key residues needed for NAD binding and catalysis. This unexpected finding strongly suggests that LF arose from the homologous clostridial or bacillus toxins by a recombinational event that captured the gene encoding a metalloprotease. Inserted into the middle of domain 2 is domain 3 (aa 298–384), which consists of four imperfect repeats of a 19-amino acid sequence that forms a helix-turn unit. This sequence closely matches a sequence within domain 2, indicating that it arose by repeated duplication of that region. Comparison of the sequences of the repeats suggests that repeat 1 (in domain 2) was duplicated to make repeat 2, repeat 2 was duplicated to make repeat 3, and then the pair 2+3 was duplicated to make 4+5. This suggests that there was continuing selective pressure to increase the size of this domain. The resulting helical bundle lies across domain 4, thereby greatly restricting steric access to the protease active site and contributing to the extremely limited substrate specificity.

Domain 4 contains the catalytic domain. The recognition that the LF sequence contains a site characteristic of zinc metalloproteases (Klimpel *et al.*, 1994) started a process that eventually led to the identification of its catalytic activity. The sequence of the entire domain is only distantly related to other zinc-dependent proteases, and the similarity was too low to be recognized by the standard homology searching programs. It is interesting in retrospect that LF has greatest sequence similarity at the active site with the *B. cereus* NprB protease, both having a HEFGHAV sequence that includes the zinc-binding HExxH motif. The limited sequence similarity suggested that LF is a zinc metalloprotease. This was supported by showing that substitution of Ala for H686, E687, or H690 in the sequence $_{686}$-HEFGH-$_{690}$ destroyed the toxicity of LF for macrophages and decreased its zinc binding ability (Klimpel *et al.*, 1994). Attempts to find substrates cleaved by LF extended over several years until the independent efforts of two labs showed MEKs to be cleaved (Vitale *et al.*, 1998; Duesbery *et al.*, 1998), as discussed below.

It was widely accepted in the older anthrax toxin literature that LF and EF are serologically distinct; no cross-reactivity was detected with polyclonal antibodies in immunodiffusion, and this was confirmed with purified components (Quinn *et al.*, 1988). However, once monoclonal antibodies to LF and EF were obtained, several were found that cross-react. In a set of 61 monoclonal antibodies to LF, three cross-reacted with EF (Little *et al.*, 1990). Eight of the LF monoclones neutralized lethal toxin in either *in vivo* or *in vitro* tests, and six of these were shown to do so by preventing LF binding to PA63. Surprisingly, only two of the six that blocked LF binding cross-reacted with EF. This suggests that the sequences shared by LF and EF and presumably involved in binding to PA63 may have

been under selective pressure to become antigenically distinct so that an immune response to one does not effectively neutralize the other.

### *LF metalloprotease activity*

Discovery by the author and his collaborators that LF cleaves MEKs grew out of parallel and independent efforts to identify additional cells sensitive to the lethal toxin and to find better tools for modulating cell signaling pathways. The author tested the cytotoxicity of lethal toxin on 60 human tumor cell lines that constitute a panel used to screen for anti-neoplastic agents (Weinstein *et al.*, 1997). The growth of some cell lines was inhibited, but no cells were lysed in the dramatic manner of mouse macrophages. Several years later, the database was queried by Duesbery and colleagues to find drugs having activity like that of PD98059, which was being used to specifically inhibit the mitogen activated protein kinase kinase 1, also designated MEK1. Of the approximately 60,000 drugs that had been tested against this panel of cells, LF (administered with PA) was the one most similar in action to PD98059. This led to experiments that resulted in the discovery that LF blocks the MAPK pathway and does so by cleaving seven amino acids from the N-terminus of MEK1 (Duesbery *et al.*, 1998). Independent work using a yeast two-hybrid screen for proteins that bind to LF led to the same conclusions (Pellizzari *et al.*, 2000). It was subsequently found that six of the seven MEK family members are cleaved by LF (Vitale *et al.*, 2000), and several are cleaved in two locations (Figure 18.5). Comparison of the sequences at the cleavage sites suggests that LF requires an amino acid sequence motif that can be represented as ++++nHn↓H, where "+" represented Arg or Lys, "n" represents any amino acid, "H" represents hydrophobic amino acids, and "↓" shows the site of cleavage. However, the specificity of LF is also determined by regions in the MEK substrates that are distant from the bond cleaved, as indicated by the ability of MEK1 lacking the N-terminal 30-amino acid cleavage site to bind to LF in the yeast two hybrid system (Vitale *et al.*, 2000). Furthermore, mutation of a region in the C-terminal kinase domain of MEK1 made it resistant to LF cleavage (Chopra *et al.*, 2003). These characteristics mimic those of the clostridial neurotoxins, which also have a highly restricted set of substrates that share specificity determinants distant from the actual cleavage site.

LF protease activity can be inhibited by various nonspecific metalloprotease inhibitors, such as zinc chelating agents. Certain agents that protect mouse macrophages from lethal toxin, including bestatin, aromatic amino acid amides, and hydroxamates (Klimpel *et al.*, 1994; Menard *et al.*, 1996b) may block protease activity, although they could also act on downstream cellular processes involved in cell death. Peptide substrates and inhibitors based on the MEK cleavage sequences have been used to assay LF protease activity and to screen for inhibitors (Cummings *et al.*, 2002; Tonello *et al.*, 2002). High throughput screening and structure-based design is being used to identify small molecule protease inhibitors for treatment of anthrax infections

**FIGURE 18.5** Sequences cleaved by LF. The N-terminal sequences of mitogen-activated protein kinase kinases are shown. The arrow indicates the bond cleaved by LF.

Sites of cleavage by LF within MEK proteins

| Substrate protein | Residue numbers relative to cleavage site | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | 7 | 6 | 5 | 4 | 3 | 2 | 1 | ⇓ | 1' | 2' | 3' |
| MEK1 | P | K | K | K | P | T | P | | I | Q | L |
| MEK2 | R | R | K | P | V | L | P | | A | L | T |
| MKK3b | K | R | K | K | D | L | R | | I | S | C |
| MKK6b | K | R | N | P | G | L | K | | I | P | K |
| MKK4 | G | K | R | K | A | L | K | | L | N | F |
| MKK4 | P | F | K | S | T | A | R | | F | T | L |
| MKK7β | R | P | R | P | T | L | Q | | L | P | L |
| MKK7β | R | P | R | H | M | L | G | | L | P | S |
| consensus | + | + | + | + | | **H** | | | **H** | | |

Data is from Vitale *et al.* (Vitale, Bernardi, *et al.*, 2000). MKK4 and MKK7β are cleaved at two positions, and sequences are shown for both. "+" and "H" indicate positively charged and hydrophobic residues, respectively.

(Turk *et al.*, 2004; Panchal *et al.*, 2004). It can be anticipated that large pharmaceutical manufacturers may use these leads to develop effective therapeutics, provided that adequate economic incentives are established.

### *LF fusion proteins as vaccines and therapeutics*

As noted above, the similarity of the N-terminal regions of LF and EF implicated this region as the PA-binding domain. The fact that two unrelated catalytic domains could be delivered to the cytosol by linkage to the N-terminal LF/EF domain suggested that this offered a flexible cytosolic delivery system. This hypothesis was confirmed by demonstrating the potency of fusion proteins containing LFn (aa 1–254) and the catalytic domains of other toxins (Arora *et al.*, 1992; Arora and Leppla, 1993; Arora and Leppla, 1994; Milne *et al.*, 1995).

The LFn fusion system has been used by a number of investigators to deliver polypeptides and proteins to the cytosol so as to stimulate cellular immunity, mimicking the generation of epitopes that occurs from degradation of proteins of intracellular pathogens. Delivery of peptide epitopes known to be presented on MHC class I molecules sensitized antigen presenting cells to lysis by specific cytotoxic T cells (Goletz *et al.*, 1997a) and induced cytotoxic T cell responses in animals (Ballard *et al.*, 1996; Lu *et al.*, 2000). Immunization with only 300 fmol (10 ng) of an LF fusion to a well-studied T-cell epitope of listeriolysin protected mice from infection.

Several types of controls showed that successful presentation of the epitope depended on active PA. When the LF fusion protein contained HIV gp120, proteasome activity was needed to process the peptide for presentation (Goletz *et al.*, 1997b). Of several bacterial toxins that have been tested for presentation of CTL epitopes, the anthrax toxin system appears to offer advantages (Goletz *et al.*, 1997b), in particular its efficiency, ability to deliver large polypeptides (Goletz *et al.*, 1997b; Lu *et al.*, 2000), the flexibility in design of LF fusions, and their ease of preparation.

LF fusion proteins have also proven effective for specifically targeting tumor cells *in vitro* and *in vivo*. High specificity for tumor cells has been achieved by replacing the furin cleavage site in PA with a sequence recognized by urokinase plasminogen activator, a protease that is overexpressed on the surface of most types of tumor cells (Liu *et al.*, 2001). In combination with an LF fusion protein to *Pseudomonas* exotoxin A domain III (LFn-PEIII), this agent greatly reduced the sizes of three diverse types of mouse tumors and in some cases led to a complete cure (Liu *et al.*, 2003).

## TOXIN ACTION ON CELLS AND ANIMALS

The anthrax toxins interact to deliver the catalytic components LF and EF to the cytosol of target cells. The role of PA is to cause binding of LF and EF to the cell surface, so that they will be internalized by endocytosis, and to provide a membrane channel for their translocation from endosomes to the cytosol. The effect of EF delivery to the cytosol is predictable from its adenylate cyclase activity and the well-known effects of cAMP and of other toxins that elevate cytosolic cAMP concentrations. LF cleaves MEKs and possibly other unidentified cytosolic proteins. This initiates processes that lead to the lysis of certain mouse macrophages and to the death of animals.

### Cell specificity and receptors

Nearly all types of eucaryotic cells possess receptors for PA. Specific binding of radiolabeled PA to cells is easily demonstrated because more than 80% of total binding can be blocked by addition of non-radioactive PA. Binding can also be demonstrated in fluorescent cell sorters using fluorescent secondary antibodies, whereas the author's lab finds that use of biotin-labeled PA and streptavidin-phycoerythrin is most effective. Quantitative analysis of binding data shows that cells possess a single class of high affinity receptors, having association constants of approximately 1 nM (Singh *et al.*, 1990; Escuyer and Collier, 1991). Different cell types have between 5,000 and 50,000 receptors. Cells with about 50,000 receptors include the L-6 rat myoblast and the human melanoma cell line LOX IMVI. The modest number of receptors, their sensitivity to trypsin, the low non-specific binding, and the linear binding curves suggested that the receptor was a single cell surface protein.

CHO cell mutants lacking functional PA receptors were obtained by selection of mutagenized populations with PA and fusion proteins containing LFn and the catalytic domains of ADP-ribosylating toxins. No cross-resistance was found to other toxins, and all mutants mapped to the same complementation group (Liu and Leppla, 2002). This proved that the receptor gene in CHO cells was functionally hemizygous (i.e., single functional allele). CHO cells of this type provided the basis for an expression cloning approach that successfully identified the receptor (Bradley *et al.*, 2001). A retroviral expression library transfected into receptor-deficient CHO cells was sorted repeatedly after fluorescent labeled for cells having enhanced receptor expression. The clone obtained contained a

cDNA that could restore PA binding to cells. This cDNA, termed ATR (anthrax toxin receptor), was recognized as matching a recently described gene denoted tumor endothelial marker 8 (TEM8), which had been isolated based on its high expression in endothelial cells of colorectal cancer tissues (St Croix *et al.*, 2000). Subsequently, a closely related gene designated capillary morphogenesis gene 2 (CMG2) was also shown to encode a functional receptor (Scobie *et al.*, 2003). Preexisting information from mRNA expression databases suggested that CMG2 is a widely expressed gene, whereas studies on TEM8 indicated that its expression is confined to tumor tissues (Nanda and St Croix, 2004). Nevertheless, there remains uncertainty about which of these receptors is expressed in widely used cultured cells, and more importantly, in the tissues of animals and humans that become infected by *B. anthracis*.

CMG2 and TEM8 contain a domain like the von Willebrand or I (inserted) domain that is characteristic of many integrins. The I domain contains a metal ion dependent adhesion site (MIDAS) that is essential for binding to the extracellular matrix molecules, such as collagens that are the recognized ligands for these integrins. Mutagenesis of this site showed it was required for PA binding (Bradley *et al.*, 2003). Mutagenesis of PA showed that the D683 side chain, previously proven to be important for PA function, was a strong candidate for a residue that would interact with the metal ion bound at the MIDAS of the I domain. Purification of recombinant forms of the extracellular domains of TEM8 and CMG2 allowed detailed study of their interaction with PA. A structure was obtained for the extracellular domain of CMG2 (Lacy *et al.*, 2004b) that was consistent with other I domain proteins. PA bound with very high affinity, Kd = 170 pM, to the recombinant CMG2 (Wigelsworth *et al.*, 2004). Most importantly, structures were obtained for the complex of PA with CMG2 (Santelli *et al.*, 2004; Lacy *et al.*, 2004a). These structures demonstrated, somewhat surprisingly, that PA interacts with CMG2 not only through the surface of domain 4 but also via regions on domain 2. The large surface area of the interaction, 1300 $Å^2$, explains the high affinity of PA binding. The other important conclusion from the structure was that the interaction with receptor is predicted to prevent the movement of the PA domain 2 loop that occurs during the acid-induced insertion into cellular membranes. This brace or clamping action of the receptor imposes a requirement that the toxin reach a late, more highly acidic endocytic compartment to undergo prepore to pore conversion. This is consistent with new data on intracellular trafficking that is discussed below.

## Proteolytic activation of PA by furin and other proteases

PA bound to cellular receptors must be activated by proteolytic cleavage at aa 167 to acquire the ability to oligomerize and to bind LF and EF (discussed above). The cellular enzyme that most rapidly activates PA is furin (Klimpel *et al.*, 1992), because furin-deficient CHO and LoVo cells are much less sensitive than parental cells to the combination of PA and LFn-PEIII (Gordon *et al.*, 1995). However, the cleavage site, RKKR, has more basic residues than the minimum furin recognition sequence RxxR, and appears to be susceptible to other cellular proteases. Thus, furin-deficient cells retain some sensitivity to wild-type PA but are totally resistant to PA mutants with a RAAR sequence. It has been found for several other toxins and viruses that furin is the dominant activating enzyme, but that other cellular proteases can also perform the activation, although less efficiently. It is also of interest that urokinase plasminogen activator, a protease abundant on tumor cells, can very efficiently activate PA mutants having appropriate target sequences substituted at aa 164. This implies that receptor-bound PA is either mobile in the lipid membrane or that any localization into membrane domains does not prevent contact with certain cell-surface proteases.

## Toxin internalization and translocation across membranes

LF and EF bind with high affinity to the proteolytically activated, cell-surface bound PA heptamer. Association constants of 150–700 pM, determined on cells with radiolabeled LF and EF or by competitive Schild plots, agree well with a value of 1,000 pM obtained for purified heptamer by surface plasmon resonance (Novak *et al.*, 1992; Elliott, Mogridge et al., 2000).

The complex of PA63 heptamer and LF and EF enters cells by receptor-mediated endocytosis and reaches an acidic vesicular compartment, because toxicity is blocked by pharmacological agents that prevent acidification, including amines (Friedlander, 1986; Gordon *et al.*, 1988) and bafilomycin, a specific inhibitor of proton pumps (Menard *et al.*, 1996a). Although the normal trafficking of the TEM8 and CMG2 receptors is not yet characterized, it has been possible to determine the behavior of the receptor-bound PA. When PA cannot be cleaved at the furin site, it remains at the cell surface for extended times, indicating that the receptors are not normally internalized in a specific manner, but only at the default rate of all membrane proteins (Beauregard *et al.*, 2000; Liu and Leppla, 2002; Abrami *et al.*, 2003). However, following protease cleavage, PA63 rapidly

associates into the heptamer, and this is localized into specialized, cholesterol-rich membrane domains called *lipid rafts*, which are then rapidly internalized (Abrami *et al.*, 2003). Somewhat surprisingly, the internalization is dependent on clathrin, which is unusual for lipid raft-dependent endocytic processes (Abrami *et al.*, 2004).

In an intracellular compartment, a more acidic environment is believed to trigger a major rearrangement of the PA heptamer that inserts the amphipathic loop sequences into the lipid bilayer. As noted above, this probably involves insertion of aa 275 to 352 as an extended β barrel, analogous to that in the structure determined for staphylococcal alpha-toxin. This event can be mimicked at the cell surface, providing a more convenient system in which to study the process. Experimentally, cells having LF associated with surface-bound PA heptamer are briefly treated with pH 5.0 buffer (Milne and Collier, 1993; Singh *et al.*, 1994). Acidification leads to toxicity, in a process that can no longer be blocked by agents that inhibit acidification of cellular compartments (Friedlander, 1986; Gordon *et al.*, 1988). Insertion to produce a plasma membrane channel can also be detected by measuring the efflux of radioactive $Rb^+$ or $Na^+$ previously loaded into the cells. PA was also shown to form ion-conductive channels in artificial lipid membranes containing phospholipids (Blaustein *et al.*, 1989; Finkelstein, 1994). Insertion requires lowering the pH to 6.5. The electrical properties of the channels are pH and voltage dependent, and the channel can be blocked by large, quaternary ammonium ions. The passage of smaller quaternary ammonium ions leads to an estimate that the lumen of the channel is approximately 11 Å at its most narrow point.

All members of the PA family have similar amphipathic β hairpin forming sequences that are likely to produce membrane-inserted β barrels (Figure 18.6). The pair of Phe residues in PA, Phe313-Phe314, previously shown to be essential for PA activity, are at the turn of the loop. It is interesting that all members of the family except PA have a His-Ser or His-Thr sequence following the β hairpin. Protonation of this or other His residues may be involved in the acid-dependent membrane insertion (Petosa *et al.*, 1997; Santelli *et al.*, 2004).

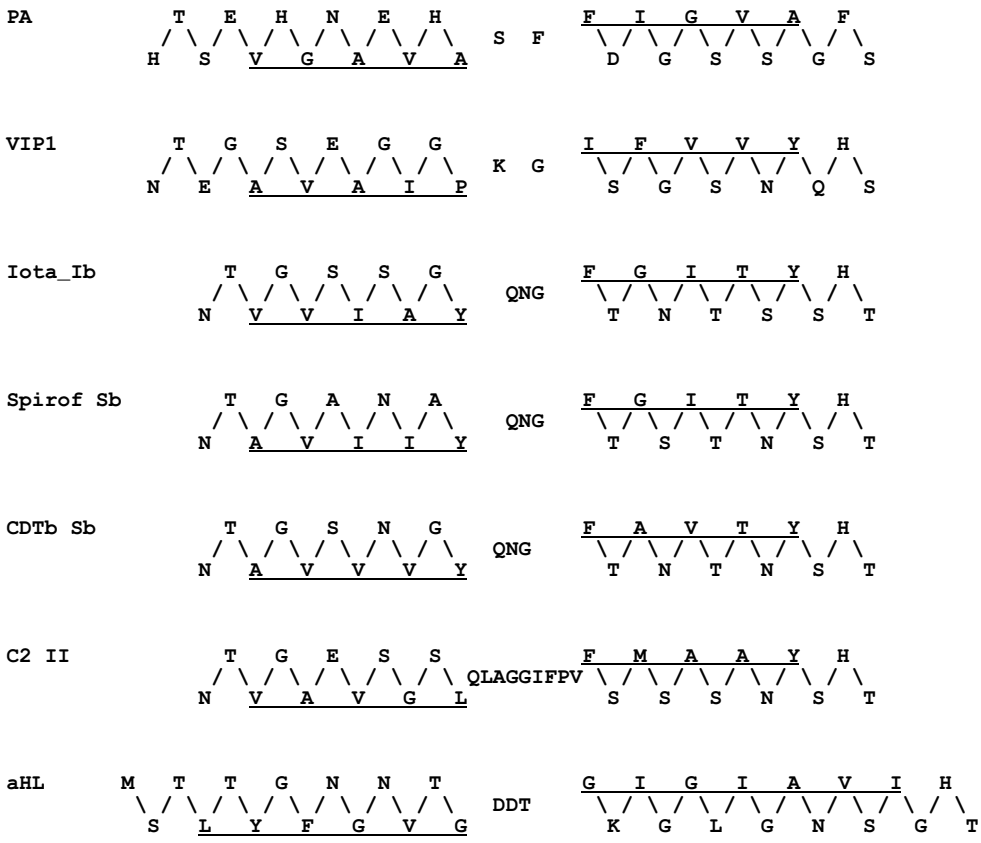

**FIGURE 18.6** Amphipathic sequences of PA family members. Sequences from PA family members that are known or proposed to form amphipathic hairpins that assemble into membrane-spanning barrel structures. Hydrophobic residues (underlined) will face the lipid bilayer and the alternating hydrophilic residues will face the lumen of the channel. Residues in the central region (SF in the case of PA) form the bend of the hairpin located on the cytosolic side of the membrane.

Prior to membrane insertion, the PA63 heptamer that assembles on the cell surface is viewed as a prepore. Experimentally, it is characterized as being quite stable, presumably being equivalent to the PA63 oligomer that is produced by trypsin treatment and MonoQ chromatography, as described above. However, this form does not survive heating in SDS, as is typically done when preparing samples for SDS gel electrophoresis (Leppla, 1991b; Milne *et al.*, 1994; Singh *et al.*, 1994; Miller *et al.*, 1999). Transition to an active pore, following acid-induced insertion into the membrane, creates a more stable structure that survives heating in SDS. The heat-stable oligomer can be produced by acid treatment of soluble PA63 or acid shock of cells having surface-bound PA63 heptamer, but is formed most efficiently by allowing normal cellular internalization to an endocytic compartment (Liu and Leppla, 2002).

Early studies based on similarities to diphtheria toxin trafficking suggested that LF and EF were translocated from early endosomes to the cytosol. However, more recent work suggests that translocation occurs more slowly, suggestive of release from a later endosomal compartment (Menard *et al.*, 1996a; Abrami *et al.*, 2004). In particular, a requirement for pH values approaching 5.0, and the structural information noted above showing that the CMG2 receptor clamps PA domains 2 and 4 to limit membrane insertion, suggested that the acidity of early endosomes (typically pH 6.0) is not sufficient to induce membrane insertion. A detailed trafficking study then showed that the SDS-resistant PA heptamer, the result of membrane insertion, was present in isolated early endosomes, but that LF translocation to the cytosol required transport to a later endosomal compartment. A model was suggested in which LF and EF are delivered into intraluminal vesicles, which later fuse back to late endosomal membranes to release their contents to the cytosol (Abrami *et al.*, 2004).

