An older study (Labbe and Duncan, 1977) determined that *cpe* mRNA may have an unusually long (~45 min) half-life. That observation raises the possibility of posttranscriptional effects, particularly message stability, also contributing to the strong production of CPE that often occurs during sporulation.

### *Release of CPE from sporulating* **C. perfringens** *cells*

The *cpe* gene does not encode a signal peptide for CPE secretion (Czeczulin *et al*., 1993). Instead, CPE accumulates in the cytoplasm of the mother cell during sporulation and is finally released into the GI tract only at the completion of sporulation, i.e., when the mother cell lyses to release its now mature endospore.

## THE INTESTINAL ACTION OF CPE

CPE is considered an enterotoxin because it induces fluid and electrolyte losses from the GI tract of many mammalian species (McDonel, 1986). Animal studies indicate that the small intestine is the principal target organ for CPE (McDonel, 1986). CPE affects all small intestinal regions, but is most active on the ileum

(McDonel, 1986). The rabbit colon does not significantly respond to CPE, even though isolated rabbit colonic cells bind the toxin at high levels (McDonel and Demers, 1982). Whether CPE affects the human colon is not yet clear.

CPE acts very quickly on the small intestines, with high toxin doses causing visible ileal damage within 30 min of treatment (Sherman *et al*., 1994). Two observations indicate that this initial histopathologic damage, which starts at the villus tips, is responsible for starting CPE-induced intestinal fluid/electrolyte transport alterations: (i) the onset of fluid/electrolyte transport alterations occurs concurrently with the development of damage in the CPE-treated rabbit ileum (Sherman *et al*., 1994), and (ii) only those CPE doses capable of inducing intestinal damage can induce fluid/electrolyte transport alterations (McDonel and Duncan, 1975).

CPE exerts "biphasic" alterations in ileal fluid/electrolyte transport (Sherman *et al*., 1994). Initially, the CPE-treated ileum shows only an inhibition of fluid/electrolyte absorption; as described previously, this initial absorption inhibition is probably attributable to the start of histopathologic damage in the CPE-treated ileum. However, as treatment time increases, frank ileal fluid/electrolyte secretion develops in the CPE-treated ileum. This intestinal secretion probably reflects a combination of (i) secondary effects of the enterotoxin on intestinal paracellular permeability (see next section) and (ii) continued development of histopathologic damage that eventually desquamates the epithelium of the CPE-treated ileum and causes severe villus shortening (Sarker *et al*., 1999).

## THE CELLULAR ACTION OF CPE

### Step one: CPE binds to cells, forming a small, SDS-sensitive complex

Recent studies (Hardy *et al*., 2001) demonstrated that the addition of CPE to protein-free artificial membranes can produce cation-selective pores. That observation clearly indicates protein receptors are not absolutely required for CPE action. However, those artificial membrane studies used very high CPE concentrations to obtain pores that developed much slower than occurs in naturally CPE sensitive cells (see CPE-Induced Plasma Membrane Permeability Alterations).

Considerable evidence indicates that protein receptors do play an important role in initiating CPE action under pathophysiologic conditions. For example, cultured mouse fibroblasts, which are unable to specifically bind CPE due to the lack of receptors, fail to respond to the moderate CPE concentrations typically present in the intestines during GI disease (Katahira *et al*., 1997a; Katahira *et al*., 1997b; Singh *et al*., 2000). However, those cells specifically bind CPE and become highly sensitive to this toxin if transfected to express certain claudins (Katahira *et al*., 1997a; Katahira *et al*., 1997b).

Besides demonstrating the importance of protein receptors for normal CPE action, the transfectant results of Katahira *et al*. also indicate that some claudins can serve as functional CPE receptors. Claudins are a recently discovered family (more than 20 members) of small (about 22 kDa) proteins that play key roles in mediating both the barrier and gate functions of epithelial tight junctions (TJs). Interestingly, only certain claudins can serve as functional CPE receptors. Mouse fibroblast transfectant studies (Fujita *et al*., 2000) indicate that claudins -3, -4, -6, -7, -8, and -14 can bind CPE, while claudins -1, -2, -5, and -10 cannot bind CPE. The importance of claudins as pathophysiologic CPE receptors for enterocytes has not yet been addressed.

Immediately upon binding to claudin (and/or other) protein receptors, CPE localizes in a small (about 90 kDa) SDS-sensitive complex (Wieckowski *et al*., 1994). Formation of the small CPE complex (Figure 45.3) appears important for the enteuotoxin's action since this complex is formed by every CPE-sensitive cell line tested to date. The complete composition and stoichiometry of small CPE complex are not yet clear, but immunoprecipitation analyses (Wieckowski *et al*., 1994) demonstrated this complex contains both CPE and a mammalian protein that runs at about 45–50 kDa on SDS-PAGE. Whether the ~45–50 protein represents aggregated claudins, an alternative CPE receptor, or a co-receptor that (along with claudins) interacts with CPE, has not yet been determined.

When present in the small complex, CPE apparently becomes trapped on the surface of the host cell membrane (Wieckowski *et al*., 1998). For example, CPE localized in small complex shows relatively limited dissociation from mammalian cells. However, CPE in small complex does not appear to be internalized or to insert in lipid bilayers as this toxin remains highly susceptible to external protease treatments.

### Step two: CPE becomes localized in large, SDS-resistant complexes

At 4°C, CPE binds and forms small complexes, but does not induce any cytotoxic effects (McClane and Wnek, 1990). However, if cells containing CPE bound at 4°C are subsequently warmed to 37°C, cytotoxicity

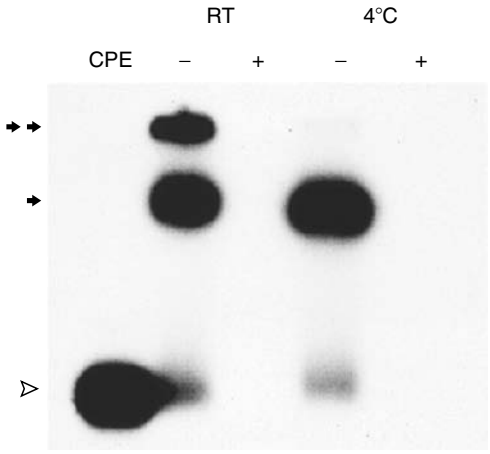

**FIGURE 45.3** Formation of CPE-containing complexes at room temperature (RT) or 4°C. For this experiment, $^{125}$I-CPE was incubated with brush border membranes in the presence (+) or absence (–) of excess native toxin. After extraction with Triton X-100, lysates were subjected to non-denaturing electrophoresis and gels were then autoradiographed. The white arrow, outlined in black, represents free $^{125}$I-CPE dissolved in Triton X-100 that had never been exposed to membranes. The single, solid black arrow depicts the location of the ~ 90 kDa small complex, while the double arrow indicates migration of higher $M_r$ complexes. Reproduced with permission from (Wieckowski *et al*., 1994).

quickly develops. Concurrent with that development of cytotoxicity, much of the CPE bound to those cells shifts (Figure 45.3) from the small complex to higher $M_r$ material (McClane and Wnek, 1990; Wieckowski *et al*., 1994). Collectively, these observations indicate (i) although important, formation of the small CPE complex is insufficient to induce cytotoxicity, (ii) small complex is a precursor for formation of the higher $M_r$, CPE-containing material, and (iii) some or all of the higher $M_r$, CPE-containing material is essential for cytotoxicity.

The importance of higher $M_r$, CPE-containing material for CPE-induced cytotoxicity receives further support from deletion mutagenesis, random mutagenesis, and site-directed mutagenesis studies (Kokai-Kun and McClane, 1997; Kokai-Kun *et al*., 1999; Smedley and McClane, 2004). Collectively, those studies identified several CPE fragments or point mutants that can bind CPE and form small complexes, yet fail to form the higher $M_r$, CPE-containing material; in all cases, those CPE fragments/point mutants are non-cytotoxic. In addition, some CPE fragments were identified that bind normally, yet form increased amounts of the higher $M_r$, CPE-containing material; those fragments also consistently exhibit two-to three-fold greater cytotoxic activity than native CPE.

Recent Western blot studies (Singh *et al*., 2000) examined suspensions of human enterocyte-like CaCo-2 cells treated with CPE at 37°C. Those studies successfully resolved (Figure 45.4) the higher $M_r$, CPE-containing material into two major SDS-resistant CPE species of about 155 kDa and about 200 kDa. A minor CPE-containing, SDS-resistant species of about 135 kDa was also sometimes detected during these studies. An important breakthrough in understanding the composition of these large CPE complexes occurred when it was found (Singh *et al*., 2000) that the TJ protein occludin is present in the ~ 200 kDa complex, but is not a component of the ~155 kDa complex (Figure 45.4). Furthermore, CPE treatment was shown (Singh *et al*., 2001) to slowly induce internalization of occludin from TJs into the cytoplasm, an effect that could contribute to CPE-induced disease (see "Consequences of CPE-Induced Cell Death: TJ Effects").

In CaCo-2 cell monolayers grown in Transwell cultures (to produce a polarized epithelium) and then treated with CPE on their apical surface, formation of the ~200 kDa complex requires about two hours (Singh *et al*., 2001). In contrast, 20 min of CPE treatment on the apical surface is enough time for these CaCo-2 cell Transwell cultures to form the ~ 155 kDa complex and exhibit the substantial $^{86}$Rb-release indicative of CPE-induced cytotoxicity (see next section). Thus, it appears that, under experimental conditions resembling *in vivo* GI disease, formation of the ~155 kDa complex is

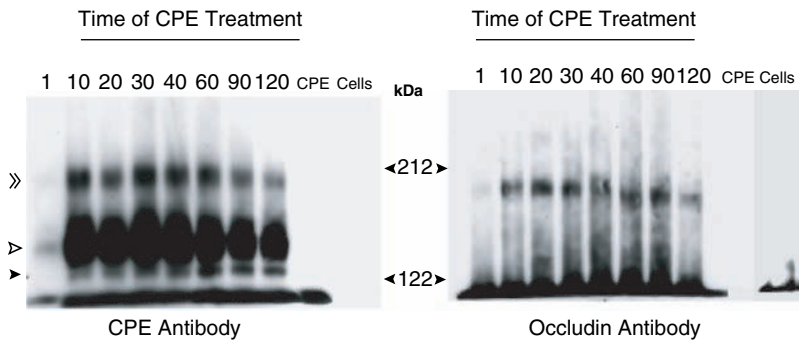

**FIGURE 45.4** The kinetics of CPE large complex formation in suspensions of CaCo-2 cells. CPE was added to a suspension of CaCo-2 cells for the indicated time at 37°C. After washing to remove unbound toxin, cells were lysed with SDS. The resultant lysates were analyzed by SDS-PAGE (no sample boiling) using 4% acrylamide gels. The gels were then Western blotted with either CPE antibodies (left) or occludin antibodies (right). The double, open, and closed arrows represent the migration of the ~ 200 kDa, ~155 kDa, or ~135 kDa complexes, respectively. Reproduced with permission from (Singh *et al*., 2000).

sufficient to initiate CPE-induced cytotoxicity in polarized monolayers of human enterocyte-like CaCo-2 cells.

Additional studies are now underway to establish the protein composition and stoichiometry of each CPE complex.

## Step three: CPE causes plasma membrane permeability changes

It was first shown back in 1979 that CPE disrupts normal plasma membrane permeability in sensitive mammalian cells (McDonel and McClane, 1979). Within 15 min of CPE treatment, sensitive mammalian cells become dramatically more permeable to small molecules (less than 200 Daltons), including ions and amino acids (McClane and McDonel, 1980, 1981; McClane, 1984; Horiguchi *et al*., 1985). Over 1–2 hours of CPE treatment, cells gradually become permeable to larger molecules up to about 3000 Daltons (McClane and McDonel, 1980; McClane, 1984).

Substantial evidence now indicates that CPE-induced permeability alterations are caused by pore formation. Electrophysiology studies demonstrated that CPE forms cation-selective pores in both artificial membranes and CaCo-2 cells (Hardy *et al*., 1999; Hardy *et al*., 2001). Furthermore, plasma membranes offer CPE in large complexes substantial protection from external proteases (Wieckowski *et al*., 1998), which is fully consistent with substantial portions of the CPE protein inserting into lipid bilayers to form pores after the toxin becomes localized in the large CPE-containing complexes responsible for CPE-induced cytotoxicity.

## Step four: CPE-induced cell death

### *Brief introduction to mammalian cell death pathways*

Mammalian cells sometimes respond to lethal insults by triggering apoptosis, a programmed cell death involving activation of specific proteases (often caspase 3/7), nuclear condensation, and cleavage of DNA into a ladder-like cleavage pattern of 200 bp increments (Majno and Joris, 1995). Apoptosis often (though not always) involves mitochondrial membrane depolarization and subsequent cytochrome C release. When it occurs, mitochondrial membrane depolarization can either result from caspase activation (i.e., be a caspase-dependent process) or can itself trigger caspase activation (i.e., be a caspase-independent process).

Alternatively, mammalian cells exposed to extreme insults can develop oncosis (formerly referred to as necrosis), which is a chaotic breakdown of cellular integrity accompanied by random cleavage of DNA in a "sheared" pattern (Majno and Joris, 1995). Oncosis does not involve either mitochondrial membrane depolarization or cytochrome C release and often can be transiently blocked by glycine. A special form of oncosis, named pyrotosis, requires caspase-1 activation (Cookson and Brennan, 2001).

### *Characterization of CPE-induced cell death*

Nearly 25 years ago, it was determined that CPE is highly cytotoxic for most mammalian epithelial cells (Matsuda and Sugimoto, 1979; McClane and McDonel, 1979). When treated with this toxin, cells rapidly lose viability and experience a simultaneous shutdown of DNA, RNA, and protein synthesis. Coincident with those effects, the CPE-treated cells develop substantial morphologic damage (cell rounding, bleb formation, and detachment).

Recent studies (Chakrabarti *et al*., 2003; Chakrabarti and McClane, 2005) investigated the cell death pathways that are activated by CPE treatment of CaCo-2 cell monolayers. As summarized in Table 45.2, a 1 μg/ml CPE dose causes CaCo-2 cells to develop morphologic damage, DNA fragmentation in a ladder-like cleavage pattern, and caspase 3/7 activation within 60 min Those effects could all be blocked by caspase-3/7 inhibitors, but not by caspase-1 or oncosis inhibitors. The 1 μg/ml CPE dose also induces rapid mitochondrial membrane depolarization and cytochrome C release in CaCo-2 cells, but those mitochondrial-related effects cannot be inhibited by any caspase inhibitors or glycine.

In contrast, CaCo-2 cells treated with a 10 μg/ml CPE dose for 30 min develop morphologic damage and a smeared pattern of DNA cleavage that can be transiently blocked by glycine, but not by any caspase inhibitors (even though modest caspase 1 activation occurs in these cells). This high CPE dose has no effect on mitochondrial membrane depolarization or cytochrome C release.

Collectively, these results indicate that a low (1 μg/ml) CPE dose induces mitochondrial membrane depolarization and cytochrome C release that causes a classic caspase 3/7-dependent apoptosis in CaCo-2 cells. In contrast, a high (10 μg/ml) CPE dose apparently induces oncosis in CaCo-2 cells. Although CPE-induced oncosis causes a modest activation of caspase 1, that effect is not required to obtain cell death, i.e., high CPE does not induce pyrotosis (the caspase 1-dependent form of oncosis). Finally, since CPE concentrations present in feces from victims of CPE-associated GI disease range from several ng/ml to greater than 100 μg/ml (Batholomew *et al*., 1985; Birkhead *et al*., 1988), both apoptosis and oncosis can probably contribute to the histopathologic damage that initiates CPE action *in vivo*.

**TABLE 45.2** Characteristics of CaCo-2 cell death induced by low (1 μg/ml) and high (10 μg/ml) CPE doses

| Characteristic | Caco-2 cells treated with low CPE dose | CaCo-2 cells treated with high CPE dose |
|---|---|---|
| Cell rounding/detachment (morphologic damage) | Develop within 60 min[1] | Develop within 30 min[2] |
| DNA cleavage | Ladder-like cleavage (develops within 60 min)[1] | Smeared cleavage (develops within 30 min)[2] |
| Caspase 3 activation | Strong (develops within 60 min)[1] | None |
| Caspase 1 activation | None | Mild (within 30 min) |
| Mitochondrial membrane depolarization | Within 15 min | None |
| Cytochrome C release | Within 15–30 min | None |
| Calmodulin involvement | Yes | Yes |
| Calpain involvement | Yes | Yes |
| Calpain activation | Mild | Strong |
| Calcium influx | Slow and mild | Fast and strong |
| Cell calcium levels | Slow, moderate increase | Fast, strong increase |

[1]Effect delayed by caspase 3/7 inhibitors

### *The role of calcium in CPE-induced cell death*

Matsuda and Sugimoto (1979) first noted that extracellular $Ca^{2+}$ is important for obtaining CPE-induced morphologic damage, but that $Ca^{2+}$ requirement had never been explained prior to a recent study (Chakrabarti and McClane, 2005). That recent study first demonstrated that CaCo-2 cells treated with CPE in the absence of extracellular $Ca^{2+}$ still develop membrane permeability alterations, i.e., extracellular $Ca^{2+}$ requirement for CPE-induced cell death occurs after the enterotoxin has bound, formed the ~155 kDa large complex, and induced plasma membrane permeability alterations. Furthermore, evidence was presented demonstrating that extracellular $Ca^{2+}$ is specifically necessary for the normal development of all events linked to either CPE-induced apoptosis or oncosis (see preceding section).

Chakrabarti and McClane also showed that the extracellular $Ca^{2+}$ requirement for CPE-induced cell death involves influx of $Ca^{2+}$, a potent second messenger capable of mediating cell death. As indicated in Table 45.2, CPE-induced $Ca^{2+}$ influx quickly raises cell calcium levels in CaCo-2 cells. Both the onset and magnitude of those cellular calcium increases are CPE dose-dependent, i.e., a faster and stronger increase in cell calcium levels occurs using a 10 vs. 1 μg/ml CPE dose.

Increases in cellular $Ca^{2+}$ levels appear to play a pivotal role in normal CPE-induced cell death. For example, caspase inhibitors and glycine (which are capable of blocking CPE-induced apoptosis or oncosis, respectively) fail to block CPE-induced increases in CaCo-2 cell $Ca^{2+}$ levels (Chakrabarti and McClane, 2005), arguing that increased calcium levels are not merely a consequence of CPE-induced cell death. Furthermore, Chakrabarti and McClane (2005) showed that the cell death pathway activated by a given CPE dose can be experimentally shifted from apoptosis to oncosis, (or vice versa) simply by manipulating the calcium content of treatment buffers to obtain greater (or lesser) increases in cell calcium levels, i.e., cell calcium levels directly select which death pathway becomes activated in a CPE-treated cell.

How do CPE-induced changes in cellular $Ca^{2+}$ levels trigger cell death? As shown in Table 45.2, inhibitor studies (Chakrabarti and McClane, 2005) indicate that two calcium-binding cytosolic proteins, i.e., calmodulin and calpain, play essential roles in CPE-induced apoptosis and oncosis. Furthermore, stronger and faster calpain activation occurs in CaCo-2 cells treated with 10 vs. 1 μg/ml CPE doses. The pathway by which calcium-induced activation of calpain and calmodulin leads to death of the CPE-treated cell is currently under study.

### *Consequences of CPE-induced cell death: Initiation of GI disease*

CPE-induced apoptosis and oncosis produce morphologic damage, which probably initiates the histopathologic damage responsible for starting fluid and electrolyte transport alterations in the CPE-treated intestines.

### *Consequences of CPE-induced cell death: Tight junction effects*

The morphologic damage resulting from CPE-induced apoptosis and oncosis should also expose the basolateral

membrane of both intoxicated and adjacent (but still healthy) enterocytes. Exposing enterocyte basolateral membranes probably has pathophysiologic relevance since it would provide free (unbound) CPE access to (previously hidden) CPE receptors present on basolateral membranes. This effect could be important since Transwell CaCo-2 cell studies detected considerably more CPE receptors on the basolateral vs. apical surface of these enterocyte-like, human polarized cells (Singh *et al*., 2001).

CPE binding to receptors on the basolateral surface of enterocyte-like cells (and, probably, enterocytes) is likely to have two effects (Singh *et al*., 2001). First, it should increase ~155 kDa complex formation, further promoting cell death. Second, it should allow bound CPE to interact with (previously inaccessible) occludin, another TJ protein. Studies with CaCo-2 cells (Singh *et al*., 2001) indicate that, when CPE binds to basolateral receptors, the ~200 kDa, occludin-containing complex forms within 1 h (this complex also forms, although considerably more slowly, when CPE binds to apical receptors).

Formation of the ~200 kDa CPE complex coincides with considerable removal of occludin from the TJ into the cytoplasm (Singh *et al*., 2001). Other studies (Sonoda *et al*., 1999) have shown that a binding-capable CPE fragment (and presumably native CPE) can induce internalization of some claudins. Collectively, these studies suggest that removal of claudins and occludin from TJs probably helps explain CPE's ability to damage TJs (McClane, 2000), which (in turn) likely explains the increased paracellular permeability observed (Sonoda *et al*., 1999) in polarized monolayers treated with CPE fragments (and, presumably, native CPE). Those CPE-induced increases in paracellular permeability likely contribute to the fluid/electrolyte secretion that occurs later in CPE action.

### *Consequences of CPE-induced cell death: Inflammation?*

Inflammation contributes to the symptoms of many infectious GI diseases, e.g., *C. difficile*-associated infections. Since oncosis is proinflammatory, the discovery that high CPE doses kill cells via oncosis suggests that intestinal inflammation could also contribute to the diarrheal and cramping symptoms of CPE-associated GI disease. As mentioned earlier, this possibility is supported by studies determining that fecal CPE concentrations from *C. perfringens* food poisoning victims often exceed the 10 μg/ml CPE dose found to induce oncosis in CaCo-2 cells. Studies are currently underway to directly evaluate the potential proinflammatory properties of CPE.

## SUMMARY: A CURRENT MODEL FOR CPE ACTION

The results described above indicate that CPE's intestinal effects are the end result of a multi-step action. The current model for CPE action proposes this process starts (Figure 45.5A) with the binding of CPE to claudin receptors (perhaps together with a co-receptor?) to form the 90 kDa small complex. Through a still unidentified process, the small CPE complex then interacts with other proteins to form the ~155 kDa CPE complex. That complex, or perhaps oligomers of that complex, forms pores that render the plasma membrane permeable to small molecules, including $Ca^{2+}$. Low CPE doses cause a moderate $Ca^{2+}$ influx that, via modest activation of calmodulin and calpain, induces mitochondrial membranes to release cytochrome C, which leads to caspase 3/7 activation and cell death from classical apoptosis. At higher CPE doses, a massive $Ca^{2+}$ influx occurs that causes, via strong activation of calmodulin and calpain, cell death via oncosis.

As indicated in Table 45.B, both oncosis and apoptosis result in morphologic damage that exposes the basolateral membranes of the intoxicated cell and adjacent neighbors. This allows CPE to bind to newly exposed basolateral claudin receptors; the basolaterally bound toxin then forms more ~155 kDa complex and also interacts with occludin to form the ~200 kDa complex. Formation of the ~200 kDa complex triggers internalization of occludin (and possibly CPE and claudins) to damage TJs. As shown in Figure 45.6, the CPE-damaged TJs can no longer properly regulate paracellular permeability; along with gross desquamation of the intestinal epithelium and severe villus shortening, altered paraceullar permeability likely contributes to CPE-induced diarrhea. When high CPE doses cause enterocytes to die from oncosis, inflammation may also contribute to diarrhea and other GI symptoms (not shown).

Finally, new evidence (Fisher *et al*., 2005) indicates that both CPE and beta2 toxin may be present in the intestines during most cases of CPE-associated non-foodborne human GI disease. Those two enterically active toxins could act together to cause the more severe and long-lasting symptoms typical of cases of CPE-associated non-foodborne GI diseases vs. cases of *C. perfringens* type A food poisoning.

## CPE STRUCTURE/FUNCTION RELATIONSHIPS

Because CPE lacks significant sequence homology with other bacterial toxins and the 3D structure of this toxin

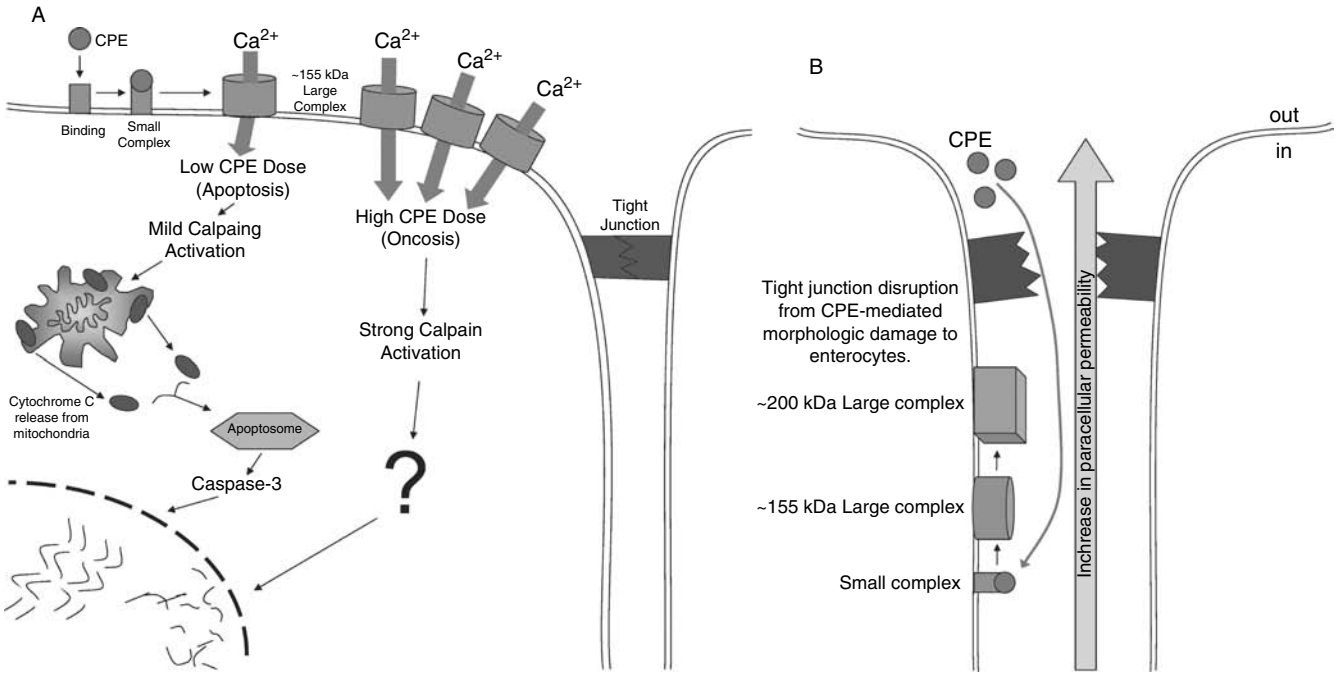

**FIGURE 45.5** Model for CPE action: early steps. A. Steps leading to CPE-induced cell death: CPE binds to receptors (possibly claudins) to form small complex. The small complex then interacts with additional proteins to form an about 155 kDa large complex whose formation leads to calcium influx, probably through a CPE-containing pore. At low CPE doses, modest calcium influx leads to activation of a classical caspase-3 dependent apopotosis mediated by mitochondria. High CPE doses cause a massive calcium influx that kills cells via oncosis. Both death pathways are mediated by activation of calpain and calmodulin (not shown in figure) and lead to morphologic damage of the CPE-treated cell. B. Secondary consequences of CPE-induced morphologic damage. Morphologic damage induced by CPE-induced cytotoxicity exposes the basolateral surface on the intoxicated cell and adjacent cells. The basolateral surface contains many CPE receptors; exposure of this surface allows more CPE binding to form more ~155 kDa complex formation and also permits initial formation of the about 200 kDa complex containing occludin. Formation of the ~200 kDa complex probably facilitates further tight junction damage.

has not yet been solved, studies of CPE structure/function relationship studies have relied upon mutagenesis approaches. Results from those structure/function studies (summarized in Figure 45.7) indicate that, like many bacterial toxins, binding and toxicity activities segregate to different regions of the CPE protein.

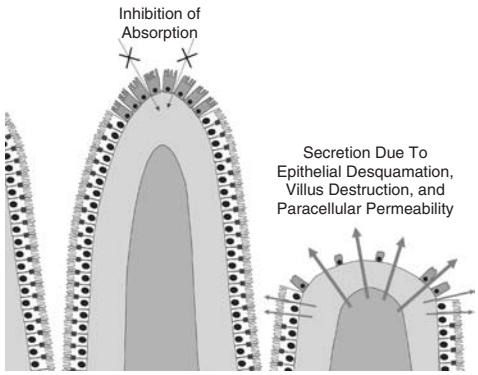

**FIGURE 45.6** Summary of the intestinal effects of CPE. Left, CPE initially kills cells at the villus tip (darkened cells in the figure), inhibiting absorption of fluids and electrolytes (Xs). Right, secretion of fluids and electrolytes develops later due to (big arrows) severe desquamation of the intestinal epithelium/villus shortening and/or (small arrows) increased CPE-induced paracellular permeability changes due to tight junction damage.

## The CPE receptor binding region

Early studies, where CPE was chemically cleaved at its single cysteine (residue 186), suggested that the

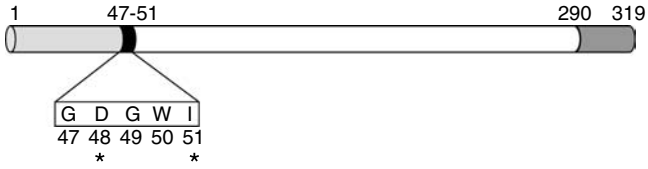

**FIGURE 45.7** CPE structure/function relationships. The N-terminal 44 amino acids of CPE are not important for cytotoxicity; their removal (which may be induced by intestinal proteases during GI disease) increases CPE potency by promoting large complex formation. The region between amino acids 47 to 51 of the native enterotoxin is important for formation of the ~155 kDa and ~200 kDa large CPE complexes, with the two residues (D48A and I51) marked by an asterisk that are specifically involved in this process. A receptor-binding region is located in the extreme C-terminus of CPE. This figure is compiled from numerous studies described in the structure/function section of the text.

C-terminal half of CPE might contain receptor-binding activity (Horiguchi *et al*., 1987). That assignment was rigorously confirmed by recombinant DNA approaches, which demonstrated that a recombinant CPE (rCPE) fragment consisting of enterotoxin amino acid residues 171 to 319 is an extremely efficient receptor-binding competitor against native CPE (Hanna *et al*., 1989). Subcloning approaches and synthetic peptide studies further localized this CPE receptor-binding activity to the C-terminal 30 amino acids of the native enterotoxin (Hanna *et al*., 1991).

### The CPE cytotoxicity region

The early structure/function studies cited above also found that, despite their ability to bind to receptors, C-terminal CPE fragments fail to induce any cytotoxicity (Hanna *et al*., 1989; Hanna *et al*., 1991). Those observations indicated that some sequences present in the N-terminal half of the enterotoxin are required for biologic activity.

However, those N-terminal cytotoxicity sequences do not include the extreme N-terminal amino acids of the native CPE protein. Early studies (Granum *et al*., 1981; Granum and Richardson, 1991) reported that removing the N-terminal 25 or 36 amino acids from CPE using the intestinal proteases trypsin or chymotrypsin, respectively, produces a two to three-fold more active toxin. This proteolytic activation, which may occur in the GI tract during disease, is not due to an enhancement of receptor binding (Hanna *et al*., 1992), which is consistent with localization of receptor-binding activity to the CPE C-terminus (see above).

Deletion mutagenesis studies (Kokai-Kun and McClane, 1997) later determined that CPE fragments lacking up to the N-terminal 44 amino acids of the native enterotoxin still exhibit this "activated toxicity" phenotype and also determined that this activation effect is due to enhanced formation of the SDS-resistant large CPE complexes. However, that study also found that deleting the first 52 amino acids produces an rCPE fragment that can bind to receptors but is completely nontoxic. This observation strongly suggested that the CPE region between residues D45 and G53 is important for toxicity. Random mutagenesis studies (Kokai-Kun *et al*., 1999) supported this conclusion by identifying a G49D rCPE mutant that is binding-proficient but non-toxic. Furthermore, those random mutagenesis studies also determined that the G49D rCPE mutant is specifically blocked for formation of large SDS-resistant complexes (including the ~155 kDa complex responsible for cytotoxicity), implying that the D45-G53 region of native CPE participates in formation of those complexes.

Recently, alanine scanning mutagenesis approaches have fine-mapped the D45-G53 region of CPE to identify the amino acid residues involved in cytotoxicity (Smedley and McClane, 2004). Those studies identified two CPE residues, D48A and I51A, as being specifically important for formation of the ~155 kDa and ~200 kDa large CPE complexes. Follow-up saturation mutagenesis studies (Smedley and McClane, 2004) then determined that both side chain length and charge are required for the D48 CPE residue to participate in large complex formation and cytotoxicity. Similar saturation mutagenesis analyses also found that residue size and/or hydrophobicity are necessary for the I51 CPE residue to participate in large complex formation and cytotoxicity.

## DEVELOPMENT OF A CPE VACCINE?

Epitope mapping studies, where C-terminal rCPE fragments were reacted with CPE-specific monoclonal antibodies, localized the linear epitope recognized by MAb3C9 to the extreme C-terminus of the enterotoxin (Hanna *et al*., 1992). Since MAb3C9 is a neutralizing antibody that blocks the binding of the enterotoxin to its receptor (Wnek *et al*., 1985), this finding provides additional evidence for the invol vement of the C-terminal CPE region in receptor binding.

Determining that a neutralizing linear epitope is present in non-cytotoxic C-terminal CPE fragments also opened the possibility of using those toxin fragments as CPE vaccine candidates. The vaccine potential of C-terminal CPE fragments received support by conjugating a 30-mer synthetic peptide (corresponding to the extreme C-terminal CPE sequence) to a thryoglobulin carrier (Mietzner *et al*., 1992). Mice immunized i.p. with that conjugate developed high titers of CPE-neutralizing serum IgG antibodies, while mice immunized with thyroglobulin alone failed to develop any protective antibody response against CPE.

While these initial results are promising, additional work is required to fully evaluate the vaccine potential of C-terminal CPE fragments in protecting against CPE-mediated intestinal disease. For example, can these fragments induce the IgA response that is probably required to prevent CPE-mediated GI disease? Such studies will be pursued only when a clear need is demonstrated for a CPE medical or veterinary vaccine.

## POTENTIAL THERAPEUTIC USE OF CPE

More than a decade of clinical experience using botulinum toxins indicates that even the most potent clostridial toxins can be safely harnessed for therapeutic use. Recent studies suggest similar potential use of CPE as a therapeutic agent against certain tumors.

The impetus for this work stemmed from studies indicating that many pancreatic, breast, and prostate cancers overexpress claudin-3 and/or claudin-4 (Long *et al*., 2001; Michl *et al*., 2001; Kominsky *et al*., 2004). The fact that those two claudins are high-affinity CPE receptors (Katahira *et al*., 1997a; Katahira *et al*., 1997b; Sonoda *et al*., 1999) suggested that the enterotoxin might be useful as a new modality for treating some or all of those cancers.

Recent results from several lab studies now support that hypothesis (Long *et al*., 2001; Michl *et al*., 2001; Kominsky *et al*., 2004). For example, pancreatic, prostate, and breast cancer cells expressing high levels of claudin CPE receptors were found to be highly sensitive to the enterotoxin *in vitro*. In contrast, cancer cells failing to express claudins are CPE-insensitive. Perhaps even more exciting are results using animal tumor models (Michl *et al*., 2001; Kominsky *et al*., 2004). For example, intratumoral injections of CPE into xenografts of panc-1 cells (human pancreatic cancer cells, Figure 45.8) or T47D cells (human breast cancer cells, not shown) cause significant tumor shrinkage, accompanied by necrosis. Equally important, mice carrying the tumor xenografts treated with CPE showed no ill effects from their therapy (Michl *et al*., 2001).

While work continues towards transitioning these preliminary findings to the clinic, obvious potential challenges remain to be addressed. For example, does the widespread distribution of claudin CPE receptors on epithelial cells restrict this approach to treatment of solid tumors? Will the development of tumor resistance to CPE treatment become a major problem? Nonetheless, growing momentum supports the potential for CPE (or binding-capable CPE derivatives) to eventually find clinical application as an antitumor agent.

## CONCLUSION

This chapter has emphasized the relatively unique nature of CPE, from its sporulation-associated expression to its ability to interact with TJ proteins to produce pores. The coming years are likely to reveal important new insights into this intriguing protein, including CPE's three-dimensional structure, how this toxin interacts with tight junction proteins, and the composition and stoichiometry of CPE complexes. The potential application of CPE or *cpe* promoters for therapeutics and vaccines, respectively, appears promising; perhaps some day CPE will be a friend as well as a foe?

## ACKNOWLEDGMENTS

Preparation of this chapter was supported by Public Health Service grant AI 19844-22 from the National Institute of Allergy and Infectious Diseases and by

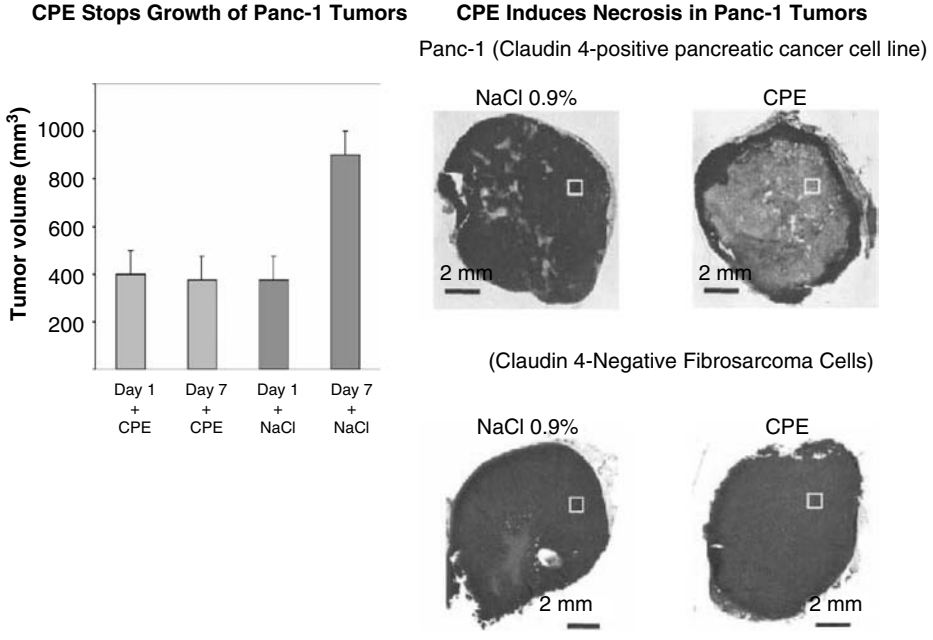

**FIGURE 45.8** CPE effects on pancreatic cancer cells expressing claudin-4. Left panel: Effect of one or seven day treatment of CPE or 0.9% NaCl on the volume of Panc-1 nude tumor xenograft models. Right panel: Histologic effects of treating claudin-4 expressing Panc-1 xenografts or claudin-4-negative HT-1080 xenografts with CPE or 0.9% NaCl. Necrotic areas appear as lighter shaded areas after H&E staining. Reproduced with permission from (Michl *et al*., 2001).

CHAPTER

# 46

# *Bacillus cereus* enterotoxins, bi- and tri-component cytolysins, and other hemolysins

*Nathalie Michelet, Per Einar Granum, and Jacques Mahillon*

## INTRODUCTION: *BACILLUS CEREUS SENSU LATO*

Whereas the virulence mechanisms of certain bacteria (*Salmonella, Shigella, Listeria*, or *Yersinia*) are in the process of being elucidated, our knowledge on the pathogenesis of other bacterial groups, including *Bacillus cereus sensu lato*, remains rather fragmentary. This chapter synthesizes our knowledge on the virulence factors found in this bacterial group. The specific toxins of each of the species constituting the *B. cereus* group are evoked in this chapter, but special attention is given to the generic virulence factors, widely distributed among the *B. cereus s.l.* species.

*B. cereus s.l.* is a group of six species of *Bacilliaceae*, displaying a large virulence spectrum. *B. anthracis*, the causative agent of anthrax, is highly monomorphic, non-mobile, non-hemolytic, and sensitive to penicillin. These phenotypic features are used to differentiate *B. anthracis* from the other members of the group (Turnbull, 1999). The other animal pathogen, *B. thuringiensis*, is active against larvae of lepidopteran, dipteran, and/or coleopteran insects. These two pathogenic organisms possess a series of virulence factors specific to their hosts. For *B. thuringiensis*, the major virulence factors are the Cry delta-endotoxins and/or Cyt cytolysins. They are produced during sporulation and form proteaneous crystals inside the sporange, a feature characteristic of this species. Upon ingestion by the insect larvae, the crystal is dissolved in the insect intestine and the protoxin is subsequently activated by the insect proteases. The free toxins specifically recognize and lyse the epithelial cells of the insect. This leads to a drop of the pH, germination of the bacterial spores, and the development of septicemia, which is frequently lethal (Schnepf *et al.*, 1998). In the case of *B. anthracis*, three proteins are necessary for the pathogen potential: the edema (EF) and lethal (LF) factors and the protective antigen (PA). The PA associates with one of the two others factors (EF or LF) to form the edema and the lethal toxins, respectively, leading to the specific syndrome of anthrax (Leppla, 1999).

*B. cereus sensu stricto* is an opportunistic bacterium known for its role in food infection and intoxication (see below), but it has also been found in other habitats (Jensen *et al.*, 2003), including the intestinal tract of arthropods, where it forms long filaments and leaves as symbiont. In this context, it is has been named *Arthromitus* (Margulis *et al.*, 1998). As indicated above, it is important to note that the only phenotypic trait used to differentiate *B. cereus* and the insect-associated *Arthromitus* from *B. thuringiensis* is the presence in the latter of the toxin crystals.

Recently, a new species, *B. weihenstephanensis*, has been proposed. This species is distinguished from the other *B. cereus* members by its psychrotolerant character and the genetic specificity of its 16S rDNA and heat shock protein *cspA* genes (Lechner *et al.*, 1998). However, these specific characteristics are still debated and do not seem to be unequivocal (Stenfors and

Granum, 2001). The two last members of the *B. cereus s.l.* group are *B. mycoides* and *B. pseudomycoides*. These species, characterized by their rhizoid growth on agar plates, can be distinguished by their fatty acid composition (Nakamura and Jackson, 1995; Nakamura, 1998). So far, no pathogenic or opportunistic activities have been associated with these bacteria.

In spite of their large virulence spectrum, members of the *B. cereus s.l.* share extremely close rDNA (Ash *et al.*, 1991; Ash and Collins, 1992; Daffonchio *et al.*, 2000) and could therefore be considered as the same species (Helgason *et al.*, 2000, 2004). Moreover, the genes coding for the entomopathogenic determinants of *B. thuringiensis* are on plasmids which can be exchanged among the different *B. cereus* members (Hu *et al.*, 2004), e. g., transforming a *B. cereus* in *B. thuringiensis* by plasmid acquisition (Thomas *et al.*, 2001). However, for simplicity and for socioeconomical reasons, it is preferable to maintain this identification system, in order to point out the specific virulence of each species.

## *BACILLUS CEREUS SENSU STRICTO*

*B. cereus s.s.*, the archetype of the *B. cereus s.l.* group, is frequently found as food toxi-infections, with symptoms of gastroenteritis (Granum, 1994). However, *B. cereus s.s.* is also a potential contaminant in hospitals because of the resistance of its spores to heat, radiation, and certain disinfectants, such as ethylic alcohol (Hsueh *et al.*, 1999). For these reasons, it is the causal agent of severe nosocomial infections in immunocompromised persons and may occasionally cause periodontitis, endocarditis, septicemia, meningitis, or pneumonia, generally after a surgical operation (Miller *et al.*, 1997; Castedo *et al.*, 1999; Gray *et al.*, 1999; Chu *et al.*, 2001; Gaur *et al.*, 2001). These cases are very rare, but the evolution of the disease is fulminating and often lethal. In each of these cases, the toxins involved are not yet precisely known. *B. cereus s.s.* is also associated with endophtalmitis, following a primary lesion. The contribution of the Hbl enterotoxin and/or phosphatidylcholine phospholipase (see below) has already been evoked. The effects of these toxins could be explained by the high proportion of phospholipids found in the retinal tissues (Beecher *et al.*, 2000; Beecher and Wong, 2000; Kotiranta *et al.*, 2000). However, after a phenotypic analysis of the corresponding *B. cereus* mutants, Callegan *et al.* could not point out differences between mutant and wild-type strains (Callegan *et al.*, 1999, 2002).

Foodstuffs potentially in contact with soil are particularly prone to *B. cereus s.s.* intoxication, for example, vegetables, fruits, milk, dehydrated milk, and spices or powdery products (Kotiranta *et al.*, 2000). The symptoms caused by *B. cereus s.s.* are divided in two types: the diarrheal and the emetic syndromes. The diarrheal syndrome was first described in Oslo in 1948, as the result of a vanilla sauce contamination in a hospital, while the emetic syndrome was noted some 20 years later following rice intoxication in London (Granum, 1997). However, the first case of food intoxication with acute gastroenteritis symptoms by *B. cereus* or a close bacterium was reported in 1906, when 300 persons in a hospital became ill after the ingestion of meatballs in which aerobic and sporulating bacteria were found (Kramer and Gibert, 1989).

The diarrheal syndromes appear 8 to 16 hours after ingestion of contaminated food, with an infective dose of between $10^5$ to $10^7$ CFU. They consist of abdominal pain, diarrhea, and often nausea and vomiting, which can last from 12 to 24 hours. For the emetic syndrome, the symptoms appear 0.5 to 5 hours after ingestion, and last from 6 to 24 hours (Granum and Lund, 1997). The emesis-causing dose is around 8 µg/kg in humans and in the house musk shrew (*Suncus murinus*) and around 10 µg/kg in the Rhesus monkey (Jaaskelainen *et al.*, 2003). The disease is characterized by nausea, vomiting, and malaise, and occasionally diarrhea (Granum and Lund, 1997). The causative agent of emesis is the cereulide, a dodecadepsipeptide synthesized by a non-ribosomal peptide synthetase, NRPS (Horwood *et al.*, 2004). It is a $K^+$-ionophoretic channel, highly resistant to pH between 2 to 11, to heat, and to proteolytic cleavage (Andersson *et al.*, 1998).

The number of intoxication cases by *B. cereus* is frequently underestimated because of the absence of severity in the symptoms. Since both types of syndromes are generally associated with particular food, their geographical repartition varies according to the feeding habits of the different regions of the world. For instance, there are 10 times more cases of emetic syndrome in Japan, whereas there is a majority of cases of diarrheal syndrome in Europe and North America (Kotiranta *et al.*, 2000).

Until now, two types of toxin detection kits have been used for the characterization of *B. cereus*. The BCET-RPLA kit (Oxoid) is based on the detection of the $L_2$ component of the HBL enterotoxin (see below) by inverse agglutination, while the TECRA kit from 3M reveals the 45k Da protein of the NHE enterotoxin by an ELISA sandwich test. However, in recent cases of food intoxication, *B. cereus* strains not expressing these two enterotoxins have been characterized (Lund *et al.*, 2000), indicating that other toxins, undetected by these methods, can play a role in the pathogenesis. Moreover, since the toxins detected by these kits are

also found in other *B. cereus s.l.* members, the detection specificity of these kits is not strictly limited to *B. cereus s.s*. Additional tests are therefore required for a more appropriate diagnostic (Guinebretière and Sanchis, 2003).

## TOXINS OF *B. CEREUS S.L.*

In addition to the specific virulence factors of *B. thuringiensis* and *B. anthracis*, most *B. cereus* group members possess secondary virulence factors involved in the invasion and/or survival of the bacteria in the host. Among these factors, some, for example, phospholipases, destroy the cell membrane by enzymatic activity while others, e.g., certain hemolysins, lyse the cells by pore formation. The virulence factors detailed in this section (Table 46.1) are the main secondary toxins for which experimental evidence has been reported or for which similarity exists with other known virulence factors.

### Phospholipases

Three types of phospholipases with different specificity have been studied in the *B. cereus s.l.* group. The sphingomyelinase (SM-PLC) cleaves sphingolipids, and the phosphatidylcholine phospholipase (PC-PLC) cleaves phosphatidylcholine, phosphatidylserine, and phosphatidylethanolamine (Martin *et al.*, 2000). However, phosphatidylinositol phospholipase (PI-PLC) cleaves not only phosphatidylinositol, but also the derived glycolipids (Hondal *et al.*, 1998). As previously indicated, phospholipases cause cell lysis by enzymatic activity, unlike most hemolysins, which act by pore formation. The enzymatic reaction consists in a hydrolysis between the glycerol and the lipidic head.

#### *Sphingomyelinase (SM-PLC)*

The 999-nt sphingomyelinase gene encodes a mature protein of 306 aa residues preceded by a 27 residue signal peptide (Yamada *et al.*, 1988). In mammalian cells, the metabolites produced by the action of sphingomyelinases (ceramide, sphingomyeline, and sphingomyeline-1-phosphate) have an important function. They are involved in signal transduction, cellular proliferation, differentiation, and apoptosis (Obama *et al.*, 2003b; Yokomatsu *et al.*, 2003). The mammalian and bacterial enzymes both act at neutral pH and need $Mg^{+2}$ for activity. However, they present distinct sequences with some conserved residues that are present in the catalytic pocket of the enzyme. The mechanism of action of SM-PLC is deduced from its

**TABLE 46.1** Enterotoxins, cytolysins, and hemolysins from *B. cereus*

| Toxins | Genetic organization | Comments | References |
|---|---|---|---|
| Sphingomyelinase (SM-PLC) | *cerB* gene in the *cerAB* operon, regulated by PlcR | Component B of cereolysin AB | Yamada *et al.*, 1988 |

| Hemolysin BL (Hbl) | *hblCDA* operon, coding for L2, L1 and B, respectively (ratio 1:1:1). Regulated by PlcR | B for binding, L1 and L2 are lytic components | Heinrichs *et al.*, 1993; Ryan *et al.*, 1997 |
| Non-hemolytic enterotoxin (Nhe) | *nheABC* operon, coding for NheABC, respectively (ratio 10:10: 1). Regulated by PlcR | NheC is a "catalyst" bringing together NheA and B. Similarities with the Hbl components | Granum *et al.*, 1999; Lindbäck *et al.*, 2004 |
| Cytotoxin K (Cyt K) | *cytK* gene, regulated by PlcR | Two forms exist: Cyt K-1 and Cyt K-2. They belong to the "β-barrel pore-forming toxin" family | Lund *et al.*, 2000; Fagerlund *et al.*, 2004 |
| Hemolysin II (Hly-II) | *hly-II* gene | Belongs to the "β-barrel pore-forming toxin" family | Baida *et al.*, 1999 |
| Hemolysin III (Hly-III) | *hly-III* gene | - | Baida and Kuzmin, 1996 |
| Cereolysin O (Clo) | *clo* gene, regulated by PlcR | Belongs to the "cholesterol-binding cytolysin" family. Synomyns are thuringiolysin O (TLO) and anthrolysin O (ALO) | Shany *et al.*, 1974 |

similarity to DNase I. The His296 residue (general base) first activates a water molecule, which, in turn, attacks the phosphodiester bond of sphingomyeline. The water molecule could interact not only with the His296, but also with the essential $Mg^{+2}$. This attack results in an electron transfer to His151 (general acid), by a penta-covalent intermediate, stabilized by $Mg^{+2}$, and the reaction ends by the liberation of ceramide (Obama *et al*., 2003a). Another essential residue is Asp195, which is thought to maintain the special arrangement of this acid-base catalyst. The His-Asp-His triad seems to be important because it is also found in the PI-PLC, which belongs to another enzyme family (Obama *et al*., 2003a).

***Phosphatydylcholine phospholipase (PC-PLC)***

The PC-PLC gene lies upstream of that of SM-PLC. This 245-aa $Zn^{+2}$ metalloprotein (28.5 kDa) provides the bacteria with a lecithinase activity but not a hemolytic activity. However, SM-PLC and PC-PLC can form an effective hemolytic complex, named cereolysin AB (CerAB). It is important to note that the α-toxin of *Clostridium perfringens* groups both activities in one gene coding for a 43-kDa protein. This observation suggests that either the intergenic space present in *B. cereus* has disappeared in *C. perfringens* or, conversely, that an intervening sequence has been inserted between the *B. cereus* genes (Gilmore *et al*., 1989). In mammalian cells, the diacylglycerol, one of the products formed by PC-PLC action, acts as a second messenger in signal transduction cascade, serving as an endogenous activator of protein kinase C (Exton, 1997). The *B. cereus* PC-PLC mimics this function when applied to eukaryotic cells (Diaz-Laviada *et al*., 1990), and expression of this toxin in fibroblasts leads to oncogenic transformation of the cells (Johansen *et al*., 1994).

The Glu4, Tyr56, and Phe66 residues of PC-PLC are present in the catalytic pocket, but are not directly involved in the catalytic process. They are components of the headgroup binding site. Mutagenesis experiments have suggested that these residues play a role in modulating substrate specificity of the enzyme. There is evidently a direct interaction between the aromatic ring of Phe66 and the substrate headgroup, especially choline and ethanolamine, since replacing this residue by another residue without an aromatic ring reduces the activity of the enzyme. The charge of residue Glu4 is important because a negatively charged residue increases choline and ethanolamine specificity, whereas a polar neutral or positively charged residue increases serine specificity. The presence of an aromatic residue at position 56 confers preference for a substrate with a positive headgroup (Antikainen *et al*., 2003).

***Phosphatydylinositol phospholipase (PI-PLC)***

The phosphatidylinositol phospholipase is a ubiquitous protein found in both eukaryotic and prokaryotic organisms. Indeed, in eukaryotes, degradation products of PI-PLC (diacyglycerol and inositol triphosphate) are signaling molecules, important in metabolic pathways (Gassler *et al*., 1997), such as activation of protein kinase C or intracellular calcium mobilization. The PI-PLC of *B. cereus* is frequently used as a model because it is smaller than its eukaryotic equivalent (Kuppe *et al*., 1989). However, the bacterial enzyme only accepts non-phosphorylated phosphatydylinositol and produces mainly cyclic inositol phosphate, whereas the mammalian enzyme prefers phosphorylated substrate and produces cyclic and non-cyclic inositol. Both proteins act by a general acid-base mechanism, but the mammalian enzyme uses $Ca^{+2}$ while the *B. cereus* PI-PLC does not use ions. In the active pocket, the location of the $Ca^{+2}$ is replaced by an arginine side chain. This residue stabilizes the transition state of the phosphoryl transfer reaction and facilitates the deprotonation of the 2-OH from the inositol ring (Kravchuk *et al*., 2003). Three residues (His82-Asp33-Arg69) are involved in the activation of the phosphate group and protonate the leaving group in a highly cooperative manner. The dyad Asp274-His32 serves as a general base. The H-bond between these two residues is a short strong hydrogen bond. This type of binding provides the stabilization energy needed for an intermediate or a transition state, as frequently seen in general acid-base catalytic mechanisms (Zhao *et al*., 2004).

The bacterial enzyme cleaves phosphatydylinositol in a rapid intramolecular transphosphorylation reaction to form diacylglycerol and D-myo-inositol-1,2-cyclic phosphate. In a second reaction, the cyclic phosphorylase activity of PI-PLC catalyzes the slow hydrolysis of the cyclic phosphate to D-myo-inositol-1-phosphate (Birrell *et al*., 2003). The enzyme activity of the first reaction is enhanced by non-substrate lipids, as phosphatidylcholine. The catalytic efficiency of the second step is enhanced by the addition of a water-soluble organic solvent, such as isopropanol, dimethylsulfoxide, and dimethylformamide and by phosphatidylcholine (Birrell *et al*., 2003; Wehbi *et al*., 2003).

Helix 42-48 and loop 237-243 of PI-PLC surround the rim of the catalytic pocket and contain a high number of hydrophobic residues exposed to the solvent. These residues penetrate in the lipid bilayer and stabilize the membrane-protein complex. Therefore, the membrane fluidity is important for the enzyme activity because the hydrophobic residues can penetrate more easily in the membrane bilayer and the complex is also more stable (Lehto and Sharom, 2002). The region at the top of the barrel rim contains two tryptophans

exposed to the solvent, which seem essential for protein binding to phosphatidylcholine and for the enzyme kinetic activation. The high number of acidic and basic residues at the surface of PI-PLC suggests the formation of enzyme aggregates. One mechanism for interfacial activation is the oligomerization of the enzyme at the lipid surface, providing the aggregate a higher activity than monomers (Zhang *et al*., 2004). So the raft formation allows a higher local concentration of substrate and increases the enzyme activity. The enzyme stays bound to the membrane for multiple catalytic turnover cycles (Lehto and Sharom, 2002).

The PI-PLC is a small enzyme of 35 kDa and 298 amino acid residues, monomeric with one active site and one subsite, which is an activator site causing an activity increase. So two substrate molecules can bind simultaneously to the enzyme. This is compatible with the interfacial activation model—the binding of the first phospholipids represents the initial step in the process that may lead to interfacial activation (Birrell *et al*., 2003). Finally, note that the PI-PLC gene is not grouped with the other two phospholipase genes and does not share similarity with them (Kuppe *et al*., 1989).

## Enterotoxins

*B. cereus* produces at least three different cytotoxins that can be involved in food poisoning (Table 46.1). The three toxins are hemolysin BL (Beecher and Macmillan, 1991; Heinrichs *et al*., 1993; Ryan *et al*., 1997), non-hemolytic enterotoxin (Lund and Granum, 1996; Granum *et al*., 1999), and Cytotoxin K (Lund *et al*., 2000). The suggested enterotoxin BceT (Agata *et al*., 1995) has just been shown to be a gene fusion product between a genomic *B. cereus* gene and a gene with homology to ORF101 in *B. anthracis* pXO1 (Hansen *et al*., 2003). Nothing is known about the role of enterotoxin FM in food poisoning, a "toxin" that has only been cloned without any biological characterization (Asano *et al*., 1997). However, enterotoxin FM has sequence homology to a cell wall hydrolase from *Bacillus subtilis* (Margot *et al*., 1998), and is probably not enterotoxic at all. The two latter proposed "toxins" are therefore not treated in this chapter.

Substantial work has been carried out on the occurrence of the three different enterotoxins in strains of *B. cereus*, and almost all strains (about 99%) contain *nhe*, about 50% contain *hbl*, and around 40% contain *cytK* (EU-project QLK-CT-2001-00854). There are two forms of CytK (Fagerlund *et al*., 2004) and only two strains have so far been found to harbor the original *cytK-1* gene (Granum *et al*., unpublished results). A mixture of the three toxins described above has been shown to not survive the stomach acid and proteolytic enzymes in the duodenum (Granum *et al*., 1993). Thus it seems likely that only when the toxins are produced and secreted in the small intestine during vegetative growth are they able to cause diarrhea, which is also supported by the fact that the incubation time is usually greater than eight hours (Granum, 2001).

All three enterotoxins from the *B. cereus* group are cytotoxic and cell membrane active toxins that will make channels or holes in the membranes (Granum, 2001). At high concentration, the membrane system will disintegrate.

### *Hemolysin BL (Hbl)*

Two of the three characterized enterotoxins from *B. cereus* have three components. The three-component hemolysin (Hbl; consisting of the B, L1, and L2 proteins) with enterotoxin activity was the first to be fully characterized (Beecher and Wong, 1994; Beecher and Wong, 1997). This toxin also has dermonecrotic and vascular permeability activities, and causes fluid accumulation in ligated rabbit ileal loops (Beecher *et al*., 1995). Although Hbl has been suggested to be a primary virulence factor in *B. cereus* diarrhea (Beecher *et al*., 1995), it should be stressed that about half of the food poisoning strains do not produce this enterotoxin (Guinebretière *et al*., 2002; Stenfors *et al*., 2002). It is also less toxic on epithelial cells than Nhe (Lund and Granum, 1997; Lindbäck *et al*., 2004). It has been shown that all three components are necessary for maximal enterotoxin activity (Beecher *et al*., 1995). It was first suggested that the B protein is the component that binds the Hbl complex to the target cells, and that L1 and L2 have lytic functions (Beecher and Macmillan, 1991). However, more recently another model for the action of Hbl has been proposed, suggesting that the components of Hbl bind to target cells independently and then constitute a membrane-attacking complex, resulting in a colloid osmotic lysis mechanism (Beecher and Wong, 1997). A 1:1:1 ratio of the three components seems to give the highest biological activity (Beecher *et al*., 1995). Substantial heterogeneity has been observed in the Hbl components, and individual strains produce various combinations of single or multiple bands of each component (Schoeni and Wong, 1999). This could be due to multiple genes of *hbl* with sequence variation, but this still needs to be established genetically.

The organization of the *hbl* operon is given in Figure 46.1. The reason for not starting with *hblA* is that the operon was cloned and sequenced in two different laboratories (Heinrichs *et al*., 1993; Ryan *et al*., 1997), and the sequence of the B-component (hblA) was published first. The proteins seem to be produced in close to a 1:1:1 ratio as judged from 2D gel studies (Gohar

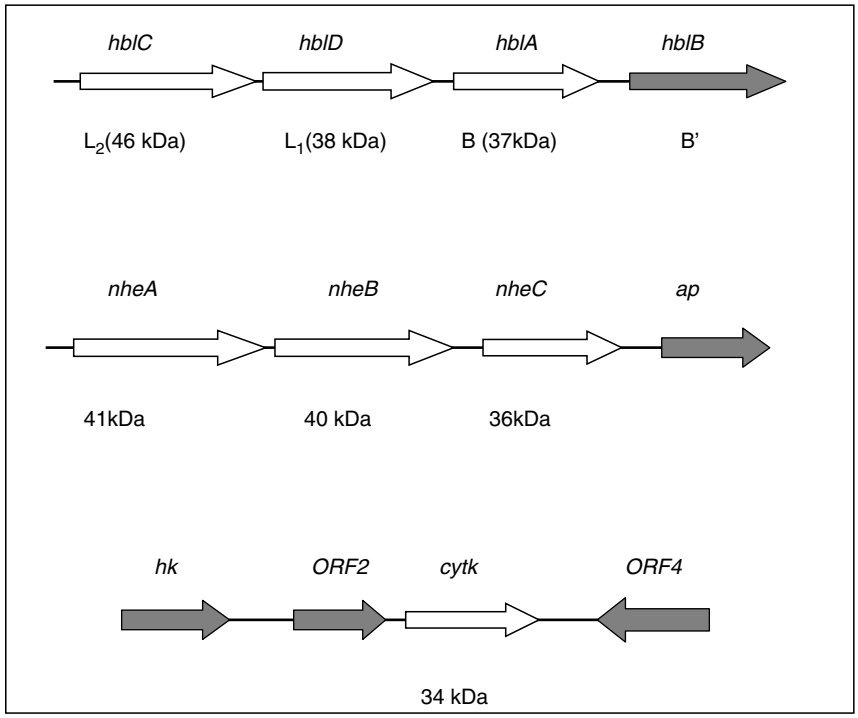

**FIGURE 46.1** Genetic organization of the three enterotoxins: *hbl*, *nhe*, and *cytK* (based on Heinrichs *et al*., 1993; Ryan *et al*., 1997; Granum *et al*., 1999; and Lund *et al*., 2000). The white arrows refer to the genes encoding the enterotoxins. There is an inverted repeat of 13 bp between *nheB* and *nheC*. An aminopeptidase gene (*ap*) is found about 600 bp downstream of *nheC*. *CytK* has an open reading frame (*ORF2*) upstream, encoding a protein of unknown function, and a histidine kinase (*hk*) further upstream. *ORF4* encodes for a long-chain-fatty-acid-CoA ligase (orientated in opposite direction to that of *cytK*). The arrowheads indicate the orientation of the genes. The name of the genes, proteins, and size of the toxin components are also indicated.

*et al*., 2002). HblB' is similar to hblB but its actual function is not known, and it is not necessary for biological activity (Lund and Granum, 1997). As the name suggests, the Hbl tri-component enterotoxin is also hemolytic, and since many papers have dealt with the properties of this protein complex, it will not be treated here.

### *The non-hemolytic enterotoxin (Nhe)*

A non-hemolytic, three-component enterotoxin (Nhe) was characterized after an outbreak involving 152 people caused by an *hbl* negative strain (Lund and Granum, 1996). These three components were different from those of Hbl, although there are similarities. A combination of the NheA and NheB components of this enterotoxin possess some biological activity after purification, but this is due to minor contamination with NheC that will always co-purify with the two other proteins (primarily with NheB) encoded by this operon (Figure 46.1) (Lund and Granum, 1997; Lindbäck *et al*., 2004). The optimal ratio between the NheA, NheB, and NheC components is 10:10:1, respectively (Lindbäk *et al*., 2004). It is also clear that it is not possible to find NheC alone in cell extracts after growth of *B. cereus* (Gohar *et al*., 2002; Lindbäck *et al*., 2004). Therefore, recombinant proteins have been used to establish the ratio between the different components (Lindbäck *et al*., 2004). An important observation is that a concentration of NheC higher than about 10% of that of NheA and NheB inhibited the toxic activity of Nhe (Lindbäck *et al*., 2004). All *B. cereus* strains seem to have an inverted repeat of 13 bp between *nheB* and *nheC* that probably contributes to (or determines) the transcribed/translated ratio between the three components. In some strains, even more complex repeated sequences have been recorded (Sekse and Granum: MSc thesis 2002, Norwegian Agriculture University). Such structures may either stabilize the mRNA upstream of *nheC* or reduce the efficiency of translational initiation since it is strongly correlated with the structure of the RBS (Schlax and Worhunsky, 2003).

Results from cell-binding experiments followed by Western immunoblotting have shown that NheB was the only individual component that bound to the Vero cells. Neither NheA nor NheC could be observed attached to the Vero cells. Also, if too much NheC is added to the reaction mixture on Vero cells, the cytotoxicity is reduced (Lindbäck *et al*., 2004). It looks as though NheC binds to NheB and prevents NheB from binding to receptors on the epithelial cells, thus reducing the total activity of the toxin complex (Lindbäck *et al*., 2004). Although we have no proof of the function of NheC, it seems likely that it functions as a "catalyst," either by bringing NheA and NheB together (after binding of NheB to the target cells) or by enhancing conformational changes to the complex components.

Although there are structural and sequence similarities between Hbl and Nhe, components from one complex cannot substitute for components from the other (Lund and Granum, 1997). The identity is highest in

the N-terminal third of the proteins. The most pronounced similarities are found between *nheA* and *hblC*, *nheB* and *hblD*, and *nheC* and *hblA*. This is not only in direct comparison of the sequences, but also in predicted transmembrane helices for the six proteins. NheA and HblC have no predicted transmembrane helices, while NheB and HblD have two each. Finally, NheC and HblA each have one predicted transmembrane helix in the same relative position (Granum *et al*., 1999).

Different types of experiments have indicated that Nhe contribute to about 80% of the cytotoxicity in strains of *B. cereus* (Märtelbauer *et al*., unpublished results). This is partly due to the difference in toxicity per weight unit (100 ng of Nhe is more toxic than 100 ng of Hbl), and partly due to differences in the production and secretion of the proteins.

### *Cytotoxin K (CytK)*

The newly discovered enterotoxin cytotoxin K (CytK), similar to the β-toxin of *C. perfringens* (and other related toxins), was the cause of the symptoms in a severe outbreak of *B. cereus* food-borne illness in France in 1998 (Lund *et al*., 2000). In this outbreak several people developed bloody diarrhea and three died. It would be fair to call this an outbreak of *B. cereus* necrotic enteritis, although it is not nearly as severe as the *C. perfringens* type C food poisoning (Brynestad and Granum, 2002). The amino acid sequence of CytK is similar (about 30% identity) to that of α-hemolysin (α-toxin, α-HL), leucocidins, and γ-hemolysin of *Staphylococcus aureus* and β-toxin of *C. perfringens*, which all belong to the family of β-barrel pore-forming toxins (Song *et al*., 1996; Prevost, 1999; Steinthorsdottir *et al*., 2000). The capacity to form pores in planar bilayers (Hardy *et al*., 2001) is consistent with CytK being a member of this family of proteins with pore-forming ability. It has been shown to be weakly anion selective and to exhibit an open channel probability close to one (Hardy *et al*., 2001). The predicted minimum pore diameter is approximately 7Å. CytK, like other β-barrel pore-forming toxins, spontaneously forms oligomers (heptamers), which are resistant to SDS, but not to boiling. These heptamers are able to form pores in planar bilayers and to kill erythrocytes, but have no cytotoxicity on epithelial cells (Fagerlund *et al*., 2004).