One of the least understood steps in anthrax toxin trafficking is the transfer of LF and EF across endosomal membranes. Questions examined have been what part of LF initiates transfer, whether translocation is through the lumen of the heptamer, whether the LF must unfold, and what drives the translocation. It was originally suggested that translocation began at the N-terminus, but LF fusion proteins having polypeptides attached at either end of LFn are both delivered (Arora and Leppla, 1994; Milne *et al.*, 1995; Ballard *et al.*, 1996). While this suggests that an internal sequence having the form of a hairpin loop must initiate translocation, additional evidence from artificial lipid membrane studies argued for initiation at the N-terminus (Zhang *et al.*, 2004a). Conceptually, it has seemed easier to imagine that translocation occurred via the 11 Å lumen of the PA63 heptamer, although this does then require partial unfolding of the transiting polypeptides. Direct evidence that LF and EF are translocated through the lumen of the heptamer comes from studies in artificial lipid membranes (Zhang *et al.*, 2004b). LFn enters and plugs the channel at low transmembrane potentials but is driven through the channel at higher voltages. The force that might drive the entire polypeptide through the lumen is less well understood, because its charge distribution does not predict a simple electrostatically-driven process (Zhang *et al.*, 2004b). One model holds that refolding of the protein on the cytosolic side provides the force to prevent reverse movement. In the case of diphtheria toxin, chaperones have been identified that assist the refolding, and thereby provide a ratchet device force to promote unidirectional membrane transit (Ratts *et al.*, 2003), but parallel studies suggested that the same chaperones are not required for LF transit (Haug *et al.*, 2003). Finally, to confirm that unfolding is required, LF fusion proteins were constructed with added, internal disulfide bonds. The inability of these to be delivered from the cell surface in the acid shock protocol supports the view that unfolding is required (Wesche *et al.*, 1998). A requirement for unfolding limits the types of polypeptides that can be delivered as fusions to LFn in the vaccine and therapeutic applications discussed above.

## Cytosolic actions and cellular effects of EF and LF

### *ET action on cells*

Edema toxin treatment of nearly all cell types causes an increase in cAMP. This provides additional evidence that most cell types possess receptors and a protease able to activate PA. The maximum levels of cAMP reached in treated cells differ greatly, from levels that barely exceed the basal concentration of about 2 μmol cAMP $mg^{-1}$ of cell protein to levels of 2000 μ mol cAMP $mg^{-1}$ (Leppla, 1984; Gordon *et al.*, 1988; Gordon *et al.*, 1989). The consequences of elevated cAMP levels have been studied for decades, following the discovery that cAMP acts as a signaling molecule or "second messenger" to activate cAMP-dependent protein kinase (protein kinase A, PKA).

Full activation of PKA requires only a modest elevation of cAMP concentration above basal levels. Activated PKA phosphorylates a number of proteins and alters many cellular processes, the full details of which cannot be described here. Very high cAMP concentrations are not lethal to cultured cells, so toxin-treated cells can recover after removal of toxin. Unlike with cholera toxin, the effects of edema toxin are rap-

idly reversed, apparently because EF is unstable in the cytosol (Leppla, 1982), with a half life of less than two hours.

There are also suggestions that cAMP produced by EF could act through PKA-independent processes. Large increases in cAMP come at the expense of its precursor, ATP, which theoretically could be depleted by >50%, thereby impacting basic cellular energy-dependent processes. Furthermore, cAMP-binding domains have been identified in proteins other than PKA (Chin *et al.*, 2002), including proteins that modulate the same MEK pathways that are targeted by LF. It also must be considered that the amounts and effects of EF-generated cAMP will vary depending on its location within various cytosolic compartments (Tasken and Aandahl, 2004).

Relatively little work has examined the consequences of ET action on cultured cells. ET is believed to play an important role early in an anthrax infection because elevated cAMP concentrations incapacitate phagocytic cells (Confer and Eaton, 1982). Thus, human polymorphonuclear cells treated with purified edema toxin are unable to phagocytose opsonized *B. anthracis* (O'Brien *et al.*, 1985). Edema toxin also has profound effects on chemotaxis and on endotoxin priming of polymorphonuclear cells (Wright *et al.*, 1988). Human monocytes treated with edema toxin produced more IL-6 and were blocked in their endotoxin-induced TNF production (Hoover *et al.*, 1994). Recent studies demonstrated that ET induces calcium effluxes from cultured polarized epithelial cells (Beauregard *et al.*, 1999) and induces a rapid calcium influx in several other cell types (Kumar *et al.*, 2002). In the latter study, the calcium influx occurred prior to the large increases in cAMP concentration and was required for this to occur. It is possible that a small initial increase in cAMP causes calcium channels to open, and the resulting increased cytosolic calcium concentration enhances EF catalytic activity. Regardless of any differences in cellular response to ET, it is clear that the high levels of cAMP produced by EF will have profound effects on nearly all types of cells.

### *LF action on cells*

The known enzymatic action of LF, cleavage and inactivation of MEKs, will effectively shut down several key MEK signaling pathways, but this would not be expected to rapidly kill cells. However, one cell type does respond in an acute manner to lethal toxin. Certain mouse macrophages (e.g., those from BALB/cJ mice) treated with lethal toxin lyse in 90–120 minutes (Friedlander, 1986). Both resident and elicited primary macrophages are susceptible, as are certain macrophage-like cell lines, including J774A.1 and RAW 264.7. However, macrophages from many inbred mouse strains (e.g., C57Bl/6J) are highly resistant to lysis, even though LT enters these cells and cleaves MEKs. This strong phenotypic difference allowed mapping of the genetic locus controlling susceptibility to a region of mouse chromosome 11 that contains the gene encoding Kif1c, a kinesin-like motor protein (Watters *et al.*, 2001). Later studies suggested that the region near the Kif1c gene contains three genes ("quantitative trait loci") that control susceptibility of mice to LT (McAllister *et al.*, 2003). However, no molecular explanation has yet been provided as to how Kif1C or the unidentified neighboring genes might control LT action. If Kif1c plays a role, it may be through regulating the subcellular location of LF or its key substrates. It may also be relevant that LF potency depends on resistance to degradation in the cytosol, which for LF has been shown to involve the proteosome (Falnes and Olsnes, 1998).

Although the rapid *in vitro* lysis of certain mouse macrophages is dramatic, more relevant to events during an anthrax infection is the observation that macrophages stimulated with bacterial cell products such as poly-glutamic acid become susceptible to LT and are killed in a process that has features more characteristic of necrosis than apoptosis. Susceptibility was found in mouse and human macrophages, regardless of the identity of the loci on chromosome 11 (Park *et al.*, 2002; Kim *et al.*, 2002). In parallel incubations lacking LT, some cell death was produced in the activated macrophages by combining inhibitors of all three MEK pathways, suggesting that the LT-induced death could be due to simultaneous inhibition of the same pathways.

Much effort has been made to understand the events leading to the rapid macrophage lysis in the inherently LT-susceptible macrophages (i.e., BALB/cJ). The earliest measured changes in LT-treated macrophages are increases in $K^+$ and $Rb^+$ ion fluxes at 45 minutes, decreases in ATP concentrations and release of superoxide at 60 minutes, and changes in morphology at 75 minutes, which progress to lysis at 90 minutes (Bhatnagar *et al.*, 1989; Hanna *et al.*, 1992; Hanna *et al.*, 1994). The changes occurring after 60 minutes can be delayed by removal of extracellular calcium and by osmotic stabilizers, suggesting that membrane integrity is compromised. Reducing agents also protect mouse macrophages from lethal toxin (Hanna *et al.*, 1994), indicating that the oxidative burst is required for cell lysis. The inability to connect cleavage of MEKs to this rapid lysis has led to the suggestion that LF may cleave other proteins that are critical to macrophage homeostatis, but searches have not identified additional LF substrates.

LT has a more limited effect on other cells studied *in vitro*. Certain cultured cells are inhibited in growth if plated at low cell densities and treated with lethal toxin for 3–7 days. A screen of the 60 tumor cell lines available in the National Cancer Institute drug screening program identified melanoma cells as especially sensitive to LT (Koo *et al.*, 2002), an effect shown to involve apoptosis. This finding is the basis for ongoing development of LT as a cancer treatment (Frankel *et al.*, 2003). Endothelial cells were reported to be killed by LT in an apoptotic process, although the fraction of cells dying after several days was variable (Kirby, 2004). Dendritic cells were found to be targeted by LT with a resultant failure to function in several aspects of the host immune responses (Agrawal *et al.*, 2003). LT has also been found to block transcriptional activation by the glucocorticoid receptor (Webster *et al.*, 2003).

## Actions of the lethal and edema toxins in animals

Anthrax toxin was first recognized by noting the edema caused by intradermal injection of bacterial culture supernatant or plasma of infected animals (Smith *et al.*, 1955). Fractionation showed that this effect was due to the mixture of components now termed *edema toxin*. Subsequent studies showed the supernatant also contained the separate lethal toxin. Unfortunately, those early studies employed toxin preparations of uncertain purity, and on reexamination provide few insights into the cellular systems that are damaged by toxin *in vivo*. However, it is accepted that the effects of lethal toxin administration closely resemble those observed in animals dying from infection with virulent *B. anthracis*. It is for this reason that the authors and others have resumed studies on the pathophysiological effects of the toxins in experimental animals. One goal of such work is to provide guidance in design of prophylactic and therapeutic agents for infected humans.

The best-characterized *in vivo* action of the lethal toxin is its rapid toxicity in rats, where it causes overwhelming pulmonary edema and death in as little as 38 minutes (Haines *et al.*, 1965; Ezzell *et al.*, 1984). The Fischer 344 rat is particularly sensitive to the toxin. The edematous fluid in the lungs of the rats has the protein composition of serum, implying a cytotoxic effect that leads to failure of the endothelial barrier, rather than stimulation of fluid secretion. Recent studies in which LT was infused into Sprague-Dawley rats to mimic toxin accumulation during an infection showed a progressive decline in cardiovascular function preceding a shock-like death. Unlike endotoxin-induced shock, there were no associated cytokine responses (Cui *et al.*, 2004). Although the causes of this rapid death in rats are not understood, the rapid lethality provides a convenient *in vivo* bioassay for evaluation of therapeutics such as neutralizing antibodies, small molecule inhibitors blocking LF catalysis, and others. An advantage of this assay is that its short duration lessens concerns about the residence time and tissue distribution of the candidate therapeutic agents.

Studies of LT action in mice were conducted to extend the finding that mouse macrophages are rapidly lysed and that the susceptibility of mice appeared to correlate with the LT susceptibility of their macrophages. LT was reported to induce IL-1 and TNF in macrophages, and blocking the action of these cytokines protected mice from death by injected LT (Hanna *et al.*, 1993). Furthermore, depletion of macrophages made mice resistant to the lethal action of LT. These studies led to the hypothesis (Hanna, 1998) that macrophages are induced to synthesize and then release unphysiologically high concentrations of cytokines, which then cause a shock-like response. However, these finding have not been confirmed in other laboratories (Erwin *et al.*, 2001) and results noted above and discussed below argue against a key role for cytokines in lethality. In fact, the general finding is that LT treatment profoundly suppresses host immune responses and limits inflammatory responses.

Extensive studies of the action of LT in a number of inbred mouse strains has led to the conclusion that death is due to a circulatory collapse and hypoxia in key organs, particularly bone marrow, liver, and spleen (Moayeri *et al.*, 2003; Moayeri and Leppla, 2004). Hypoxia, liver necrosis, and pleural edema were noted. There was no clear correlation within a set of inbred strains between sensitivity of the mice and of their macrophages to LT, arguing against a key role of macrophage lysis in lethality. Thus, BALB/cJ mice (having LT-sensitive macrophages) died more rapidly and showed a rapid but transient cytokine burst, whereas C57Bl/6J mice (having LT-resistant macrophages) were also killed, although more slowly and with no cytokine burst. A clear test of the contribution of macrophages came from comparing two nearly isogenic BALB/cJ mouse strains differing only in the Kif1c region on chromosome 11. It was found that the LT-induced lysis of macrophages in the mice having sensitive macrophages was needed to obtain the transient cytokine burst, suggesting this explained their slightly increased lethality (Moayeri *et al.*, 2004). It was also shown that the relative sensitivities of many other inbred mouse strains to LT depends on genetic factors in addition to those in the Kif1c region.

In this laboratory, studies have also begun on the action of purified ET in animals. These studies became possible after improved methods for EF production

were developed (Soelaiman *et al.*, 2003). Somewhat surprisingly, ET rapidly killed mice and did so at doses lower than those required for LT (Firoved *et al.*, submitted, 2004). Extensive effusions in the gastrointestinal tract and hemorrhage of the ileum and adrenal glands were observed. Changes in nearly every biochemical parameter measured indicated that ET damages many organs and tissues and probably kills by inducing multi-organ failure. It will now be useful to extend these studies to characterize any synergistic effects of ET and LF in animals.

## CONCLUSION

It is clear from the data presented above that the anthrax toxins play a dominant role in the pathogenesis of anthrax infections. Strains unable to produce the toxin are avirulent, and animals are protected against infection only if they possess antibodies to the toxin. Other bacterial pathogens depend on protein exotoxins for their virulence, but in most cases the toxins have a less complex design. A unique feature of the anthrax toxins is the segregation of the receptor binding and translocation functions on a protein separate from the effector function. This binary design is clearly an effective one, because it is utilized by at least five other toxins produced by Gram-positive pathogens.

Rapid progress has occurred in recent years in understanding the interaction of the anthrax toxin proteins with cells. The toxin receptor has been identified as a blood vessel protein, which may explain the increasing evidence that LT targets the vascular system. The role of furin in proteolytic activation of PA has been detailed. The structure and function of the protein-conducting heptameric PA channel is now one of the best characterized membrane channel proteins. The catalytic activity of LF has been identified and its role in targeting MEK pathways characterized. There remain important questions about how the edema and lethal toxins act in cells and animals to cause the pathology associated with anthrax infection. We can anticipate important progress in connecting the initial catalytic steps, in particular the proteolytic action of LF, to the subsequent pathologic effects in cells and tissues.

The recognition of the need for improved anthrax vaccines has led to a great deal of study on ways to induce antibodies to PA, and to a lesser extent, LF and other potential immunogens. In fact, the great diversity of vaccine carriers being used to deliver PA will allow a useful comparison of their relative efficacies that will have a wide impact on design of other vaccines. Finally, the greatly increased knowledge of the toxin's structure and function has provided a firm basis for the design of a diverse set of therapeutic agents designed to protect and treat anthrax infections. Increased government support for anthrax vaccines and therapeutics assures that a number of effective agents will become available in the next few years.

CHAPTER

# 19

# Attack of the nervous system by clostridial toxins: physical findings, cellular and molecular actions

*Bernard Poulain, Bradley G. Stiles, Michel R. Popoff, and Jordi Molgo*

## INTRODUCTION

This chapter summarizes the known pathophysiological and molecular actions on nerve terminals and nerve tissue of several potent toxins produced by *Clostridium species*. This includes the botulinum and tetanus neurotoxins, which are to date the best documented toxins acting on neurotransmitter release. These metalloproteases specifically target neurons (see Chapter 15, this volume), where they cleave the SNARE proteins involved in neuroexocytosis. Although their molecular mechanisms of action were deciphered a decade ago, progress in understanding the exocytotic mechanisms makes an update of the molecular, cellular, and tissual consequences of their actions necessary. During the last decade, many proteins have been identified as playing a role in exocytosis. This is the case for small GTPases of the Rho and Ras subfamilies and, not surprisingly, the several bacterial toxins that modify these GTPases (see also Chapters 8 and 17, this volume) exert a very potent action on neurotransmission. This has pathophysiological relevance because neurological symptoms are often associated with the pathologies caused by these cytotoxins.

The first part of this chapter is aimed at providing background on neuroexocytotic mechanisms. The two other sections summarize what we know about the above mentioned toxins. To simplify the text, much of the literature data has been summarized in tables. Due to space limitation, we have been obliged to quote only a fraction of the relevant references, and thus given priority to the most recent literature published during the last decade. Many of the valuable earlier papers should have been quoted as well, and their references can be found in the reviews we often invite the reader to consult.

## THE CELLULAR AND MOLECULAR MECHANISMS INVOLVED IN EXOCYTOSIS: AN OVERVIEW

### An overview of neurotransmission

Transmission of information or "orders" along neurons is based on propagated bursts of "action potentials," in which each consists of a depolarized wave in the plasma membrane due to transient opening and closing of voltage-gated, ionic channels. Transfer between neurons, or neurons and target cells (muscle fibers, endocrine cells, etc.) is most often chemical in nature and occurs at highly specialized contact sites termed *synapses*. Here, the release of neurotransmitter molecules by presynatic elements enables activation of receptors localized on the postsynaptic target. Conventional neurotransmitters are acetylcholine (ACh), catecholamines like dopamine or noradrenaline, serotonin, glutamate, γ-aminobutyric acid (GABA), glycine, adenosine-triphosphate (ATP), and numerous peptides such as substance P, calcitonin gene-related

peptide (CGRP), etc. Binding of neurotransmitter molecules to postsynaptic receptors can activate intracellular pathways (metabotropic receptors) or ionic channels (ionotropic receptors). Depending upon the charge of an ion species ($Na^+$, $K^+$, $Ca^{2+}$, $Cl^-$) that flows through the ionic channel/receptor and the transmembrane electrochemical gradient for these ions, activation of a channel/receptor gives rise to inward or outward currents through the plasma membrane. In turn, this causes depolarization or hyperpolarization of the postsynaptic plasma membrane, respectively (i.e., the evoked endplate potential at muscle fibers following stimulation of the motor nerve).

In nerve terminals, transmitter molecules are stored in synaptic vesicles. These small lucent vesicles, approximately 50 nm in diameter and containing small organic molecules, are formed by either budding from the early endosome or recycling of empty vesicles (Jahn and Sudhof, 1999; Jahn *et al.*, 2003; Murthy and De Camilli, 2003). Large dense core vesicles, analogous to the secretory granules present in endo- and exocrine cells, contain a peptide rich matrix and, similar to many cargo vesicles, are formed by budding from the trans-Golgi system. The number of synaptic vesicles per nerve terminal can vary from several tens, to hundreds, of thousands at the motor nerve endings. Synaptic vesicles and certain large dense core vesicles are equipped with a vacuolar-type ATPase that creates a proton gradient that drives specific vesicular transporters, thereby allowing storage of neurotransmitter molecules inside these vesicles. To release their content into the synaptic cleft or lumen of a gland, the synaptic vesicles, large dense core vesicles, or secretory granules must fuse their membranes with the plasmalemma, which then allows content diffusion into the surrounding medium. Neurotransmitter release, as well as hormone secretion, is an exocytotic process triggered by increased cytosolic concentrations of $Ca^{2+}$ ions.

## Mechanisms of exocytosis and SNAREs

More than 100 proteins are implicated in $Ca^{2+}$-dependent exocytosis; however, only a dozen of them participate in the core machinery required for transmitter release, while the others serve regulatory roles (reviewed by Jahn and Sudhof, 1999; Doussau and Augustine, 2000; Rettig and Neher, 2002; Jahn *et al.*, 2003; Murthy and De Camilli, 2003; Bader *et al.*, 2004; Galli and Haucke, 2004). Interestingly, several of these proteins are targeted and disabled by various bacterial toxins. We shall now review how these toxins affect the exocytosis of neurotransmitters. However, in order to address the physiology of poisoning at the molecular level, we summarize the many molecular events involved in this process.

Synaptic vesicles are routed towards the release sites, which in most neurons are identified by a special presynaptic matrix termed as the "active zone." Interaction of synaptic vesicles with the actin filaments, under control of the synapsins, maintains a reservoir of transmitter-loaded vesicles at close proximity to the release sites. This reserve can be mobilized very quickly following phosphorylation of synapsins, thus allowing nerve terminals to support release rates beyond the synaptic vesicle refilling/recycling capacity (Doussau and Augustine, 2000; Garner *et al.*, 2000).

When synaptic vesicles arrive at the fusion site, they bind to the scaffold proteins associated with the "active zone" (Garner *et al.*, 2000). However, when the synaptic vesicles are tethered to the fusion site, they are not yet fusogenic. They must acquire fusion competence, and the needed "priming" corresponds to a sequence of molecular events culminating in assembly of a fusion particle comprised of the soluble *N*-ethylmaleimide-sensitive factor (NSF), attachment protein receptors (SNAREs) found on synaptic vesicles and secretory granules (v-SNAREs: VAMP [vesicle-associated membrane protein]/synaptobrevins) on the target plasma membrane (t-SNAREs: SNAP-25 and syntaxin) (Söllner *et al.*, 1993). In brief, priming is initiated by interaction of the vesicular GTPase Rab3 with the plasma membrane-associated protein Rim (step 1 in Figure 19.1). Rim appears to recruit/activate Munc-13 and, in turn, this triggers de-chaperoning of the t-SNARE syntaxin by Munc-18 (Brose *et al.*, 2000; Garner *et al.*, 2000; Segev, 2001; Gallwitz and Jahn, 2003). Following its de-chaperoning, syntaxin adopts an open configuration that exposes its helical domain H3 and then binds to SNAP-25, the other t-SNARE. SNAP-25 is associated with plasma membrane via palmytoils and has two α-helical arms. Therefore, when SNAP-25 associates with the H3 helix of syntaxin, a heterodimeric complex is formed (step 2 in Figure 19.1). These priming events occur at the plasma membrane level, where the v-SNARE-VAMP adopts an open configuration. Availability for open VAMP is regulated by binding to synaptophysin (an integral vesicle protein), cytosolic $Ca^{2+}$-calmodulin, or other proteins (Quetglas *et al.*, 2000; Pennuto *et al.*, 2003; de Haro *et al.*, 2004). Syntaxin and SNAP-25 constitute an acceptor complex for VAMP, thus generating a four helix bundle (step 3 in Figure 19.1) that is a stable, SDS-resistant, highly packed "rod" of about 10Å diameter (step 4 in Figure 19.1). SNARE complex formation is not enough for promoting fusion (Jahn *et al.*, 2003; Szule and Coorssen, 2003). Indeed, although membranes are pulled into close proximity such that the inner leaflet of the plasma

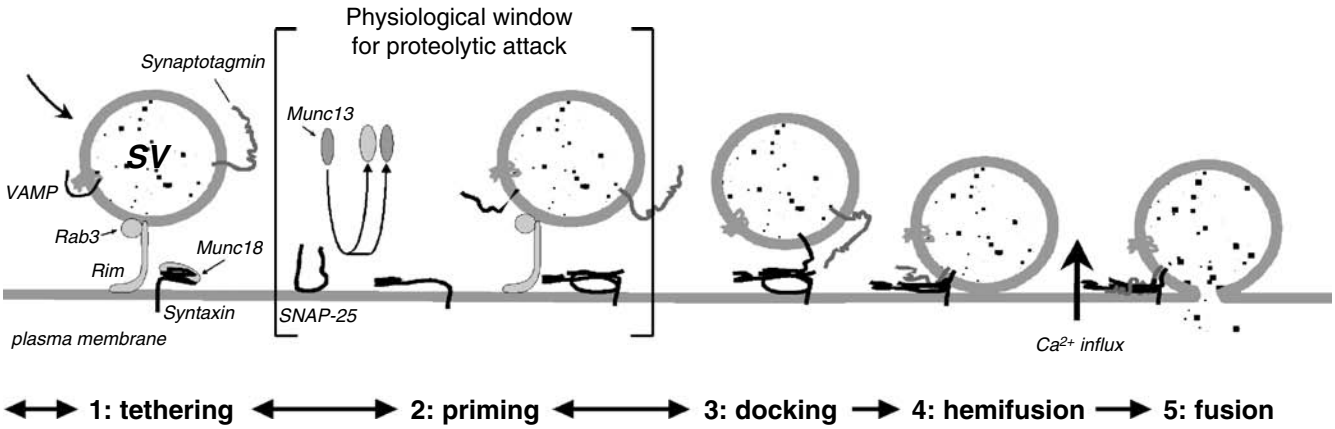

**FIGURE 19.1** Exocytosis is a multiple-step process. Exocytosis follows a sequence of steps during which free synaptic vesicles tether (1) to the plasma membrane via scaffold proteins (not shown). Interaction of Rab3 with Rim signals the onset of priming (2), during which the three SNAREs (VAMP, SNAP-25, and syntaxin) assemble into a complex. Syntaxin is released from Munc-18 and then associates with SNAP-25. Recruitment of VAMP to SNAP-25/syntaxin forms a four helix SNARE complex. Synaptotagmin is also recruited, and at this time synaptic vesicles are "docked" (3). Zippering of the SNARE complex into the highly tight form permits hemifusion (4) of the outer leaflet of synaptic vesicles with the inner leaflet of plasma membranes. $Ca^{2+}$ influx via voltage-gated channels activated by nerve terminal depolarization (i.e. upon action potential arrival) allows $Ca^{2+}$ binding to synaptotagmin and termination of the fusion process (5), which ultimately causes exocytosis of synaptic vesicle content.

membrane mixes with the outer leaflet of the synaptic vesicle membrane, the fusion process seems to stop at this hemifused state.