Two forms of CytK have been characterized, the original CytK (Figure 46.1; renamed CytK-1) and CytK-2 with a deduced amino acid sequence 89% identical to that of the original CytK-1. There are only marginal differences among variants of the *cytK-2* (97–99% identity in amino acid sequences) found in the majority of *B. cereus* strains (Fagerlund *et al*., 2004). Only two strains out of several hundred have the original *cytK-1* gene, and it is also organized in an identical manner on the chromosome/plasmid (P.E. Granum, unpublished results). CytK-1 is about five times more toxic on epithelial cells than CytK-2, but the activity on erythrocytes seems to be very similar. In the strain that killed three people in France, CytK-1 was the only protein present with cytotoxic activity towards epithelial cells. It is therefore tempting to speculate that CytK-1 forms ulcerative and hemorrhagic lesions in the intestine when secreted alone without the other two enterotoxins that result in watery diarrhea. Several strains that produce CytK-2 have also been reported to cause food poisoning without causing bloody diarrhea (Fagerlund *et al*., 2004).

The CytK-2 proteins show relatively high sequence similarity (39% identity) to the deduced product of *hly-II* (Baida *et al*., 1999). However, in aligning the deduced sequences of *cytK* and *hly-II*, 6% gaps are present, whereas none are observed when comparing CytK-1 and the CytK-2 proteins. Also, Hly-II is unlikely to contribute to food poisoning since there is a lysine residue at the end of the β-barrel loop penetrating the cell membrane. This will readily be cut by trypsin in the small intestine, and inactivate the toxin as for the *C. perfringens* β-toxin (Fagerlund *et al*., 2004).

## Hemolysins

### *Cereolysin AB (CerAB)*

As mentioned above, phospholipases PC-PLC and SM-PLC can act together to induce hemolytic activity, e.g., against human erythrocytes (Gilmore *et al*., 1989). This complex is named cereolysin AB.

### *Hemolysin II (Hly-II)*

The 412-residue Hly-II protein (45.6 kDa and 42.3 kDa without its signal peptide) displays about 30% identity with a toxin family called β-barrel pore-forming toxins, with α-hemolysin of *S. aureus* or CytK of *B. cereus* (see above) (Sinev *et al*., 1993; Baida *et al*., 1999). This family of heptameric toxins is characterized by two anti-parallel transmembrane and glycin-rich strands (Menestrina *et al*., 2001). Hly-II possesses 94 additional amino acids, in comparison with the other members of the toxin family. These residues do not seem to be essential to the activity, and the addition of this tail to the other toxins of the family does not cause problems. However, the specific activity of hemolysin II seems higher than that of the other β-barrel pore-forming toxins (Baida *et al*., 1999; Miles *et al*., 2002). The hemolysin II displays an important Arrhenius effect (regain of activity after a short increase of temperature up to 90–100°C), and a long lag period before appearance of hemolysis in the activity tests with blood-containing media (Sinev *et al*.,

1993). Distribution studies of the toxin in *B. cereus* and *B. thuringiensis* suggest that the toxin is most frequently found in *B. thuringiensis*, but its distribution remains limited (Budarina *et al*., 1994).

### *Hemolysin III (Hly-III)*

Hemolysin 3 is the least characterized hemolytic toxin from the *B. cereus* group. Its *hly-III* gene, cloned and characterized in *Escherichia coli*, is 657 nucleotides long and encodes a product with a calculated molecular mass of 24.4 kDa (Baida and Kuzmin, 1995). The toxin acts by oligomeric pore formation in three steps: the protein first binds to the erythrocyte surface, monomers are then assembled to form the transmembrane pore, leading to erythrocyte lysis. While the first two steps are temperature dependent, the final lysis is not (Baida and Kuzmin, 1996).

### *Cereolysin O (CLO)*

The cereolysin O (CLO, also named thuringiolysin O in *B. thuringiensis*, or anthrolysin O in *B. anthracis*) (Shannon *et al*., 2003) is a member of the cholesterol-binding cytolysins (CBC). This family groups cytolysins of certain pathogens, such as *Streptococcus pyogenes* (streptolysin O), *C. perfringens* (perfringolysin O), or *Listeria monocytogenes* (listeriolysin O). As the name indicates, they bind to cholesterol at the cell surface (Shany *et al*., 1974). They are inactivated by oxidation, but the addition of a reducing agent restores the activity. Most of the toxin family members possess one cysteine located in the most conserved, 11-aa domain of the protein (ECTGLAWEWWR). However, this cysteine does not seem to be essential to the toxin activity, whereas the tryptophan residues seem absolutely necessary. They are needed for the membrane insertion with their large hydrophobic core. The pore formed by CBC is more than 150 Å, which is about 50 monomers and permits the passage of large molecules (Palmer, 2001). Distribution studies on the cereolysin O gene have shown its ubiquity in all the *B. cereus s.l.* members. Moreover, the gene seems to be much conserved (more than 95% of identity) and does not differentiate the six species. It is also suggested that the gene is present in more than one copy in some strains (Michelet and Mahillon, unpublished results).

## REGULATION OF VIRULENCE FACTORS IN *B. CEREUS S.L.*

What do we know about the regulation of virulence genes of *B. cereus s.l. ?* One central pleiotropic transcriptional regulator (PlcR) has been characterized in the *B. cereus s.l.* by the group of Lereclus and colleagues. (Lereclus *et al*., 1996; 2000). It regulates the expression of a large number of virulence-related genes (possibly more than 100), among which some have been confirmed experimentally: *plcA* (PI-PLC), *plcB* (PC-PLC), *cerB* (SM-PLC), *hblCDA* (Hbl), *nheABC* (Nhe), *cytK*, *clo*, *colB* (collagenase), *sfp* (protease), and three metalloprotease genes *inhA2*, *nprB*, and *nprP2*.

It was shown that inactivation of the *plcR* gene caused drastic diminution of the pathogenic potential of *B. cereus* and *B. thuringiensis* in mice and insects (Salamitou *et al*., 2000). All the PlcR-regulated genes possess a palindromic consensus sequence (TATG-NANNNNTNCATA) found from 35 to 250 nucleotides before transcription starts (Agaisse *et al*., 1999). Some divergences of this palindromic sequence can arise without drastically affecting the PlcR activation. It is the case for the *cytK* gene (Brillard and Lereclus, 2004) and for *inhA2* encoding the InhA2 metalloprotease (Fedhila *et al*., 2003).

PlcR regulates its own expression, and downstream of the PlcR gene is a short ORF of 48 amino acids. This peptide (PapR for peptide activating PlcR) is secreted by the bacteria, processed extracellularly in a pentapeptide, and reimported into the cell by an oligopeptide permeation system (Opp A, B, C, D, and E), which is essential for PlcR regulation. PapR binds PlcR and promotes the fixation of the molecule to DNA. The regulation is controlled by the bacterial concentration (quorum sensing). In growth phase, low concentration of PapR does not allow the expression of PlcR regulon, while at the start of stationary phase, concentration increases and the *plcR* transcription is activated (Lereclus *et al*., 1996; Gominet *et al*., 2001; Slamti and Lereclus, 2002). An additional regulation mechanism involves Spo0A. Two fixation sites of Spo0A are found upstream from the *plcR* gene. In sporulation medium, Spo0A is activated and binds DNA, inhibiting the expression of *plcR*. So, in poor medium, *plcR* is blocked and virulence genes are not expressed. In rich medium, the transitory phase is long, and the expression of *plcR* is effective during this period, before the activation of Spo0A (Lereclus *et al*., 2000).

*B. anthracis* possesses an arsenal of virulence genes similar to those found in the other members of the *B. cereus* group. Yet, *B. anthracis* has a truncated *plcR* gene (Agaisse *et al*., 1999). So the PlcR regulon is not expressed, but it can be reactivated by the incorporation of active PlcR (Mignot *et al*., 2001). However, Pomerantsev *et al*., have constructed a plasmid with PlcR-PapR that did not activate the hemolytic genes (Pomerantsev *et al*., 2003). Conversely, a plasmid harboring a deletion in the PlcR and PapR intergenic region induced hemolytic activity without the PapR

secretion, processing, and reimportation (Pomerantsev *et al*., 2004).

Recently, the *B. anthracis* hemolytic genes were induced by strictly anaerobic conditions, suggesting an alternative regulatory mechanism for the expression of virulence genes (Klichko *et al*., 2003). It also seems that activating factors may be found in Brain-Heart-Infusion medium because hemolytic activity was found for *B. anthracis* growing in this medium compared to LB medium (Shannon *et al*., 2003). An alternative activation pathway is also suggested by the recent work on cereolysin O, which does not seem to follow the PlcR expression timing (Michelet and Mahillon, unpublished results).

Finally, an interesting *B. thuringiensis* mutant defective in swimming and swarming has been characterized. It lacked the peritrichous flagella found in the *B. cereus s.l.* family. This mutant is interesting because the absence of flagella was correlated with the absence of secretion of the Hbl and PC-PLC toxins. In fact, it is a mutation in the *flhA* gene that causes this phenotype. FlhA is involved in the export of structural protein of the flagellum. In the mutant, the flagella protein, as well as the Hbl and PC-PLC proteins, were expressed but not secreted. However, the thuringiolysin/cereolysin O, Hly-II, and Hly-III were apparently produced normally by these mutants (Ghelardi *et al*., 2002). Thus, the exact interconnections among these regulatory circuits (motility versus virulence) remain to be elucidated.

## CONCLUSION

The species belonging to the *B. cereus s.l.* group are genetically closely related (their 16S rRNA are almost identical), and the generic virulence determinants are largely distributed among them. Yet, they display a large spectrum of pathogenesis. Until now, the particular contribution of each of these virulence factors was not well understood. Which of them are involved in the different types of pathogenesis? Do they act independently or synergistically? Why do some species possess virulence genes without exploiting them, at least apparently? Are they non-functional or potentially active under certain conditions? These questions are particularly relevant because of the presence, in this group, of key bacteria. It is the case for *B. thuringiensis*, which is the most important biopesticide used for several decades in the control of insect pests or vector of human and animal diseases. Is this bacterium a potential human virulent agent?

*B. anthracis* represents another important issue because of the severity of the disease it causes. Although the inactivation of its transcriptional regulator PlcR has now been well documented, alternative regulatory pathways have been suggested. Do the other bacteria of the group possess these alternative solutions for virulence gene expression? Determination of the complete genome sequences of several *B. cereus s.l.* will certainly permit us to point out the diversity of the virulent genes and their regulatory sequences. Ultimately, however, the only way to unravel the precise role(s) of the toxins in pathogenesis will be to study mutants inactivated for (or strains lacking) individual or combinations of virulence factors.

# 47

# Uropathogenic *Escherichia coli* cytolysins

*Tobias A. Oelschlaeger and Jörg Hacker*

## INTRODUCTION

Uropathogenic *Escherichia coli* (UPEC) strains encode a variety of toxins. One toxin type is the cytolethal distending toxin. It is encoded by three genes (*cdtABC*) and blocks the cell cycle in G2 phase (Scott and Kaper, 1994). The block is due to keeping the mitosis promoting factor in an inactive form (Comayras *et al*., 1997). Another toxin type is CNF (cytotoxic necrotizing factor), for which two variants are known. CNF1 is chromosomally encoded, and CNF2 is plasmid encoded (Oswald *et al*., 1989). This toxin induces multinucleation in cell culture and causes necrosis in rabbit skin (De Rycke *et al*., 1990). Furthermore, CNF1 was shown to be an important virulence factor of UPEC and to activate Rho GTPases (Rippere-Lampe *et al*., 2001).

Another group of toxic proteins secreted by UPEC are members of the SPATE (serine protease autotransporters of *Enterobacteriaceae*) family (Dutta *et al*., 2002). Two SPATE types have been identified so far in UPEC. One is Sat (secreted autotransporter toxin), and the other is PicU (Parham *et al*., 2004; Guyer *et al*., 2000). All SPATE are characterized by the presence of a serine protease active site motif in the passenger domain, which is necessary for phenotypic functions. For Sat, vacuolation of target cells was demonstrated *in vitro* and *in vivo* (Guyer *et al*., 2002). However, most frequently UPEC produce a cytolysin toxin. Genetic analysis revealed that UPEC often contain the cytolysin A gene (*clyA*, *hlyE*, *sheE*). However, *clyA* of UPEC is non-functional in all UPEC strains tested, due to deletion(s) in the *clyA* locus. In contrast, a functional allele of *clyA* is present in many strains of intestinal *E. coli* pathotypes and even in *E. coli* K-12 strains (Ludwig *et al*., 2004). Therefore, the cytolytic activity of UPEC is not due to ClyA but to the expression of α-hemolysin.

This cytolysin is termed α-hemolysin because its cytolytic activity can be demonstrated easily by hemolysis. It is the prototype of the RTX (repeats-in-toxin) family of exoproteins produced by a diverse group of Gram-negative pathogens. Other members of this toxin family are the hemolysin of enterohemorrhagic *E. coli* (EhxA) (Schmidt *et al*., 1996), the leukotoxin of *Pasteurella haemolytica* (Strathdee and Lo, 1987), and the hemolysins and leukotoxins of *Actinobacillus* spp.(Welch *et al*., 1995). The toxins of this family are grouped on the basis of their specificity: Hemolysins exhibit little target cell specificity, while leukotoxins have pronounced species- or cell-specific effects. All of these toxins share up to 70% sequence identity with *E. coli* HlyA. Other characteristics shared by this toxin family are (i) post-translational modification, (ii) a C-terminal calcium-binding domain of acidic glycin-rich repeats, which has the consensus sequence GGXGXDX[L/I/V/W/Y/F] (X stands for any amino acid) and that has led to the RTX family nomenclature, and (iii) secretion by type I secretion systems (Koronakis and Hughes, 1996; Lilie *et al*., 2000). Posttranslational modification and calcium binding are absolute requirements for cytotoxic activity (Rowe *et al*., 1994; Ostolaza *et al*., 1995) of this toxin.

## GENETICS OF α-HEMOLYSIN

The generic RTX toxin operon consists of four genes. The genes required for hemolysis by UPEC are *hlyC*, *hlyA*, *hlyB*, and *hlyD* in transcriptional order (Hacker and Hughes, 1985). HlyC is responsible for the post-translational modification of HlyA by internal acylation of two lysine residue epsilon-amino groups. Hemolysin produced in the absence of HlyC is biologically inactive. HlyB and D are essential for HlyA secretion (Wagner *et al*., 1983). HlyB, an inner membrane traffic ATPase containing an ATP-binding cassette, is responsible for supplying the energy for the HlyA secretion and for the translocation across the inner membrane (Koronakis *et al*., 1995). The transport through the periplasm of HlyA is mediated by HlyD, a member of the membrane fusion proteins family. HlyD is anchored in the inner membrane and forms a channel connecting HlyB in the inner membrane and TolC in the outer membrane (Schlor *et al*., 1997). TolC is a general outer membrane protein that is part of at least four different export systems (Paulsen *et al*., 1997; Zgurskaya and Nikaido, 2000). The *hly*-determinant of UPEC is either encoded by transmissible plasmids or by chromosomally located pathogenicity islands, suggesting that this determinant can be transmitted by horizontal gene transfer among Gram-negative bacteria.

A well-studied example of an α-hemolysin encoding plasmid is pHly152 (Noegel *et al*., 1981). Furthermore, the determinant can be lost due to deletion of the whole pathogenicity island or plasmid, resulting in severely attenuated mutants (Knapp *et al*., 1986). Certain UPEC strains contain even two α-hemolysin determinants on two different pathogenicity islands (Nagy *et al*., 2000). This is the case for UPEC strain 536 (Blum *et al*., 1994), as well as for strain J96 (Blum *et al*., 1995; Swenson *et al*. 1996). Also for the third prototypic UPEC strain, CFT073, the α-hemolysin determinant is encoded by a pathogenicity island (Guyer *et al*., 1998). Typically, the pathogenicity islands are inserted in tRNA-genes. The α-hemolysin genes encoding pathogenicity islands of UPEC strain 536 are located in *selC* and *leuX*, of UPEC strain J96 in *pheV* and *pheR*, and in UPEC strain CFT073 in *metV* (Kao *et al*., 1997; Swenson *et al*., 1996; Blum *et al*., 1994). As a remnant of the probable phage origin, these pathogenicity islands each harbor also an integrase gene (Middendorf *et al*., 2004). The integrase is made responsible not only for the integration of the pathogenicity island after horizontal transfer, but also for deletion of the pathogenicity island by recognizing the direct repeats flanking this genetic unit.

## REGULATION OF α-HEMOLYSIN EXPRESSION

The expression of the α-hemolysin in *E. coli* is regulated by environmental signals. Most expression studies made use of plasmids pHly152 or pANN202-312 (Vogel *et al*., 1988; Welch and Pellet, 1988). The *hlyCABD* operon is transcribed from a promoter located upstream of *hlyC*, and several mechanisms are in place for its regulation. The transcription is strongly polar, owing to the presence of a rho-independent terminator in the *hlyA-hlyB* intergenic region (Welch and Pallett, 1988). This termination is suppressed by the elongation protein RfaH and a cis-acting 5′-DNA sequence termed the JUMPstart element or ops (operon-polarity suppressor) element, which must act together to allow the efficient transcription of the entire *hly* operon (Bailey *et al*., 1992). One important signal for regulation of *hly*-operon expression is temperature. Low temperature represses expression (Mourino *et al*., 1996). Another signal influencing *hly*-expression is osmolarity. The expression of the hemolysin genes is repressed when *E. coli* cells grow in a medium-to-high osmolarity medium (Carmona *et al*., 1993). Mediators of *hly* expression are H-NS and Hha. H-NS is a major component of the bacterial nucleoid and plays a central role as a modulator of gene expression in response to osmolarity and temperature changes (Atlung and Ingmer, 1997). It binds preferentially to curved DNA and is able to generate bends in non-curved DNA, thereby affecting the expression of a large number of genes, and it is considered a general negative transcriptional regulator (Hommais *et al*., 2001). H-NS binds *in vitro* more efficiently to sequences upstream of *hlyC* at low temperature, correlating with the more efficient transcriptional repression caused by H-NS at low temperature and with the hemolytic phenotype of *hns* mutants (Madrid *et al*., 2002).

The two binding sites for H-NS are located upstream of *hlyC*. One of them, more than 1.5 kb upstream of *hlyC*, is within the regulatory sequence termed *hlyR*, which contains an antiterminator element (the *ops* element). Deletion of *hlyR* results in strong repression of hemolysin expression (Vogel *et al*., 1988; Nieto *et al*., 1996). The other H-NS binding site is close to *hlyC*, partially overlapping the promoter region of the *hly* operon. The role of the *IS*2 element separating both H-NS binding sites remains unclear, since no *hly* promoter function has been assigned to this element and its deletion has only a moderate effect on *hly* transcription, which is most likely due to the resulting topological modifications (Madrid *et al*., 2002). The Hha protein belongs to a family of modulators, which include the

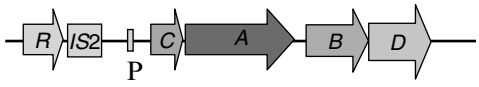

**FIGURE 47.1** Physical map of the α-hemolysin determinant. Arrows indicate open reading frames/genes for the regulatory sequence (*R*), the activator gene (*C*) responsible for internal acylation of the α-hemolysin encoded by *hlyA* (*A*), the gene for the inner membrane ATPase (*B*) and the gene for the membrane fusion protein (*D*). The orientation of the arrows reflects the direction of transcription. *IS*2: Insertion sequence 2; P: promoter.

YmoA protein of *Yersinia enterocolitica*, regulating expression of different virulence factors in a temperature-dependent manner (Cornelis *et al*., 1991). Hha interacts with H-NS, and this complex is an important component in the thermo-osmotic regulation of the *hly* operon. This view is supported by the observation of loss of both thermo- and osmoregulation in *hha/hns* double mutants (Nieto *et al*., 2000). Expression of Hha itself is modulated by osmolarity in that its expression reaches a maximum in the exponential growth phase in LB medium, but depletion of NaCl leads to a significant decrease in expression (Mourino *et al*., 1998). The Hha/H-NS complex bound to both H-NS binding sites could occlude the *ops* sequence and the promoter region as well, thus repressing transcription and abolishing the antitermination effect of *ops* (Madrid *et al*., 2002). However, the Hha- and H-NS-mediated repression of the *hly* operon is not an on-off process but rather a gradual one. This conclusion is drawn from the observation of an increase in α-hemolysin production by hns mutants grown under 37°C compared to isogenic wild-type strains grown under identical conditions (Nieto *et al*., 2000). Obviously, the H-NS- and Hha-regulated repression of α-hemolysin synthesis is influenced by different environmental factors that cause variations in the physicochemical parameters of DNA or sequestering or degradation of H-NS.

## ACTIVATION OF α-HEMOLYSIN

The HlyA toxin is synthesized as an inactive 1,024-residue protoxin, pro-HlyA, which is activated intracellularly in the HlyA-producing bacterial cell to the mature toxin by the action of the co-synthesized HlyC. HlyC is a homodimeric acyltransferase using acyl-acyl carrier protein (acyl-ACP) as the fatty acid donor. Indeed, two internal fatty-acylated lysine residues, K564 and K690, were identified, and resistance of the acylation to hydroxylamine suggested that the fatty acid is amide linked. Acylation of both sites is required for *in vivo* toxin hemolytic activity (Stanley *et al*., 1994; Stanley *et al*., 1996). Also, the other HlyA-related toxins secreted by pathogenic Gram-negative bacteria all require HlyC-type protoxin activation and many (PvxA, MmxA, ApxIA, and LktA) have been activated by *E. coli* HlyC (Forestier and Welch, 1990; Gygi *et al*., 1990; Koronakis *et al*., 1987). The ability of HlyC to transfer an acyl group to an internal lysine residue or a target protein distinguishes HlyC from all other bacterial acyltransferases. This is strongly supported by the fact that *hlyA*$^+$*hlyC* strains are non-hemolytic, despite the various constitutive acyltransferases present in *E. coli*, which are obviously unable to substitute for HlyC to even a small degree. This uniqueness is also reflected in the lack of significant sequence homology of HlyC with known acyltransferases, such as the lipid A acyltransferases (Clementz *et al*., 1997). Myristoyl-ACP gave the highest hemolytic activity of HlyA acylated *in vitro* with a range of fatty acids and *in vivo* HlyA is indeed predominantly myristoylated (Issartel *et al*., 1991; Ludwig *et al*., 1996). Two independent HlyC recognition domains have been identified on pro-HlyA, each of which spans one of the target lysine residues (Stanley *et al*. 1996). Although both HlyC recognition domains of HlyA have the same function, there is surprisingly little primary sequence identity (only 21%). The lack of identity between both recognition domains in pro-HlyA and corresponding sites on related protoxins currently deters an explanation for basis of HlyA recognition by HlyC. It is worth mentioning that both membrane immunoglobulin and insulin receptors appear to possess identical amide-linked, internal fatty acylation, as found on HlyA. In addition, the Ras and Src componentsof these signaling pathways, and the heterotrimeric G-proteins and their coupled receptors, all have acylated residues (Stanley *et al*., 1998). It is therefore speculated that cytokine-inducing proteins produced by bacteria as HlyA are the evolutionary precursors of mammalian cytokines (Henderson *et al*., 1996).

## THE α-HEMOLYSIN SECRETION SYSTEM

Pro-HlyA is synthesized and activated in the cytoplasm of the bacterial cell and subsequently secreted across both membranes. The secretion system of α-hemolysin is the prototype of type I secretion systems. Type I secretion systems are characterised by (i) containing only three different transport components, two in the inner membrane, which are specific for the passenger protein (here HlyA), and one that forms a general pore in the outer membrane; (ii) these proteins

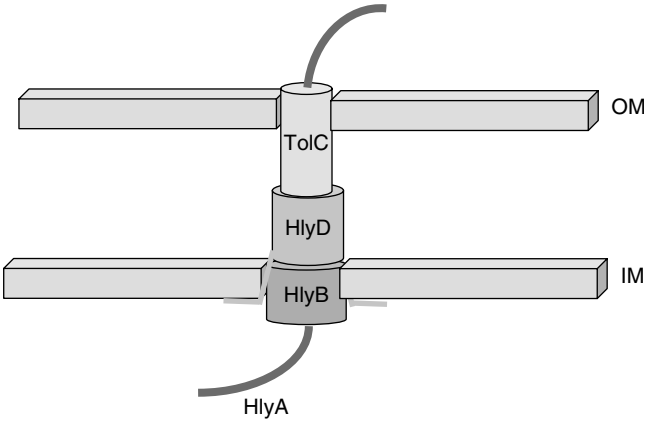

**FIGURE 47.2** Model of the α-hemolysin export apparatus. After interaction of HlyA with HlyB and HlyD, the inner membrane ATPase HlyB, the membrane fusion protein HlyD, and the outer membrane protein TolC connect and form a channel-tunnel for the secretion of HlyA. OM: outer membrane; IM: inner membrane.

form a tunnel that links the inner and outer membrane; (iii) the passenger proteins are secreted directly into the extracellular medium without the formation of periplasmic intermediates; (iv) the secretion signal recognized by these secretion systems are located at the C-terminus of the secreted protein; (v) in general, the secretion signal is not cleaved off during or after secretion (for a recent review see Andersen 2003).

The activation by acylation is not necessary for secretion of HlyA, because pro-HlyA is secreted as efficiently as mature HlyA (Ludwig *et al*., 1987). The HlyA secretory apparatus comprises HlyB (an inner membrane traffic ATPase), HlyD (an inner membrane protein that bridges the periplasm by connecting the inner with the outer membrane), and TolC (an outer membrane protein). In *E. coli*, as in most other pathogens, TolC is encoded by a gene separated from the *hlyCABD* operon (Gentschev *et al*., 2002).

The first component, HlyB, of the hemolysin type I secretion system belongs to the ATP-binding cassette (ABC) superfamily of eukaryotic and prokaryotic protein transporters (Holland and Blight, 1999). This inner membrane protein couples ATP hydrolysis to the export of the substrate. Experimental data obtained suggest that HlyB is inserted in the inner membrane by eight hydrophobic α-helical transmembrane domains. These transmembrane domains extend from amino acid positions 39 to 432 of HlyB (Koronakis *et al*., 1995; Gentschev and Goebel, 1992).

The second component (HlyD) is one of the best-characterized members of the membrane fusion protein (MFP) family. HlyD is anchored in the cytoplasmic membrane by a single transmembrane domain and possesses a large periplasmic domain within the carboxy-terminal 100 amino acids, which are highly conserved among MFPs (Schülein *et al*., 1992). A recent study grouped the members of the MFP family within the superfamily of periplasmic efflux proteins (PEP) (Johnson and Church, 1999).

The third component (TolC) is a general outer membrane protein (OMP) that is part of at least four different export systems (Zgurskaya and Nikaido, 2000). The crystal structure of TolC shows that its trimeric state forms a trans-periplasmic channel-tunnel with an internal diameter of 35 Å and is about 140 Å in length, comprising a 40 Å-long OM β-barrel (the channel domain) anchoring a contiguous 100 Å-long α-helical barrel that projects across the periplasmic space (the tunnel domain) (Koronakis *et al*., 2000; Andersen *et al*., 2001).

HlyA carries a C-terminal secretion signal located with the last 50–60 amino acids. The precise nature of the secretion signal remains basically unknown. However, a peptide consisting of just the C-terminal 60 amino acids of HlyA is secreted in the presence of HlyB-HlyD-TolC with the same efficiency as HlyA itself. In contrast, in some other type I–secreted proteins, the repeats within these proteins are required for efficient secretion (Jarchau *et al*., 1994).

## RECEPTOR(S) AND MECHANISM(S) OF ACTION

The term hemolysin for α-hemolysin of *E. coli* was coined because of the ability of mature HlyA to efficiently lyse erythrocytes; even so, α-hemolysin is able to lyse a great variety of cell types from various hosts. It is also suggested that leukocytes are the main target for α-hemolysin. This finding made it hard to imagine a receptor for α-hemolysin (e.g., on erythrocytes), despite the general rule for bacterial toxins to possess domains for target cell recognition. However, for the HlyA-sensitive HL-60 cell line, two polypeptides were identified (CD11a and CD18) to which HlyA binds, and a monoclonal antibody specific for these polypeptides protected HL-60 cells from the cytolysis by HlyA. CD11a and CD18 are subunits of lymphocyte-function-associated antigen 1 (LFA-1), a $\beta_2$ integrin that is found in circulating leukocytes, but not on cells of non-hematopoetic origin. On erythrocytes, glycophorin, present in high numbers in the cytoplasmic membrane of this cell type, has been identified as the receptor for HlyA (Cortajarena *et al*., 2001). Furthermore, the corresponding receptor-binding domain in α-hemolysin was identified as the region comprising residues 914 to 936 in HlyA. A deletion mutant of HlyA lacking these residues showed a hemolytic activity 10,000-fold decreased compared to the wild-type (Cortajarena *et al*., 2003).

Lysis of target cells, e.g., erythrocytes, occurs via formation of transmembrane pores in the cytoplasmic membrane (Bhakdi *et al*. 1986). The pores seemed to be formed by oligomeres of HlyA (Benz *et al*., 1989). In addition, the identification of several different functional regions responsible for pore formation, calcium-dependent membrane binding, and pore stability were reported. The C-terminal half of HlyA contains 12 repeats of the consensus nonapeptide X-Leu-X-Gly-Gly-X-X-Gly-Asp-Asp-Asp. The repeat sequence (residues 739–849) represents the $Ca^{2+}$-binding domain and is essential for function. Eight transmembrane segments of the hydrophobic region of HlyA were predicted to be part of the pore-forming structure (Ludwig *et al*., 1988; Ludwig *et al*., 1991). The HlyA pores were reported to be cation-specific with an inner diameter of 1–2 nm (Benz *et al*., 1989). Pore formation was further supported by direct visualization in model systems and by path clamp characterization with human macrophages (Menestrina *et al*., 1996).

This view of α-hemolysin action was challenged by Soloaga *et al*. (1999). They presented data supporting a model for the membrane-inserted HlyA to occupy only the outer layer of phospholipids of the host cell cytoplasmic membrane and not to form a transmembrane pore. The insertion into the outer layer of the membrane is mediated by 10 amphipathic helices of HlyA. This interaction would also lead to cell leakage or lysis of host cells by inducing an increase in the lateral pressure in the outer monolayer of the membrane lipids. Beyond a certain increase, the monolayer will reach a point of transient breakdown and subsequent leakage of contents (Soloaga *et al*., 1999).

Whatever model for HlyA interaction with host cell membranes comes closest to reality, the effects of the interaction is more than just cell lysis. The release of inflammatory mediators from human polymorphonuclear granulocytes as $O_2^-$ and β-glucuronidase, as well as leukotriene generation, was reported by König *et al*. (1999). In addition, these authors demonstrated histamine release from human lymphocyte/monocyte basophil cells and serotonin release and 12-hydroxyeicosatetronic acid generation from human platelets. All these effects were dependent on wild-type α-hemolysin and not observed with HlyA-mutants deficient in pore-forming activity (König *et al*., 1994). In addition, HlyA induced massive shedding of receptors for interleukin 6 (IL-6R) and lipopolysaccharide (CD14). Shedding was not PKC-dependent (Walev *et al*., 1996). Trans-signaling by soluble IL-6R and soluble CD14 is known to dramatically broaden the spectrum of host cells for IL-6 and lipopolysaccharide and is thus an important mechanism underlying their systemic inflammatory effects. Hence, these findings highlight a mechanism by which HlyA can promote inflammatory processes. More recently, HlyA was demonstrated to induce low-frequency oscillatory $[Ca^{2+}]_i$ response in target primary rat renal epithelial cells. The observed response depended on calcium influx through L-type calcium channels, as well as from internal stores gated by inositol triphosphate. Internal calcium oscillations induced in a renal epithelial cell line stimulated production of cytokines interleukin 6 and interleukin 8. Obviously, α-hemolysin can act as an inducer of an oscillating second messenger response in target cells, e.g., kidney cells, and thereby fine-tune gene expression during the inflammatory response (Uhlen *et al*., 2000).

## CONCLUSION

The α-hemolysin of UPEC seems to be important for urinary tract infections by UPEC. However, the *hly*-determinant is also found in a considerable number of fecal *E. coli* isolates, which express the α-hemolysin, at least *in vitro*. It has been intensively studied by several research groups for the past few decades, but many questions regarding its activation, secretion, and mode of action are still open. Why is acylation of HlyA essential for its hemolytic action? What is the nature of the C-terminal secretion signal? Does HlyA really form pores in host cell membranes? How can HlyA have so many different effects on host cells? More effort will be needed to answer these and other questions regarding HlyA. These answers will not only further our academic knowledge, but will form the basis for more efficient treatment and hopefully the prevention of urinary tract infections.

CHAPTER

# 48

# *Escherichia coli*, *Vibrio*, and *Yersinia* species heat-stable enterotoxins

*J. Daniel Dubreuil*

## INTRODUCTION

Pathogenesis manifestation of enteric pathogens represents a complex and coordinated expression of several virulence factors. These factors enable the bacterial pathogen to breach host defenses to effectively colonize its niche. Among many proteins elaborated during such processes, the heat-stable enterotoxins (STs) are important molecules involved in the diarrhea resulting from such infections in humans and animals. The heat-stable toxins comprise a family of cysteine-rich peptides elaborated by various bacterial species, of whom many are more or less related structurally and functionally. Diarrhea induced by STs is of the secretory type involving the small intestine with no signs of inflammation.

ST was first described in enterotoxigenic *Escherichia coli* (ETEC). Based on structure-function, the ETEC STs are divided into two distinct types, namely STa (or STI) and STb (or STII) (Burgess *et al*., 1978; Weikel and Guerrant, 1985). STa differs from STb by its resistance to proteases, its solubility in methanol, and its activity in the suckling-mouse model. On the other hand, STb is particularly sensitive to proteolysis, insoluble in methanol, and was shown to be active solely in weaned piglets. Addition of protease inhibitors to the tested sample was later shown to render other animals (i.e., rats, mice, rabbits, and calves) sensitive to STb (Whipp, 1990, 1991). In enteroaggregative *E. coli* (EAEC), a heat-stable toxin was identified. This toxin coined EAST1 has been shown to cause diarrhea principally in humans. EAST1 is often compared to STa as it shows structural similarities, as well as an increase in the synthesis of the same signaling molecule.

Apart from *E. coli*, other enteric bacteria produce ST toxins (Figure 48.1). These include strains from *Vibrio cholerae* O1 producing O1-ST (Takeda *et al*., 1991a; Mallard and Desmarchelier, 1995), *V. cholerae* non-O1 or non-O139 serotypes producing NAG-ST (Takao *et al*., 1985a; Arita *et al*., 1986), H-ST from Hakata strains of *V. cholerae* non-O1 (Arita *et al*., 1991a), and *Vibrio mimicus* producing M-ST (Arita *et al*., 1991b; Yuan *et al*., 1994; Ramamurthy *et al*., 1994). *Yersinia enterolitica* produces Y-ST with subtypes Y-STa, Y-STb, and Y-STc (Takao *et al*., 1984; Delor *et al*., 1990; Huang *et al*., 1997; Ramamurthy *et al*., 1997). In addition, Yk-ST is elaborated by *Yersinia kristensenii* (Delor *et al*., 1990; Ibrahim *et al*., 1992), C-ST from *Citrobacter freundii* (Guarino *et al*., 1987a, 1989a), and ST-like toxin by *Klebsiella pneumoniae* (Guarino *et al*., 1989b).

## DISEASES CAUSED BY *E. COLI*, *YERSINIA*, AND *VIBRIO*

ETEC are a major cause of diarrheal disease in humans and animals. They are responsible for diarrhea by production of two distinct types of enterotoxin: the heat-labile (LT) toxin with two subtypes (LTI and LTII) and a family of heat-stable (ST) enterotoxins. LT is a high-molecular-mass toxin (85 kDa) with two subtypes (LTI and LTII) functionally and structurally related to

**FIGURE 48.1** Primary sequences of *Escherichia coli* STaH and STaP compared to other heat-stable enterotoxins of bacterial origins (including *Vibrio*, *Yersinia*, and *Citrobacter*). The sequence *of Conus geographus*, $\alpha$-conotoxin $G_I$, is also represented as it demonstrates some homology to STa. Guanylin and uroguanylin sequences of human and rat origin are also aligned for comparison purposes. The number of amino acids comprised in the mature molecules is indicated. In bold are represented the consensus sequence found in most heat-stable toxins. In the box, the consensus N-P-A-C sequence conserved at least partially between all the molecules appearing in the figure.

*V. cholerae* enterotoxin (Sprangler, 1992). STs of two types are produced (STa and STb). Some strains may produce one or both of these types of toxins. Colonization of the intestinal mucosa allows for the localized delivery of these enterotoxins. The biological activities lead to net fluid secretion occurring in the jejunum and ileum, with a greater fluid loss in the jejunum resulting in a watery diarrhea characteristic of ETEC infection. About 46% of ETEC isolates express STa alone, 25% express LT alone, and 29% express both STa and LT (Wolf, 1997). EAST1 originally isolated from an EAEC strain has been proposed to be implicated in the pathogenesis of EAEC leading to diarrhea. EAEC strains harboring *astA* gene, coding for EAST1 toxin, as the only identified virulence factor have been associated with outbreaks and sporadic cases of diarrhea (Itoh *et al*., 1997; Kawano *et al*., 1998; Zhou *et al*., 2002). EAST1 was proposed as another possible cause of traveler's disease (Gascon *et al*., 1998; Vila *et al*., 2000).

*V. cholerae* is the causative agent of cholera. Of the numerous serotypes, only serotypes O1 and 139 are associated with the disease known as cholera. The other serotypes known as non-O1 non-O139 are recognized as the etiological agents of gastroenteritis and some extraintestinal infections. Sometimes, the clinical features of diarrhea caused by non-O1 non-O139 serotypes cannot be distinguished from cholera (Morris *et al*., 1990). Some strains of *V. cholerae* O1, V. *cholerae* non-O1 (Hakata strains), and *V. mimicus* produce ST and have been implicated in diarrheal disease (Takeda *et al*., 1991a; Arita *et al*., 1991a; Ramamurthy *et al*., 1994). *V. mimicus*, another human pathogen, produces a ST responsible for cases of diarrhea. It was determined that *V. mimicus* is the reservoir of the ST gene (*stn*) (Yuan *et al*., 1994).

*Yersinia enterolitica* is a well-established enteric pathogen capable of causing a variety of clinical disorders in humans. While diarrhea is the most commonly recognized clinical manifestation, it can also be responsible for invasive diseases like mesenteric lymphoadenitis, ileitis, and septicemia. It can also be associated with various autoimmune manifestations, including

arthritis and erythrema nodosum (Cover and Aber, 1989). Production of Y-ST by *Y. enterolitica* is postulated to be important in the pathogenesis of watery diarrhea. Its production depends on culture medium, temperature, and growth phase (Boyce *et al*., 1979; Delor *et al*., 1990; Amirmozafari and Robertson, 1993). In commonly used culture media, Y-ST is detected only when the temperature is below 30˚C. This finding was difficult to reconcile with diarrhea sustained for long periods at body temperature. We now know that production of Y-ST can be observed at 37°C, when the osmolarity and pH of the culture medium are similar to those of the intestinal environment (Mikulskis *et al*., 1994). The biological expression of Y-ST is detected using the suckling mouse assay (Pai and Mors, 1978).

## *E. COLI* STa ENTEROTOXIN

### STa polypeptide

STa represents a family of toxins of approximately 2,000 Da composed of a single peptide chain (Dreyfus *et al*., 1983; Thompson and Gianella, 1985). Toxins produced by human (STaH) and porcine (STaP) strains differ slightly. The STaH primary structure comprises 19 amino acid residues compared with 18 for STaP. The amino acid sequences of the two toxin subtypes are not identical (Figure 48.1). To date, STaP polypeptide has been observed in isolates from animals species including pigs, calves, lambs, chickens, and horses and also from humans. In contrast, STaH is produced solely by human isolates. These toxins share a highly conserved sequence of 15 amino acid residues, which reside in the carboxy-terminus. This sequence represents a common antigenic determinant. The amino-terminal amino acids to the first cysteine can be cleaved from the molecule and the remaining peptide is fully active (Staples *et al*., 1980).

Both toxins are synthesized as larger precursors (propre-STa) that are subsequently cleaved to the active mature toxin. Six cysteine residues involved in disulfide bond formation are present at the same position in both STaH and STaP (Figure 48.2). The tertiary structure formed by the disulfide bonds is critical and required for full biological activity (Okamoto *et al*, 1987). Chemically synthesized STa behaves in a similar manner to ETEC-produced STa (Gyles, 1994; Takeda *et al*., 1991b).

Native STa toxins are poorly immunogenic. However, they can be conjugated to carrier proteins in order to produce polyclonal antisera and monoclonal antibodies (Aitken and Hirst, 1993; Brandwein *et al*., 1985). The toxicity of STaH and STaP can be neutralized by homologous but also by heterologous antisera (Takeda *et al*., 1983).

### Biochemical characteristics

STa enterotoxin is a heat-stable molecule, and its small size is responsible for this biochemical characteristic. It is an acidic peptide with a pI of 3.98 (Dreyfus *et al*., 1983). The molecule is soluble in water and organic solvents, including methanol, and resistant to several proteases, such as pronase, trypsin, and chymotrypsin. It is resistant to acidic but not to basic pH. The toxin is completely inactivated by reducing and oxidizing agents, which disrupt disulfide bonds (Dreyfus *et al*., 1983).

### *estA* gene

The genes encoding STa are found on plasmids of varying molecular sizes (Harnett and Gyles, 1985). For animal ETEC isolates, it is common to find gene coding for STa, colonization factor, drug resistance, and production of colicin on the same plasmid. For human isolates, the same plasmid was shown to carry *estA* and an antibiotic resistant gene (Gyles *et al*., 1977; Echeverria *et al*., 1978). Genetic studies demonstrated the existence of two types of *estA*. The gene was first cloned from a bovine isolate (STaP) and shown to be part of a transposon (Tn *1681*) that is flanked by inverted repeats of IS*1* (So and McCarthy, 1980). STaP genes from ETEC isolated from other animal species (including humans) are also part of the same transposon (Sekizaki *et al*., 1985). Genes encoding STaH and STaP may be carried by a single human ETEC strain. Synthesis of STa by *E. coli* is subject to catabolite repression, and optimal yields of toxin are obtained in glucose-free media (Alderete and Robertson, 1997a, 1977b; Stieglitz *et al*., 1988). A study by Sommerfelt *et al*. (1989) revealed that loss of STa production is the result of deletions of DNA fragments harboring the toxin gene rather than loss of plasmids.

### Secretion of STa and formation of disulfide bonds

STa is produced as a 72 amino acid precursor molecule referred to as pre-pro-STa (Stieglitz *et al*., 1988; Okamoto and Takahara, 1990). The 72 amino acid polypeptide consists of a 19 amino acid signal peptide (pre-STa), a 35 amino acid pro sequence, and then an 18 or 19 amino acid mature STa (Figure 48.2B). Whereas the pro-STa is translocated accross the cytoplasmic membrane and seems to require *secA*-dependent transport, the signal sequence is cleaved by peptidase 1 (Rasheed *et al*., 1990). Yamanaka and Okamoto (1990) subsituted the charged amino acids at positions 29 to 31 of the pro-region of STa. Hydrophobic or basic residues significantly reduced STa translocation across

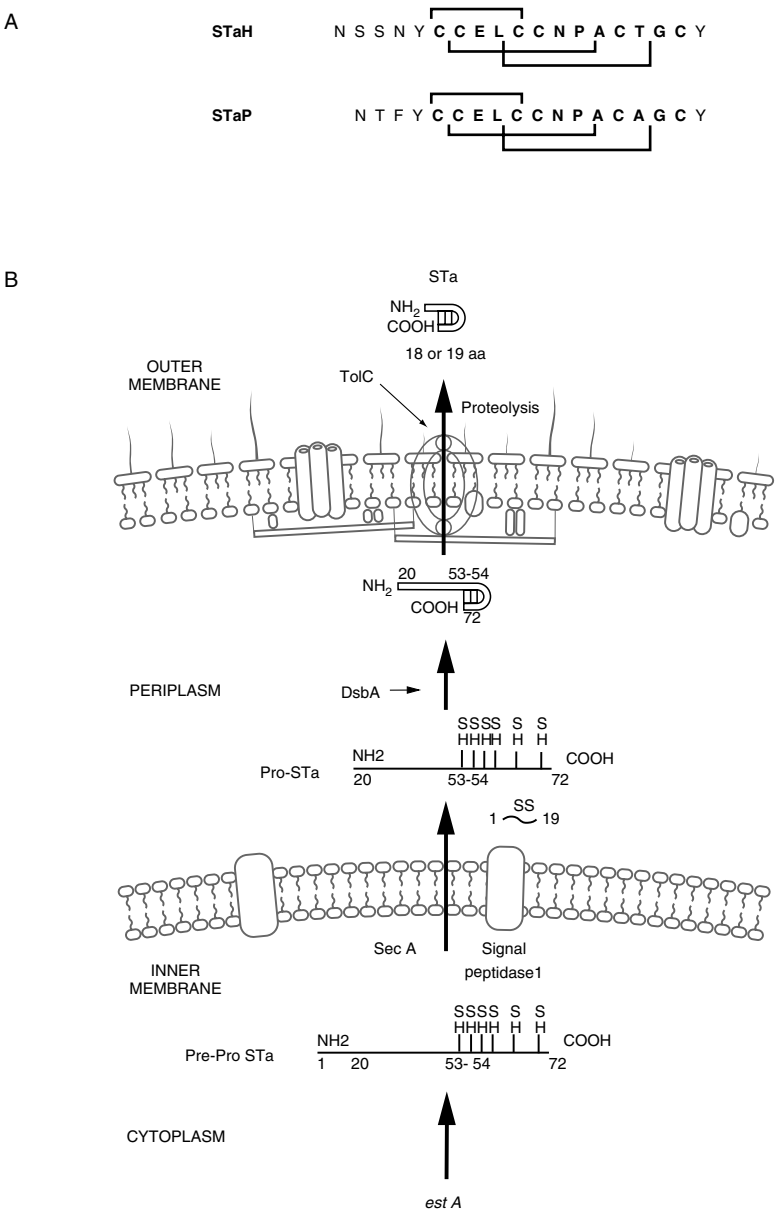

**FIGURE 48.2** A) Primary sequences of STaH and STaP showing the disulfide bond structure. In bold, the 13 amino acid residues constituting the toxic domain. B) Disulfide bonds formation and secretory pathways, as determined for STa toxin.

the inner membrane, indicating that a net negative charge near amino acid 30 is important for efficient translocation. The pro-region was shown to guide STa into the periplasmic space (Yamanaka *et al*., 1993). However, this region does not seem to be involved in transport of the peptide extracellularly (Okamoto and Takahara, 1990).

In the periplasm, the three intramolecular disulfide bonds, important for toxicity, are formed by DsbA protein prior to secretion (Okamoto *et al*., 1995; Yang *et al*., 1992; Sanchez *et al*., 1993). In the pro-region, the cysteine-39 residue is important for the correct recognition by DsbA and proteases during maturation of STa (Yamanaka *et al*., 1994). A negative charge at position 7 in mature STaP (Glu) was shown to be required for toxin interaction with DsbA in the periplasm and formation of the intramolecular disulfide bonds *in vivo* (Yamanaka *et al*., 1998b).

A second proteolysis event occurs extracellularly, owing to an undefined protease, to produce biologically active 18 and 19 amino acids STa (Rasheed *et al*., 1990). STa toxin is secreted from the cell as it is synthesized and is not cell-associated. Mature STa diffuses across the outer membrane (Yamanaka *et al*., 1994; Yang *et al*., 1992). TolC is involved in the crossing of the outer membrane as STa was not secreted by a TolC-deficient strain (Yamanaka *et al*., 1998a). Yamanaka *et al*. (1997) demonstrated, by mutating every cysteine

residue of STa, that the formation of the three intramolecular disulfide bonds is not absolutely necessary for the mature toxin to pass through the outer membrane.

The three intramolecular disulfide bonds in STaH link cysteines 6 and 11, 7 and 15, and 10 and 18; in STaP disulfide bonds link cysteines 5 and 10, 6 and 14, and 9 and 17 (Figure 48.2A). The use of STa analogues demonstrated that the second disulfide bond was essential for toxicity, but analogues lacking the first or the third disulfide bond showed only a reduced toxicity (Hidaka *et al*., 1991). In conclusion, the disulfide bonds between cysteines 7 and 15 of STaH or 6 and 14 of STaP are essential for biological activity.

## Structure of STa and identification of the toxic domain

The three-dimensional structure of STa was determined using nuclear magnetic resonance spectroscopy and x-ray crystallography. The tertiary structure consists of a folded peptide backbone assembled as a right-handed spiral from the first cysteine at the $NH_2$-terminus to the last cysteine residue at the COOH-terminus (Ozaki *et al*., 1991). Three β-turns are located along this spiral and are stabilized by the three intramolecular disulfide bonds (Gariépy *et al*., 1986, 1987). The disulfide bonds are responsible for the spatial structure of STa and this 3D structure is required for toxicity. The STa molecule appears to be hydrophobic, but there are three hydrophilic areas (i.e., $Cys^6$–$Leu^8$, $Cys^{10}$–$Asp^{11}$, and $Pro^{12}$–$Cys^{17}$) in STaP (Ozaki *et al*., 1991).

Overall, a 13 amino acid sequence from the amino-terminal cysteine to the carboxyl-terminal cysteine is essential for toxic activity of both STaH and STaP (Yoshimura *et al*., 1985; Carpick and Gariépy, 1991; Waldman and O'Hanley, 1989). Thus, this segment constitutes the toxic domain of STa (Figure 48.2A). For this region, a striking identity is shared with other heat-stable enterotoxins secreted by other enteric pathogens such as *Citrobacter freundii, Yersinia enterolitica, Vibrio cholerae* O1 and non-O1 strains, and *Vibrio mimicus* (Figure 48.1). The second β-turn at residues 11 to 14 (STaP) is proposed to be the most important for toxicity of STa, as this region of the molecule directly interacts with its receptor (Ozaki *et al*., 1991; Sato *et al*., 1994). More specifically, alanine at position 13 in STaP and at position 14 in STaH is essential for toxicity. The methyl side chain of this alanine is directed outward of the molecule and could interact directly with a hydrophobic area located on the surface of the receptor.

The four amino acids (N-P-A-C) are conserved in STaP and STaH and other heat-stable enterotoxins produced by other bacterial species (Figure 48.1). This sequence is also conserved in the marine snail *Conus geographus,* α-conotoxin $G_I$. In guanylin and *E. coli* EAST-1 toxin, an alanine followed by a cysteine residue is partially conserved (i.e., X-X-A-C). For human and rat uroguanylin, the conserved sequence is N-X-A-C. It is interesting to note that in guanylin, the endogeneous ligand for STa receptor, these amino acids interact with the receptor (Greenberg *et al*., 1997).

## Receptor identity

Since the mid-1980s, numerous studies have demonstrated that STa can bind non-covalently, with high or low affinity, to several proteins in the plasma membrane of susceptible eucaryotic cells (Dreyfus and Robertson, 1984b; Waldman *et al*., 1986).

STa stimulates particulate guanylate cyclase in intestinal epithelial cells, resulting in elevation of cyclic GMP (cGMP) (Field *et al*., 1978; Hughes *et al*., 1978). The same studies also demonstrated that 8-bromo-cGMP mimics the effect of STa in animal systems. Thus, the activity of STa is mediated by the intracellular second messager cGMP and research was focused on evaluating binding of STa to cellular proteins and on demonstration of the possible guanylate cyclase activity of the molecule.

The STa receptor has been the subject of intensive studies. Several solubilization and cross-linking experiments using $^{125}$I-STa and intestinal brush border membranes aimed at identifying the STa receptor were carried out. For example, de Sauvage *et al*. (1992) have identified proteins of 49, 56, 68, 81, 133 and 153 kDa, whereas Hirayama *et al*. (1992) identified a 200-kDa protein cross-linked to radioiodinated STa. Purification of the receptor by ligand-affinity chromatography identified a protein subunit of 74 kDa to which $^{125}$I-STa was binding (Hughes *et al*., 1992). The molecules identified in these studies were glycoproteins, but none showed guanylate cyclase activity as expected. The heterogeneity of the proposed intestinal receptors for STa is exemplified by additional studies (Thompson and Gianella, 1990; Ivens *et al*., 1990; Hakki *et al*., 1993; Cohen *et al*., 1993; Hughes *et al*., 1991).

Conclusive identification of STa receptor was achieved when the STa receptor was cloned from cDNA libraries of rat (Schulz *et al*., 1990), pig (Wada *et al*., 1994), and human intestine (de Sauvage *et al*., 1991). New members of the guanylyl cyclase family were looked for in the small intestinal mucosa using degenerated oligonucleotide primers based on conserved sequences in the catalytic domains of membrane and soluble guanylyl cyclases. When the cDNA was transfected into naive COS cells, specific STa binding activity and guanylate cyclase activity were expressed (Schulz *et al*., 1990). The deduced amino acid

sequence and functional expression in mammalian cells indicated that the STa receptor was guanylyl cyclase C (GC-C) belonging to the atrial natriuretic peptide receptor family that included GC-A and GC-B. (Chang *et al*., 1989; Hirayama *et al*., 1992; Vaandrager *et al*., 1993a, 1993b). For these receptors, the binding site and the catalytic activity of guanylate cyclase resided on the same protein.

The GC-C unglycosylated protein has a Mr of 120 kDa and it is found as a 140- to 160-kDa glycoprotein after N-linked glycosylation (Mann *et al*., 1993). At the $NH_2$-terminus, it consists of an extracellular receptor domain, a transmembrane domain, and cytoplasmic domain, including a kinase homology domain and a guanylyl cyclase catalytic domain at the COOH-terminus. GC-C null mice are refractory to the secretory action of STa, proving that the GC-C receptor is necessary for the diarrheal response induced by this toxin (Mann *et al*, 1997).

Thus, STa activates particulate guanylate cyclase. Particulate guanylate cyclases are brush border membrane glycoproteins. In the human intestine, approximately 75–80% of the total guanylate cyclase activity is particulate; the rest is soluble (Garbers *et al*, 1991; Schulz *et al*, 1991). GC-C also contains a carboxy-terminal tail of about 60 amino acids. The function of this segment is uncertain, but possibly links the molecule to the cytoskeleton. The endogeneous agonist for GC-C was later found to be a 15-amino acid hormone called guanylin (Greenberg *et al*., 1997). This hormone appears to play a role in the regulation of fluid and electrolyte absorption in the gut. Guanylin is 50% homologous to STa and it contains 4 cysteine residues that are involved in disulfide bond formation and are essential for biological activity (Figure 48.1). This hormone is less potent than STa in activating GC-C and in stimulating chloride secretion ($Cl^-$) (Currie *et al*., 1992; Wiegand *et al*., 1992; Forte *et al*., 1993; Carpick and Gariépy, 1993; Kuhn *et al*., 1994; Greenberg *et al*., 1997). It thus appears that STa opportunistically utilizes GC-C to alter the basal gut homeostasis.

A form of guanylin circulates in the blood of patients with chronic kidney failure (Kuhn *et al*, 1993). There also exists in animal and human urine a guanylin-like molecule called uroguanylin (Hamra *et al*., 1993; Kita *et al*., 1994). It is clear from their sequences that guanylin and uroguanylin are the products of separate genes. It thus appears that guanylin but also uroguanylin are endogeneous ligands for GC-C and could be modulators of $Cl^-$ secretion in the intestine, and also in kidneys and other organs (Giannella, 1995; Greenberg *et al*., 1997). The receptor for these molecules is located on enterocytes, colonocytes, and cells of various extraintestinal tissues.

## *In vitro* studies involving cell lines and *in vivo* analysis of the receptor distribution

Intestinal cell lines were used to study the *in vitro* binding of STa and its biological action. For example, both human cancer cell lines Caco-2 and T84 possess the specific receptor for STa (Guarino *et al*., 1987b; Cohen *et al*., 1993). Binding of STa to these cell lines is coupled to cGMP production as was previously observed in the rat. When T84 polarized cells are mounted in a Ussing chamber they can be induced to secrete $Cl^-$ by addition of STa (Huott *et al*., 1988). Other intestinal cell lines like IEC-6 (rat cell line) can also bind STa; however, the receptor is not coupled to guanylate cyclase (Thompson and Gianella, 1990). Nevertheless, the relevance for humans of the data first obtained with rats was confirmed by studying the normal human intestinal mucosa (Cohen *et al*., 1986, 1988).

These studies revealed that STa receptors are found throughout the human intestine and colon with a decreasing number along the longitudinal axis of the gut (Krause *et al*., 1994). Specific binding of radioiodinated STa was noted in both crypts and villi of the small intestine and in crypts and surface epithelium of the colon (Field *et al*., 1989a, 1989b). Binding was also maximal in the villus preparations and decreased along the villus-to-crypt axis (Cohen *et al*., 1992).

A relationship was found between the number of STa receptors and age. The number was highest at birth, decreased in the first 1–3 weeks of life, and was stable thereafter (Cohen *et al*., 1988). The large number of receptors observed in infants could account for the severity of diarrhea due to STa in young children (Guarino *et al*., 1987c). A similar age-related difference in the number of STa receptors had already been observed in rats (Cohen *et al*., 1986).

A study by Swenson *et al*. (1996) indicated that GC-C was present in mouse intestinal crypts and villi of adult small intestine and surface epithelium of the colon. The presence of GC-C in mouse intestinal crypts supports the putative role of GC-C in fluid secretion and electrolyte homeostasis and resembles the pattern seen with human tissues.

## Alternative STa receptor

A number of smaller STa-binding proteins previously identified cross-reacts with anti-GC-C antibodies, indicating that these polypeptides could be the result of GC-C extracellular binding domain proteolysis (Cohen *et al*., 1993; Vaandrager *et al*., 1993a; Scheving and Chong, 1997). This observation can most probably account for numerous proteins with varying Mr previously described as STa receptors. In fact, similar lower

molecular mass STa-binding proteins were also observed in cells transfected to express GC-C, supporting the occurrence of processing and/or proteolysis of a single STa binding molecule (de Sauvage *et al*., 1992; Vaandrager *et al*., 1993a; Hirayama *et al*., 1992).

Now, at least one receptor for STa has been clearly identified as being GC-C. Nevertheless, the existence of other receptors for STa was suggested by different studies. Non GC-C-linked STa receptors may also exist and those could be linked to more than a single signal transduction system as will be discussed later.

## Mechanism of action

STa is a highly potent toxin with a rapid action (reaching maximal levels of cGMP within 5 min) but of short duration. For example, 6 ng of STa result in a positive fluid response in mouse intestine compared with 200 ng of STb or CT in the same model (Hitotsubashi *et al*., 1992a, 1992b). STa (and guanylin) binds to particulate guanylate cyclase in the jejunum and ileum brush border, leading to elevation of cGMP levels. GC-C is found primarily, but not exclusively, in intestinal cells lining the small intestine (Krause *et al*., 1994).

STa enterotoxin utilizes GC-C to alter ion transport in the gut. Following binding of STa to its receptor, a cascade of events ensues (Figure 48.3). The end result of STa action is the inhibition of $Na^+$-coupled-$Cl^-$ absorption in villus tips and stimulation of electrogenic $Cl^-$ secretion in crypt cells, resulting in a net fluid secretion in the lumen of the intestine (Forte *et al*., 1992; Dreyfus *et al*., 1984a; Huott *et al*., 1988; Field *et al*., 1978).

Inhibition of NaCl absorption could be attributed to binding of STa to enterocyte villi responsible for NaCl absorption (Almenoff *et al*., 1993; Cohen *et al*., 1992). Treatment of Caco-2 cells with STa prevented uptake of taurine, which is coupled to $Na^+$ absorption. This mechanism could also contribute to decrease the absorption of sodium (Brandsch *et al*., 1995).

GC-C is composed of a receptor, a transmembrane domain, a kinase-like domain, and a catalytic domain. In the basal state, GC-C is a homotrimer. After binding of a STa molecule, a bond between two of the three subunits is stabilized, as activation of GC-C may require the interaction of STa with two cyclase domains. Thus, internal dimerization within the homotrimeric GC-C appears as a key step in activation of guanylate cyclase by STa (Vaandrager *et al*., 1994). Rudner *et al*. (1995) recently proposed that the binding of STa to GC-C removes the inhibitory effects of the kinase-homology domain and promotes an interaction between the GC catalytic domains. Adenine nucleotides were shown to regulate the binding of STa to its receptor. It actually

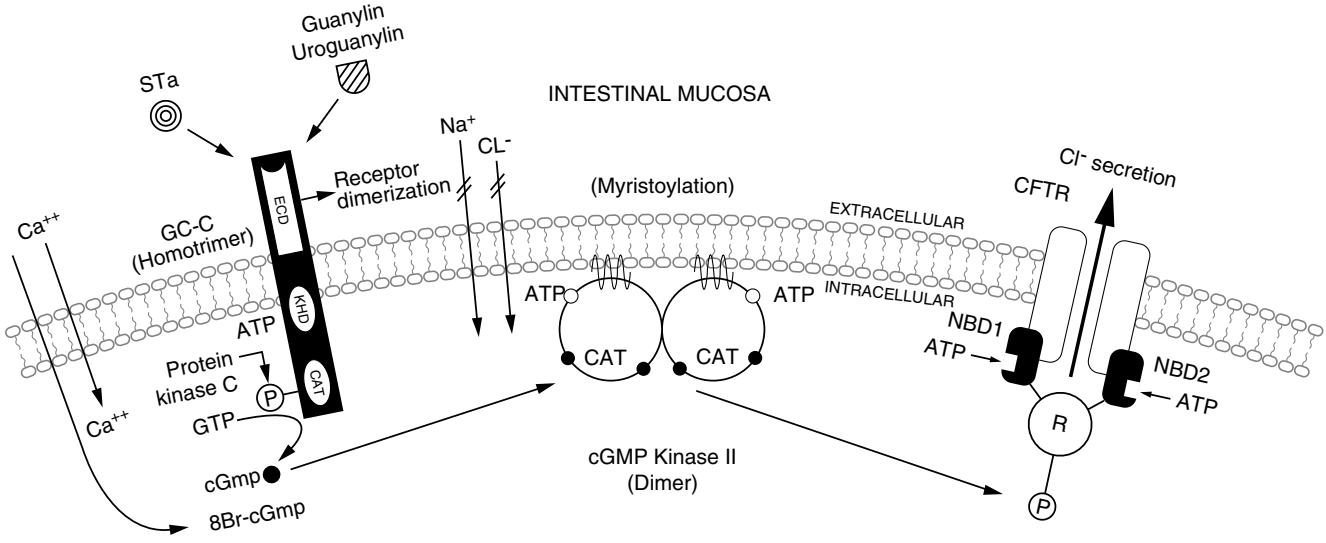

**FIGURE 48.3** Molecular model for the induction of a secretory response by STa toxin. STa and guanylin (uroguanylin) interact with guanylate cyclase C. GC-C is a homotrimer composed of a receptor domain (ECD), a transmembrane domain, a kinase-homology domain (KDH), and a catalytic domain (CAT). Interaction of STa with the receptor domain results in dimerization of two of the three CAT domains. Following STa-receptor interaction, $Ca^{++}$ influx occurs and this event activates protein kinase C, which phosphorylate CAT. Conversion of GTP in cGMP takes place and the $Na^+$ -$Cl^-$-coupled influx is blocked. cGMP or 8 br-cGMP but not 8-br-cAMP can then activate a cGMP-dependent protein kinase II (cGMP kinase II), which is a dimer molecule linked to the membrane via myristoyl molecules. The catalytic (CAT) domain of cGMP kinase II phosphorylates the R (Regulatory) domain of CFTR (cystic fibrosis transmembrane conductance regulator), a $Cl^-$ conductory pore. The R domain interacts with NDB1 and NDB2 (nucleotide binding domains). Then $Cl^-$ secretion is achieved via the CFTR channel. The cGMP-signaling enzyme (GC-C), the signal transducer cGMP kinase II, and the effector (CFTR) are co-localized on the membrane of intestinal epithelial cells.

decreases binding, but stimulates guanylate cyclase activity (Gazzano *et al*., 1991; Katwa *et al*., 1992). Activation of GC-C results in an increased level of cGMP, resulting in a net fluid secretion involving $Cl^-$.

An interaction between protein kinase C and the STa receptor was suggested by Weikel *et al*. (1990), who showed that treatment with phorbol ester, an active analogue of PKC, doubled STa-stimulated cGMP production in cultured intestinal cells. This increase was also observed by Crane *et al*. (1990) in STa-stimulated T84 cells. Crane *et al*. (1992) later demonstrated that treatment of T84 cells with purified PKC similarly increased STa-stimulated guanylyl cyclase activity. This increased response was blocked by PKC inhibitors and by ATP-δ-S, a biologically non-hydrolysable ATP analogue, indicating that PKC regulated the STa receptor through a phosphorylation step. They also presented evidence that PKC could phosphorylate and activate the STa receptor both *in vivo* and *in vitro*. In addition, using synthetic peptides, they have indicated that Ser-1029 of the STa receptor is most probably a phosphorylation site for PKC. A study by Wada *et al*. (1996) supported this hypothesis. It can thus be concluded that PKC activity in target cells modulates the cellular sensitivity to *E. coli* STa enterotoxin.

*In vivo*, the increase in cGMP results in a cGMP-dependent protein kinase activation of a linear chloride channel known as CFTR (cystic fibrosis transmembrane conductance regulator). CFTR is a $Cl^-$ channel encoded by the cystic fibrosis gene. The role of CFTR in secretion was confirmed by the observation of a lack of potential difference response, but not of a cGMP response to STa in the colon of cystic fibrosis (CF) patients (Goldstein *et al*., 1994). In addition, CFTR knockout mice were insensitive to STa (Pfeifer *et al*., 1996).

The CFTR protein contains two transmembrane domains forming the $Cl^-$ conducting pore, two nucleotide-binding domains, and a regulatory domain, where multiple phosphorylation sites for cAK (Gadsby and Nairm, 1994) and cGK (French *et al*., 1995), which are cAMP- and cGMP-dependent kinases, respectively, are present.

*In vivo*, following STa binding of STa to its receptor, only cyclic GMP-dependent kinase type II (cGKII) can effectively phosphorylate the R domain and gate the CFTR $Cl^-$ channel (French *et al*., 1995; Vaandrager *et al*., 1997a). cGKII is a membrane-associated cGMP-dependent kinase, whereas cGKI is a soluble kinase. cGMP cross-activation of cAK does not occur in native intestinal epithelium, but is observed *in vitro* in cGK-deficient T84 intestinal tumor cell lines (Forte *et al*., 1992; Lin *et al*., 1992; Tien *et al*., 1994). The level of activation and $Cl^-$ secretion of CFTR is dependent upon the level of phosphorylation (Akabes, 2000).

Recent studies strongly support a central role of cGKII and not cGKI or cAK as the signal transducer in STa- and cGMP-induced $Cl^-$ secretion (Vaandrager *et al*., 1997b). In fact, synthesis of endogenous cGKII in crypt cells corrolates well with the ability of STa and 8-Br-cGMP (and not 8-Br-cAMP) to stimulate $Cl^-$ secretion (Markert *et al*., 1995). STa could not stimulate $Cl^-$ secretion in the colon where cGKII is not found. Homozygous cGKII knockout mice and rat intestine pretreated with cGKII inhibitors lost the potential of intestinal $Cl^-$ secretion by STa and 8-Br-cGMP. A native membrane environment appears to be crucial for cGKII-selective phosphorylation of CFTR. The amino-terminal myristoyl groups present in cGKII dimer could be responsible for bringing cGKII and CFTR in close apposition so that the dimer can effectively phosphorylate and activate the channel, ultimately resulting in $Cl^-$ secretion (Vaandrager *et al*., 1996, 1997b).

The cGMP signaling enzyme (GC-C), the signal transducer (cGMP-dependent protein kinase II), and the effector (CFTR) are co-localized in the apical membrane of intestinal cells (Markert *et al*., 1995).

## STa action via alternative pathways

Non-GC-C STa receptor, if present, may be linked to alternative signaling pathways. Although the CFTR $Cl^-$ channel accounts for the main secretory pathway stimulated by STa, there is still a controversy as to whether cGMP is the sole signal transducer. In fact, as different pharmaceutical agents could alter the secretory response of STa, alternative pathways responsible for fluid secretion have been proposed (Table 48.1). Overall, to date, important major contradictory results have been reported from different research teams, adding to the perplexity of the situation. For example, as STa-secretory response was completely abolished by 5-hydroxytryptamine (5-HT or serotonin) receptor antagonists, this secretagogue has been proposed as an important mediator of secretion (Beubler *et al*., 1992). Interestingly, in these experiments, the cGMP response was not influenced. Thus, 5-HT could possibly mediate STa secretion by affecting prostaglandin synthesis (5HT-2 receptors) and/or neurons (5HT-3 receptors) (Lundgren, 2004). In support of this mechanism of action, it was shown that the cyclooxygenase inhibitor indomethacin caused an inhibition of STa-mediated fluid secretion in suckling mice (Madsen and Knoop, 1978). However, this inhibition was not observed by Kuhn *et al*. (1994) in the human intestine. Thus, the potential role of 5-HT and prostaglandin or leukotrienes remains controversial.

In fact, studies involving prostaglandin synthesis inhibitors and isolated rat intestinal epithelial cells

suggested that STa secretion could result from phosphatidylinositol and diacylglycerol release coupled with elevation of intracellular calcium levels and activation of protein kinase C (Greenberg *et al*., 1982; Thomas and Knoop, 1982; Banik and Ganguly, 1988, 1989; Chaudhuri *et al*., 1993; Chaudhuri and Ganguly, 1995; Ganguly and Talukder, 1985; Knoop *et al*., 1991).

In contrast, Dreyfus *et al*. (1984a) refuted the evidence for a role of prostaglandins and leukotrienes, calcium, and/or calmodulin in STa secretory action. Supporting this study, it was shown that STa increased cGMP levels in T84 cells, resulting in $Cl^-$ secretion, although no elevation of calcium levels and no hydrolysis of phospholipids were noted (Huott *et al*., 1988; Vajanaphanich *et al*., 1993).

STa was shown to cause changes in the myoelectric activity of the small intestine, indicating that the enteric nervous system could play a role in STa secretion. Following the use of neuronal inhibitors, a reduction in STa secretory response was observed *in vivo* and *in vitro* (Eklund *et al*., 1985; Mathias *et al*., 1982; Rolfe and Levin, 1994). The observed changes in myoelectric activity could result in the loss of normal peristaltism (Gianella *et al*., 1983; Roussel *et al*., 1992).

Finally, the secretory response of T84 cells to STa was reported to involve microfilament (F-actin) rearrangement at the basal pole of these polarized cells (Matthews *et al*., 1993). More recently, Rolfe and Levin (1994) showed that STa-activated electrogenic $Cl^-$ secretion through a myenteric secretory reflex with afferent C fiber component. A study by Nzegwu and Levin (1996) corroborated this observation.

For now, no definitive consensus can be reached with respect to the alternative pathway that STa could use to stimulate fluid secretion.

## *E. coli*-EAST1 TOXIN

### Generalities

Enteroaggregative *Escherichia coli* heat-stable enterotoxin 1 (EAST1) is a small protein, which was recognized more than a decade ago in an enteroaggregative *E. coli* (EAEC) strain isolated from the stools of a child suffering from diarrhea (Levine *et al*., 1988; Savarino *et al*., 1991). The EAST1-coding gene, *astA*, is not only found in EAEC, but also in other categories of *E. coli* responsible for diarrhea (Ménard and Dubreuil, 2002). Strains expressing EAST1 were shown to induce diarrhea principally in humans, but were also associated with disease in piglets and calves. EAST1 toxin has been proposed as a virulence factor implicated in the pathogenesis of EAEC, and it could play a role in the virulence of other enteropathogens as well (Paiva de Sousa and Dubreuil, 2001). This toxin is often compared to *E. coli* STa enterotoxin because it shares some physical and mechanistic similarities. However, it does not react with anti-STa antibodies or hybridize with DNA probes specific for STa (Savarino *et al*., 1991).

### Enteroaggregative *E. coli*

EAEC can adhere to HEp-2 cells and other cell surfaces in a characteristic aggregative pattern, sometimes described as a stacked-brick configuration. For many years, EAEC has been recognized as an agent of diarrhea, mostly in children living in developing countries (Nataro *et al*., 1993; Bhan *et al*., 1989). The adherence factors associated with EAEC are the aggregative adherence fimbriae I and II (Nataro *et al*., 1993; Savarino *et al*., 1994; Nataro *et al*., 1995). These fimbriae are morphologically and genetically different, but both are implicated in the aggregative adherence phenotype observed. Several other putative or established virulence factors are associated with EAEC, such as a 108-kDa cytotoxin named Pet (for plasmid-encoded toxin), hemolysins, various outer membrane proteins, and the enterotoxin designated EAST1 (Nataro and Kaper, 1998; Nataro *et al*., 1998; Law and Chart, 1998; Yamamoto *et al*., 1997b). However, not all studies indicate that EAEC is an agent of diarrhea (Nataro *et al*., 1998; Law and Chart, 1998). EAEC may represent an opportunistic pathogen for children or immunocompromised persons (Wanke *et al*., 1998). Moreover, virulence factors associated with EAEC strains are multiple, and deciphering their individual roles in disease is

complex. Among these virulence factors, EAST1 toxin seems implicated in the pathogenesis of EAEC leading to diarrhea. The role of EAST1 in diarrhea is still questioned because some volunteers challenged with EAST1-producing EAEC strains did not develop diarrhea even if the strains could effectively colonize the intestine (Nataro *et al*., 1995).

Some studies demonstrated that the presence of *E. coli astA*-positive in the stools of adults and children without diarrhea can be as high as 38% (Savarino *et al*., 1996; Gascon *et al*., 1998; Vila *et al*., 1998; Stephan and Untermann, 1999; Vila *et al*., 2000; Gascon *et al*., 2000). The existence of EAST1-producing *E. coli* in healthy subjects suggests that some persons could be asymptomatic carriers and that these strains could provoke diarrhea only under certain conditions.

The prototype EAEC strain 17-2 was isolated from a Chilean child with diarrhea (Levine *et al*., 1988). This strain caused diarrhea and sometimes death in a gnotobiotic piglet model (Tzipori *et al*., 1992). In pig, the moderate hyperemia of the distal small intestine and caecum, the swelling of small intestinal villi, plus the absence of an inflammatory response were pointing toward an enterotoxin-induced diarrhea (Tzipori *et al*., 1992).

## EAST1 in humans and animals

First associated with EAEC, subsequent studies demonstrated that EAST1 gene was also present in other diarrhea-causing *E. coli* and also in some other human enteric pathogens, such as *Salmonella* (Savarino *et al*., 1996; Paiva de Sousa and Dubreuil, 2001). EAST1 is not associated with a particular *E. coli* serotype, even though it may be more prevalent in some serogroups (Paiva de Sousa and Dubreuil, 2001; Rich *et al*., 1999; Yamamoto and Taneike, 2000). EAST1-producing *E. coli* have been primarily associated with diarrhea in children, but were later found in adults as well (Savarino *et al*., 1996; Vila *et al*., 1998). The prevalence of *astA* in EAEC strains isolated from stools from humans with diarrhea varies from 26–86.6% (Savarino *et al*., 1993, 1996; Paiva de Sousa and Dubreuil, 2001; Gascon *et al*., 1998; Yamamoto and Echeverria, 1996). Some *E. coli* strains isolated from humans with diarrhea were found to harbor no known virulence determinant other than EAST1 (Paiva de Sousa and Dubreuil, 2001; Nishikawa *et al*., 1999; Zhou *et al*., 2002). EAST1 is not only found in human strains but also in *E. coli* strains associated with diarrhea in cattle and pigs (Yamamoto and Echeverria, 1996; Yamamoto and Nakazawa, 1997; Choi *et al*., 2001a, 2001b; Bertin *et al*., 1998). For example, in a study on 476 *E. coli* strains isolated from weaned pigs with diarrhea and/or edema, 31.3% of the strains carried the EAST1 gene. Among them, 44.3% harbored no known fimbrial or other toxin gene (Choi *et al*., 2001b). Another study indicated that there may be a link between CS31A adhesin and EAST1 in pathogenic bovine *E. coli* (Bertin *et al*., 1998).

## Toxicity evaluation

EAST1 toxicity is generally detected in the Ussing chamber using rabbit intestinal tissues (Savarino *et al*., 1991). Enterotoxicity of culture filtrates of EAST1-producing ETEC strains has also been observed in the suckling mouse assay (McVeigh *et al*., 2000). ETEC strains harboring more than one copy of *astA* were toxic in the mouse assay, while bacteria with a single copy of the gene were not (McVeigh *et al*., 2000). It is tempting to hypothesize that detection of enteroactivity in either test may depend on the amount of EAST1 produced and present in the culture filtrates. Concordance between the presence of *astA* and toxicity of live bacterial strains or culture filtrates has been assayed and a correlation could be established for several strains (Savarino *et al*., 1996). However, the Ussing chamber assay can, for unknown reasons, fail to detect production of EAST1, as it was observed for EAEC strains provoking acute diarrhea in Brazilian children (Savarino *et al*., 1996; Monteiro-Neto *et al*., 1997). This result could be explained by a lack of toxin expression under *in vitro* growth conditions or due to a mutation silencing the EAST1 gene without altering significantly its nucleotide sequence (Savarino *et al*., 1996).

## EAST1 polypeptide

The amino acid sequence of EAST1 was deduced from the open reading frame named *astA*. EAST1 is a 38 amino acid peptide with a molecular weight of 4100 Da and a calculated pI of 9.25 (Figure 48.4)(Savarino *et al*., 1993). Knowledge on EAST1 was acquired through the use of culture filtrates or use of EAST1-producing strains, as EAST1 toxin was only recently purified (Ménard *et al*., 2004). Fractions of culture filtrates of EAEC strain 17-2, heated at 65°C for 15 min, demonstrated partial heat stability (Savarino *et al*., 1991). Among the 38 amino acids composing EAST1, there are four cysteines at positions 17, 20, 24, and 27, which were proposed to be involved in the formation of two disulfide bridges. Indirect evidence for the importance of disulfide bridges' integrity for toxicity expression was determined when cysteine 17 was replaced by an alanine abolishing the toxicity (Fasano, 1999; Uzzau and Fasano, 2000). Unlike STa and STb, a classic signal peptide was not observed in the $NH_2$-terminus of the predicted EAST1 sequence (Savarino *et al*., 1993). Polyclonal anti-STa antibody could not neutralize the

biological activity of EAST1 in Ussing chamber. Thus, EAST1 was defined as being immunologically different from STa (Savarino *et al*., 1991). A synthetic peptide composed of residues 8 to 29 of EAST1 induced a response in Ussing chamber, indicating that the toxic activity was contained within this large fragment (Savarino *et al*., 1993). Because EAST1 bears some similarities to STa, the suckling mouse assay, the standard bioassay for STa, was proposed to evaluate enterotoxicity. Using concentrates (20X and 50X) of culture supernatant (fraction between 2 and 5 kDa) of strain 17-2 and six other EAEC strains EAST1-positive isolates produced a gut-to-body-weight ratio, in CD-1 mouse strain, below the determined threshold for the bioassay (Savarino *et al*., 1991). It was concluded that EAST1 toxin could not be detected by the suckling mouse assay under conditions in which STa was active.

### *AstA gene*

The enterotoxin EAST1 is encoded by the gene *astA*, a 117-bp-long DNA sequence. There is no homology between *astA* and *estA*, the structural gene for STa. The G+C content of *astA* is 53%, which is similar to the mean value for *E. coli* (50.8%), while for *estA* (coding for STa) it is 30.6% (Savarino *et al*., 1993; Lai *et al*., 1999). *astA* has an atypically low codon adaptation index (0.132), which represents a deviation from the preferred codon usage for *E. coli* (McVeigh *et al*., 2000). The presence of *astA* in EAEC strains was associated with a 60-MDa plasmid mediating aggregative adherence, but was also observed on other plasmids, in EAEC, and other bacteria (Savarino *et al*., 1993; Savarino *et al*., 1996; Yamamoto *et al*., 1996). EAST1 gene is strongly linked to the aggregative adherence fimbriae I (AAF/I), implicated in the aggregative adherence phenotype. Both EAST1 and AAF/I genes are on a 60-MDa plasmid found in EAEC strain 17-2 (Nataro *et al*., 1993). Czeczulin *et al*. (1999) have shown that aggregative adherence plasmids are transmissible horizontally, presumably through conjugation. EAEC has a pattern of plasmid transmission similar to *Rhizobium* species, in which a virulence plasmid is acquired and then maintained among clonal descendants (Czeczulin *et al*., 1999). *astA* was observed on plasmids, but was also found on the chromosome of various bacteria in one or more copies (McVeigh *et al*., 2000). The presence of more than one copy of *astA* in bacteria was not restricted to ETEC, as one EHEC O157:H7 strain had two copies of *astA* (Savarino *et al*., 1996). The nucleotide sequence flanking the *astA* ORF has not been characterized yet, and no promoter or regulator of expression has been identified. Actually, very little is known about the genetic regulation of EAST1 expression. Nucleotide sequences upstream of *astA* from porcine and bovine ETEC strains were identical, but were divergent from human ETEC, DAEC, and EAEC (Yamamoto *et al*., 1996; Yamamoto and Echeverria, 1996; Yamamoto *et al*., 1997a, 1997b). There seems to be a certain consensus among flanking sequences of *astA*, even though the results obtained by Yamamoto and Nakazawa (1997) point toward a heterogeneity of DNA sequences between *E. coli* affecting humans and animals. As mentioned before, the EAST1 gene seems to be present among numerous diarrheagenic *E. coli* and also some *Salmonella agona* strains (Paiva de Sousa and Dubreuil, 2001). Several studies reported the presence of *astA* on transposon-like sequences, near insertion elements or inverted repeats, which could represent means of transmission for the EAST1 gene.

## Mechanism of action

The secondary messenger involved in the response of EAST1 was investigated among the following three molecules: cAMP, cGMP, and calcium. Only pretreament of tissue with 8-BrcGMP (a cGMP analogue) abrogated the biological response to a culture supernatant fraction (2–5 kDa) of strain 17-2, pointing toward cGMP as a possible second messenger involved in the mechanism of action of EAST1. Savarino *et al*. (1991) also observed that under both $Cl^-$-free and $HCO3^-$-free conditions, the short circuit current, for the 2- to 5-kDa fraction, was significantly less, suggesting that these ions may be involved in the generated electrical response. The small size and relative heat stability of this protein and the finding that cGMP may be acting as a second messenger led to the comparison of EAST1 with *E. coli* STa toxin.

In Ussing chamber, EAST1, STa, and STb induce a reaction in approximately 30 to 40 min (Fasano, 1999;

| Molecules | Number of residues | Mature amino acid sequences | References |
|---|---|---|---|
| **EAST1 17-2** | 38 | MPSTQYIRRPASSYASCIWC**T**TACASCHGRTTKPSLAT | Savarino *et al.* (1993) |
| **EAST1 0-42** | 38 | MPSTQYIRRPASSYASCIWC**A**TACASCHGRTTKPSLAT | Yamamoto *et al.* (1997) |

**FIGURE 48.4** Primary sequence of *Escherichia coli* EAST1 17-2 and O-42. In bold, the amino acid at position 21 that differs between these two variants. The box shows the partially conserved N-P-A-C sequence.

Thompson and Giannella, 1985; Dreyfus *et al*., 1983; Field *et al*., 1978). EAST1 protein shares 50% identity with the enterotoxic domain of STa (amino acid residues 6 to 18) (Savarino *et al*., 1993). By aligning STa family members (STaH and STaP) with guanylin and EAST1, the following common motif can be observed: a small nonpolar amino acid residue-alanine-cysteine-small nonpolar residue-small polar residue-cysteine (Figure 48.1) (Savarino *et al*., 1993; Uzzau and Fasano, 2000). EAST1 is structurally and functionally similar to guanylin, both having four cysteines and activating the production of cGMP (Savarino *et al*., 1991). A study on T84 cells and COS cells transfected with GC-C suggest that EAST1 interacts with GC-C to elicit an increase in cGMP (Fasano, 1999; Uzzau and Fasano, 2000). This interaction could occur through the N-P-A-C motif common to the ST toxins and partially conserved for EAST1 (i.e. X-X-A-C) (Figure 48.1).

### EAST1 variants

The first detected *astA* gene was in EAEC strain 17-2 and a variant of this gene was later observed in EAEC strain O-42 (Nataro *et al*., 1995; Yamamoto *et al*., 1997b). EAEC strain 17-2 (serotype O3:H2) was isolated from a Chilean child with diarrhea, while EAEC strain O-42 (O44:H18) was isolated from a Peruvian child with diarrhea (Savarino *et al*., 1991; Nataro *et al*., 1995; Henderson *et al*., 1999). This EAST1 variant differs from strain 17-2 sequence by one base at codon 21 (ACA→GCA), resulting in a change in the amino acid threonine to alanine. Nataro *et al*. (1995) observed heterogeneity in the virulence of EAEC strains 17-2 and O-42. As strain O-42 (sometimes referred to as strain JPN10) was able to provoke diarrhea in volunteers, whereas strain 17-2 did not, it has been proposed that the EAST1 variant of O-42 could contribute to the virulence of EAEC in a more significant way (Nataro *et al*., 1995; Yamamoto *et al*., 1997b). Moreover, the EAST1 toxin produced by strain O-42 can be observed more frequently in epidemiological studies than EAST1 of strain 17-2 (Yamamoto *et al*., 1997b; Lai *et al*., 1999). It should be specified that these two EAEC strains differ not only in their EAST1 sequence, but also in the fimbrial antigen they express. Strain 17-2 harbors AAF/I fimbrial antigen, while strain O-42 expresses AAF/II (Elias *et al*., 1999a and b; Nataro *et al*., 1996). Strains 17-2 and O-42 have distinct nucleotide sequences flanking *astA*. These differences may explain the variation of pathogenicity observed for those two variants (Nataro *et al*., 1995; Yamamoto *et al*., 1997b).

Other variants of EAST1 have been observed through various epidemiological studies (Yamamoto *et al*., 1997a, 1997b; Yamamoto and Taneike, 2000). These variants have usually been reported only once and probably represent less frequently distributed molecules. The toxicity of these occasionally observed variants has not been evaluated, thus precluding their importance as a virulence factor.

## *VIBRIO* AND *YERSINIA* STs

### Genetics

Significant divergence was noted between *E. coli* STaH and STaP and the NAG-ST gene (*stn*) of *V. cholerae* non-O1, although the three toxins share a similar DNA sequence at the COOH-terminal region. The gene *stn* is chromosomally encoded and despite the nucleotide sequence divergence with STa, the amino acid sequence shows considerable structural similarity, with respectively 39 or 36 of the 78 amino acids of NAG-ST being identical to STaH or STaP (Ogawa *et al*., 1990). The hydropathy plot analysis for the precursors, as well as the sequence identity analysis, suggested that NAG-ST and *E. coli* STa have a common evolutionary origin (Ogawa *et al*., 1990). *V. cholerae* O1-ST gene (*sto*) is very similar to *stn* and both genes are flanked by 123-bp direct repeats, and they both include inverted repeats with at least 93% homology (Ogawa and Takeda, 1993). Strains of *V. cholerae*, *V. mimicus*, *V. metschnikovii*, *V. hollisae*, and *Y. enterolitica* possess the direct repeat sequences, regardless of the presence of ST gene. The direct repeats appear to play a role in the evolutionary process by mediating chromosomal rearrangements. Nevertheless, not all *V. cholerae* have direct repeats sequences, indicating it could represent a transposable element or that it is unstable in the chromosome. Three transitions and three transversions between *sto* and *stn* ORFs are responsible for four codon changes without altering the mature ST amino acid sequences (Ogawa and Takeda, 1993). For *sto* and *stn*, in contrast to *estA*, no typical transposon or insertion sequence is found in the flanking region (Ogawa and Takeda, 1993).

Among *Y. enterolitica*, three defined molecular ST types are documented. They include Y-STa, Y-STb, and Y-STc (Yoshino *et al*., 1993, 1994). The structural gene for Y-STa (*ystA*) is located on the chromosome and encodes a polypeptide of 71 amino acids (Delor *et al*., 1990). Sequence comparisons between *ystA* and *estA1* (encoding STaH) indicate a divergence of 58% with only 23 conserved amino acids. At the 3′ end of the *ystA* gene it shows 80% homology, resulting in 11 out of 13 identical amino acids. Deduced precursor protein amino acid sequences of Y-STb showed more homology with Yk-ST (*Y. kristensii*) (68%) than with Y-STa (57%) and Y-STc (60%) (Ramamurthy *et al*., 1997).

## Polypeptide structure and biological property comparison

STs produced by diverse enteropathogenic bacteria share a highly conserved sequence of 13 amino acids residing in the COOH-terminal domain. This sequence includes six cysteines that are linked by three disulfide bonds with the position being conserved in all STs (Shimonishi *et al*., 1987; Hidaka *et al*., 1988). Peptides with only one disulfide bond show no biological activity. The shared sequence is the following: C-C-[E/D]-[L/I/V]-C-C-N-P-A-C-[A/T/F]-G-C (Nair and Takeda, 1998) (Figure 48.1). This tridecapeptide constitutes the minimal structure essential for toxicity. It has been designated as the "toxic domain" (Yoshimura *et al*., 1985). A four amino acid sequence (N-P-A-C) is present and conserved in all STs family members (Figure 48.1). This sequence was shown for STa and guanylin, the endogeneous ligand for GC-C, to be responsible for receptor binding (Greenberg *et al*., 1997).

The biological activity of STs is a function of the correct formation of the three disulfide bonds. These bridges are necessary for toxicity as they stabilize the spatial structure as was first shown for *E. coli* STaH (Yamasaki *et al*., 1988).

For *V. cholerae* O1-ST, the toxicity of ST is increased with the loss of the $NH_2$-terminal amino acids (Yoshino *et al*., 1983). A ST molecule truncated of the first 11 amino acids (O1-ST1, comprising 17 amino acids) has a minimal effective dose 10 times less than the entire toxin (28 amino acids)(O1-ST4) (Yoshino *et al*., 1993). STs produced by members of the genus *Vibrio* (O1-ST, NAG-ST, HT-ST, and M-ST) are less potent than *E. coli* STaH and *Y. enterolitica* Y-STb (Takao *et al*., 1985b; Arita *et al*., 1991 a,b; Yoshino *et al*., 1993).

Chimera-peptide analysis indicated that the higher potency of *Y. enterolitica* Y-STb over Y-STa (20 times more potent) is due to the presence of a -E instead of -N in position 20. The higher toxicity of Y-STb compared to Y-STa is also due to the substitution of -Y for -N in position 17 (Yoshino *et al*., 1994). Y-STc, a molecule comprising 53 amino acid residues and being the largest known ST, showed maximal potency as it has a lower minimal effective dose (4 times more potent) than *E. coli* STaH, which for many years was thought to represent the most toxic ST molecule. The COOH-terminal core sequence conserved domain is responsible for the heat stablility of STs, whereas the NH2-terminal region is not involved (Yoshino *et al*., 1995). In Y-STc, replacement of -N by -W contributes to higher potency of Y-STc compared to Y-STa (80 times more potent), and it also confers resistance to proteases (Aimoto, *et al*., 1983; Ikemura *et al*., 1984). *In vivo*, the COOH-terminal portion of Y-STc is susceptible to various proteases in the host's intestine.

## Maturation and secretion

Like *E. coli* STa toxin, ST precursor proteins comprise three regions, namely the pre-region, the pro-region, and the mature toxin. *V. cholerae* O1-ST is synthesized as a pre-pro-toxin (Ogawa and Takeda, 1993). Similar to other ST-producing bacteria, the signal sequence consists of 18 amino acids, and it is cleaved upon export to the periplasm (Sjostrom *et al*., 1987).

Y-STs are also produced as pre-pro-toxin (Okamoto *et al*., 1990; Rasheed *et al*., 1990). Y-STa is a 71 amino acid pre-pro-toxin that is processed like STa, but leaving a 30 amino acid mature toxin (Delor *et al*., 1990). A 53 amino acid peptide results from signal peptidase 1 cleavage. This pro-toxin is then translocated to the periplasm where the three essential disulfide bonds are formed by DsbA protein before secretion is possible (Yamanaka *et al*., 1994). The pro-region plays an important role in the formation of disulfide bonds, but it does not contribute to toxicity of the molecule. Since for Y-STc the pro-region consisting of 53 amino acids is secreted as the mature toxin, the Y-STc precursor is a useful tool in understanding the maturation and secretion processes of the ST toxin family (Yoshino *et al*., 1995; Huang *et al*., 1997). In fact, it implied that the proteolytic processing of a pro-toxin in the periplasm is not essential for the secretion of the mature toxin through the outer membrane (Rasheed *et al*., 1990; Yang *et al*., 1992). The existence of ST and its subtypes among *V. cholerae* and *Y. enterolitica* indicates that multiple enzymes are involved in the maturation process.

## Receptor

The STs act by binding to a receptor found on the brush border membrane of epithelial cells. A region sharing striking identity with STaH and STaP (amino acids 5–17 and 6–18, respectively) and ST of *V. cholerae* and *Y. enterolitica* is found (Figure 48.1). This region is known to confer binding and full enterotoxic activity. Despite this fact, for now, we can only speculate on the receptor involved and the mechanism of action retained by STs for toxicity expression.

Purified Y-ST stimulates increased cGMP levels in mouse intestine and in cells in culture (Inoue *et al*., 1983). Activation of GC-C results in increased levels of intracellular cGMP that stimulate chloride secretion and/or inhibit its adsorption, resulting in net intestinal fluid secretion. Although the toxic domain of STs

secreted by enteric bacteria including *V. cholerae* and *Y. enterolitica* shares a striking identity with *E. coli* STa, it is not proven that these STs elevate intracellular cyclic GMP via activation in a similar way to guanylate cyclase type C (Sears and Kaper, 1996). The N-P-A-C sequence known, for STa and guanylin, to bind to GC-C is found more or less conserved in all ST sequences (Figure 48.1). Nevertheless, the mechanism by which *Vibrio* and *Yersinia* STs stimulate intestinal secretion is thought to be similar or identical to that used by *E. coli* STa.

### Immogenicity and antigenic relationships

Due to their peptide nature, STs are poor immunogens. Neutralization assays using monoclonal antibodies specific for *E. coli* STaH and STaP and NAG-ST permitted the analysis of antigenic determinants of STs. These assays indicated that toxicity of Y-STa was abolished by NAG-ST monoclonal, but only weakly neutralized by *E. coli* STaH (Takeda *et al*., 1990). Y-STb toxicity was neutralized by both monoclonals. Y-STc activity was abolished by *E. coli* STaH monoclonal, but not by NAG-ST antibodies. Overall, this indicated that Y-STb and Y-STc appear more immunologically related to *E. coli* STaH than Y-STa.

## CONCLUSION

Almost 20 years of research have been devoted to the study of STa, positioning it as a prototype for the later discovered heat-stable toxins. These studies have led to the precise knowledge of the structure, toxic domain, and more recently the identification of the STa receptor. This information culminated rapidly in a general understanding of the secretory pathway exploited by STa. Now that CG-C has been identified as the STa receptor, cGKII as the signal transducer, and CFTR as the secretory effector, drugs that interfere either with the processes leading to secretion or directly on the $Cl^-$ channel could be used to abolish or limit STa action. Future studies should now be directed at determining, for STa, if the alternative secretory pathways are truly exploited and, if so, to what extent compared to the CFTR $Cl^-$ channel.

For now, even though ST toxins are produced by various bacterial groups, the links between the presence of ST gene, ST production, and the occurrence of diarrheal disease is not always clearly intertwined. Concerning *E. coli* EAST1 and STs produced by *Vibrio* and *Yersinia*, the identity of the receptor, as well as the mechanism of action by which they produce diarrhea, has to be demonstrated.

SECTION IV

# SUPERANTIGENIC TOXINS

CHAPTER

# 49

# What are superantigens?

*Joseph E. Alouf and Heide Müller-Alouf*

## INITIAL INVESTIGATIONS

Pioneering investigations undertaken during the latter 1980s discovered unexpected immunological properties attributed to the highly mitogenic staphylococcal enterotoxins (SEs) on T lymphocytes. Such findings subsequently opened new research avenues into basic and clinical microbiology as well as immunology, which particulary delved into the domain of bacterial protein toxins. The triggering of lymphocyte proliferation by SEs requires selective and simultaneous binding of these molecules by both major histocompatibility (MHC) class II molecules at the surface of accessory cells (e.g., peripheral blood mononuclear cells) and T cell receptors (TcR) on target lymphocytes. In this respect, SEs appear as functionally bivalent molecules cross-linking TcR and MHC class II molecules in a unique manner. It was shown that the dependence on class II molecules was not due to an immunological "recognition" of SEs as is commonly known for conventional antigens, since there was no restriction by polymorphic determinants of human MHC class II molecules (HLA) and even xenogenic class II molecules (Fleischer and Schrezenmeier, 1988; Fleischer *et al*., 1989; Carlsson *et al*., 1988; Fraser, 1989; Uchiyama *et al*., 1989a; Mollick *et al*., 1989; Scholl *et al*., 1989). In contrast to classical antigens, the T cell response towards SEs showed extensive heterogeneity regarding T cell clonal activation (Fleischer and Schrezenmeier, 1988; Fleischer *et al*., 1989). The target of SEs on T cells was identified as polypeptide segments of the variable β chain (Vβ) region on the TcR with relatively little or no involvement from other parts of the receptor (White *et al*., 1989; Choi *et al*., 1989; Marrack and Kappler, 1990). Moreover, the binding of SEs to MHC class II molecules required no processing and occurred outside of the conventional epitope binding groove (Dellabona *et al*., 1990). These newly identified properties of SEs (Kappler *et al*., 1989) and also staphylococcal toxic shock syndrome toxin 1 (TSST-1) (Uchiyama *et al*. 1989a) led White *et al*. (1989) to coin the term "superantigen" (SAg) to designate these particular properties of SEs and thereafter that of other microbial proteins sharing the same properties (Marrack and Kappler, 1990).

SAg activation of immune system cells was also shown to trigger elevated secretion levels of cytokines such as interferon γ tumor necrosis factor-α (TN F-α) interleukin-1 β, and interleukin-2 (Cavaillon *et al*., 1982; Parsonnet *et al*., 1985; Parsonnet and Gillis, 1988; Jupin *et al*., 1988; Uchiyama *et al*., 1989b; Fast *et al*., 1989; Fischer *et al*., 1990). As described in another section, the *in vivo* release of these effectors may result in various diseases of a severe, acute, and chronic nature.

## MAJOR FUNCTIONAL FEATURES OF SUPERANTIGENS

There is no doubt that the initial seminal studies that led to the superantigen concept have subsequently spurred a wealth of intense research by many laboratories over the last fourteen years. A combination of experimental approaches that include biochemistry, biophysics, microbiology, molecular biology, genomics, immunology, cell biology, crystallography, animal models, and the clinical sciences has facilitated

the considerable progress made towards understanding these fascinating molecules. The state of the art concerning the multifaceted aspects of SAgs, from basic molecular mechanisms to the patient's bed, is presented in the following four chapters (50 to 54) of this volume. In this chapter, we briefly highlight our current knowledge of bacterial SAgs that particularly involve the mechanisms by which these proteins react with immune system cells and the resulting powerful responses by the host, which can corrupt normal immune responses to infection, favor autoimmune processes, and contribute to the pathogenesis of a number of diseases. Recent reviews may help the reader to globally appreciate the recent achievements linked to these molecules and their study (Leung *et al*., 1997; Kotb, 1997; Florkin and Aaldering, 1997; Krakauer, 1999; Alouf *et al*., 1999; Li *et al*., 1998; Fraser *et al*., 2000; McCormick *et al*., 2001b; Müller-Alouf *et al*., 2001a; Llewelyn and Cohen, 2002; Alouf and Müller-Alouf, 2003; Krakauer and Stiles, 2003; Baker and Acharya, 2004; Baker *et al*., 2004; Petersson *et al*., 2004).

The SAgs of viral origin are beyond the scope of this review. Therefore, we refer the reader to articles by Marrack and Kappler, 1990; Huber *et al*. 1996; Conrad *et al*., 1997; Stauffer *et al*., 2001; Llewlyn and Cohen, 2002; Wirth *et al*., 2000; Sutkowski *et al*., 2004.

## INTERACTION OF SAGS WITH IMMUNE SYSTEM CELLS

This interaction leads to the formation of trimolecular complexes via simultaneous cross-linking of SAgs to both MHC class II molecules on the surface of antigen presenting cells (APC) and T cell receptors at the surface of CD+4 and CD+8 T cells (Abe *et al*., 1991; Akatsuka *et al*., 1994; Li *et al*., 1999; Baker and Acharya, 2004; Petersson *et al*., 2004).

### Interaction with the T cell receptor

As mentioned above, SAg binding to TcR requires an interaction with residues found in the variable (V) region of the β chain, known as the Vβ elements. The other four variable elements of the TcR (e.g., Dβ, Jβ, Vα, and Jα) have little or no effect on TcR-SAg interaction except in rare cases (see below). The human TcR repertoire comprises about 25 different patterns of Vβ elements, known as Vβ families (Tomai *et al*., 1992; Champagne *et al*., 1993; Norrby-Teglund *et al*., 1994; Miyoshi-Akimaya *et al*., 2003; Omoe *et al*., 2004). Each SAg recognizes a specific subset of Vβ families which serves as a characteristic "signature" for an individual SAg (Kotb, 1997; Llewelyn and Cohen, 2002). For example, *S. pyogenes* pyrogenic exotoxin A (scarlet fever/erythrogenic toxin) triggers the activation and expansion of human T cells bearing the Vβ 2, 12, 14, 15 motifs while the pyrogenic exotoxin C recognizes theVβ 1, 2, 5.1, 10 motifs. In contrast, the staphylococcal TSST-1 molecule binds only Vβ 2 motifs (see Alouf and Müller-Alouf, 2003).

The percentage of responding T cells is dictated by the number of Vβ families that interact with a given SAg, as well as by the frequency of expression of SAg-specific Vβ families in an individual's repertoire. As a consequence, SAgs stimulate 5 to 30% of the human T cell repertoire at nano- to picogram concentrations, versus conventional antigen epitopes, which activate and expand less than 0.01% of T cells (Kappler *et al*., 1989; Krakauer 1999; Krakauer and Stiles, 2003).

Certain SAgs (e. g., staphylococcal enterotoxin A and TSST-1) bind to variable elements of the γδ chain of T lymphocytes bearing the appropriate γδ chains (Rust *et al*., 1990; Arvand *et al*., 1995; Morita *et al*., 2001). Interestingly, the staphylococcal enterotoxin H was shown to bind to variable elements of the α chain of TcR (Petersson *et al*., 2003).

### Interaction with MHC class II molecules

SAgs bind to conserved elements of MHC class II molecules with high affinity. Each SAg binds preferentially to distinct alleles of specific MHC isotypes, suggesting differents sites or modes of contact with MHC class II molecules (Choi *et al*., 1989; Scholl *et al*., 1989; Marrack and Kappler, 1990; Imanishi *et al*., 1992; Krakauer, 1999). For example, most staphylococcal enterotoxins bind HLA-DR, whereas many streptococcal pyrogenic exotoxins bind better to HLA-DQ. Differences between different HLA-DR and -DQ alleles might lead to differences between individual susceptibility to particular SAgs (Ulrich *et al*., 1995). Recently, Llwelyn *et al*. (2004) demonstrated that the binding of streptococcal and staphylococcal SAgs to HLA class II is influenced by allelic differences in class II molecules. For the streptococcal pyrogenic exotoxin A, class II binding is dependent upon DQ alpha-chain polymorphisms, such that HLA-DQA1*01 alpha-chains possess greater binding than DQA1*03/05 alpha-chains. The functional implications of differential binding on T cell activation were investigated in various experimental systems using human T cells and murine Vβ 8.2 transgenic cells as responders. Quantitative and qualitative differences resulting from differential HLA-DQ binding were found, as well as changes in T cell proliferation, cytokine production, and Vβ specific changes in T cell repertoire that have hitherto been regarded as a

defining feature of an individual SAg. These observations reveal a mechanism for the different outcomes seen following infection with SAg-producing bacteria. For detailed studies or reviews of SAg interactions with MHC class II molecules and TcR, see Kline and Collins, 1997; McKormick *et al*., 2001; Krakauer and Stiles, 2003; and Petersson *et al*., 2004.

## Structural aspects of SAgs with their receptors

Over the last ten years, X-ray crystallographic determinations of the three-dimensional structures for a substantial number of staphylococcal and streptococcal SAgs, which includes complexes formed with TcR as well as MHC class II molecules, have provided a great deal of information regarding the intricate interactions between these effectors and their receptors (Li *et al*., 1998; Sundberg *et al*., 2002; Baker and Acharya, 2004; Baker *et al*., 2004; Petersson *et al*., 2004; and Chapter 53 of this volume). Certain SAgs were found to possess one or two zinc binding sites, which may have implications in binding to MHC class II molecules. Overall, these studies have shown that despite their common molecular architecture and functional similarities, each SAg may have adopted subtly different ways to cross-link TcR and MHC class II molecules through the use of various structural regions within each SAg.

## Physiological and pathophysiological consequences of SAg interaction with immune system cells

### In vitro *investigations*

As a result of SAg-induced T cell proliferation, a wide array of pro-inflammatory, anti-inflammatory, and regulatory cytokines are massively released *in vitro* by stimulated cells with streptococcal and staphylococcal SAgs. These cytokines are namely comprised of monocyte-derived interleukins IL-1α and β, IL-8 and TNF α-molecules, as well as IL-2, TNF-β, and IFN-γ produced by type 1 helper T lymphocytes (Th1). Besides these pro-inflammatory cytokines, the anti-inflammatory cytokines, IL-4 and IL-10 derived from type 2 helper T lymphocytes (Th2), and the monocyte-derived soluble IL-1 receptor antagonist, are also released following SAg stimulation (Hackett and Stevens, 1993; König *et al*., 1994; Akatsuka et.*al*., 1994; Rink *et al*., 1996; Müller-Alouf *et al*., 1994, 1996, 1997, 2001b; Kotb *et al*., 1997; Krakauer, 1999). Moreover, IL-5, IL-12-, IL-13, and granulocyte-monocyte stimulating factors were also elicited *in vitro* (Müller-Alouf *et al*., 1997). These processes take place through a myriad of up-regulated and down-regulated immunological networks, transduction signals, and the cooperation of adhesion molecules on target cells (see Florkin and Aaldering, 1997; Krakauer, 1999), which ultimately lead to a cascade of events including further release (besides cytokines) of other pharmacologically active products that particularly involve the arachidonic acid/lipid pathways (Hensler *et al*., 1993).

The superantigen-induced up-regulation of cutaneous lymphocyte-associated antigen (CLA) may possibly contribute to the pathogenesis of streptococcal or staphylococcl superantigen-induced skin inflammation (Leung *et al*., 1995c; Zollner *et al*., 1996; Müller-Alouf *et al*., 2001b).

### *Clinical investigations*

*In vivo* pathological overproduction of cytokines and other immunomodulators, particularly those involving the inflammatory cytokine cascade, can be quite harmful. This process may overwhelm the host regulatory network, corrupt immunity (Llwelyn and Cohen, 1992), and cause shock that includes hypotension, tissue damage, and multiorgan failure, which may result in disease and even death (Stevens, 1992; Uchiyama *et al*., 1994; Ulrich *et al*., 1995; Schafer and Sheil, 1995; Leung *et al*., 1995a; Florquin and Aaldering, 1997; Norgren and Eriksson, 1997; Kotb, 1997; Bernal *et al*., 1999; McCormick *et al*., 2001b; Kikuchi *et al*. 2003; Bisno *et al*., 2003). These contentions are supported by a considerable body of experimental (animal models) and clinical evidence. Several investigations revealed the presence of high levels of various cytokines (TNF-α, TNF-β, Il-1α, Il-6, Il-8, IFN-γ) in the acute-phase plasma and/or in the cerebrospinal fluid of patients with severe infections by SAg-producing group A streptococci, particularly in streptococcal toxic shock syndrome (Hackett and Stevens, 1993; Nadal *et al*., 1993; Norrby-Teglund *et al*., 1995; Sriskandan *et al*., 1996). Host variation in cytokine responses to superantigens was shown to determine the severity of invasive group A streptococci (Norrby-Teglund *et al*. 2000, 2001). The detection of streptococcal SAgs in acute-phase serum samples from patients with severe streptococcal diseases has been also reported (Sriskandan *et al*., 1996; Proft *et al*., 2003b).

Tissue biopsy samples from patients with severe invasive streptococcal infections revealed increased expression of IL-1, TNF-β, IFN-γ, and CLA at the local site of infection (Leung *et al*., 1995c; Norrby-Teglund *et al*., 2001).

Other direct evidence for the role of SAgs in disease was also derived from studies that examined specific changes in the TcR Vβ repertoire of patients (Vβ expansion or depletion) during acute illness (Kotb, 1997). For example, flow cytometric analysis of peripheral blood

mononuclear cells from neonates with staphylococcal toxic shock syndrome (TSS) showed specific expansion of TcR Vβ2 positive T lymphocytes (Matsuda *et al*., 2003), thus suggesting *in vivo* stimulation of these cells by the staphylococcal SAg TSST-1. Similar selective expansion of T cells expressing Vβ2 motifs in TSS was earlier reported by Choi *et al*. (1990). Michie *et al*. (1994) reported that lymphocytes collected from two patients with streptococcal toxic shock syndrome (STSS) during the acute phase of the illness possessed: (i) a marked decrease in CD4+ and CD45 RA+(naive) T lymphocytes expressing the Vβ2 chain and (ii) an increase in cells expressing CD+8 and CD45 RO markers. A depletion of Vβ1, Vβ5.1, and Vβ12 patterns was observed in patients with severe streptococcal infections (Watanabe-Ohishi *et al*., 1995).

## IMMUNOPATHOPHYSIOLOGICAL PROPERTIES OF SAGS

Streptococcal and staphylococcal SAgs exhibit a remarkable spectrum of biological and pharmacological activities. These activities concern: (i) the pyrogenic effects elicited by those toxins as a consequence of released IL-1 and TNF-α, and their action upon the hypothalamus; (ii) reticuloendothelial system blockade and enhancement of host susceptibility to lethal shock by endotoxin; (iii) immunosuppression of humoral and cell-mediated responses, deletion of T-cell repertoire, anergy as well as apoptosis of lymphocytes, and (iv) autoimmune disorders (White *et al*., 1989; Marrack and Kappler, 1990; Leung *et al*., 1995a, b; Mahlknecht *et al*., 1996; Florkin and Aaldering, 1997; Norgren and Eriksson, 1997; Monday and Bohach, 1999; Macphail, 1999; Alouf *et al*., 1999; Llewelyn and Cohen, 2002; Mietke *et al*., 1996; Takahashi *et al*., 2001; Krakauer and Stiles, 2003).

## REPERTOIRE OF BACTERIAL SUPERANTIGENS

To date the continually expanding literature describes at least 40 bacterial SAgs produced by Gram-positive bacteria like *Staphylococcus aureus, Streptococcus pyogenes* (and other species), as well as those produced by Gram-negative bacteria such as *Yersinia pseudotuberculosis* and the wall-less *Mycoplasma arthritidis* (see Cole *et al*., 1981, 1991, 1996, 1997; Hodstev *et al*., 1998; Sawitzke *et al*., 2000; Mu *et al*., 2001; Shio *et al*., 2004). It is to be noted that according to Krakauer *et al*. (1997) *C. perfringens* enterotoxin is not a superantigen, which is in contrast to an earlier report by Bowness *et al*. (1992). The superantigenicity of *S. aureus* exfoliatins A and B has been reported (Zollner *et al*., 1996; Monday *et al*., 1999). However, other data indicate that these toxins are not SAgs (Plano *et al*., 2000).

## STAPHYLOCOCCAL SUPERANTIGENS

The repertoire of *S. aureus* SAgs (Lina *et al*. 2004) comprises at least 26 members (including natural molecular variants): (i) the classical staphylococcal enterotoxins (SEs) A, B, C (C1, C2, C3 variants, C ovine, C bovine), D, E and the recently identified enterotoxins G, H, I, J, K, L, M, N, O, P, Q, R (Monday and Bohach, 1999; Jarraud *et al*., 1999; Orwin *et al*., 2001, 2003; McCormick *et al*., 2001a, b; Omoe *et al*., 2004). All SEs are single-chain globular proteins with a molecular mass ranging from 25 to 28k Da (Monday and Bohach, 1999; Alouf and Müller-Alouf 2003; Uchiyama in this volume); (ii) the toxic shock syndrome toxin-1 (TSST-1) (Deresiewicz *et al*., 1994). As its name suggests, TSST-1 discovered in 1981 is the key agent of toxic shock syndrome (TSS). TSST-1 (formerly designated enterotoxin F; see Monday and Bohach, 1999) is a protein consisting of 194 amino acids (22,490 Da), which lacks a disulfide loop and does not induce emesis. An ovine variant of TSST-1 (TSST-O) produced by a mastitis-isolate of *S. aureus* differs from TSST-1 at seven residues (Deresiewicz *et al*., 1994). Both SEs and TSST-1 are relatively heat-stable and resistant to inactivation by proteases. It is worth mentioning that each staphylococcal (and streptococcal) strain generally produces one or more SAgs.

## STREPTOCOCCAL SUPERANTIGENS

A great number of SAgs have been discovered from several species of the *Streptococcus* genus: *Streptococcus pyogenes* (Group A streptococci) (Bisno *et al*., 2003), *Streptococcus equi* (Group C streptococci) (Artiushin *et al*., 2002), Group C and G *Streptococcus dysgalactiae subspecies equisimilis* (Sachse *et al*., 2002; Miyoshi *et al*, 2003; Igwe *et al*., 2003).

### Group A streptococci

To date, the repertoire of *S. pyogenes* SAgs includes eleven structurally and functionally related single-chain proteins with molecular weights ranging from about 23 to 27 kDa (Alouf and Müller-Alouf, 2003,

2004; Petersson *et al*., 2004). Most of these proteins have been purified to homogeneity and include: (i) the classical erythrogenic (scarlet fever) toxins A and C, also designated streptococcal pyrogenic exotoxins A and C (SPE A, SPE C) identified in 1924 and 1960 respectively (see Alouf, 1980; Alouf *et al*., 1999; Norgren and Eriksson, 1997; Alouf and Müller-Alouf, 2003). SPE A (25787 Da) and SPE C (24354 Da) are respectively encoded by bacteriophage genes *speA* and *speC;* and (ii) a series of recently discovered mitogenic exoproteins, namely streptococcal superantigen (SSA) (Mollick *et al*., 1993), SMEZ (for streptococcal mitogenic exotoxin Z) isolated by Kamezawa *et al*. (1997), SPE G, SPE H, SPE I, SPE J (Proft et al., 1999, 2000; McCormick *et al*., 2001a), SPE L, and SPE M (Smoot *et al*., 2002b; Proft *et al*., 2003a).

The occurrence of some of these exotoxins discovered over the past twelve years was initially inferred by genome mapping of *S. pyogenes* serotypes M1, M3, and M18 (Ferretti *et al*., 2001; Beres *et al*., 2002; Smoot *et al*., 2002a). The respective genes were further transcribed and the superantigenicity as well as lethality of corresponding SAg proteins established experimentally (Smoot *et al*., 2002b). Serologic studies showed the presence of antibodies against these SAgs in patients (Proft *et al*., 2003a).

## Genetic determinants of *S. pyogenes*

All known streptococcal SAgs with the exception of SMEZ, SPE G, and SPE J are encoded by bacteriophage genes integrated into the bacterial chromosome (Ferretti *et al*., 2001; Proft *et al*., 2003 b). Four naturally occurring *speA* alleles have been found in strains recovered from patients with severe invasive diseases. Three of these, *speA1*, *speA2*, and *speA3,* encode toxins differing by just a single amino acid. The toxin encoded by *speA4* was 9% divergent from the others with 26 amino acid changes. Strains expressing *speA2* and *speA3* have caused the majority of STSS episodes in the past twelve years, suggesting that the gene products SPE A2 and SPE A3 may be the more bioactive forms of the toxin (Alouf and Müller-Alouf, 2003). This may be due to higher affinity for the HLA-DQ molecule. Four and 24 different alleles of the *spe*C and *smez* genes have been identified, respectively (Proft *et al*., 1999; Arcus *et al*., 2000). Detailed studies on SMEZ-2 (Proft *et al*., 2000) and SMEZ-16 (Müller-Alouf *et al*., 2001b) proteins showed that they are the most potent SAgs (in terms of mitogenic activity) discovered thus far.

## Molecular relatedness

Determination of the nucleotide sequences from the eleven streptococcal SAgs identified to date has revealed various degrees of structural relatedness at both the amino acid sequence and three-dimensional levels. These SAgs share important structural homologies with various *S. aureus* enterotoxin SAgs. Interestingly, certain streptococcal SAgs are more similar to some staphylococcal SAgs than to other streptococcal SAgs. The genomic and structural relatedness suggests that these SAgs share a common ancestor (Arcus *et al*., 2000; Sundberg *et al*., 2002), and these issues are discussed in detail within the ensuing chapters.

## Other streptococcal superantigens

The identification of *spe M, ssa, and smeZ* genes from invasive strains of group C and G *Streptococcus dysgalactiae subspecies equisimilis* isolated from humans has been reported by Igwe *et al*. (2003). The identification of a *spe G* gene in human isolates of *S.dysgalactiae* group C and G was also reported by Sachse *et al*. (2002). A novel SAg produced by *S. dysgalactiae* designated SDM (for *S. dysgalactiae-derived* mitogen) was isolated by Miyoshi-Akiyama (2003). The SDM molecule (212 amino acids) is about 30% homologous with other SAgs at the amino acid sequence level. Phylogenetic analysis indicated that SDM belongs to a family distinct from the established SAgs.

Artiushin *et al*. (2002) identified two novel SAgs, SePE-H (27.5 kDa) and SePE-I (29.5kDa), from *Streptococcus equi*, which cause strangles, an inflammatory disease of the upper respiratory tract and associated lymph nodes of equine species. The two SAgs are respectively related to *S. pyogenes*, SPE H and SPE I, but share only 32% overall homology.

# CONCLUSION

The wealth of information on bacterial SAgs obtained during the past fifteen years has provided a great deal of knowledge regarding the molecular structure, the genetic aspects, and the interaction of these fascinating molecules with the immune system. The key role of SAgs in the pathogenesis of various acute, chronic, and certain autoimmune diseases has afforded new insights into elucidating pathophysiological effects of these molecules. Many questions remain unanswered as yet. New achievements will certainly emerge in the coming years, such as the design and use of novel therapeutical strategies (drugs and vaccines) in the management of SAgs-induced diseases, prophylaxis of susceptible populations against SAg-producing antibiotic resistant (e.g., vancomycin) *S. aureus*, and SAgs targeting toward tumor cells (Kotb, 1999; Macphail, 1999; Krakauer and Stiles, 2003; Arad *et al*., 2004; Petersson *et al*., 2004; Baker and Acharya, 2004).

CHAPTER

# 50

# Staphylococcal superantigens and the diseases they cause

*Takehiko Uchiyama, Ken'ichi Imanishi, Tohru Miyoshi-Akiyama, and Hidehito Kato*

## INTRODUCTION

Seventeen years have passed since the superantigen (SAG) concept was proposed for several exotoxins from *Staphylococcus aureus* (*S. aureus)*, such as toxic shock syndrome (TSS) toxin-1 (TSST-1) and enterotoxin A (SEA) and B (SEB) (White *et al*., 1989; Kappler *et al*. 1989). The binding structures essential for their SAG activity were also found in the same year to be MHC class II molecules (Fraser *et al* 1989; Herrmann *et al* 1989; Mollik *et al* 1989; Scholl *et al* 1989; and Uchiyama *et al*., 1989). Subsequently, a few other microbial species, such as *Streptococcus pyogenes* (*Str. pyogenes*) (Imanishi *et al*., 1990), mammary tumor virus in mice (Held *et al*., 2004), *Mycoplasma arthritidis* (Cole *et al*., 1991), and *Y. pseudotuberculosis* (*Y. ptbc*.) (Abe *et al* 1993; Uchiyama *et al*., 1993; and Miyoshi-Akiyama *et al*. 1995), were found to produce a handful of SAGs. Recently, staphylococcal and streptococcal species other than *S. aureus* and *S. pyogenes* were also reported to produce SAGs. To date, approximately 30 bacterial SAGs have been identified. A remarkable biological feature of SAGs is their capacity to stimulate T cells in vast numbers in a T cell receptor (TCR) Vβ element-specific manner in direct association with MHC class II molecules on antigen-presenting cells (APCs). It is well known that some staphylococcal enterotoxins cause food poisoning. In addition, the primary involvement of T cell activation by several SAGs, including TSST-1 in the pathogenesis of infectious diseases manifesting acute and systemic clinical symptoms, such as toxic shock syndrome (TSS) (Uchiyama *et al*., 1986, 1987, 1989a, and 1989b), and neonatal TSS-like exanthematous diseases (NTED) (Takahashi *et al*., 1998 and 2000) has been established. Another bacterial SAG is also a key pathogenic factor in *Y. ptbc*. infection (Abe *et al*. 1993; Uchiyama *et al*., 1993). A number of excellent reviews on bacterial SAGs have recently been published (Alouf and Muller-Alouf, 2003; McCormick *et al*., 2001; and Proft and Fraser, 2003).

Herein, we will review progress in research into new staphylococcal SAGs and the infectious diseases they cause, focusing on pathogenic mechanisms and early definitive disease diagnosis.

## EMERGENCE OF STAPHYLOCOCCAL SAGS

Staphylococcal SAGs, the location of SAG genes, and Vβ elements in the TCR β chain expressed in SAG-reactive T cells are presented in Table 50.1. Some staphylococcal enterotoxins were originally identified as enterotoxins because of their emetic activity. The international nomenclature committee on staphylococcal SAGs has proposed that only toxins exhibiting emetic activity after oral administration in a primate model be designated staphylococcal enterotoxins (Lina *et al*., 2004). Other related toxins lacking emetic activity or as yet untested for this activity were recommended to be designated "staphylococcal enterotoxin-like toxin type X (SElX)." In Table 50.1, names of toxins lacking emetic activity or which have not yet been tested for

this activity are listed according to the originally reported names and names arbitrarily revised by our group according to the SEIX nomenclature.

Of approximately 20 staphylococcal SAGs, SEA, SEB, staphylococcal enterotoxins C, D, and E (SEC1, SEC2, and SEC3, SED, SEE), and TSST-1 had already been discovered prior to proposal of the SAG concept. All of these toxins other than TSST-1 were well known to have emetic activity and to cause food poisoning (Bergdoll, 1979). Nucleotide sequences of the genes encoding these toxins were fully elucidated during the 1985–1990 period: SEA (Betley and Mekalanos, 1988), SEB (Ranelli *et al*., 1985), SECs (Bohach and Schlievert, 1985 and 1987; and Hovde *et al*., 1990), SED (Bayles and Iandolo, 1989), SEE (Cough *et al*., 1988), and TSST-1 (Blomster-Hautamaa *et al*., 1986). A group of enterotoxins share in common a disulphide bond, which is not directly involved in the aforementioned activity, but plays a role in maintaining the tertiary structure needed for this activity (Hovde *et al*., 1994). As to TSST-1, two research groups independently isolated a toxin from *S. aureus* strains isolated from patients with TSS and found this toxin to be the cause of TSS in 1981. The toxins were initially called pyrogenic exotoxin (Schlievert *et al*., 1981) or enterotoxin F (Bergdoll *et al*., 1981). Ultimately, however, the toxin was renamed TSST-1 because it was identified as the same molecule based on amino acid profiles and immunological cross-reactivity (Bonventre *et al*., 1983). TSST-1 was found to be produced by all of *S. aureus* strains isolated from TSS patients, and at low rates in isolates from individuals with no history of TSS (Bonventre *et al*. 1983; Cohen *et al*., 1983). In five (17.2%) of 29 TSS patients, sera contained antibodies (Abs) to the toxin, but only four (4.6%) of 87 isolates from other sources contained these antibodies (Bergdoll *et al*., 1981). TSST-1 was recognized as a pyrogen that enhanced susceptibility to lethal shock caused by endotoxin (Schlievert *et al*., 1981). These findings strongly suggested that TSST-1 is the major causative toxin of TSS. A key finding elucidating the pathogenic mechanism of TSS was the potent capacity of TSST-1 to activate T cells, a finding that was independently reported by three groups of investigators in the mid-1980s (Calvano *et al*., 1984; Poindexter and Schlievert, 1985; Uchiyama *et al*., 1986). The SAG activities of staphylococcal toxins described have been reviewed already elsewhere (Uchiyama *et al*., 1994). SEA, SEB, and SEC can function as pathogenic toxins in TSS in addition to TSST-1, because *S. aureus* strains producing these toxins in the absence of TSST-1 have been isolated from TSS patients (Crass and Bergdoll, 1986).

SEG and SEI were purified and their DNA sequences were determined in 1998 (Munson *et al*., 1998). The former exhibited emetic activity and a disulphide bond, while the latter lacked a disulphide bond and exhibited significantly less emetic activity. Both were also found to be produced by strains isolated from TSS patients negative for production of either SEA-SEE or TSST-1 (Jarraud *et al*., 1999), suggesting their involvement in the pathogenesis of TSS. SEG and SEI selectively activate human T cells with TCR expressing Vβ14, and T cells with Vβ5.1 and Vβ7, respectively (Jarraud *et al*., 2001). SEH was purified from a TSST-1 negative strain isolated from a TSS case, and its DNA sequence was determined in 1994 (Ren *et al*., 1994). This toxin showed emetic activity in rhesus monkeys (Su and Wong, 1995) and had the disulphide bond. SEH appears to be unique in that it stimulates T cells in a TCR Vα10-selective, but not TCR Vβ-selective manner (Petersson *et al*., 2003). An SED-encoding plasmid was found to encode a previously unidentified enterotoxin designated SEJ (Zhang *et al*., 1998). Grouping of SEJ into the SAG family may have to be delayed, however, because its SAG activity has not yet been determined. Genes for SEK and SEL were detected in a family of mobile pathogenicity islands of *S. aureus* (Lindsay *et al*., 1998). SEK

**TABLE 50.1** Staphylococcal SAGs and TCR Vβ repertoires of human T cells reactive with them, and gene location of them

| SAGs reported names | Arbitrarily revised names | Human TCR Vβ (Vα) specificity | Gene location |
|---|---|---|---|
| SEA | | 1.1, 5.3, 6.3, 6.4, 6.9, 7.3, 7.4, 9.1, 18 | phage |
| SEB | | 3, 12, 14, 15, 17, 20 | PI |
| $SEC_1$ | | 3, 6.4, 6.9, 12, 13.2, 14, 15, 17, 20 | |

| SEL | SElL | 5.1, 5.2, 6.7, 16, 22 | PI |
| SEM | SElM | 18, 21.3 | PI |
| SEN | SElN | 9 | PI |
| SEO | SElO | 5.1, 7, 22 | PI |
| SElP | | 5.1, 6, 8, 16, 18, 21.3 | phage |
| SEQ | SElQ | 2, 5.1, 5.2, 6.7, 21.3 | PI |
| SElR | | 3, 11, 12, 13.2, 14 | unidentified |
| SEU | SElU | ND | PI |
| TSST-1 | | 2, 4 | PI |

SEA-SEU, staphylococcal enterotoxin A-U; TSST-1, toxic shock syndrome toxin-1; SElJ-SElU, staphylococcal enterotoxin-like toxin type J-U; PI, pathogenicity island

and SEL selectively activate human T cells with TCR expressing Vβ5.1, Vβ5.2, and Vβ6.7, and TCR expressing Vβ5.1, Vβ5.2, Vβ6.7, Vβ16, and Vβ 22, respectively (Orwin *et al*., 2001, 2003). Both molecules lack the disulphide bond. SEL was found to have no emetic activity, while SEK was not examined in this regard. Sequence analysis of *seg-sei* intergenic DNA and flanking regions revealed that open reading frames for new SAGs, SEM, SEN, and SEO, in addition to *seg* and *sei*, were encoded in a tandem orientation (Jarraud *et al*., 2001). Although SEN and SEO were initially designated SEK and SEL, respectively, these toxins were different from the SEL and SEK reported by Orwin *et al*. in 2001 and 2003. The authors renamed their toxins SEN and SEO (Jarraud *et al*., 2001). It was found that the recombinant forms of these SAGs activate human T cells with TCR expressing Vβ21.3 in SEM, Vβ9 in SEN, and Vβ 5.1 and Vβ 7 in SEO. The gene *selp* that codes SElP (staphylococcal enterotoxin-like toxin P) was cloned from an *S. aureus* strain causing food poisoning. Recombinant SElP activates human T cells in a Vβ 5, 6, 8, 16, 18, 21-selective manner (Omoe *et al*., 2005). A gene coding SEQ was cloned from an *S. aureus* strain isolated from TSS patients, and a recombinant SEQ selectively activated human T cells with TCR expressing Vβ 2, Vβ 5.1, Vβ 5.2, Vβ 6.7, and Vβ 21.3 (Orwin *et al*., 2002). SEQ did not show emetic activity and lacked the disulphide bond. A gene coding SElR (staphylococcal enterotoxin-like toxin type R) was cloned from a strain of *S. aureus* that had caused an outbreak of food poisoning, and its recombinant protein was initially designated staphylococcal enterotoxin R (Omoe *et al*., 2003). The molecule, which was later renamed SElR according to the nomenclature committee due to lack of emetic activity testing, selectively activates human T cells with TCR expressing Vβ 3, Vβ 11, Vβ 12, Vβ 13.2, and Vβ 14 (Omoe *et al*., 2004). This toxin contains the disulphide bond. A gene coding SEU (staphylococcal enterotoxin U) was identified within the *egc* cluster that codes SEG, SEI, SEM, SEN, and SEO (Letertre *et al*., 2003). Its SAG and emetic activities have not as yet been examined, however.

A dendrogram of staphylococcal SAGs is presented as Figure 50.1. Apparently, staphylococcal SAGs can be divided into three major monophyletic groups and two minor groups. Group 1 contains the classic SAGs SEA, SED, and SEE, and some newly identified SAGs. Group 2 contains the classic SAGs SEB and SEC, and some newly identified SAGs. Group 3 is composed of only newly recognized SAGs alone. Groups 4 and 5 contained TSST-1 and SEH alone, respectively. Proteins in groups 1, 2, and SEH have the disulphide bond, and emetic activity has been confirmed as being present or absent. Proteins in group 3 and TSST-1 lack the disulphide bond, and activity has been confirmed as being low or absent, or has not yet been tested.

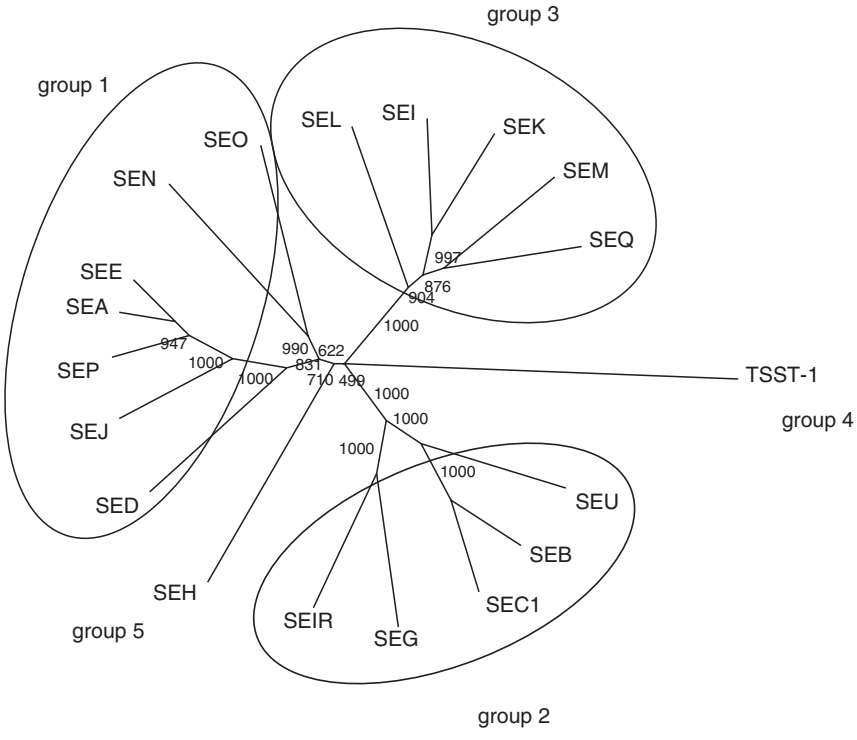

**FIGURE 50.1** Dendrogram of staphylococcal SAGs. The amino acid sequences of staphylococcal SAGs were aligned using the Clustal W program. Evolutionary distances were determined according to the correction of Kimura, and distance values were used to construct a dendrogram by the neighbor-joining method with the Clustal W program. The SAG dendrogram was drawn with the TREEVIEW program. The numbers at the nodes represent the bootstrap values based on 1,000 resampling trials.

Recent analyses have suggested that staphylococcal species other than *S. aureus* produce SAGs. For example, a molecule designated $SEC_{canine}$, which has high sequence identity with SEC2 and SEC3, has been identified from *S. intermedius* (Edwards *et al*., 1997). This molecule exhibited emetic activity and selectively stimulates human T cells with TCR Vβ repertoires similar to those of SEC1.

Recent genome analyses revealed that clusters of genes, 26 genes in total, coding SAG-like proteins, designated staphylococcal enterotoxin-like toxins (SETs), are encoded in the pathogenicity island at chromosomal region RD13 of several organisms (Williams *et al*., 2000; Kuroda *et al*., 2001; and Baba *et al*., 2002), mainly methicillin-resistant *S. aureus* (MRSA) strains. The crystal structure of one member of the SET family, SET3, shows low amino acid sequence homology with TSST-1 (26%), and shares a structure that is conserved in all bacterial SAGs. Several studies have shown, however, that SETs have no capacity to stimulate human T cells (Arcus *et al*., 2002; Kato *et al*., manuscript in preparation). The nomenclature committee recommended renaming members of this protein family the "staphylococcal superantigen-like" (SSL) proteins (Lina *et al*., 2004). It is our current opinion that these "SSL" proteins cannot be grouped into the SAG family.

## SAG ACTIVITY AND T CELL-DEPENDENT PATHOGENIC ACTIVITY OF STAPHYLOCOCCAL TOXINS

Staphylococcal SAGs exhibit potent T cell-stimulating activities that are closely related to the pathogenic mechanisms of TSS and NTED.

### SAG activity

Conventional protein antigens bind to MHC class II molecules inside their antigen-binding groove on the surfaces of APCs, such as macrophages and dendritic cells, after being processed into peptides by these cells, and the resulting complexes of peptides and MHC class II molecules activate T cells in small numbers. T cells use all five variable elements of the TCR, including Vα and Jα elements in the α chain and Vβ, Dβ, and Jβ elements in the β chain, to recognize activating antigenic complexes (we estimate activated cells to be at a level of $10^2$/respective peptide antigen). By comparison, SAGs behave toward T cells like "super antigens." They bind directly to MHC class II molecules outside their antigenic peptide-binding groove on the surfaces of APCs without being processed. Subsequently, the SAG . MHC class II complexes selectively activate virtually all T cells expressing particular Vβ elements in the TCR β chain. Variable elements other than Vβ are not intimately involved in the recognition of SAGs with the exception of SEH. For example, TSST-1 activates at quite low *in vitro* doses (1–10 pg/ml) virtually all human T cells expressing Vβ2 or Vβ4 in the TCR β chain, which account for more than 10% of total T cells, to induce proliferation and the production of various cytokines. SEH is reported to stimulate human T cells in a TCR Vα-selective manner. Human T cells expanded in response to stimulation with SEH, expressing TCR Vα10, while no TCR Vβ-specific expansion was seen (Petersson *et al*., 2003).