Termination of fusion is triggered by a rise in intracellular $Ca^{2+}$ levels, which may be caused by $Ca^{2+}$ influx through voltage-gated channels (e.g., at nerve terminals), $Ca^{2+}$ release from intracellular stores, or both (e.g., at many neuroendocrine cells) (Augustine, 2001; Rettig and Neher, 2002; Petersen, 2003). The principal $Ca^{2+}$ sensor for triggering fusion is synaptotagmin, an integral synaptic vesicle protein that interacts in a $Ca^{2+}$-dependent way with SNAREs, notably with the C-terminus of SNAP-25 (Chapman, 2002; Jahn *et al.*, 2003; Koh and Bellen, 2003). Synaptotagmin is equipped with two "C2-domains," which acquire high affinity for membrane lipids upon binding to $Ca^{2+}$ ions. It has been hypothesized that following $Ca^{2+}$ binding to synaptotagmin, the two C2 domains "plunge" into the inner leaflet of the plasma membrane, and this increases local membrane bending. Several SNAREs-synaptotagmin complexes (possibly three) must act in tandem to allow fusion of one synaptic vesicle (Poirier *et al.*, 1998; Hua and Scheller, 2001). Lipids from the outer leaflet of the plasma membrane mix with those from the inner leaflet of the synaptic vesicle membrane, thus enabling fusion pores to then open and release vesicle contents (Jahn *et al.*, 2003), step 5 in Figure 19.1. According to this scenario, formation of the SNARE complex allows pre-fusion of tethered synaptic vesicles, but is not sufficient alone to drive exocytosis. Only the last fusion step is lacking, thus explaining why a delay between the $Ca^{2+}$ rise and vesicle fusion is so brief (< 100μs).

## Actin cytoskeleton and small GTPases in exocytotic mechanisms

Several other proteins play key roles in synaptic vesicle trafficking and priming of tethered synaptic vesicles. Inside nerve terminals, vesicles traffic along actin filaments and this implicates molecular motors like myosins II or V, and small GTPases of the Rab family (Rab3 and others) (Augustine, 2001; Segev, 2001). Reorganization of the actin cytoskeleton is coupled to $Ca^{2+}$-regulated exocytosis in endocrine cells; however, in neurons this is far from being clear (Doussau and Augustine, 2000; Eitzen, 2003; Bader *et al.*, 2004). In secretory cells, but not neurons, the subplasmalemmal actin network serves as a physical barrier, and the transient depolymerization of actin filaments is needed for secretory granule access to fusion sites. Moreover, it is possible that actin activates exocytosis by governing vesicle-granule trafficking towards release sites during fusion events (Eitzen, 2003; Bader *et al.*, 2004).

Organization of the actin-based cytoskeleton is controlled by several proteins, including several small GTPases like the Rho proteins (Hall, 1998) and ADP-ribosylation factor (ARF). Like most small GTPases, ARF and Rho proteins cycle between GDP-bound (inactive) and GTP-bound (active) states, thereby

acting as signal transducers that respond to upstream signals for activating downstream effector molecules to carry out their biological functions.

Rho proteins (Rho, Rac, Cdc42) are widely expressed, monomeric GTPases. Their translocation to specific membrane domains enables intervention of distinct biological functions, which include: (i) regulation of actin cytoskeletal dynamics; (ii) cell cycle progression; (iii) gene transcription; (iv) membrane transport; and (v) exo-/endo-cytosis (Hall, 1998; Bader *et al*., 2004). In chromaffin and PC12 cells, RhoA associates with secretory granules, whereas Rac1 and Cdc42 are found in the subplasmalemmal region (Bader *et al*., 2004). Activation of phosphatidylinositol 4-kinase by RhoA leads to phosphatidylinositol 4,5-bisphosphate (PIP2) residing on the granule membrane. This may promote the formation of granule-associated actin filaments and/or stabilize the subplasmalemmal actin barrier (Bader *et al*., 2004). In chromaffin cells, Cdc42 and Rac1 control actin polymerization and secretion (Li *et al*., 2003; Gasman *et al*., 2004). The Cdc42-controlled pathway seems to specifically target polymerization of local actin filaments at the granule docking sites in order to regulate expansion and/or closure of the fusion pore (Bader *et al*., 2004; Gasman *et al*., 2004). In neurons, Rac1 is associated with synaptic vesicles and plasma membrane (Doussau, 2000). Rac1 is involved in a post-docking step of neuronal exocytosis during which it controls in an all-or-none manner the functionality of release sites (Doussau *et al*., 2000; Humeau *et al*., 2002), possibly via regulation of phospholipase D (PLD) activity (Hammond *et al*., 1997; Humeau *et al*., 2002) (Figure 19.2).

ARF GTPases regulate exocytosis in various cell types including melanotrophs, adipocytes, neutrophils, mast cells, gastric parietal cells, insulin-secreting pancreatic β cells, chromaffin cells, PC12 cells, and neurons (Bader *et al*., 2004). In secretory cells, ARF6 is bound to secretory granules, whereas in neurons, it is on the plasma membrane and associated with recycling of clathrin-coated vesicles (Krauss *et al*., 2003). ARF6 activates plasma membrane PLD (Vitale *et al*., 2002) and PIP5-kinase, leading to the local production of phosphatidic acid (PA) and PIP2. Therefore, ARF6 may act during the priming events by regulating Munc-13 and synaptotagmin, which are also regulated by phosphoinositide levels (Cremona and De Camilli, 2001; Osborne *et al*., 2001).

The Ral GTPase is abundant in nerve terminals and associates with synaptic vesicles (Bielinski *et al*., 1993). This molecule apparently plays a key role in neurotransmitter release by regulating the pool size of readily releasable, synaptic vesicles (Polzin *et al*., 2002). Ral has been implicated in regulating PLD activity (Luo *et al*., 1998).

PLD produces PA and, as mentioned above, is the final target of several pathways implicating small GTPases (ARF6, Ral, and various Rho GTPases). It may be speculated that PLD is activated by these GTPases upon docking of synaptic vesicles, or secretory granules, at the release sites. PLD activation is an important event for exocytosis in neurons and many secretory cell types (Humeau *et al*., 2001a; Vitale *et al*., 2001; Choi *et al*., 2002); and review by Bader *et al*., 2004). PLD-produced PA may activate enzymes and serve as an attachment site for proteins of the fusion machinery, like synaptotagmin or VAMP, or alternatively the PA molecule may act as a precursor for lipid signaling. PA is also a cone-shaped lipid, and biophysical studies have revealed that its local accumulation promotes a negative curvature of the inner (cytoplasmic) plasma membrane leaflet (Chernomordik and Kozlov, 2003). Therefore, it has been hypothesized that PA facilitates formation of the hemifusion intermediates required for vesicle fusion to the plasma membranes, downstream from SNARE complex formation (Humeau *et al*., 2001a; Vitale *et al*., 2001; and review by Chernomordik and Kozlov, 2003) (Figure 19.2).

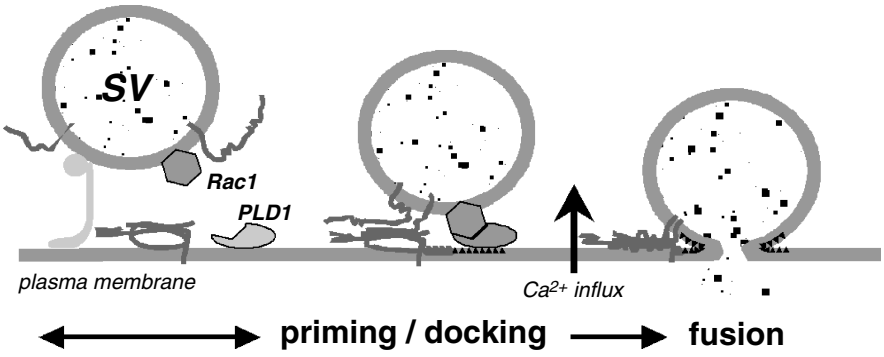

**FIGURE 19.2** Hypothetical model for the role of Rac1 and PLD1 in exocytosis at nerve terminals. Upon synaptic vesicle tethering, vesicular Rac GTPase is activated (i.e., undergoes GDP to GTP exchange) and recruits/activates plasma membrane associated PLD. Local production of cone-shaped phosphatidic acid (denoted here as small, **closed** triangles on the plasma membrane) promotes membrane bending and hemifusion intermediates required for forming exocytotic fusion pores.

## BOTULINUM AND TETANUS NEUROTOXINS

### Toxins from C. *tetani*

Tetanus neurotoxin (TeNT), also called *tetanospasmin*, is produced by *C. tetani* and is responsible for all the neurological disorders of tetanus caused by this bacterium. Only one toxinotype of TeNT is known, and those bacteria producing TeNT display homogeneous bacteriological characteristics that uniformly form *C. tetani*. Some *C. tetani* strains become non-toxigenic and indistinguishable from the toxigenic strains by phenotype and DNA/DNA homology. Toxigenic *C. tetani* strains contain a large plasmid (74 kbp) harboring the *tent* gene.

*C. tetani* also produces a chromosomally encoded hemolysin called tetanolysin O, which belongs to the cholesterol-dependent, pore-forming group of toxins. The complete genome sequence of *C. tetani* has revealed additional virulence factors possibly involved in *C. tetani* invasion into host tissues, which include: (i) two predicted hemolysins; (ii) the ColT collagenase related to *Clostridium histolyticum* collagenases; (iii) a cysteine protease related to the clostripain family; (iv) two fibronectin-binding proteins; (v) three internalin A homologues, which in *Listeria* mediate their entry into host cells; (vi) six surface layer and/or adhesion proteins; and (vii) three membrane proteins related to other bacterial virulence proteins. The ColT molecule is plasmid encoded, while genes for the other putative virulence factors are located on the chromosome (Brüggemann *et al*., 2003).

### Toxins from C. *botulinum* and related *Clostridium species*

#### *Botulinum neurotoxins*

Botulinum neurotoxin (BoNT) was originally defined as a toxin inducing a flaccid, often lethal, paralysis, and the bacteria producing this protein are called *C. botulinum*. However, in contrast to *C. tetani*, the BoNT-producing clostridia are physiologically and genetically heterogeneous and thus belong to several bacteriological groups and species. According to their antigenic properties, BoNTs were identified as seven different toxin types (A, B, C1, D, E, F, and G), and the *C. botulinum* species were divided into four physiological groups:

- group I: *C. botulinum* A, and proteolytic strains of *C. botulinum* B and F.
- group II: *C. botulinum* E, and glucidolytic strains of *C. botulinum* B and F.
- group III: *C. botulinum* C and D.
- group IV: *C. botulinum* G. This group, which also includes non-toxigenic strains previously identified as *Clostridium subterminale* and *Clostridium hastiforme*, is metabolically distinct from the others and has now been assigned to a different species called *Clostridium argentinense* (Suen *et al*., 1988).

*C. botulinum* A, B, and E are mainly involved in human botulism, whereas *C. botulinum* C and D are predominantly responsible for animal botulism (type C in birds and minks, and type D mainly in cattle).

The taxonomic position of *C. botulinum* became even more ambiguous since BoNT is produced by clostridia clearly distinct from *C. botulinum*, yet these strains are biochemically and genetically related to different species such as *Clostridium butyricum* and *Clostridium baratii*. Neurotoxigenic *C. butyricum* strains produce a BoNT/E highly related (96.9% identity at the amino acid level) with those of *C. botulinum* E. These strains have been identified in infants and young people in Italy, as well as during botulism outbreaks throughout China following consumption of fermented paste made of soybeans and wax gourds (Aureli *et al*., 1986; Meng *et al*., 1997; Fenicia *et al*., 1999). Toxigenic *C. baratii* producing a BoNT/F was also responsible for one case of infant, and two cases of adult, botulism in the United States (Hatheway, 1993).

Genes encoding for the different types of BoNT are present on various genetic elements that include phages, plasmids, and chromosomes, depending upon the species and strain. In *C. argentinense*, like in *C. tetani*, the neurotoxin gene is present within a large plasmid. Plasmids of various sizes and bacteriophages are evident in *C. botulinum* A, B, E, and F strains, but toxigenicity has not been associated with these genetic elements. The genes encoding for these neurotoxins are chromosomal but, in neurotoxigenic *C. butyricum* strains, the location of the BoNT/E gene is still undefined. However, in *C. botulinum* C and D, it is clear that BoNT is encoded by bacteriophages. *C. botulinum* C and D strains cured of their phages do not produce BoNT/C1 or BoNT/D, respectively. Such organisms can be converted into neurotoxigenic strains of C or D by respective reinfection with phages obtained from toxigenic *C. botulinum* C or D strains. The BoNT/C1 and BoNT/D genes have been cloned and sequenced from purified phage DNA of *C. botulinum* C-468 and *C. botulinum* D-1873, respectively (Popoff and Marvaud, 1999).

Usually, a *C. botulinum* strain produces only one type of neurotoxin and the locus is present as a single copy on the genome. Rare strains synthesize two types of neurotoxins, such as A-B, B-F, or A-F. In the multiple toxin-producing strains, the neurotoxins are usually

produced at different levels. Thereby, in A-B and B-F producers, 10 times more BoNT/B is synthesized than BoNT/A and BoNT/F. Other strains, although they produce only one BoNT toxinotype, contain an additional silent *bont* gene. Thus, several *C. botulinum* A strains possess a *bont/B* gene containing a proximal stop codon, two amino acid deletions, and two single nucleotide deletions that cause two shifts in the reading frame and multiple stop signals (reviewed in Popoff and Marvaud, 1999).

Overall similarity between the available neurotoxin sequences ranges from 34 to 97% identity. Neurotoxin sequences from the same toxinotype and physiological group are almost identical, except for BoNT/A1 and BoNT/A2, which are highly related (90% identity) yet differ in sequence deletions by 129 residues. BoNTs of the same toxinotype produced by strains from different *C. botulinum* groups or *Clostridium species* possess a high level of identity (70 to 97%). BoNT sequences from *C. botulinum* E and *C. butyricum* share 97% identity. BoNT/B sequences from proteolytic and non-proteolytic *C. botulinum* B share 93% identity, but BoNT/F from *C. botulinum* F and *C. baratii* have only 70% identity. Both variants of BoNT/B seem equipotent in mouse lethal assays. No differences in epidemiology and clinical manifestations have been reported in botulism type B due to proteolytic and non-proteolytic strains. In addition, mosaic structures of *bont* genes have been identified. Molecular characterization of BoNT/D from strain Dsa reveals that the N-terminal region (residues 1 to 522) is highly related to the corresponding region of BoNT/D (96% identity), but the C-terminal region (residues 945 to 1285) is related to the corresponding segment of BoNT/C (74% identity). Inversely, BoNT/C produced by strain C6813 has an N-terminal region related to BoNT/C and a C-terminal region from BoNT/D. However, the central region (residues 523 to 944) remains quite common (83–92% identity) to the hybrid and typical C, as well as D, strains. Thus, genetic analysis suggests that the clostridial BoNT genes are derived from a common ancestor, which has evolved by duplication, mutation, and recombination (reviewed in Popoff and Marvaud, 1999).

### *Additional toxins*

*C. botulinum* C and D strains produce the C2 enterotoxin, which is a binary toxin that ADP-ribosylates monomeric actin within the cytosol and subsequently depolymerizes the actin cytoskeleton. These strains also synthesize an exoenzyme, called C3, which ADP-ribosylates Rho GTPase that leads to disorganization of the actin filaments. C2 toxin genes are located on the chromosome, whereas that of C3 is on phage DNA which also contains the *bont/C1* or *bont/D* genes. To date, the pathological significance of C2 and C3 during *C. botulinum* disease is not clearly known. Finally, various *C. botulinum* strains usually produce a hemolysin, or botunolysin, related to the cholesterol-dependent pore forming toxins (Haque *et al*., 1992) (see Chapter 26 this volume).

## Structure of clostridial neurotoxins

BoNTs and TeNT share a common structure that is first synthesized as a precursor protein (about 150 kDa), which is inactive or weakly active. The precursor, which does not contain signal peptide, is possibly released from the bacterium by a cell-wall exfoliation mechanism. The precursor is proteolytically activated in the extra-bacterial medium either by *Clostridium* proteases or by exogenous proteases, such as those naturally found in the intestinal content. The active neurotoxin consists of a light (L) chain (~ 50 kDa) and a heavy (H) chain (~ 100 kDa), which remain linked by a disulfide bridge. Activation of BoNT/A by an endogeneous protease from *C. botulinum* cleaves between Lys438-Thr439, thus removing 10 amino acids (Thr439-Lys448) (Krieglstein *et al*., 1994). In BoNT/E, cleavage occurs at Lys419-Gly420 and Arg422-Lys423, thus excising a Gly420-Ile-Arg422 peptide (Antharavally and DasGupta, 1997). Proteases produced by *C. tetani* cleave TeNT at Glu449 and Ala456 (Krieglstein *et al*., 1991). For the other BoNTs, cleavage occurs at one or two sites, which include: Arg444/Ser445 and Lys449/Thr450 for BoNT/C; Lys442/Asn443 and Arg445/Asp446 for BoNT/D; as well as Arg435/ Lys436 and Lys439/Ala440 for BoNT/F (Sagane *et al*., 1999).

The crystallographic structures of BoNT/A, BoNT/B, as well as the C-terminal domain of TeNT have been solved and reveal three distinct domains: an L-chain containing α-helices and β-strands that include the catalytic zinc binding motif; the N-terminal part of the H-chain (Hn) forming two unusually long and twisted α-helices; and the C-terminal part of the H-chain (Hc), consisting of two distinct subdomains involved in receptor recognition (Umland *et al*., 1997; Lacy *et al*., 1998; Lacy and Stevens, 1999; Emsley *et al*., 2000; Swaminathan and Eswaramoorthy, 2000; Fotinou *et al*., 2001).

### *The binding domain*

The Hc binding domain of BoNTs and TeNT consists of two distinct subdomains, the N-terminal (Hc-N) and C-terminal (Hc-C) halves, with few protein-protein contacts between them. Hc-N has two seven-stranded β-segments arranged in a jelly roll motif quite similar

to that of lectins. The amino acid sequence of this subdomain is highly conserved among clostridial neurotoxins, thus suggesting a similar folding pattern. The Hc-C subdomain contains a modified β-trefoil folding motif present in several other proteins that possess recognition and binding functions, such as interleukin-1, fibroblast growth factor, and the Kunitz-type trypsin inhibitors. However, the Hc-C sequence is poorly conserved among clostridial neurotoxins. The critical importance of the last 34 residues from Hc-C, and in particular His1293 of TeNT, for binding the oligosaccharide portion of polysialogangliosides was recently demonstrated by photoaffinity labeling (Shapiro *et al*., 1997). In BoNT/B and BoNT/A, one ganglioside binding site was mapped within the Hc-C, whereas TeNT binds simultaneously to two ganglioside molecules (Swaminathan and Eswaramoorthy, 2000; Fotinou *et al*., 2001; Rummel *et al*., 2003; Rummel *et al*., 2004). These data are supportive of a double receptor model of binding for clostridial neurotoxins to the presynaptic membrane. One subdomain binds to a glycoprotein, which differs for the various clostridial neurotoxins, and the other subdomain binds to polysialogangliosides. A major difference between the Hc-C of TeNT and BoNT/A resides in the loop structures, thus suggesting that these external segments may bind to unique protein receptors. However, the Hc-N and Hc-C subdomains are required for neurotoxin interactions with neuronal surface receptors. Thereby, antibodies against Hc-N or Hc-C are poorly protective, whereas antibodies raised against the whole Hc domain efficiently neutralize BoNT/A. The whole BoNT/A Hc domain, and especially the native structure of the interfacial region between Hc-N and Hc-C, is necessary to generate efficiently protective antibodies (Tavallaie *et al*., 2004). In addition, the Hc-C domain of TeNT sufficiently mediates binding to neuronal cells (Herreros *et al*., 2000).

### *The translocation domain*

The Hn regions are highly homologous among the various clostridial neurotoxins, and the conformations of these domains are quite similar in BoNT/A and BoNT/B (Lacy *et al*., 1998; Swaminathan and Eswaramoorthy, 2000). Hn has a cylindrical shape determined by a pair of unusually long (10 nm), twisted α–helices corresponding to peptide segment 685–827 (BoNT/A numbering), which is overall reminiscent of the α-helical hairpin found in some colicins. At both ends of the helical pair, there is a shorter α-helix, which lies parallel to the main helices and, in addition, several strands pack along the two core helices. The segments involved in ion channel formation at low pH remain unidentified, but the overall structure of Hn resembles that of some viral proteins which undergo an acid-driven conformational change (Bullough *et al*., 1994).

### *The catalytic domain*

The metallo-protease domain (L chain, 55 Å × 55 Å × 62 Å) contains both α-helix and β-strand secondary structures, and has little similarity with related enzymes of known structure, apart from the α–helix segment including the zinc binding motif. In addition to the imidazole rings from two histidines of the His-Glu-X-X-d His motif and a water molecule bound to the glutamic acid, the zinc atom is coordinated by another glutamic acid conserved among all clostridial neurotoxins (Rigoni *et al*., 2001; Rossetto *et al*., 2001). The Glu residue is particularly important because it coordinates the water molecule directly implicated in proteolytic hydrolysis. Its mutation leads to complete inactivation of these neurotoxins (Li *et al*., 2000). The active site is similar to that of thermolysin and identifies a primary sphere of residues essential for catalysis, which coincides with the zinc coordinating residues. In addition, there is a secondary layer of amino acids more distant from the zinc center, in which Arg362 and Tyr365 (BoNT/A numbering) are reportedly involved in catalysis by stabilizing the transition state (Rigoni *et al*., 2001; Rossetto *et al*., 2001; Binz *et al*., 2002). The active site of BoNT/A is in a deep recess (20–24 Å) shielded by the H chain; it only becomes accessible to the substrate following reduction of the interchain disulfide bridge, and it appears capable of accommodating a 16 residue segment. Upon reduction at physiological temperature (37°C), BoNT/A loses most of its native tertiary structure and adopts a molten globule conformation that correlates with binding to unstructured SNAP-25 and optimum endopeptidase activity (Cai and Singh, 2001). In contrast, the belt region of BoNT/B formed by the Hc-N domain does not completely occlude the active site, which remains accessible to small molecule inhibitors (Swaminathan and Eswaramoorthy, 2000). However, BoNT/B also requires reduction of the disulfide bridge between L and H chains to activate its endopeptidase activity (Herreros *et al*., 1999; Schiavo *et al*., 2000). Most of the L chain is required for enzymatic activity. The BoNT/A L chain can only tolerate an eight amino acid truncation at the N-terminus, and a 32 amino acid deletion at the C-terminus; however, in contrast the TeNT L chain is still functional following a 16 or even 65 amino acid deletion at the C-terminus (Kurazono *et al*., 1992). The L chain C-terminus likely participates in solubility, stability, and catalysis via stabilizing the tertiary structure (Baldwin *et al*., 2004). Additionally, BoNT/A activity is higher when SNAP-25 is inserted into the membrane

or in liposomes containing negatively charged phospholipids versus soluble SNAP-25, thus indicating that a membrane substrate conformation is better recognized by the toxin and/or phospholipids may facilitate an electrostatic toxin-substrate interaction (Caccin *et al*., 2003).

## Botulinum complexes

BoNTs are associated with non-toxic proteins (ANTPs) to form large complexes also known as progenitor toxins. ANTPs encompass a non-toxic and non-hemagglutinin component (NTNH), as well as several hemagglutinin components (HAs) (reviewed in Oguma *et al*., 1999; Quinn and Minton, 2001; Sharma *et al*., 2003) (Figure 19.3). Botulinum complexes, in which proteins are not covalently linked, are formed in cultures and naturally contaminated food, are stable at acidic pH, and dissociate at alkaline pH (≥pH 8). In contrast, TeNT does not yield any complex, and related botulinum *antp* genes are not evident in the *C. tetani* genome (Brüggemann *et al*., 2003).

*C. botulinum* A produces three types of Botulinum complexes complex designated LL (19S, 900 kDa), L (16S, 500 kDa), and M (12S, 300 kDa). The 12S complex results from a BoNT/A plus NTNH association, and does not possess any hemagglutinating activity. NTNH has a cleavage site within the N-terminus and is

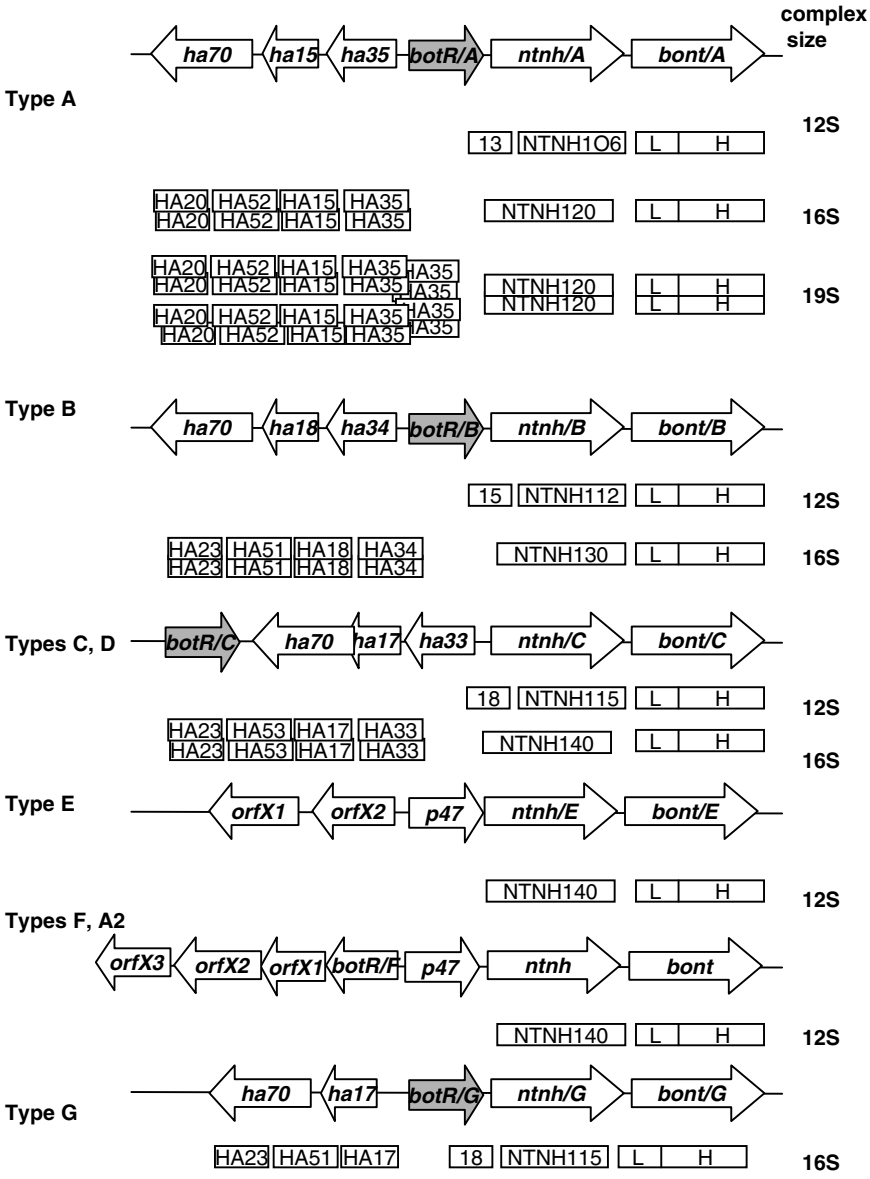

**FIGURE 19.3** Composition of the BoNT complexes from the various *Clostridium botulinum* types.

separated into 13 and 106 kDa fragments as assessed by SDS-PAGE. The 16S complex consists of BoNT/A, NTNH, and HAs (HA33, HA17, and HA70) at a presumed 1:1:2 ratio. HA70 is proteolytically cleaved into HA50 and HA20. The 19S complex has the same protein composition as the 12S complex, but the ratio of HA33 is about twice that found in the 12S complex. The 19S complex is likely a dimer of the 16S complex cross-linked by HA33 (Oguma *et al*., 1999; Sharma *et al*., 2003). The composition of Botulinum complexes types A2 and A1 from strain NCTC2916, which contains different proteins like P47, OrfX1, OrfX2, and OrfX3, remains undetermined (Dineen *et al*., 2003).

*C. botulinum* B, C, and D yield two complex types, L and M, the composition of which is equivalent to those of *C. botulinum* A (Oguma *et al*., 1999; Arimitsu *et al*., 2003). The complete subunit structure of *C. botulinum* D strain 4947 L complex (650 kDa) was determined as one BoNT/D, two HA70, four HA33, and four HA17b molecules, with intermediate complexes (540 and 610 kDa) constituted of various HA subunits. In addition, an intermediate M complex (410 kDa) contains BoNT/D, NTNH, and two molecules of HA70 (Kouguchi *et al*., 2002; Mutoh *et al*., 2003). *C. botulinum* A2, E, and F only produce M complexes devoid of hemagglutinating activity, and *C. argentinense* produces only L complex (Oguma *et al*., 1999).

NTNHs from different *C. botulinum* types possess a high identity level (76–83.5%), and are the most conserved proteins in various Botulinum complexes (Popoff and Marvaud, 1999). NTNH/A, NTNH/C, and NTNH/D contain a cleavage site within their N-terminus, yielding 15 kDa N-terminal and 115 kDa C-terminal fragments. NTNH/A is split into 13 and 106 kDa fragments by cleavage between Pro144/Phe145 (Fujita *et al*., 1995). NTNH/C and NTNH/D are cleaved at Lys127 by a trypsin-like protease with 7–13 amino acids removed from the N-terminus of the 115 kDa fragment that subsequently results in three proteins starting at Leu135, Val139, or Ser141 (Sagane *et al*., 2000). NTNH is only cleaved in the 12S (M) complexes from *C. botulinum* types A, C, and D, but not in the L (16S) or LL (19S) complexes. The cleaved NTNH molecules constitute a nicked structure since the two fragments still remain together after NTNH purification (Sagane *et al*., 2000). In contrast, NTNH/E and NTNH/F show an identical deletion of 33 residues in the corresponding region of NTNH/A, NTNH/C, and NTNH/D encompassing the cutting site, and NTNH/G possesses a slightly different sequence in this region. It is presumed that the processing and additional sequence of NTNH in *C. botulinum* A, C, and D are responsible for forming 12S-, 16S-, and 19S-sized complexes. The inability of *C. botulinum* E and F to form L complexes may result from the absence of HA or other related proteins that bind to NTNH, and from the absence of a putative binding site in NTNH/E and NTNH/F (Oguma *et al*., 1999; Popoff and Marvaud, 1999).

HA33-35 is the most abundant hemagglutinin component of the Botulinum complexes. Type A HA35 binds to oligosaccharides containing galactose-β1-4glucose-*N*-acetyl-D-neuraminic acid (Galβ1-4GlcNAc) (Inoue *et al*., 2001). Thereby, hemagglutination induced by 16S and 19S type A Botulinum complex is mainly mediated through HA35 binding to erythrocyte membrane glycolipids and glycoproteins containing Galβ1-4GlcNAc, such as paragloboside and glycophorin A (Inoue *et al*., 1999; Inoue *et al*., 2001). Similarly, HA33 from types C and D Botulinum complexes bind to paragloboside on Galβ1-4GlcNAc and also sialylglycolipids (GM3), as well as sialoglycoproteins (sialosylparagloboside) on the *N*-acetyl-D-neuraminic acid-α2–3–galactose–β1 motif (Fujinaga *et al*., 2004). The importance of HA33-35 in hemagglutination is also supported by monoclonal antibody studies. Type C-specific monoclonal antibodies against HA33 inhibit hemagglutination, contrary to those against HA50 and HA17 (Mahmut *et al*., 2002b). However, type C HA70 and its derivative HA50 recognize sialosylparagloboside and GM3 at the *N*-acetyl-D-neuraminic acid-α2–3–galactose–β1motif in erythrocyte membranes, like the corresponding 16S Botulinum complex. Thus, HA50 could also be involved in hemagglutination (Fujinaga *et al*., 2004). HA35 purified from *C. botulinum* A is predominantly a dimeric, β-sheet protein in aqueous solutions. In *C. botulinum* A, five N-terminal amino acids are removed from HA35, but similar posttranslational modification has not been observed in HA33 from *C. botulinum C*. The significance of HA35 processing on its biological activity is not known (Sharma *et al*., 1999). It was first discovered that the 31 C-terminal amino acids, which contain a predicted carbohydrate recognition site, play an essential role in hemagglutination (Sagane *et al*., 2001). Structure of type C HA33 shows two β-trefoil domains consisting of a six stranded, antiparallel β-barrel capped on one side by three β-hairpins. Related β-trefoil structures bind to oligosaccharides and are found in other proteins, including various lectins like the ricin B-chain, cytokines, trypsin inhibitor, xylanase, as well as the C-terminal part of BoNTs. Type A HA35 retains a similar structure related to the carbohydrate binding site of ricin, a plant toxin. It is noteworthy that Asp263 and Asn285 of HA35, which are conserved in the lactose-binding site for ricin B chain, are critical for carbohydrate binding (Arndt *et al*., 2005; Inoue *et al*., 2003).

## Tetanus and dissemination of tetanus toxin within the host

### *Tetanus*

Tetanus is a major infectious disease caused by a wound contaminated with *C. tetani*, and it is characterized by persistent tonic muscle spasms with episodes of exacerbation.

Several clinical forms of tetanus have been described: local, generalized, cephalic, and neonatal (Bleck, 1989). Each form has a clinical relevance because of its prognostic value; however, these clinical entities share common cellular and molecular mechanisms. In all these forms, TeNT is the only etiological cause of neurological symptoms. Other secreted proteins like tetanolysin do not act on nerve cells, but their cytotoxicity may favour abscess formation and growth of *C. tetani* in an anaerobic environment.

Although the gut may sometimes offer physiological conditions that promote spore germination of various clostridia, including *C. tetani*, until now there has been no evidence for an intestinal form of tetanus. It has been hypothesized that the lack of associated protective proteins facilitates toxin degradation in the digestive tract. It is also possible that TeNT cannot cross the gut-barrier due to a paucity of receptors that might otherwise enable transepithelial movement (Maksymowych and Simpson, 1998).

### *Dissemination of TeNT and physical findings during tetanus and poisoning experiments*

Local tetanus consists of persistent muscle spasms in close proximity to the infection site. A rare variant is cephalic tetanus, which is caused by *C. tetani* growth in a wound on the head or neck. The spastic paralysis (i.e., a peripheral physical finding) observed during local tetanus has a central origin with disinhibited motoneurons. TeNT cannot cross the blood brain barrier composed of tightly sealed endothelial cells that form the spinal cord and brain capillaries. Compelling evidence (Wellhöner, 1992) has shown that the entry port of TeNT into the central nervous system is the motoneuron, which essentially acts like a Trojan horse. Indeed, the TeNT molecules first bind to motor cholinergic nerve endings responsible for innervating striated muscles, followed by endocytosis and transport towards the spinal cord (Chapter 20, this volume). Transport studies with $^{125}$I-labeled TeNT reveal a retrograde axonal ascent of TeNT along the motor axons. Indeed, $^{125}$I-TeNT was found in the ventral roots (i.e., containing motor axons) and ventral horn of the spinal cord (i.e., the area containing motoneuron cell bodies). Apparently, α-motoneurons that innervate striated muscle fibers and γ-motoneurons that innervate the muscle spindle can both take up, as well as transport, TeNT. Toxin labeling of the dorsal root, which contains sensory fibers, has also been reported. However, this toxin transport does not seem relevant for the pathophysiology of tetanus because ligature of the dorsal (sensory) root does not prevent labeling of the spinal cord. Moreover, recent studies with a recombinant, fluor-labeled TeNT-fragment reveal binding, uptake, and transport of TeNT in motoneurons, but only binding without transport in dorsal root neurons (Wellhöner, 1992; Halpern and Neale, 1995; Bigalke and Shoer, 2000).

Identification of receptors at motor nerve endings that enable internalization of TeNT, as well as the identity of any facilitating molecule(s) implicated in retroaxonal transport, still remain unresolved. Although not presented here, these issues are fully discussed in Chapter 20, this volume.

TeNT molecules, when retroaxonally transported, arrive at the motoneuron soma and dendrites where they are released into the extracellular space. This transcytosis through motoneurons allows the toxin to bypass the blood-brain barrier and reach the vicinity of nerve terminals that are afferent onto the motoneurons. High TeNT concentrations can be found in particular compartments of the central nervous system during tetanus: for instance, release of one TeNT molecule into a small volume like a synaptic cleft (~1 μm × 1 μm × 50 nm) leads to a "concentration" of ~30 nM! According to *in vitro* experiments, TeNT molecules are recaptured by different types of nerve endings, independent of the type of neurotransmitter molecules they release (Wellhöner, 1992; Bigalke and Shoer, 2000). Consistent with the preferential blocking action of TeNT on GABA and glycine release observed *in vitro*, TeNT suppresses the inhibitory inputs afferent to motoneurons, while the excitatory inputs, which constantly fire motoneurons, are not modified. Therefore, motoneurons are disinhibited and their firing rate increases, inducing sustained muscle contractions that lead to spasms and rigidity. Both the inhibitory descending controls and spinal reflexes that converge onto motoneurons are deeply altered (Figure 19.4). Spindle sensory inputs conveyed by Ia fibers during physiological conditions positively activate the synergistic motoneurons afferent to the same (homonymous) muscle, and simultaneously inhibit motoneurons to antagonize muscles through inhibitory interneurons. Therefore, upon TeNT-induced blockade, or when TeNT blocks the inhibition pathway mediated by Ia interneurons (step 1 in Figure 19.4), the myotactic reflex is deeply altered and leads to co-contraction of agonist and antagonist

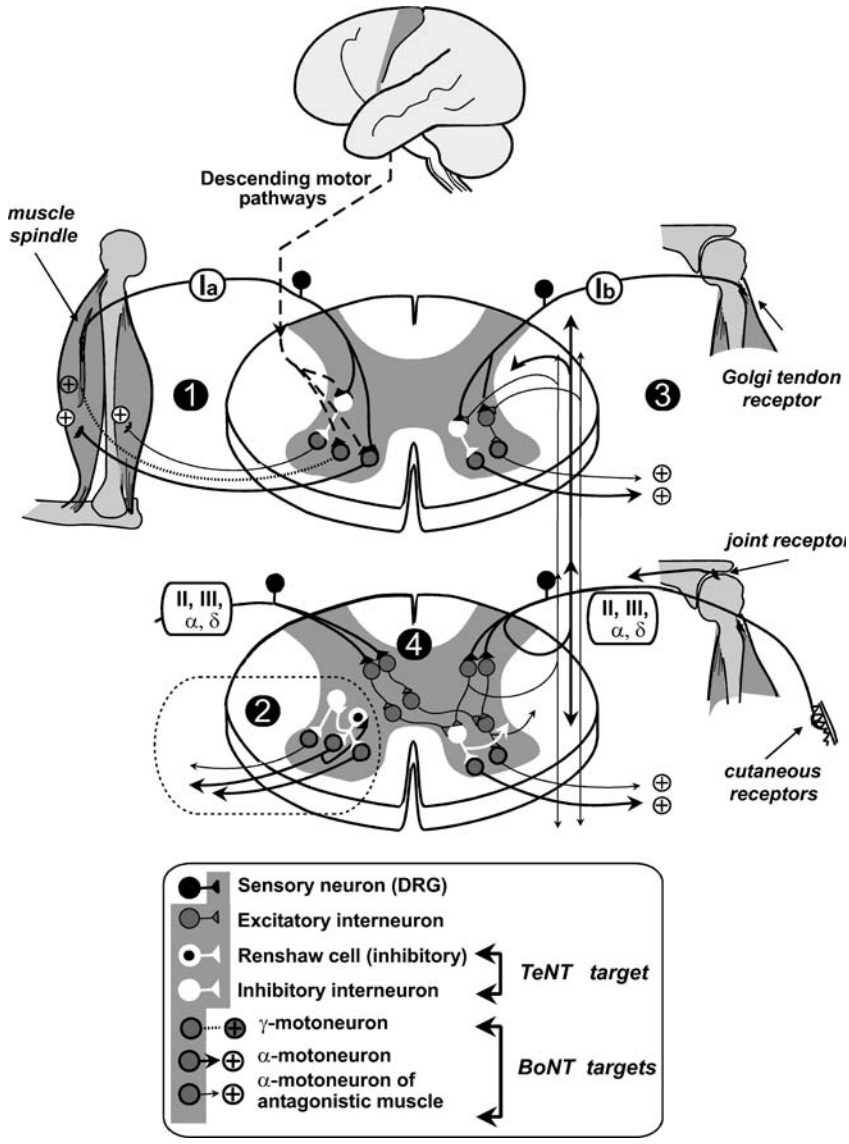

**FIGURE 19.4** Schematic organization of neuronal circuits in the spinal cord. Descending direct or indirect pathways originating from cortical motor areas project onto both motoneurons and interneurons. (1) The neuronal circuit for a myotactic reflex. Ia afferent fibers coming from the muscle spindle excite monosynaptic motoneurons of the homonymous (or synergistic) muscle from which they arise and inhibit neurons to antagonist muscles through an inhibitory neuron. (2) Recurrent inhibition involves the inhibitory Renshaw cells that are excited by collateral branches of motoneurons. Renshaw cells also disinhibit antagonist muscles by inhibiting Ia inhibitory interneurons. (3) The inverse myotactic reflex circuitry. (4) The circuitry for reflexes originating from cutaneous or deep receptors. Note that the latter polysynaptic circuit crosses the spinal cord midline, allowing extension of reflexes to the contralateral side. Moreover, collateral branches allow activation of interneurons in the neighbouring (upper or lower) spinal segments.

Inhibitory neurons (in white) release GABA or glycine, and are the main targets of TeNT. Nerve terminals of α- and γ-motoneurons represent the targets of BoNTs.

muscles working the same joint. TeNT also depresses recurrent inhibition, implicating Renshaw cells (step 2 in Fig. 19.4). Inverse myotactic reflex involves Ib fibers coming from the Golgi tendon organ and participates in a negative feedback system preventing further development of muscle tension upon reaching the desired point. Alteration of this reflex (step 3 in Fig. 19.4) leads to an uncontrolled increase in muscle tension, causing muscle and tendon damage. In a similar way, the many reflexes based on polysynaptic circuits converging on inhibitory interneurons are disorganized (step 4 in Fig. 19.4). Therefore, all local stimuli causing an increase in excitatory input (e.g., sensorial or noxious stimuli) leads to local exacerbation of muscle contractions (Bleck, 1989; Wellhöner, 1992).

The situation is not too different in generalized tetanus. TeNT molecules primarily taken up by motor endings can undergo other transcytotic cycles throughout neurons of second, third, etc. order (Manning *et al*., 1990). Thereby, TeNT entering a single peripheral site and released into the spinal cord disseminates vertically to proximal spinal segments and horizontally to the contralateral side of the spinal cord, thus resulting in progressive muscle rigidity in all muscles. Retroaxonal transport of TeNT along a chain of functionally connected neurons has been exploited to trace the projection pathways between distant brain structures (Cabot *et al*., 1991). Furthermore, to study trafficking pathways and connectivity in sensorimotor circuits, several fusion proteins have been engineered using the atoxic TeNT

C-subunit (TTC) fused to a reporter gene such as *lacZ*, GFP (Green Fluorescent Protein), or EGFP (Enhanced Green Fluorescent Protein) after direct injection of the hybrid proteins (Coen *et al*., 1997; Miana-Mena *et al*., 2002), or expression as a transgene in mice (Maskos *et al*., 2002). When there is a hematogenous portal of entry for TeNT, it enters all motor-nerve terminals and reaches the spinal cord at a number of sites. The most dramatic form of the disease, called *generalized tetanus*, then occurs and is characterized by an overall increase in muscle tone, rigidity, and trismus (Bleck, 1989). Almost all spinal reflexes based on GABAergic and glycinergic transmission are abolished, leading to horizontal and vertical spreading of the response from any stimulus. Therefore, a local stimulus leads to a general response. For example, application of a cutaneous stimulus on a limb can induce profuse contraction of the face, neck, trunk, arms, and legs. When the spasm affects the diaphragm, respiratory failure and death can ensue. Although TeNT injected directly into the brain can induce epilepsy (Benke and Swann, 2004), no central disorder like seizure is observed during tetanus (Bleck, 1989). Therefore, the intrathecal dissemination of TeNT remains largely confined to the spinal cord.