### T cell-dependent pathogenic mechanisms of TSS and other SAG-induced diseases

Histopathological findings of fatal TSS cases examined during the late 1970s and the early 1980s in the United States showed aseptic inflammatory lesions in multiple organs and abnormal changes in lymphoid tissues, including lymphopenia or lymphocytosis and erythrophagocytosis by macrophages (Larkin *et al*., 1982; Paris *et al*., 1982), suggesting that TSST-1-induced activation had occurred in the lymphoid tissues of patients. Rabbits receiving continuous administration of TSST-1 via implanted diffusion chambers filled with TSST-1-producing *S. aureus* (Rasheed *et al*., 1985) or osmotic pumps filled with TSST-1 (Parsonnet *et al*., 1987) exhibited histopathological changes similar to those in human TSS cases. TSST-1 is a potent T cell stimulant inducing massive proliferation and production of cytokines, as described previously. Side effects resembling clinical symptoms observed in TSS patients were seen in humans administered large doses of cytokines, which could be induced by TSST-1 (Gutterman *et al*., 1980; Lotze *et al*., 1985). TSST-1 produced no direct cytotoxic effect on cultured cell lines, while orthodox bacterial toxins, such as Shiga toxin and diphtheria toxin, were cytotoxic in such cell cultures. Taking these findings into consideration, it was hypothesized in the late 1980s that lymphokines produced in excess amounts by T cells activated with TSST-1 were primarily involved in the pathogenic mechanism of TSS (Uchiyama *et al*., 1986, 1987, 1989a, 1989b).

Later, T cell activation by TSST-1 was shown to be involved actually in the pathogenic mechanism of TSS. Examinations of T cells in peripheral blood mononuclear cells (PBMs) from patients with TSS by semiquantative PCR showed that massive expansion of $V\beta2^+$ T cells occurred at the acute phase (Choi *et al*., 1990). Recently, we determined the percentage of $V\beta2^+$ T cells using an immunologic method in which PBM T cells

were stained with various fluorescent dye-labeled Abs. It was found that the percentage of Vβ2$^+$ T cells increased beyond the control level in the acute phase in TSS patients (Matsuda *et al*., 2003) and NTED patients (Takahashi *et al*., 1998, 2000), as shown in Figure 50.2, and approached the control levels during recovery. The percentage of Vβ2$^+$CD4$^+$ T cells strongly expressing CD45RO was increased from the control level (5–8%) to approximately 28% in a TSS case and 24% in a NTED case. CD45RO is expressed in recently activated T cells. The results showed that activation of TSST-1-reactive T cells with TSST-1 occured in TSS and NTED patients. Experimental findings using mice also supported the validity of this view. Wasting was seen in normal mice, but not in mice lacking T cells, when mice were repeatedly injected with SEB from the neonatal stage (Marrack *et al*., 1990). Mutated SEB, which retains the ability to bind to MHC class II molecules but lacks T cell-stimulating activity, did not induce wasting.

A question arises as to the involvement of SAG activity in the emetic activity of staphylococcal enterotoxins. Investigations have supported the notion that the emetic activities of SEA and SEB are not mediated via their effects on T cells (Alber *et al*., 1990; Harris and Betley, 1995; Hoffman *et al*., 1996).

Nearly 10 years ago, a report claimed that TSST-1 was involved in the pathogenesis of Kawasaki disease, an acute febrile illness in infants and children with systemic clinical symptoms. As the clinical symptoms are quite similar in many respects with those of SAG-induced diseases, TSS, NTED, and *Y. ptbc*. infection, that report had an impact on our thinking. However, no further study supporting this contention was subsequently published. Likewise, we have found no evidence supporting this suggestion (Uchiyama, and Kato, 1999).

## Mode of *in vivo* T cell response to SAGs in humans and animals

SAG-induced expansions of human and mouse T cells are clearly demonstrated by *in vitro* experimental systems employing either $^3$H-thymidine uptake or PCR and immunological methods. However, we have long faced a discrepancy in the modes by which SAG-reactive T cells expand *in vivo* in mice versus humans. Analysis of the expansion of TSST-1-reactive Vβ2$^+$ T cells in TSS patients using the PCR method (Choi *et al*., 1990) suggested that Vβ2$^+$ T cells exhibited prolonged expansion, i.e., for more than 40 days, after onset of the illness. By comparison, in mice injected with SEA or SEB, which exhibit a level of T cell stimulating activity in human T cells *in vitro* similar to that of TSST-1, T cells reactive with these antigens exhibited only a transient expansion on day 2 or 3 after the injection, when examined using an immunological method (Rellahan *et al*., 1990; Kawabe and Ochi, 1991). The findings obtained in mouse experiments had been widely considered to reflect the *in vivo* response of T cells activated by SAGs. Over- or underestimation of Vβ2$^+$ T cells possibly associated with the semiquantitative PCR could not, however, explain this discrepancy. Recently, we have used

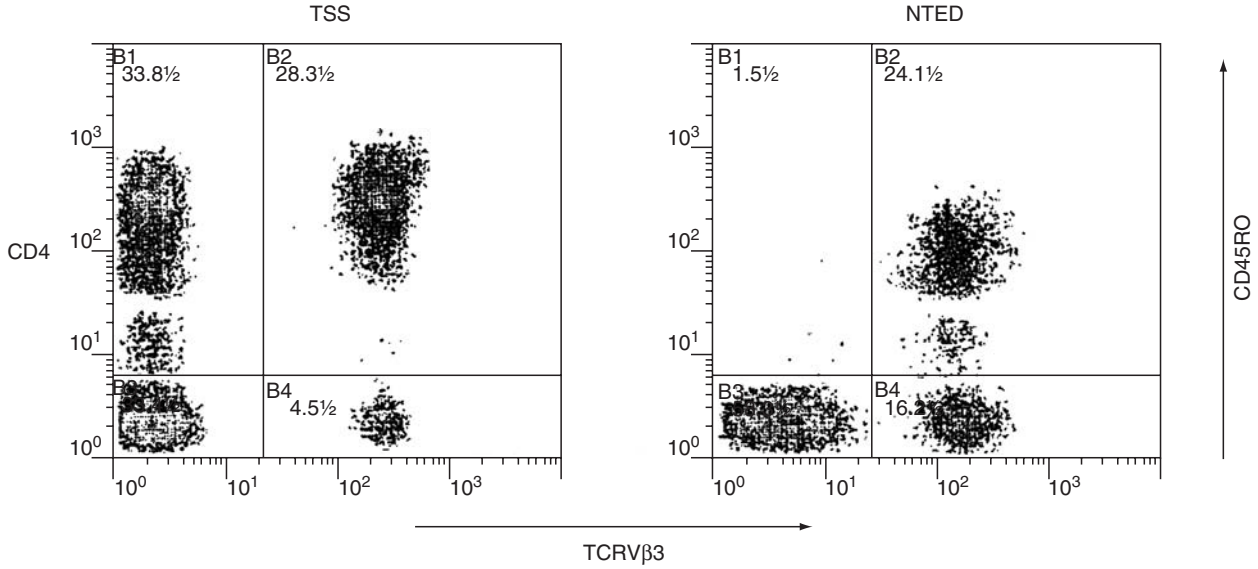

**FIGURE 50.2** Expansion of Vβ2$^+$ T cells in an adult patient with TSS and a neonate with NTED. Adult and neonatal patients manifesting acute and systemic clinical symptoms caused by MRSA were examined for the percentages of Vβ2$^+$CD4$^+$ T cells in PBM. Vβ2$^+$CD4$^+$ T cells comprised less than 10% of PBMs in healthy neonatal and adult controls. The percentages of CD45RO$^+$ cells among Vβ2$^+$ T cells are below 50% in healthy adults and below 5% in healthy neonates.

an immunologic method to observe the response patterns of Vβ2$^+$ T cells in PBM from two adult patients with TSS who contracted the illness as puerperal infection (Figure 50.3) (Matsuda *et al*., 2003). Both CD4$^+$Vβ2$^+$ T cells and CD8$^+$Vβ2$^+$ T cells in PBM expanded to 5 to 7 times the control level in the acute phase of the illness, and subsequently decreased gradually toward the control level over a period of 40 to 60 days or more, confirming the findings obtained by PCR.

It is reasonable to assume that adult patients with TSS have been exposed to TSST-1 continuously for a long period, while SAG-injected mice have been exposed to SAG for only a short period. The mechanism by which T cells are exposed to SAGs *in vivo* might account for the discrepancy. To address this question, C57BL/6 mice were injected with 10 μg of SEA or implanted with an osmotic pump containing 10 μg SEA, to be delivered continuously for approximately seven days. These mice were monitored for the percentages of SEA-reactive Vβ3$^+$ and Vβ11$^+$ T cells in splenic CD4/CD8 subsets at various time points after the treatments (Figure 50.4) (Chen *et al*., 2002). In mice injected with SEA, all four SEA-reactive T cell fractions uniformly exhibited a transient expansion, though at low levels, two days after injection. By comparison, in mice implanted with the SEA pump, massive Vβ3$^+$CD4$^+$ T cell expansion had occured by day 6 after implantation, and was maintained at comparably high levels for more than 10 days with only a slight subsequent reduction. Vβ11$^+$CD4$^+$ T cells had expanded moderately by day 6 after implantation and then decreased gradually to the control level, indicating that Vβ3+ T cells are highly responsve to SEA, while Vβ11$^+$CD4$^+$ T cells are moderately responsive. The SEA-reactive CD8$^+$ T cells exhibited only a transient expansion. In the aforementioned study of two TSS patients, the Vβ2$^+$CD8$^+$ fraction behaved in a manner similar to the CD4$^+$ fraction (Figure 50.3). However, in several other TSS cases Vβ2$^+$CD8$^+$ T cells responded weakly as compared with Vβ2$^+$CD4$^+$ T cells (Matsuda *et al*., manuscript in preparation). Findings were similar in patients with *Y. ptbc*. infection and mice implanted with an osmotic pump containing YPM. In the late acute phase patients, T cell expansion was observed only for Vβ3$^+$ T cells among three YPM-reactive (Vβ3$^+$, Vβ9$^+$, and Vβ13$^+$) human T cell populations (Abe *et al*., 1997). In the mouse experiments, Vβ7$^+$CD4$^+$ T cells corresponding to human Vβ3$^+$CD4$^+$ T cells exhibited prolonged expansion, while other YPM reactive CD4$^+$ T cell populations showed transient expansion (Chen *et al*., 2002). Taken together, these results indicate that the response pattern of SAG-reactive T cells *in vivo* differs markedly depending on which TCR Vβ elements the T cells express and the subsets of CD4/CD8. It appears likely that the Vβ2$^+$ T cells of the two TSST-1-reactive human cell populations respond strongly to TSST-1 *in vivo*.

## INFECTIOUS DISEASES CAUSED BY STAPHYLOCOCCAL SAGS

TSS and NTED have been established as being caused by staphylococcal SAGs. In this section, we will describe clinical features and early definitive diagnosis of these two diseases.

### TSS

#### *General description of TSS*

In 1978, Todd *et al*. originally reported a new disease entity characterized by multiple organ failure in seven children aged 8 to 17 manifesting high fever, profound hypotension, profuse diarrhea, skin rash, mental confusion, and renal failure (Todd *et al*., 1978).

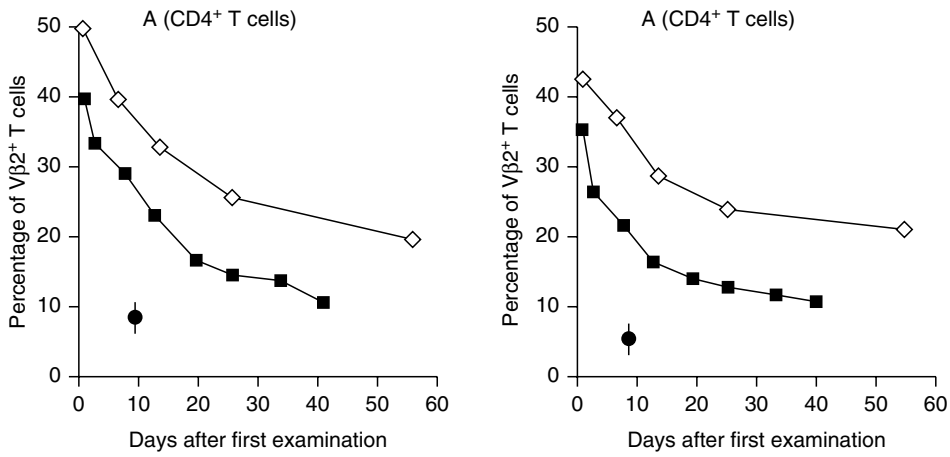

**FIGURE 50.3** Expansion of TCR Vb2$^+$ T cells in two women with TSS. The percentages of Vβ2 $^+$CD4$^+$ T cells (left panel) and Vβ2 $^+$CD8$^+$ T cells (right panel) in PBMs were determined since day 6 after disease onset in case 1 (closed squares), and day 5 after disease onset in case 2 (open squares). The two patients refer to the same cases as in the text and Table 50.2. ● represents mean ± standard deviation in healthy adults (four men and three women). From Matsuda *et al*., 2003.

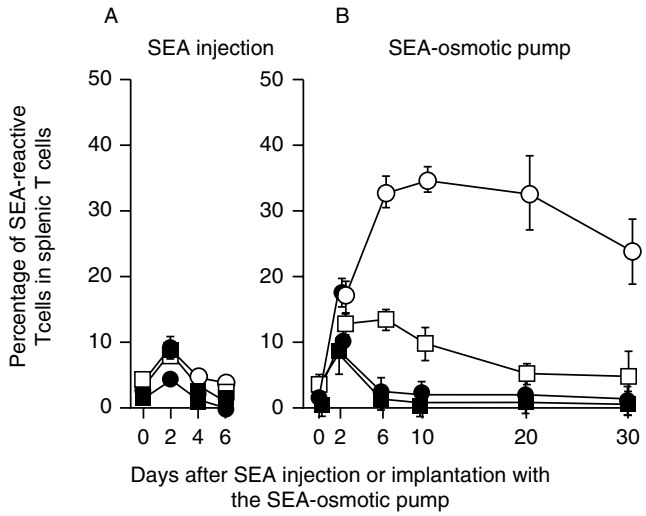

**FIGURE 50.4** TCR Vβ and CD4/CD8 subset-dependent expansion of SEA-reactive T cell fractions in mice implanted with SEA-osmotic pumps. C57BL/6 mice were injected with 10 μg of SEA (three to four per group) (A), or implanted with an osmotic pump containing 10 μg of SEA (six to eight per group) (B), and then monitored individually for the percentages of SEA-reactive T cells among splenic T cells (○). Vβ3 $^{+}$CD4$^{+}$ T cells; (●), Vβ3 $^{+}$CD8$^{+}$ T cells; (❒), Vβ11 $^{+}$CD4$^{+}$ T cells; (■), Vβ11$^{+}$CD8T cells. From chen *et al.*, 2002.

The disease was named toxic shock syndrome, because some of the patients were positive for *S. aureus* at foci of infection while blood, cerebrospinal fluid, or urine was negative, suggesting an association of the illness with a toxin from infectious organisms rather than direct invasion by these organisms. In the early 1980s, this multisystem disease was frequently observed in women with onset mainly during menstruation. The case fatality ratio was initially high, at 5–6%. Retrospective analysis has shown that around 1700 cases, mainly female patients whose onsets were during menstruation, were reported to the Centers for Disease Control and Prevention from 1970 to 1982. It seems likely that this major outbreak of TSS was related to a new type of tampon which had been contaminated with *S. aureus* (Todd, 1988). As to toxins causing TSS, TSST-1 was discovered in 1981, as described previously. Many papers have suggested that SEA, SEB, SEH, SEI, and SEJ in addition to TSST-1 are involved in the pathogenic mechanism of TSS, because *S. aureus* strains that produced the above toxins were isolated, without TSST-1, from some patients with TSS. These toxins were thus considered to have caused TSS. Surveillance in the United States showed that the incidence of TSS subsequently declined until 1996 (Hajjeh *et al.*, 1999). In recent years, however, the calculated incidence of TSS has reportedly been increasing from one case of TSS per month in 2000 to four cases per month in 2003 in an area with a population of approximately 3,000,000 (Schlievert *et al.*, 2004). In Japan no data are available as to whether the incidence of TSS is increasing. It would appear to be necessary to determine the TSS incidence rate in Japan, because we occasionally see TSS patients who manifest the illness as a puerperal infection.

We have observed several TSS patients who contracted the illness during the course of a puerperal infection. Some of these women manifested clinical symptoms that did not meet the clinical criteria for TSS, but the diagnosis of TSS was confirmed by determining the percentage of Vβ2$^{+}$ T cells in PBM.

### *Early definitive diagnosis of TSS*

In Japan, clinicians have described several puerperal infection cases caused by *S. aureus*, which suggested TSS, but could not be diagnosed as such according to either the strict clinical criteria for TSS (Shands *et al.*, 1989) or the revised criteria (Tofte and Williams, 1981). Diagnosis of TSS according to clinical features, irrespective of the strict or revised criteria, requires a minimum of several days' observation to obtain a reliable diagnosis. As TSS is often life-threatening, an early definitive diagnosis is crucial. We speculate that determining the percentage of Vβ2$^{+}$ T cells would provide a valuable clue to making a reliable diagnosis of TSS, because this method is based on the key pathogenic mechanism of TSS. Under this assumption, we have been monitoring the percentage of Vβ2$^{+}$ T cells in the PBMs of our patients using an immunological method. The patients investigated are women who manifest acute and systemic clinical symptoms as puerperal infections caused by *S. aureus*. Results obtained are sent to the wards within five hours after obtaining PBM specimens. Two TSS cases are presented in detail herein (Matsuda *et al.*, 2003). Clinical symptoms of case 1 were too severe and complex to permit diagnosis according to the clinical criteria without evaluation of Vβ2$^{+}$ T cells.

**Case 1:** A 29-year-old Japanese woman underwent cesarean section at a private clinic after premature membrane rupture. On postpartum day 3, shock with hypotension developed (day of disease onset), and she was transferred to our University Hospital. On admission, her body temperature was 39°C, systolic blood pressure 80 mmHg, respiratory rate 44 breaths /min., and heart rate 140 beats/min. She showed neither skin rash nor desquamation. MRSA, later confirmed to produce TSST-1, was detected in vaginal discharge. The clinical symptoms and laboratory data suggested a diagnosis of septic shock with disseminated intravascular coagulation (DIC). The clinical criteria for definite TSS and the revised form, as well as the

compatibility of her clinical symptoms and laboratory data with TSS are presented in Table 50.2. The clinical symptoms and laboratory data did not meet either set of criteria during her entire clinical course. On day 3 after admission (day 6 after disease onset), examination of Vβ2$^+$ T cells in PBM showed a marked expansion of Vβ2$^+$ T cells (Figure 50.3), indicating the illness to be TSS.

**Case 2:** A 33-year-old Japanese woman had a fever one week after an uncomplicated spontaneous vaginal delivery at a private clinic (day of disease onset). She was transferred to our University Hospital. On admission, her body temperature was 38.8°C, blood pressure 80/52. A diffuse erythematous rash starting on the chest had spread to the face and extremities, and resolved within eight days after admission. One day after admission, MRSA was isolated from vaginal discharge and breast milk. The clinical symptoms and laboratory data suggested a diagnosis of TSS. Examination of Vβ2$^+$ T cells on day 5 after admission (day 5 after disease onset) showed marked expansion of Vβ2$^+$ T cells, confirming the illness to be TSS.

Puerperal infection is a major cause of maternal death. Postpartum TSS has received attention as a potential cause of puerperal infection (Davis *et al*., 1998). Although we do not consider the incidence of TSS to be high in Japan, we are concerned that this disease is not rare in small private clinics. The immunological method described herein appears to be suitable for making an early definitive diagnosis of TSS.

**TABLE 50.2** Two types of clinical criteria for TSS and the compatibility to the criteria of the clinical symptoms and test results of two TSS cases

## Neonatal TSS-like exanthematous disease

### *General description of NTED*

In the mid-1990s, Takahashi *et al*. described a number of neonates who developed systemic exanthema, fever, low-positive serum C-reactive protein values, and thrombocytopenia within the first week of life, and described it as a new disease entity (Takahashi *et al*., 1995b). Many cases with this illness have been observed in hospitals in Japan since that report. Clinical symptoms and laboratory data of 20 patients are presented in Table 50.3 (Takahashi *et al*., 1998). A fever occurred on the second or third day of life and lasted for one day in most term infants, but was not seen in most of the preterm infants. Typical exanthema featuring a macular erythema spreading from the trunk to the face and extremities including the palms and soles lasted two to three days in term infants and two to six days in preterm infants. There was no desquamation, even during recovery. Platelet counts reach their lowest points on day 2–3 after the onset of exanthema in both preterm and term infants. CRP values were above the upper limit of normal in most patients. Microbiological tests showed all nasopharyngeal or umbilical swabs taken to be positive for TSST-1-producing MRSA. Blood cultures were all negative for MRSA, except in patient 20. Most term infants recover spontaneously without active treatment within a week of disease onset. Complications including apneic attacks and gastrointestinal signs were seen in many of the preterm infants, but were rare in the full-term neonates. Two of the preterm infants died as a result of tracheo-oesophageal fistula and necrotizing enterocolitis, respectively.

### *The pathogenic mechanism of NTED*

The findings of microbiological tests strongly suggested the pathogenic mechanism of this neonatal disease to be closely related to TSS, although clinical symptoms of most patients did not meet the clinical criteria for TSS. In a collaborative study, we theorized

that examination of the percentage of Vβ2$^+$ T cells in PBM T cells from patients might provide a clue to the pathogenesis of the neonatal disease.

PBM T cells from four of the 20 patients described in Table 50.3 during the acute and recovery phases and PBM T cells from four MRSA-free neonates on postnatal day 5 (control) were stained with Abs to Vβ2, Vβ3, Vβ9, Vβ12, and CD45, and examined for the percentages of T cell fractions expressing the respective Vβ elements using flow cytometry (Table 50.4) (Takahashi *et al*., 1998). It was found that the percentage of Vβ2$^+$ T cells was significantly higher in the four acute phase patients, and these percentages decreased to the control level during the recovery phase. The percentages of Vβ3$^+$, Vβ9$^+$, and Vβ12$^+$ T cells, which react with SEA, SEB, or SEC, were similar in the patients and controls, irrespective of the illness phase. Many of the Vβ2$^+$ T cells in the four patients expressed CD45RO in both acute and recovery phases. The results indicated that the illness was TSS in neonates with umbilical or nasopharyngeal MRSA colonization. As this neonatal disease could not be diagnosed as TSS, despite its pathogenesis being fundamentally the same as that of TSS, we proposed designating this disease neonatal TSS-like exanthematous disease (NTED) (Takahashi *et al*. 1998).

While monitoring the percentage of Vβ2$^+$ T cells in NTED patients after disease onset, we initially found that the mechanism of Vβ2$^+$ T cell expansion differed strikingly between adult patients with TSS and neonates with NTED. The percentages of Vβ2$^+$CD4$^+$ and Vβ2$^+$CD8+ T cells in NTED patients were high in the acute phase, but decreased rapidly approaching the con-

**TABLE 50.4** Expansion of Vβ2-positive T cells in NTED patients

From Takahashi *et al*., 1998.

trol level within 10 days and were within 10% of the control level by one or two months after disease onset (Figure 50.5) (Takahashi *et al*., 2000). By comparison, Vβ2$^+$ T cells in adult patients with TSS exhibited a prolonged expansion over 40–50 days after the disease onset (Figure 50.3). Reasons for the different response patterns seen in the two diseases will be discussed later. Next, we noticed that the percentage of Vβ2$^+$ T cells was occasionally quite low, dropping below the control level early in the illness, then increasing rapidly to 10 times the control level at the first examinations two or three days later (Kato *et al*., 2002). Currently, we consider T cells activated with TSST-1 to have disappeared from peripheral blood in the early acute phase due to being mobilized into lymph nodes or the spleen. As preterm infants with NTED manifest severe clinical symptoms and signs, the examination of Vβ2$^+$ T cells would be useful in making an early definitive diagnosis of NTED.

We have questioned whether T cells of asymptomatic MRSA carriers are affected by TSST-1. Examination of PBM T cells from 10 asymptomatic neonatal MRSA carriers on postnatal day 5 showed the percentages of Vβ2$^+$CD4$^+$ and Vβ2$^+$CD8$^+$T cells to be within normal range, but expression of CD45RO in Vβ2$^+$CD4$^+$ T cells increased in three of the 10 neonatal carriers (Takahashi *et al*., 2000), suggesting that Vβ2$^+$ T cells were only activated marginally by TSST-1 in some asymptomatic MRSA carriers.

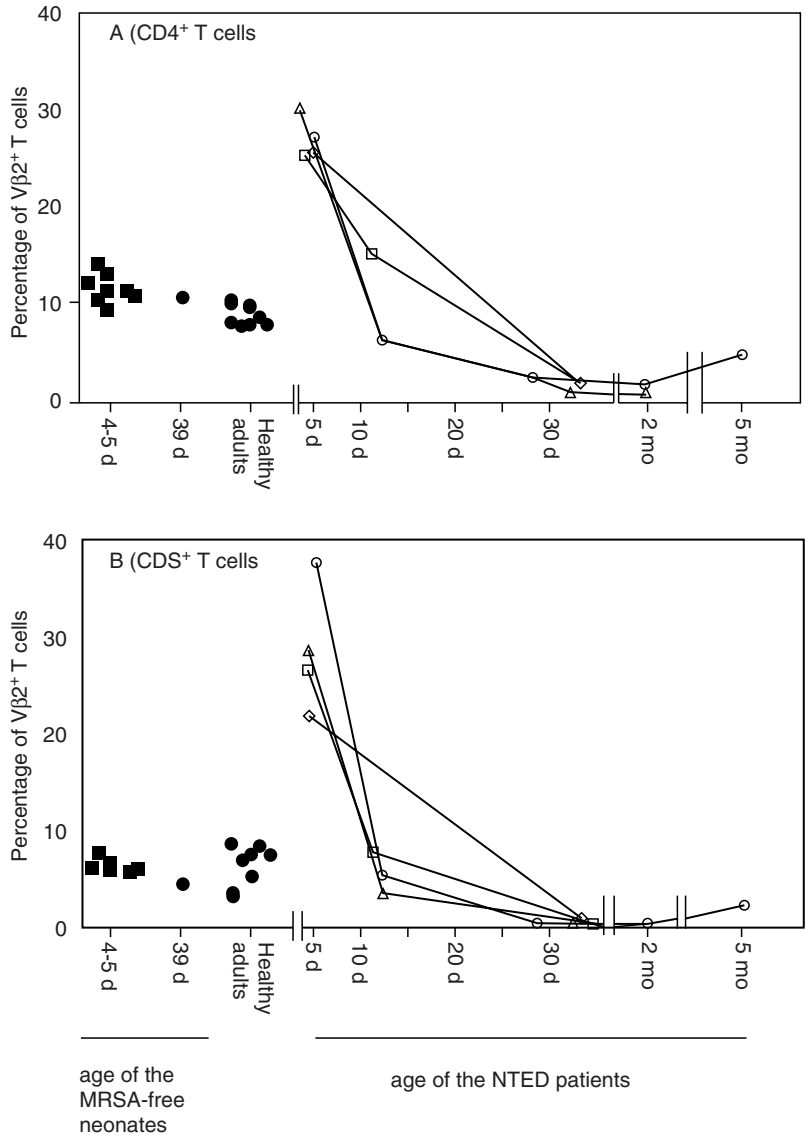

**FIGURE 50.5** Fate of TCR Vβ2$^+$ T cells in NTED patients. Four NTED patients (○, □, △,◇), nine MRSA-free neonates on postnatal days 5 (■) or 39 (◆), and seven healthy adults (●) were examined for the percentages of Vβ2 $^+$CD4$^+$ T cells (A) andVβ 2$^+$CD8$^+$ T cells (B) in PBMs. From Takahashi *et al*., 2000.

### *Protective role of maternal anti-TSST-1 Abs against development of NTED*

Anti-TSST-1 Abs are known to play a protective role against the development of TSS in adults. As neonates are generally protected from developing various diseases by specific Abs transferred transplacentally or by breast milk from their mothers, it is possible to speculate that a similar mechanism operates in neonates colonized with MRSA. Serum anti-TSST-1 IgG Abs were below detectable limits in the acute phase of the disease in all four NTED patients examined, but later rose markedly in three of these infants (Takahashi *et al*., 2000). In three of the 10 asymptomatic MRSA carriers with moderately activated $V\beta2^+$ T cells, the Abs were undetectable on postnatal day 5, and increased thereafter, while high on postnatal day 5 in four of the other seven asymptomatic carriers without activated $V\beta2^+$ T cells (Takahashi *et al*., 2000). These results indicate anti-TSST-1 IgG Abs transferred transplacentally to play a role in protecting neonates from NTED development.

## CORRELATION BETWEEN THE LEVEL OF T CELL ACTIVATION AND CLINICAL SYMPTOM SEVERITY IN TSS AND NTED

The view that TSST-1-induced T cell activation is primarily involved in generation of pathologic changes in TSS and NTED would appear to explain why the illness is severe in TSS and mild in NTED (Table 50.5). From the findings that the expanded state of $V\beta2^+$ T cells persists for a much longer period in adult patients with TSS than in neonates with NTED (Figs 50.3 and 50.5), it is possible that the magnitude of the T cell activation response to TSST-1 is much higher in the former than in the latter. The illness is quite severe in adult patients with TSS as compared with neonates with NTED. Cytokines, which have been strongly implicated in pathogenic changes, would be produced in much higher amounts in adult patients with TSS than in neonates with NTED. The clinical course of a term infant with NTED who manifested exceptionally severe clinical symptoms including DIC supports the above view. The expansion of $V\beta2^+$ T cells among PBMs from this patient was relatively prolonged (Miki *et al*., manuscript in preparation).

There are two possible explanations as to why the magnitude of the TSST-1-induced T cell response *in vivo* differs between adult and neonatal patients. First, the degree of T cell maturation is lower in neonates than in adults, resulting in the lower T cell response in NTED patients than in adult TSS patients.

**TABLE 50.5** T cell response to TSST-1 and clinical symptoms are quite different between neonates and adults

| | Neonates | Adults |
|---|---|---|
| Diseases induced by TSST-1 | NTED | TSS |
| Clinical symptoms | Not severe in most cases of term infants | Severe, often life-threatening |
| Fate of TSST-1-reactive T cells in patients | Transient expansion | Prolonged expansion |
| Maturition of T cells in the peripheral lymphoid organs | Immature | Maturated |

Alternatively, the relative amount of TSST-1 to which patients are exposed is much lower in the former than in the latter. According to Burnet's clonal selection theory, self-reactive lymphocytes in the neonatal period are eliminated upon encountering their corresponding self antigens because of their intrinsic immaturity (Burnet, 1959). Recent analyses have substantiated the above notion regarding human T cells (Takahashi *et al*., 1995; Imanishi *et al*., 1998; Kobayashi *et al*., 2003). For example, we have observed that cord blood $CD4^+$ T cells and human $CD1a^-CD4^+$ thymic T cells in the final stage of maturation in the thymus, which are believed to be the major source of cord blood T cells, were highly susceptible to anergy induction with TSST-1 *in vitro*, while $CD4^+$ T cells in adult PBM were highly resistant (Takahashi *et al*, 1995a; Imanishi *et al*., 1998). We have proposed that a defect in the interaction between the Src family kinase Lck and phosphatase CD45 after stimulation with antigens including SAGs is mainly responsible for the immaturity of neonatal T cells (Fujimaki *et al*., 2001). In most NTED patients, causative bacteria have been detected on the body surface but not in blood, while bacteria have often been detected in blood and damaged tissues in adult TSS patients, supporting the second possible explanation. These two factors may have worked synergistically to exacerbate the illness in adult patients while ameliorating neonates.

CHAPTER

# 51

# Streptococcal superantigenic toxins

*Thomas Proft and John D. Fraser*

## INTRODUCTION

*Streptococcus pyogenes* (or Lancefield group A streptococcus, GAS) is a Gram-positive commensal bacterium that colonizes human tissue. It is estimated that between 5–15% of healthy individuals harbor the bacterium, usually in the respiratory tract, without causing disease. However, when the host immune system is compromised or when the bacteria are able to penetrate the physical barrier of the skin (e.g., wound infection), *S. pyogenes* can cause a wide range of diseases. Mild GAS diseases include pharyngitis and tonsillitis, which occur primarily among children 5–15 years of age and in confined institutions, like military camps. If untreated, these diseases can develop into severe conditions such as acute rheumatic fever (ARF), rheumatic heart disease (RHD), and poststreptococcal acute glomerulonephritis (Cunningham, 2000; McDonald *et al*., 2004). Penetration of the skin barrier by GAS can cause bacteremia and severe invasive deep tissue infections, such as cellulitis, myositis, and necrotizing fasciitis (also known as the "flesh-eating disease") (Stevens, 1992, 2000; Seal, 2001; McCormick *et al*., 2001b).

During the late nineteenth century, GAS caused epidemic outbreaks of scarlet fever and ARF in Europe and in Northern America. After World War II, incidence rates for scarlet fever and ARF sharply declined and by the 1970s reached their lowest point. However, since the 1980s there has been an alarming increase in GAS-mediated invasive disease, not only in frequency, but also in severity.

The most severe form of invasive infection results in clinical symptoms similar to staphylococcal toxic shock syndrome and was therefore described as streptococcal toxic shock syndrome (STSS). This life-threatening disease (30–70% mortality) was first recognized in 1983 (Willoughby and Greenberg, 1983) and has been observed worldwide since 1987 (Stevens 1992, 1995, 2000; McCormick *et al*., 2001). Characteristic symptoms of STSS include hypotension, fever, rash, vomiting, diarrhea, multiple organ failure, and shock (Working Group on Severe Streptococcal Infections, 1993).

It is widely believed that the resurgence of invasive GAS infections is the result of an interplay between changes in bacterial virulence and host susceptibility (Schwartz *et al*., 1990). The acquisition of novel virulence factors might have resulted in the development of more aggressive GAS strains (Bisno *et al*., 2003). Virulence factors include several adhesion molecules and a large number of secreted proteins (over 30) comprising the streptococcal superantigens (this chapter), cytolysins, proteases, DNAses, and various hydrolytic enzymes.

## SUPERANTIGENS

The term "superantigen" (SAg) was coined in 1989 by the research group of Philippa Marrack and John Kappler and describes a group of proteins with extremely high potency to stimulate human, and to a certain degree, other mammalian CD4 and CD8 T cells (White *et al*, 1989).

Unlike conventional peptide antigens, SAgs bind to major histocompatibility class II (MHC II) molecules outside the peptide-binding groove and are presented as unprocessed molecules to T cells carrying a T cell receptor (TcR) with a particular Vβ region (Dellabona

*et al*., 1990; Herman *et al*., 1991; Seth *et al*., 1994). Since the number of different Vβ regions in the human T cell repertoires is restricted to less than 50, comprising about 24 major types of Vβ elements, and since most SAgs can bind more than one Vβ, up to 25% of an individual's T cell population can be activated, resulting in massive release of pro-inflammatory cytokines and T cell mediators (Herman *et al*., 1991; Miethke *et al*., 1992; Hackett and Stevens, 1993; Müller-Alouf *et al*., 1996). In contrast, conventional peptide presentation results in activation of only one in $10^5$–$10^6$ T cells (0.001–0.0001%). This makes SAgs the most powerful T cell mitogens ever discovered. Concentrations of less than 0.1 pg/ml of a bacterial superantigen are sufficient to stimulate the T lymphocytes in an uncontrolled manner, resulting in fever, shock, and death (Jupin *et al*., 1988; Fast *et al*., 1989; Herman *et al*., 1991; Miethke *et al*., 1992; Lavoie *et al*., 1999; Bohach *et al*., 1990; Marrack and Kappler, 1990; Fraser *et al*., 2000; McCormick *et al*., 2001b).

There are two major categories of SAgs: the viral SAgs and the bacterial SAgs. Viral SAgs comprise the minor lymphocyte stimulating (Mls) antigens from the mouse mammary tumor virus (MMTV) and the recently discovered SAgs encoded by human endogenous retroviruses.

The bacterial SAgs are small, secreted exotoxins (15–28 kDa) produced by *Staphylococcus aureus*, *Streptococcus pyogenes*, *Streptococcus equi*, *Streptococcus disgalactiae*, *Yersinia pseudotuberculosis*, and *Mycoplasma arthritidis.*

## GROUP A STREPTOCOCCAL SUPERANTIGENS

### Discovery and nomenclature

The discovery of streptococcal superantigens can be divided into two major periods: the pre-genomic era and the post-genomic era. During the pre-genomic era, streptococcal SAgs were identified in a cell culture supernatant based on their mitogenic activity. The toxins were biochemically enriched to a purity that was sufficient for functional studies and for analysis by N-terminal sequencing. In the post-genomic era, novel streptococcal SAgs were identified by database mining of GAS genomes and recombinant forms of the toxins were used for functional studies. Eleven GAS superantigens are currently known, but the number will most likely increase when more GAS genomes are analyzed. The GAS superantigens share amino acid sequence identities between 48% (SPE C and SPE J) and 17% (SSA and SPE L/M) (Figure 51.1). Furthermore, the streptococcal SAgs are part of an even larger family together with the structurally related staphylococcal SAgs.

#### *The pre-genomic GAS superantigens*

In 1924, Dick and colleagues intradermically injected culture filtrates from hemolytic streptococci of scarlatinal origin into healthy volunteers and observed an erythematous and edematous skin reaction in susceptible individuals 24 hours after injection (Dick and Dick, 1924). The injection of larger doses induced scarlet fever–like symptoms (also called miniature scarlet fever) with fever, nausea, vomiting, and a transient scarlatiniform rash. They postulated that this reaction (also known as the "Dick reaction") was caused by an erythrogenic toxin, which they named "scarlet fever toxin." However, it was later suggested that the skin rash resulted from a hypersensitivity reaction to a number of different streptococcal products and not alone from erythogenic toxin (Kim and Watson, 1970; Schlievert *et al*., 1979).

A second toxin (toxin B) was identified in 1934 (Hooker and Follensby, 1934). Toxin B, which is immunologically different from erythrogenic toxin A, was later purified and biochemically characterized by Stock and Lynn (1961).

In 1960, Watson discovered yet another toxin that was immunologically different from toxins A and B. Toxin C was isolated from a culture filtrate of a strain (serotype M18) associated with scarlet fever (Watson, 1960). By the 1970s, several different biological activities had been described for the three toxins, in particular the ability to induce fever when injected into rabbits (pyrogenicity) and the enhancement of animal susceptibility to lethal endotoxic shock. Since pyrogenicity was believed to be the primary effect of the toxins, Kim and Watson designated the toxins as streptococcal pyrogenic exotoxins A, B, and C (SPE A,B,C) (Kim and Watson, 1970).

During the late 1980s, the three toxin genes were cloned in *E. coli* and recombinant forms were produced. The *speA* gene was cloned from bacteriophage T12, and DNA analysis revealed an open reading frame consisting of 756 base pairs encoding a 252 amino acid precurser protein (Weeks and Ferretti, 1986). The N-terminal 30 amino acids represent a signal peptide that is removed during secretion to produce the mature toxin. Recombinant SPE A was produced in *Bacillus subtilis* and shown to mimic the biological activity of native preparations (Kreiswirth *et al*., 1987). A novel biological activity for SPE A was demonstrated by Schlievert and Grey (1989), who found that SPE A is identical to a previously identified T cell mitogen, Blastogen A. One year later, it was demonstrated that SPE A activates murine T cells in a MHC II-dependent and TcRVβ-specific mode, finally establishing its function as a superantigen (Imanishi *et al*., 1990).

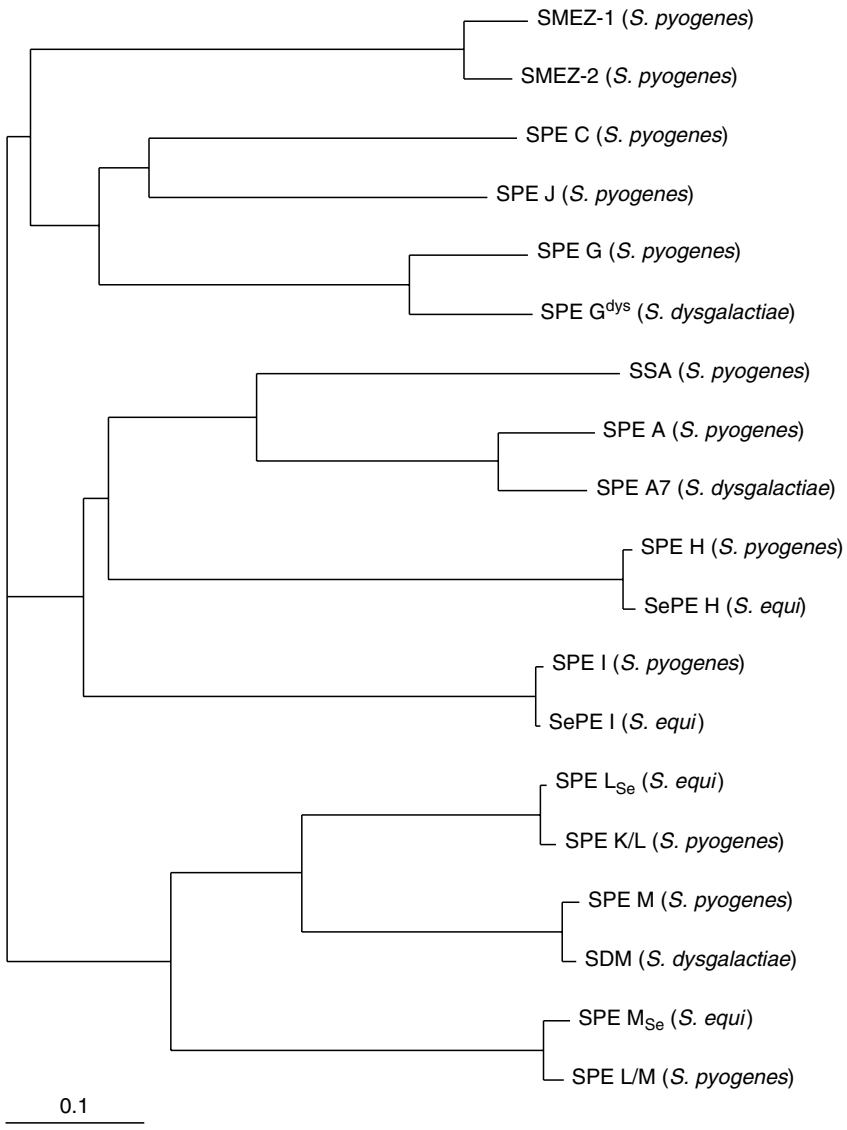

**FIGURE 51.1** Streptococcal superantigen family tree. The tree was created using Clustal W and TreeViewPPC version 1.5.3 and is based on primary amino acid sequence homology of the mature toxins.

The *speB* gene was cloned from a serotype M12 GAS strain (Bohach *et al*., 1988) and shown to be identical to streptococcal cysteine protease (SCP), confirming earlier results that showed immunological cross-reactivity between SPE B and SCP (Gerlach *et al*., 1983). Earlier reports that demonstrated SPE B induced T cell proliferation (Abe *et al*., 1991) were later disputed by others, who used SPE B preparations of very high purity and argued that the initial findings were due to contamination with an unknown superantigen (Braun *et al*., 1993; Gerlach *et al*., 1994). It is now widely accepted that SPE B is not a superantigen.

The *speC* gene was cloned from the chromosome of *S. pyogenes* strain T18P by Goshorn *et al*. (1988). The status of SPE C as superantigen was established in 1991, when Leonard *et al*. (1991) showed MHC II/TcRVβ-dependent T cell mitogenicity.

A novel superantigen was discovered in the cell culture supernatant of *S. pyogenes* strain Weller (serotype M3) and named streptococcal superantigen (SSA) (Mollick *et al*., 1993). SSA showed a higher degree of amino acid sequence similarity to the staphylococcal enterotoxins B, C1, and C3 (SEB, SEC1, and SEC3) than to SPE A or SPE C. SSA targets T cells bearing the Vβ1, 3, and 15 regions, in contrast to SPE A, which mainly targets Vβ12 and 14, or SPE C, which mainly targets Vβ2 (Table 51.1).

Yet another novel SAg was reported by Kamezawa *et al*. (1997) and named streptococcal mitogenic exotoxin Z (SMEZ). This toxin was purified from *S. pyogenes* serotype M1/T1 strain and showed a unique TcR binding specificity targeting mainly Vβ4 and 8 regions. An allelic variant of this toxin was later purified from an *S. pyogenes* serotype T12 strain and designated SPE-X/SMEZ3 (Gerlach *et al*., 2000).

**TABLE 51.1** Functional properties of streptococcal superantigens

| SAg | MW [kDa] | Organism | Crystal structure | Zinc binding | MHC II binding α/β chain | Human TcR Vβ specificity | $P_{50}$ (h) [pg/ml] | Reference |
|---|---|---|---|---|---|---|---|---|
| SPE A | 26.0 | *S. pyogenes* | + | + | +/− | 2.1, *12.2*, *14.1*, 15.1 | ? | Weeks and Ferretti, 1986; Abe *et al.*, 1991 |

The major TcRVβ targets are italicized and underlined.

### *The post-genomic GAS superantigens*

The completion of the first *S. pyogenes* sequencing project (a serotype M1 strain) was the start in microbial genomics of GAS (Ferretti *et al*., 2001). The University of Oklahoma *S. pyogenes* M1 database was accessible on the Internet from the very beginning of the project and contained regularly updated sequence contigs derived from a shotgun plasmid library. The DNA sequence database could be mined for genes of interest from anywhere in the world long before completion of the project. Although streptococcal and staphylococcal SAgs only share limited amino acid sequence homology (sometimes less than 25%), they all share the two highly conserved "family signature motifs" Y-G-G-[LIV]-T-X(4)-N (Prosite entry PS00277) and K-X(2)-[LIVF]-X(4)-[LIVF]-D-X(3)-R-X(2)-L-X(5)-[LIV]-Y (PS00278). Mining of the *S. pyogenes* M1 genome database with these two motifs resulted in the discovery of four novel *sag* genes, which were designated *speG*, *speH*, *speI*, and *speJ* (Proft *et al*., 1999, 2001). The genes were cloned and expressed in *E. coli*. Functional analysis using recombinant forms of the novel toxins showed that they bound to MHC II and stimulated T cells with high potencies in a Vβ-dependent mode, confirming their predicted role as SAgs. Furthermore, SPE J induced fever in rabbits and was lethal in two rabbit models of STSS (McCormick *et al*., 2001a). In addition, a putative gene fragment encoding a nonfunctional peptide with sequence similarity to the C-terminal region of SPE C was found and named *speK* (Ferretti *et al*., 2001).

Another novel *sag* gene, *speL*, was identified in Japan after DNA analysis of the 41,769 bp temperate phage ΦNIH1.1 from a serotype M3 strain (Ikebe *et al*., 2002). In the same year, the complete *S. pyogenes* M3 genome was analyzed in the U.S. and led to the discovery of the same *sag* gene, which was designated *speK* (Beres *et al*., 2002), a name that had previously been assigned to a pseudogene on the *S. pyogenes* M1 genome (Ferretti *et al*., 2001). In this chapter, we will refer to this SAg as SPE K/L. The *speK/L* gene was also found on a serotype M89 strain from New Zealand and named *speL* in accordance with the Japanese designation (Proft *et al*., 2003). It was identified by PCR analysis with a specific DNA primer pair designed from a novel *sag* gene that was discovered by mining of a *Streptococcus equi* database and named $speL_{Se}$ (see below). The same strategy also led to the discovery of a hitherto unknown *sag* gene in serotype M80 that was designated *speM* (Proft *et al*., 2003b). The SAg nomenclature turned increasingly confusing when another *S. pyogenes* genome (serotype M18) was completed in the U.S. revealing two novel *sag* genes, which were named *speL* and *speM* (Smoot *et al*., 2002a). *SpeL* is identical to *speM* found on the M80 strain and will be referred to here as *speL/M*, while *speM* from the M18 strain has not been reported before. Recombinant forms of SPE K/L and SPEL/M were shown to be potent mitogens targeting T cells in a Vβ-specific and MHC II-dependent mode, which confirmed their role as SAgs (Smoot *et al*., 2002b; Proft *et al*., 2003b).

### *The "false" GAS superantigens*

With the generation of increasingly pure SAg preparation and the use of recombinant proteins, it has become evident that some of the earlier reported mitogenic activities were due to contamination with potent SAgs. For example, mitogenic activity toward T cells carrying the Vβ2, 4, and 8 was found in early preparations of SPE B. Since none of the SAgs known at the time targeted Vβ8 T cells, it was postulated that the activity was caused by traces of a potent unknown SAg, which was called SPE X (Braun *et al*., 1993). Interestingly, Vβ2, 4, and 8 activity was also reported for the so-called mitogenic factor (MF) described by Yutsudo *et al*. (1992)—also designated as SPE F (Norrby-Teglund *et al*., 1994b)—and for pepM5, an M protein-derived peptide from *S. pyogenes* M5 (Tomai *et al*., 1992), while Vβ4 and 8 specific activity was reported in preparations of the *S. pyogenes* mitogen-2 (SPM-2) (Rikiishi *et al*., 1997).

It is now widely believed that the observed superantigenic activities were due to contaminations with SPE C and SMEZ and that SPE X is, in fact, SMEZ (Gerlach *et al*., 1994, 2001; Proft *et al*., 1999; Sriskandan *et al*., 2000).

The gene encoding SPM has never been identified, while SPE F has been shown to be identical to streptococcal DNaseB (Sriskandan *et al*., 2000).

## MOLECULAR BIOLOGY OF STREPTOCOCCAL SUPERANTIGENS

### Genomic location and frequency of GAS superantigen genes

The GAS *sag* genes can be located on the chromosomal backbone or on an integrated bacteriophage region (see Table 51.2), which allows horizontal gene transfer between GAS strains. The first evidence for a mobile GAS *sag* gene was provided by Zabriskie (1964), who showed the conversion of the non-lysogenic $speA^-$ strain $T25_3$ to a $speA^+$ strain by the ϕT12 phage from the *S. pyogenes* strain T12g1. The recent completion of five GAS genome projects has provided further insight into the genomic localization of streptococcal *sag* genes. These included serotypes M1 (Ferretti *et al*., 2001), M3 (Beres *et al*., 2002; Nakagawa *et al*., 2003), M6 (Banks

*et al*., 2004), and M18 (Smoot *et al*., 2002a). Only three of the currently known eleven *sag* genes, *smez*, *speG*, and *speJ*, were found not to be associated with a bacteriophage. Genotyping of 94 clinical GAS isolates from New Zealand showed the *smez* and *speG* genes in 100% of the analyzed isolates, confirming their stable chromosomal location (Proft *et al*., 2000). Interestingly, *speJ* was not found on the M3 and M18 genomes, suggesting that, although not associated with phage, *speJ* might be located on an unstable region on the chromosome.

Comparative genomics revealed that *sag* genes are positioned on a variety of temperate phages and that related phages sometimes harbor different *sag* genes, supporting the idea of recombinational evolution of GAS prophages (Table 51.2) (Ferretti *et al*., 2001; Banks *et al*., 2004).

Four allelic forms of the *speA* gene were identified. *SpeA*1 was found on ϕ8232.1 in *S. pyogenes* MGAS8232 (serotype M18), *speA*3 was found on ϕSPsP2 (strain SSI-1, serotype M3) and on the identical ϕ315.5 (strain MGAS315, serotype M3), while *speA*4 was found on ϕ10394.2 (strain MGAS10394, serotype M6). Apart from the M3 type associated ϕSPsP2 and ϕ315.5, the *speA* containing phages are highly divergent. Instead, ϕ8232.1 (M18) is closely related to ϕ315.1 (M3), which does not contain any *sag* gene.

The *speC* gene was identified on ϕSF370.1 (strain SF370.1, serotype M1) and on the unrelated ϕ8232.2 (M18). Phage 8232.2 (M18) is most closely related to ϕ10394.3 (M6) that carries the *speK/L* gene, while ϕSF370.1 (M1) is related to the M3 type phages ϕ315.4 and ϕSPsP3 (identical to ϕNIH1.1; Ikebe *et al*., 2002), which both also contain the *speK/L* gene. These four prophage elements are inserted at analogous sites, which is the predicted $T12_{att}$ site. Another T12-like phage that inserts at the predicted $T12_{att}$ site is ϕ315.2 (strain MGAS315, M3), which contains the *ssa* gene. Interestingly, the almost identical ϕSPsP5 (strain SSI-1, M3) does not contain *ssa*, nor any other *sag* gene. Instead, in SSI-1, *ssa* is translocated to ϕSPsP6, which is almost identical to ϕ315.1 in MGAS315.

The *speI* and *speH* genes were originally identified in tandem orientation on the defective (non-inducible) phage 370.2 (M1) (Ferretti *et al*., 2001). In addition, a truncated variant of *speI* and a *speH* pseudogene containing 14 internal stop codons were found on ϕ10394.2 (M6), which also contains *speA*4. Phage 370.2 (M1) is most closely related to ϕ8232.3 (M18) that carries the *speL/M* and *speM* genes.

Genotyping of 50 GAS isolates comprising 29 different M types and 3 non-typeable strains has shown *speA*, *speC*, *speH*, *speI*, *ssa*, *speK/L*, and *speL/M* gene frequencies of 30%, 36%, 22%, 12%, 26%, 28%, and 4%, respectively (Proft *et al*., 2003b). Interestingly, only 12% of the isolates contained both *speI* and *speH* (located in tandem orientation on phage 370.2 (M1)). None of the isolates carried the *speI* gene without the *speH* gene. In all the temperate phages analyzed, the *sag* genes were located at the distal end of the integrated phage genome (with respect to the integrase gene), suggesting that these genes may have been acquired (or lost) in the past through some aberrant excision event where host genomic material was acquired by the phage (Ferretti *et al*., 2004). In a study by Ikebe *et al*. (2002), it was shown that none of 10 M3 isolates recovered during or before 1973 carried the *speK/L* gene, whereas all of 18 M3 isolates collected during or after 1992 contained *speK/L*, suggesting a rather recent gene transfer event.

Epidemiological studies have shown associations between *sag* gene frequencies and certain GAS diseases. For example, Yu and Ferretti (1989) showed that among 146 isolates from patients with scarlet fever, 45% were shown to contain *speA*, while only 15% of 300 isolates from patients with various other diseases contained *speA*. In another study, 34 GAS isolates from STSS patients were analyzed and *speA* was found in 85% (Hauser *et al*., 1991). In a study conducted by Reichardt *et al*. (1992), *speA* and *speC* were found in 64%

**TABLE 51.2** Location of the phage-encoded GAS *sag* genes

| SF370 (M1) | | SSI-1 (M3) | | MGAS315 (M3) | | MGAS10394 (M6) | | MGAS8232 (M18) | |

## Allelic variation in superantigen genes

Allelic variation has been reported for several *sag* genes. However, in most of the cases the divergences were minimal. For example, *speA*1, *speA*2, and *speA*3 encode toxins that differ by a single amino acid (G110S in SPE A 2 and V106I in SPE A 3). In contrast, SPE A4 differs from SPE A-1 by ≈11% and was reported to be frequent in serotype M6 (Nelson *et al*., 1991; Banks *et al*., 2004). *SpeA*5 differs from *speA*4 by four synonymous and one non-synonymous mutation, while *speA*6 differs from *speA*1 by a single synonymous mutation. It has been suggested that *speA* arose from two phylogenetic lineages designated lineage I (*speA*1, *speA*2, *speA*3, *speA*6) and lineage II (*speA*4, *speA*5) (Bessen *et al*., 1999)

Minor allelic variations were also reported for the *speC* gene. The *speC*2 allele differs from *speC*1 by two silent A/G transitions (Kapur *et al*., 1992), while *speC*3, *speC*4, and *speC*5 differ from *speC*2 by one base pair resulting in non-synonymous amino acid changes (Norrby-Teglund *et al*., 1994a). Bessen *et al*. (1999) found a significant non-random association between exotoxin alleles and *emm* patterns. They showed that in 160 GAS isolates, the *speA* and *speC* alleles of organisms harboring the *emm* marker for tissue tropism pattern A–C (pharyngeal reservoir) differed from *spe* alleles that predominate in organisms of pattern D (impetigo). Pattern A–C organisms mainly harbored *speA* lineage I alleles, while pattern D organisms mainly harbored *speA* lineage II alleles. Barriers that prevented horizontal gene transfer were suggested to be responsible for unequal distribution.

Significant allelic variation has also been reported for the *smez* gene. DNA sequence analysis of a *smez* gene cloned from *S. pyogenes* 2035 showed nucleotide changes in 36 positions (=5%) compared to the *smez* gene and was designated *smez-2* (Proft *et al*., 1999). The deduced protein sequence differs in 17 amino acid residues (=8.1%) and the most significant difference is an exchanged pentapeptide sequence at position 96–100, where the EEPMS sequence of SMEZ is converted to KTSIP in SMEZ-2. In a follow-up study, *smez* DNA sequences of 37 GAS isolates were analyzed, representing 22 different M/*emm* types, 5 MNT isolates, and two isolates of unknown M type (Proft *et al*., 2000). As a result, 22 novel *smez* alleles were identified, which appeared to be in linkage equilibrium with the M/*emm* type. Three of the *smez* sequences (*smez-6*, *smez-19*, and *smez-23*) represented pseudogenes that have single base pair deletions causing frame shifts. Interestingly, the *smez* gene shows a significant mosaic structure, suggesting that the polymorphism has arisen from homologous recombination events rather than random point mutations. The biological function of SMEZ, e.g., binding to MHC class II and Vβ-specific stimulation of T cells, was not affected by the allelic variation. However, the SMEZ variants showed antigenic differences. Neutralization responses of individual human sera from healthy donors against different SMEZ variants varied significantly.

## Regulation of superantigen production

The production of SPE A and SPE C in GAS cell culture supernatant was shown to differ significantly between individual isolates. Eleven strains from various M/T serotypes were shown to produce between 0.03 and 16 mg/ml, while the amounts of SPE C produced by three different strains were 0.9, 1.2, and 1 mg/ml (Gerlach *et al*., 1981). Higher amounts of toxin were produced by 26 isolates from patients with STSS, with average concentrations of 3.2 mg/ml of SPE A and 0.6 mg/ml of SPE C (Lee and Schlievert, 1989). In contrast, many strains isolated from patients with STSS in France, Sweden, and Chile produced very low or no detectable amounts of both toxins (Köhler, 1990; Reichardt *et al*., 1992). It has been suggested that *speA* expression varies in a clonal manner with respect to the M serotype (Kim and Schlievert, 1997). However, several recently conducted experiments have put a different light on this topic. It now seems that *sag* gene expression is tightly controlled and that host factors might be involved in the up-regulation of SAgs during infection. Broudy *et al*. (2001) reported the up-regulation of SPE C in GAS that were co-cultured with human pharyngeal cells. This also led to the induction of the bacteriophage that harbors the *speC* gene, and the induction event was mediated by a soluble factor produced by the pharyngeal cells. Co-culture of strain MGAS315 with Detroit 562 (D562) human epithelial pharyngeal cells induced the prophage encoding *speK/L* (ϕ315.4). However, no significant production of SPE K/L was observed (Banks *et al*., 2003). Surprisingly, the production of SPE A increased during co-culture of GAS with D562 cells despite the lack of induction of the prophage encoding *speA* (ϕ315.5).

Using a mouse infection chamber model, Kazmi *et al*. (2001) monitored *speA* gene induction *in vivo* at various time points after infection. They implanted Micropore Teflon diffusion chambers subcutaneously in BALB/c mice and inoculated the chambers with clonal M1T1 isolates expressing no detectable amounts of SPE A *in vitro*. After seven days postinfection, SPE A expression was detected in the chamber fluid of all animals tested. Interestingly, isolates recovered from the chamber and

grown *in vitro* continued to produce SPE A even after 21 passages, suggesting a stable switch on the *speA* gene.

The molecular mechanisms of *sag* gene regulation are only poorly understood. However, a recent study has shown that the *speA* gene and several other virulence genes are under the control of the Nra transcription regulator, a member of the RofA-like protein (RALP) family (Podbielski *et al*., 1999). Nra represses the expression of several virulence genes, including *speA*. Maximum expression of Nra occurs in the early stationary growth phase, but does not appear to respond to changing atmospheric conditions.

## SUPERANTIGENS FROM NON-GAS

Group C streptococcus (GCS) and group G streptococcus (GGS) are commonly regarded as commensals usually found in association with the normal flora of human skin, pharynx, and intestine. Recently, there have been an increasing number of reports implicating GCS and GGS with severe invasive infections, such as necrotizing fasciitis and toxic shock syndrome (Oster and Bisno, 2000). Although mitogenic activity in supernatant of clinical GCS and GGS isolates had been reported over several years, superantigens had not been identified until recently. The first report came from Timoney's group who identified two superantigens in *Streptococcus equi*, a bacterium that causes strangles in horses, but can also infect humans. The *Streptococcus equi* pyrogenic exotoxins (SePE)H, I, are highly homologous to their *S. pyogenes* counterparts SPE H and SPE I (greater than 98% amino acid sequence identities), indicating horizontal gene transfer from *S. pyogenes* to *S. equi* or vice versa (Artiushin *et al*., 2002). Similar to GAS, *sepe-I* and *sepe-H* were found in tandem orientation at the distal end of an integrated phage genome. Interestingly, both genes were not found in the closely related *Streptococcus zooepidemicus*, and it was suggested that the acquisition of the *sag* genes might be an important event in the formation of a more virulent *S. equi* strain from its putative *S. zooepidemicus* ancestor (Artiushin *et al*., 2002). SePE I and SePE H both elicited strong mitogenic responses from horse peripheral blood mononuclear cells. Moreover, both toxins were pyrogenic for rabbits, but only SePE I was pyrogenic in ponies. Horses recovered from strangles or immunized with SePE I were seropositive and resistant to the pyrogenic effects of SePE I, suggesting a potential role for this toxin in strangles.

Another two *sag* genes were identified by data mining of the *S. equi* genome at the Sanger Centre and named $speL_{Se}$ and $speM_{Se}$ due to the homology to their *S. pyogenes* counterparts, *speL* and *speM* (here described as *speK/L* and *speL/M*) with 99% and 98.1% nucleotide identities, respectively (Proft *et al*., 2003b). Interestingly, both genes were not detected in eight genetically different *S. equi* isolates, suggesting that, like their GAS counterparts, these genes are also rare in GCS isolates.

Four SAgs have been identified from *Streptococcus dysgalactiae* subsp. *equisimilis*. All of them are highly similar to their GAS counterparts SPE A, SPE C, SPE G, and SPE M. *Streptococcus dysgalactiae*-derived mitogen (SDM) is 99% similar to SPE M (Miyoshi-Akiyama *et al*., 2003), and SPE $G^{dys}$ is 86% similar to SPE G (Sachse *et al*., 2002). Kalia and Bessen (2003) analyzed 34 genetically distinct group C/G streptococci and found the *speA* gene in three isolates and *speC* in one isolate. The *speA* alleles from two isolates were identical to GAS alleles *speA*2 and *speA*4, respectively, while the third *speA* allele is characterized by two unique nucleotide substitutions that are not observed among *speA* alleles from GAS. This was designated *speA*7. However, the translated protein is 100% identical to the SPE A5 variant of GAS. The *speC* allele was found to be identical to *speC*1 of GAS.

In all non-GAS toxins, amino acid exchanges are outside the MHC class II and TcR binding sites, suggesting that the GAS toxins and the non-GAS toxins are orthologues with identical functions. A recent study has shown that GAS, GCS, and GGS exchange housekeeping genes by horizontal gene transfer with strong net directionality of gene movement from GAS donors to GCS and GGS recipients (Kalia *et al*., 2001). The fact that all GAS counterparts of GCS/GGS *sag* genes, except *speG*, were found on prophages and the strong homology between the orthologues suggests that commensal GCS/GGS strains might have acquired these *sag* genes from pathogen GAS generating more virulent GCS and GGS.

## BIOCHEMICAL PROPERTIES OF SUPERANTIGENS

### Binding to MHC class II

All SAs bind to MHC class II as a prerequisite for T cell recognition. The molecular mechanism of this interaction is not only different from the binding of conventional peptide antigens, but also significantly varies between individual SAgs. In general, SAgs can be divided into three groups according to their binding mode to MHC class II; (i) SAgs that bind to the invariant MHC class II α-chain only; (ii) SAgs that bind to the polymorphic MHC class II β-chain only; and (iii) SAgs that bind to both MHC class II chains.

### *Streptococcal SAgs that bind to the MHC class II β-chain*

With the exception of SPE A and SSA, all streptococcal SAgs appear to bind to the MHC class II β-chain only. The first evidence for this mode of binding was provided for the staphylococcal enterotoxin A (SEA), when Herman *et al*. (1991) showed that SEA binds effectively to most HLA-DR alleles and isotypes, such as DR1, but only poorly to DRw53. The difference in binding was localized to a single amino acid residue at position 81 in the beta 1 domain, a highly conserved histidine that is replaced by a tyrosine in DRw53. It was later shown that H is 81 is part of a zinc coordination that also involves SEA residues His187, His225, and Asp227 (Hudson *et al*., 1995). The relative binding affinity of this interaction is about 100-times higher than the generic low-affinity site ($10^{-7}$ M) that SEA and several other SAgs use for binding to the MHC class II α-chain and has therefore been referred to as the "high-affinity binding site." The first streptococcal SAg shown to possess this mode of binding was SPE C. Li *et al*. (1997) reported that SPE C binding to MHC class II was completely abolished in the presence of EDTA, but could be restored by excess of $Zn^{2+}$ over EDTA. Moreover, SPE C did not prevent binding to MHC class II of two typical MHC class II α-chain binding SAgs from *S.aureus*, staphylococcal enterotoxin B (SEB), and toxic shock syndrome toxin (TSST). Structural analysis of SPE C revealed a zinc-binding site in the C-terminal domain, similar to that in SEA involving SPE C residues His167, His201, and Asp203 (Roussel *et al*., 1997). The complete zinc coordinated binding was finally confirmed with the successful co-crystallization of SPE C with HLA-DR2a bearing a peptide derived from myelin basic protein (MBP). The structure not only showed the conserved tetrameric zinc complex, but also revealed extensive interaction of the bound peptide, such that the peptide accounts for approximately one-third of the surface area of the MHC class II molecule buried in the complex (Li *et al*., 2001; Petersson *et al*., 2001). This is comparable to the contribution of the antigenic peptide in the TcR-MHC complexes. SPE C makes several conserved interactions with bound peptide, in particular Gln113 of SPE C, which forms a hydrogen bond to the backbone of the P3 residue of the peptide. Certain other interactions involving peptide side chains are unique to the bound peptide, suggesting a wide range of affinities for SAg-binding to the MHC class II peptide complex. It has been suggested that SPE C may optimize T cell responses by mimicing the peptide dependence of conventional antigen presentation and recognition (Li *et al*., 2001).