Several other symptoms are detected during generalized tetanus and indicate that TeNT acts also on the autonomous nervous system (e.g., hypertension due to vasomotor spasm, tachycardia, etc.). This hypersympathetic condition is due to disinhibition of the sympathetic reflexes, analogous to that for motoneurons. This is fully consistent with a report that TeNT is also taken up and retrogradely transported in adrenergic neurons. This is followed by toxin delivery to the inhibitory interneurons, whose terminals are afferent to the cell body of adrenergic neurons. Alteration of functions linked to the parasympathetic system has been reported, too (Bleck, 1989; Wellhöner, 1992). All of the above mentioned physical findings observed during local tetanus have a unique origin: TeNT blockade of inhibitory neurotransmitter (GABA and glycine) release.

When the local concentration of TeNT is high, it can also block the release of other neurotransmitters. A high dose of TeNT injected into the lateral rectus muscle of the cat blocks both inhibitory and excitatory synapses simultaneously in abducens neurons (Gonzalez-Forero *et al*., 2003). At the neuromuscular junction (NMJ), TeNT inhibits ACh release, thereby inducing flaccid muscle paralysis *in vitro* (Wellhöner, 1992) and during disease (e.g., cephalic tetanus in humans) (Bleck, 1989). In certain animal species, flaccid motor paralysis may be the only action of the toxin. For instance, application of TeNT into the periphery of goldfish does not produce central actions, but it inhibits ACh release from motor nerve endings. This is consistent with motor terminals being the primary binding targets for TeNT. When captured by motoneuron endings, TeNT is preferentially routed to a transport compartment whose neutral pH prevents translocation into the cytosol of motor nerve terminals. This preferential routing is not absolute, and TeNT appears far less potent than BoNTs in inhibiting ACh release by a factor of 100–1000. This trafficking seems to depend strongly upon the TeNT receptor. Indeed, when the active moiety of TeNT is recombined with the binding domain of BoNT, it acquires a very high efficacy in cholinergic nerve terminals (Wellhöner, 1992).

To summarize, the clinical and experimental findings of tetanus reveal a prominent inhibitory action of TeNT on the release of GABA and glycine. Complexity of the neuronal network and an inherent difficulty in dissociating direct from indirect effects has not allowed identification of other neuronal targets for TeNT. However, the *in vitro* experiments clearly indicate that TeNT blocks release of many, if not all, neurotransmitters.

## Botulism and dissemination of BoNTs within the host

### *Botulism*

Botulism is a severe disease affecting vertebrates, and three main etiological forms are evident in humans. Food-borne botulism has been recognized since the nineteenth century and is induced by ingesting food containing preformed toxin from *C. botulinum* types A, B, E, F, or *C. butyricum*. The second main etiological form of botulism is due to colonization of the gut by *C. botulinum* types A, B, or F, and sometimes neurotoxigenic *C. baratii*. This is the case for infant botulism, which only affects babies up to six months old, and certain cases of gastrointestinal botulism in adults. In addition, like other clostridia (*C. tetani*, *C. perfringens*, etc.), proteolytic strains of *C. botulinum* types A and B can grow quite well in necrotic wounds, which provide appropriate substrate and anaerobic conditions. BoNT is produced *in vivo* at the site of infection, causing "wound-botulism." Note that a "wound" can also occur in the intestinal tract, as this rare form of botulism has been reported in parenteral drug abusers and intranasal cocaine users with sinusitis (Tacket and Rogawski, 1989; Tunkel and Pradhan, 2002).

### *Dissemination of the BoNTs during botulism*

During food-borne botulism, preformed Botulinum complex is ingested with food. Although the several ANTPs associated with BoNTs do not contribute to

poisoning (see below), they seem to play a crucial role in protecting BoNT against acidity and proteases from the stomach. Indeed, oral toxicity of the Botulinum complex is higher than that for BoNTs alone (Ohishi *et al*., 1977; Ohishi and Sakaguchi, 1980). The Botulinum complex has increased helical content in low pH, thus indicating a conformational change (Chen *et al*., 1998). However, the molecular basis for Botulinum complex resistance to low pH and proteases is not yet fully understood. Since type A HA35 is highly resistant to proteolysis by trypsin with or without sugars, this HA may protect Botulinum complex against proteases of the gastrointestinal tract (Fu *et al*., 1997; Sharma *et al*., 1999).

Moreover, HA proteins of the Botulinum complexBotulinum complex seemingly favor BoNT and Botulinum complex adherence to intestinal epithelial cells. Thus, type C Botulinum complex containing HA33, and HA50 binds to microvilli of enterocytes from the upper small intestine of guinea pigs. While HA33 binding is neuraminidase-insensitive, that of HA50 is neuraminidase-sensitive. Type C Botulinum complex containing HA (16S) is much more efficiently absorbed from the intestinal content into the serum than the 12S complex or BoNT/C alone (Fujinaga *et al*., 1997; Fujinaga *et al*., 2000; Fujinaga *et al*., 2004). In human colon carcinoma cells (HT-29), type C 16S Botulinum complex binds to surface glycoproteins like mucin (Nishikawa *et al*., 2004). In addition, local immunization with NTNH and HAs partially protect mice from oral administration of 16S type C or D Botulinum complex (Mahmut *et al*., 2002a). However, in an *in vivo* mouse model, BoNT/A does not require ANTPs for transport from the gastrointestinal tract into the circulatory system (Maksymowych *et al*., 1999). Additionally, in T84 and CaCo-2 human colon carcinoma or Calu-3 human pulmonary cells, ANTPs do not facilitate BoNT/A transcytosis and H chain alone is apparently sufficient for toxin transport through epithelial monolayers (Maksymowych and Simpson, 1998; Park and Simpson, 2003).

When the pH becomes neutral or basic (i.e., when the stomach is buffered by biliary flow in the duodenum, jejunum, and upper intestine), Botulinum complex dissociates and releases BoNT (Simpson, 2004), which then binds to receptors localized on the apical membrane of gut epithelial cells. The BoNT/acceptor complex is endocytosed and directed, via intracellular vesicle trafficking, to the baso-lateral membrane of enterocytes. Here, BoNT is secreted by exocytosis (Maksymowych and Simpson, 1998; Maksymowych *et al*., 1999). This transcytosis allows BoNT, but not the ANTPs, to cross the intestinal barrier and disseminate within the whole organism through the circulatory and lymphatic systems.

While dissemination of the toxin during infant or intestinal botulism is almost identical to that described above for food botulism, there is an interesting difference with wound botulism. Indeed, both BoNTs and ANTPs are produced and found in the extracellular medium. It is not yet documented whether Botulinum complex remains intact during neutral conditions in the extracellular medium, and whether BoNT formed in wounds can undergo hematogenous dissemination. This point deserves further consideration because of its close analogy with the dissemination of small toxin amounts causing side effects when Botulinum complex is injected into tissue for therapeutic purposes (Brin *et al*., 2002). Another point is the recent discovery that proteins associated with BoNT can enhance its action (discussed below).

As all large proteins, BoNTs cannot directly reach the central nervous system. Indeed, tight junctions between endothelial cells of brain and spinal cord capillaries (i.e., the so-called blood-brain barrier) prevent free diffusion of proteins from blood plasma to the cerebro-spinal fluid. Therefore, the action of BoNT is almost restricted to the peripheral nerve system, which includes all of the nerve ganglia.

### *Clinical symptoms and physical findings during botulism and poisoning experiments*

Although dissemination of the BoNT occurs via different routes, there is no clear distinction in symptoms and physical findings displayed by the various forms of botulism (Table 19.1). The clinical picture of botulism often initiates as a dysautonomia, followed by motor paralysis. Initial symptoms of dysautonomia include visual symptoms (blurring, diploplia, and presbytia), followed by dry mouth and constipation. The nausea, vomiting, and diarrhea often reported during food botulism may be due to ill-defined enterotoxins unrelated to BoNT or to action of BoNT on enteric nervous system. Note that during wound botulism, the gastrointestinal symptoms are lacking. Several of the cardiovascular reflexes can be abnormal. Loss of vagal cardiac control, hypothermia, and urinary retention pinpoint an action of BoNT upon the parasympathetic system. Hypotension without reflex tachycardia and depressed vasomotor response to postural changes indicate an action upon the sympathetic nervous system. Dysautonomia induced by BoNT can sometimes be the only manifestation of botulism, and likely corresponds to a benign form of the disease associated with very low amounts of toxin. This is consistent with dysautonomic symptoms, as per side effects observed following therapeutic injection of toxin,

[1] BoNT/A-induced paralysis is less marked on juvenile as compared to adults (Bambrick and Gordon, 1989; Ma *et al.*, 2002)

[2] but TeNT blocks spontaneous quantal events in the central nervous system of the rat (Capogna *et al.*, 1997).

[3] No effect at the NMJ from animals having central effects (J. Molgo, unpublished observation).

which correspond to hematogenous dissemination of minute amounts of BoNT from the injection site (Dressler and Benecke, 2003).

The many symptoms of autonomic dysfunction during botulism are consistent with BoNTs acting upon both cholinergic and catecholaminergic neurotransmission. Effects of BoNTs are likely exerted at pre- and post-ganglionic levels, since ganglions are not insulated by the blood-brain barrier. Gastrointestinal troubles observed during foodborne and infant, but not wound, botulism suggest that BoNT can directly (without hematogenous dissemination) affect neurons of the enteric nervous system. This action has promoted BoNT use for treating overactive smooth muscles and sphincters, such as the lower esophageal sphincter for esophageal achalasia, internal anal sphincter for anal fissures, or secretory disorders like drooling and hyperhydrosis (Tscheng, 2002; Brisinda *et al*., 2004; Cordivari *et al*., 2004; Naumann and Jost, 2004).

The second series of manifestations during botulism consists of symmetric weakness or descending paralysis. Observation of this symptom prompts the clinician to diagnose botulism. However, confusion in making a diagnosis as Guillain-Barre or myasthenic syndrome may occur, but botulism is characterized by an absence of sensory symptoms. Flaccid paralysis clearly indicates BoNT effects on the motor system, which initially affects striated muscles innervated by cranial nerves producing ptosis, followed by a depressed gag reflex, dysphagia, dysarthria, facial paralysis, tongue weakness, and several neuro-ophthalmological signs. After these early symptoms, general paralysis extends from proximal, to distal, muscles of the neck and limbs. The deep tendon reflex is strongly depressed. When the diaphragm is attacked, respiration is depressed and the need for mechanical ventilation becomes imperative (Tacket and Rogawski, 1989; Low, 2002).

Overall, the clinical picture of botulism indicates that flaccid neuromuscular paralysis is due to selective inhibition of neurotransmission between α-motoneurons and striated muscle fibers. This paralytic action of the BoNTs is now widely exploited in therapeutics (Brin *et al*., 2002; Turton *et al*., 2002; and Chapter 58 of this volume).

Experiments performed at the NMJ reveal that following application of BoNTs to isolated nerve-muscle preparations, the postsynaptic responses (i.e., endplate potentials resulting from nerve stimulation) have amplitudes insufficient to reach the threshold for an action potential in muscle, thereby causing paralysis (Table 19.2) (Habermann and Dreyer, 1986; Simpson, 1989; Molgo *et al*., 1990; Van der Kloot and Molgó 1994). An approximately 20% decrease in the endplate potential amplitude sufficiently prevents muscle fiber contraction. Asphyxia occurs when fewer than 10% of the diaphragm fibers are paralyzed. The most dramatic form of botulism follows ingestion of ~0.1 to 1 μg BoNT. Therefore, the circulating/extracellular BoNT concentrations causing death (<<0.001 nM) are below those inducing muscle paralysis *in vitro* (~0.01–0.1 nM), and far from those (1–10 nM) required to induce a nearly complete inhibition of ACh release from nerve terminals (Molgo *et al*., 1990; Poulain *et al*., 1996). BoNT also blocks transmission between the γ-motoneurons and the muscle spindle, albeit with different kinetics as compared to the motor endplate (Filippi *et al*., 1993; Rosales *et al*., 1996). This latter action of BoNTs alters the spinal reflexes initiating from the muscle spindle via the sensory Ia fibers.

*In vitro* studies also revealed that BoNTs prevent release of various neurotransmitters other than ACh, such as adrenaline, noradrenaline, dopamine, ATP, glutamate, aspartate, GABA, and neuropeptides like substance P or CGRP (Habermann and Dreyer, 1986; Wellhöner, 1992; Bigalke and Shoer, 2000; Humeau *et al*., 2000; Purkiss *et al*., 2000; Welch *et al*., 2000; Foran *et al*., 2003; Durham *et al*., 2004). To summarize, like TeNT, none of the BoNTs are specific for a given neurotransmitter and thus cannot be considered as only "anti-cholinergic" neurotoxins.

**TABLE 19.2** Steps of neuromuscular transmission altered by botulinum neurotoxins (BoNTs), after local injection

| Steps of neuromuscular transmission | Effect of BoNTs |
|---|---|
| Action potential at nerve endings | Unchanged |
| • $Ca^{2+}$ influx | Unchanged |
| • ACh exocytosis | Inhibited |
| • Responsiveness of postsynaptic AChRs | Enhanced by the increased number of AChRs and changed properties |
| • End Plate Potential (EPP) | Overall, it is diminished* |
| • Muscle action potential | Abolished if subthreshold EPP. Change in the α-subunit of Na channels ($Na_V1.4$ to $Na_V1.5$) |
| Nerve evoked single muscle fiber contraction | Abolished if subthreshold EPP |
| • Nerve evoked muscle twitch | Gradually diminished, but non-linearly correlated with inhibited ACh-release |

*Due to fast muscle fiber atrophy, the membrane impedance (input resistance and capacitance) increases in muscle fibers. During moderate poisoning, this can balance the decrease in ACh release, leading to unchanged EPPs.

### *Do BoNTs directly affect the central nervous system during botulism or after peripheral application?*

Very few cases of botulism associated with pyramidal signs have been reported (Santini *et al.*, 1999). Motoneuron disinhibition after intramuscular injection of Botulinum complex/A, and changes in the reciprocal inhibition after injection of Botulinum complex/A for therapeutic purposes, have been reported. Injection of Botulinum complex/A into cat extraocular muscles changes the discharge patterns of motoneurons innervating both the ipsi- and contra-lateral eye muscles (Moreno-Lopez *et al.*, 1997). Morphological alterations in the synaptic organization surrounding motoneurons (Pastor *et al.*, 1997) and several changes in the motor system (brainstem and cortical levels) have also been reported (Curra *et al.*, 2004). One cannot exclude that these central actions are indirect, resulting from alterations of the sensorimotor integration through a direct action of BoNT on peripheral sensory mechanisms (i.e., the action of BoNT on the cholinergic innervation of the muscle spindle). Several of the brain stem and cortical changes reported after administration of BoNTs to patients are likely indirect (Curra *et al.*, 2004). In opposition to this theory, it is conceivable that BoNTs enter the central nervous system at a few sites where the blood-brain barrier is discontinuous, due to fenestrated capillaries (e.g., the portal vasculature in the hypophysis and pituitary stalk). This may explain some of the autonomic symptoms, since hypothalamic neurons are at a short diffusional distance from the hypophysal portal system. In fact, the main possibility that deserves consideration is transcytosis of BoNT/A throughout the motoneuron, as this does occur for TeNT. Indeed, retroaxonal ascent of $^{125}$I-BoNT/A up to the motoneuron bodies has been well documented (Wellhöner, 1992). Are BoNTs secreted by motoneurons and do these molecules disseminate into the spinal tissue, thus altering synaptic transmission? The BoNTs can alter synaptic transmission in the central nervous system, because their direct administration into the spinal cord or brain (Luvisetto *et al.*, 2003), brain slices, or cultured neurons blocks release of various neurotransmitters (Wellhöner, 1992; Humeau *et al.*, 2000).

### *Characteristics of BoNTs and TeNT blocking action on synaptic transmission in* ex vivo *or* in vitro *experiments*

The main action of BoNTs or TeNT on neurotransmitter release evoked by nerve action potential dramatically reduces the postsynaptic amplitude response to practically nil (Table 19.2) (Habermann and Dreyer, 1986; Simpson, 1989; Molgo *et al.*, 1990; Wellhöner, 1992; Humeau *et al.*, 2000).

Propagation of the nerve action potential at the nerve terminal, and the ensuing $Ca^{2+}$ influx across the presynaptic membrane (Table 19.3), are not significantly altered by BoNTs or TeNT. Overall, postsynaptic cells respond normally to applied neurotransmitter, and no obvious structural abnormalities or degenerative changes have been observed that account for inhibited synaptic transmission. With BoNT/C, a subtle disorganization of active zones has been reported (Stanley *et al.*, 2003). A high dose of TeNT causes retraction of presynaptic inhibitory buttons and postsynaptic spines when the local concentration of TeNT in the central nervous system is high. This is an indirect effect, due to the silencing of postsynaptic neurons after inhibition of both inhibitory and excitatory inputs (Gonzalez-Forero *et al.*, 2004). Therefore, neurotransmission inhibited by TeNT or the BoNTs is attributable to reduced numbers of synaptic vesicles fusing with the plasma membrane following nerve stimuli. However, the BoNTs and TeNT do not inhibit nonvesicular release of compounds like nitric oxide (NO) that diffuse (Morris *et al.*, 2001), or are transported (McMahon et al., 1992), across the plasma membrane.

Spontaneous exocytosis of transmitter, which gives rise to spontaneous miniature responses, is almost completely abolished after exposure to the BoNTs or

[1]J. Molgo, unpublished observation

TeNT (Habermann and Dreyer, 1986; Simpson, 1989; Molgo *et al.*, 1990; Humeau *et al.*, 2000). Moreover, BoNT/A can block quantal transmitter release from certain glial cells like astrocytes (Verderio *et al.*, 1999; Araque *et al.*, 2000; Abdipranoto *et al.*, 2003). The number of synaptic vesicles docked at the presynaptic membrane appears elevated versus untreated terminals. The latter findings pinpoint TeNT and BoNTs action downstream from docking of synaptic vesicles at the active zones, possibly during the fusion process.

Several electrophysiological studies have reported decreased amplitude and an increased time course for the elementary postsynaptic responses (the so-called "quanta") elicited by the exocytosis of a single synaptic vesicle. This change seems more pronounced for BoNT/A than for the other neurotoxins. These effects superpose to the above described toxin actions and appear to have both pre- and post-synaptic origins. Although the synaptic vesicle contents are unchanged because BoNTs and TeNT affect neither the synthesis nor storage of neurotransmitter, it is conceivable that the quantity of ACh delivered after synaptic vesicle fusion is diminished because the time period for opening of the fusion pore is shorter. This possibility is consistent with the notion that neurotransmitter release may implicate transient opening of a fusion pore, as postulated in the "Kiss and Run" model for transmitter release. However, there has been no detectable change in the fusion pore openings of chromaffin cells (Graham *et al.*, 2000). On long-lasting experiments (e.g., *in vivo* poisoning followed by *ex vivo* examination), postsynaptic changes in receptor densities and conductance are also likely. Therefore, small amplitude and slow elementary synaptic responses might be an indirect consequence of the synaptic remodeling produced by the toxins.

The blockage induced by TeNT and BoNT/B, D, and F exhibits several features that make it clearly distinct from that induced by BoNT/A, C, and E, as revealed by *ex vivo* examination of NMJs poisoned *in vivo* (Tables 19.3 and 19.4). This gross distinction correlates with identification of toxin targets (see below). For example, the few synaptic vesicle fusions triggered by BoNT/A, C, or E at nerve terminals remain synchronized, whereas those occurring after TeNT or BoNT/D and F are characterized by a temporal dispersion. Any treatment aimed at increasing the release probability of BoNT/A involves: (i) raising extracellular $Ca^{2+}$; (ii) tetanic-nerve stimulation; and (iii) enhancing phasic $Ca^{2+}$ influx, thus increasing the number of synaptic vesicles that fuse upon arrival of the action potential at the nerve endings, provided that transmitter release is not fully blocked. Under these conditions, a recovery of synaptic responses may occur with amplitudes sufficient to depolarize the membrane over the threshold needed for generating a muscle action potential and twitching. In contrast, at TeNT-, BoNT/B-, D-, or F-poisoned NMJs, these treatments have a very low efficacy (Table 19.4) since the remaining asynchrony of release events prevents build-up of postsynaptic responses large enough to allow transmission recovery (Molgo *et al.*, 1990; Humeau *et al.*, 2000; Szule and Coorssen, 2003).

Similar distinctive actions between the various BoNT serotypes or TeNT were revealed following α-latrotoxin (α-LTX) induction of synaptic vesicle fusion at BoNT- or TeNT-poisoned NMJs (Table 19.4). Indeed, at normal NMJs, black widow spider venom or its major component, α-LTX, induces an asynchronous release of ACh quanta that exhausts the synaptic vesicles contained in the nerve terminals (Van der Kloot and Molgó, 1994; Schiavo *et al.*, 2000). Black widow spider venom or α-LTX also stimulates vesicle fusion at BoNT/A-poisoned nerve terminals that leads to exhaustion of the existing synaptic vesicle pool, whereas this venom/toxin has only moderate action upon BoNT/B- or TeNT-treated NMJs.

## The molecular mechanisms of action for clostridial neurotoxins

### *BoNTs and TeNT specifically cleave VAMP, SNAP-25, or syntaxin in nerve terminals*

The light chain of BoNTs and TeNT inhibits transmitter release via $Zn^{2+}$-dependent, endopeptidase activity, which *in vitro* requires reduction of the disulfide interchain bridge linking the heavy and light chains (Herreros *et al.*, 1999; Schiavo *et al.*, 2000; Turton *et al.*, 2002; Lalli *et al.*, 2003; Simpson, 2004).

Three synaptic proteins have been originally identified in mammalian nerve terminals as the proteolytic targets for clostridial neurotoxins. Namely, these are VAMP-2 (Table 19.5), which is cleaved by TeNT, BoNT/B, D, F and G; SNAP-25 (Table 19.6), which is attacked by BoNT/A, C, and E; as well as syntaxin-1 (Table 19.7), which is exclusively proteolyzed by BoNT/C. As discussed above, these three proteins are the SNAREs involved in synaptic vesicle fusion with the plasma membrane. Experimental findings that demonstrate proteolytic inhibition of neuroexocytosis are discussed later.

Several closely related homologues of the SNAREs are also cleaved by the clostridial neurotoxins (Tables 19.5–7). It is beyond the scope of this chapter to review all the SNAREs cleaved by these toxins. Their susceptibility to cleavage may display marked differences, as compared to proteolysis of the three original SNAREs. Mouse SNAP-23 is cleaved by BoNT/E, but to a reduced extent by BoNT/A. Mouse VAMP-1 (also present in nerve terminals), -2, and -3 are cleaved by TeNT and some BoNTs with similar efficacy. Syntaxins-2 and -3, but not syntaxin-4, are cleaved by BoNT/C. The main reasons for differences in proteolytic susceptibility are point mutations at the cleavage site or flanking regions. Variations in the amino acid sequence of SNAREs have occurred throughout time and subsequently made several animal species resistant, or partially resistant, to subsets of the clostridial neurotoxins (Tables 19.5–7). For example, rat VAMP-1 resists proteolysis by either TeNT or BoNT/B due to point mutations at the cleavage site. Leech SNAP-25 cannot be cleaved by BoNT/A due to a mutation at the dipeptide site attacked by the toxin. Human SNAP-23 can neither be cleaved by BoNT/A nor BoNT/E, and the resistance towards BoNT/E is due to an amino acid exchange within a region flanking the cleavage site. In general, most toxin-insensitive VAMPs are generated by mutations within the cleavage site (Table 19.5), while toxin-resistant isoforms of SNAP-25, or related analogues, result from amino acid substitutions in and around this site (Humeau *et al.*, 2000). Keep in mind that resistance to the BoNTs also results from a lack of receptors on nerve terminals, as demonstrated by the inability of BoNT/D and BoNT/B to alter ACh release at human and frog NMJs, respectively (Coffield *et al.*, 1997; Coffield *et al.*, 1999).

### *How do BoNTs and TeNT recognize specifically the SNAREs*

Selectivity of the clostridial neurotoxins for their substrate reportedly arises from a highly conserved recognition domain, distinct from the cleavage site, that is specific to the SNARE proteins (Rossetto *et al.*, 1994; Schiavo *et al.*, 2000). Furthermore, TeNT exploits a second exosite, adjacent to the cleavage site (Cornille *et al.*, 1997). Changes in the amino acid sequence at the recognition site affect cleavage of SNARE by a toxin. For example, the splice variant SNAP-25a expressed during early development is partially resistant to BoNT/A, but not BoNT/E (Puffer *et al.*, 2001). The amino acid sequence around the cleavage site is identical in both SNAP-25a and b isoforms, but the N-termi-

nal half that contains three of the four recognition sites differs and thus leads to partial proteolytic resistance of SNAP-25a (Puffer *et al.*, 2001).

### *Do ANTPs enhance the proteolytic activity of BoNTs within nerve terminals?*

Unexpectedly, the ANTPs probably play a role in the endopeptidase activity of BoNTs. Thus, type A Botulinum complex is more active (15–17 fold) than pure BoNT/A under reducing or non-reducing conditions *in vitro* and *in vivo* (Cai *et al.*, 1999). Among ANTPs, type A HA35 enhances 21–25 fold the proteolytic cleavage of SNAP-25 by BoNT/A or BoNT/E *in vitro* under non-reducing conditions, and by 13-fold in synaptosomes (Sharma and Singh, 2004). HA35 does not reduce the disulfide interchain bridge, which is not required for activity. HA35 strongly binds to BoNT/A and likely exposes the enzymatic site in an active conformation for substrate without opening the belt formed by Hn. This is consistent with the molten globule structure of BoNT/A. HA35 also binds to synaptotagmins, which are proposed receptors for the BoNTs (see Chapter 20, this volume), and possibly enters synaptosomes in support of subsequent enhancements of intracellular activity for BoNT/A (Sharma and Singh, 2004). This novel possibility has to be carefully considered when toxin complex is injected for therapeutic purposes.

### *Physiology of BoNTs and TeNT access to the SNAREs in living nerve terminals*

With regard to their low $k_{cat}$ and Michaelis constant $K_m$, TeNT, and BoNTs are rather poor enzymes (Li *et al.*, 2000). This is surprising for toxins that are considered the most potent blockers known of synaptic function. At *Aplysia* synapses, the blockage of ACh release by an intracellular concentration of 10 nM of TeNT, BoNT/A, or BoNT/B starts with a delay of only a few (4–10) minutes after the intracellular injection of toxin (Poulain *et al.*, 1996). Considering that the mean diameter of *Aplysia* nerve terminals is around 2.5 μm, the nerve ending volume is about 16 femtoliter, and a 10 nM concentration corresponds to less than 100 L chain molecules per button. This represents very few molecules as compared to the 50–80 $\times$ $10^3$ synaptic vesicles (each decorated with approximately 10 VAMP molecules) and the 400–600 release sites present in each nerve terminal (Humeau *et al.*, 2002). Therefore, the very short delay between the clostridial neurotoxin injection and blockage (Poulain *et al.*, 1996) suggests that the toxin molecules are targeted to key sites where proteolytic action has immediate consequences upon exocytosis.

A mechanism that likely accelerates neurotransmitter inhibition is the prepositioning of L chain near the release site. Indeed, BoNT/A-L chain contains a sequence within the N-terminus that facilitates plasma membrane localization and concentration near the fusion sites (Fernandez-Salas *et al.*, 2004).

A second important factor determining SNARE attack by the different L chains involves the quaternary structure. Since the BoNTs and TeNT bind to their targets via at least two distant sites (i.e., those involved in cleavage and recognition), the accessibility of substrate cleavage into the catalytic cleft in the toxin L chain is dictated by the interaction of SNAREs with partner proteins. Biochemical evidence demonstrates that SNARE proteins are protected from proteolytic attack when bound in a ternary complex (Hayashi *et al.*, 1994). Structural studies reveal masking of cleavage sites and/or recognition motifs within the SNARE complex core (Sutton *et al.*, 1998). Therefore, it is likely that when the four-helix bundle is formed (i.e., when synaptic vesicles are docked at the fusion sites), the clostridial neurotoxins cannot attack their respective SNAREs. When SNAP-25 forms a dimer with syntaxin-1, it is also protected against BoNT/A (Margittai *et al.*, 1999).

On the contrary, certain protein-protein interactions are not protective: SNAP-25 bound to synaptotagmin can be cleaved by either BoNT/A or E (Schiavo *et al.*, 2000). When VAMP forms a dimer or associates with synaptophysin, it also becomes substrate for cleavage (Reisinger *et al.*, 2004). Thus, a possible rule is that when the SNARE domains involved in SNARE-partner interactions do not comprise the recognition motif or cleavage site, the SNARE can be proteolyzed. The physiological relevance of this proposal is indicated by several functional studies. For example, consistent with the notion that Rab3 acts as an upstream regulator of the Rim/Munc-13/Munc-18/syntaxin/SNAP-25 cascade, which regulates transition of SNAREs between open and closed configurations at the release site, intraneuronal application of a Rab3 dominant negative mutant delays blocked release induced by BoNT/A, BoNT/B, and TeNT on *Aplysia* synapses (Johannes *et al.*, 1996). $Ca^{2+}$-calmodulin binds to VAMP, thereby impeding its cleavage by TeNT but not BoNT/B, which uses another recognition site. Indeed, the VAMP domain that binds $Ca^{2+}$-calmodulin is located immediately adjacent to the C-terminal side of the peptide bond cleaved by TeNT (Quetglas *et al.*, 2000; de Haro *et al.*, 2004) and overlaps with the second recognition exosite exploited by TeNT (Cornille *et al.*, 1997). Obviously, this provides a rationale for the observation that VAMP cleavage by TeNT, but not BoNT/B, is nerve terminal-activity dependent (Hua and Charlton, 1999). In the same line, several experimental findings suggest that other environmental conditions modify cleavage accessibility of the SNAREs. For example, the blockage kinetics of intracellularly applied BoNT/B or TeNT, but not BoNT/A, are strongly temperature dependent (Poulain *et al.*, 1996). Interactions of the SNAREs with the lipid environment likely condition their folding and modify their accessibility for cleavage. Indeed, the proteolytic activity of BoNT/A-L chain is higher when SNAP-25 is inserted into membranes or liposomes containing negatively charged phospholipids versus soluble forms of SNAP-25. Possibly, the membrane conformation of SNAP-25 is better recognized by the toxin, or phospholipids facilitate an electrostatic toxin-substrate interaction (Caccin *et al.*, 2003). A similar role for a lipid environment has also been suggested for the cleavage of VAMP by TeNT (de Haro *et al.*, 2004). Altogether, these biochemical and functional observations indicate that the recognition domains and cleavage sites of the various SNAREs are sequestered under the same physiological circumstances. In other words, toxins likely access their substrate only during defined "physiological windows" (Figure 19.5, top panel), which do not necessarily coincide for all toxins. The open configurations of the SNAREs are acquired mainly during the late exocytotic events. Therefore, we speculate that the "windows" during which the toxins have easy access to their targets are open when synaptic vesicles tether and dock at the active zones, which is also when the SNAREs dissociate from their

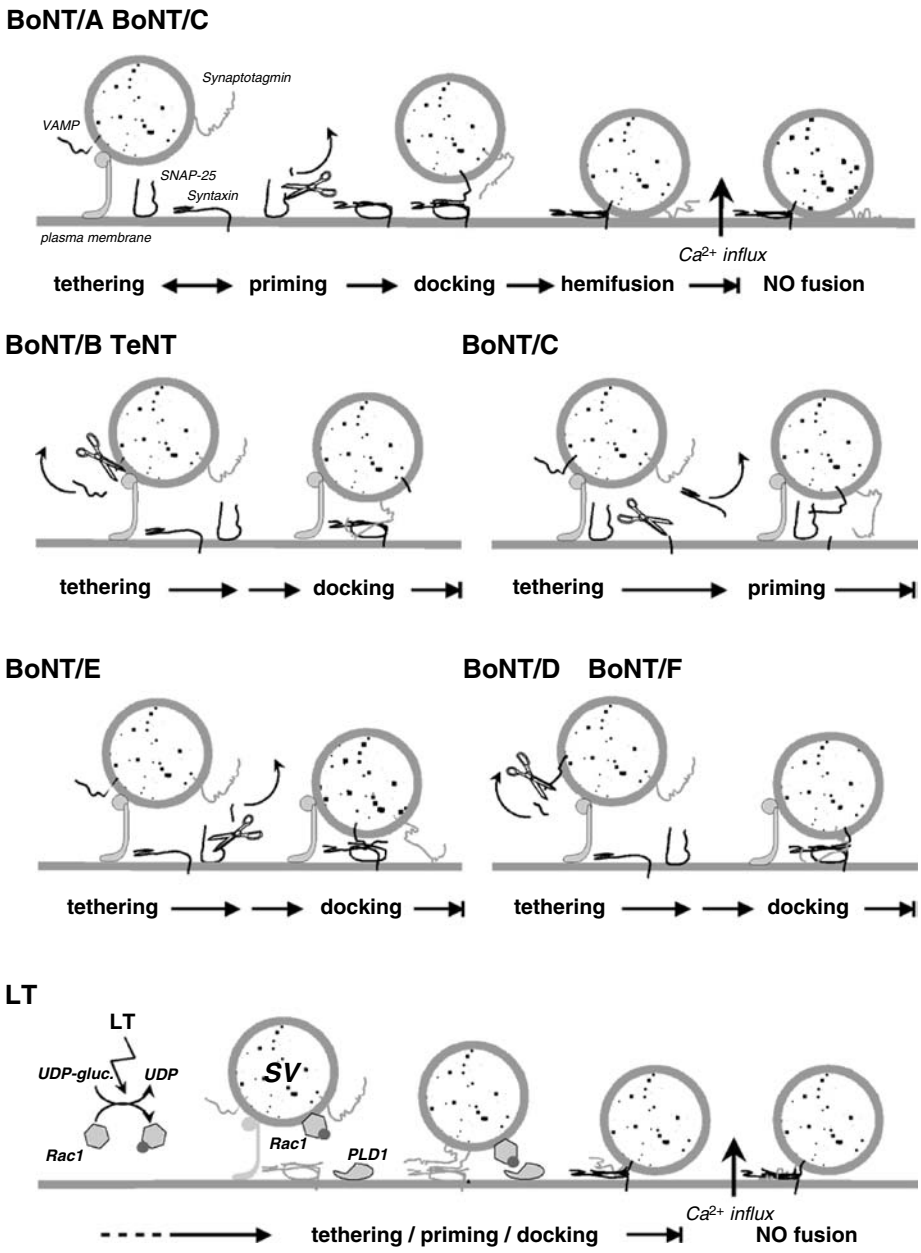

**FIGURE 19.5** Models for the inhibitory action of BoNTs, TeNT, and LT on exocytosis. During the priming events that precede assembly of the SNAREs into a complex, an open configuration is adopted by the SNAREs (VAMP, SNAP-25, or syntaxin). This defines a "physiological window" during which TeNT or the various BoNTs have free access to the respective cleavage site. A commonality of all the BoNTs and TeNT is that the peptide released into the cytosol, following target proteolysis, is likely to diffuse from the exocytosis sites (as denoted by a curved arrow). Therefore, assembly of intact and truncated SNARE into complex may be impossible (BoNT/C acting on syntaxin, BoNT/B, TeNT), altered (BoNT/E, BoNT/D, BoNT/F), or complete (BoNT/A, BoNT/C acting on SNAP-25). Therefore, only a limited number of steps can occur during the sequence of events that lead to membrane fusion (compare with Fig.19. 1). In all cases, the process stops before fusion.

The action of LT is quite different, while converging upon disruption of the fusion step. Glucosylated, vesicle-bound Rac cannot stimulate PLD and ensuing production of fusogenic phospatidic acid, which is necessary for membrane fusion (compare with Fig.19. 2).

chaperones and have not yet assembled into the fusogenic SNARE complex.

To summarize, prepositioning of toxin L chains near the release site enables toxin attack upon their protein targets during the defined "physiological window," which mainly corresponds to the molecular events preceding exocytosis by a few seconds. Thus, the toxins likely affect the small pool of synaptic vesicles undergoing exocytosis, leading to immediate physiological consequences. This probably amplifies toxin efficacy and provides a rational explanation for the paradox that TeNT and BoNTs are poor enzymes, yet they quite effectively block synaptic function.

### *Relationship between SNARE cleavage and blockade of neurotransmitter release*

*Blockade induced by SNAP-25 cleavage*

The clear-cut demonstration that cleavage of SNAP-25 blocks BoNT/A action was first provided by elegant studies with the leech synapse. Indeed, leech SNAP-25 cannot be cleaved by BoNT/A, and accordingly cultured Retzius cells are resistant to BoNT/A. However, the sensitivity of serotonin release to BoNT/A action

could be conferred by replacing amino acids 196–209 of leech SNAP-25 with those from the rat protein (Bruns *et al.*, 1997). A further, albeit indirect, demonstration of the causal link between SNAP-25 cleavage and exocytosis blockade was obtained with insulin secreting cells. Human SNAP-23 can replace SNAP-25 in SNARE complexes, and due to BoNT/A resistance, overexpression rescues insulin secretion after blockade by BoNT/A (Sadoul *et al.*, 1997), although SNAP-23 is less efficient than SNAP-25 in mediating secretion (Sorensen *et al.*, 2003). In cultured rat hippocampal neurons intoxicated with BoNT/A or BoNT/E, only glutamatergic synapses are blocked, whereas GABAergic synapses show exo-/endo-cytotic activity. This correlates with different expression levels of SNAP-25. Relative to glutamatergic neurons that express SNAP-25, GABAergic neurons lack SNAP-25. Possibly, SNAP-25 is replaced by SNAP-23 or other unidentified homologues of BoNT-insensitive SNAP (Verderio *et al.*, 2004). Expression in chromaffin cells of mutated SNAP-25 lacking the last nine amino acids reduces secretion to a similar extent as BoNT/A (Wei *et al.*, 2000). Expression of mutated SNAP-25 not cleaved by BoNT/A allows full recovery of secretory activity (O'Sullivan *et al.*, 1999). SNAP-25 immunoreactivity decreases when synaptic inhibition occurs at both central synapses and at the NMJs, albeit this correlation is not strict (Capogna *et al.*, 1997; Kalandakanond and Coffield, 2001a; Kalandakanond and Coffield, 2001b; Keller and Neale, 2001). Several findings are still puzzling; although *Torpedo* SNAP-25 is not cleaved by BoNT/A *in vitro* (Washbourne *et al.*, 1997), this toxin abolishes ACh release from the *Torpedo* electric organ.

After SNAP-25 proteolysis by BoNT/A, transition of the ternary SNARE complex in a SDS-resistant state still occurs (Hayashi *et al.*, 1994) (Figure 19.5); therefore, BoNT/A (or BoNT/C) is unlikely to abolish irreversibly the fusion process *per se*. The C-terminal domain of SNAP-25, which contributes one helix to the four-helix bundle, has been implicated in the final step of $Ca^{2+}$-dependent exocytosis (Chen *et al.*, 1999). Truncation of SNAP-25 by BoNT/A or BoNT/E alters both SNAP-25 and $Ca^{2+}$ binding to synaptotagmin (Gerona *et al.*, 2000; Tucker *et al.*, 2004). Thus, a likely model for the blocking action of BoNT/A (and partially for BoNT/C) is that removal of the nine C-terminal amino acids of SNAP-25 deeply disrupts the coupling between $Ca^{2+}$ sensing and the final step in exocytosis (Figure 19.5, top panel). Overall, this is consistent with the observation that any treatment aimed at increasing $Ca^{2+}$-influx forces the blocked step and rescues synaptic transmission at BoNT/A-treated synapses (Table 19.4), albeit this latter action may also refer to interactions between the SNAREs and other $Ca^{2+}$-dependent partners of the secretion machinery (Quetglas *et al.*, 2000; Zhang *et al.*, 2002). Another possibility has to be considered: SNAP-25 cleaved by BoNT/A (or BoNT/C) maintains its association with syntaxin (Bajohrs *et al.*, 2004), possibly slowing the docking (i.e., formation of the heterotrimeric fusion complex comprised of SNAP-25, syntaxin, and VAMP) or favoring a complex composed of a second syntaxin molecule leading to a stable four-helix complex obstructing the binding site for VAMP (Fasshauer and Margittai, 2004). Therefore, truncated SNAP-25 can behave as a dominant negative mutant upon the exocytotic process. This additional consequence of SNAP-25 cleavage is fully consistent with: (i) blocking release due to both functional elimination of SNAP-25 and accumulating cleavage product that competitively inhibits exocytosis (Keller and Neale, 2001); and (ii) BoNT/A slows down a secretory step before fusion *per se*, and before the step affected by BoNT/E (Xu *et al.*, 1998).

The mechanisms by which BoNT/E blocks secretion are quite different from those of BoNT/A. Truncation of SNAP-25 by BoNT/E destabilizes the four-helix bundle of the SNARE complex. This is not enough to explain the inhibitory action of BoNT/E because discontinuous SNAP-25 mediates fusion (Chen *et al.*, 1999; Chen *et al.*, 2001). Two other factors have to be taken into account. First, SNAP-25 truncated by BoNT/E is not retained by syntaxin (Bajohrs *et al.*, 2004) and is rapidly eliminated. Second, inhibition of exocytosis by BoNT/E can be rescued by supplementing the C-terminal portion of SNAP-25 removed by the toxin (Chen *et al.*, 1999; Chen *et al.*, 2001; Schuette *et al.*, 2004). Therefore, this means that the C-terminal 26mer released upon proteolysis of SNAP-25 by BoNT/E is lacking at the release sites. In fact, it is likely to diffuse far away from the active zone because of its diffusional sinking in the very large axon volume. This also suggests that although expression of this fragment inhibits exocytosis, possibly because it destabilizes or prevents formation of the four-helical fusogenic bundle (Ferrer-Montiel *et al.*, 1998), it is unlikely that the C-terminal 26mer contributes significantly to the BoNT/E-induced inhibitory action. Thus, blockade of exocytosis by BoNT/E is only due to cleavage of SNAP-25, not the production of competitive antagonists of SNARE complex formation, as discussed above for BoNT/A. This also agrees with the findings that treatments enhancing the release probability have a low efficacy for restoring muscle contraction at BoNT/E-poisoned motor-nerve terminals (Table 19.4). Thus, blockade of exocytosis by BoNT/E is only due to elimination of functional SNAP-25 and not due to production of competitive antagonists of SNARE complex formation, as discussed above for BoNT/A. This also agrees with

findings that treatments for enhancing the release probability are minimally efficacious for restoring muscle contraction at BoNT-E-poisoned motor-nerve terminals (Table 19.4).

*Blockade induced by VAMP cleavage*

The causal relationship between proteolysis of VAMP by TeNT, BoNT/B, D, or F, and preventing exocytosis was first deduced from observations that: (i) peptides encompassing the VAMP cleavage site for TeNT, or BoNT/B, can compete with VAMP and diminish the inhibitory action of these neurotoxins; and (ii) presynaptic injection of VAMP-specific antibodies into *Aplysia* cholinergic neurons prevents specifically the blocking action of TeNT or BoNT/B, but not that of BoNT/A, which cleaves SNAP-25. Furthermore, transfection of insulin-secreting cells with mutated VAMP not cleaved by TeNT allows partial restoration of secretory properties (Humeau *et al.*, 2000; Schiavo *et al.*, 2000). In addition, immunocytochemical studies with rat hippocampus (Capogna *et al.*, 1997), as well as frog (Raciborska *et al.*, 1998), crayfish (Hua and Scheller, 2001), and mouse (Kalandakanond and Coffield, 2001b; Whelchel *et al.*, 2004) NMJs reveal that blocked neurotransmitter release correlates well with diminished VAMP immunoreactivity. This correlation is far less clear in catecholaminergic synaptosomes in which almost complete inhibition of evoked release was observed with partially proteolyzed VAMP. The fact that BoNT cleaves VAMP at distinct sites has pertinent physiological correlates. Thus, at mouse motor terminals, both VAMP-1 and -2 can be cleaved by TeNT, or BoNT/B, and there is a significant decrease in spontaneous quantal release (Table 19.1). In contrast, rat VAMP-2 but not VAMP-1 are cleaved by TeNT and BoNT/B (Table 19.5) with a concomitant small decrease in spontaneous quantal release at the NMJ treated with TeNT, despite a clear decrease in rat hippocampal synapses (Capogna *et al.*, 1997; Humeau *et al.*, 2000). BoNT/D and BoNT/F cleave both VAMP-1 and -2 rat isoforms, as well as strongly diminish spontaneous quantal release at rat motor nerve endings. At the crayfish motor synapses, BoNT/D significantly reduces the frequency of spontaneous quantal events unlike BoNT/B- and TeNT-L chains, which share the same cleavage site (Hua *et al.*, 1998).