Crystal structures and computer-generated models of SPE G, SPE H, SPE I, SPE J, SPE K/L, SPE L/M, SPE M, and SMEZ showed the conserved zinc-binding site in the C-terminal domain of all of these proteins. Zinc dependency was demonstrated by biochemical analysis: When binding to MHC class II was completely abolished in the presence of EDTA, but could be restored by excess of $Zn^{2+}$ over EDTA (Proft *et al*., 1999, 2001). Furthermore, these toxins lack the generic MHC class II α-chain binding motif (a hydrophobic loop region in the N-terminal domain) and did not prevent SEB and TSST from binding to MHC class II in competition experiments (Proft *et al*., 1999, 2001, 2003b). On the other hand, Scatchard blot analysis of SPE G, SPE H, SMEZ-1, and SMEZ-2 revealed two distinct binding affinities: a high affinity binding of 16–65 nM, similar to the zinc-dependent MHC class II β-chain binding of SEA, and a low-affinity binding of 1–2 μM. Moreover, these toxins only partially competed against each other for MHC class II binding with a clear hierarchical order [(SPE C, SMEZ-1) > SMEZ-2 > SPE H > SPE G], where SPE G did not compete with any other toxin. Due to the lack of any potential MHC class II α-chain binding motifs in the toxin sequences, it was suggested that some toxins have a more restricted repertoire of MHC class II molecules defined by the bound antigenic peptide and that the multiphasic Scatchard blots resulted from a variety of affinities ranging from nanomolar to micromolar defined by the bound peptide (Proft *et al*., 1999). Further evidence was provided when the SPE C – HLA-DR2a structure revealed extensive interaction of the bound peptide (Li *et al*., 2001). This raises the possibility that certain bound peptides could enhance the potency of the SAg by promoting high-affinity but low-density binding to MHC class II (Wen *et al*.,1996; Hogan *et al*., 2001). This mechanism might be important to avoid T cell apoptosis through supra-optimal signaling caused by high ligand densities.

### *Streptococcal SAgs that bind to the MHC class II α-chain*

Only two streptococcal SAgs, SPE A and SSA, lack the C-terminal zinc-binding site and are therefore unable to bind to the MHC class II β-chain. Both SAgs bind to the generic MHC class II α-chain, predominantly to HLA-DQ, rather than HLA-DR1 molecules.

The overall structure of SPE A is more closely related to the staphylococcal enterotoxins B and C (SEB, SEC) than to any other streptococcal SAg (Papageorgiou *et al*., 1999). It has been shown that SPE A competes with SEB for binding to HLA-DR1 molecules, suggesting that both toxins have a common recognition site for MHC class II (Hartwig *et al*., 1994). SEB is a prototype SAg for MHC class II α-chain binding. A struc-

tural study of SEB complexed with HLA-DR has shown that this toxin possesses an exposed hydrophobic loop region within the N-terminal β-barrel domain to bind to a hydrophobic groove located in the distal region of the DR α1 domain with binding affinities of $10^{-5}$ M (Jardetzky *et al*., 1994). This interaction has been referred to as the "generic" or the "low-affinity" binding site. In addition, SEB binds to a protruding loop of the DR1 α-chain using a hydrophilic pocket on the SEB surface created by Glu67, Tyr89, and Tyr115. However, there are differences in binding affinity for MHC class II. SPE A has a greater affinity for HLA-DQ than it does for HLA-DR or HLA-DP, while SEB has a greater affinity for HLA-DR, suggesting that SPE A and SEB have similar but not identical MHC class II binding sites. Lys39 from HLA-DR1, a key residue present in all three allotypes, forms a salt bridge with Glu67 of SEB, and this residue is conserved in SPE A (Glu61), suggesting that SPE A might also target Lys39 on the MHC class II α-chain, but in a binding conformation different from SEB binding (Papageorgiou *et al*., 1999). In another study, alanine substitutions of each of the SPE A residues Leu42, Asp45, Leu46, Ile47, Tyr48, and Tyr83 resulted in significant decrease in affinity for HLA-DQ (Kline and Collins, 1996). With the exception of Leu42 and Tyr83, these residues are conserved in SEB, but do not appear to be involved in MHC class II binding. Hence, these residues might form a binding interface specific to SPE A. Structural analysis of SPE A has also revealed a zinc-binding site involving residues Asp77, His106, and His110 (Papageorgiou *et al*., 1999). This site is structurally equivalent to the zinc-binding site in SEC2, but different from the "classical" zinc-binding site of the other streptococcal SAgs. From structural modeling of the SPE A -HLA-DR interaction, a potential zinc-dependent binding to the MHC class II β-chain has been suggested, but this hypothesis has not yet been experimentally confirmed (Baker *et al*., 2001).

SSA is structurally closer related to SEB. Structural modeling showed that the SEB residues Glu67, Tyr89, and Tyr115 of the hydrophilic pocket are conserved in SSA (Glu67, Tyr89, and Tyr110). Furthermore, presentation by an HLA-DR1α K39A mutant decreased SSA-induced T cell proliferation by two to three log-fold (Stevens, K. *et al*., 1996). However, the mitogenicity of each of the three SSA mutants, E67A, Y89A, and Y110A, was only slightly decreased relative to SSA wild-type when presented by HLA-DR1 expressing cells. Moreover, competition-binding studies showed that SEB and SSA did not cross-compete, despite effectively competing for DR1 binding and despite the common involvement of DR1α Lys39 (Stevens, K. *et al*., 1996). This lack of competition was later shown to be due to the preference of SSA for HLA-DQ molecules. Five residues were implicated in conferring HLA-DQ binding specificity to SSA as compared to SEB. These included Gln46, His47, Lys65, Asn69, and Asn92 (Sundberg and Jardetzky, 1999).

### *Binding to the T cell receptor*

Until recently, little was known about how SAgs interact with TcR molecules, mainly due to the lack of suitable amounts of recombinant TcR protein for crystallization. In 2002, two complexes were determined—that of SPE A bound to mouse Vβ8.2 and of SPE C bound to human TcR Vβ2.1 (Sundberg *et al*., 2002a). The SPE A-mVβ 8.2 complex is quite similar to the previously reported SEB-mVβ8.2 complex, which is probably not much of a surprise considering the structural homology between SPE A and SEB. The TcR binding site is located in a shallow groove between the two globular domains of the SPE A molecule created by residues from the α2 helix, the β2-β3 loop, the β4 strand, the β4-β5 loop, the β5 strand, and the α5 helix. In the mTcR Vβ8.2 molecule, residues from the complementary-determining region 2 (CDR2), framework region 2 (FR2), and, to a lesser extent, hypervariable region 4 (HV4) and FR3 were found to be involved in SAg recognition. In contrast to the SEB-mVβ8.2 complex, SPE A also interacts with the mVβ8.2 CDR1 loop via a hydrogen bond between Glu94 on the disulfide loop region of SPE A and Asn28 on the mVβ8.2 CDR1 loop. The positionally equivalent residue in SEB (Thr99) is unable to form an intermolecular contact with the CDR1 loop due to differences in side chain length. There are also a number of other hydrogen bonds that involve side chain atoms of both SPE A and mVβ8.2, which is in sharp contrast to the exclusive use of main chain contacts in the SEB-mVβ8.2 complex (Li *et al*., 1998). Extensive mutational analysis of SPE A has shown that eight mutant toxins (S13A, N17A, N20A, D45A, I47A, Y55A, Y84A, and L198A) showed an intermediate capability to stimulate human Vβ2.1-positive cells, while amino acid substitutions at five positions (L24A, Y55A, C90S, C98S, and Q194A) resulted in decreased ability to stimulate human Vβ12.2 expressing cells, and twelve mutant toxins (N17A, N20A, L24A, V30A, N54A, Y55A, Y83A, Y84A, C90S, C98S, Q194A, and L198A) showed a reduced capability to stimulate human Vβ14.1-positive cells (Kline and Collins, 1997). Compared to the SPE A-mVβ8.2 complex, only five of the mutated residues (Asn17, Asn20, Asn54, Tyr84, and Gln194) make contact with the mouse Vβ8.2 region, and there is no correlation between the effect of specific mutations and the SPE A residues involved in binding mVβ8.2. Thus, it is most probable that the SPE A-mVβ8.2 complex shows a binding mode that is distinct from the binding of SPE A to other Vβ regions.

The interaction between SPE C and hVβ2.1 is different altogether and includes a significantly larger buried surface area than the other complexes. The number of intermolecular contacts is higher and also includes the highly variable hVβ2.1 CDR3 loop. Interestingly, SPE C displays a much higher specificity to stimulate T cells than SEB or SPE A, targeting primarily the hVβ2.1 TcR. It has been proposed that this specificity derives from two single amino acid insertions, one each in CDR1 and CDR2, and an extended CDR3 loop. The CDR1 insertion shifts this loop towards the SPE C molecule, resulting in additional intermolecular contacts involving hydrogen bonds with SPE C residues Arg45, Tyr49, and Asn79, while the CDR2 insertion produces a non-canonical CDR2 loop that positions the inserted residue for optimal contact with SPE C. The CDR2 contact region includes hydrogen bonds with SPE C residues Tyr15, Glu178, and Arg181. Mutational analysis confirmed the crucial role of Tyr15 in TcR binding when the Y15A mutant was shown to decrease mitogenicity by nearly 1,000-fold without affecting MHC class II binding (Yamaoka *et al*., 1998).

Recently, the crystal structure of SPE J has been resolved (Baker *et al*., 2004). SPE J is structurally most closely related to SPE C and also primarily targets T cells carrying the hVβ 2.1 TcR. Mutational analysis of SPE J revealed Tyr14 and Arg181 (corresponding to SPE C residues Tyr15 and Arg181, respectively) are key residues for TcR binding. Both SPE J mutants, Y14A and R181A, decreased T cell mitogenicity by 10,000-fold compared to wild-type. In addition, SPE J mutant F77A reduced potency by 100-fold, although like the corresponding residue in SPE C (Leu78), it can only form van-der-Waals interactions. The neighboring residue in SPE C (Asn79) is hydrogen bonded to TcR, but mutation in the equivalent SPE J residue (T78A) had only little effect. Interestingly, SPE C residue Tyr49, which forms hydrogen bonds with the CDR1 loop, is replaced by Phe48 in SPE J and can only form van-der-Waals interactions. Furthermore, an F48A mutant did not result in a detectable decrease in mitogenicity. Thus, despite the structural similarity between SPE C and SPE J and the common preference for the hVβ2.1 TcR, there appears to be a certain degree of variation in the TcR binding mode.

Based on structural observations, three categories of SAg-TcR complexes have been proposed: (i) highly promiscuous T cell activators, including SEB and SEC3, that bind TcR β chains in a simple conformation-dependent manner and interact only with a single CDR loop, CDR2; (ii) moderately promiscuous T cell activators, including SPE A, that form direct side chain/side chain contacts overlayed onto the conformation dependence of the first group, and the additional involvement of the CDR1 loop; (iii) highly selective T cell activators, including SPE C (and probably SPE J), that bind to TcRVβ domains with the highest degree of structural dissimilarity, and the usage of all three CDR loops (Sundberg *et al*., 2002b).

## Dimer-formation of streptococcal superantigens

SPE C was the first streptococcal SAg shown to exist in both monomeric and dimeric forms at neutral or alkaline pH (Li *et al*., 1997). The results were supported by the SPE C crystal structure, which showed that the surface that forms the generic MHC class II α-chain binding site in several other superantigens is used to create a SPE C dimer (Roussel *et al*., 1997). Dimerization appears to be stabilized by an additional zinc-binding site (Zn-B) in which $Zn^{2+}$ is complexed by four SPE C residues, His35, and Glu54 from each of the two monomers. However, zinc does not appear to be essential as dimerization is not affected by EDTA. The biological function of SPE C dimer formation is unknown, but it has been suggested that it might lead to cross-linking of MHC class II molecules on the surface of antigen-presenting cells and that this may have a stimulatory effect on the antigen-presenting cells (Roussel *et al*., 1997). Such an effect has been demonstrated previously for SEA (Tiedemann and Fraser, 1996). MHC class II cross-linking by SEA (a bivalent staphylococcal SAg that binds to both MHC class II chains) resulted in rapid induction of homotypic B cell aggregation, tyrosine kinase activation, and proinflammatory cytokine gene expression. Homotypic B cell aggregation has also been demonstrated for SPE C (Li *et al*., 1997).

The recently resolved crystal structure of SPE J revealed a different mode of homodimerization (Baker *et al*., 2004). SPE J uses the same interface that is used for TcR binding in other SAgs. Site-directed mutagenesis showed that this face is also used for TcR binding in SPE J, and it was implicated that SPE J may have dual functions—cross-linking of MHC class II and TcR as a monomer and cross-linking of two MHC class II molecules as a dimer.

A similar mechanism has recently been demonstrated for SSA (De Marzi *et al*., 2004). Monomeric and dimeric forms of SSA were found in supernatants of GAS cultures. Dimer formation occurred via an intermolecular cysteine bridge involving Cys26 and, like in the SPE J dimer, most probably occludes the TcR interaction site. Intermolecular cysteine bridge formation is also responsible for homodimerization of SPE K/L (Proft, unpublished data).

These observations suggest that at least some streptococcal SAgs might have other function(s) in addition to T cell mitogenicity.

## BIOLOGICAL AND PHARMACOLOGICAL ACTIVITIES

### Potency and Vβ-specificity

The potency of SAgs is generally described as half-maximum response ($P_{50}$), which is the amount of toxin needed to achieve 50% of the maximum T cell proliferation. Within the streptococcal SAgs, $P_{50}$ values range between 0.02 pg/ml (SMEZ-2) and 50 pg/ml (SPE H). SMEZ-2 is the most potent of all known SAgs and recombinant SMEZ-2 was shown to be still active at less than 0.1 fg/ml on human peripheral blood lymphocytes (Proft *et al*., 1999). Streptococcal SAgs also cause T cell proliferations in certain animals, such as rabbits and mice. The $P_{50}$ values, however, are usually significantly higher.

A hallmark of SAgs is their specificity for particular TcRVβ regions (see Table 51.1). Considering the fact that the human genome codes for 50 different Vβ regions of which around 20 are commonly expressed, it seems rather interesting that the streptococcal SAgs appear to possess a significant preference for binding certain Vβs. For example, SPE C and SPE J primarily target T cells carrying the Vβ2 TcR, a target that is also used by SPE A, SPE G, SPE H, and SMEZ. Another common target are T cells carrying the Vβ1 TcR, which are primarily stimulated by SPE K/L, SPE M/L, and SPE M (Smoot *et al*., 2002b; Proft *et al*., 2003b), and less frequently by SSA. The reason for the preferential stimulation of certain T cell subpopulations remains a mystery.

### Pyrogenicity and augmentation of endotoxin activity

Pyrogenicity, or the induction of fever, is believed to be a common feature of all streptococcal superantigens, although this has not been experimentally confirmed for all toxins. The IV injection of rabbits with either SPE A or SPE C resulted in elevated temperatures up to 4–5 h after a 30–60 min latency as reported by Schuh *et al*. (1970). The minimal pyrogenic dose of SPE A and SPE C determined 3–4 h after injection ranged between 0.1 and 0.7 μg/kg. The ability to cause fever in rabbits has also been reported for SPE J (McCormick *et al*., 2001a) and for SMEZ (Müller-Alouf *et al*., 2001). It has been suggested that pyrogenicity is due to SAg-induced release of IL-1 and TNF-α by macrophages and the effect of these cytokines on the hypothalamus (Fast *et al*., 1989).

Streptococcal SAgs can enhance the host's susceptibility to lethal endotoxic shock. Rabbits that received SPE C alone showed fevers only, but those given both SPE C and endotoxin showed initial fever followed by hypothermia, labored breathing, diarrhea, evidence of vascular collapse, and finally death (Schlievert, 1982). Susceptibility of rabbits to lethal shock by endotoxin was enhanced by as much as 50,000-fold. It has been suggested that endotoxin and superantigen might act synergistically as a double-hit, resulting in toxic shock in the absence of a typical focus of bacterial infection (Llewelyn and Cohen, 2002).

### Cytokine induction

Superantigens are potent inducers of cytokines. Toxin-mediated activation of T cells results in a rapid systemic release of TNF-α and TNF-β, followed sequentially by IL-2, IL-6, IL-1, and IFN-γ (Jupin *et al*., 1988; Miethke *et al*., 1992; Hackett and Stevens, 1993). In particular, TNF-α increases dramatically within the first few hours of SAg stimulation as demonstrated in animal studies. TNF-α induces the production of IL-1 and IL-6 and acts synergistically with IL-1 to cause fever and shock. Besides these pro-inflammatory cytokines, the release of anti-inflammatory cytokines, such as IL-4, IL-5, IL-10, and IL-1 RA, and the production of hematopoietic cytokines, such as IL-3 and granulocyte macrophage colony-stimulating factor (GM-CSF) after stimulation with SPE A or SPE C, has also been reported (Müller-Alouf *et al*., 1996, 1997; Rink *et al*., 1996). A comparative study with SPE A and SMEZ revealed that both toxins elicited the release of substantial amounts of pro- and anti-inflammatory, chemotactic, and hematopoitic cytokines. However, the cytokine-inducing capacity of SMEZ was approximately 10-fold higher than that of SPE A (Müller-Alouf *et al*., 2001). Furthermore, disruption of the *smez* gene in an M89 GAS strain abrogated the immunoactive properties of the strain completely. Despite the capability to produce several other SAgs, supernatant from the *smez*-mutant was unable to elicit production of IFN-γ, TNF-α, TNF-β, IL1β, or IL8 from PBMCs, suggesting that SMEZ might be the major immunoactive SAg produced by GAS (Unnikrishnan *et al*., 2002).

## SUPERANTIGENS AND HUMAN DISEASE

### Invasive GAS disease and STSS

GAS is associated with a number of severe invasive diseases, including cellulitis, myositis, and necrotizing fasciitis (or flesh-eating disease) (Stevens, 1992, 2000; McCormick *et al*., 2001b; Seal, 2001). The most severe form of invasive GAS disease is STSS with mortality rates of 30–70%.

The clinical symptoms are very similar to those in staphylococcal toxic shock, but STSS is often associated with bacteremia, myositis, or necrotizing fasciitis. STSS is characterized by rash, hypotension, and multiple organ failure.

Several lines of epidemiological, experimental, and clinical observations strongly imply that at least some SAgs play a pivotal role in the pathogenesis of STSS and possibly in other invasive GAS diseases.

### *Epidemiological studies*

Serotype M1 and M3 strains have been predominantly isolated from patients with STSS. Both strains frequently produce SPE A and SPE C (Yu and Ferretti, 1989). The *speA* gene was found in a majority (40–90%) of GAS isolates from the USA associated with invasive GAS disease and STSS, but only in a minority (15–20%) of isolates from non-invasive diseases like pharyngitis (Yu and Ferretti, 1989; Hauser *et al*., 1991). A high frequency of *speA* (80%) was also observed in isolates from STSS patients collected in Australia (Carapetis *et al*., 1995). A study by Reichardt *et al*. (1992) of 53 strains from patients with STSS from Europe and Chile found *speA* and *speC* in 64% and 28%, respectively. In contrast, a more recent study by Hsueh *et al*. (1998) showed no significant difference in the frequency of *speA* between invasive and non-invasive GAS isolates collected in Taiwan (39% and 36%, respectively). Furthermore, among the invasive strains, *speA* was found in only 18% of the isolates associated with STSS cases. The recent discovery of several novel streptococcal *sag* genes, with *speG* and *smez* present on all strains analyzed thus far, might explain the development of STSS in these cases. In addition, regulation of *sag* gene expression appears to play an important role (see above).

### *Animal infection models*

Using a baboon model of GAS bacteremia that mimics human STSS, Stevens, D.L. *et al*. (1996) showed that intravenous infusion of a SPE A-producing serotype M3 strain resulted in profound hypotension, leukopenia, metabolic acidosis, renal impairment, thrombocytopenia, and disseminated coagulopathy within three hours. Serum TNF-α peaked at three hours and anti-TNF-α antibodies markedly improved arterial pressure and survival, indicating the important role of TNF-α in STSS.

Experiments with isogenic GAS strains lacking the *speA* gene administered into rabbits showed that only the wild-type strain caused STSS, while the *speA*-knockout strain did not (Schlievert *et al*., 1996). Sriskandan *et al*. (1996a) used an isogenic *speA*$^-$strain to evaluate the role of SPE A in a murine model of bacteremia and streptococcal muscle infection. Surprisingly, disruption of *speA* was not associated with attenuation of virulence and paradoxically the *speA*$^-$ mutant led to increased bacteremia and a reduction of neutrophils at the site of primary muscle infection. A possible explanation for this unexpected result is that SAgs are significantly less active on murine PBLs (Proft *et al*., 1999), probably due to inefficient binding to murine MHC class II. Indeed, different results were obtained in studies with HLA-DQ transgenic mice (Welcher *et al*., 2002; Sriskandan *et al*., 2001). Expression of HLA-DQ rendered the mice susceptible to SPE A-induced lethal shock that was accompanied by massive cytokine production. Immune activation during GAS infection was manifested by Vβ-specific T cell repertoire changes and widespread lymphoblastic tissue infiltration. In contrast, lymphoid activation was undetectable in transgenic mice infected with an isogenic *speA*$^-$ strain, demonstrating the pivotal role of a single SAg in pathogenesis of invasive GAS disease.

*In vivo* experiments using an i.p. model of infection demonstrated that SMEZ did not contribute to mortality or impede bacterial clearance in HLA-DQ transgenic mice, but led to a rise of Vβ11 T cells in the spleen (Unnikrishnan *et al*., 2002). Interestingly, infection with an isogenic M89 *smez*$^-$ strain failed to elicit a significant cytokine production compared with the parent strain, but resulted in a clear rise in murine Vβ4 T cells, suggesting a role for SMEZ as a repressor of cognate anti-streptococcal response.

### *Clinical studies*

SPE A has been detected by ELISA in the sera of STSS patients, and its presence was associated with elevated levels of TNF-β, providing some evidence of SPE A-induced T cell activation (Sriskandan *et al*., 1996b). In a more recent study, strong mitogenic activities were observed in the serum of two patients with STSS, one of whom died. Although the infecting GAS strains carried several *sag* genes, including *speA*, *speC*, *speG*, *speJ*, and *smez*, the mitogenic activity could be wholly attributed to SMEZ, with a small contribution of SPE J in one case (Proft *et al*., 2003a). The quantity of circulating toxin was estimated to be in the order of 100pg/ml. The surviving patient developed neutralizing antibodies against SMEZ during convalescence, providing further evidence for the importance of SMEZ in STSS. Furthermore, the results suggested that the lack of neutralizing antibodies against SAg might be a risk factor for invasive GAS disease. Supportive evidence also came from other studies. Eriksson *et al*. (1999) reported that neutralization of SPE A lymphocyte mitogenicity was totally absent in sera from patients with STSS and

low in sera from patients with uncomplicated bacteremia, compared with levels in sera from uncomplicated erysipelas. Another study showed that the levels of neutralizing anti-SPE A antibodies in plasma samples from severe and non-severe invasive GAS infections were significantly lower than in age- and geographically matched healthy controls (Basma *et al*., 1999).

### *Genetic background of the host*

Recent results suggested that the genetic background might influence the susceptibility for invasive GAS disease. In particular, HLA polymorphism might play a role in disease susceptibility. Evidence was provided by Kotb and coworkers, who found that SPE A triggered significantly higher proliferative responses when presented by HLA-DQ compared to HLA-DR1, -DR4, or -DR5 alleles. In contrast, SPE C was preferentially presented by DR4 (Norrby-Teglund, 2002). Moreover, patients with the DRB1$^{*}$1501/DQB1$^{*}$0602 haplotype mounted significantly reduced responses to streptococcal SAgs and were less likely to develop severe systemic disease compared to individuals with risk or neutral haplotypes (Kotb *et al*., 2002). The dependence of SPE A on HLA-DQ α-chain polymorphism was demonstrated by Llewelyn *et al*. (2004), who showed that SPE A binds more strongly to HLA-DQA1*01 than to HLA-DQA1*03/05 and that differential HLA-DQ binding results in quantitative and qualitative differences in T cell proliferation, cytokine production, and Vβ-specific changes in the T cell repertoire.

## Acute rheumatic fever (ARF)

ARF is a postinfection sequelae and the leading cause of preventable pediatric heart disease. It usually occurs in school-age children and young adults after pharyngeal infection with *S. pyogenes*. ARF is a cross-reactive immune response to the host's cardiac tissue, and it has been proposed that the reactive T cells might be driven by SAgs. Recently, several novel streptococcal SAgs have been identified from ARF-associated serotypes. The genes for SPE K/L were found in high frequencies on serotypes M3 (USA and Japan) (Beres *et al*., 2002; Ikebe *et al*., 2002) and on M89 (New Zealand) (Proft *et al*., 2003b), while SPE L/M and SPE M were found in M18 (USA) (Smoot *et al*., 2002a). It was shown that antibodies against SPE L/M and SPE M were more common in convalescent sera from ARF patients compared to patients with pharyngitis (Smoot *et al*., 2002b). Interestingly, a common target of the SAgs SPE K/L, SPE L/M, and SPE M are T cells bearing the TcRs with Vβ1.1.

## Kawasaki disease (KD)

KD is an acute multi-system vasculitis of unknown etiology that affects mostly young children and is now recognized as the leading cause of acquired heart disease in children in the developed world. Although KD has been reported all over the world, it is overexpressed among Asian populations, especially Japanese (Cimaz and Falcini, 2003).

KD is associated with marked activation of T cells and monocytes, and there is a remarkable similarity among KD, staphylococcal toxic shock, STSS, and scarlet fever in the clinical symptoms. Intravenous immunoglobulin therapy is highly effective when given early, suggesting that the causative agent is a toxin. Several investigators reported the selective expansion of T cells bearing the Vβ2.1 TcR, which points towards a SAg involvement in the disease (Abe *et al*., 1992; Konishi *et al*., 1996). Elevated plasma levels of IL-1β, IL-2, IL-6, IL-8, IL-10, IFN-γ, and TNF-α were observed in the acute phase of KD and levels of anti-SPE C antibodies were significantly higher in patients with acute and convalescent KD than in age-matched controls (Yoshioka *et al*., 1999).

CHAPTER

# 52

# The superantigenic toxin of *Yersinia pseudotuberculosis*

*Christophe Carnoy, Nadine Lemaitre, and Michel Simonet*

## INTRODUCTION

Superantigens are produced by a range of pathogenic bacteria and viruses and elicit powerful host immune responses via an unconventional mechanism. The superantigens are presented to T cells by direct binding to major histocompatibility (MHC) molecules present on the antigen-presenting cell (APC) surface, without MHC restriction, and specifically recognize the variable region of the β chain (Vβ) of T cell receptors (TCR) (Marrack and Kappler, 1990). As a consequence of this interaction, T cells and APCs release large amounts of inflammatory cytokines, which can cause toxic shock and tissue damage (Llewelyn and Cohen, 2002). The Gram-positive *Staphylococcus aureus* and *Streptococcus pyogenes* are considered to be the principal sources of bacterial superantigens (Müller-Alouf *et al*., 2001; Alouf *et al*., 2005). However, in 1993, a mitogen with superantigenic features was characterized in the Gram-negative bacillus *Yersinia pseudotuberculosis*.

## *YERSINIA PSEUDOTUBERCULOSIS*, AN ENTEROPATHOGENIC BACTERIUM

Malassez and Vignal first described *Y. pseudotuberculosis* in 1883 as the causative agent of tuberculosis-like lesions (pseudotuberculosis) in guinea pigs. Seventy years later, Knapp and Mashoff isolated the germ from the enlarged, ileocaecal lymph nodes of two German children who had undergone surgery for suspected appendicitis. There have been many subsequent reports of human *Y. pseudotuberculosis* infections in Europe, North America, Japan, and Eastern Russia. With the exception of a few outbreaks in Finland, Eastern Russia, and Japan (Somov and Martinevsky, 1973; Inoue *et al*., 1984; Tertti *et al*., 1984; Nakano *et al*., 1989; Pebody *et al*., 1997; Jalava *et al*., 2004; Nuorti *et al*., 2004), most cases are sporadic. In Eurasia and North America, *Y. pseudotuberculosis* is enzootic in various mammal and bird species, which may harbor this microorganism as healthy carriers (Fukushima and Gomyoda, 1991). Human infection is most probably established by ingestion of food or water contaminated by the excreta of infected animals. In immunocompetent hosts, infection is self-limited and causes relatively mild illness. The most frequent clinical symptoms are fever and abdominal pain rather than the diarrhea and vomiting usually associated with gastrointestinal infections. Abdominal pain in the right fossa mimics acute appendicitis (pseudoappendicular syndrome) and can prompt surgery; while considerable mesenteric adenitis and/or acute terminal ileitis are observed peroperatively, the appendix itself appears normal. Several cases of Crohn's ileitis following *Y. pseudotuberculosis* infection have been also reported in the literature, but whether this bacterium triggers this inflammatory bowel disease is subject to debate (Blaser *et al*., 1984; Treacher and Jewell, 1985; Homewood *et al*., 2003; Hugot *et al*., 2003). In debilitated patients (especially those with cirrhosis due to alcoholism or hemochromatosis or other liver diseases), microorganisms have the propensity to spread from the digestive

tract to deep organs via the blood, and septicemia is often fatal (Butler, 1983).

A typical feature of *Y. pseudotuberculosis* infection is the occurrence of post-infection complications, such as reactive arthritis and erythema nodosum (Butler, 1983; Tertti *et al*., 1984; Tertti *et al*., 1989). Commonly, arthritis lasts for six months, and the clinical course of the illness can range from an acute, self-limiting form in most cases to intermittent, relapsing, or chronic arthritis in a few cases (Simonet, 1999). Erythema nodosum, sometimes associated with reactive arthritis, is characterized by typical aseptic and inflammatory nodules on the patient's legs. In Japan, where pseudotuberculosis is often epidemic, infection in children frequently associates fever, conjunctival injection, a biphasic erythematous rash, lip changes (fissure, redness, or crust), induration of hands or feet, erythema of palms of the hands or the soles of the feet, desquamation of the peripheral extremities, strawberry tongue, inflamed oral mucosa, enlarged lymph nodes, erythema nodosum, and arthritis (Sato *et al*., 1983). These clinical manifestations, rarely reported in European countries, resemble Kawasaki disease and the Far East scarlet fever disease reported in Eastern Russia during the 1960s (Somov and Martinevsky, 1973). It has been suggested that *Y. pseudotuberculosis* might be a possible but non-exclusive etiologic agent of these illnesses. Finally, approximately 10% of *Y. pseudotuberculosis*-infected patients develop renal complications. The most frequent one (80% of cases) is acute renal failure, probably due to tubulointerstitial nephritis, but acute nephritic syndrome, IgA nephropathy, and hemolytic uraemic syndrome have been also described (Takeda *et al*., 1991; Cheong *et al*., 1995).

## *Y. PSEUDOTUBERCULOSIS* PRODUCES AN EXOTOXIN WITH SUPERANTIGEN ACTIVITY

The typical post-infection immunopathological complications that may occur after infection with *Y. pseudotuberculosis* (reactive arthritis, erythema nodosum, Kawasaki disease, etc.) suggested the involvement of a superantigen-like molecule. In 1993, a substance with mitogenic activity on human peripheral blood mononuclear cells (PBMCs) was simultaneously described in a *Y. pseudotuberculosis* strain involved in a mass outbreak in Japan (Uchiyama *et al*., 1993) and in an isolate from a patient presenting Kawasaki-like symptoms (Abe *et al*., 1993; Yoshino *et al*., 1994). The substance was designated YPM for "*Y. pseudotuberculosis*-derived mitogen" (Miyoshi-Akiyama *et al*., 1993). YPM has a molecular weight of 14,524 as demonstrated by electrospray ionization mass spectrometry (Yoshino *et al*., 1994). Cloning and sequencing of the corresponding gene revealed a 456-base pair (bp) open reading frame (*ypm*) that codes for a 151 amino acid product, which is then processed into a mature 131-residue form after cleavage of a 20 amino acid hydrophobic signal sequence (Figure 52.1) (Ito *et al*., 1995; Miyoshi-Akiyama *et al*., 1995). The presence of a signal peptide suggests that YPM is secreted via the general secretory pathway found in most Gram-negative bacteria.

YPM expands human T lymphocytes expressing the Vβ3, Vβ9, Vβ13.1, and Vβ13.2 variable regions (Abe *et al*., 1993; Uchiyama *et al*., 1993) with a preference for the $CD4^+$ T cells, although some $CD8^+$ lymphocytes can also proliferate (Ito *et al*., 1995). YPM is active at concentrations as low as 1pg/ml (Ito *et al*., 1995), and requires the presence of MHC class II molecules to be mitogenic. This is evidenced by the observation that (i) YPM stimulates T cells in the presence of fibroblasts transfected with HLA-DP, HLA-DQ and HLA-DR class II molecules, with a higher degree of expansion in the presence of HLA-DR (DR4 subtype) and (ii) YPM-induced T lymphocyte expansion can be inhibited by monoclonal antibodies directed against HLA-DR (Abe *et al*., 1993; Uchiyama *et al*., 1993). Paraformaldehyde fixation of HLA-DR-transfected fibroblasts does not alter YPM-induced cellular stimulation, suggesting that YPM binds directly to HLA class II molecules without being processed (Abe *et al*., 1993; Uchiyama *et al*., 1993). Taken as a whole, these studies suggest that the mitogen produced by *Y. pseudotuberculosis* displays all the criteria of a superantigenic toxin as defined by Marrack and Kappler (1990).

**FIGURE 52.1** YPM variant amino acid sequences deduced from the nucleotide sequence of *ypmA, ypmB,* and *ypmC*. Amino acids are represented by a single letter code. Shaded letters correspond to the amino acid residues that differ from the YPMa reference sequence. YPMa signal sequence is underlined.

## THE THREE YPM VARIANTS ARE UNRELATED TO OTHER BACTERIAL SUPERANTIGENS

A few years after the initial characterization of YPM, Ramamurthy *et al*. (1997) reported that some mitogenic *Y. pseudotuberculosis* isolates failed to hybridize with a *ypm* probe and showed that these strains harbored a gene coding for a 150 amino acid protein sharing 83% homology with YPM. As a result of this report, the first described *Y. pseudotuberculosis* superantigen was called YPMa and the second variant was referred to as YPMb. The lowest amino acid homology between these YPM variants is seen in the central part of the mature protein, between amino acids 65 and 86 (Figure 52.1). YPMa contains two cysteines (at positions 32 and 129), whereas YPMb possesses an additional cysteine residue at position 66. These differences do not impair TCR recognition since YPMa and YPMb both stimulate T cells bearing Vβ 3, 9, 13.1, and 13.2 regions (Ramamurthy *et al*., 1997). Screening a *Y. pseudotuberculosis* strain collection by hybridization under mild stringency conditions with a *ypmA*-specific probe, followed by sequencing of the internal region of the superantigen encoding genes, enabled the authors to discover another *ypm* allele with a single nucleotide difference relative to *ypmA*. This new variant, in which the histidine residue at position 51 of the mature protein is replaced by tyrosine, was designated YPMc (Figure 52.1) (Carnoy and Simonet, 1999; Carnoy *et al*., 2002). *ypmA* is by far the most frequent allele, since it is found in 83% of superantigenic isolates, whereas *ypmB* and *ypmC* are respectively present in 5% and 12% of these strains (Fukushima *et al*., 2001). Molecular typing of the YPM producers, based on analysis of the genomic distribution of the IS*1541* insertion sequence, strongly suggested that the *ypmB* allele is the ancestral gene and that *ypmC* recently emerged from a *ypmA*-expressing clone (Carnoy and Simonet, 1999). This latter finding is consistent with the exclusive presence of *ypmC* in serotype O:3 strains (Fukushima *et al*., 2001).

The small size of the YPM toxins (14.5 kDa) compared to those of other bacterial superantigens, which range from 20 to 30 kDa, soon prompted the suggestion that YPMs were probably unrelated to other superantigens (Petersson *et al*., 2004). This hypothesis was confirmed by phylogenetic analysis based on protein identity of 22 superantigens that clearly demonstrated that YPMs diverged from Gram-positive superantigens and from the MAM superantigen produced by *Mycoplasma arthritidis*, a pathogen involved in arthritis in mice (Müller-Alouf *et al*., 2001).

## YPMA DISPLAYS A JELLY-ROLL FOLD

YPMa has recently been crystallized, and x-ray crystal analysis revealed a jelly-roll fold comprising two β sheets, each with four antiparallel strands (Figure 52.2) (Donadini *et al*., 2004). Nuclear magnetic resonance (NMR) analysis of YPMa in solution confirmed the three-dimensional (3D) structure. Surprisingly, the superantigen was found to be monomeric in solution, whereas it packed as a trimer in crystals (Figure 52.2). The *in vivo* relevance of the YPM trimer seen in crystals is questionable. However, YPMa trimerization might occur in other high-density molecular environments, for example when the superantigen cross-

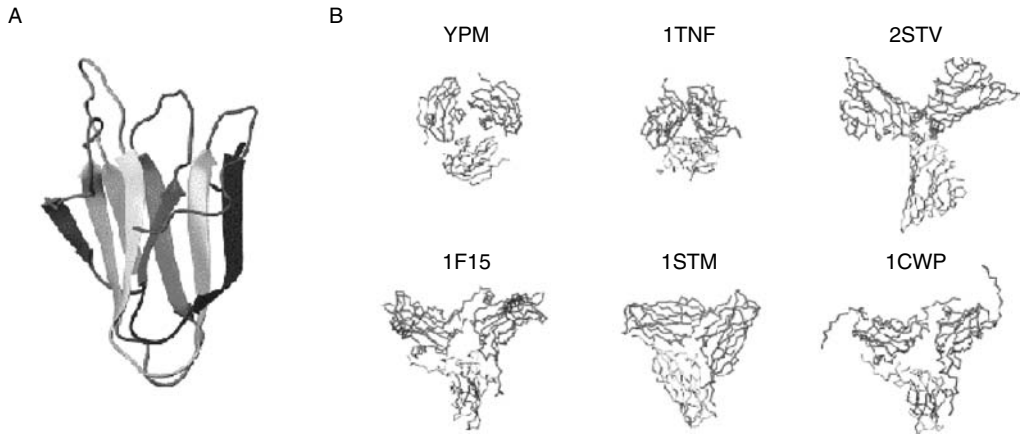

**FIGURE 52.2** Three-dimensional structure of YPMa. A. Ribbon diagram showing the secondary structure of YPMa as determined by NMR spectroscopy. B. YPMa trimer assembly in the crystal structure, compared to TNF-α (1TNF) and proteins from satellite tobacco mosaic virus (2STV), cucumber mosaic virus (1F15), satellite panicum mosaic virus (1STM), and cowpea chlorotic mottle virus (1CWP) (Donadini *et al*., 2004).

links to MHC molecules and TCRs (Donadini *et al*., 2004). Interestingly, searches for structurally related proteins indicated that YPMa exhibits strong similarities, especially when in its trimeric form, with Tumor Necrosis Factor (TNF) superfamily proteins, as well as with human, plant, and insect viral capsid proteins (Figure 52.2) (Donadini *et al*., 2004). These findings, which primary amino acid sequence homology analysis had failed to reveal, favor the hypothesis whereby YPM has a viral origin. The absence of 3D structural homology with the staphylococcal and streptococcal superantigens that have been crystallized to date (Petersson *et al*., 2004) also confirms that YPM is unique in the superantigen world.

Elucidation of YPMa 3D structure represents an important milestone in the understanding of the biological activity of this original superantigen. However, the molecular mechanisms underlying the interaction between YPM and its ligands (i.e., TCRs and MHC class II molecules) are still poorly understood, despite several structure-function studies. Initial comparison of YPMa and YPMb variants revealed a markedly different amino acid composition in the central region (residues 65 to 86) of the mature proteins (Ramamurthy *et al*., 1997) (Figure 52.1). Since both variants exhibit the same Vβ specificities, the central region was thought not to be crucial for TCR recognition. In a preliminary investigation, Yoshino *et al*. (1996) tested the blocking effect of synthetic YPMa internal peptides on superantigen-induced stimulation of PBMCs and observed that the peptide corresponding to the first 23 amino acids of the mature protein was found to be the best inhibitor. However, only 50% of YPM-triggered cellular expansion was abrogated by this peptide. This indicates that domains other than the N-terminus might also contribute to YPM cell proliferation properties. Involvement of the N-terminal region was also suggested by a deletion mutant study: Removal of 11, 19, or 29 residues at the N-terminal end of the protein abolishes the proliferative properties and affects YPM binding to HLA-DR (Ito *et al*., 1999). Further studies, based on random mutagenesis, mapped the protein residues responsible for the superantigen biological activity (Ito *et al*., 1999; Seprenyi *et al*., 1999). The most exhaustive work characterized single and double YPM mutants with low mitogenicity (less than 25% of wild-type YPM activity) (Ito *et al*., 1999). Some of them (K37N, D124G, L46S, L64R/T115I, G71E/L94I, and H117D) still bound to HLA-DR molecules, whereas other point mutants (L7Q/D79G, S52F, L112S) lost this ability. Random mutagenesis also showed that cysteine residues at positions 32 and 129 of the mature polypeptide were essential for YPMa biological activity (Ito *et al*., 1999). Of the 14 amino acid substitutions that confer low activity onto YPM, only six (E30K, K37N, Y47H, N56S, V116G, and H117D) were found to be solvent-exposed on the 3D structure of the molecule (Donadini *et al*., 2004). These residues represent good candidates for binding to MHC class II or TCR molecules. Nevertheless, there currently are not enough structure-function data to specify YPM MHC class II and TCR binding sites.

## YPM IS CHROMOSOMALLY ENCODED

Not all *Y. pseudotuberculosis* strains produce YPM (Chain *et al*., 2004). This ability, which is O-serotype independent, differs according to the isolate's geographical origin: *ypm* is detected in almost all strains (more than 95%) from Far Eastern countries and, strikingly, in only one fifth (less than 20%) of strains isolated in Western countries (Yoshino *et al*., 1995; Fukushima *et al*., 2001). This finding argues for an exogenous origin of the *Y. pseudotuberculosis ypm* gene. Many bacterial superantigen-encoding genes are either borne on plasmids, phages, or pathogenicity islands. In *Y. pseudotuberculosis* superantigenic strains, *ypm* alleles are located on the chromosome, upstream of an open reading frame with similarities to *Salmonella pagO*, a PhoP/PhoQ-activated gene (Figure 52.3) (Carnoy *et al*., 2002). A new *Y. pseudotuberculosis*-specific insertion sequence, designated IS*1398*, is present in the vicinity of the *ypmA* and *ypmC* alleles (downstream of *pagO*), but is absent in the *ypmB* allele genetic locus. No other mobile genetic elements, such as phage genes or remnants, were found in the *ypm* alleles' genetic environment. The *ypm* genes are located about 250 bp downstream of a 26-bp motif called *yrs* (for *Yersinia* recombination site), which is homologous to *dif*, a site-specific recombination target in *Escherichia coli* and a filamentous phage integration locus in *Xanthomonas campestris*. Interestingly, *yrs* contains a 19-bp consensus sequence common to many Gram-negative species, thus indicating the ubiquity of this element (Figure 52.3) (Carnoy *et al*., 2002).

Instability is an important feature of the *ypm* locus. *In vitro* experiments showed that deletions within the *ypmA* chromosomal region occur about 250 times more frequently than deletions within a housekeeping gene locus (the urease operon) (Carnoy *et al*., 2002). Characterization of six independent mutants indicated that DNA deletions (i) were distinct for each mutant and were not site-specific, indicating a random event, and (ii) always spared the *yrs* site, arguing in favor of the involvement of *yrs* in the process. Analysis of the superantigen locus in *ypm*-negative *Y. pseudotuberculosis* revealed that DNA rearrangements occurred in very few strains, suggesting that the random deletion process might be less frequent in nature than in the

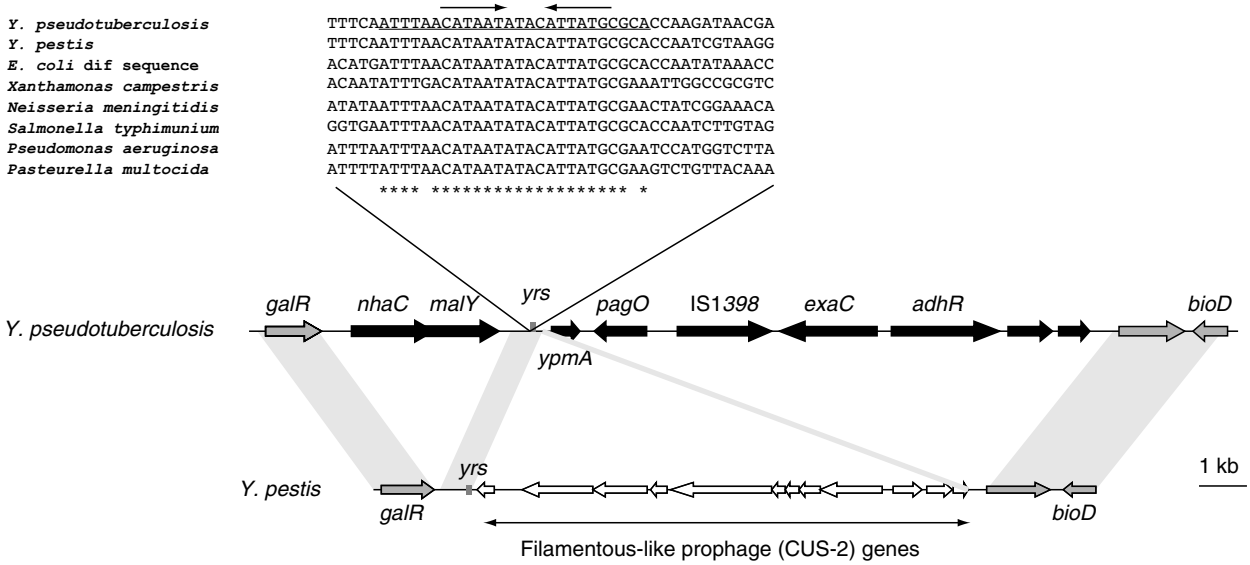

**FIGURE 52.3** Genetic organization of the *ypmA* locus from *Y. pseudotuberculosis* compared to the corresponding locus in *Y. pestis*. Gray arrows and shaded areas represent the coding sequences (CDSs) and the region common to *Y. pseudotuberculosis* and *Y. pestis*. Black-and-white arrows indicate CDSs that are specific to *Y. pseudotuberculosis* and *Y. pestis,* respectively. CDSs are identified with the name of the best hit using Blastn (http://www.ncbi.nlm.nih.gov/BLAST/). The nucleotide sequence of the *Yersinia* recombination site (*yrs*) is presented and aligned with the homologous sequences found in various Gram-negative microorganisms. Asterisks specify identical nucleotides corresponding to the consensus sequence. Arrows above the *Y. pseudotuberculosis yrs* sequence represent the two inverted repeats found in the consensus sequence (Carnoy *et al*., 2002).

laboratory. In fact, most of the non-superantigenic *Y. pseudotuberculosis* strains never acquired the *ypm* gene (Carnoy *et al*., 2002).

## *Y. PSEUDOTUBERCULOSIS* IS THE ONLY PATHOGENIC YERSINIAE THAT PRODUCES SUPERANTIGENS

In addition to *Y. pseudotuberculosis*, three other *Yersinia* species are pathogens in animals and humans: *Y. pestis*, the causative agent of plague, and *Y. enterocolitica*, another enteropathogenic microorganism. Although DNA-DNA hybridization indicates greater than 90% relatedness between *Y. pseudotuberculosis* and *Y. pestis*, Miyoshi-Akiyama *et al*. (1997) failed to detect the *ypm* gene in the latter. *In silico* analysis of three *Y. pestis* genomes further confirmed the absence of *ypm* in this species (Parkhill *et al*., 2001; Deng *et al*., 2002; Song *et al*., 2004). Interestingly, the *yrs* site is present on the chromosome of *Y. pestis*, but unlike the situation in *Y. pseudotuberculosis*, it is surrounded by filamentous phage-like (CUS-2) genes, confirming the phage integration function of the *yrs* site (Figure 52.3) (Carnoy *et al*., 2002; Gonzalez *et al*., 2002).

In the early nineties, Stuart and Woodward (1992) isolated a mitogen from a *Y. enterocolitica* lysate that stimulated mouse T cells bearing Vβ 3, 6, and 11 (and possibly 7 and 9). This protease-sensitive substance was found also to be active on human Vβ 3, 12, 14, and 17 T cells in a MHC class II-dependent manner (Stuart *et al*., 1995). Even though the *Y. enterocolitica* mitogen has been partially purified, a DNA sequence is still unavailable at present. The question of whether the mitogen shares homology with YPM remains unanswered. Nevertheless, several features argue in favor of two, distinct yersiniae superantigens. First, the species' respective mitogenicity-associated Vβ specificities are different. Second, experimental approaches have demonstrated the absence of *ypm* in more than 200 *Y. enterocolitica* strains and notably in the strain described as a mitogen producer (Yoshino *et al*., 1995; Carnoy and Simonet, 1999). Finally, *in silico* analysis of the *Y. enterocolitica* 8081 genome has not revealed any *ypm* homologues (http://www.sanger.ac.uk/Projects/Y_enterocolitica/).

## A SCENARIO FOR THE ACQUISITION OF YPM BY *Y. PSEUDOTUBERCULOSIS*

On the basis of genetic and experimental findings, an evolutionary scenario explaining the acquisition of *ypm* by *Y. pseudotuberculosis* can be proposed (Figure 52.4). Molecular typing of *Y. pseudotuberculosis* strains suggested that *ypmB* was the ancestral gene and that *ypmC* recently derived from a *ypmA* clone following a point mutation (Carnoy and Simonet, 1999). Interestingly,

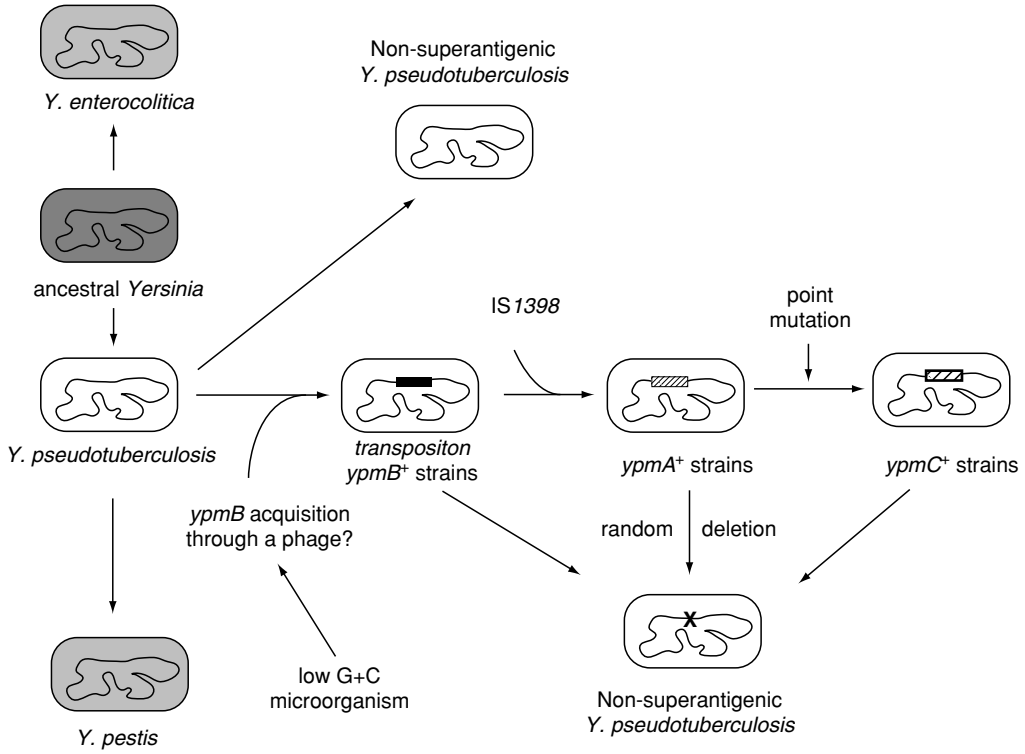

**FIGURE 52.4** A speculative scenario for *ypm* acquisition by *Y. pseudotuberculosis*. The proposed evolutionary model is based on several experimental findings: (i) *ypmB* is the ancestral gene and *ypmC*-positive strains correspond to a clonal expansion from *ypmA*-positive *Y. pseudotuberculosis*, (ii) the G+C content of the *ypmB* allele is low compared to that of the *Y. pseudotuberculosis* genome (35% versus 47%, respectively), (iii) the YPMa structure is homologous to viral capsid proteins, (iv) *ypm* alleles are located downstream of *yrs*, a phage integration site, (v) IS*1398* is never found in *ypmB*-positive strains and (vi) non-superantigenic strains can be obtained by random deletion of the *ypm* locus (Carnoy and Simonet, 1999; Carnoy *et al.*, 2002; Donadini *et al.*, 2004).

*ypmB* has only been found in strains isolated from the environment (e.g., river water) and wild animals (e.g., moles and wild mice), but never from humans (Fukushima *et al.*, 2001). This suggests that the superantigen gene ancestor would first have been acquired by non-human strains. In contrast, *ypmA* is the allele found most frequently in human isolates.

It is known that *Y. enterocolitica* and *Y. pseudotuberculosis* derive from a common ancestor and that *Y. pestis* recently emerged from *Y. pseudotuberculosis* (Achtman *et al.*, 1999). The absence of *ypm* in *Y. enterocolitica*, *Y. pestis*, and in some *Y. pseudotuberculosis* strains strongly suggests that the superantigen-encoding gene was introduced into *Y. pseudotuberculosis* after its divergence from *Y. enterocolitica*, and that *Y. pestis* derived from a non-superantigenic *Y. pseudotuberculosis* clone. This indicates that *ypm*-positive strains represent a clonal population that gained the superantigen through a horizontal gene transfer. Hence, specification of the original source of the *ypm* ancestral gene is an important issue. *ypm* genes have a guanine and cytosine (G+C) content of about 35%, whereas that of the *Y. pseudotuberculosis* genome is 47% (Carnoy *et al.*, 2002). This indicates that *ypm* might have originated from a low G+C content microorganism. Since they display low G+C contents, superantigen-producing species, such as *S. aureus*, *S. pyogenes*, and *M. arthritidis*, could be good candidates as gene donors; however, *in silico* analysis of their genomes failed to detect any putative *ypm* ancestors.

The involvement of a phage in the horizontal acquisition of *ypm* by *Y. pseudotuberculosis* is an attractive hypothesis. It is strongly supported by the location of the superantigen genes close to a phage integration site and by the presence of phage genes in the corresponding *Y. pestis* locus. Furthermore, the structural homology of the trimeric form of YPM with viral capsid proteins reinforces the idea that YPM was initially a phage-related protein. This assumption was further strengthened by a recent epidemiological study on a large *Y. pseudotuberculosis* strain collection, which revealed that *ypm* genes are closely associated with the YAPI pathogenicity island-borne *pil* operon, encoding type IV pili (Collyn *et al.*, 2005). It is known that besides their contribution to bacterial adherence, pili may serve as bacteriophage receptors (Bradley, 1973; Mindich *et al.*, 1999; Budzik *et al.*, 2004). By analogy

with *Vibrio cholerae*, in which TCP type IV pili allow attachment for enterotoxins encoding filamentous prophage CTXΦ and further bacterial lysogeny (Waldor and Mekalanos, 1996), we can speculate that *Y. pseudotuberculosis* type IV pili would be a target for *ypm*-containing phage. In this hypothesis, *Y. pseudotuberculosis* would have acquired the *pil* operon before the *ypmB* gene. Many questions remain unanswered in this model, and experimental evidence is now required to confirm the proposed evolutionary scenario.

## YPM IS A BACTERIAL VIRULENCE FACTOR

Since the discovery of YPM in 1993, very few experimental data on its role in human pathological disorders are available. A serological study established that 61% of sera from Japanese patients with acute *Y. pseudotuberculosis* infections contained elevated levels of anti-YPM antibodies (with a higher titer in patients suffering from systemic complications), demonstrating the expression of YPMa *in vivo* (Abe *et al*., 1997). In the acute phase of yersiniosis, there are higher levels of Vβ3-expressing T cells (but not those expressing Vβ9, Vβ13.1, and Vβ13.2) in the patient's blood. To explain these *in vivo* and *in vitro* discrepancies, Abe *et al*. (1997) hypothesized that of the Vβ T cells expanding in lymph nodes, only the major subset (Vβ3) can be detected in the blood. This assertion was partially confirmed by analysis of the T cells from a *Y. pseudotuberculosis*-infected patient who showed an enhancement of Vβ3 and Vβ13.2 subsets in the mesenteric lymph nodes, whereas only the Vβ3 subset was detected in the PBMCs.

A geographical correlation between the clinical mani festations and the prevalence of superantigen genes tends to point to YPM as a virulence factor. Indeed, in Europe where the frequency of isolation of superantigenic strains is low, i.e., less than 20%, *Y. pseudotuberculosis* mainly induces gastrointestinal symptoms, whereas in the Far East where the prevalence of superantigen-positive strains is high, i.e., greater than 95%, the clinical forms of illnesses are frequently more severe, with a variety of systemic manifestations, such as Izumi fever or Kawasaki disease (Fukushima *et al*., 2001).

Experimental models have been developed to assess the impact of YPM during infection with *Y. pseudotuberculosis*. Parenteral administration of purified recombinant YPM into D-galactosamine pre-sensitized C57BL/6 or BALB/c mice can induce a T cell-dependent lethal shock, as demonstrated by survival of T cell-deficient SCID mice injected with the superantigen (Miyoshi-Akiyama *et al*., 1997; Kano *et al*., 2004). The MHC class II-dependent T lymphocyte activation produces T cell blasts expressing Vβ7 or Vβ8 variable regions on the TCR (Miyoshi-Akiyama *et al*., 1997). These Vβ7, Vβ8 cells are required for the YPM-induced shock, since treatment with anti-Vβ7 or anti-Vβ8 monoclonal antibodies protects the mice from YPM toxicity. However, tissular proliferation of the two T cell subsets differs: In a murine model of long-term (7-day) exposure to YPM, it was found that $V\beta7^+$ $CD4^+$ T cells expanded at a much higher rate than $V\beta8^+$ $CD4^+$ T cells in the spleen. This indicated that YPM preferentially activated T cells carrying the Vβ7 region and had a greater affinity for the Vβ7 domain than for the Vβ8 domain. When monitoring the distribution of $V\beta8^+$ T lymphocytes in BALB/c mouse tissues, Kano *et al*. (2004) reported that the cells left the bloodstream within one hour after injection of the toxin and migrated into the liver, but not the spleen or the lymph nodes, demonstrating hepatotropism of the YPM-activated $V\beta8^+$ T cells. YPM also altered cell viability, and apoptosis occurred in the liver 12 hours after YPM administration (Kano *et al*., 2004). Nevertheless, the exact role of cellular migration and hepatocyte apoptosis in mouse lethality is still unclear and deserves further investigation. Additionally, YPM injection into BALB/c or C57BL/6 mice elicits synthesis of interferon-gamma (INF-γ) and TNF-α but not of interleukin (IL)-10. Blocking of inflammatory cytokines by anti-TNF-α and anti-IFN-γ monoclonal antibodies neutralizes YPM toxicity *in vivo*, demonstrating the involvement of these cytokines in shock (Miyoshi-Akiyama *et al*., 1997; Kano *et al*., 2004). However, overproduction of IFN-γ and TNF-α is not YPM-specific, since it is frequently associated with superantigen-mediated host immune responses (Muller-Alouf *et al*., 2001; Petersson *et al*., 2004). YPM also affects functionality of cultured colonic epithelial cells (the human T84 cell line) by increasing cell permeability and by reducing active ion transport in response to prosecretory stimuli. The biological effect, which is PBMC-dependent, can be abolished by addition of monoclonal antibodies against TNF-α and IFN-γ (Donnelly *et al*., 1999). In contrast, intrarectal instillation of YPM into BALB/c mice does not impair ion transport in the colonic mucosa, but does trigger local inflammation (Lu *et al*., 2003). Like other superantigens, YPM could be an inductor of inflammatory bowel diseases.

YPM effects may be different when mice are administered whole bacteria instead of the purified toxin. To assess the impact of YPM in the presence of *Y. pseudotuberculosis*, parenteral inoculation in OF1 mice of isogenic YPM-producing or YPM-deficient *Y. pseudotuberculosis* were performed. This experimental model revealed that the superantigen exacerbates bacterial virulence (Carnoy *et al*., 2000). In infected mice, the major immunological findings, that have been related

to bacterial YPM production are splenomegaly and IL-2 and IL-4 overproduction. Flow cytometry analysis of splenocytes from *Y. pseudotuberculosis*-infected mice indicated that YPM-dependent splenomegaly is related to T cell expansion, especially of $V\beta7^+$ and $V\beta8^+$ subsets, thus confirming the phenotype of the T cells activated *in vitro* by YPM (Carnoy *et al*., 2003). Furthermore, *in vitro* stimulation of murine thymic T cells by YPM induces blasts, which selectively express Vβ7 and Vα14 chains on the TCR (i.e., a NKT cell phenotype) and which produce substantial amounts of IL-2 and IL-4 (Yagi *et al*., 1999). Therefore, it is tempting to speculate that NKT cells might support YPM-induced toxicity in the mouse, but, to date, experimental evidence in support of this attractive hypothesis is lacking. In *Y. pseudotuberculosis*-infected mice, YPM induces neither IFN-γ overproduction nor TNF-α synthesis in the spleen and blood. This contrasts with the cytokine expression profile of animals injected with the toxin alone. Abrogation of TNF-α production in the animals after injection of *Y. pseudotuberculosis* can, in fact, be attributed to YopJ, a toxin which inhibits NF-κB activation and consequently suppresses TNF-α production (Palmer *et al*., 1998; Schesser *et al*., 1998).

## DOES YPM TRIGGER KAWASAKI DISEASE?

First described in the 1960s, Kawasaki disease is an acute multisystem vasculitis complicated by the development of coronary abnormalities (including diffuse dilatation and aneurysm formation), which primarily affects children under five years of age (Kawasaki, 1967; Kawasaki *et al*., 1974). The disease's clinical symptoms and epidemiology (with the predominantly seasonal occurrence of epidemics) strongly suggest that an infectious agent is the cause, or at least an inciting agent (Burns and Globé, 2004). Kawasaki disease is associated with elevated levels of various inflammatory cytokines and the selective expansion of some specific, Vβ-expressing T lymphocytes in the patient's peripheral blood during the active phase of the illness. The condition is also associated with the development of auto-antibodies, especially anti-endothelial cell antibodies. Taken as a whole, these features are characteristic of superantigen-induced disease. *Y. pseudotuberculosis* was cited as a possible etiologic agent, since the germ was recovered from patients with clinical manifestations resembling those of Kawasaki disease (Sato *et al*., 1983; Baba *et al*., 1991; Konishi *et al*., 1997). Additionally, YPMa was actually purified from a strain of *Y. pseudotuberculosis* isolated from a patient suffering from this illness (Yoshino *et al*., 1994). However, neither an increase or decrease in the T cell subsets bearing the Vβs recognized by YPMs (Vβ 3, 9, 13.1, and 13.2) nor the presence of anti-YPM antibodies has been described in patients suffering from Kawasaki disease.

## CONCLUSION

The discovery of a superantigen produced by *Y. pseudotuberculosis* brought new insights to the understanding of the post-infection, immunopathological complications frequently associated with this Gram-negative microorganism. Although structurally and genetically unrelated to streptococcal, staphylococcal, and mycoplasmal superantigens, YPM exhibits all the classical features of a superantigenic toxin (absence of APC processing, requirement for MHC class II molecules, Vβ-specific T cell stimulation). The YPM structural and genetic originality raises the central question of what makes a molecule a superantigen. YPM interaction with its ligands is still unknown but deserves serious attention. The recent characterization of the toxin 3D structure will undoubtedly unveil the molecular mechanism responsible for YPM-mediated mitogenicity. Furthermore, although the toxicity of YPM has been extensively demonstrated in experimental models, the role of this superantigen in *Y. pseudotuberculosis*-associated immunopathologies, especially Kawasaki disease, remains to be proven.

CHAPTER

# 53

# Comparative three-dimensional structure of bacterial superantigenic toxins

*Matthew D. Baker and K. Ravi Acharya*

## INTRODUCTION

From a historical perspective, the discovery and characterization of bacterial superantigens (SAgs) is heavily indebted to the structural techniques used to probe their many functions. From the first three-dimensional structure of a bacterial superantigen (Swaminathan *et al*., 1992) to the complexes of these toxins with their receptors (Jardetzky *et al*., 1994; Kim *et al*., 1994; Fields *et al*., 1996; Li *et al*., 1998a, 2001; Petersson *et al*., 2001), the complete archaeology of these molecules has been mapped and a wealth of information has been obtained. The ability to assign specific functions to discrete regions of the toxin and to assess the roles of individual amino acid residues by a combination of mutagenesis and structural techniques has enabled detailed comparisons of the entire bacterial superantigen family of proteins. In general, the nature of these toxins makes them particularly suitable for structural analysis by x-ray crystallography. Crystallization requires large quantities of protein, and these toxins can be expressed and purified in high quantities from their native bacteria (Chu *et al*., 1966; Avena and Bergdoll, 1967; Robern *et al*., 1975; Ende *et al*., 1983; Reynolds *et al*., 1988; Brehm *et al*., 1990) or in a recombinant form (Munson *et al*., 1998; Proft *et al*., 1999; Sundberg and Jardetzky, 1999; Donadini *et al*., 2004; Zhao *et al*., 2004). Crystallization also dictates that numerous trials may need to be carried out at different temperatures over wide pH ranges and at various concentrations of salts and precipitants. Luckily, these purified toxins are very stable, being highly resistant to proteases, denaturation from heat, and extreme pH (Marrack and Kappler, 1990) characteristics that have proved to be vital for structural studies.

Superantigens are powerful T cell stimulatory molecules produced primarily by *Staphylococcus aureus* and *Streptococcus pyogenes*. The action of these toxins as SAgs can be attributed to their ability to cross-link MHC class II molecules and T cell receptors to form a trimolecular complex (Marrack and Kappler, 1990). In contrast to conventional antigens, they are not processed internally by antigen presenting cells (APC) and act as an intact fully folded protein rather than an antigenic peptide located in the peptide-binding groove of the MHC class II molecule. Structural evidence shows SAgs bind to APCs on the outside of MHC class II molecules (Jardetzky *et al*., 1994; Kim *et al*., 1994; Li *et al*., 2001; Petersson, 2001) and to T cells via the external face of the T cell receptor (TCR) $V_\beta$ element (Li *et al*., 1998a; Fields *et al*., 1996) (Figure 53.1).

The number of known bacterial proteins with superantigenic properties and/or high homology with known SAgs has grown considerably over the last decade. Staphylococcal enterotoxins (SEs), A, B, C1–3, D, E, H, I, J; toxic shock syndrome toxin-1 (TSST-1), the streptococcal pyrogenic exotoxins (Spes) A, C, H; and streptococcal mitogenic exotoxin SME-$Z_2$ and streptococcal superantigen (SSA) are the most well studied bacterial SAgs to date (for recent reviews see Papageorgiou and Acharya, 2000; Baker and Acharya 2003, 2004). Other pathogens, such as *Mycoplasma arthritidis* and *Yersinia enterocolitica* have also been shown to secrete superantigenic proteins (Cole *et al*., 1996), and

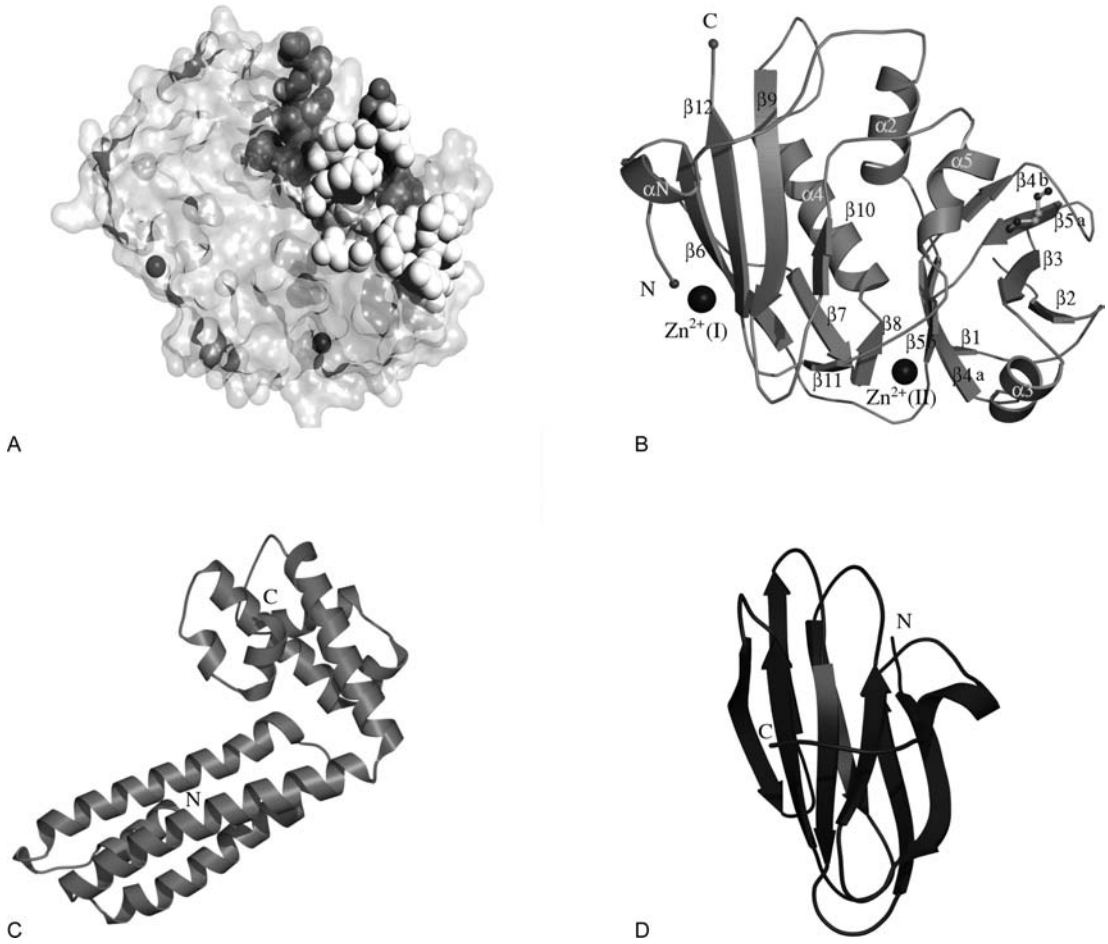

**FIGURE 53.1** (A) Surface representation of a typical staphylococcal/streptococcal superantigen with TCR binding region (dark grey) and MHC class II binding region (white) indicated; (B) Ribbon diagram of SEA representative of the common structural features of the staphylococcal and streptococcal superantigen family. Spheres represent the positions of the two zinc sites. The cysteine residues that form the disulphide loop are shown in ball-and-stick representation and all secondary structure elements are labeled; (C) The crystal structure of MAM (helical structure); (D) The crystal structure of YPM with a β-barrel motif.

the characterization of these toxins has recently been helped by the elucidation of their crystal structures (Donadini *et al*., 2004; Zhao *et al*., 2004).

Staphylococcal and streptococcal SAgs can be grouped into four subfamilies based on amino acid sequence and structure (Williams *et al*., 2000; Thomas *et al*., 2004). The first group is made up of the staphylococcal enterotoxins SEA, SED, SEE, SEH, SEI, and SEJ. Both staphylococcal and streptococcal toxins form the second group, which is comprised of SEB, SEC1-3, SpeA1-3, SSA, and SEG. The third group contains streptococcal pyrogenic and mitogenic toxins; SpeC, SpeJ, SpeG, SpeH, SME-Z, SME-$Z_2$, and streptococcus dysgalactiae-derived mitogen (SDM). The staphylococcal superantigen–like proteins (SSL, previously named as SET) and TSST-1 form the fourth group. Mycoplasma arthritidis mitogen (MAM) and Yersinia pseudotuberculosis mitogen (YPM) have no sequence homology to the rest of the bacterial SAgs and cannot be grouped with any of these subfamilies (Cole *et al*., 1996; Ito *et al*., 1999). In addition, the bounty of information from genomics initiatives (Kuroda *et al*., 2001; Ferretti *et al*., 2001) has led to the discovery of new putative SAgs based on amino acid sequence alignment; examples include SEQ (Orwin *et al*., 2002), SER (Omoe *et al*., 2003), SpeL, and SpeM (Proft *et al*., 2004). Due to the growing number of potential SAgs, the International Nomenclature Committee for Staphylococcal Superantigens has proposed a new procedure for the naming of newly described SAgs and the renaming of some previously described SAgs (Lina *et al*., 2004).

On comparison of the three-dimensional structures of SAgs (see Papageorgiou and Acharya, 2000 and references therein), a two-domain architecture is apparent. The two domains (N- and C-terminal domains) are separated by a long, solvent-accessible α-helix, which

spans the center of the molecule (Figure 53.1). The N-terminal domain is characterized by the presence of hydrophobic residues in its solvent-exposed regions and has considerable structural similarity to the oligosaccharide/oligonucleotide binding–fold (OB-fold). Despite this similarity, SAgs have not been shown to bind DNA or recognize carbohydrates. The C-terminal domain comprises a four-stranded β-sheet capped by a central α-helix and resembles the β-grasp motif. Other features common to a significant number of family members include a highly flexible disulphide loop, which is located in the N-terminal domain (Figure 53.1 and Table 53.1). This flexible loop is thought to be involved in the emetic properties of the staphylococcal and streptococcal toxins, as substitution of the two cysteine residues that form this disulphide loop to alanine abolishes the emetic activity in SEC1 (Hovde *et al*., 1994). The corresponding cysteine residues in SpeA1 have also been shown to be involved in T cell stimulation, as their mutation significantly reduces the ability of the toxin to stimulate certain populations of T cells (Kline and Collins, 1997). The recent structures of the staphylococcal superantigen-like proteins SSL5 and SSL7 have revealed that the common architecture is preserved among these related groups of proteins (Arcus *et al*., 2002; Al-shangiti *et al*., 2004). SSL5 is most closely related to TSST-1, but shows two notable structural differences from other members of the superantigen family. First, the β6 and β7 strands of the C-terminal domain are extended such that the β6–β7 loop extends significantly from the molecular surface of the molecule. Second, there is a widespread positive charge over the surface of the protein, particularly concentrated at the central α-helix and the outer face on the N-terminal domain. SSL7 is most closely related to SpeC, but like SSL5 shows no superantigenic activity (Al-Shangiti *et al*., 2004). SSL7 is also thought to be able to form dimers via the interaction of the β-grasp domains of two monomers to form an intermolecular β-sandwich. At present, it is not known if the features of either of these proteins have any biological significance.

Two recently obtained crystal structures for Mycoplasma arthritidis mitogen (MAM) and Yersinia pseudotuberculosis mitogen a (YPMa) have extended the topology of the family further (Zhao *et al*., 2004; Donadini *et al*., 2004). The crystal structure of MAM reveals the toxin to have an entirely different architecture to the staphylococcal and streptococcal toxins (Figure 53.1). MAM is composed of two α-helical domains forming an L-shape. The N-terminal domain consists of four α-helices and a 25 residue long N-terminal loop that wraps around the four-helix bundle. The C-terminal contains six α-helices. Yersinia pseudotuberculosis mitogen a (YPMa) is much smaller than the classical staphylococcal and streptococcal toxins with a molecular mass of 14 kDa. It consists of a jelly-roll fold comprising two β-sheets, each containing four anti-parallel strands (Donadini *et al*., 2004). The structure is unlike any known SAgs, being structurally similar to viral capsid proteins and members of the tumor necrosis factor superfamily (Figure 53.1).

## BINDING TO MHC CLASS II MOLECULES

Structural analyses using x-ray crystallography have shown that MHC class II molecules possess two distinct binding sites for the classical staphylococcal and streptococcal SAgs (Papageorgiou and Acharya, 2000). The first, a low-affinity binding site (referred to as the generic site) is located on the α-chain of the MHC class II molecule and the second, a high-affinity (about 100 times higher affinity than the generic site), zinc-dependent site is located on the β-chain (Figures 53.2 and 53.3). The structures of SEB and TSST-1 in complex with HLA-DR1 via the low-affinity site (Jardetzky *et al*., 1994; Kim *et al*., 1994), SpeC in complex with HLA-DR2 (Li *et al*., 2001), and SEH in complex with HLA-DR1 (Petersson, 2001) via the high-affinity site have yielded a great deal of information about the binding of SAgs to MHC class II molecules. It appears that each superantigen binds to different alleles of class II molecules to varying degrees. While the majority of the SAgs including TSST-1, SEB, and MAM bind preferentially to HLA-DR alleles, SAgs such as SEC, SpeA, and SSA bind predominantly to HLA-DQ alleles (Sundberg and Jardetzky, 1999; Etongue-Mayer *et al*., 2002).

It is apparent that both SEB · and TSST-1 · HLA-DR1 complexes have similar binding modes to the DR1 α-chain, with the solvent-exposed, hydrophobic core at the N-terminal domain of the toxin playing an important role. Similar hydrophobic ridge regions exist in several other SAgs and form the generic MHC class II binding site. However, in the case of TSST-1, additional contacts with the peptide antigen were also present (Kim *et al*., 1994). Indeed, truncating the C-terminal end of the peptide dramatically affects TSST-1 binding to murine I-Ab (Wen *et al*., 1997).

Many members of the superantigen family (except SEB, TSST-1, SSA, SET1-5, and YPM) possess either one or two zinc binding sites (Papageorgiou and Acharya, 2000) (for details see Table 53.1, Figures 53.2 and 53.3). Zinc ions have been shown to be important for the recognition of the MHC class II β-chain. Mutational and structural analyses have identified a high-affinity zinc-binding site in SEA at the C-terminal domain with a $K_d$ of 100 nM for DR1 recognition (Fraser *et al*., 1992).

**TABLE 53.1** The bacterial superantigen family

| Superantigen | Mr (kDa) | MHC-II generic site | Zinc usage | Dimer formation | Disulphide loop |

#Proposed residues based on sequence alignment

In comparison, the zinc-independent generic site at the N-terminal domain has considerably lower affinity ($K_d$ of 10 μM) for class II binding. If the two binding sites coexist, SEA shows a $K_d$ of 13 nM. Mutation of residues in either of these sites results in a toxin unable to induce cytokine expression in peripheral blood mononuclear cells (PBMC) (Abrahmsen *et al*., 1995). It would seem that SEA possesses two distinct MHC class II binding sites, which may enable it to form trimeric SEA·MHC·SEA complex, a phenomenon that has been observed in solution experiments (Tiedemann *et al*., 1995). Similar arguments can be put forward for SEE, as both SEA and SEE possess identical zinc ligands.

The high-affinity site of SEA is not present in SEC or SpeA. Instead, a new zinc binding site with somewhat lower affinity compared with the high-affinity zinc binding described above (the estimated dissociation constant for the zinc ion in SEC2 is less than 1 μM) was identified at the N-terminal domain, which also appears to be important for MHC class II binding (Figures 53.2 and 53.3) (Papageorgiou *et al*., 1999). This site is known as the secondary zinc-binding site. In SED (Sundstrom *et al*., 1996) and SpeC (Roussel *et al*., 1997), the dimerization mechanism varies slightly. SED can form zinc-dependent homodimers, while SpeC forms zinc-independent homodimers. Both SED and SpeC bind to the β-chain of MHC class II molecules through a zinc-mediated mechanism similar to that of SEA and formation of trimers and/or tetramers is a possibility. A similar binding mechanism has been proposed for SEH, which also lacks a generic MHC class II binding site (Hakansson *et al*., 2000).

The crystal structures of SpeC in complex with HLA-DR2 (Li *et al*., 2001) and SEH in complex with HLA-DR1 (Petersson, 2001) via a high-affinity, zinc-dependent site

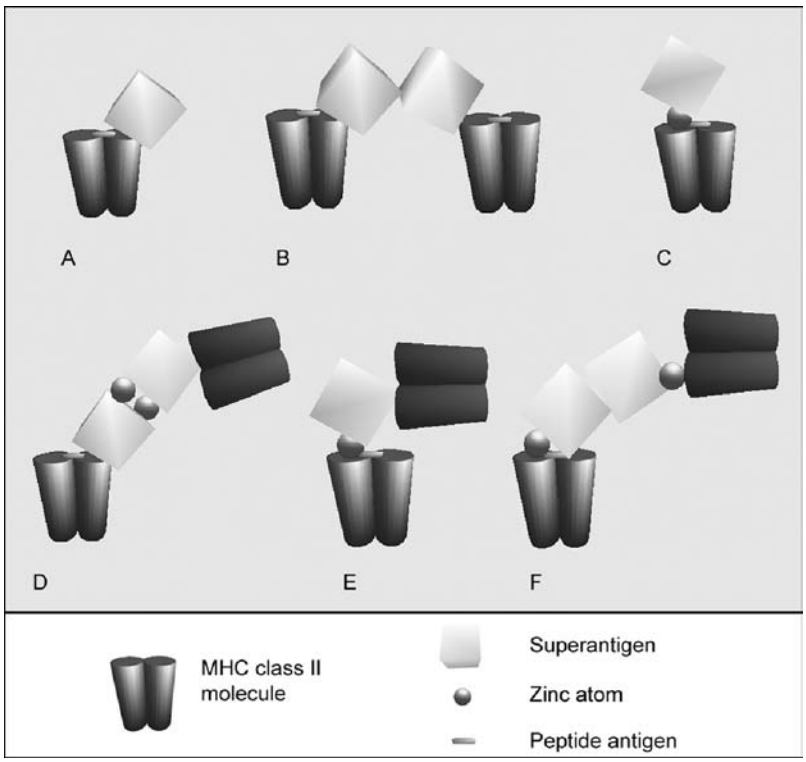

**FIGURE 53.2** Schematic diagram illustrating the multiple modes by which SAgs can interact with MHC class II molecules; (A) Interaction with a single MHC class II molecule via the generic binding site on the α chain; e.g., SEB and TSST-1; (B) Interaction of a non-zinc linked superantigen dimer with two separate MHC class II molecules via the α chain generic site; e.g., MAM; (C) Interaction of a superantigen with MHC class II β chain via a high-affinity zinc site; e.g., SEH and SpeC; (D) A zinc-linked superantigen dimer interacting with two MHC class II molecules via their α chain generic binding sites; e.g., SE; (E) Interaction of a single superantigen with two MHC class II molecules—both via the generic site (α chain) and the high-affinity zinc site on the β chain; e.g., SEA and SEC2; (F) Dimeric superantigen bound to two MHC class II molecules via their high-affinity zinc sites; e.g., SpeC and SpeA1.

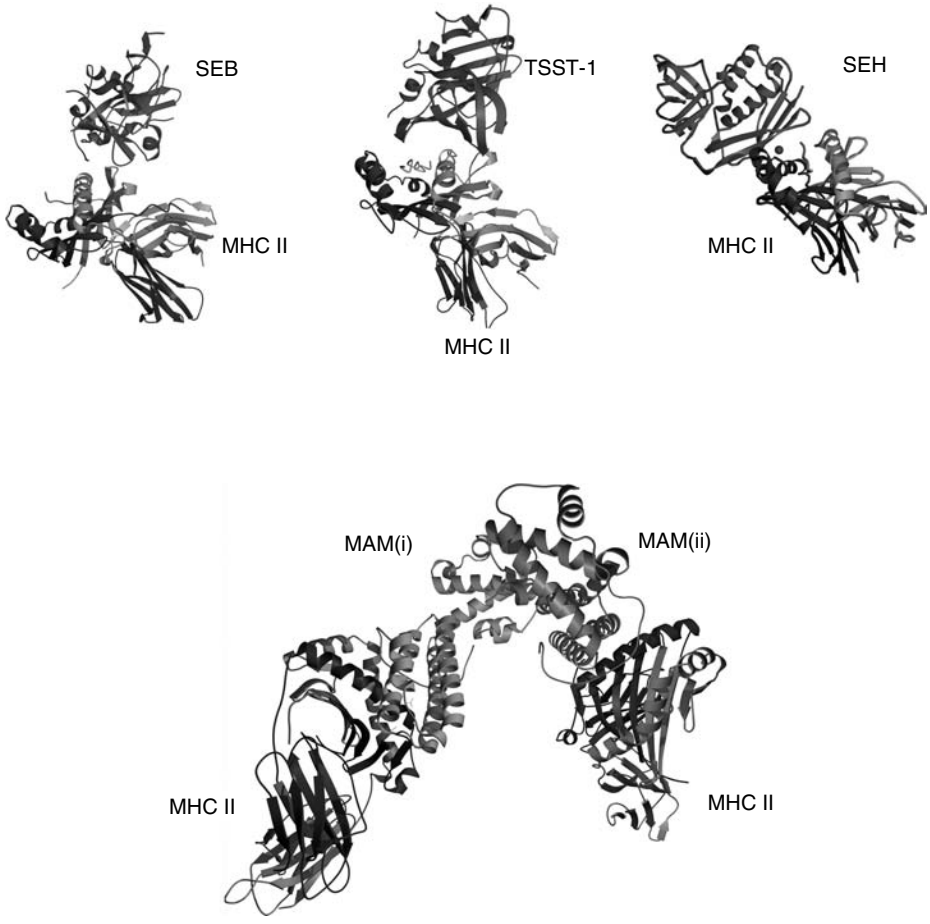

**FIGURE 53.3** Crystal structures of SAgs in complex with MHC class II molecules. **Top left:** SEB in complex with MHC class II molecule (HLA-DR1) via the generic site. **Top middle:** TSST-1 in complex with HLA-DR1 via the generic site. **Top right:** SEH in complex with HLA-DR1 via a high-affinity zinc site. **Bottom**: MAM dimer in complex with two HLA-DR1 molecules via a generic site.

have shed more light on the interactions of SAgs with MHC class II molecules (Figure 53.3). The interactions between both SAgs and their MHC class II molecules are governed by a bridging zinc ion, which tetrahedrally coordinates three ligands from the SpeC (His 167, His 201, and Asp 203) and two from SEH (His 206, Asp 208, and a water molecule) with one from the MHC class II β1 helix (His 81). Approximately ⅓ of the contact area between SpeC and MHC class II is taken up by antigenic peptide. Similarly, stability of the SEH–MHC class II complex is also achieved through interaction with the antigenic class II associated peptide, and in both cases a majority of the interactions with the antigenic peptide are via its backbone atoms. Hence, both the SpeC and SEH complexes have similar interactions with the antigenic peptide despite differences in peptide composition. This indicates that although the peptide plays an important role in the complex interaction, binding to MHC class II is not entirely peptide specific.

Zinc is also shown to play a role in the binding of SME-$Z_2$, SpeG, and SpeH to MHC class II molecules, as the binding of all three of these SAgs to LG-2 cells is significantly reduced by the addition of EDTA (Proft *et al*., 1999). The proposed zinc binding site in each of these SAgs is shown to be closest to that of SEA and SpeC, both of which have geometrically and spatially equivalent sites (Roussel *et al*., 1997; Proft *et al*., 1999). As the presence of the zinc-binding ligands suggest, all three of these SAgs bind to MHC class II molecules in a zinc-dependent fashion. Recently, a second zinc binding site was discovered in SEC2 (Papageorgiou *et al*., 2004). This binding site is located close to the generic MHC class II binding site and is postulated to serve as a site of dimerization for SEC2. If this is the case, the generic MHC class II site would be blocked by the dimer interface, and binding to MHC class II molecules would have to be mediated by the SEC2 primary zinc-binding site. This would result in SEC2 being able to bind to MHC class II molecules via a zinc-mediated dimer. SpeA1 and SpeC are also able to form zinc-independent homodimers. SpeA1 has recently been shown to exist in a disulphide linked dimeric form (Baker *et al*., 2004b) via cysteine residues located within the flexible disulphide loop, while the SpeC dimer is formed by using the surface that is usually used as a generic MHC class II binding site (Roussel *et al*., 1997). The crystal structure of SpeJ is also shown to bind to MHC class II molecules in a zinc-dependent fashion (Baker *et al*., 2004a).

The SSL proteins are unique among the superantigen family in that they do not bind to MHC class II molecules and do not appear to be superantigenic (Arcus *et al*., 2002; Al-Shangiti *et al*., 2004). Hence, the conserved amino acids appear to be playing a role in preserving the superantigen fold, and the large number of non-conservative substitutions within the generic MHC class II binding site mean that MHC II binding is unlikely.

Zinc was also thought to play a role in MAM binding to MHC class II molecules or in dimerization of the toxin (Etongue-Mayer *et al*., 2002; Langlois *et al*., 2003). However, the absence of zinc from the crystal structure of dimeric MAM in complex with HLA-DR1 (Zhao *et al*., 2004) supported no such role, and the exact role of zinc in the action of this novel superantigen requires further investigation.

Although the structure of MAM complexed with HLA-DR1 bears no resemblance to the classical staphylococcal and streptococcal SAgs, there are some similarities in the general mechanism of binding. Upon complex formation, there are no major structural changes at the interface between MAM and MHC class II molecules, which is consistent with the complexes of other bacterial SAgs with MHC class II. The MAM·HLA-DR1 complex is formed through contacts between the N-terminal domain of MAM and the several regions of HLA-DR1; specifically, the β1-β2 loop, the β3-β4 loop, and the α1 helix of the DR1 α chain; the β1 helix of the DR1 β chain; and the hemagglutinin (HA) peptide bound in the peptide binding groove of the HLA-DR1 molecule. The particular regions on the N-terminal domain of MAM that contact HLA-DR1 are α3- and α4-helices, which interact with the α1 helix of the DR1 α chain and both the β1-β2 loop and the β3-β4 loop of the DR1 α chain. The N-terminal loop of MAM also makes extensive contact with the HA peptide. Comparison of the binding of MAM to MHC class II molecules with other SAgs reveals that the MAM binding site on HLA-DR1 also overlaps with the generic binding site for staphylococcal and streptococcal SAgs. Indeed, SEB and TSST-1 have been shown to block MAM binding to MHC class II on THP-1 cells (Bernatchez *et al*., 1997). MAM binding is also abolished by superantigen binding to the high-affinity zinc site, as the MAM binding site on MHC class II also encompasses a region on the MHC β chain within which His 81 is located (Zhao *et al*., 2004). The binding mode of each of the two MAM monomers with a single HLA-DR1 is identical. MAM is shown to exist as both monomer and homodimer in solution, indicating that it may be able to act on MHC class II molecules as both monomer and dimer. The interaction between the two molecules does not involve the zinc ion and is formed by the C-terminal domain on one monomer sitting in the V-shaped cleft formed by both the N- and C-terminal domain of the second monomer (Figure 53.3).

Presently, the mechanism of YPM binding to MHC class II molecules is unknown. In the absence of a structure in complex with MHC class II and no homology to

the rest of the superantigen family, mutagenesis studies have been employed in the hope of shedding further light on this problem (Ito *et al*., 1999). However, the crystal structure of YPM has revealed that a majority of the mutations that affected activity were buried within the structure. Therefore, it is likely that these mutations caused conformational changes and/or misfolding of the protein. As such, it is imperative that further work be carried out in order to characterize the functional regions of this toxin.

It appears that there is an ever-broadening array of mechanisms by which SAgs can mediate binding with MHC class II molecules. This can be either through zinc-mediated interaction or via the generic site or as a homodimer (which in turn can be either zinc and non-zinc mediated) or involving a combination of all three mechanisms.

## BINDING TO THE T CELL RECEPTOR

The interaction of SAgs with T cell receptors is seemingly a much simpler affair; SAgs were thought to bind exclusively to TCR via the $V_\beta$ element through a universally similar mechanism in which the binding is mediated by interactions between the side chains of the superantigen and the $V_\beta$ backbone atoms. The net result is that each superantigen expands T cells bearing certain $V_\beta$ elements, while others are excluded (Kappler *et al*., 1989).

The characterization of a superantigen TCR binding region reveals a similar framework with specific differences that may reflect differences in $V_\beta$ specificity. The TCR binding site involves the shallow cavity between the two domains of the molecule. In SEB this cavity is formed by residues 22–33 (mostly α2 helix), 55–61 (β2-β3 loop), 87–92 (β4 strand and β4-β5 loop), 112 (β5 strand), and 210–214 (α5 helix) (Swaminathan *et al*., 1992) (Figure 53.1), and equivalent sites for SEC and SEA have also been suggested using the structure-based sequence alignment. Crystal structures of SAgs with various TCR $V_\beta$ elements have been elucidated (Fields *et al*., 1996; Li *et al*., 1998a; Sundberg *et al*., 2002). The structures of SEB, SEC2, SEC3 appeared to back up this simple binding mechanism with a majority of the contacts being made in the form of interactions between the side chains of the superantigen and backbone atoms of the TCR $V_\beta$ chain. For SEC2, SEC3, and SEB the main interactions are shown to be between the side chain atoms of the superantigen and complementary determining regions one and two (CDRs 1 and 2), and hypervariable region 4 (HV4) of the $V_\beta$ chain. Comparison of this TCR binding site (from SEC2/3) with the corresponding regions of SEA and SEB identifies an invariant asparagine residue (Asn23 in SEB/SECs; Asn25 in SEA) as being crucial for direct interactions with the TCR. Mutation of this residue in SEB results in the loss of T cell stimulation (Kappler *et al*., 1992). This residue is solvent exposed in SEA, SEB, and SEC, and is thought to have similar interactions in all the SEs. Alanine scanning mutagenesis of individual SEC3 residues involved in the stabilization of the SEC3/$V_\beta$ complex in the crystal structure (Fields *et al*., 1996; Leder *et al*., 1998) showed that Asn23, Tyr90, and Gln210 had the most effect on controlling binding to the TCR β-chain. Tyr90 and Gln210 are conserved among SEC1-3, SEB, and SpeA, and SSA has analogous residues Asn49, Tyr116, and Gln223 (Swaminathan *et al*., 1995; Stevens *et al*., 1996). The variance between SAgs with regard to TCR affinity and specificity can be accounted for by several residues unique to each particular superantigen, as well as any topological influence that each of these might have. For example, residue Tyr26 of SEC2 confers specificity between SEC1 and SEC2 via its interaction with Gly53 from the $V_\beta$ chain (Deringer *et al*., 1996) and is not conserved in SEA or SEB. Val91 of SEC2 is also implicated in TCR binding and is not conserved in SEA (Tyr94) or SEB (Tyr91) either (Tiedemann *et al*., 1995). It is possible that the switching of Val91 for a tyrosine residue in SEB may be responsible for its decreased affinity for the Vβ8.2 chain (Fields *et al*., 1996). SEA specificity for TCR is thought to be governed by Ser206, Asn207, and Thr21 (Swaminathan *et al*., 1995). Further evidence for this is provided by the exchange of residues 206 and 207 in SEA for the homologous residues in SEE. This causes a switch in the profile of $V_\beta$ elements on the responding T cells to change to that of the profile normally seen for T cells stimulated by SEE (Hudson *et al*., 1993). Ser206 and Asn207 in SEA correspond to Gln210 and Ser211, respectively, in both SEB and SEC2. Those residues that define the specificity of a superantigen for particular $V_\beta$ elements make the greatest energetic contribution to the overall stability of the $V_\beta$ superantigen complex (Li *et al*., 1998b), and as the above evidence shows, these residues are relatively few in number.

The crystal structure of SpeA1 in complex with mouse $V_\beta$ 8.2 and SpeC in complex with human $V_\beta$ 2.1 add extra dimensions to the apparently simple mechanism of TCR binding of SAgs (Sundberg *et al*., 2002). First, it is evident that SpeC binds to significantly more $V_\beta$ residues than the SEC2/3 or SEB and encompasses areas of the CDR1 and CDR3 loops of the TCR β chain. This increased number of contacts is thought to be due to the deeper and broader cleft between the N- and C-terminal domains of SpeC where the TCR binding site is located. In addition, SpeC forms numerous interactions with both main chain and side chain atoms of

the TCR $V_\beta$ chain. While interaction of SpeA1 with the TCR $V_\beta$ chain is similar to that of SEB (conserving the three hydrogen bonds seen between SEB and the TCR), it has an additional five hydrogen bonds compared to SEB. The differences in the TCR binding sites of these two SAgs and the interactions of amino acid side chains on both the superantigen and the TCR $V_\beta$ chain suggest that binding to TCR receptors is not merely one of simple conformational dependence (Fields *et al*., 1996; Li *et al*., 1998b). The crystal structure of SpeJ and subsequent mutagenesis work on its TCR binding site is shown to be very similar to that of SpeC (Baker *et al*., 2004a). However, SpeJ has also been shown to use its TCR binding site to form homodimers, an action that would occlude its ability to bind to TCR molecules. At present, the ramifications of this mode of dimeriztion for TCR binding by SpeJ are unclear.

The TCR binding site of TSST-1 is as yet not fully characterized. As it is structurally similar to SpeC and SpeJ, it is possible that it shares similar TCR binding features. The available mutagenesis data suggest that the TCR binding site of TSST-1 is located in the C-terminal domain on the long α2 helix and between the β7–β8 and α2–β9 loops as part of the α1 helix. In this regard, it is unique from the SEs (Acharya *et al*., 1994). Mitogenicity is lost either partially or completely by mutation of residues in the region 115–144. In particular, residues Tyr115, Glu132, His 135, Ile140, His 141, and Tyr144 are all of great importance for TSST-1 binding to TCR (Acharya *et al*., 1994; Deresiewicz *et al*., 1994). Mutation of these residues produces substantially fewer mitogenic toxins, yet they can still be recognized by a specific antibody, suggesting that the toxins produced are still intact (Deresiewicz *et al*., 1994).

Given the high degree of similarity between the SET proteins and TSST-1, it is somewhat surprising that they do not stimulate T cells in a $V_\beta$ restricted manner (Arcus *et al*., 2002). Closer examination of the structure of SSL5 reveals that amino acid conservation is restricted to those residues that confer structural integrity, particularly in and around the region joining the N- and C-terminal domains where the TCR binding site is located in TSST-1. Additional changes to specific surface residues further serve to change the nature of the protein, making it unable to interact with TCR molecules.

Both MAM and YPM are known to bind to the TCR $V_\beta$ chain (Cole *et al*., 1991; Abe *et al*., 1993; Uchiyama *et al*., 1993). Although their crystal structures have allowed some speculation as to how they may interact with TCRs, at present there is not enough data to fully characterize these interactions, and it will be interesting to see if these novel SAgs bind to TCR in a similar manner to the staphylococcal and streptococcal SAgs.

Structural biology has enabled us to characterize the TCR $V_\beta$ chain binding sites of several SAgs. While the interactions with TCR share a common core of residues, it is evident that specificity for particular $V_\beta$ elements comes from amino acid residues unique to each toxin. This in turn demonstrates that there are also multiple modes by which SAgs can interact with the TCR. First, there is a high-specificity binding mode involving many contacts by both backbone atoms and side chain atoms over an increased area, as demonstrated by SpeC. This mode has a high affinity for only a few TCR $V_\beta$ elements; second, there is a moderate specificity mode with fewer interactions over a reduced contact area. This mode has a modest affinity for a larger group of TCR $V_\beta$ elements, such as those seen in SpeA1. Thirdly, there is a promiscuous binding mode, such as is seen in SEB and SEC2, that binds to TCR $V_\beta$ chains in a simple conformation-dependent manner. A further complication to this mechanism was unearthed when it was discovered that SEH, in contrast to all other SAgs, stimulates T cells in a $V_\alpha$ specific fashion with a complete absence of any $V_\beta$ expansion (Petersson *et al*., 2003). It is postulated that SEH may bind to TCR in this way due to its presentation by MHC class II molecules via a zinc atom. Whether other SAgs that are presented to TCR by MHC class II in the same way can bind to $V_\alpha$ in the same fashion remains to be seen, and further investigation is essential. As more superantigen TCR complexes are characterized structurally, the complexities of the interactions that lead to each superantigen having a distinct $V_\beta$ (or $V_\alpha$) profile will be better understood.

## OTHER STRUCTURAL FEATURES AND IDIOSYNCRASIES

The ability of TSST-1 to cause systemic or localized symptoms in a site-dependent manner led to the proposal that it, in contrast to the other SEs, must be able to transverse the epithelial barrier (Schlievert *et al*., 2000). The mechanism by which it is able to do so could include either passive diffusion or cellular receptors. If a cellular receptor is required, then what is the structural evidence for such a binding site on TSST-1? Obvious structural differences between TSST-1 and the other SAgs include the lack of an α-helix in the C-terminal domain, the long N-terminal extension, and the absence of a disulphide loop. TSST-1 also has unique patches of hydrophobic and neutral residues on the front and rear of the β-barrel at the N-terminal

domain. Many of these features could combine to produce a receptor-specific binding site in order for TSST-1 to traverse epithelial cells and allow systemic shock.

The SET group of proteins are most closely related to TSST-1, yet have no superantigenic activity (Arcus *et al*., 2002). The structure of SSL5 reveals a widespread positive charge over the protein's surface, which is suggested to be the likely binding site for negatively charged binding partners. By modeling the sequences of several of the SSL proteins onto the structure of SSL5, it was found that the surface features were altered. This supports the hypothesis that the conserved staphylococcal and streptococcal superantigen fold has been used by the SET family to produce a group of proteins, each with differing functions.

One common feature of superantigen exposure is vomiting and diarrhea. Little is known about how superantigen structure relates to emesis and diarrhea, and how these activities are associated to superantigenicity. Recent work indicates that the emetic properties of SAgs may not be completely correlated with their superantigenicity (Harris and Betley, 1995). His225 of SEA has been demonstrated to be important for both superantigenic and emetic activity, while His61 appears to be important only for emetic activity (Hoffman *et al*., 1996), and further areas in the N-terminal region of SEA that are important for both emetic and superantigenic function have also been identified (Harris and Betley, 1995). Carboxymethylation of histidine residues in SEB was found to abrogate emetic activity, but still induces peripheral blood cell proliferation in monkeys (Alber *et al*., 1990). This is consistent with the hypothesis that the two activities are separable in SEs. In support of this, intravenous administration of a C-terminal fragment of SEC1 was found to induce diarrhea but not emesis in primates (Spero *et al*., 1978). One of the main regions of these toxins thought to be responsible for emesis is the disulphide bond and loop (Hovde *et al*., 1994). Although the disulphide bond itself is not an absolute requirement for emetic activity, the conformation within or adjacent to the loop is important for emesis. Further work is required in order to assess the contribution of certain amino acids to the various biological activities shown by SAgs in the context of the diseases they cause.

## FORMATION OF THE TRIMERIC COMPLEX FOR SIGNAL TRANSDUCTION

The complex course of events at the cell surface that leads to the formation of the MHC II·SAg·TCR complex is still ambiguous. The prospect of dimeric SAgs and SAgs with multiple MHC class II binding sites being able to form complexes with more than one MHC class II molecule or TCR means that even further diversity exists in the ability of these toxins to interact with the immune system.

When considering the formation of a complex, the character of membrane-bound receptors must be taken into account (Davis *et al*., 2003). In order for a complex to form, cell membranes need to be in close proximity to each other, and the receptors must diffuse to the site of interaction. It has been shown that in order for superantigenic T cell activation to occur, less than 0.3% of the MHC class II molecules must be occupied by superantigen (Lavoie *et al*., 2001). At higher concentrations of bound toxin, the resulting T cell response is aborted by apoptosis after a few cell divisions. Thus, a low local concentration of MHC class II molecules on the cell interface is preferable for optimum superantigenicity. It is thought that the binding of a superantigen to TCR induces clustering of the TCRs on the cell surface and the acquirement of the intracellular components required to transduce a signal (Germain, 1997). This is thought to occur in a manner that mimics peptide antigens with regard to receptor clustering (Woodland *et al*., 1997), either through direct clustering events as proposed by the TCR oligomerization model or by the binding of superantigen homodimers to multiple MHC class II molecules, which in turn would promote T cell clustering (Tiedemann *et al*., 1995). Molecular modeling suggests that signal transduction stimulated by SEA through large-scale assembly is limited to four or five TCR·(DR1β·SEA·DR1α) tetramers and requires the dimerization of MHC class II molecules. While TCRs would be clustered together in this model, TCR dimerization is thought unlikely (Cuff *et al*., 2003). SEA is not unique in its ability to form zinc-mediated dimers (Tiedemann *et al*., 1995). SED (Sundstrom *et al*., 1996) and SEC2 (Papageorgiou *et al*., 2004) can form zinc-dependent homodimers, while SpeA1 forms a non–zinc mediated disulphide-linked dimer (Baker *et al*., 2004b), and a SpeC dimer is also formed in the absence of zinc (Roussel *et al*., 1997). MAM has also been shown to be able to form zinc-dependent (Langlois *et al*., 2003) and zinc-independent dimers (Zhao *et al*., 2004); YPM is thought to be able to form zinc-independent trimers (Donadini *et al*., 2004). Clearly, SAgs have evolved slightly different ways of inducing receptor clustering. Superantigens that act as monomers and possess only a single MHC class II binding site appear to rely on the interactions of the TCR $V_\alpha$ with MHC class II-β1, which increases the stability of the ternary complex to within the range seen for conventional antigens. A stable MHC-superantigen-TCR complex with an extended half-life would therefore assist receptor clustering.

SECTION V

# CLINICAL, IMMUNOLOGICAL ASPECTS AND APPLICATIONS OF BACTERIAL PROTEIN TOXINS IN CELL BIOLOGY AND THERAPY

CHAPTER

# 54

# Induction and modulation of inflammatory networks by bacterial protein toxins

*Steffen Backert, Wolfgang König, Ralf Arnold, and Brigitte König*

## INTRODUCTION

The field of cellular microbiology and in this regard the knowledge of the precise function of bacterial protein toxins has broadened our understanding in microbial pathogenicity, cellular biology, and immunology. It is well known that toxins by themselves may activate, and/or down-regulate not only individual cellular functions but also the complex network in host defense. Recently, it became obvious that an understanding of infectious pathobiology also needs to consider the combined action of bacterial toxins in conjunction with the whole microorganism, as well as its soluble exoproducts in a complete system. This may result in altered cellular responses compared to the individual toxin on its own. In addition, not only single cells but the cellular network of epithelial and endothelial cells, leukocytes, lymphocytes, fibroblasts as well as smooth muscle cells are activated by microbial toxins alone, as well as by microbial exoproducts in combination with defined toxins (Beutler, 2004; Boyle and Finlay, 2003; Brandtzaeg and Pabst, 2004; Brom *et al*., 1992; Burns *et al*., 2003; Janeway, 1989; Kaufmann *et al*., 2004; Maus *et al*., 2004). Obviously, one has to analyze primarily the action of a particular toxin with a defined cell to understand its mode of action. For our knowledge on the pathobiology of infectious diseases, the mechanisms of host defenses and potential anti-infective strategies, one has to consider a highly complex scenario of different cells and inflammatory mediators.

The past years have led to a novel understanding with respect to the recognition of microorganisms, and toxins, as well as soluble exoproducts, by delineating the importance of the innate immune system and also by the recent progress in understanding how microbial signals are received and transmitted from the cell surface via various steps of the signal transduction cascade leading to the induction of cellular responses (Akira *et al*., 2001; Baggiolini, 2001; Barbieri *et al*., 2002; Beutler, 2004; Boquet, 2003; Chen and Greene, 2004; Cook *et al*., 2004; Finlay and Falkow, 1997; Galan and Collmer, 1999; Henderson *et al*., 1996; Hornef *et al*., 2002; Kotwal, 1997; Medzhitov and Janeway, 2000; Schiavo and van der Goot, 2001; Zychlinsky and Sansonetti, 1997). In this chapter, we will focus on individual pathogenicitiy factors, but also on defined and up to now unresolved disease processes. The complexity of host defense will be described with emphasis on the mucosal system, as well as inflammatory cells and mediators.

### Microbial recognition—role of epithelial and dendritic cells

The mucosal immune system has the complex task of responding to a vast number of signals presented by the myriad of ingested and inhaled antigens. Under normal physiological conditions, immunological tolerance is induced to food, airborne antigens, and commensal bacteria, whereas potent effector immune responses are generated only to dangerous pathogenic

microorganisms (Kelsall and Rescigno, 2004; Svanborg *et al*., 1999). In contrast, in pathological conditions such as allergy or inflammatory bowel disease, an abnormal immune response to harmless antigens results in damaging inflammation (Hadjivassiliou *et al*., 2004). How the discrimination between dangerous and innocuous antigens is achieved at mucosal surfaces is not yet fully clear and is presently being investigated. A principal function has been raised for epithelial as well as for dendritic cells in regulating the induction of mucosal immune responses. In particular, data have emerged that mucosal dendritic cells have unique functions that are not shared by dendritic cells from other tissues, suggesting that the tissue microenvironment can influence the phenotype and functional responses of dendritic cells (Kagnoff and Eckmann, 1997; Liston and McColl, 2003; Mackay, 2001; Muzio *et al*., 2000; Re and Strominger, 2001; Romani *et al*., 1997; Shortman and Wu, 2004; Silverman and Fitzgerald, 2004; Visintin *et al*., 2001; Vogelmann *et al*., 2004).

Epithelial cells are actively involved in determining how mucosal dendritic cells take up antigens. In organized mucosal tissues, such as Peyer's patches and colonic follicles, epithelial cell-derived M cells transport antigens directly from the lumen to underlying dendritic cells. Clearly, a distinction of the function of dendritic cells is obtained by the differentiation of these cells under the influence of various cytokines and a complex cellular network. Obviously, epithelial cells in this regard are not passive barriers but by virtue of chemotactic factors generate an epithelial-endothelial link allowing the transmigration of neutrophils from the blood vessel into the tissue. Neutrophils, once activated, combat pathogenic microorganisms. The network of inflammatory mediators, as well as the cross-talk of various cells under the influence of defined microbial antigens and toxins, allows the priming of regulatory T cells (Treg) with the generation of Th1 and Th2 immune responses.

Recent data on the epitope specificity of microbial antigens have led to novel ideas as to the mechanisms of intestinal colonization, microbial invasion, as well as microbially induced inflammation (Arnold *et al*., 1993; Brandtzaeg and Pabst, 2004; Cossart and Sansonetti, 2004; Dalton *et al*., 2004; Frandji *et al*., 1996; Galli, 1997; Mantovani *et al*., 1997; Monack *et al*., 2004).

## Bacterial protein toxins, inflammatory responses, and signals

Protein toxin release by bacteria can activate and paralyze host defense mechanisms in many ways, which ultimately also affects inflammatory responses (Brom and König, 1992; Eriksson *et al*., 2000; Hensler *et al*., 1994; Hensler *et al*., 1991; Holst, 2003; König and König, 1991; König and König, 1993; König, B. *et al*., 1997). The cell biological action of several protein toxins relevant to this chapter will be described. With the exception of pore-forming toxins, most bacterial protein toxins have an enzymatic activity towards specific cytoplasmic targets (Tomita and Kamio, 1997). This implies that the toxin must cross the bilayer and penetrate the target cell (Burns *et al*., 2003). Toxins often undergo endocytosis followed by transport to specific intracellular organelles before they translocate into the cytosol. In many cases, this coincides with the activation of nuclear responses, such as transcription factor NF-κB or AP-1, involved in regulating the expression of inflammatory mediators and programmed cell death (apoptosis) modulators (Chen and Greene, 2004; De Haan and Hirst, 2004; Dragneva *et al*., 2001; Hollenbach *et al*., 2004; Kayal *et al*., 2002). For example, infection with Stx-positive enterohemorrhagic *E. coli* (EHEC), a gastrointestinal pathogen that causes acute intestinal inflammation and diarrhea, activated p38 and Erk (extracellular-regulated kinase), two typical mitogen-activated protein kinases (MAPK), and the nuclear translocation of NF-κB leading to IL-8 secretion. In addition, cytokine expression arrays were used to determine the effect of recombinant Stx1 on various chemokine genes at the mRNA level in intestinal epithelial cells, including IL-8, GRO-α, GRO-β, GRO-γ, and ENA-78 (Berin *et al*., 2002; Hauf and Chakraborty, 2003). *Staphylococcus aureus* α-toxin is a pore-forming exotoxin that has been implicated as a significant virulence factor in human staphylococcal diseases. Purified α-toxin provoked the rapid-onset phosphatidylinositol (PtdIns) hydrolysis, as well as the liberation of nitric oxide (NO) and the prostanoids $PGE_2$, $PGI_2$, and thromboxane $A_2$ in primary epithelial cells. In addition, α-toxin led to a sustained up-regulation of pro-inflammatory IL-8 mRNA expression and chemokine secretion. α-toxin pore-associated transmembrane ion flux and phosphatidylinositol hydrolysis-related signaling with downstream activation of protein kinase C (PKC) and nuclear translocation of NF-κB are suggested to represent important underlying mechanisms. Other protein toxins are specialized to enter host cells via specific pathways and bind to eukaryotic receptor molecules. This is very important because these toxins exhibit a remarkable cell type specificity.

For example, some toxins enter host cells through clathrin-coated vesicles, such as *Pseudomonas* exotoxin A or diphteria toxin, while others, such as heat-labile enterotoxin from *E. coli* or cholera toxin, enter through the putative caveolar pathway.

Toxins may mediate their biological effects via several mechanisms. Microbial toxins, as well as other

bacterial exoproducts, modify different classes of G proteins by ADP-ribosylation (Bishop and Hall, 2000; Black and Bliska, 2000; Boquet, 2003; Brom, J. *et al*., 1993; Chimini and Chavrier, 2000; Duesbery *et al*., 1998; Falnes and Sandvig, 2000; Gao and Kwaik, 2000; Novick, 2000; Wiegers *et al*., 1991). In this regard, cholera toxin and *E. coli* enterotoxin activate the α-subunit of heterotrimeric $G_s$ proteins downstream to stimulatory G-protein-coupled receptors ($GPCR_s$), leading to the constitutive activation of adenylyl cyclase and rapid elevation of cellular levels of cyclic AMP (cAMP). Pertussis toxin instead inactivates the α-subunit of G proteins coupled to inhibitory GPCR ($GPCR_i$). This modification causes the silencing of the inhibitory input and induces the indirect activation of downstream effectors. The mechanisms of the vacuolating cytotoxin VacA of the gastric pathogen *Helicobacter pylori*, which binds to a cellular receptor called Git1 (G protein-coupled receptor kinase-interactor 1) via interaction with the protein tyrosine phosphatase type Z (PTP-ζ) in gastric epihelial cells, has been outlined recently .

Another recurring target of bacterial protein toxins is eukaryotic cell adhesion molecules (CAMs) (Kerr, 1999). They are involved in many processes, including recognition by circulating phagocytes at the site of inflammation, transmigration through the endothelial barrier, diapedesis through the basement membrane and extracellular matrix, as well as the release of effector mechanisms at the infected site. CAMs are involved in the pathogenetic effects of the RTX toxins of *Pasteurella haemolytica* and the superantigen exotoxins of *Staphylococcus aureus* and *Streptococcus pyogenes*. The epithelial apical-junctional complex is another key regulator of cellular functions. Many pathogens exploit intestinal permeability through the modulation of the cell cytoskeleton and intercellular tight junctions to survive, proliferate, and sometimes persist within a host. In addition, another important mode of entry, bypassing the intestinal epithelial barrier, is used by *Salmonella* and *Shigella* and occurs through a specialized cell type, the M cell (Fasano and Nataro, 2004; Finlay and Falkow, 1997).

A specific class of bacterial toxins catalyzes the covalent modification of actin or Rho GTPases, which are involved in several responses, such as the control of the host actin cytoskeleton and bacterial invasion. It is important to point out that the control of the actin cytoskeleton by Rho GTPases is also directly and indirectly linked to the activation of several nuclear transcription factors, such as NF-κB, c-Jun, or Elk-1, involved in regulating the expression of inflammatory mediators, defenses, and apoptosis modulators (Bishop and Hall, 2000; Black and Bliska, 2000; Hensler *et al*., 1994b; Just *et al*., 1995; MacMicking, 2004; Marinissen and Gutkind, 2001). Rho GTPase regulation of inflammatory cytokines and cell death modulators might also reflect its participation in the host-cell defense. Consistent with this interpretation is that Rac positively regulates NADPH oxidase, thus directly linking Rho GTPases to pathogen attack. The NADPH oxidase complex is composed of several subunits in the plasma membrane (cytochrome $b_{558}$ subunits $p22^{phox}$ and $gp91^{phox}$) and a number of activity-regulating proteins in the cytoplasm ($p40^{phox}$, $p47^{phox}$, and $p67^{phox}$). This NADPH oxidase complex assembles to generate superoxide ($O_2^-$) in phagocytes, which may then react with chloride ions to generate hypochlorous acid (HOCl). In this way, neutrophils form a highly toxic environment within the phagosomes and in the cell surroundings to kill a broad range of microbes (Quinn and Gauss, 2004). *Pseudomonas* ExoS/T block bacterial host cell entry and, by inhibiting activation of NF-κB, interfere with innate immunity mediators but facilitate apoptosis through a lack of production of anti-apoptotic factors. Activators of Rho, Rac, and Cdc42 have an opposite effect, inducing phagocytosis, blocking apoptosis, and activating the inflammatory response. Consequently, activation or down-regulation of this GTPase signaling by bacterial protein toxins has important impact on inflammatory responses (Allen, 2003; Berger *et al*., 2002; Brom, J. *et al*., 1993; Raveh *et al*., 1998).

Toxins can also mediate their biological effects by interfering with kinases and via generation of prostanoids directly and indirectly with nuclear hormone receptors, such as peroxisome proliferators-activated receptors (PPAR). These receptors function as an important regulator of cell differentiation, proliferation, and apoptosis in various cell types, i. e., stromal cells (adipocyte, macrophage, endothelium, and smooth muscle, as well as parenchymal epithelial cells).

PPAR-γ is also a key mediator in cellular signaling pathways, such as Akt, MAPK, TGF-β, and NF-κB. Quite recently, it was shown that PPAR-γ agonists have anti-inflammatory effects and reduce neutrophil influxes in various compartments of the mucosal system, e. g., the lung (Arnold and König, 2004b; Asada *et al*., 2004; Murphy and Holder, 2000, Riches, 2004). Interestingly, recent data demonstrated that CD36, a scavenger receptor, is up-regulated by PPAR-γ on mononcytes and macrophages. PPAR-γ modulates CD36 gene expression through direct interaction with the proximal promoter via a specific response element. The primary function of CD36 has been shown to be associated with the clearance of apoptotic cells arising during development, normal homeostasis, and

inflammation. At the inflammatory sites, CD36 functions as a receptor for apoptotic neutrophils, which mediates their phagocytosis by macrophages. During early inflammatory processes, neutrophils are recruited from the circulation in response to a series of coordinated signals. In the resolving phase, the accumulated neutrophils undergo apoptosis and are subsequently phagocytosed by macrophages. This removal of apoptotic neutrophils by macrophage phagocytosis is a critical process for the resolution of inflammation. In the lung, it is thus hypothesized that the activation of PPAR-γ enhances CD36 expression by alveolar macrophages, which in turn augments their phagocytic capacity for apoptotic neutrophils.

This regulatory process is impaired in cystic fibrosis. A recent study demonstrated an increased local production of 15d-$PGJ_2$ in acute lung inflammation (Riches, 2004). The exudate levels of prostaglandins, such as $PGE_2$, $PGD_2$, and 15d-$PGJ_2$, were measured. It was shown that $PGD_2$ and 15d-$PGJ_2$ increased at both initial and, to a greater extent, later phases of lung inflammation, while $PGE_2$ was produced only at the initial phase. These data suggested that the profiles of prostaglandins produced during inflammation may change from a $PGE_2$-dominant profile to $PGD_2$- and 15d-$PGJ_2$-dominant pattern during the resolution of inflammation. Based on these findings, locally generated 15d-$PGJ_2$ during the late phase of lung inflammation could activate PPAR-γ in alveolar macrophages, which in turn reduces their cytokine production and increases their CD36 expression together with an enhancement of their phagocytic capacity. A dysregulation of these events is obtained during bacterial and viral infection. Obviously, bacterial toxins can induce an increase in free cytosolic $Ca^{2+}$ in targeted host cells, required for the toxin-mediated effects. Toxin-induced $Ca^{2+}$ responses may result in NF-κB-dependent activation of gene expression, as reported for the induction of IL-6, IL-8, or mucin. Thus, $Ca^{2+}$ acts as an important messenger used by toxins to regulate intracellular and intercellular signaling pathways. Such signals can induce or amplify cellular responses towards pathogens, and are likely to play a crucial role in mounting and modulating the inflammatory response (TranVan Nhieu *et al*., 2004).

## The role of chemokines and their receptors

Microbial toxin recognition and induction of inflammation is mediated by chemokines or chemotatic cytokines, which have chemoattractant properties for inflammatory cells (Bergmann *et al*., 1989; Hensler *et al*., 1994; König and König, 1993; König, B. *et al*., 1996a; König, B. *et al*., 1994a; König, W. *et al*., 1990). Chemokines are commonly divided into four structural families, based on the spacing of highly conserved cysteine residues (CXC, CC, C, and $CX_3C$). Whereas the CXC chemokines are involved in neutrophil recruitment and activation, the CC chemokines act towards various lymphocyte subsets, monocytes, eosinophils, and basophils. About 50 human chemokines and nearly 20 receptors have been identified and characterized since the discovery of IL-8 (Baggiolini, 2001; Baggiolini and Clark-Lewis, 1992; Kunkel *et al*., 199; Loetscher and Clark-Lewis, 2001; Mackay, 2001; Mahalingam and Karupiah, 1999; Stevenson *et al*., 2004; Tsai *et al*., 2000). Cytokines and chemokines regulate immune function by controlling growth, proliferation, differentiation, and migration of leukocytes. Many cytokines act via pathways such as the Jak/STAT and MAPK pathways. Chemokines are small structurally-related cytokines that induce migration of various immune cells via interactions with the seven transmembrane GPCRs. They can activate protein kinases such as ERK, JNK, and AKT to induce cell growth. Other chemoattractants, like fMLP, a formylated tripeptide released by bacteria at the site of infection, also signal via GPCRs and thereby induce migration of phagocytic cells such as neutrophils, macrophages, and monocytes. Neutrophil chemoattractants like IL-8 and fMLP regulate cell migration and extravasation, and thus attract cells toward inflammatory sites. Both fMLP and IL-8 can also cause the release of granular enzymes, oxygen burst, and stimulate the adherence of neutrophils to endothelial cells via adhesion molecules such as Mac-1.

IL-8 is the prototype of CXC chemokines and the best-studied member of this group. Increased IL-8 levels have been observed in many bacterial infections and obtained from various sites of infection, e. g., sputa from CF, mucin of gastrointestinal diseases (Becker *et al*., 2004; Dai *et al*., 1994). Microbial infection and activation of inflammatory cells may also increase gene expression of a specific receptor for IL-8, the CXC-R1 (CXC receptor 1). IL-8 in addition to its chemotactic and granulocytic activating and secretory properties has been implicated to reduce the potency of IFN-α *in vivo*, thus aggravating viral infections. Thus, bacterial exoproducts and toxins (e.g., leukocidins) may also contribute via IL-8 to viral infection. IL-8 also stimulates endothelial cells by activation of CXCR1 and CXCR2 and thus facilitates cell polarization and migration in response to chemokines. The capacity of the different microbes, their exoproducts, and toxins to trigger IL-8 release is a subject of significant variability (Deng *et al*., 2004; Ji *et al*., 1997; Köller *et al*., 1993). Depending on the presence of pro-inflammatory cytokines, various microorganisms by virtue of distinct pathogenicity

factors are able to selectively recruit inflammatory cells (Gröner *et al*., 1992; Howard *et al*., 2001; König, W. *et al*., 1992). For each of these agents, receptors are expressed on the granulocyte, which signal through the seven-span superfamily of integral membrane proteins with seven transmembrane domains, such as CXC-R1. The relationship between chemokines and chemokine receptors is highly promiscous, with most receptors binding many chemokines, and most chemokines binding several receptors.

Neutrophils are equipped with a machinery to sense the site of an infection, to crawl towards the pathogen, and to ingest and kill them. After egress of neutrophils from the bone marrow to the blood circulation, the neutrophils adhere to the vascular lining and move into the infected tissues. This process involves two major adhesion molecules (E-selectin [CD62E] or P-selectin [CD62P]) and is termed diapedesis or transendothelial migration (TEM). TEM of immune cells can be investigated using the Transwell *in vitro* model system. The interaction of bacteria, and most specifically protein toxins and other virulence factors, with immune effector cells does not only induce the release of IL-8; a complex network of host reactions with the generation of both pro- and anti-inflammatory molecules is also involved. For example, chemotactic peptides are released by infecting microbes (e.g., fMLP, formyl-methionyl-leucyl-phenylalanine) and the host complement system (the anaphylatoxins, the split product of activated C3 and C5 [C3a, C5a]). Lipid mediators, such as leukotriene $B_4$ ($LTB_4$) and the platelet-activating factor (PAF), are also strong chemoattractants generated by phospholipases from membrane phospholipids during toxin-as well as bacterial-induced inflammation (Iyer *et al*., 2004; König, W. *et al*., 1990; Kotone-Miyahara *et al*., 2004; Neuber *et al*., 1991). In addition, activating receptors expressed on neutrophils and monocytes infiltrating into infected tissues (but not inflammatory lesions *per se*) have been identified as the triggering receptor expressed on myeloid cells TREM-1 and TREM-2 (triggering receptor expressed on myeloid cells). These molecules are upregulated on neutrophils by bacteria (*P. aeruginosa, S. aureus*) or their products (LTA or LPS) and probably interact with a yet unknown ligand (Bouchon *et al*., 2001).

The role of chemokines is not limited to chemotaxis alone. Chemokines also function in Th1/Th2 differentiation, T cell co-stimulation, granulocyte activation, gene transcription, mitogenesis, apoptosis, hematopoesis, angiogenesis, and cell development. In the context of defining human diseases, the dichotomy of type-1 (Th1-like) and type-2 (Th2-like) cytokines is commonly used. Quite recently, the role of diverse T regulatory cells (Treg) skewing Th1 and Th2 responses have been described. In general, type-1 cytokines favor the development of a strong cellular immune response, whereas type-2 cytokines facilitate a humoral immune response; once excessively generated, they may trigger allergic inflammatory reactions (König, W. *et al*., 1991; Leung, 1998; Maggi, 1998; Neuber and König, 1992; Smith *et al*., 2004; Tvinnereim *et al*., 2004; Zhu *et al*., 2004). The production of pro-inflammatory cytokines, such as TNF-α, IL-1, IL-8, and IL-12, by host cells upon sensing bacterial products is crucial in the innate and adaptive immune responses to infection (Hoebe *et al*., 2004; Janeway, 1989; Silverman and Drazen, 2003; Strieter *et al*., 2003; Trinchieri, 1998). The latter cytokines play a critical role in enhancing the anti-bacterial function of professional phagocytes, recruiting additional innate immune cells to sites of infection, inducing dendritic cell maturation, and directing the resulting immune response to the invading microbes. Bacterial protein toxins, microbial exoproducts, or bacterial protein toxins with microbial exoproducts combined can actually interfere with each pathway of the innate immune system and either initiate or down-regulate inflammatory responses in the course of infection (Merrell and Falkow, 2004; Moese *et al*., 2002; Vergnolle *et al*., 2001).

## Th1-/Th2-cell responses during microbial infection—contribution of innate immunity

Several aspects shall be discussed. Whether the unique functions ascribed to mucosal dendritic cells are due to their intrinsic properties or are conferred by the local microenvironment remains an open question. However, it appears that epithelial cells may have a key function in "instructing" mucosal anti-inflammatory dendritic cells. In co-culture studies of epithelial cell monolayers, dendritic cells, and bacteria, it was demonstrated that products of epithelial cells condition dendritic cells to release IL-6 and to prime Th2 responses in an allogeneic response, even after encounter with pathogenic *Salmonella typhimurium*. These Th2 responses could help to maintain the homeostasis of the gut to encountered commensal bacteria. However, a more difficult issue is how protective Th1 responses can be initiated to intracellular pathogens such as salmonella that first encounter dendritic cells in mucosal tissues, particularly because pathogens and commensal bacteria share many if not most ligands for pathogenicity molecules (such as lipopolysaccharide and flagellin) and can stimulate dendritic cells to mature and to produce cytokines similarly *in vitro* (Singer and Sansonetti, 2004). In models of Th1-mediated inflammatory bowel disease that are similar

to Crohn's disease in humans, dendritic cells seem to have a dominant function both in the induction of Th1 cell responses as well as in driving counter-regulatory T cell responses (Bodger and Crabtree, 1998; Enarsson *et al*., 2004; Ishihara *et al*., 2004; Ye *et al*., 1997). In fact, the *Helicobacter pylori*-induced inflammation is dominated by Th1 immune responses.

By analyzing the various strategies of microbial colonization, invasion, and induction of inflammation, one is certainly surprised that the mechanisms of innate and adaptive immune recognition are essential for the outcome of the result. Indeed, innate immune mechanisms shape the adaptive immune response, and inflammatory mediators released during the adaptive immune response further focus innate immune reactions (Medzhitov and Janeway, 2000). In this regard, novel concepts fit into this scheme very well and will be discussed below. Antimicrobial proteins and peptides serve as antiinfective molecules and are released from granulocytes, monocytes, macrophages, epithelial cells, mast cells, eosinophils, and lymphocytes, as well as from non-leukocyte sources.

Initial studies as to their functional activities were focused on their microbicidal actitiy (Devine, 2003; Diamond *et al*., 2000; Galli, 1997; Kao *et al*., 2004; Kaufmann *et al*., 2004; Kimata *et al*., 1996; Labor, 2000; Levy, 2004; Mécheri and David, 1997; Vergnolle *et al*., 2001). However, with the growing appreciation of the role of acute inflammatory responses triggered by the recognition of microbial surface components, there is increasing knowledge as to their effects on the activity of microbial toxins, as well as on the Toll-like receptor (TLR) pathway.

In addition, trefoil factors (TFFs) are critically involved in responses to intestinal injury after infection, primarily by their ability to promote epithelial restitution and the rapid spreading and migration of existing cells following injury. They also interfere with the binding of microorganisms to epithelial cells and thus impair their toxin production and release (Nikolaidis *et al*., 2003). TFFs are small (7–12kD), protease-resistant proteins, composed of a characteristic three-loop structure, formed by three conserved cysteine disulfide bonds, and secreted by the gastrointestinal mucosa in a lineage-specific manner. Because of the established role of defined TFF2 in gastrointestinal repair responses, TFF2 is a novel candidate gene likely to be involved in the remodeling and repair responses associated with allergic and inflammatory lung disorders. TFFs directly interact with mucin proteins, molecules that are overproduced in asthmatic and inflammatory lung responses. A specific regulation of TFF2 by diverse allergens and antigens, as well as the Th2 cytokines IL-4 and IL-13, has been shown.

## Role of Toll-like receptors (TLRs)

How innate immunity discriminates between non-invasive bacterial pathogens and commensals is unclear. It is well established that sensing of bacteria by the innate immune system is based on the interaction between pattern-recognition receptors (PRRs) and bacterial-associated molecules, such as lipopolysaccharide (LPS), peptidoglycan, DNA containing unmethylated CpG motifs, flagellin, and lipoteichoic acid absent from self-tissues (Akira *et al*., 2001; Amorim *et al*., 2002; Arbour *et al*., 2000; Beutler, 2004; Horng *et al*., 2002; Iwasaki and Medzhitov, 2004; Park *et al*., 2004; Sabroe *et al*., 2002; Shimazu *et al*., 1999). Although the bacterial elicitors of PRRs are generally defined as pathogen-associated molecular patterns (PAMPs), this definition has to be carefully used because they are structural components of both pathogenic and harmless (or even useful) bacteria (Dunzendorfer *et al*., 2004; Hajjar *et al*., 2002; Kawei *et al*., 2004; Knodler *et al*., 2001; Takeuchi *et al*., 2000).

The largest and best-studied family of PRRs comprises the TLRs, which are membrane-associated and have an external leucine-rich repeat recognition domain and an intracellular Toll-interleukin 1 receptor signaling domain. In addition to TLRs, a second class of PRRs, consisting of the Nod1 and Nod2 cytoplasmic proteins, is essential in intracellular bacterial sensing. Obviously, these protein receptors can also detect extracellular bacteria. Like TLRs, Nod proteins have a leucine-rich repeat recognition domain linked to a signaling motif called the caspase activation and recruitment domain. TLRs and Nod1 trigger similar signaling pathways characterized by the activation of the transcription factor NF-κB, leading to the production of pro-inflammatory cytokines. In contrast, Nod2 has a regulatory function in TLR signaling, which might explain why mutations in the human gene encoding Nod2 are associated with inflammatory disorders, e. g., Crohn's disease (Cook *et al*., 2004; Giradin *et al*., 2003; Gutierrez *et al*., 2002; Haehnel *et al*., 2002; Hoshino *et al*., 1999). Nod1 and Nod2 recognize two different forms of peptidoglycan-derived motifs called muropeptides, which are normally released from bacteria during growth. Nod2 is elicited by muramyl dipeptide, a muropeptide present on peptidoglycan from all bacteria, whereas Nod1 recognizes GM-tri-DAP (*meso*-diaminopimelate-containing *N*-actylglucosamine-*N*-actylmuramic acid tripeptide), which is only present in Gram-negative bacteria and in a subset of Gram-positive bacteria (Boone *et al*., 2004; Viala *et al*., 2004).

How the epithelial cells, which are constantly exposed to all classes of bacteria and are considerably challenged, discriminate between dangerous and harmless bacteria, avoiding undesirable innate imm-

une reactions leading to chronic inflammation, is currently investigated. One potential mechanism is based on compartmentalization of PRRs (De Gregorio and Rappuoli, 2004). In this regard, TLR4, which is the sole LPS sensor, is generally associated with the plasma membrane of human myeloid immune cells such as macrophages, thus reacting to extracellular LPS derived from bacteria that have invaded internal organs or bloodstream, which are usually sterile. In contrast, in intestinal epithelial cells, which are constantly exposed to external bacteria, TLR4 expression is intracellular and therefore recognizes only internalized LPS or possibly LPS associated with bacteria that have been internalized and survived in intracellular compartments. Similarly, the cytoplasmic localization of Nod1 in intestinal epithelial cells has been linked to the selective recognition of invasive pathogenic Gram-negative bacteria. In addition to the sensing by TLRs, non TLR-mediated effector functions have also been described. Furthermore, TLR polymorphisms have to be considered, leading to inadequate innate responses (Arnold *et al*., 2004; Beutler, 2004; Lazarus *et al*., 2004). Clearly, our view as to the induction of inflammatory mediators, chemokines, their receptors, the skewing of T cell responses, the maturation of dendritic and of T regulatory cells has significantly expanded and contributed in a substantial way to our modern understanding of cellular microbiology. In this regard, the research on *Helicobacter pylori*, on inflammatory mechanisms in cystic fibrosis (CF), as well as inflammatory reactions induced by bioprosthetic devices, are important examples to understand host defense mechanisms against microorganisms, toxins, and/or microbial exoproducts embedded in a biofilm. The latter components may activate the immune system, thus impairing host and antibiotic defense strategies.

In this chapter we will summarize our recent results in: (i) modulation of host cells responses by *Helicobacter pylori*, (ii) inflammatory reactions in cystic fibrosis, and (iii) the role of biopolymers and microbial exoproducts/toxins in inducing aseptic and septic inflammation.

## *HELICOBACTER PYLORI* — GENERAL VIRULENCE MECHANISMS

### Pathogenicity and virulence factors

*Helicobacter pylori* is a highly successful gastric pathogen that has been recognized as the causative agent of chronic gastric inflammation, a disease that can progress to peptic ulcer, mucosa-associated lymphoid tissue (MALT) lymphoma, or even gastric cancer (Covacci *et al*., 1999; Montecucco and Rappuoli, 2001; Peek and Blaser, 2002). The severity of *H. pylori*-related disease varies greatly among infected individuals and appears to be influenced by both host and bacterial factors. *H. pylori* is genetically diverse, a feature shown to contribute to the wide spectrum of clinical manifestations. Virulent isolates are characterized by the presence of disease-associated genetic components, such as the vacuolating cytotoxin (VacA) and the *cag* (cytotoxin-associated genes) pathogenicity island (*cag*PAI). The latter encodes about 30 protein components of a type IV secretion system required for the delivery of the immuno-dominant effector protein CagA and probably other proteins into the target cells. Seven of the *H. pylori cag*PAI genes are homologous to the well-characterized virulence genes *virB4, virB7, virB8, virB9, virB10, virB11*, and *virD4* from conserved type IV secretion systems of *Bordetella pertussis, Legionella pneumophila, Rickettsia prowazeki, Brucella*, and *Bartonella* species (Covacci *et al*., 1999; Backert *et al*., 2002). *In vitro* studies have shown that only *H. pylori* strains with a functional *cag*PAI induce strong cytoskeletal modifications involved in "cell scattering," as well as transcription factor NF-κB-dependent pro-inflammatory responses in gastric epithelial cells. A model showing the main virulence factors involved in persistent colonization and disease development is presented in Figure 54.1. Other known virulence determinants of *H. pylori* include: flagella-driven motility in the stomach mucus layer, local buffering of stomach acid by urease (UreA, UreB, and accesory proteins), adhesion to gastric epithelial cells mediated by several adhesins (including BabA, SabA, AlpA/B, or HopZ), and adherence of neutrophils to endothelial cells induced by the neutrophil-activating protein NapA. Other described virulence factors are the catalase KatA with a proposed function in the oxidative defense of *H. pylori* and IceA, a restriction endonuclease homologue, whose expression is induced by contact with the gastric epithelium.