How does VAMP cleavage inhibit secretion? *In vitro* studies indicate that cleavage of VAMP-2 by TeNT, BoNT/B, D, F, or G does not completely prevent assembly of VAMP-2, SNAP-25, and syntaxin into ternary SNARE complexes, but noticeably fewer complexes are formed following TeNT and BoNT/B treatment (Yersin *et al.*, 2003). Two possible scenarios can account for blocked exocytosis induced by these toxins. First, when VAMP is cleaved by TeNT, BoNT/B, or BoNT/G, the VAMP portion (~20 amino acids) remaining in the synaptic vesicle membrane does not contain interaction sites for the other SNAREs. Therefore, the synaptic vesicle membrane is no longer linked to a SNARE complex, and fusion with the plasma membrane cannot occur. Second, when VAMP is cleaved by BoNT/D or F, the C-terminal fragment remaining in the vesicle membrane is long enough to anchor the synaptic vesicle to the SNARE complex, but fusion cannot occur because the thermally stable, four-helix bundle cannot be formed. Hence, despite the appearance of docked synaptic vesicles, treatments that increase neurotransmitter release remain unsuccessful in reversing toxin action (Table 19.4). An additional component during the blockade is a VAMP cytoplasmic fragment released upon proteolysis by TeNT or BoNT/B (Cornille *et al.*, 1995; Tucker *et al.*, 2004). Possibly, this fragment competes with intact VAMP and prevents pairing of the SNAREs during complex formation and vesicle docking.

How can one explain the asynchronous release observed after treatment with TeNT, BoNT/B, and BoNT/D? Several recent studies suggest that fusion of the synaptic vesicle with the plasma membrane requires several (possibly three?) SNARE complexes (Poirier *et al.*, 1998; Hua and Scheller, 2001). Our speculation is that the few desynchronized exocytotic events, which occur when the release probability is increased at TeNT-, BoNT/B-, BoNT/D-treated NMJs, might represent a small fraction of synaptic vesicles that are docked to the release site by both functional and disabled SNARE complexes. In this regard, some of the docked vesicles observed after VAMP-cleavage might correspond to synaptic vesicles anchored to the plasma membrane by an incomplete set of SNARE complexes, as well as to vesicles tethered to the plasma membrane by other proteins like Rab3 bound to Rim, and synaptotagmin bound to the plasma membrane or $Ca^{2+}$-channels.

*Blockade induced by syntaxin cleavage*

BoNT/C cleaves both syntaxin-1 and SNAP-25; therefore, determining which of these two targets is cleaved during BoNT/C-induced blockade is an important issue for understanding BoNT/C mechanisms of action. *In vitro* cleavage of SNAP-25 by BoNT/C occurs with low efficiency (~1000-fold difference) versus cleavage by BoNT/A or E (Humeau *et al.*, 2000; Schiavo *et al.*, 2000). Immunocytochemical studies with frog and mammalian NMJs show that immunoreactivity of the SNAP-25 C-terminus (removed following BoNT/A, C, or E action) remains nearly intact when syntaxin immunoreactivity is

greatly decreased (Raciborska *et al*., 1998; Kalandakanond and Coffield, 2001b). However, in cultured hippocampal slices or spinal neurons, BoNT/C is very efficient at removing nearly all SNAP-25 immunoreactivity (Capogna *et al*., 1997). A clear-cut demonstration of the causal relationship between syntaxin cleavage and blockade of neurotransmitter exocytosis has been obtained with the giant squid synapse. BoNT/C cleavage of squid syntaxin-1, but not squid SNAP-25 (O'Connor *et al*., 1997), completely inhibits transmitter release. Additionally, the secretory blockade in chromaffin cells by BoNT/C is very distinct from that produced by BoNT/A (Xu *et al*., 1998). Furthermore, the action of BoNT/C is very similar to the blockade of both evoked and spontaneous quantal transmitter release that characterizes *Drosophila* mutants lacking syntaxin. Thus, depending on the cell type, the secretory blockade is likely due to syntaxin and/or SNAP-25 cleavage.

A possible molecular model for BoNT/C-induced inhibition of exocytosis involves SNARE complex formation that despite a tight, SDS-resistant, four-helix bundle, facilitates loose docking, but not fusion, of the synaptic vesicle to the plasma membrane. The vesicles remain tethered to the plasma membrane via SNAP-25 and other proteins (Rab3/Rim, synatotagmin, etc.). This is consistent with altered scaffold ribs at the release site of NMJs poisoned with BoNT/C, but not BoNT/A (Stanley *et al*., 2003). The blocked exocytosis evident after BoNT/C cleavage of SNAP-25 is similar to that produced by BoNT/A (see above).

*Common consequences of SNARE cleavage on exocytosis*

Despite the scenario that blocking actions by various BoNTs and TeNT differ at the molecular level, they all share several commonalities. Indeed, in all cases following toxin action, the SNARE complex is no longer fusogenic. Thus, synaptic vesicles remaining docked at the fusion site with slightly increased numbers suggest that when tethered to the plasma membrane or docked in an unproductive complex, not only exocytosis but also undocking cannot proceed. Therefore, it is likely that synaptic vesicles docked with unproductive complexes can irreversibly plug the fusion sites that would normally accommodate intact vesicles. Obviously, this should amplify toxin effects and may also explain why there is some discrepancy between the amount of SNARE cleaved and the extent of blocked transmitter release (Kalandakanond and Coffield, 2001a).

### *Other cell consequences of SNARE cleavage*

*Alteration of the vesicle cycle beyond fusion*

Each step of the synaptic vesicle cycle involving SNAREs may be affected by toxin. For example, VAMP cleavage abolishes its interaction with the adaptator protein AP3, and affects synaptic vesicle recycling via early endosomes (Salem *et al*., 1998). Although interaction of synaptophysin-1 with VAMP-1 is controversial, a report that the cytosolic cleavage product of VAMP-2, but not VAMP-1, released upon TeNT or BoNT/B activity blocks neurotransmitter release (Cornille *et al*., 1995) may refer not to an alteration of the SNARE complex function, but to a disturbance in the synaptophysin-1/VAMP-2 interaction.

*Alteration of $Ca^{2+}$- and $K^{+}$-channel functions*

Different voltage-gated $Ca^{2+}$-channels (N-, P/Q-, R-, and L-types) are involved in neurotransmitter and hormone release by neurons, as well as excitable neuroendocrine and endocrine cells. In addition, store-mediated $Ca^{2+}$ entry allows $Ca^{2+}$ influx in nonexcitable cells (Augustine, 2001; Rettig and Neher, 2002; Petersen, 2003). Syntaxin promotes inactivation of N-, P/Q-, R-, or L-type $Ca^{2+}$ channels, and this inactivation is removed when proteins of the fusion complex (i.e., SNAP-25, VAMP, synaptotagmin, etc.) bind to syntaxin and/or $Ca^{2+}$ channels (Wiser *et al*., 1999; Degtiar *et al*., 2000; Stanley *et al*., 2003; Cohen and Atlas, 2004). In this line, SNAP-25 controls $Ca^{2+}$ responsiveness to depolarization (Verderio *et al*., 2004). These findings support the hypothesis that t-SNAREs not only play a key role in exocytosis, but also control $Ca^{2+}$ dynamics. Possibly, docking of synaptic vesicles to the fusion site (i.e., formation time of the ternary SNARE complex) reactivates $Ca^{2+}$ channels, thereby making possible $Ca^{2+}$ influx only at the sites occupied with readily releasable synaptic vesicles (Atlas, 2001).

The syntaxin domain (synprint) interacting with the $\alpha$-subunit from a $Ca^{2+}$ channel is very close to the site cleaved by BoNT/C. The question is whether cleavage of syntaxin by BoNT/C, or cleavage of other SNAREs by other BoNTs or TeNT, might inhibit $Ca^{2+}$ influx and thereby contribute to the toxin-induced blockage of exocytosis. Cleavage of syntaxin by BoNT/C abolishes the regulation of $Ca^{2+}$ channels by heterotrimeric G-protein (Stanley and Mirotznik, 1997). However, despite a complete block of neurotransmitter release by BoNT/C in isolated mammalian nerve terminals, no clear alteration of evoked fast $Ca^{2+}$ entry was detected, while slow $Ca^{2+}$ influx was potentiated (Bergsman and Tsien, 2000). In contrast, $Ca^{2+}$ entry was significantly decreased by BoNT/C in *Torpedo* preparations (Aleu *et al*., 2002). Cleavage of VAMP or SNAP-25 with the other BoNTs failed to produce a significant change in $Ca^{2+}$ influx (Bergsman and Tsien, 2000; Aleu *et al*., 2002), thus confirming previous results obtained at motor nerve terminals of the NMJs (Molgo *et al*., 1989). Overall, these findings suggest that alterations in $Ca^{2+}$

influx at exocytotic sites are unlikely to significantly inhibit neurotransmitter release from neurons.

However, this is not the case for secretion from other cell types. Indeed, SNAP-25 modulates L-type channels (Ji *et al*., 2002) and entry of $Ca^{2+}$ mediated by store-operated channels in pancreatic acini that secrete amylase, or human platelets. In these cells, $Ca^{2+}$ influx is strongly depressed after SNAP-25 cleavage, possibly blocking $Ca^{2+}$-dependent exocytosis by BoNT/A (Rosado *et al*., 2005). Because of a very high concentration of toxin (~100 nM), this effect is unlikely to have any pathophysiological relevance for botulism.

With the same thoughts as presented above, physical as well as functional interactions between syntaxin-1A and voltage-gated, $K^+$-channels (Kv1.1 type) of the brain have been discovered recently (Fili *et al*., 2001). Activity of the Kv2.1 channel, a prevalent delayed rectifier channel in endocrine and neuroendocrine cells, is also strongly modulated by syntaxin and SNAP-25 (Michaelevski *et al*., 2003; Tsuk *et al*., 2004). Regulation of $K^+$ channels by SNARE proteins may play a role in membrane excitability and exocytosis. This raises the question of whether exocytosis may be altered by BoNTs via changes in activation of Kv2.1 currents.

## Putative, non-proteolytic molecular actions of BoNTs and TeNT

Several controversial observations support the idea that additional mechanisms may contribute to the neuroinhibitory action of BoNTs and TeNT. Indeed, intracellular application of TeNT mutants devoid of proteolytic activity *in vitro* into intact neurons induces substantial blockade of neurotransmitter release (Ashton *et al*., 1995). Tissue transglutaminase type II is reportedly activated (non-proteolytically) by TeNT, affecting neurotransmitter release via the synapsins (Humeau *et al*., 2000). Another unexpected effect of TeNT is modification of the actin cytoskeleton, which involves inhibited rearrangements of subcortical microfilaments that accompany secretion in chromaffin cells (Marxen and Bigalke, 1991). This is consistent with TeNT-induced alteration of the actin cytoskeleton when TeNT light chain is expressed in murine Sertoli cells (Eisel *et al*., 1993). TeNT also affects the depolarization-stimulated phosphorylation and redistribution of synapsin I (Presek *et al*., 1992). However, this may refer both to changes in the actin cytoskeleton organization and activation of tissue transglutaminase type II by TeNT. Furthermore, DasGupta and Tepp (1993) published the *in vitro* observation that BoNT/E light chain cleaves actin at every potential site (n=11) involving Arg or Lys residues in the *P*′1 position, exactly as that found in SNAP-25. In line with the mentioned cytoskeletal alterations, and consistent with the well documented implication of small GTPases like Rho in the dynamics and organization of actin-based cytoskeletons (Hall, 1998), BoNT/A reportedly targets RhoB to the proteasome, causing both blockade of exocytosis and actin cytoskeleton disorganization (Ishida *et al*., 2004). This possibly reflects a cross talk between remodeling of the actin cytoskeleton and SNARE-/Rho-GTPase-dependent mechanisms of exocytosis, as recently illustrated for Cdc42 and VAMP-2 during insulin secretion (Nevins and Thurmond, 2005).

The intracellular action of TeNT is also associated with changes in synaptic phosphoinositide levels and/or protein kinase C activity (Humeau *et al*., 2000). This action of TeNT involves the binding domain, because the C-terminal fragment of TeNT heavy chain activates protein kinase signaling pathways in cultured cortical neurons (Gil *et al*., 2003; Chaib-Oukadour *et al*., 2004). Possibly, the unexpected inhibition of $Na^+$-dependent uptake of 5-hydroxy trytamine (5HT) induced by the C-terminal half of TeNT heavy chain (Inserte *et al*., 1999; Najib *et al*., 1999) is linked to these pathways. This suggests that the acceptor for TeNT is coupled to a tyrosine kinase, receptor-dependent pathway.

## Long-term effects of BoNTs

### *BoNTs trigger sprouting of motor neurons and differentiation of new endplates*

A local injection of BoNT into adult skeletal muscles of animals and humans blocks quantal ACh release, resulting in flaccid muscle paralysis namely restricted to the injection site. Although a marked atrophy of skeletal muscle occurs during paralysis, there is no evident damage of motor nerve terminals. The duration of neuromuscular blockade (Table 19.8) depends upon: (i) BoNT serotype; (ii) dose of BoNT; and (iii) animal species. In general, higher doses are needed to paralyze amphibian, versus mammalian, skeletal muscles (Poulain *et al*., 2000). An attractive feature of using BoNTs is that the neuromuscular blockade in any animal species is not permanent, as recovery of neuromuscular transmission returns within a few weeks to months.

In mammals, muscle paralysis following a single injection of BoNT/A elicits within 3–5 days a nerve outgrowth or sprouting that occurs along intramuscular axons at the nodes of Ranvier (nodal sprouting) and at motor nerve terminals of the NMJs (terminal sprouting). Nodal sprouts are more metabolically costly to the motoneuron than are terminal sprouts, which predominate in mature muscles treated with BoNT/A. Nerve terminal sprouting is also produced by other agents

**TABLE 19.8** Duration of skeletal muscle paralysis induced by various BoNTs in humans and rodents

| | BoNT/A | BoNT/B | BoNT/C | BoNT/E | BoNT/F |
|---|---|---|---|---|---|
| Human* | 4–6 months | 2–3 months | 4–5 months | 4–6 weeks | 2 months |
| Rodents** | 21–30 days | 7–10 days | 21–30 days | 3–5 days | 7–10 days |

*Human values were obtained in different skeletal muscles after a single BoNT local injection.
**Data were obtained by either monitoring *in vivo* the recovery of nerve-evoked muscle contraction via the digit abduction score assay, or *ex vivo* via intracellular electrophysiological recordings.

that render the muscle inactive via prolonged blockade of either nerve conduction or muscle nAChRs. Interestingly, restoration of muscle activity by direct stimulation prevents nerve sprouting induced by BoNT/A (Brown *et al*., 1981).

Sprouting is greater in younger animals, generally increases with time after BoNT injection, and depends upon the contractile properties of the muscle as defined by its innervation pattern. Thus, sprouting is more prominent in slow (e. g., *soleus*), than in fast (e. g., *extensor digitorum longus*), contracting muscles. In addition, sprouting is more abundant in muscles innervated by short axons (Meunier *et al*., 2002). Nerve terminal sprouts evoked by BoNT/A in mouse *levator auris longus* muscle appear as thin, unmyelinated filaments usually oriented parallel to the longitudinal axis of the muscle extending beyond the original nerve terminal (Angaut-Petit *et al*., 1990; Molgo *et al*., 1990; de Paiva *et al*., 1999). After a BoNT/A injection, the sprouts usually increase in length as well as complexity for about 40–50 days and continue to grow for 30–40 days, despite the recovery of nerve-evoked muscle twitches (Juzans *et al*., 1996a), as confirmed by time-lapse imaging of the same mouse NMJ (de Paiva *et al*., 1999). The persistence of nerve terminal sprouts has also been reported in the human orbicularis muscle after repeated injections of BoNT/A (Holds *et al*., 1990). Nerve terminal sprouting was also detected in mouse *levator auris longus* muscle injected with BoNT/D (Comella *et al*., 1993) and BoNT/C (Molgo *et al*., unpublished), as well as in mouse sternomastoid muscle injected with BoNT/F (Meunier *et al*., 2003). Interestingly, no sprouts were visible in the mouse sternomastoid muscle following BoNT/E injection (Meunier *et al*., 2003), which is probably due to short-lived muscle inactivity since recovery from paralysis starts within 2–3 days after neurotoxin administration.

In BoNT/A-paralyzed muscles, the glial component of the NMJ (i. e., the perisynaptic Schwann cell also known as the *terminal Schwann cell* that covers nerve terminal arborizations) plays an important role by inducing and guiding sprouts along muscle fibers. Schwann cells extend processes into every nerve terminal sprout. In some cases, these processes appear even longer than the sprouts growing beside them (Son and Thompson, 1995). The perisynaptic Schwann cells sense synaptic activity at the NMJ and regulate expression of certain genes. Thus, blockade of transmitter relaese from motor nerve terminals is known to evoke gene expression for the glial fibrillary acidic protein (GFAP) (Georgiou *et al*., 1994). This protein may be important in extending perisynaptic Schwann cell processes. Schwann cells produce various neurotropic factors and also synthesize cell adhesion molecules, such as N-CAM, Ng-CAM/L1, N-cadherin, and L2/HNK-1, which form basement membranes containing many extracellular matrix proteins like laminin, fibronectin, and tenascin. The CGRP neuropeptide reportedly stimulates Schwann cell proliferation by increasing cyclic adenosine monophosphate (cAMP) levels (see below) that regulate mitogenic factors (Cheng *et al*., 1995). Apart from a presynaptic role in guiding sprouts triggered by BoNTs, perisynaptic Schwann cells may also play a postsynaptic role by expressing active agrin isoforms that enhance aggregation of nAChRs on muscles (Yang *et al*., 2001).

Electrophysiological focal recordings in the original nerve terminal and along newly formed terminal sprouts provide evidence that sprouts are endowed with voltage-dependent $Na^+$ channels, allowing an active propagation of action potentials throughout their length. Additionally, the presence of voltage-dependent $Ca^{2+}$ channels and $Ca^{2+}$-dependent, $K^+$ channels in the sprout membrane has been reported (Angaut-Petit *et al*., 1990). At mature NMJs, P/Q type voltage-dependent $Ca^{2+}$ channels are coupled to the evoked release process (Van der Kloot and Molgó, 1994). However, blockers of L- and N-type $Ca^{2+}$ channels can reduce nerve-evoked neurotransmitter release during the first four weeks following an injection of BoNT/A (Santafe *et al*., 2000). This time period is characterized by an abundance of nerve terminal sprouts. Interestingly, a transient involvement of both L- and N-type $Ca^{2+}$ channels coupled to neurotransmitter release has also been reported in motor nerve terminals of new-born mammals (Rosato Siri and Uchitel, 1999).

Thus, it is likely that the transient expression of different $Ca^{2+}$ channels may be necessary for activating regulatory pathways during synaptogenesis induced by BoNTs. Thereafter, and upon functional recovery of neuromuscular transmission in BoNT/A-treated muscles, only P/Q-type $Ca^{2+}$ channel blockers affect evoked neurotransmitter release.

During the growth and maturation of BoNT/A-induced sprouts, there is a sequential appearance of intrinsic cytoskeletal axonal components like neurofilaments and tubulin that can be visualized using immunocytochemical staining (Alderson *et al*., 1989). In addition, after about two weeks post-injection of BoNTs, synaptic proteins like synaptophysin, synaptotagmin-II (Juzans *et al*., 1996a; Juzans *et al*., 1996b), VAMP, and SNAP-25 (de Paiva *et al*., 1999; Meunier *et al*., 2003) accumulate in sprouts at synaptic contact points with muscle fibers and growth cones. In addition, clustering of postsynaptic nicotinic ACh receptors (nAChRs) with the growing sprouts can also be visualized with rhodamine-labeled α-bungarotoxin.

During BoNT/A-induced synaptic remodeling, there is a large increase in immunoreactivity for CGRP (Hassan *et al*., 1994; Sala *et al*., 1995; Meunier *et al*., 2002). CGRP is synthesized by motoneurons and transported to motor nerve terminals where it is stored in large, dense-core vesicles that are released upon stimulation (Van der Kloot and Molgó, 1994). An increase in CGRP observed during nerve terminal outgrowth can only partially account for the accumulation of vesicles containing CGRP in the original nerve terminus and sprouts (Meunier *et al*., 2002). Such remarkable CGRP accumulation in BoNT/A-treated nerve terminals results probably not only from inhibition of CGRP release by the neurotoxin, as recently shown in primary cultures of rat trigeminal neurons (Durham *et al*., 2004), but also from upregulated synthesis in motoneuron's somata (Sala *et al*., 1995; Tarabal *et al*., 1996).

*In vivo* (Buffelli *et al*., 2001) and tissue-culture studies (New and Mudge, 1986; Fontaine *et al*., 1987) have consistently shown that CGRP increases nAChR mRNA and protein expression, with a subsequent increase in nAChR molecules on muscle cell fibers. This appears mediated by increased levels of intracellular cAMP with a concomitant activation of protein kinase A (PKA). Therefore, it can be hypothesized that the release of CGRP from nerve terminal sprouts may provide a localized signal to stimulate nAChR gene expression by subsynaptic nuclei, thus resulting in a localized nAChR synthesis along the sprouts. However, given the redundant factors involved in nAChR accumulation, further experiments are needed before finally concluding that CGRP is an endogenous factor by which motoneurons regulate expression of junctional nAChRs along the sprouts. Interestingly, recent studies indicate that CGRP also regulates and maintains acetylcholinesterase expression during the development of NMJs (Rossi *et al*., 2003). Available evidence indicates that nerve terminal sprouts and the muscle fiber possess the molecular machinery for ACh release and its detection, supporting the view that terminal sprouts play a role in recovering neuromuscular transmission following BoNT/A treatment. Figure 19.6 shows a typical example of the electrophysiological characteristics during blockade of neuromuscular transmission, and its recovery, following the action of BoNT/A.

Progression of events leading to the maturation of newly-formed sprouts, development of the first nerve-muscle contacts, and differentiation of new endplates after BoNT exposure is a remarkable demonstration of synaptic plasticity in mature NMJs. Throughout this period, important communications occur that involve multiple stages and signaling molecules between synaptic partners like the perisynaptic Schwann cells, nerve terminal, nodal sprouts, and muscle fibers. Paralysis results in up-regulation of cell surface and basal lamina components that promote axonal

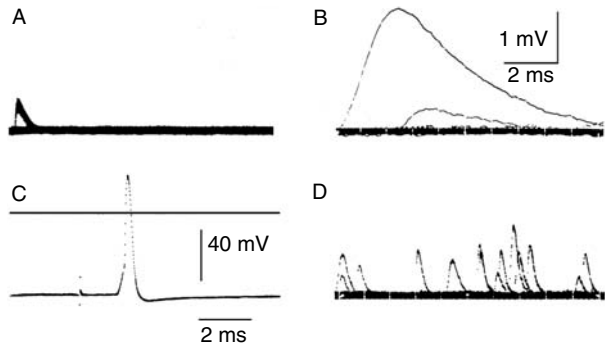

**FIGURE 19.6** Electrophysiological recordings obtained from junctions in mouse muscles injected with BoNT/A at 3 (A), 5 (B) and 30 days (C, D) post-toxin injection. Panel A. Oscilloscope superimposed tracings of endplate potentials evoked by nerve stimulation at 0.5 Hz. Note that only 15% of nerve impulses give rise to synaptic responses, while 85% of nerve impulses failed to evoke transmitter release. Panel B. Spontaneous endplate potential recorded in another junction during prominent sprouting of motor nerve endings. Note, the same time-scale as in A. The ACh giving rise to these spontaneous events does not contribute to evoked transmitter release. Panel C. Nerve-evoked muscle action potential triggered by synaptic activity. The upper line denotes the 0 mV membrane level. Panel D. Superimposed tracings of spontaneous miniature-endplate potentials recorded from another junction of the same muscle as in panel C, in which neuromuscular transmission has recovered. All recordings were performed at 37°C in standard Krebs-Ringer solution.

growth (Sanes and Lichtman, 1999), and some of these molecular components could possibly guide sprouts along muscle fibers.