We and our collaborators have established a dynamic 2-D-PAGE database with multiple subproteomes of *H. pylori* (http://www.mpiib-berlin.mpg.de/2D-PAGE), which facilitates identification of bacterial proteins important in pathogen-host interactions, as well as their subcellular localization (Backert *et al*., 2005). In a recent study using real-time quantitative (TaqMan) RT-PCR, we also determined the mRNA expression of clinical *H. pylori* isolates in response to a changing host environment, which enabled us to identify variable and strain-specific gene expression profiles for *cagA*, *ureA*, *napA*, *katA*, and *vacA* alleles in a sensitive and reproducible manner. The expression profiles of these genes varied according to the strain, and were mainly either up-regulated or unchanged upon bacterial contact with

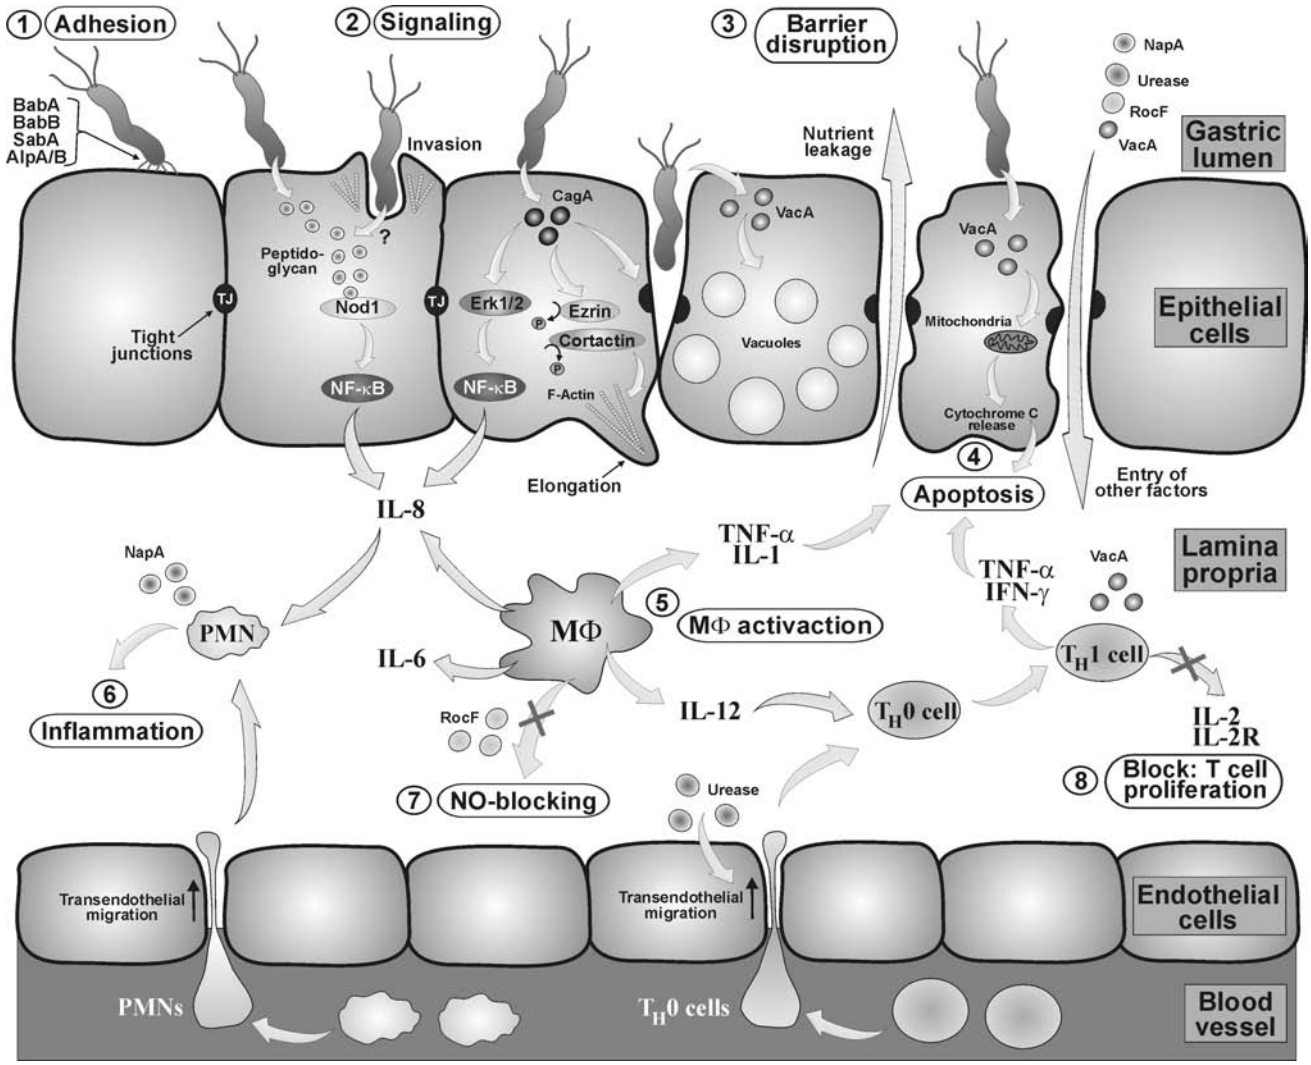

**FIGURE 54.1** Model for *Helicobacter pylori*-induced gastric damage and inflammation.
The interplay between target cell and a variety of pathogenicity factors modulates multiple host responses, leading to both chronic gastritis and persistent colonization. (1) *H. pylori* expresses several adhesins, such as BabA, SabA, and AlpA/B, that mediate binding to gastric epithelial cells. (2) After adherence, *H. pylori* can translocate effector molecules such as CagA and peptidoglycan into the host cell by a type IV secretion-dependent process. Peptidoglycan binds to the intracellular receptor Nod-1 and activates transcription factor NF-κB to induce IL-8 release (Viala *et al*., 2004). *H. pylori* is also able to occasionally enter host cells (Kwok *et al*., 2002), but it is not clear if this could contribute to the stimulation of the Nod1 pathway as known from other intracellular pathogens. Injected CagA can be phosphorylated by Src tyrosine kinases (Selbach *et al*., 2002). Phosphorylated CagA then binds to a number of host cell signaling molecules to trigger several signaling cascades (Mimuro *et al*., 2002; Selbach *et al*., 2003; Tsutsumi *et al*., 2003; Amieva *et al*., 2003). For example, CagA contributes substantially to the induction of IL-8 by activation of an Erk1/2-NF-κB-dependent pathway (Brandt *et al*., 2004). (3) Translocated CagA is also involved in the induction of overall actin cytoskeletal rearrangements and disruption of the tight junction (TJ) complex of infected host cells (Selbach *et al*., 2003; Amieva *et al*., 2003). One major effect of phosphorylated CagA is the inactivation of its own kinase (Src) by a negative feedback loop mechanism (Selbach *et al*., 2003). Inactivation of Src leads to the dephosphorylation of a number of host proteins, including cortactin and ezrin (Selbach *et al*., 2003; Selbach *et al*., 2004). These events are crucial for CagA-induced actin cytoskeletal rearrangements and host cell elongation. Disruption of the TJs by CagA and cellular effects induced by the vacuolating cytotoxin VacA contributes to the disruption of the epithelial barrier. Internalization of VacA into the cells leads to the formation of large vacuoles and gastric damage, a hallmark of the ulceration process. (4) VacA can also trigger apoptosis when recruited to the mitochondria to induce the release of cytochrome c (reviewed by Montecucco and Rappuoli, 2001; Peek and Blaser, 2002). Finally, disruption of epithelial barrier functions by *H. pylori* may cause leakage of nutrients into the gastric lumen and the ability of other pathogenicity factors to cross the epithelial layer. (5) Thereby, *H. pylori* antigens can activate macrophages (MΦ) to release several pro-inflammatory cytokines, such as IL-8, IL-6, IL-1, and IL-12. This and the aforementioned induction of IL-8 by epithelial cells, constitutes crucial determinants for the *H. pylori*-triggered inflammatory responses. (6) These cytokines can alter the secretion of mucus, because they induce changes in gastric-acid secretion and homeostasis, as well as attract other immune cells such as PMNs to infiltrate from the blood stream into the gastric mucosa. The IL-12 micro-environment induced by macrophages is particularly important for shifting the $CD4^+$ helper response into a prominent Th1 type. T cells can be recruited from the bloodstream by stimulating their transendothelial migration. Bacterial pathogenicity factors, such as the *H. pylori* urease and yet unidentified *cag*PAI components, appear to enhance the latter effect (Enarsson *et al*., 2004). The production of TNF-α, IFN-γ, and IL-1 from T cells and macrophages, respectively, supports the VacA-induced apoptosis of epithelial cells. *H. pylori* modulates the immune response by (7) inhibition of NO release from macrophages by bacterial RocF activity (Gobert *et al*., 2001) and (8) blocking T cell proliferation by VacA based on down-regulation of IL-2 and IL-2R transcription (Gebert *et al*., 2003; Bonacristiano *et al*., 2003).

AGS cells (Gieseler *et al*., 2005). In contrast, upon contact with granulocytes, the majority of the investigated genes were repressed in *H. pylori*. The only notable exception was the predominant up-regulation of *napA* and *vacA* genes in many strains during infection of both AGS cells and PMNs. The following major results were obtained: (i) genetically diverse *H. pylori* exhibit different mRNA expression profiles, (ii) the expression patterns were strain-specific and time-dependent, and (iii) the regulation of expression profiles was host-cell dependent. Our data suggest that contact with target cells leads to an active cross-talk between the pathogen and its host, and that the genetic diversity of *H. pylori* is contributed not only by significant strain-to-strain variation in DNA sequence, but also by the existence of a complex repertoire of coordinated gene regulatory mechanisms in *H. pylori*, which are subject to modulation by the host cells (Gieseler *et al*., 2005).

### *Induction of cellular responses in gastric epithelial cells*

A series of well-studied phenotypical responses elicited during infection of both gastric epithelial cells or phagocytes with *H. pylori in vitro* is shown in Figure 54.2. This includes the induction of motility and dra matic cytoskeletal modifications in gastric epithelial cells, where the *cag*PAI and CagA have been shown to play a role, and the induction of vacuolization and apoptosis by VacA (Montecucco and Rappuoli, 2001; Peek and Blaser, 2002; Backert *et al*., 2002; Amieva *et al*., 2003; Monack *et al*., 2004). The classical activity of VacA in epithelial cells is vacuolization. Several other cellular effects of VacA have also been observed, including: (i) perturbation of vesicle trafficking, (ii) increase in transepithelial ion conductivity, (iii) inhibition of cell proliferation, and (iv) entry into mitochondria followed by cytochrome C release and induction of cell death. It has also been demonstrated that VacA in the presence of CagA plays an important role in the disruption of the epithelial barrier (Amieva *et al*., 2003). Molecular evidence has recently emerged showing that CagA induces a global rearrangement of the host cell actin cytoskeleton, characterized by cellular elongation and cell scattering. First, translocated CagA is phos phorylated on tyrosine residues by Src family kinases on specific EPIYA sequence motifs (Selbach *et al*., 2002). Subsequently, CagA interacts with several cellular

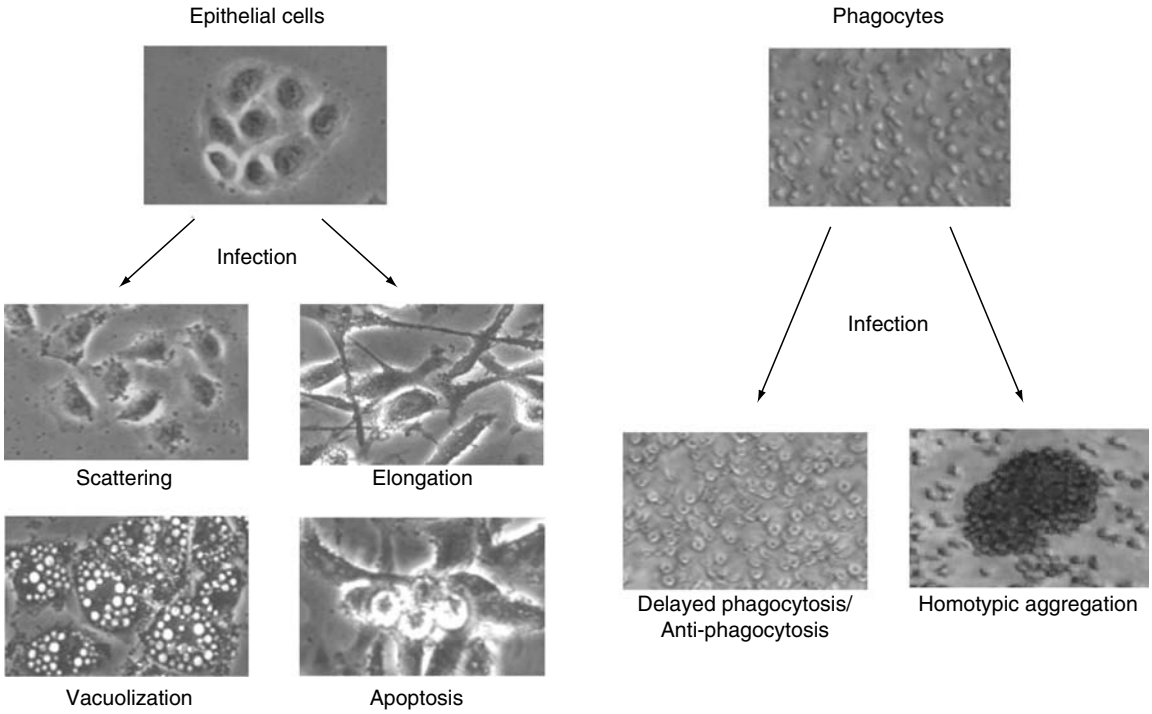

**FIGURE 54.2** Phenotypical responses during *in vitro* infection of AGS gastric epithelial cells and phagocytes with *Helicobacter pylori*.
Infection of AGS cells with *H. pylori* results in different phenotypes that can be observed in a time- and strain-dependent manner. First, AGS infected with *cag*PAI$^+$ *H. pylori* exhibit a strong motility response (after 1–2 hours) followed by elongation of the cells (after 3–4 hours). Vacuole formation can be observed during infection with VacA$^+$ *H. pylori* (after 3–6 hours). Both the *cag*PAI and VacA are also implicated in triggering apoptosis of the infected epithelial cells (after 24–48 hours). Infection of phagocytes by *cag*PAI$^+$ *H. pylori* can induce delayed phagocytosis (Allen *et al*., 2000) or anti-phagocytosis (Ramarao *et al*., 2000) and homotypic aggregation of the infected cells (Moese *et al*., 2002).

proteins in a phosphorylation-dependent or phosphorylation-independent manner (Higashi *et al*., 2002; Mimuro *et al*., 2002) and inhibits the catalytic activity of Src by a negative feedback loop mechanism (Selbach *et al*., 2003). Finally, Src inactivation leads to tyrosine dephosphorylation of the Src substrates ezrin and cortactin (Selbach *et al*., 2003; Selbach *et al*., 2004; Backert *et al*., 2004). Since cortactin and ezrin are key players in regulating the dynamics of the host actin cytoskeleton, this raises the possibility that CagA-induced tyrosine dephosphorylation of these proteins might stimulate actin polymerization via the Arp2/3 complex and N-WASP (neural Wiskott-Aldrich syndrome protein). Indeed, concomitantly with the dephosphorylation events, cortactin relocalizes to the tips of characteristic actin-rich cellular protrusions (Selbach *et al*., 2003). Apart from the reorganization of global actin cytoskeleton, there is also evidence that *H. pylori* can induce local actin polymerization involved in a moderate level of host cell invasion (Kwok *et al*., 2002).

*Helicobacter pylori* is generally considered to be an extracellular pathogen. Until recently, it remained unclear as to how the innate immunity could recognize this pathogen. For example, endotoxin (LPS) is normally a potent inflammatory mediator. LPS of *H. pylori*, however, appears to have a very low biological activity in activating macrophages (Perez-Perez *et al*., 1995). Furthermore, the two *H. pylori* flagellins, FlaA and FlaB, have a markedly low potential to activate TLR5 (Lee *et al*., 2003). The finding that epithelial cells recognize the peptidoglycan-derived GM-tri-DAP muropeptide of *H. pylori* delivered by the type IV secretion system might well be an intriguing answer to the enigma (Viala *et al*., 2004). Based on the fact that a functional *cag*PAI is required for *H. pylori*-induced NF-κB activation in gastric epithelial cells (Covacci *et al*., 1999; Selbach *et al*., 2002), recent data suggest that injected muropeptide by the type IV secretion system is recognized by the intracellular receptor Nod1 (Viala *et al*., 2004). This function of Nod1 in the host defense against *H. pylori* seems to be physiologically important, because Nod1-deficient mice have higher bacterial loads after *H. pylori* infection than do wild-type mice. These results thus extend the function of Nod1 to the detection of both intracellular and extracellular pathogens. Thus, it was proposed that sensing of *H. pylori* by Nod1 could represent a new model for the host recognition of non-invasive or weakly invasive pathogens. In addition, we could recently show that translocated CagA is also able to induce IL-8 release *via* Erk1/2 and NF-κB signaling pathways (Brandt *et al*., 2004). Our results suggest that NF-κB is triggered by multiple pathways, one of which is CagA-dependent. Thus, CagA is a multifunctional protein capable of affecting both actin-remodeling and innate immune responses via the activation of NF-κB.

A major effect of the activation of NF-κB is the induction of the chemokine IL-8 (Viala *et al*., 2004; Brandt *et al*., 2004). The release of IL-8 then attracts inflammatory cells for infiltration into the gastric mucosa. The recruitment and activation of immune cells in the underlying mucosa as part of non-specific immunity are likely to be orchestrated by the combined actions of *H. pylori* muropeptides, epithelial-derived chemokines (e.g., IL-8 and GRO-α), and pro-inflammatory cytokines liberated by PMNs (TNF-α, IL-1 and IL-6) in response to *H. pylori* infection (Bodger and Crabtree, 1998).

### *Modulation of the expression of inflammatory mediators*

The adherence of *H. pylori*, release of VacA, as well as function(s) of the *cag*PAI components such as CagA and peptidoglycan, all contribute to direct epithelial damage and disruption of its barrier function *in vivo* and *in vitro* or to indirect epithelial damage resulting from the host inflammatory response. This damage eventually leads to leakage of nutrients into the mucus layer, which may on the one hand support *H. pylori* growth and survival and on the other hand attract PMNs and other immune cells. For example, it has recently been shown that urease and the *cag*PAI are involved in the induction of transendothelial T cell migration (Enarsson *et al*., 2004). *H. pylori* might be able to come into direct contact with PMNs during infection and epithelial damage. We established an *in vitro* system to study virulence gene expression during interaction of *H. pylori* with these immune cells. In these experiments, we demonstrated that *napA* and *vacA* genes were significantly up-regulated in a number of clinical *H. pylori* isolates during infection of PMNs, a finding that is in agreement with the importance of VacA and NapA proteins for immunomodulatory effects induced by this pathogen (Gieseler *et al*., 2005).

In order to survive in the host, *H. pylori* not only needs to adapt its gene expression pattern, but also has to modulate the host transcriptional profile for its own benefit. Hence, since the regulation of host gene expression by *H. pylori* may play an important role in the development of pathogenesis, we studied the expression of several host cell signaling molecules, including chemokines, NADPH oxidase, lipid mediators, TLRs, and other cell surface receptors in infected PMNs by a variety of methods such as RT-PCR, real-time Taqman-PCR, ELISA, and FACS analyses (Figure 54.3). For example, it was observed that *H. pylori* modulated the expression of CD11b, CXCR2, CD62 ligand (CD62L), and the fMLP receptor in a time-dependent

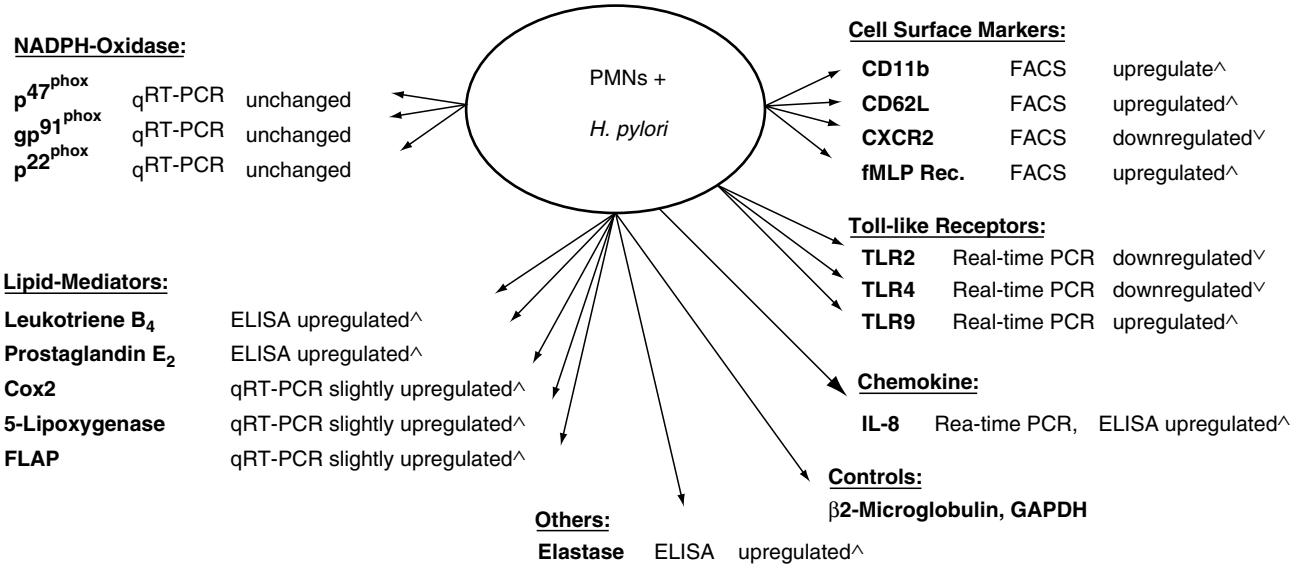

**FIGURE 54.3** Modulation of immune responses by PMNs infected with *H. pylori*.
Several host responses can be quantitated during infection of PMNs with *cag*PAI$^+$ *H. pylori* by FACS, ELISA, RT-PCR, and real-time (Taqman) PCR. The up- and down-regulation of components of the NADPH oxidase complex, lipid mediators, cell surface receptors (including TLRs), and chemokines are indicated.

manner. Stimulation with the specific agonists (fMLP, PMA, or NaF) prior to infection, as compared to stimulation with *Helicobacter* alone, showed marked changes in the immunological parameters, suggesting that the various clinical *Helicobacter* strains exert these events time-dependently but also initiate signal transduction cascades; these either lead to additive, synergistic, or suppressive events. Similar observations were obtained for the *H. pylori*-triggered release of IL-8, TNF-α, $LTB_4$, and $PGE_2$.

The aforementioned changes in chemokine and receptor molecule expression during *H. pylori* infection of immune cells are accompanied by the formation of large homotypic aggregates of infected macrophage-like cells (Figure 54.2). This occurs through up-regulation and recruitment of ICAM-1 to the cell surface of infected cells, which then mediates the aggregation via lymphocyte function-associated molecule 1 (LFA-1), a signaling pathway that may regulate cell-cell interactions and inflammatory responses (Moese *et al*., 2002). However, the actual effector molecule, which appears not to be CagA, remains to be identified.

### *Evasion of the host immune response*

From the evolutionary point of view, the development of severe gastritis and its progression to more serious tissue destruction appears to be against the interest of *H. pylori* to persist in the human stomach. In this context, it is important to note that only a minority of colonized patients indeed develop disease (fewer than 20%), whereas the majority of patients remain largely asymptomatic. Thus, it appears that establishing a balance with the host immune system is one of the major goals for *H. pylori* to ensure a persistent infection. A long-term acquisition of *H. pylori* in the human stomach therefore requires the development of mechanisms to evade killing by the host immune system.

There are a few possible mechanisms for *H. pylori* to impair the bactericidal functions of immune cells. First, *H. pylori* actively retards its uptake by macrophages and subsequently persists inside large vacuoles called megasomes, which result from phagosome fusion (Allen *et al*., 2000). It has been shown that regulation of local actin polymerization and phagocytosis by atypical PKCζ plays a role in the delay of uptake (Allen and Allgood, 2002). Second, in studies using human blood monocytes and PMNs, *H. pylori* has been shown to actively block its own uptake (Ramarao *et al*., 2000). Each of these phenotypes depends on the presence of a functional *cag*PAI secretion system and an yet unknown effector molecule that appears not to be CagA. Third, an arginase (encoded by *rocF*) is expressed by *H. pylori* to down-regulate eukaryotic nitric oxide (NO) production (Gobert *et al*., 2001). The antimicrobial effect of NO is an essential part of innate immunity. The down-regulation of NO thus allows *H. pylori* to evade the immune response.

*H. pylori* has evolved to modulate not only the innate but also the adaptive immune response. The latter is based on MHC-class-II-restricted ($CD8^+$) T cells, and to a lesser degree MHC-class-I-restricted ($CD4^+$) T cells. The *H. pylori* cytotoxin VacA blocks specifically the antigen-dependent proliferation of T cells by interfering with IL-2-mediated signaling (Gebert *et al*., 2003; Bonacristiano *et al*., 2003). This occurs by inhibition of $Ca^{2+}$ mobilization and, subsequently, down-regulation of the activity of the $Ca^{2+}$-dependent phosphatase calcineurin. This in turn inhibits the activation of the transcription factor NFAT (for nuclear factor of activated T cells). In this way, NFAT is kept in a phosphorylated state and hence nuclear translocation is prevented. The target genes, such as IL-2 and the high-affinity IL-2 receptor (IL-2Rα), are, therefore, not expressed. VacA, however, exerts a different effect on human primary $CD4^+$ T cells, whose proliferation is inhibited through the TCR and CD28 (Sundrud *et al*., 2004). In the study of Sundrud and co-workers, VacA is shown to suppress IL-2-induced, cell-cycle progression and proliferation of primary T cells without affecting NFAT. Thus, VacA may inhibit the clonal expansion of T cells that has been activated by bacterial antigens, thereby allowing *H. pylori* to evade the adaptive immune response, resulting in chronic infection. Another possible function of VacA in subverting the adaptive immune response is its ability to interfere with antigen presentation by MHC class II (Montecucco *et al*., 2001).

In antigen-presenting cells (APCs), the processing of bacterial proteins into peptide epitopes is greatly reduced in the presence of VacA, indicating that VacA can abrogate antigen presentation in these cells. The importance of VacA in establishing an infection *in vivo* has been corroborated using animal models (reviewed by Montecucco and Rappuoli, 2001; Peek and Blaser, 2002).

Urease, CagA, VacA, and NapA, apart from being crucial determinants of *H. pylori* colonization and pathogenicity, are also major antigens in the human immune response to *H. pylori* infection. During the past 15 years, these antigens have been examined in numerous animal studies and each of them has been found to elicit immune responses that might either protect from or eradicate a pre-existing infection by *H. pylori*. Clinical trials of test vaccines are underway with the aim of achieving oral or systemic immunization of human patients. If the clinical studies are successful, the chapter on the co-evolution of this pathogen with humans that started more than 150,000 years ago will soon be drawn to an end.

## CYSTIC FIBROSIS

### Inflammatory mechanisms in cystic fibrosis—novel views and approaches

Cystic fibrosis (CF) is the most common fatal genetic disease in white populations (about 1 in 2,500 live births). CF occurs due to recessive mutations in the CF transmembrane conductance regulator (*Cftr*) gene, which encodes the transmembrane chloride channel expressed in the epithelium of multiple organs. Classic CF lung disease presents with a progression of inflammation and infection, and a decline in lung function marked by mucopurulent plugging, bronchiectasis, and intermittent bronchopneumonia (Chmiel *et al*., 2002; Chow *et al*., 2003; Griese *et al*., 2004; Hashimoto *et al*., 2000; Jaeger *et al*., 1992). The role of CFTR in the pathogenic process is widely unclear. It is suggested that the reduction of airway liquid volume results in deficient mucociliary clearance, so entrapped pathogens are not efficiently removed and hypoxic mucous microenvironments encourage the formation of bacterial biofilms (Yu *et al*., 1998; Middleton *et al*., 2003).

In CF, a complex inflammatory reaction of acute and chronic inflammatory mediator generation concomitantly occurs and is decisive for inflammation, immunosuppression, and tissue destruction. Clearly, a multitude of soluble factors, as well as a cross-talk of various cells, determines the clinical outcome of the patients. Early infection of the lungs of patients with CF occurs by *Staphylococcus aureus* or *Haemophilus influenzae*. Later, most patients become chronically infected with *Pseudomonas aeruginosa*, and a minority with *Burkholderia cepacia* complex species (Speert *et al*., 2004). *P. aeruginosa* can convert to a mucoid phenotype, forming biofilms that are highly resistant to conventional antibiotics and are the major cause of respiratory failure in patients with CF. Viruses, non-tuberculous mycobacteria, and fungi may also play a role. A vigorous host response is required to effectively clear the organisms from the lungs. This host defense is dependent on the recruitment and activation of neutrophils and macrophages. It was shown that the CXC chemokines are critical mediators of neutrophil-mediated host defense in *Pseudomonas* pneumonia (Bergmann *et al*., 1989; Dayer *et al*., 1998; Lin *et al*., 2004).

Airway inflammation is a hallmark of CF lung disease. Compared with normal individuals, airway fluids of patients with CF show an increased number of neutrophils and increased levels of the pro-inflammatory cytokines tumor necrosis factor TNF-α, IL-6, IL-8, and $LTB_4$, but decreased levels of anti-inflammatory IL-10. The overproduction of IL-8 is the

probable cause of excessive neutrophil infiltration in the CF lung. Reduced responsiveness to IL-8 of neutrophils from patients with cystic fibrosis is associated with receptor desensitization as a result of exposure to high systemic levels of IL-8 (Cannon *et al*., 2003). Attracted neutrophils, either live or dead, then release noxious compounds, including oxidants, proteinases, and DNA. Additional results showed that peripheral blood neutrophils from normal subjects and individuals with CF contained similar amounts of neutrophil elastase (NE), but after preincubation with CF bronchoalveolar lavage (BAL) fluid, significantly more NE was released by CF peripheral blood neutrophils, a release that was amplified further by incubation with opsonized *Escherichia coli* (Devaney *et al*., 2003; DiMango *et al*., 1998; Taggart *et al*., 2000).

The production of IL-8 and other cytokines in response to *P. aeruginosa* was increased in cells with a CF-like phenotype. However, primary cultures of airway epithelial cells from patients with CF exhibited variable production of IL-8 when exposed to pro-inflammatory stimuli under different culture conditions. It was speculated whether infection is the cause or consequence of the pulmonary inflammation in CF (Moser *et al*., 1997; Muir *et al*., 2004). Several hypotheses have been proposed to explain the predisposition of CF airways to chronic infection. Obviously, CFTR has as a key function an innate immunity to lung infection with *P. aeruginosa*. In addition to its role as an ion channel, wild-type (WT) CFTR acts as a specific receptor for the binding and internalization of *P. aeruginosa* by respiratory epithelia. This ingestion event serves as a protective function against *P. aeruginosa* infection in the normal lung. The steps following internalization of the CFTR/*P. aeruginosa* complex that lead to clearance of the organism are only partially known, and apoptosis could be a key component in both induction of shedding of the infected cells, as well as termination of pro-inflammatory signaling (Pier *et al*., 1997; Wong and Choi, 1997). Regardless of the underlying mechanism, the decreased internalization and delayed apoptosis of cells expressing only mutant CFTR may contribute to the pathogenesis of pseudomonal infection in the patient with CF by allowing for more prolonged bacterial residence time on the lung mucosa, which gives the microbe the opportunity to proliferate and establish infection (Weinrauch and Zychlinsky, 1999; Wolf and Green, 1999). Once established, the chronic infection and inflammatory response does lead to ongoing inflammation and apoptosis in the lung, but it is the failure to initiate and resolve *P. aeruginosa* infection shortly after bacterial exposure within the CF lung that underlies the hypersusceptibility of the patients to *P. aeruginosa* infection.

As the airway epithelium is potentially exposed to a large number of diverse inhaled bacteria, TLRs involved in defense of the airways must be broadly responsive, available at the exposed apical surface of the cells, and highly regulated to prevent activation following trivial encounters with bacteria. These receptor complexes include myeloid differentiation protein (MyD88), IL-1 receptor-activated kinase-1, and TNF receptor-associated factor 6. Recent results indicate that the MyD88-dependent pathway is essential for the development of early host responses to *P. aeruginosa* infection, leading to the clearance of this bacterium, and that TLR2 and TLR4 are involved in this process (Epelman *et al*., 2004; Lorenz *et al*., 2004; Power *et al*., 2004). Consistent with their function in protecting the respiratory tract from inhaled pathogens, there is selective mobilization of TLR2 to the apical surface of the airway cells in response to bacteria, and specifically in response to CF pathogens. However, there is no evidence that TLR-associated signaling is directly affected by CFTR dysfunction.

**Pseudomonas aeruginosa**

It is well accepted that the strategy of *P. aeruginosa* infection allows a change in the expression pattern of pathogenicity factors, which subsequently modulates the pattern of inflammatory mediator induction from human inflammatory effector cells (König B. *et al*., 1996; Schmidt *et al*., 1996). In this regard, we previously showed that *P. aeruginosa* from the early disease stage (acute phase) induced significant amounts of $LTB_4$, release of lysosomal enzymes and histamine from human peripheral cells. *P. aeruginosa* of late-stage disease (chronic phase) was the most pronounced inducer of IL-8, but no longer of $LTB_4$ and enzyme release. During the chronic course of infection, *P. aeruginosa* undergoes an additional conversion from a non-mucoid to a mucoid phenotype. The convergence to the mucoid phenotype of *P. aeruginosa* in CF still seems to be associated with increased inflammation, respiratory decline, and a poor prognosis. This led us to further precisely analyze the bacteria–host cell interaction with the focus on the chemotactic factors IL-8 and $LTB_4$. We selected *P. aeruginosa* strains from CF patients (n = 5) who were colonized by one *P. aeruginosa* strain expressing the non-mucoid and the mucoid phenotype in parallel. The non-mucoid and the mucoid *P. aeruginosa* pairs were subjected to RFLP analysis for clonal characterization. We then analyzed the efficacy of mucoid and non-mucoid *P. aeruginosa* to induce neutrophil migration in a transwell system. In this regard, mucoid *P. aeruginosa* strains dose-dependently attracted up to 20% of the neutrophils during a defined time interval, as

compared to non-mucoid strains with a maximum of 6% attracted neutrophils (Figure 54.4A).

In parallel, the expression of CXCR2, one of the two IL-8 receptors on neutrophils, was markedly down-regulated on neutrophils migrating towards *P. aeruginosa* bacteria expressing the mucoid phenotype, indicating the pronounced response of the neutrophil and also its activation. The results for CXCR1/CXCR2 expression were confirmed by FACS analysis as well as by quantitative RT-PCR (Figure 54.4B). The more pronounced down-regulation of CXCR2 by the mucoid *P. aeruginosa* bacteria, as compared to the non-mucoid *P. aeruginosa*, suggests autocrine or paracrine differences in cell surface regulation of chemokine receptors and IL-8 release. Clearly, the various chemotaxins differ in their effect on CXCR1 and CXCR2 surface expression on PMNs. In comparison to PMN migrating towards $LTB_4$, neutrophils attracted by IL-8 revealed a more pronounced down-regulation of CXCR2 surface expression, indicating the specificity for the receptor and the appropriate chemokines.

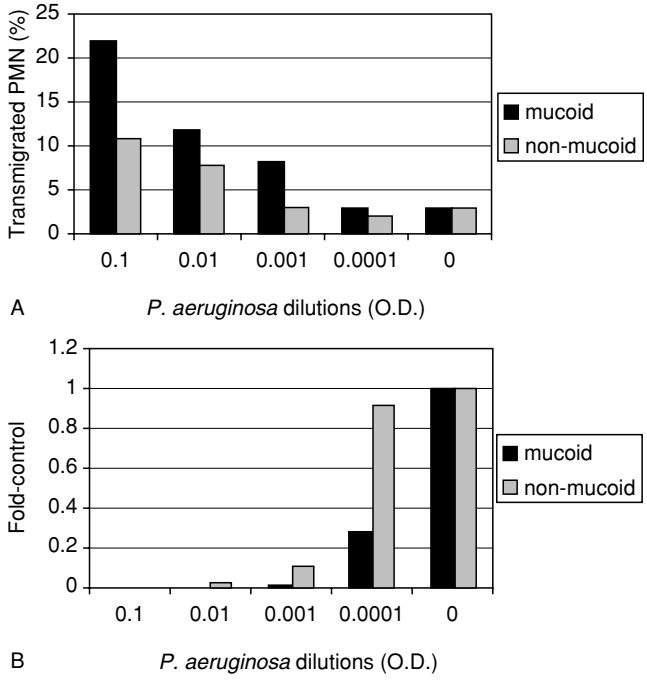

**FIGURE 54.4** Neutrophil CXCR2 mRNA expression in *P. aeruginosa* attracted neutrophils.
In a Transwell system with a 5fm-pore-size polycarbonate filter, the upper compartment was filled with neutrophils ($2\times10^5$ in 200µl), the lower compartment contained 800µl of control buffer or the respective dilutions (optical densities at 600nm of 0.1, 0.01, 0.001, 0.0001) of *P. aeruginosa* bacteria expressing either the mucoid or the non-mucoid phenotype. The incubation proceeded for 4h at 37°C in a $CO_2$ incubator. **A)** The migrated cells in the lower compartment were counted and **B)** were submitted for quantitative real-time RT-PCR. CXCR2 mRNA expression was quantified as CXCR2-specific copies per neutrophil, and data were expressed as stimulation index as compared to untreated neutrophils. Data was the mean of 4 independent experiments.

The epithelial-endothelial link is a key regulator of neutrophil sticking, extravasation, and migration. In this regard, it has been shown that epithelial cells by their complex strategy of chemokine induction activate endothelial cells for neutrophil migration and activation. Our studies extended this current view by using a transendothelial transwell system. For this purpose, transwell chambers were coated with human umbilical endothelial cells, and the transendothelial migration of indicator neutrophils was studied with regard to mucoid versus non-mucoid *P. aeruginosa* strains. A concentration-dependent transmigration of neutrophils was obtained, which was again more pronounced for mucoid than non-mucoid *P. aeruginosa* strains. This correlated again with a pronounced down-regulation of the CXCR2 mRNA expression in response to the mucoid, as compared to the non-mucoid *P. aeruginosa* strain. As has been shown in the past by previous investigators, the bactericidal activity of neutrophils is governed by the functional activity and complexity of the NADPH oxidase complex. Consequently, the activation of granulocytes induces the up-regulation of the various components of the NADPH oxidase complex, leading to a functional respiratory burst. Under normal conditions, the bactericidal activity is of major importance for the killing of bacteria; it also has adverse effects once it is directed toward the adjacent tissue. This is obviously valid in the deleterious process of CF disease.

In a set of further experiments, we analyzed the $p22^{phox}$ and $p47^{phox}$ mRNA expression in neutrophils after their transendothelial migration towards mucoid and non-mucoid *P. aeruginosa* bacteria. For comparison, we used PMN after their transendothelial migration toward the chemotactic factors IL-8, $LTB_4$, and C5a. It could be clearly demonstrated that the chemotactic factors differ in their activation pattern of the membrane-bound $p22^{phox}$ subunit and the cytoplasmic $p47^{phox}$ subunit of the NADPH oxidase complex. IL-8 induced an up-regulation of $p22^{phox}$ and $p47^{phox}$ mRNA expression only at high concentrations (10–100ng), $LTB_4$ over a wide concentration range (0.1–100 ng/ml), and C5a revealed nearly no $p22^{phox}$ or $p47^{phox}$ mRNA expression. A comparison of *P. aeruginosa* mucoid versus non-mucoid strains clearly indicated that the mucoid strain over a wide concentration range induced a significant expression of $p22^{phox}$ and $p47^{phox}$ mRNA, unlike the non-mucoid strains (Figure 54.5). This again indicates differences in the functional activity of PMN exposed towards mucoid versus non-mucoid strains and suggests a potent activity of the mucoid strains on the NADPH oxidase complex.

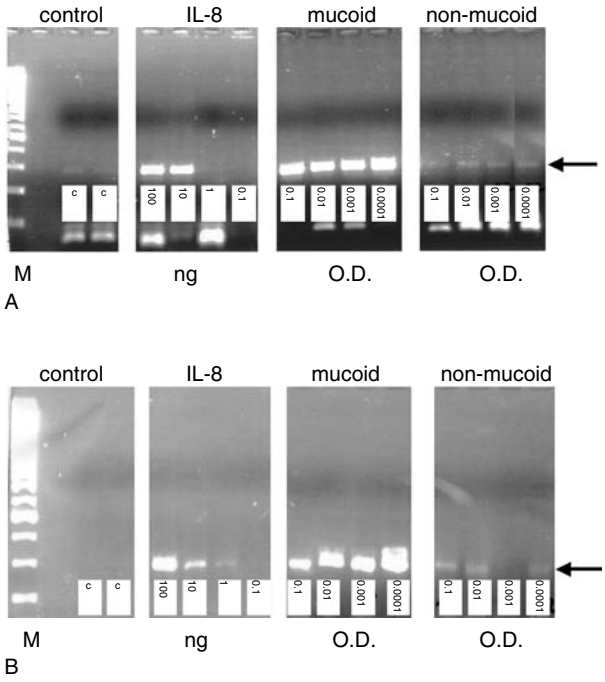

**FIGURE 54.5** Activation of the NADPH complex by *P. aeruginosa*. In a Transwell system, the 5µm-pore-sized polycarbonate filter was overlayered with endothelial cells (human umbilical endothelial cells) and the upper compartment was filled with neutrophils ($2\times10^5$ in 200µl), the lower compartment contained 800µl of control buffer (c) or the chemokine IL-8 (100-, 10-, 1-, 0.1ng) or bacteria from a *P. aeruginosa* isolate, expressing either the mucoid or the non-mucoid phenotype. The bacteria were used at different concentrations, which were determined via the optical density (O.D) at 600nm. The incubation proceeded for 4h at 37°C in a $CO_2$ incubator. The migrated cells in the lower compartment were counted and were submitted for qualitative RT-PCR. A) $p22^{phox}$ mRNA expression; B) $p47^{phox}$ mRNA expression. The results from one typical experiment are shown.

TLRs are major sensors of microbial recognition, as well as soluble exoproducts. With regard to the CF disease process, a major role has to be attributed to the expression of TLR2, 4, and 9. Quite recently, it was shown by the use of microarray analysis that upon *P. aeruginosa* conversion to mucoidity, there is a massive and preferential induction of genes encoding bacterial lipoprotein. Bacterial lipoproteins are potent agonists of TLR2 signaling. In parallel, the authors could show an increased expression of TLR2 in human respiratory epithelial cells as was ascertained by Western blot analysis. Thus, the excessive inflammation in CF is the result of a global induction in mucoid *P. aeruginosa* of lipoproteins that act as pro-inflammatory toxins superimposed on the hyperexcitability of CF cells. Moreover, bacteria can alter the acylation state of their LPS in response to environmental changes. *P. aeruginosa* synthesizes more highly acylated (hexa-acylated) LPS structures during adaptation to the CF airway. Therefore, a change in the recognition patterns by TLRs occurs. Although one failed to detect a global effect of CFTR dysfunction on TLR expression in the lung, the participation of TLR2 in airway cell responses to bacteria has been appreciated. Both *S. aureus* and *P. aeruginosa* stimulation appeared to be signaled through TLR2, despite the presence of TLR4 in these cells. The availability of TLR2 on the apical surface of respiratory epithelial cells suggests a role for this TLR in airway responses to Gram-negative as well as Gram-positive pathogens (Soong *et al*., 2004). The participation of specific TLRs in airway cells clearly differs from what is observed in cells of hematopoietic origin. TLR4, which is critical in signaling systemic responses to LPS, was substantially less involved in epithelial signaling, although clearly present in the epithelial cells (Yamamoto *et al*., 2002). Airway epithelial cells, like other mucosal epithelia, are not particularly responsive to LPS, as compared with myeloid cells. We investigated the quantitative TLR mRNA expression in human neutrophils using real-time Taqman RT-PCR. Neutrophils expressed high levels of TLR2-specific mRNA, ranging donor-dependently from $10^6$ up to $1.5\times10^7$ copies/$10^6$ neutrophils (n = 12). TLR4-specific mRNA was detected to a lesser degree with a mean of $5.4\times10^3 \pm 3\times10^3$ copies/$10^6$ neutrophils (n = 14). TLR7 and TLR9 mRNA expression were barely detected with less than $10^2$ copies/$10^6$ neutrophils. Additionally, we confirmed the expression of TLR2 and TLR4 at the protein level. In this regard, neutrophils showed significant higher signals for surface TLR2 as compared to surface TLR4. Therefore, TLR2 seems to play a predominant role in the innate immune response of neutrophils.

In addition, we analyzed to what extent the migration of human neutrophils towards $LTB_4$, C5a, or IL-8 is accompanied by changes in TLR2 mRNA expression. Obviously, these chemotaxins are abundantly generated and released in CF. Our results showed that the chemotactic factors differ markedly in their effects on TLR2 mRNA expression. Transmigrated neutrophils towards IL-8 (from 0.1 up to 100ng) showed an upregulation of TLR2, which was most prominent at the highest concentrations. An opposite dose dependency is obtained with $LTB_4$, reflecting low TLR2 expression at the highest concentration of $LTB_4$ (100 ng), as compared to the lowest concentration (0.1 ng/ml) (Figure 54.6). Whether these differences in TLR2 expression towards the two key chemokines IL-8 and $LTB_4$ reflect the increased inflammatory response seen in the chronic CF airways has to await further studies.

We extended our studies using additional chemokines such as GCP-2 GRO-α and NAP2, as well

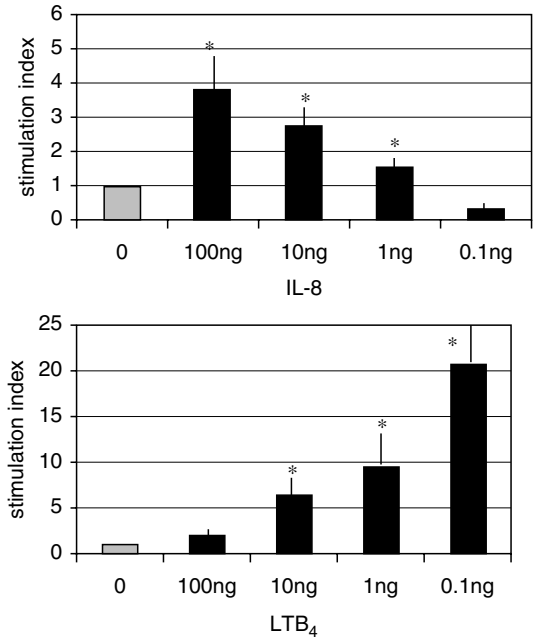

**FIGURE 54.6** Neutrophil TLR2 mRNA expression in chemoattracted neutrophils.
In a Transwell system with a 5µm-pore-size polycarbonate filter, the upper compartment was filled with neutrophils ($2\times10^5$ in 200µl), the lower compartment contained 800µl of control buffer or the chemoattractants IL-8 or $LTB_4$ at the indicated concentrations (100-, 10-, 1-, 0.1ng). The incubation proceeded for 4h at 37°C in a $CO_2$ incubator. The migrated cells in the lower compartment were counted and were submitted for quantitative real-time RT-PCR. TLR2 mRNA expression was quantified as TLR2-specific copies per neutrophil, and data were expressed as stimulation index as compared to untreated neutrophils. Data were the mean ± SEM of 10 independent experiments, with significant differences in TLR2 mRNA expression, as compared to spontaneously migrated neutrophils indicated: **, $p < 0.01$; *,$p<0.05$

as ENA-78, which are released from different cell sources during inflammation after immunological and non-immunological activation of different cells. The TLR2 mRNA copies per transmigrated neutrophils were studied. Obviously, over a wide concentration range (0.1 up to 100ng), the chemotactic factors respond differently with regard to the induction of Toll-like receptor 2 expression showing the highest activity for ENA-78>NAP2>GRO-α>GCP-2>IL-8. In comparison, IL-8 has the highest chemotactic potential, followed by GCP-2 and GRO-α with similar chemotactic activities and by NAP-2. ENA-78 expressed the weakest chemotactic activity towards neutrophils in a transwell system. Thus, a reverse pattern of TLR2 expression versus chemotaxis is obtained for the transmigrated neutrophil. However, in a complex scenario of microbial-cell interaction the different maturation stages of granulocytes, as well as their individual variations in functional activities and quite recently the polymorphism of TLRs, have to be considered and are described (Beutler, 2004; Kaufmann *et al*., 2004; Maggi, 1998).

Taken together, these data clearly indicate that the neutrophil effector function is not only modulated by microbial pathogenicity factors and/or toxins, but also by individual chemokines. Obviously, the scenario of CF is even more complex since the disease process is further complicated by, e.g., microbial biofilm formation. In addition, the impact of antibacterials on parameters of the non-specific immune system has become of increasing interest (Van Vlem *et al*., 1996). Novel data have been raised for the effect of fluoroquinolones (Ciprofloxacin, Moxifloxacin) on various cell functions including neutrophils. Therefore, we analyzed the influence of the fluoroquinolone moxifloxacin on the migration of neutrophils towards the chemotactic factors IL-8, $LTB_4$, and C5a. The choosen concentrations of moxifloxacin (from 0.08 up to 80mg) were within the physiological concentrations achievable in patients (König, B. *et al*., 2004; Soman *et al*., 1999). The presence of moxifloxacin resulted in an increased migration of PMNs towards IL-8 by up to 166±8%, but suppressed the migration towards $LTB_4$ down to 1.15±0.87% and showed no effects with regard to C5a. In parallel, moxifloxacin down-regulated the TLR2 mRNA expression in PMN, migrating towards IL-8 by approximately 90% and up-regulated TLR2 mRNA expression in PMN migrating towards $LTB_4$ up to 300%. Further data indicate that antimicrobials also affect toxin release to a various degree from viable bacteria, which modulate host defense strategies (Aoki *et al*., 1994; Fischer and Adam, 2001; Gemmell, 1993; Labro, 1993; Mueller *et al*., 1999). In the context of CF, these studies are necessary to benefit from a precise time-scheduled use of antimicrobials such as the fluoroquinolones.

### Staphylococcus aureus

*S. aureus* is often the first pathogen to infect the respiratory tract of CF patients. In the pre-antibiotic era, *S. aureus* and *H. influenzae* caused substantial morbidity and mortality in infants with CF, but with the advent of antibiotic therapy effective against these pathogens, the life expectancy of infants with CF has increased. However, the eradication of *S. aureus* apparently favors the colonization with *P. aeruginosa*, suggesting a protective role of *S. aureus* in the early disease process. The later disease stages are complicated by the presence of small colony variants of *S. aureus* (Kahl *et al*., 2003).

#### *The role of superantigens in pathogenesis*

*S. aureus and Streptococcus pyogenes*, as well as a few other bacteria and viruses, produce and secrete a group

of exotoxins called superantigens (SAGs) (Becker *et al*., 2003; Hensler *et al*., 1993; Saloga *et al*., 1996; Silverman, 1997). SAGs have received a great deal of attention since the discovery of their mechanisms in 1989. At least 20 SAGs (or molecules with SAG-like activity) have been identified, and are synthesized by the bacteria that occur in the gut, at least sporadically. The most well-characterized SAGs are the staphylococcal enterotoxins (SE) A, B, C (antigenic variants C1–3), D, E, and the recently discovered enterotoxins G to Q, and toxic shock syndrome toxin-1 (TSST-1), as well as the streptococcal SAGs, including the pyrogenic exotoxins (SPEs and antigenic variants A1–4), C, G–J, L and M, streptococcal mitogenic exotoxins (SMEZ), and the streptococcal SAG (Baker and Acharya, 2004; McCormick *et al*., 2001; Petersson *et al*., 2004). It appears that each strain of these pathogens produces a distinct set of SAGs, but not all different types of SAGs. Structural studies over the last 10 years have provided a large amount of knowledge regarding the complex interactions of these molecules with their receptors. This knowledge, combined with the wealth of new information from genomic and biochemical studies as well as the availability of crystal structures, has shown the molecular architecture of some toxins and revealed a variety of molecular mechanisms of action (Li *et al*., 1998; Li *et al*., 2001; Papageorgiou *et al*., 1996).

SAGs bind specifically to both APCs and MHC class II molecules. Unlike conventional antigens, SAGs remain unprocessed by the APCs, instead binding direcly on the outside of MHC class molecules. Here, cross-linking occurs to both MHC class II α and β chains (Campbell and Kemp, 1997; Dinges *et al*., 2000; Drynda *et al*., 1995; Hofer *et al*., 1995; Mueller-Alouf *et al*., 1996; Mueller-Alouf *et al*., 1997; Petersson *et al*., 2001; Petersson *et al*., 2003). The existence of two distinct MHC class II binding sites enabled the formation of a trimeric SEA-MHC-SEA complex as observed in solution experiments. Almost all known SAGs interact exclusively with the Vβ region of the TCR, resulting in T cell stimulation. In this context, it is important to note that while investigating the TCRV profile for SEH toxin, it was discovered that in contrast to all other SAGs, it activated T cells via $TCRV_{\alpha}$ and independent from TCRVβ (Petersson *et al*., 2003).

Recently, we described the effect of leukocidin and various superantigens on innate as well as adaptive immunity. We showed that the composition of the binary toxin leukocidin determines the potency of inflammatory reactions, as well as the down modulatory activity of the granulocyte in response to stimulatory chemotactic factors (König B. *et al*., 1997; König B., *et al*., 1995; Prévost *et al*., 1995). With regard to the various SAGs, we showed that mutant proteins as well as peptides were able to skew the T effector function, as well as initiate and modulate the cytokine production from various human effector cells (e.g., TNF-α, IL-8, IL-10, IL-12) (Drynda *et al*., 1995; Neuber *et al*., 1991; Veldkamp *et al*., 2000).

Although the presence of *S. aureus* has also been documented as a common pulmonary pathogen in CF, there is similarly little or no information on the possible role of staphylococcal SAGs in this disease. Moreover, quite recently, methicillin-resistent *S. aureus* (MRSA) were observed in CF patients. Obviously, MRSA reflects a changing epidemiology (Lina *et al*., 2003; Vandenesch *et al*., 2003). In this regard, a dynamic occurrence of methicillin-resistant *S. aureus* strains has been observed, including the appearance of community-acquired MRSA expressing distinct pathogenicity profiles (Novick *et al*., 2001; Tiemersma *et al*., 2004). About 200 consecutive MRSA recovered during a one-year period were analyzed (Ghebremedhin *et al*., 2004). We determined the antibiotic susceptibility: The isolates were typed by multilocus sequencing (MLST), by a multiplex PCR for the staphylococcal cassette chromosome *mec* (SCC*mec*), by allelle-specific PCR for the staphylococcal accessory gene regulator (*agr*), and by PCR for the presence of toxin genes (*sea–sej*, *tsst-1*, *hlgA, C, B*, *lukE/D*, *luk-PVL*) (Enright *et al*., 2000; Enright *et al*., 2002; Gouaux *et al*., 1997; Jarraud *et al*., 2002; Jarraud *et al*., 2001; Oliveira and Lencastre, 2002; Omoe *et al*., 2002). All strains possessed the genes for *seg* and *sei*. Besides *seg* and *sei*, 119 *S. aureus* isolates were found to be positive for one or more SE genes. Amoung them, 33 strains were positive for *sea*, one for *seb*, 58 positive for *sec*, 27 for *sed*, none for *see*, *seh*, and *sej* gene. No MRSA strain expressed genes for the superantigens ETA, ETB, or TSST-1. Only 12 strains harbored two additional SE genes. With regard to the leukocidins, all strains were positive for *hlgA-hlgB/hlgC-B* and for *lukD/E*. Only eight isolates were positive for the Panton-Valentine leukocidin gene. These results clearly reflected the heterogeneity of *S. aureus* and in particular MRSA with regard to their pathogenicity profile expression. Thus, we have to consider a similar heterogeneity of MRSA as well as of MSSA in CF patients. With regard to the *agr* type, recent data have been described by Kahl *et al*., (2003).

Among the multitude of actions on immune effector cells by superantigens (cytokine induction, T cell skewing, IgE antibody synthesis), recent data have focused on their role on chemokine receptor expression. Adaptive immunity has been considered to be either Th1 or Th2 regulated in cooperation with T regulatory cells. It has been described that Th1 and Th2 cells express a defined set of chemokine receptors. Staphylococcal SAG producing *S. aureus* can be frequently

isolated from the skin of patients with atopic dermatitis. Epicutaneous application of intradermal injection of staphylococcal enterotoxins induces inflammation of the skin, which is T cell dependent. The interaction between chemokines and chemokine receptors (CKRs) is an important step in the control of T cell migration into sites of inflammation (Chambers, 2001; Leung, 1998; Lina *et al*., 1999; Neuber *et al*., 1992; Saloga *et al*., 1996).

Our studies were focused on the role of the staphylococcal superantigen B on chemokine receptor expression. Human peripheral blood mononuclear cells were used as target cells, as well as Jurkat T cells. We systemically investigated the association of 14 CKRs (CCR1-9, CXCR1-5) with CD4+ T cells from peripheral blood mononuclear cells (PBMC) with or without SAG staphylococcal enterotoxin B (SEB) stimulation. CKRs expression on CD4+ T cells from PBMC were analyzed by flow cytometry and RT-PCR. Cytokine secretion was assessed by ELISA in the supernatants from SEB-stimulated PBMC. SEB increased the surface antigen expression (CD45RO, CD31, CD25, CD69, CD54, and FAS) and induced the cutaneous lymphocyte-associated antigen (CLA) on T cells, the homing receptor for skin T cells. A wide range of CC-chemokines were produced by SEB-treated PBMC. These included MIP-1α, MIP-1β, MCP-1, eotaxin, and RANTES, which bind the chemokine receptor CCR3-5. In addition, peripheral cells of these patients showed a pronounced hyper-releaseability of chemokine release and inflammatory mediators (Neuber *et al*., 1991). SEB preferentially up-regulated CCR3, CCR4, CCR5, and CXCR3 on the surface of CD4+ T cells from normal individuals. The maximum effects were observed after 5–7 days of incubation. Furthermore, PBMC were polarized towards Th1 or Th2 cytokine-expressing T cells after incubation in the presence of IL-12/anti-IL-4 or IL-4/anti-IL-12. In polarized Th2 CD4+ T cells, SEB up-regulated CCR4 (Th2-associated CKRs), but suppressed CCR3. Similarly, SEB induced an up-regulation of CCR4-mRNA on isolated CD4+ T cells from atopic donors. CXCR3 (Th1-associated CKRs) was found to be expressed at high levels on Th0 cells after SEB stimulation. In polarized CD4+ T cells, SEB led to a slight down-regulation of CXCR3 (Th1-associated CKRs).

Our results thus demonstrate that SEB modulates CD4+ T cells with regard to chemokine release and chemokine receptor expression. Furthermore, SEB influences Th1- and Th2-associated chemokine receptors. A dynamic pattern of chemokine receptor gene expression may control the tissue-specific migration of effector cells and thus trigger Th1 and/or Th2 immune effector reactions.

### *Emerging microorganisms*

Long-term survival of CF patients is improving due to a better understanding of the basic underlying defects. Some of the common pathogens in CF have led to new treatment strategies, including antibiotic prophylaxis, prevention of colonization of the lungs with *P. aeruginosa*, and the development of new drugs and methods of drug delivery, such as nebulized antibiotic therapy. Difficult new issues, in addition to the increasing pattern of antibiotic-resistant organisms (e.g., MRSA), include the emergence of a number of microorganisms whose relevance in CF is not yet clear. In focus are the non-tuberculous mycobacteria and also respiratory viruses.

#### *Non-tuberculous mycobacteria (NTM)*

In the past years, an increasing prevalence of NTM colonization among the CF population was observed (König, B. *et al*., 2004). Various studies suggest that NTM play an important role in the impairment of pulmonary disease in patients with CF. In this regard, at the case report level, *Mycobacterium abscessus* has been associated with poor outcomes. Mainly due to the misidentification of *M. abscessus*, its role for the clinical outcome in CF is not yet clear. We studied 1,700 sputum samples of CF patients for the presence of NTM. We detected 57 *M. abscessus* isolates belonging to seven CF patients. A correct identification was obtained by sequencing the *hsp65* gene or the 16S-23S intergenic sequence. Our data showed distinct *M. abscessus* strains among the CF patients. Thus, the future challenge is to consider the clinical relevance and proper treatment of NTM species, especially of *M. abscessus* in CF patients and also their contribution to toxin-mediated lung infection.

#### *Respiratory viruses*

Several studies suggest that some patients with CF may be at increased risk of respiratory virus infections that have pronounced and long-lasting effects on those patients, resulting in significant decline in lung function, increasing both the frequency and duration of hospitalization (Abman *et al*., 1988; Armstrong *et al*, 1998; Black *et al*., 1998; Hiatt *et al*., 1999; Zhang *et al*., 2002). Deleterious effects on patients with CF have been reported for most viruses studied, but the effects of respiratory-syncytial-virus (RSV) and influenza are most severe. Epidemiological, viral, and host factors account for the severity. With regard to the latter, production of nitric oxide, an important part of the inflammatory response to viral infections, is reduced in infants with CF. We analyzed about 300 RSV isolates from four associated study centers (Hamburg, Bochum, Dresden,

Freiburg) during the study year 1999–2000 with regard to their genetic relatedness by sequencing the first hypervariable region of the RSV-G-protein. The circulating RSV strains could be divided into three clusters. There was a significant correlation between RSV cluster 2 and disease severity (Struck *et al*., 2004). The mechanism of pathogenicity has to be elucidated.

Quite recently, the human Metapneumovirus was first isolated from children in the Netherlands. The HMPV belongs to a newly discovered virus from young children with respiratory tract disease (see König, B. *et al*., 2004). HMPV produces RSV-like illness in children, ranging from upper respiratory tract disease to severe bronchiolitis or pneumonia. We tested in the population-based prospective PRI.DE multicenter study (Germany, two years) 3,369 nasopharyngeal secretions from children under three years of age with lower respiratory tract infections (LRTI) for RSV A and B, influenza viruses (IV) A and B, and parainfluenza viruses (PIV) 1–3 (König B. *et al*., 2004). Of children requiring intensive care ($n$ = 85), 18% had HMPV, 60% of them in combination with RSV. In a randomly selected subset of RSV-positive nasopharyngeal secretions (n = 120) from children not requiring intensive care support, we did not detect hMPV. In virus-negative samples from patients without intensive care support (n = 620) hMPV was detected in fewer than 1%. Our data support the hypothesis that RSV and hMPV together are more severe than either RSV or hMPV alone, at least in non-CF children below the age of three years. A role of HMPV alone or in combination with RSV in the CF population has to be considered. Furthermore, there is substantial evidence that respiratory virus infections may facilitate bacterial infections. In this regard, the appearance of *Staphylocoocus aureus*, producing the Panton-Valentine leucocidin (Luk-PVL) in influenza-infected children leads to a fatal outcome (Krell *et al*., 2003).

We focused on RSV since this virus is the most common cause of viral infection in infants and children. To develop a better understanding of how RSV infects the lung and of the pathophysiological consequences of viral infection, we investigated the respiratory virus-epithel cell interactions. The F and G proteins are two largely glycosylated proteins expressed on the surface of the viral envelope (Arnold *et al*., 2004; Arnold and König, 2005; Arnold and König, 2005).

At present, there is a concern to use the RSV in gene replacement therapy in CF. For the development of strategies to deliver therapeutic transgenes to the airways of patients with diseases such as CF, it is of fundamental importance to exploit the mechanisms that RSV has evolved to infect the respiratory epithelium. This then might allow us to reduce the recurrent bacterial infection and the toxin-induced destruction of the lung tissue.

### *Microecology*

As long as gene therapy is not yet available, antimicrobial treatment must be optimized, along with measures for the prevention of early infection and the transmission of the pathogens among CF patients. These measures largely rely on the knowledge of the microbial status of the CF patient at all times. CF is dominated by the presence of microbial biofilm formation; the expression and release of microbial pathogenicity factors and toxins are modulated by the cooperative interaction of the microorganisms. Molecular biological methods seem to be appropriate for a more precise analysis of microbial pathogenicity.

Recently, we described the so called T-RFLP method (**T**erminal **R**estriction **F**ragment **L**ength **P**olymorphisms) for the complete qualitative and quantitative analysis of the respiratory microecology (Trotha *et al*., 2002). The method allows us to track static and dynamic changes in the microbial communities under antibiotic therapy; thus, a better knowledge of interactions between commensal and/or pathogenic microbes with each other and with the human host is obtained. We used model microbial communities consisting of CF relevant microorganisms, e.g., *P. aeruginosa, S. aureus, Klebsiella pneumoniae, Burkholderia cepacia, Stenotrophomonas maltophilia, Alcaligenes xylosoxydans*, and *Mycobacterium abscessus*. Fifty-one sputum samples from 15 patients suffering from cystic fibrosis at different stages of disease and antibiotic therapy were analyzed. Our extended studies showed the changes in the microbial pattern after antibiotic treatment (Figure 54.7). This technique will also allow us to determine the fluctuating pattern of microbial communities, the formation of biofilms, as well as of the regulation of bacterial toxin production. In this regard, the virulence of *S. aureus* is dependent on the temporal expression of a diverse array of virulence factors, including both cell-associated products, such as protein A, collagen- and fibronectin-binding protein, and secreted products including lipases, proteases, alpha-, beta-hemolysin, and the respective superantigens. We studied to what extent *P. aeruginosa* is able to modulate the expression of staphylococcal SAGs, e.g., enterotoxin A. Both microorganisms were co-cultured over various times, and the expression pattern of staphylococcal SEA-specific mRNA was analyzed, representative for the classical superantigens. We have clearly shown that the presence of *P. aeruginosa* at increasing concentrations down-regulated the SEA-mRNA expression of *S. aureus* prior to a decrease of the colony-forming units of *S. aureus* (Figure 54.8).