Direct electrical stimulation of muscle previously paralyzed by Botulinum complex/A reportedly prevents sprouting (Brown *et al*., 1981), which likely involves muscle-derived signaling factors in sprout generation. Expression of insulin-like growth factors (IGF) is evidently up-regulated in BoNT/A-paralyzed muscle, and IGF-binding proteins delivered locally to paralyzed muscles prevent nerve sprouting (Caroni *et al*., 1994). An increase in muscle plasminogen activator has also been described during paralysis induced by BoNT/A (Tian *et al*., 1995), and it is expected that this protease may disintegrate some components of the junctional basal lamina that play a role in neuromuscular formation and plasticity.

***Changes induced by BoNTs in skeletal muscle fibers***

One striking feature of skeletal muscles paralyzed with BoNT/A is that they undergo a progressive atrophy, which begins during the first week after toxin injection and progresses throughout the following weeks. A more rapid progression of atrophy following BoNT/A injection has been reported in "slow," versus "fast," contracting muscles. These changes are characterized by a noticeable decrease in muscle weight following diminished fiber diameter, as compared to controls. The atrophy of skeletal muscle is usually rather heterogeneous between fibers of a given muscle, probably because some unpoisoned fibers maintain their normal diameter. The muscle atrophy induced by BoNTs in animal models and humans is largely reversible, even after repeated BoNT injections.

The fact that NMJs remain intact in BoNT-paralyzed muscle, since no degenerative changes are detected among its components, does not preclude the presence of some denervation-like alterations. Thus, muscle fibers treated with BoNT/A exhibit a small decrease in resting membrane potential, develop spontaneous fibrillation and action potentials (directly elicited by electrical stimulation), which become partially resistant to tetrodotoxin, which normally blocks voltage-sensitive $Na^+$ channels (Thesleff, 1989; Thesleff *et al*., 1990). Insensitivity towards tetrodotoxin results from an overexpression of mRNA encoding tetrodotoxin-insensitive, voltage-dependent $Na^+$ channels ($Na_V1.5$/SkM2) (Yang *et al*., 2001). In human adult, BoNT/A-treated skeletal muscles, such insensitivity declines when functional recovery of neuromuscular transmission occurs. In addition to these changes, muscles treated with BoNT/A become susceptible to innervation by foreign nerves. During development, BoNT/A-blockade delays and impedes the retraction of polyneuronal innervation in muscle and prevents motoneuron cell death (Thesleff *et al*., 1990). In addition, BoNT/A-paralyzed muscles express a high endocytotic activity limited to the endplate region (Thesleff *et al*., 1990). When taken altogether, these observations support the view that paralyzed muscles secrete factors essential for growth and survival of motoneurons.

Every adult skeletal muscle fiber contains an important population of nuclei, a few of which cluster into the endplate region. These synaptic nuclei are larger and more round than extrasynaptic nuclei, and they are transcriptionally specialized, since they express genes that encode different synaptic proteins, which include nAChR subunits at levels far higher than those of extrasynaptic nuclei (Burden, 1993). After treatment with BoNT/A, atrophic muscle fibers contain a large number of synaptic nuclei located not only in the original endplate area, but also in the vicinity of nerve terminal sprouts. Concomitant with these changes, spatial distribution and levels of the different subunit-specific mRNAs encoding nAChRs also vary. Consequently, mRNA levels for the alpha-subunit of the nAChR increase (Lipsky *et al*., 1989), and changes in the levels as well as distribution of gamma- and epsilon-subunit specific mRNAs correlate well with fetal and adult nAChR channel subtypes appearing along muscle fibers (Witzemann *et al*., 1991; Koltgen *et al*., 1994). In BoNT/A-paralyzed muscle fibers, the density of nAChRs increases dramatically, as determined by specific binding with radiolabeled [$^{125}$I]-α-bungarotoxin (Bambrick and Gordon, 1987), or by fluorescence staining with rhodamine-labeled α-bungarotoxin. This explains the ACh supersensitivity observed a few weeks after poisoning in BoNT-poisoned muscles (Tonge, 1974; Thesleff *et al*., 1990). The increase in $^{125}$I-α-bungarotoxin binding sites induced by BoNT/A occurs to a lesser extent in neonatal, than in adult, rat skeletal muscles (Bambrick and Gordon, 1992). Detection of nAChRs in muscles injected with BoNTs reveals clear reorganization of the postsynaptic elements within NMJs, with distinguishable patches of α-bungarotoxin staining abutting the sprouts. Paralysis by BoNT/A is also associated with changes in the molecular pattern of acetylcholinesterases anchored to the basal lamina of skeletal muscle.

In conclusion, after axonal sprouting and reformation of functional NMJs, the muscle eventually regains its normal size and both acetylcholinesterase and nAChR reconcentrate at the NMJ. Sprouts largely degenerate and the endplate eventually regains its normal morphology and function.

### *Duration of BoNT actions*

One of the important aspects of BoNT action is the duration of muscle paralysis. As shown in Table 19.8, the average duration of muscle paralysis induced by BoNT/A in humans and rodents exceeds that resulting from exposure to other BoNT serotypes, with the exception of BoNT/C, which has a slightly less duration of action than BoNT/A (Eleopra *et al*., 1998; Meunier *et al*., 2003). Thus, according to their duration of action, BoNTs can be classified into three groups: (i) long-lasting (BoNT/A and BoNT/C); (ii) intermediate (BoNT/B and BoNT/F); and (iii) short-lasting (BoNT/E). It is still unclear why the functional recovery time in rodents is shorter than in humans after BoNT exposure.

Proteolytic activity of BoNT/A and C, with the appearance of cleavage product in cultured neurons or chromaffin cells, persists beyond 80 days, whereas activity of the other BoNTs like BoNT/E is much shorter (<1 day) (Keller *et al*., 1999; O'Sullivan *et al*., 1999; Foran *et al*., 2003; Whelchel *et al*., 2004). Long-term persistence of BoNT/A, and possibly BoNT/C molecules inside nerve terminals, may provide an explanation for different durations of inhibition for these two toxins (O'Sullivan *et al*., 1999; Foran *et al*., 2003). BoNT/A, but not BoNT/E, L-chains possess a sorting signal (di-leucine motif), which may facilitate interaction with adaptator proteins and redirection to the active zones (Fernandez-Salas *et al*., 2004). However, the timescale for BoNT/E-induced paralysis was surprisingly shorter than that for BoNT/A (Eleopra *et al*., 1998; Meunier *et al*., 2003). It has been hypothesized that truncated SNAP-25 lacking a C terminal 9mer, released by BoNT/A proteolysis, has a longer life span than SNAP-25 with a 26mer deletion induced by BoNT/E (Keller *et al*., 1999; Humeau *et al*., 2000; Meunier *et al*., 2003). Recent findings support strongly this possibility as evidenced by SNAP-25 truncation by BoNT/A, but not BoNT/E, and subsequent interactions with syntaxin (Bajohrs *et al*., 2004). The syntaxin/SNAP-25 complexes formed with BoNT/A-truncated SNAP-25 induce long-term retention within the active zone (Bajohrs *et al*., 2004). Since this SNAP-25 fragment is not fusogenic, long-term impeding of synaptic vesicle fusion becomes evident. Possibly, membrane retention prevents degradation of SNAP-25 by intracellular proteases. In contrast, the SNAP-25 fragment generated by BoNT/E cannot bind to syntaxin. SNAP-25 produced by BoNT/A also acts as substrate for BoNT/E (Lawrence *et al*., 1997). Therefore, the long life span of the unproductive complex comprising syntaxin and SNAP-25 truncated by BoNT/A is shortened by further cleavage with BoNT/E, thus explaining how BoNT/E shortens paralysis induced by BoNT/A.

## OTHER TOXINS WITH DISTINCT NEUROTOXIC ACTIVITIES

### *Clostridium perfringens* epsilon toxin

Epsilon toxin acts on different cell types, including those of neuronal origin. It is not a strict neurotoxin as defined previously for the BoNTs and TeNT, but epsilon toxin is involved in neurological symptoms. Epsilon toxin represents the major virulence factor of *C. perfringens* types B and D, which are the etiological agents of fatal enterotoxemia in sheep as well as goats, and more rarely of cattle (see Chapter 35 of this volume). Overgrowth of *C. perfringens* in the intestine of susceptible animals, generally a consequence of overeating high starch/sugar-containing foods, results in large amounts of epsilon toxin. The toxin is absorbed through the intestinal mucosa and spreads into different organs by the circulatory system, ultimately causing hypertension, vascular permeability, lung edema, and kidney necrosis (pulpy kidney disease in lambs). The disease is rapidly fatal with neurological disorders that include excitation symptoms.

Major pathological changes are observed in the brain following epsilon intoxication, which include: congestion and edema of the meninges; perivascular and intercellular edema; as well as necrotic foci of the nervous tissue. Epsilon toxin passes through the blood-brain barrier and accumulates specifically in the brain (Nagahama and Sakurai, 1991; Nagahama and Sakurai, 1992). The toxin damages endothelial cells of the blood-brain barrier by altering the endothelial barrier antigen localized to luminal endothelial cell membranes, thus causing leakage of endogenous albumin (Zhu *et al*., 2001). The specific receptor for epsilon toxin on neuronal and endothelial cells is not yet known, although a membrane sialoglycoprotein seemingly mediates toxin binding (Buxton, 1978; Nagahama and Sakurai, 1992). In the brain, epsilon toxin increases vascular permeability, leading to a rapid, severe, and diffuse edema that exerts a direct cytotoxic effect upon neurons. Neuronal damage is characterized by progressive cytoplasmic vacuolization plus necrosis, and in some cells there is hyperchromatosis and nuclear pyknosis (Finnie *et al*., 1999).

The neurological disorders linked to epsilon toxin, which likely result from an excessive release of glutamate, include retraction of the head, opisthotonus, convulsions, agonal struggling, and hazardous roaming. Indeed, epsilon toxin injected intravenously into mice preferentially excitates hippocampal neurons that induce an increased glutamate efflux blocked by a specific inhibitor (Miyamoto *et al*., 1998; Miyamoto *et al*., 2000).

The molecular basis for epsilon neurotoxicity is not known, but the toxin is a pore former, which structurally mimics *Aeromonas hydrophila* aerolysin (Cole *et al*., 2004) (see Chapter 35 of this volume). In Madin Darby Canine Kidney (MDCK) cells, which is a rare cell line sensitive to epsilon toxin, the toxin recognizes a specific unknown receptor, heptamerizes, and forms pores that lead to an efflux of $K^+$, influx of $Na^+$, $Cl^-$ and $Ca^{2+}$, cell swelling, and membrane blebbing/disruption (Petit *et al*., 1997; Petit *et al*., 2001; Miyata *et al*., 2002). In addition, epsilon toxin rapidly decreases membrane barrier permeability of polarized MDCK cells (Petit *et al*., 2003). Epsilon toxin also forms heptamers in synaptosomal membranes (Miyata *et al*., 2001; Miyata *et al*., 2002), which involves detergent-resistant membrane microdomains called lipid rafts, but it is not yet defined whether the toxin-induced glutamate release is due to pore formation or another specific mechanism.

## Toxins active on Rho-GTPases and possessing neurotoxicity

### *Toxins that inactivate Rho-GTPases*

Clostridial glucosylating toxins, also known as the large clostridial toxins, such as *Clostridium sordellii* lethal toxin (LT) and *Clostridium difficile* toxin B (ToxB), inactivate Rho-and/or Ras-GTPases by modifying a conserved threonine within the effector domain of target molecules (see Chapters 9 and 21, in this volume). ToxB catalyzes glucosylation of Rho proteins (Rho, Rac, and Cdc42), whereas the several variants of LT modify Rac, sometimes Cdc42, and various Ras proteins (i.e., Ras, Rap, Ral). *C. difficile* and *C. sordellii* toxins use UDP-glucose as cosubstrate, and *Clostridium novyi* α-toxin uses UDP-*N*-acetylglucosamine. GDP-bound GTPase is the preferred substrate, since the modified Thr35 and Thr37 residues are only exposed on the surface of this GTPase form. Although glucosylated GTPases can bind to their target membrane and undergo GDP-GTP exchange when stimulated by guanylate exchange factors, modification of Thr37/35 localized within switch I of GTPases prevents recognition with their effectors. In addition, intrinsic GAP (GTPase activating protein)-stimulated GTPase activity is reduced, inhibiting the GDP-GTP cycling of modified GTPases between the membrane and cytosol. Thereby, glycosylated GTPases act as dominant-negative mutants.

*C. botulinum* C3 enzyme is an ADP-ribosyltransferase, which specifically inactivates Rho (see Chapter 1 of this volume). C3 ADP-ribosylates Asn41, which is localized within the switch I loop near Thr37. C3-mediated ADP-ribosylation of Rho inhibits translocation to the membrane and therefore prevents interaction with its effectors. ADP-ribosylated Rho is trapped by guanine dissociation inhibitor (GDI) in an inactive, cytosolic form.

### *Neuronal alterations caused by toxin inactivation of Rho GTPases*

Several small GTPases of the Ras superfamily are present in nerve terminals and include RhoA, RhoB, Rac1, and Cdc42. Additionally, Rac1 associates with synaptic vesicles as well as the plasma membrane (Doussau *et al*., 2000; Humeau *et al*., 2002). The Ral molecule also binds to synaptic vesicles (Bielinski *et al*., 1993). Intraneuronal application of C3 exoenzyme, ToxB from *C. difficile*, or LT from *C. sordellii* (strain IP82 or VPI9048) blocks $Ca^{2+}$-dependent vesicular ACh release from *Aplysia* synapses (Doussau *et al*., 2000; Humeau *et al*., 2002). LT exhibits the highest activity upon neurotransmitter release, being 100- –1000- fold more potent than ToxB or the C3-exoenzyme from *C. botulinum* (Doussau *et al*., 2000). Similarly, LT blocks spontaneous glutamate release in cultured rat cerebellar slices (Kojima and Poulain, unpublished observation). These observations are consistent with reports that Rho-acting toxins block the secretory process in many cell types, including mast cells (Prepens *et al*., 1996; Kowluru *et al*., 1997; Gasman *et al*., 1999; Djouder *et al*., 2003). In muscles isolated from mice previously injected with LT, nerve-evoked muscle twitch is blocked. This effect results from both a presynaptic block of ACh release and depressed muscle contractility (Barbier *et al*., 2004). This is consistent with the high lethality of LT ($\sim 0.3 \times 10^6$ mouse $LD_{50}$/mg protein) injected intraperitoneally, which is probably due to respiratory failure. Because of the potent blocking action of LT on nerve endings, a question arises whether the intestinal disorders that characterize enterotoxemia caused by the clostridia producing Rho-acting toxins are linked to intestinal epithelial damage and/or stimulation of the enteric nervous system (Pothoulakis *et al*., 1998).

Identity of the downstream pathway whose silencing blocks exocytosis by LT or ToxB has been addressed in different cell systems. Apparently, the affected pathways can vary in different cell types. In several types of secretory cells, experimental findings indicate that the toxins induce remodeling of the actin cytoskeleton, thereby altering intracellular granule trafficking towards the plasma membrane, which possibly includes fusion (Prepens *et al*., 1996; Kowluru *et al*., 1997). Another interesting configuration has been deciphered in rat blood leukemia-mast cells. In these cells, exocytosis is triggered by a rise in intracellular $Ca^{2+}$ levels induced by stimulation of either the Fc-epsilon receptor or muscarinic-type AChR. The Rac GTPase is

the only one involved in $Ca^{2+}$ mobilization within these cells, and the blockade of exocytosis by ToxB or LT is due to inhibition of capacitative $Ca^{2+}$ entry exclusively through store-operated $Ca^{2+}$ channels (Djouder *et al*., 2000; Djouder *et al*., 2003). In nerve endings, the blockade of neurotransmitter exocytosis caused by ToxB and LT appears to have another origin. Studies performed with *Aplysia* cholinergic synapses reveal that following inactivation of Rac by LT or ToxB, the exocytosis process starts normally, but then stops, possibly during the priming events. This results in a dramatic decrease in the number of functional release sites (Humeau *et al*., 2002), which is very similar to the gross action of TeNT or BoNTs.

What is the role of Rac during priming? Rac, Rho, Cdc42, Ral, and PLD1 all participate in a multiprotein complex termed "exocyst," which is comprised of Sec6/Sec8 proteins and regulates polarized secretion as well as docking of vesicles to plasma membrane regions specialized in exocytosis (reviewed by Short and Barr, 2002). Therefore, one cannot exclude that Rho-acting toxins block exocytosis by disabling exocyst function in nerve endings. However, implication of an exocyst role during exocytosis of neurotransmitter is disputed. A likely possibility implicating PLD1 in the exocytosis process is that by catalyzing PA generation, formation of lipid bilayer intermediates becomes favored during membrane fusion. PLD1 activity is inhibited in LT-poisoned cells (Ben El Hadj *et al*., 1999), and Rac plus Cdc42 regulate PLD1 activity (Hammond *et al*., 1997). The intraneuronal application of a catalytically inactive mutant of PLD1 reproduces the potent inhibitory effect of LT (Humeau *et al*., 2001). Therefore, we envisage the following model for LT and ToxB action at the presynapse, which initially involves glucosylation of Rac by the toxins, thus preventing activation of PLD1 upon synaptic vesicle docking. Production of fusogenic PA is not stimulated, and despite the $Ca^{2+}$ influx triggering SNARE complex zippering, fusion of synaptic vesicle with plasmalemma cannot occur because the lipid composition at release sites remains inadequate. The synaptic vesicles equipped with modified Rac plug exocytosis sites and prevent fusion of synaptic vesicles equipped with intact Rac. This contributes to reduced numbers of active release sites by LT or ToxB.

In addition to the presynaptic actions mentioned above, clostridial cytotoxins affecting Rho GTPases can also block neurotransmission by altering postsynaptic cell capabilities to detect transmitter. For example, neurotransmitter-receptor density is diminished in neurons treated with toxins that affect Rac or Cdc42 (Meyer *et al*., 2000). The observation that LT prevents long-term potentiation (Murray and O'Connor, 2004) is consistent with inhibiting insertion of new receptors into the post-synaptic membrane. Note that it is not yet clear whether changes in receptor density refer to the role of Rho proteins during the exocytotic process, which includes receptor insertion into the plasma membrane, and/or organization of the post-synaptic actin cytoskeleton involved in receptor clustering (Triller and Choquet, 2003).

Much evidence suggests that apoptosis plays a crucial role in cell homeostasis, which depends upon the expression of various genes implicated in controlling life and death. Incubation of rat primary cerebellar granule neurons in culture with either ToxB or LT reportedly induces cell death with biochemical and morphological hallmarks of neuronal apoptosis (Linseman *et al*., 2001). In these cells, selective inhibition of Rac/Cdc42 function promotes: (i) phosphorylation and expression of the transcription factor c-Jun; (ii) activation of caspase-3; and (iii) nuclear condensation, as well as fragmentation. Interestingly, apoptosis occurs independently of F-actin-cytoskeletal disruption, since agents that directly disassemble F-actin (*C. botulinum* C2 toxin, cytochalasin D, and latrunculin A) do not induce cell death within 24 h. These results indicate that Rac/Cdc42 GTPases are critical for survival of cerebellar granule neurons in primary culture. Additionally, these data are the first to establish a prosurvival function for Rho GTPases in a primary neuronal cell model.

## ENTEROTOXINS AND THE ENTERIC NERVOUS SYSTEM

Increasing evidence suggests that some enterotoxins mediate diarrhea by not only acting directly upon enterocytes, but also by interfering with/stimulating the enteric nervous system (Pothoulakis *et al*., 1998). The enteric nervous system is comprised of the myenteric plexus involved primarily in motor control of the gut and the submucosal plexus, which plays a central role in sensing the chemical status of the intestine and regulating secretion. Neuronal cell bodies of the enteric nervous system (intrinsic afferent neurons, interneurons, motor- and secretory-neurons) are clustered in ganglia and connected to parasympathetic and sympathetic systems. More than 20 neurotransmitters have been identified in the enteric nervous system. Among them, substance P, ACh, GABA, glutamate, and 5HT modulate motility, absorption, and secretion of the intestine (Farthing, 2000; Farthing *et al*., 2004).

Cholera toxin (CT) is well known to mono-ADP-ribosylate heterotrimeric G-proteins leading to adenylcyclase stimulation, increased intracellular levels of cAMP, plus

$Cl^-$ and water secretion from the cell into the intestinal lumen (see Chapter 15 of this volume). In addition, CT stimulates 5HT release from entero chromaffin cells localized to the villus of the small intestine. Although the cascade-response involving the enteric nervous system is still unclear, it is suggested that 5HT activates afferent nerves in the lamina propria containing ACh or substance P as neurotransmitter, which subsequently stimulate secretory neurons releasing vasoactive intestinal polypeptide (VIP) and possibly NO. VIP recognizes specific receptors on the basolateral membrane of crypt cells and induces an adenyl cyclase-cAMP-dependent secretion of NaCl and water. Antagonists of 5HT, substance P, and VIP markedly reduce CT-induced secretion (Farthing, 2000).

The *Escherichia coli* heat labile enterotoxin (HLT) is structurally related to CT, sharing a classic 1A (enzyme component):5B (cell binding component) structure of approximately 85 kDa; however, HLT does not stimulate the release of (5HT?) from enterochromaffin cells. HLT-induced secretion is not inhibited by substance P, but lignocaine and the ganglionic blocker hexamethonium have a preventive effect, suggesting that the enteric nervous system is involved in the enteric activity of HLT (Farthing, 2000).

The much smaller *E. coli* heat stable enterotoxins (ST; 2–5 kDa) activate guanylate cyclase, increase cyclic guanosine monophosphate (cGMP) levels, and subsequently open $Cl^-$ channels (see Chapter 48 of this volume). Since ST-induced secretion is blocked by tetrodotoxin, lignocaine, and hexamethonium, the entero nervous system also likely supports ST activity (Farthing, 2000).