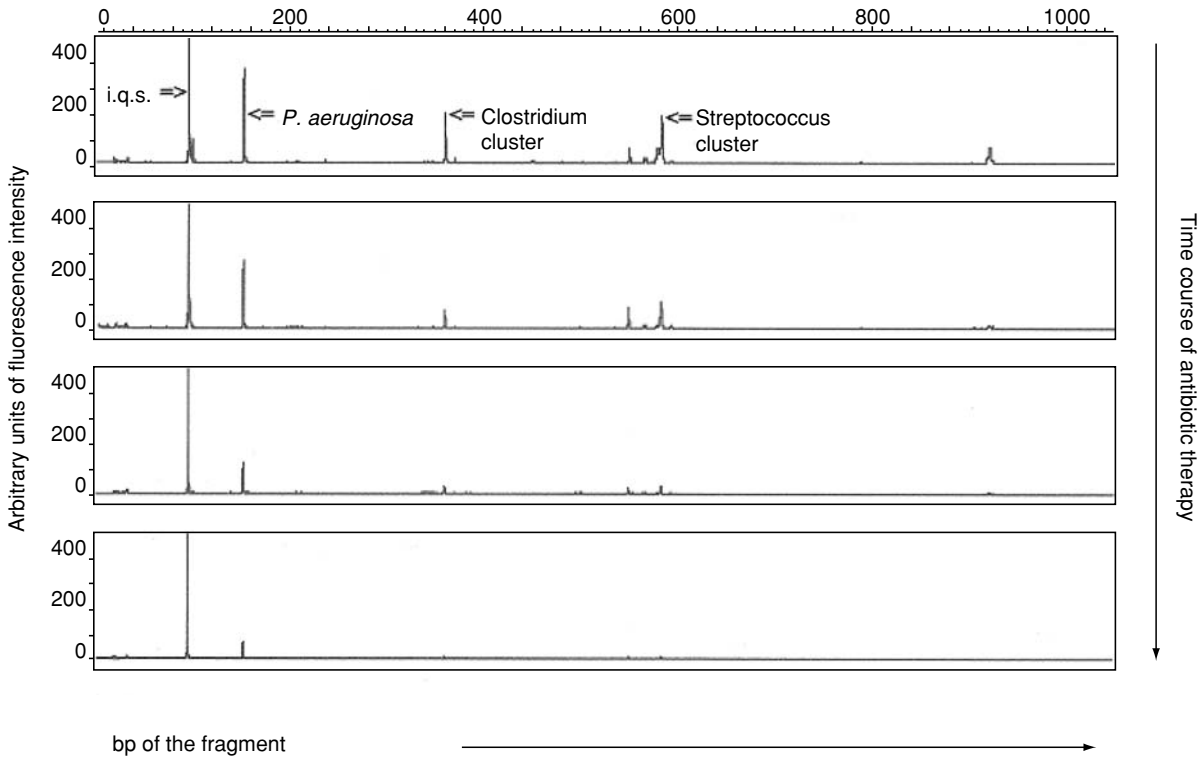

**FIGURE 54.7** Therapy-related changes in the T-RFLP pattern of CF sputum samples.
The T-RFLP pattern in the sputum samples from one individual CF patient at the beginning of antibiotic therapy and at 3, 9, and 14 days after the onset of antibiotic therapy was determined. The 155 bp peak for *P. aeruginosa*, as well as the peaks for the *Clostridium and Streptococcus ssp*. clusters, are decreasing during antibiotic therapy. The 98 bp internal quantification standard is not influenced by the antibiotic therapy

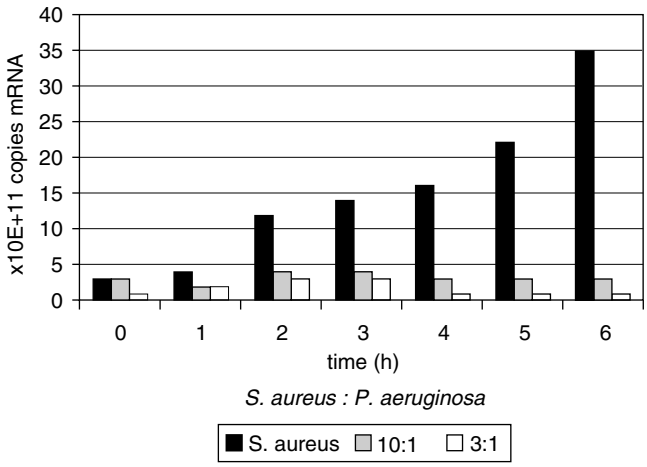

**FIGURE 54.8** *Pseudomonas aeruginosa—Staphylococcus aureus* interaction.
*S. aureus* bacteria were cultivated in the absence or in the presence of *P. aeruginosa* PAO1 (10:1; 3:1) in a total volume of 10ml for up to 6h in Lydia broth medium at 37°C with gentle agitation. After the indicated time intervals, a) the colony forming units of *S. aureus* as well as of *P. aeruginosa* were determined; b) total RNA was prepared and the staphylococcal enterotoxin A specific (SEA) mRNA copies were determined by quantitative real-time RT-PCR. Values represent SEA-specific mRNA copies per ml culture.

At present, we focus on multimicrobial cultures by applying chemostat procedures for biomodeling purposes. Mathematical models will predict the microbial disease status, the pathogenicity profile of the relevant microorganisms, and the efficacy of treatment in CF patients, but also in other infectious diseases. Thus, toxin-mediated cellular and cell-biological events can be exactly quantitated and evaluated in the future.

## ROLE OF BIOPROSTHETIC DEVICES AND BACTERIAL EXOPRODUCTS / TOXINS

Biomaterials implanted for many months or years must meet two criteria: First, they must have specific mechanical properties to replace the functions of defective body tissues or organs, and, second, they must be accepted and integrated by the host in a controlled and predictable way. No implanted artificial material can be considered totally inert in the body and can lead to aseptic and furthermore septic inflammation. The incidence of infections ranges from 1–25% and are mostly attributed to *S. aureus* and/or *S. epidermidis*.

## Biopolymers and inflammation

The mechanisms of a variable host response towards different categories of biomaterial implants are complex and still poorly understood. Depending on the circumstances, some of these materials can elicit a chronic inflammatory response, also called a foreign-body reaction, which has the following characteristics: After an initial acute inflammatory reaction, a chronic granulomatous tissue reaction may persist, even after encapsulation has occurred. The foreign-body reaction seems to be induced by continuous chemical or mechanical stimuli arising from the biomaterial implants. Morphological analysis of this reaction reveals the presence of a large number of macrophages, which generally attempt to phagocytize the material.

Some of the macrophages then merge their cytoplasm to become multinucleated giant cells, also called foreign-body giant cells. If the foreign body cannot be degraded by phagocytes, granulation tissue is formed to encapsulate the foreign body and to isolate the implant from the rest of the body tissues. The foreign-body reaction is further characterized by the presence of the inflammatory cells, namely, the polymorphonuclear leukocytes (Cross and Welsh, 2001; Waldvogel and Bison, 2000). Activation of phagocytes that come into contact with the non-phagocytosable foreign material leads to the secretion of inflammatory mediators, including acidic or neutral hydrolases, activated complement components, TNF, interleukins, prostaglandins, plasminogen activator, and coagulation factors. These secreted factors interact in a complex manner to control and maintain acute and chronic phases of the inflammatory response to implants. Materials in contact with blood must fulfill additional requirements; they must not damage blood cells and/or encourage the formation of blood clots (Waldvogel and Bison, 2000).

Infections associated with indwelling medical devices are caused predominantly by staphylococci. These infections are initiated by bacteria adhering either directly to the device prior to implantation or to host proteins that coat the implant surface after implantation. The first mechanism is considered to be most important for *Staphylococcus epidermidis*, while *Staphylococcus aureus* infection is thought to be mediated by protein adhesions on the bacterial cell surface that recognize fibrinogen and fibronectin among the host proteins that rapidly coat biomaterial surfaces after implantation. The composition of the complex mixture of host factors that are deposited on the implant surface changes as the implant ages. Fibrinogen is a major component of newly implanted biomaterial and is the dominant ligand promoting *S. aureus* adherence. After longer exposure, deposited fibrinonectin becomes the dominant ligand. *S. aureus* can adhere to many other host plasma and matrix proteins, such as vitronectin, collagen, laminin, and von Willebrand factor, but the relevance of these interactions to device-related infections is unclear. Invasive strains of staphylococci have been reported to bind more fibronectin than commensal strains can do. Although *S. aureus* binding to collagen has received considerable attention in recent years as a potentially important mechanism to trigger osteomyelitis, septic arthritis, or native valve endocarditis, no significant association between these infections and the presence of indwelling devices has been presented so far. The molecular characterization of several genes encoding *S. aureus* adhesins, namely two fibrinogen-binding proteins called ClfA (also named clumping factor) and ClfB, one collagen adhesion, one elastin-binding protein, and two distinct but related fibronectin-binding proteins, has been achieved. Site-specific mutants of *S. aureus* specifically defective in adhesion to fibrinogen, fibronectin, or collagen have been described and used in various *in vitro* and *in vivo* studies. In contrast, *S. aureus*, *S. epidermidis*, and other clinically relevant species of coagulase-negative staphylococci exhibit weaker interactions with host proteins. Molecular studies also indicate that coagulase- negative staphylococci express a more limited repertoire of adhesins. Recent reports suggest the presence in coagulase-negative staphylococci of a distant homologue of the clfA gene of *S. aureus* as a putative fibrinogen-binding surface protein called Fbe, and two non-homologous types of surface proteins combining adhesive and autolytic properties. One of them allows *S. epidermidis* to interact with human vitronectin, while the other one expresses fibronectin-binding activity in *S. saprophyticus*.

The production of pyogenic exudates or abscesses by *S. aureus* infections indicates a major role for neutrophils in the host defense against such infections. Another important aspect of the host response to staphylococcal infection is the directed migration of the phagocytes toward an infectious focus, which is acting as a stimulus. Establishment of an inflammatory focus leads to the liberation of humoral mediators, which attract and modulate the cellular components of the inflammatory response. This complex set of events involves activation or inactivation of several humoral pathways, which interact with the migrating phagocytes.

Mostly *S. epidermidis*, but sometimes also mixed cultures, have been isolated from colonized catheters recovered from patients. In addition, infection of catheters has been shown by scanning electron microscopy to demonstrate the mode of adhesion (Peters *et al*., 1981). Bacterial cells, primarily those of

staphylococci, followed by *Acinetobacter calcoaceticus* and *P. aeruginosa*, were shown to be attached to the inner surface of the catheter. The thickest bacterial layers were found in catheters infected by coagulase-negative staphylococci (CoNS). The bacteria appeared to be closely packed and cemented together by a slimy matrix. Biofilms have been demonstrated on nearly all kinds of catheters. In addition to *S. epidermidis*, *Staphylococcus aureus* and *Candida parapsilosis* are able to form a biofilm, which indicates that bacteria and yeasts colonize intravascular catheters by an adherent biofilm mode of growth. Both *S. aureus* and *Enterococcus faecalis* have been isolated from biofilm; occasionally, fungal cells or *Proteus mirabilis* have been identified. During the course of polymer colonization, staphylococcal cells produce large amounts of extracellular slime in which the cells are embedded and finally completely covered. The slime substance is not a true capsule, but is loosely bound to the staphylococcal cells.

Production of slime is necessary for *S. epidermidis* colonization and is also observed with many other pathogens, including *S. aureus*. The chemical composition of slime has been characterized for *S. aureus*, as well as *S. epidermidis.* Mack *et al*. (1996) purified a specific polysaccharide antigen of the biofilm-producing strains of *S. epidermidis* and were able to distinguish two polysaccharide fractions. The structure of this polysaccharide is unique and, according to its function of cellular aggregation, it is referred to as polysaccharide intercellular adhesion (PIA). Infections involving coagulase-negative staphylococci lead to a higher mortality rate (30.5%), compared with those without coagulase-negative staphylococci bacteria (16.9%). The virulence of the commensal *S. epidermidis* is a result of the foreign-body implant, which acts to inhibit the normal host defense. The biofilm reduces the effectiveness of antibiotic therapy, leaving explantation of infected devices as often the only available treatment. Therefore, the aim of much research has been directed at elucidating the mechanisms of bacterial adhesion and colonization of the device biomaterials. The reactivity of various biopolymers to interact with immunological or bacterial ligands and/or toxins has not been clarified.

## Effect on human effector cells

Our investigations were addressing the following questions:

1. The properties of the various bioprosthetic devices on their own to interact with human PBMCs as well as human neutrophils. For this purpose, PBMC after their isolation and purification were also stimulated with staphylococcal enterotoxin B (SEB), phorbol-12,13-myristate-acetate (PMA), or with sodiumfluoride (NaF). PMNs after interaction with bioprosthetic devices were stimulated with the bacterial peptide fMLP, PMA, as well as NaF. These agonists stimulate the target cells via different mode of actions (MHCII-TCR, heterotrimeric G-proteins, PKC, as well as low molecular weight G-proteins).
2. The stimulatory and down-regulatory properties of bioprosthetic devices coated with SEB, fMLP, LPS, $LTB_4$, C5a, IL-8, GRO-α, ENA-78, GCP-2, NAP2. The effects and cell surface markers, as well as inflammatory mediator release, were studied.
3. The release of various cytokines (e.g., IL-10, IL-12, TNF-α), as well as inflammatory mediators (e.g., $LTB_4$, $PGE_2$), enzyme release (e.g., elastase).
4. The expression of essential molecules in innate immunity (e.g., TLR2, 4-9), chemokine receptors (CXCR1, CXCR2), fMLP receptors, the components of the NADPH oxydase ($p22^{phox}$, $p47^{phox}$, $p67^{phox}$, $gp91^{phox}$), as well as enzymes for lipid mediator induction and metabolism (e.g., cyclooxygenase 2 and receptors for prostaglandins EP1-4). As an example are shown the effects of several bacterial as well as immunological ligands (fMLP, SEB, LPS).

Four different bioprosthetic devices were used in our studies: (i) silver collagen polyester, (ii) collagen polyester, (iii) prosthetic device ePTFE, (iv) prosthetic device ePTFE gelatine. The bioprosthetic devices were equally sized (0.5 x 0.5 cm) and cut under sterile conditions. They were used plain or precoated with various ligands. Subsequently, they were dried by air and used if needed. In additional experiments bioprosthetic devices were also incubated with either human endothelial cells or human fibroblasts. The supernatant of the various activated cells was assessed for IL-8, TNF-α, IL-10, IL-12, $PGE_2$ release. Cell surface expression of various receptors were studied by FACS analysis. It was shown that the various devices coated with different ligands affect IL-10 release (Figure 54.9A&B) significantly. Similarly, elastase release from human neutrophils occurs, depending on the device and the appropriate ligand (Figure 54.10A&B).

Our data support the following results:

1. The four different prosthetic devices interact differently with regard to the induction of cytokines.
2. Bioprosthetic devices precoated with various ligands exert differences with regard to cytokine release.
3. The expression of Toll-like or chemokine receptors or chemotaxin receptors on the effector cells differs depending on the nature of the bioprosthetic device and its ligand.
4. The various microbial products interact differently with regard to the nature of the bioprosthetic devices.

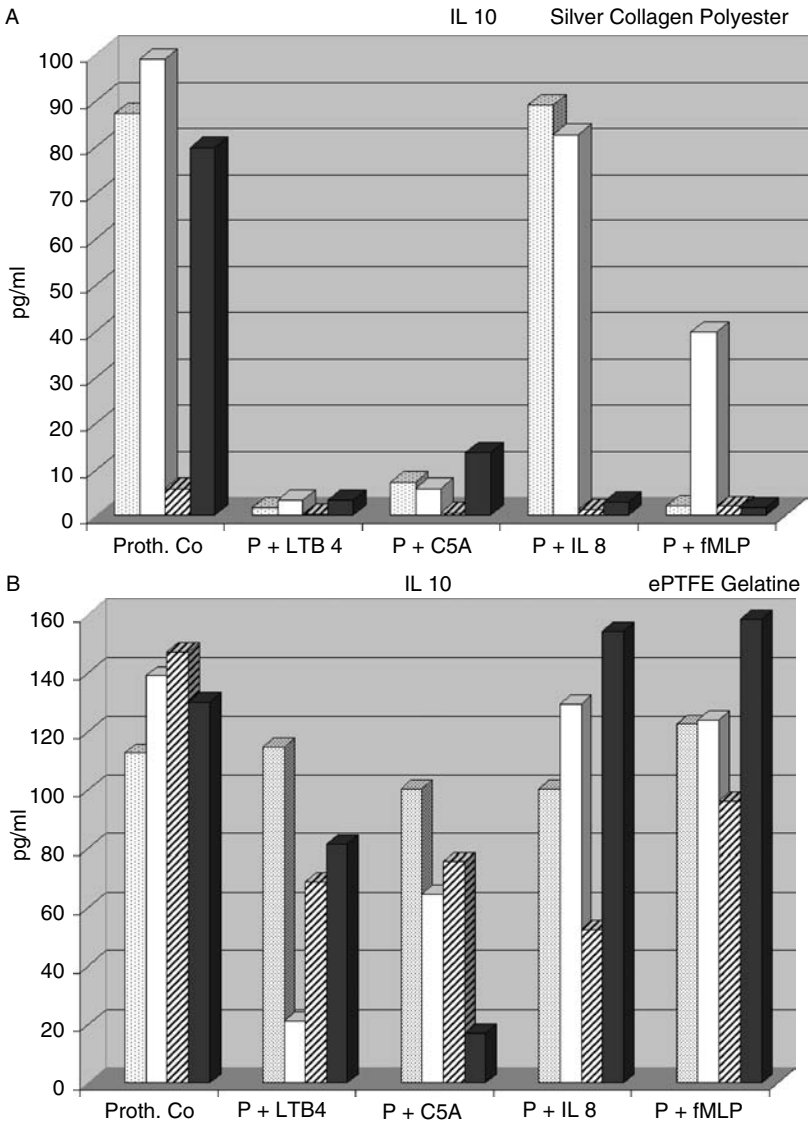

**FIGURE 54.9** IL-10 release from human peripheral mononuclear cells (PBMC).
PBMC ($1\times10^6$) were preincubated with bioprosthetic (P) devices, coated with $LTB_4$ (100 ng/ml), C5a (100 ng/ml), IL-8 (10 ng/ml), fMLP (0.1 µmol/ml) for 24 hours. Subsequently, they were stimulated with buffer (▨), SEB (□ 10 ng/ml); PMA (▨ 25 ng/ml); NaF (■ 5 nM) for further 24 hours. IL-10 was analyzed from the supernatant. Bioprosthetic devices: **A** – silver collagen polyester, **B** – ePTFE gelatine.

The results thus indicate that microbial toxins and exoproducts will bind to biopolymers and thus are responsible for induction of aseptic and most likely septic inflammation by facilitating the adherence of various bacteria. A more detailed analysis will contribute to our understanding of the role of bacterial protein toxins and/or microbial exoproducts when discussing immunopathological reactions induced by alloplastic devices.

## CONCLUSION

Our current knowledge of the strategies used by bacteria to interfere with innate and adaptive immunity and escape host defenses is largely incomplete. Nevertheless, the diverse disciplines in immunology, microbiology, infectious diseases, and cell biology have contributed much to the exciting progress we have made over recent years (Iwasaki and Medzhitov, 2004; Kanaoka and Boyce, 2004; Kaufmann *et al*., 2004; Schaffner *et al*., 2004; Stock *et al*., 2004; Yao *et al*., 1999). Today, sophisticated biochemical and genetic tools are being used to elucidate the molecular details surrounding host-pathogen interactions. These studies continue to provide detailed information on basic cellular mechanisms and offer novel avenues of potential chemotherapeutic intervention and even the possibility of introducing beneficial agents into eukaryotic cells. However, bacterial proteins including toxins can enter the cells, they can integrate themselves, and sometimes they abuse eukaryotic signaling mechanisms or deviate the immune response by their mimicry (Müllbacher *et al*., 2004; Nagata, 1997; Ruckdeschel *et al*., 2004).

Although a wide range of microbe-host relation ships can ultimately lead to disease, the two most general strategies used by pathogenic microbes may be

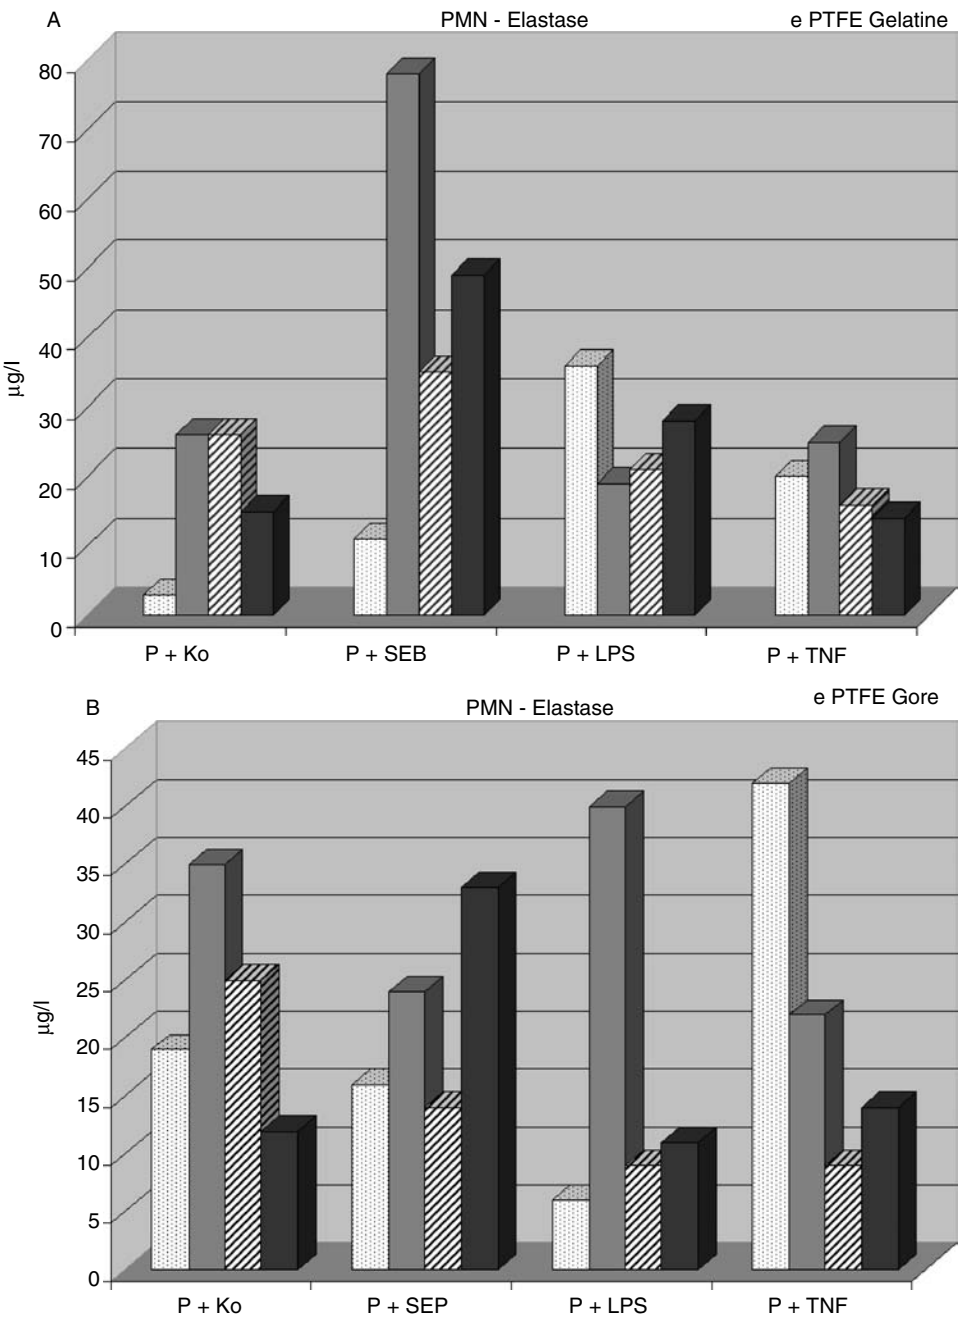

**FIGURE 54.10** Elastase release from human neutrophils in the presence of bioprosthetic devices (P) coated with various ligands SEB (10 ng/ml), LPS (500 pg/ml), TNF (100 U/ml). Neutrophils ($1\times10^6$/ml) were preincubated for 20 minutes and subsequently incubated with phosphate buffer (▨), fMLP (■);0.05 µmol/ml), PMA (▨); 25 ng/ml), NaF (■); 10 nM).
Bioprosthetic devices: **A** – ePTFE gelatine, **B** – ePTFE gore. Elastase release was analyzed from the cell supernatant.

described in military terms as "frontal" and "stealth" assaults. Pathogenic microorganisms make use of both of these approaches. Typically, frontal assault strategies require that the infecting microbes rapidly replicate, induce disease symptoms that overwhelm the innate defences of the host, and find a new host before engagement of the "adaptive" or "acquired" immune system, in which antigen-specific lymphocytes respond to antigen exposure. Stealth assaults, on the other hand, typically involve a slower infection process, in which the microbes subvert the host's innate and adaptive immune systems to set up a chronic or persistent infection. Bacterial protein toxins make use of both strategies.

Currently, we have to extend our views as to the effect of bacterial protein toxins by considering that toxins and other microbial exoproducts and/or microorganisms combined interact with host immune effector cells and furthermore that within bacterial biofilms toxins may exert persisting effects on the host immune response. The latter mechanisms are presently poorly understood and represent a future challenge in basic and clinical research.

## ACKNOWLEDGMENTS

The excellent secretarial support of Mrs. Kerstin Brennecke and Mrs. Marion Rentsch is greatly appreciated.

CHAPTER

# 55

# Clostridial toxins in the pathogenesis of gas gangrene

*Amy E. Bryant and Dennis L. Stevens*

## INTRODUCTION

The genus *Clostridium* encompasses over 60 species of Gram-positive anaerobic spore-forming rods that cause a variety of infections in humans and animals. Strains of clostridia, such as *C. perfringens, C. histolyticum, C. septicum*, *C. novyi*, and *C. sordellii,* cause aggressive necrotizing or histotoxic infections of the soft tissues, attributable in part to the elaboration of bacterial proteases, phospholipases, and cytotoxins (Table 55.1). Historically, the major lethal toxins of the clostridia were assigned Greek letters, with the letter "α" always used to designate the most potent or most significant lethal factor (Table 55.1). A marvelous review of these data can be found in the monograph by Smith (Smith, 1975b). Over the last 50 years, modern science has provided a greater understanding of mecha nisms of action of some of these factors.

The term "histotoxic clostridial infection" historically referred to gas gangrene and malignant edema in humans and blackleg in cattle. More recently, novel histotoxic infections have been described, such as necrotic enteritis, neutropenic enterocolitis, and spontaneous gas gangrene—all of which occur exclusively in humans—and abomasal ulceration in cattle (Table 55.1). In each case, the infection is rapidly progressive, associated with gas in tissue, and manifests impressive tissue destruction, shock, and frequently death. This review chapter will discuss briefly the clinical characteristics of some of these infections and will describe the role of extracellular toxins in the manifestations of disease.

## THE MAJOR HISTOTOXIC CLOSTRIDIAL INFECTIONS

### Traumatic gas gangrene

Gas gangrene, or clostridial myonecrosis, is one of the most fulminant Gram-positive infections of humans. A well-known complication of battlefield injuries, clostridial gas gangrene can develop rapidly (within 6–8 hrs) following any trauma that is sufficient to compromise the blood supply (crush injury, gunshot or knife wound, open fractures). *Clostridium perfringens* is isolated in over 80% of such infections, the remaining cases being caused by *C. septicum*, *C. novyi* type A, *C. histolyticum*, and *C. bifermentans*. Gas gangrene is characterized by excruciating pain at the infection site (MacLennan, 1962), the onset of which is "sometimes so sudden as to suggest a vascular catastrophe" (MacLennan, 1962). Destruction of healthy tissue can occur at a rate of several inches per hour despite appropriate antibiotic therapy (McNee and Dunn, 1917; MacLennan, 1962), and radical amputation remains the single best lifesaving treatment. Shock and organ failure frequently accompany gas gangrene and when patients become bacteremic, the mortality exceeds 50%.

The mechanisms responsible for the early onset of severe pain and the rapid regional destruction of tissues in this infection have not been completely elucidated; however, toxin-mediated microvascular thrombosis contributes to reduced tissue perfusion,

**TABLE 55.1** Major virulence factors of the histotoxic clostridia

| Clinical Infection | Organism | Virulence Factor | Mechanism of Action |
|---|---|---|---|
| Traumatic gas gangrene | *Clostridium perfringens* Type A | alpha toxin | phospholipase C |
| | | theta toxin | cholesterol-dependent cytolysin |
| | | kappa toxin | collagenase |
| | | mu toxin | hyaluronidase |
| | | nu antigen | deoxyribonuclease |
| Traumatic gas gangrene | *Clostridium histolyticum* | alpha toxin | non-hemolytic, cytotoxic, lethal, antigenically related to alpha toxin of *C. septicum* |
| | | beta toxin | collagenase |
| | | gamma toxin | thiol-activated protease |
| | | delta toxin | elastase |
| | | epsilon toxin | thiol-activated, cholesterol-binding cytolysin |
| Traumatic gas gangrene | *Clostridium novyi* | alpha toxin | large clostridial cytotoxin with glycosyltransferase activity; modifies small GTPases controlling actin cytokeleton; dermonecrotic, causes gelatinous edema |
| | | gamma toxin | phospholipase C |
| | | delta toxin | thiol-activated, cholesterol-dependent cytolysin |
| Traumatic or spontaneous gas gangrene; Neutropenic enterocolitis in humans | *Clostridium septicum* | alpha toxin | cytotoxic, lethal, hemolytic, antigenically related to alpha toxin of *C. histolyticum* |
| | | beta toxin | deoxyribonuclease |
| | | gamma toxin | hyaluronidase |
| | | delta toxin | cholesterol-dependent cytolysin |
| Gas gangrene and malignant edema | *Clostridium sordellii* | alpha toxin | phospholipase C |
| | | beta toxin | "edema producing factor" |
| | | gamma toxin | protease |
| | | ? | phospholipase A |
| | | ? | lysolecithinase |
| | | ? | thiol-activated cytolysin |
| | | ? Lethal Toxin (LT) and Hemorrhagic Toxin (HT) | large clostridial cytotoxins with glycosyltransferase activity; modifies small GTPases controlling actin cytokeleton |
| Enteritis necroticans | *Clostridium perfringens* Type C | beta toxin | cytolytic for intestinal villi |
| Abomasal ulceration in cattle | *Clostridium perfringens* Type A | see above | |
| Blackleg in cattle | *Clostridium chauvoei* | alpha toxin | lethal, necrotizing |
| | | beta toxin | deoxyribonuclease |
| | | gamma toxin | hyaluronidase |
| | | delta toxin | thiol-activated cytolysin |

hypoxia, and subsequent regional tissue necrosis. Clinical observations support this concept. First, the speed with which skin, subcutaneous tissue, fascia, and muscle are destroyed in gas gangrene is similar to the rate of tissue death following acute arterial thrombosis. Second, intense pain is a prominent feature in clinical conditions that involve occlusion of the arterial blood supply, such as myocardial infarction. Third, tissues that are being rapidly destroyed in the progression of gas gangrene do not bleed. This classic observation has become dictum for surgeons who routinely remove necrotic tissue until bleeding is encountered. Indeed, tissues from experimental animals in the early stages of gas gangrene demonstrate numerous occlusive thrombi throughout adjacent musculature. Taken together, these observations suggest that severe pain and rapid tissue destruction associated with clostridial gas gangrene result from vascular occlusion that begins as a local ischemic process and expands regionally until an entire limb is destroyed.

## Spontaneous, non-traumatic gas gangrene due to *Clostridium septicum*

Spontaneous gas gangrene is characterized by the abrupt onset of excruciating pain and a heavy sensation or numbness of the affected limb (MacLennan, 1962; Alpern and Dowell, Jr., 1969; Smith, 1975b; Stevens *et al*., 1990; Johnson *et al*., 1994). In this instance, *C. septicum* is the principal etiologic agent. Extremely rapid progression of gangrene follows, with demonstrable gas in the tissues, marked swelling, and the

appearance of hemorrhagic bullae in the overlying skin. The skin itself often has a purple hue, likely reflecting vascular compromise resulting from bacterial toxins diffusing into surrounding tissues (Stevens *et al*., 1990). Histopathology of the affected soft tissues demonstrates cell lysis, gas formation, and a notable absence of acute inflammatory cells (Stevens *et al*., 1990). The mortality of spontaneous gangrene ranges from 67–100%, with the majority of deaths occurring within 24 hours of onset. Predisposing host factors include colonic carcinoma, diverticulitis, and gastrointestinal surgery—pathologies that permit bacterial access from the intestine to the bloodstream from which the aerotolerant *C. septicum* can seed and proliferate in normal tissues (Smith, 1975b).

*C. septicum* produces four main toxins (Table 55.1): alpha toxin (α, lethal, hemolytic, necrotizing activity); beta toxin (β, DNase); gamma toxin (γ, hyaluronidase); and delta toxin (δ, septicolysin, an oxygen labile hemolysin) (Smith, 1975b). The *C. septicum* alpha toxin does not possess phospholipase activity and is thus distinct from the alpha toxin of *C. perfringens*. Active immunization against alpha toxin significantly protects against challenge with viable *C. septicum* (Ballard *et al*., 1992). The alpha toxin is secreted as an inactive prototoxin that is cleaved near the C-terminus by eukaryotic proteases, such as trypsin or membrane-bound furin, to form the active toxin (Gordon *et al*., 1997). The toxin then oligomerizes on the membrane and inserts, forming a membrane pore and resulting in colloid-osmotic lysis (Sellman *et al*., 1997). It is unclear at this point in time just how these virulence factors cause tissue necrosis.

## Necrotizing enteritis

Defects in the immune system, such as leukemia, neutropenia (cyclic, congenital, or acquired), lymphoproliferative disorders, and more recently, AIDS (Alpern and Dowell, Jr., 1969; Stevens *et al*., 1990; Johnson *et al*., 1994) or those induced by cancer chemotherapy and radiation therapy, also predispose to *C. septicum* infection (Farnell, 1987; Bartlett, 1990; Gorbach, 1992). Neutropenia in particular is associated with necrotizing enterocolitis (Farnell, 1987)—a fulminant form of enteritis characterized by copious watery diarrhea, abdominal pain, and distention, and systemic signs of toxicity such as tachycardia, fever, and delirium. Rupture of the bowel with peritonitis and bacteremia results in death in 100% of cases. In most cases, immunofluorescence studies demonstrate invasion of the bowel wall by *C. septicum*.

Other forms of necrotizing enteritis have occurred endemically in New Guinea (e.g., pigbel, Lawrence and Walker, 1976), in epidemic proportion in Germany following World War II (Guerrant, 1990), and sporadically in Africa, Southeast Asia, and the United States (Bartlett, 1990; Gorbach, 1992). All cases are associated with the ingestion of meats contaminated with *C. perfringens* type C. Clinical courses vary between abdominal pain, fever, and diarrhea, which resolves spontaneously, to bloody diarrhea, ruptured bowel, and death. Beta toxin from *C perfringens* type C, which paralyzes the intestinal villi and causes necrosis of the bowel wall, is the principal cause of these infections. Predisposing factors include malnutrition, specifically in those with diets low in protein and rich in trypsin inhibitors, such as sweet potato or soy bean (Lawrence and Walker, 1976; Guerrant, 1990). In addition, *Ascaris lumbricoides* is commonly found in such patients, and it, too, secretes a trypsin inhibitor. These protease inhibitors protect beta toxin from intraluminal proteolysis. Immunization of children in New Guinea with a beta toxoid vaccine has dramatically reduced the incidence of this disease (Lawrence *et al*., 1979).

## Lethal, necrotizing clostridial infections in injecting drug users

Recently, outbreaks of severe soft tissue infection have been described among extravascularly injecting drug (heroin) users in Scotland, Ireland, England, and the United States (Centers for Disease Control and Prevention, 2000; McGuigan *et al*., 2002; Jones *et al*., 2002; Kimura *et al*., 2004). Clinical findings included severe injection site necrosis with massive edema and a rapidly fatal systemic illness characterized by hypotension, pulmonary edema, pericardial and pleural effusions, and leukocytosis. Of the 23 definite cases described in the Scottish outbreak, 15 had necrotizing fasciitis, and 20 died (McGuigan *et al*., 2002). Among these, *C. novyi* Type A and *C. perfringens* were the principal isolates (Centers for Disease Control and Prevention, 2000). More recently, similar cases in Europe have been attributed to *C. histolyticum* (Brazier *et al*., 2004). Of the nine cases described in California (Kimura *et al*., 2004), all developed necrotizing fasciitis, marked leukocytosis and hypotension, and four died. Cultures from six of the patients yielded *C. sordellii*. While the mechanisms resulting in necrotizing fasciitis in these infections remain unknown, soft tissue and pulmonary edema, hypotension, and hemoconcentration are likely due to capillary endothelial cell disruption by related members of the large clostridial cytotoxin family, including *C. novyi* alpha toxin and *C. sordellii* hemorrhagic and lethal toxins (Bette *et al*., 1991). These toxins possess glucosyltransferase activity and specifically modify small GTPases (e.g., Rho, Rac, Cdc42),

controlling actin polymerization (Schirmer and Aktories, 2004). In contrast, edema associated with cases of *C. histolyticum* infection may be related to beta toxin (i.e., collagenase)–induced production of bradykinin (Legat *et al*., 1994).

## THE ROLE OF EXOTOXINS IN C. *PERFRINGENS* GAS GANGRENE

### The major C. *perfringens* exotoxins

Of the myriad of extracellular toxins produced by *C. perfringens* (Table 55.1), only alpha and theta toxins have been implicated in pathogenesis. Alpha toxin is a lethal, hemolytic toxin that has both phospholipase C and sphingomyelinase activities. Two recent independent studies have demonstrated that alpha toxin is an essential toxin in the disease process. First, an alpha toxin gene (*plc*) deficient mutant was shown to be avirulent in a mouse myonecrosis model (Awad *et al*., 1995). Complementation of the chromosomal mutation with a recombinant plasmid carrying a wild-type *plc* gene restored the ability to cause disease. Second, vaccination with the C-terminal alpha toxin domain (amino acids 247 to 370) has been shown to protect mice from experimental *C. perfringens* infection (Williamson and Titball, 1993) in part, by improving tissue perfusion and restoring the tissue inflammatory response (Stevens *et al*., 2004).

Theta toxin (also known as perfringolysin O, PFO) is a member of the thiol-activated, now termed cholesterol-dependent, cytolysin family (CDCs) that includes streptolysin O, pneumolysin, listeriolysin, septicolysin, and others (Alouf and Geoffroy, 1991). These pore-forming toxins contain a conserved ECTGLAWEWWR amino acid motif. Despite its hemolytic activity, theta toxin, by itself, is not essential in causing mortality since isogenic mutant strains lacking an intact theta toxin structural gene (*pfoA*) are still lethal in the mouse myonecrosis model (Awad *et al*., 1995). However, these same genetic studies, as well as passive immunization studies in mice (Bryant *et al*., 1993), suggest that theta toxin does contribute to pathogenesis by enhancing the morbidity associated with gas gangrene, likely via its effects on cells of the vascular and immune systems (Bryant *et al*., 1993; Bryant and Stevens, 1996; Stevens *et al*., 1997).

### Stages in the pathogenesis of C. *perfringens* gas gangrene

The development of gas gangrene occurs in five distinct stages, and alpha and theta toxins feature prominently in disease progression.

#### *Stage 1: Introduction of* C. perfringens *into devitalized tissue*

Vegetative clostridia or their spores often contaminate traumatic wounds; however, proliferation of *C. perfringens* in tissue requires trauma sufficient to interrupt the blood supply to large muscle groups. Loss of perfusion rapidly results in a drop in oxidation reduction potential from +170 to +50 mV, which, at neutral pH, is sufficient for growth of most anaerobic bacteria including the clostridia. Hypoxic muscle shifts to anaerobic metabolism, producing a lactic acid–driven increase in hydrogen ion concentration that allows clostridia to proliferate at oxidation reduction potentials higher than +50 mV (Smith, 1975b). In addition, hypoxia induces release of endogenous lysosomal enzymes that convert muscle protein into peptides that are vital to clostridial growth and toxin production (Smith, 1975a). Interestingly, intramuscular injection of recombinant alpha toxin in experimental animals results in a major drop in local pH as measured by nuclear magnetic resonance imaging (D.L. Stevens, unpublished observations).

#### *Stage 2: Proliferation of organisms*

As organisms begin to proliferate locally, end products of bacterial metabolism further reduce tissue pH, and bacterial proteases continue tissue degradation, thereby optimizing conditions for continued growth and toxin production. Production of *C. perfringens* alpha toxin increases in the presence of (i) peptides containing glycine and branched chain amino acids such as valine, or tyrosine-containing peptides of low molecular weight; (ii) a carbohydrate source of starch, dextran, or fructose, but not glucose; (iii) pH below 7.0; (iv) total electrolyte concentration of 0.1–0.15 M with a ratio of sodium to potassium of 2:1.

#### *Stage 3: Attenuation of the tissue inflammatory response*

Histologically, gas gangrene is characterized by the virtual absence of a tissue inflammatory response and is thus distinctly different from infections caused by bacteria such as *Staphylococcus aureus*, *Hemophilus influenzae*, or *Streptococcus pneumoniae* in which an abundant pyogenic tissue inflammatory response is the norm. Studies performed during the first half of the twentieth century suggested that this characteristic finding was bacterial toxin–mediated (McNee and Dunn, 1917). A 1917 report in the *British Medical Journal* described the histopathology of serial sections of single muscle bundles from freshly amputated limbs of soldiers with gas gangrene (McNee and Dunn, 1917). At the advancing edge of the infection, few organisms were present and muscle fibers appeared ischemic and necrotic,

being degraded by a toxic fluid that spread between the fibers in advance of the organisms themselves. Leucocytes were "generally conspicuous by their absence" from involved tissues but were seen in the interfascial planes (McNee and Dunn, 1917). In this region, leukocytes exhibited altered morphology and karyolysis (Robb-Smith, 1945), suggesting that the clostridial exotoxins were directly cytotoxic.

This characteristic lack of a tissue inflammatory response in *C. perfringens* gas gangrene is, at first, surprising since the organism is known to activate the complement cascade with the generation of serum-derived chemotactic factors and opsonins via the alternative complement pathway (Stevens *et al*., 1987). In addition, alpha toxin is known to stimulate production of the potent chemokine interleukin-8 (IL-8) (Bryant and Stevens, 1996) and to up-regulate endothelial cell adherence molecules necessary for diapedesis (Bryant and Stevens, 1996; Bunting *et al*., 1997). Thus, a normal inflammatory response to *C. perfringens* infection should result. Indeed, this initial immune response likely arrests bacterial proliferation in most patients since progression to full-blown clinical gas gangrene develops in only 0.03–5.2% of traumatic open wounds despite the fact that 4–39% of these wounds are contaminated with histotoxic clostridial species (Altemeier and Fullen, 1971).

However, in those patients who develop clinically recognized clostridial gas gangrene (Stevens, 1995), and in experimental wild-type *C. perfringens* infection (Bryant *et al*., 1993), the lack of a tissue inflammatory response and concomitant vascular leukostasis are hallmark features. Alpha and theta toxins each uniquely contribute to these pathologies. Experimental histopathology studies demonstrated that the robust tissue inflammatory response to killed, washed *C. perfringens* could be completely inhibited by either a crude clostridial toxin preparation (Robb-Smith, 1945), or recombinant clostridial alpha (Bryant *et al*., 1995) or theta toxins (Bryant *et al*., 1993). Instead, leukocytes accumulated within small vessels near the demarcation between healthy and necrotic tissues (Bryant *et al*., 1993). Similarly, roles for both theta and alpha toxins in the anti-inflammatory response has been demonstrated in studies utilizing isogenic mutants strains of *C. perfringens* lacking these toxins (Awad *et al*., 1995; Stevens *et al*., 1997). More recently, immunization against the C-domain of alpha toxin, which was 100% protective against live challenge, restored the local inflammatory response (Stevens *et al*., 2004) (Figure 55.1). Since production of both alpha and theta toxins occurs at the site of the experimental infection by 4 hrs (Noyes *et al*., 1964), the earliest events of the initial encounter of the host immune system with the pathogenic organism determine the outcome of infection.

The mechanism of attenuation of the host's inflammatory response can be inferred from *in vitro* studies demonstrating direct and unique concentration-dependent effects of alpha and theta toxins on leukocyte structure and function. Specifically, low concentrations of theta toxin prime PMNL for increased respiratory burst activity and superoxide anion generation (Stevens *et al*., 1987; Bryant *et al*., 1993) and enhance ingestion of complement-opsonized particles due to theta toxin–induced functional up-regulation of complement receptor 3 (CR3, CD11b/CD18) on neutrophils (Bryant

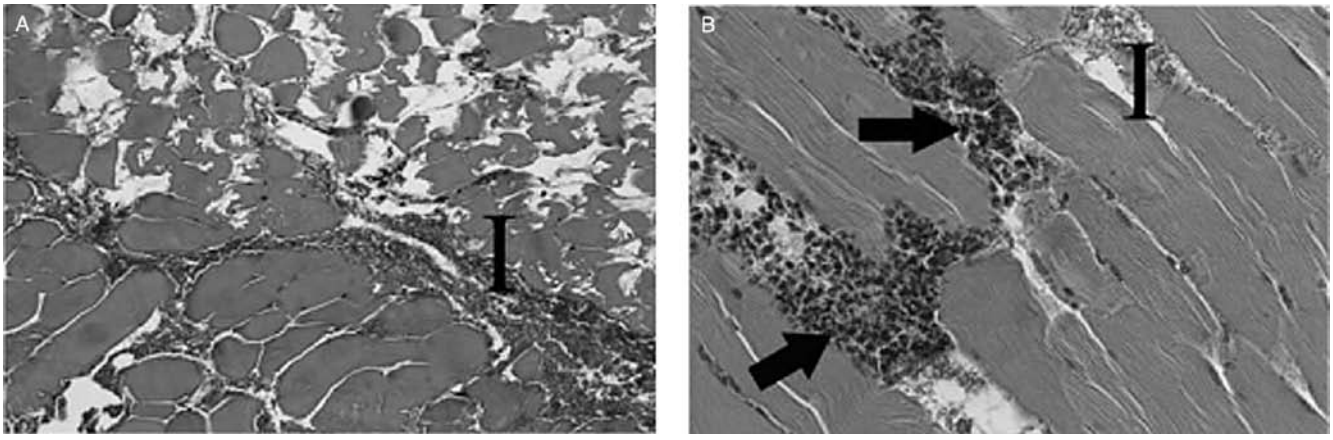

**FIGURE 55.1** Immunization with the C-domain of *C. perfringens* PLC restores the tissue inflammatory response. Mice were immunized against adjuvant alone (sham) or adjuvant plus the C-domain of *C. perfringens* PLC and then infected intramuscularly with $3.75\times10^8$ washed, log phase *C. perfringens* ATCC 13124 in the right thigh. At 1 hr post infection, tissue from the infected site was harvested and processed for routine hematoxylin/eosin staining. Sham-immunized animals (A) had extensive tissue necrosis and infiltrating PMNL were absent. In contrast, in the C-domain immunized animals (B), muscle had a relatively good appearance and PMNL influx was clearly visible. I = bacterial inoculum. Solid arrows indicate infiltrating PMNL.

*et al*., 1993). At higher concentrations, theta toxin significantly impairs these functions, decreases PMNL viability (Stevens *et al*., 1987), induces a hyperadhesive state (Stevens *et al*., 1987; Bryant *et al*., 1993), and causes desensitization of chemotactic factor receptors (Bryant and Stevens, 1996). These latter two effects specifically abrogate neutrophil directed migration.

The effects of alpha toxin on phagocyte function are no less remarkable. Alpha toxin primes resting PMNL respiratory burst in response to opsonized zymosan with resultant maximal generation of oxygen radical production (Stevens *et al*., 1987; Bryant *et al*., 1991). Morphologically, PMNL treated with alpha toxin assume a cytokineplast form with multiple daughter cells connected by a cytoplasmic bridge (Stevens *et al*., 1989; Bryant *et al*., 1991). Premature priming of cells derails anaerobic glycolysis in favor of hexose monophosphate shunt activity, subverting generation of ATP necessary for the cytoskeletal rearrangements involved in chemotaxis and ingestion.

The net effect is an inhibition of the tissue inflammatory response and an increase in the adherence of highly activated PMNL to vascular endothelium—a scenario that not only leaves the infection unchecked, but also promotes vascular injury.

### *Stage 4: Progression of local and regional tissue destruction*

*Platelet-mediated microvascular thrombosis*

Platelet aggregation is a well-known biological effect of *C. perfringens* alpha toxin, having been described since the mid-1970s (Sugahara *et al*., 1976). Topical application of alpha toxin to the mesentery of rats revealed platelet thrombi in adjacent vessels that occluded mesenteric blood flow, leading the investigators to conclude that thrombosis was likely an early step in the pathogenesis of necrosis due to alpha toxin (Ohsaka *et al*., 1978). Similarly, we have recently demonstrated that intramuscular injection of *C. perfringens* alpha toxin induced a rapid (less than 2 min) and irreversible decline in skeletal muscle perfusion that occurred concomitantly with the formation of intravascular aggregates of activated platelets, leukocytes, and fibrin (Bryant *et al*., 2000b) (Figure 55.2). These aggregates were freely moving until achieving sufficient size to completely and irreversibly occlude capillaries, venules, and arterioles (Figure 55.3). Only at the later stages did these heterotypic aggregates appear fixed to the endothelium (Bryant *et al*., 2000a; Bryant *et al*., 2000b).

This sequence of events was strikingly different from that which occurs following traumatic vessel injury in which tethering of platelets to the injured site is mediated by platelet gpIbα binding to von Willebrand factor (Ruggeri, 1997). This adhesion then stimulates "outside-in" signaling events that result in activation of the platelet fibrinogen receptor gpIIbIIIa (Lipfert *et al*., 1992; Law *et al*., 1996) and in redistribution of platelet membrane phospholipids. These events promote the adherence of additional platelets and interactions with elements of the clotting cascade to generate a highly localized clot.

However, the appearance of non-adherent, freely mobile and growing platelet/leukocyte aggregates suggested that alpha toxin induces cellular aggregation

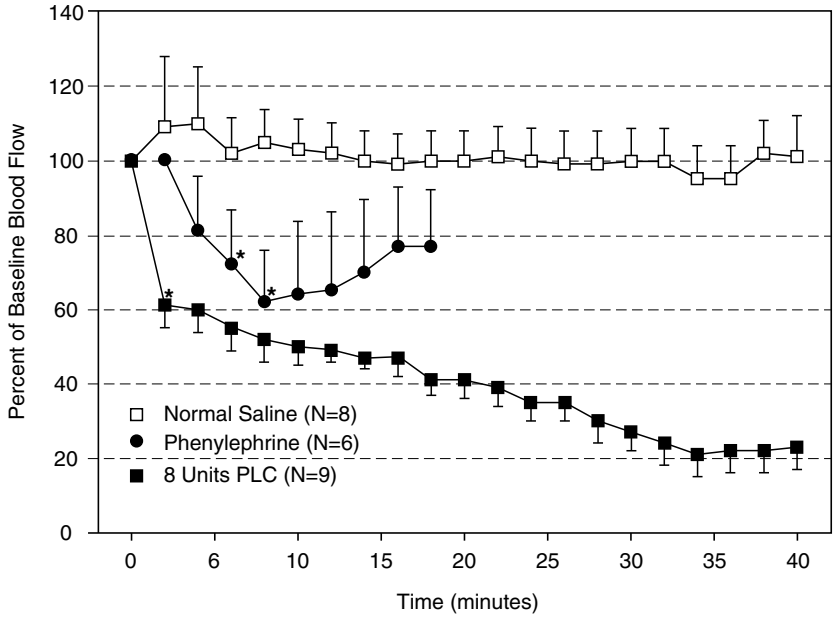

**FIGURE 55.2** Intramuscular injection of clostridial toxins irreversibly reduces muscle perfusion. Rat abdominal muscles were injected with 0.1 mL of either normal saline, a clostridial toxin preparation diluted to contain 8 units of PLC activity, or the vasoconstrictor phenylephrine. Blood flow was measured by a laser Doppler blood perfusion monitor and was expressed as the percent of baseline perfusion ± standard error. Phenylephrine transiently reduced perfusion. In contrast, toxin-induced perfusion deficits were progressive and irreversible.

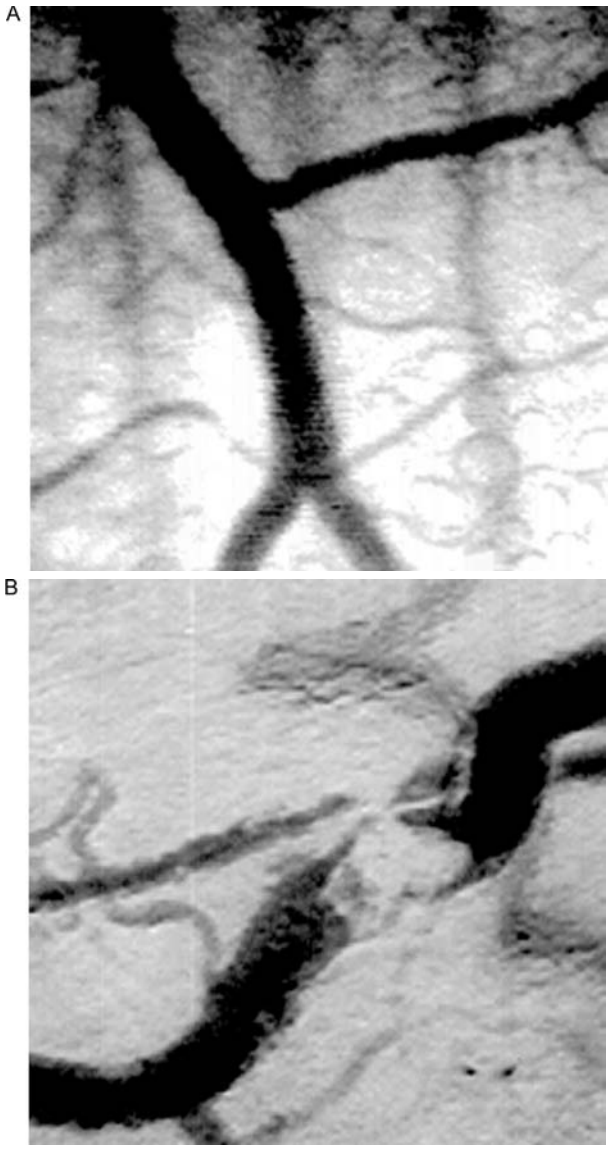

**FIGURE 55.3** Toxin-induced intravascular aggregates block blood flow in venules and arterioles. Still image of intravascular aggregates in vessels taken from representative videotapes following intramuscular injection of saline or a clostridial toxin preparation containing 8 U PLC. Venule under baseline conditions (i.e., before toxin injection); magnification = 210× (A). Venule and arteriole at 11 min after toxin injection (B). Both the large venule and the adjacent smaller arteriole are occluded by large stationary aggregates; magnification = 267×.

in a completely different manner. For circulating platelets to co-aggregate and to bind other cell types, a conformational change in platelet gpIIbIIIa is necessary to permit fibrinogen binding (Blockmans *et al*., 1995). Indeed, flow cytometric analyses of alpha toxin–treated whole blood demonstrated that the formation of both platelet/platelet and platelet/leukocyte aggregates was mediated by the activation of platelet gpIIbIIIa (Bryant *et al*., 2000a). Alpha toxin–induced activation of gpIIbIIIa was highly calcium dependent since pharmacologic inhibitors of intracellular calcium release and of store-operated plasma membrane calcium channels blocked gpIIbIIIa activation (Bryant *et al*., 2003). Surprisingly, alpha toxin–induced activation of gpIIbIIIa was protein kinase C (PKC)–independent despite the fact that PKC was strongly activated by alpha toxin treatment (Bryant *et al*., 2003). This finding was unexpected since most agonists that directly or indirectly activate PKC also activate gpIIbIIIa. However, treatment of platelets with *C. perfringens* alpha toxin resulted in the proteolytic cleavage of soluble PKC into a calcium- and phosphospholipid-independent, but enzymatically active, low molecular weight form of the kinase (Tapley and Murray, 1984) that does not support gpIIbIIIa activation.

Thus, alpha toxin initiates an "inside-out" signaling cascade that begins with depletion of internal calcium stores, is sustained by an influx of calcium through store-sensitive channels, and culminates in functional activation in gpIIbIIIa. Further, the lack of involvement of PKC suggests that the response to alpha toxin does not follow receptor-linked, G-protein-mediated signaling with inositol trisphosphate generation. This conclusion is further supported by the fact that $PGE_1$, a known inhibitor of Gαi-mediated signaling, had no effect on alpha toxin-induced activation of gpIIbIIIa (Bryant *et al*., 2003). Instead, neutralization studies with monoclonal antibody against alpha toxin suggest that activation of gpIIbIIIa is a direct consequence of the toxin's phospholipase C and/or sphingomyelinase activities and not receptor occupancy. This model does not, however, exclude a potentiating role of other mediators (e.g., thromboxane production) in the alpha toxin–induced effects.

*Leukostasis and vascular injury*

Experimental studies (Bryant *et al*., 1993; Stevens *et al*., 1997), as well as classical clinical observations (McNee and Dunn, 1917), demonstrate not only an absence of PMNL at the site of active infection (see above), but also accumulation of PMNL within the post-capillary venules. Binding of neutrophils to endothelial cells is a multi-step process involving numerous adherence molecules on both cell types, and while many of these are required for normal margination and diapedesis, hyperadhesion of neutrophils promotes vascular injury and disrupts chemotaxis. *In vitro* studies suggest that theta toxin and alpha toxin each up-regulate early (i.e., rapidly expressed) endothelial adherence molecules, P-selectin (Bunting *et al*., 1997; Bryant *et al*., 2000b), and platelet activating factor (PAF) (Whatley *et al*., 1989; Bunting *et al*., 1997). Theta toxin-induced

PAF synthesis follows phospholipase $A_2$ ($PLA_2$) activation induced by the influx of calcium through membrane pores formed by theta toxin. $PLA_2$ hydrolysis of phosphatidylcholine releases arachidonic acid, and subsequent incorporation of acetyl-CoA into the Sn-2 position of lysophosphatidylcholine yields PAF (Whatley *et al*., 1989). Alpha toxin, via its sphingomyelinase and phospholipase C activities, produces the intracellular messengers ceramide (Ochi *et al*., 2004) and diacylglycerol, leading to activation of protein kinase C and generation of PAF (Bunting *et al*., 1997).

In contrast to the rapidly expressed endothelial cell adherence molecules, alpha and theta toxins have dichotomous effects on those adherence molecules that required *de novo* protein synthesis. Specifically, alpha toxin markedly up-regulates both E-selectin and ICAM-1 by 4 and 12 hr, respectively, whereas theta toxin stimulates only ICAM-1 expression (Bryant and Stevens, 1996). Additionally, theta toxin functio nally and quantitatively up-regulates neutrophil CD11b/CD18 (Bryant *et al*., 1993) (Figure 55.4). Coincubation of PMNL and endothelial cells in the presence of theta toxin demonstrates tight adherence of PMNL to endothelium via a CD11b/ CD18 mechanism (Bryant *et al*., 1993). Occurring *in vivo*, such adherence could attenuate blood flow and damage endothelial cells by neutrophil-dependent mechanisms such as degranulation (release of hydrolytic enzymes) and oxygen radical production (Stevens *et al*., 1997).

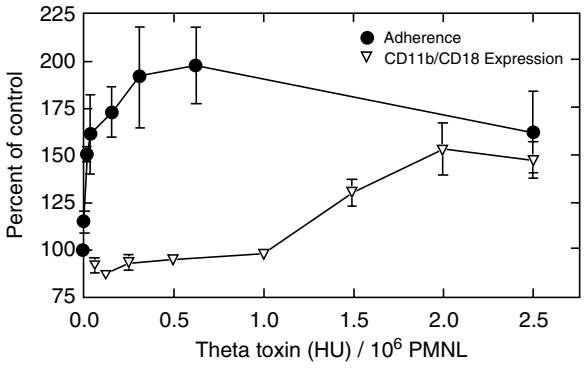

**FIGURE 55.4** Theta toxin functionally up-regulates neutrophil CD11b/CD18. Purified PMNL were exposed to increasing concentrations of recombinant theta toxin. Adherence of PMNL to gelatin-coated tissue culture wells (a CD11b-dependent event) and surface expression of CD11b were measured by Rose Bengal staining and flow cytometry, respectively. Functional up-regulation of CD11b (i.e., increased adherence) preceded its quantitative increases in surface expression induced by theta toxin.

***Stage 5: Shock and organ failure***

Cardiovascular collapse and end organ failure occur late in the course of gas gangrene. "Tachycardia with feebleness of the pulse has followed the onset of pain and characteristically, has been out of proportion to the degree of elevation of the temperature" (Altemeier and Fullen, 1971). This description offers a striking contrast to the early manifestations of septic shock caused by Gram-negative bacteria such as *Escherichia coli*, where a hyperdynamic picture is most common even in the face of low blood pressure. For example, a rapid heart rate is generally associated with high cardiac outputs and a bounding pulse. In gas gangrene, at the onset of tachycardia, the blood pressure is normal but then drops precipitously. Though these descriptions made in the 1970s are useful, the subsequent clinical literature has not offered more modern measurements of cardiovascular parameters in humans with clostridial gas gangrene. Experimental studies in animals do provide some useful insights into the dynamics of cardiovascular dysfunction induced by *C. perfringens* toxins.

In an awake rabbit model, recombinant theta toxin caused a significant increase in heart rate within 60 min of toxin infusion (Asmuth *et al*., 1995), but did not cause a significant drop in mean arterial pressure. Recombinant alpha toxin caused a significant reduction in blood pressure, but the onset of alpha toxin–induced hypotension was one hour later (i.e., at 180 min post toxin infusion) than that caused by the crude toxin (120 min post toxin). These data suggest additive or even synergistic interactions of alpha and theta toxins on cardiovascular function.

Both recombinant alpha toxin and crude toxin caused significant drops in cardiac index as early as 90 min after infusion of the respective toxins (Asmuth *et al*., 1995), suggesting that one mechanism of cardiovascular dysfunction induced by recombinant alpha toxin could be related to direct myocardial toxicity. Indeed, a direct and dose dependent reduction in myocardial contractility (dF/dt) was found in isolated atrial strips bathed with recombinant alpha toxin (Asmuth *et al*., 1995). Alpha toxin has also been shown to affect the ionotropic cardiac response in isolated embryonic chick heart preparations (Regal and Shigeman, 1980). However, alpha toxin may also contribute indirectly to shock by stimulating production of endogenous mediators, such as tumor necrosis factor (TNF) (Stevens and Bryant, 1997) and PAF (Bunting *et al*., 1997).

Theta toxin reduces systemic vascular resistance and markedly increases cardiac output (Stevens *et al*., 1988; Asmuth *et al*., 1995). This afterload reduction occurs undoubtedly through induction of endogenous

mediators that cause relaxation of blood vessel wall tension, such as PAF and prostaglandin $I_2$ ($PGI_2$) (Whatley *et al*., 1989). Reduced vascular tone develops rapidly, and in order to maintain adequate tissue perfusion, a compensatory host response is required to either increase cardiac output or rapidly expand the intravascular blood volume. In contrast, patients with Gram-negative sepsis compensate for hypotension by markedly increasing cardiac output; however, this adaptive mechanism may not be possible in *C. perfringens*-induced shock due to direct suppression of myocardial contractility by alpha toxin (Stevens *et al*., 1988). Theta toxin, like other thiol-activated cytolysins, likely contributes to septic shock through additional indirect routes, including augmented release of TNF, interleukin-1 (IL-1), and interleukin-6 (IL-6) (Houldsworth *et al*., 1994). The roles of TNF, IL-1, and IL-6, as well as the potent endogenous vasodilators bradykinin and nitric oxide, in shock associated with *C. perfringens* gas gangrene, have not been elucidated.

## CONCLUSION

In summary, in the absence of a host response sufficient to limit bacterial growth, clostridial proliferation is rapid and leads to the local accumulation of toxin. Small amounts of toxin contribute to microvascular thrombosis, reduced perfusion, and extension of the anaerobic environment, whereas higher concentrations inhibit PMNL influx and promote vascular leukostasis. At these concentrations, direct cytotoxicity is observed in emigrated leukocytes, vascular endothelium, and cells of muscle and soft tissues. As more toxin is absorbed, the series of events is propagated regionally until late in the course when the myocardium itself is directly affected, resulting in cardiovascular collapse and death.

CHAPTER

# 56

# Staphylococcal exfoliative toxins

*Shamez N. Ladhani*

## INTRODUCTION

Staphylococcal skin infections remain one of the most common childhood conditions (Ladhani and Garbash, 2005). Of these, the staphylococcal scalded skin syndrome (SSSS) produces the most dramatic skin changes, with exfoliation of almost the entire body surface in severe cases (Ladhani and Evans, 1998; Ladhani *et al*., 1999a; Ladhani and Newson, 2000). While most cases are easily treated, it remains a potentially fatal condition, particularly in adults with underlying disease (Cribier *et al*., 1984). SSSS is caused by the staphylococcal exfoliative toxins, which have an exquisite ability to target and destroy desmoglein-1, a key component of the cytoskeleton in the epidermis (Ladhani, 2001; Ladhani, 2003). This results in disruption of the protective epidermal barrier, which presumably allows the organisms to proliferate and spread beneath this barrier (Amagai *et al*., 2000). At least four different exfoliative toxin serotypes (ETA, ETB, ETC, and ETD) are produced by *Staphylococcus aureus*, of which ETA, ETB, and possibly ETD produce disease in humans. At least six serotypes (SHETA, SHETB, ExhA, ExhB, ExhC, and ExhD) responsible for exudative dermatitis in piglets are produced by *Staphylococcus hyicus* (Sato *et al*., 2000; Ahrens and Andersen, 2004). Although the exfoliative toxins were discovered as far back as 1970, the mechanism by which exfoliation occurs has taken over 30 years to elucidate. This chapter will briefly summarize the clinical spectrum, histological features, risk factors, and the organisms responsible for SSSS and will then focus on the unique serine protease and superantigenic activities of the exfoliative toxins. Potential areas for future research, including development of new diagnostic tests, specific antitoxin therapies, and targeted drug delivery systems, are discussed at the end.

## CLINICAL FEATURES

SSSS was first described in 1878 by Baron Gotfried Ritter von Rittershain, a German physician who called the condition "dermatitis exfoliativa neonatorum" after observing almost 300 pediatric cases in a Czechoslovakian foundling asylum over a 10-year period (von Rittershain, 1878). The clinical features of SSSS vary from localized blisters to severe exfoliation affecting almost the entire body surface (Ladhani and Joannou, 2000). The localized forms of SSSS are also known as bullous impetigo, tropical bullous impetigo, measles pemphigoid, and bullous varicella (Lyell, 1979; Melish, 1982). Epidemiological studies on antitoxin antibodies suggest that, in the localized form, *S. aureus* enters the skin through a break in the skin barrier and produces the toxin locally, but hematogenous spread is limited by the presence of antitoxin antibodies (Melish *et al*., 1981), which may have been acquired from previous exposure to the toxins, for example, or, in young infants, from the mother through the placenta or during breastfeeding (Machida, 1995). Patients usually present with a cluster of characteristic fragile, thin-roofed, flaccid bullae, filled with fluid that varies from cloudy amber to frank pus (Melish, 1982). The surrounding skin remains normal, and there are no systemic symptoms or signs (Ginsburg, 1991). In neonates, the lesions are found mostly on the perineum, around the umbilicus, or both, while in older children, they occur mostly on the extremities (Melish, 1982).

In generalized SSSS (Figure 56.1), which is also known as Ritter's disease and pemphigus neonatorum in neonates, lack of protective host antibodies (Melish *et al*., 1981) allows widespread involvement of the entire skin surface with sparing of the mucous membranes (Melish *et al*., 1974; Pollack, 1996). Generalized SSSS can follow a localized staphylococcal infection of the skin, upper and lower respiratory tracts, the ears, conjunctiva, umbilical stumps, joints, and muscles (Melish, 1982; Wong *et al*., 1993; Bailey *et al*., 1995; Raymond *et al*., 1997), although in many cases, no primary focus is found (Cribier *et al*., 1984). Patients with generalized SSSS initially develop fever, malaise, lethargy, poor feeding, irritability, and a generalized, tender erythematous rash, which usually begins on the head and neck and spreads to the rest of the body over the next few days (Ochsendorf *et al*., 1988; Itani *et al*., 1992; Hoffmann *et al*., 1994). The rash is more marked in flexural creases, and the Nikolsky sign (gentle rubbing of uninvolved or healed skin produces dislodgement of the superficial epidermis) is usually positive. Soon after, large, fragile, thin-roofed blisters appear that rapidly rupture on the slightest pressure, resulting in large sheets of epidermis sloughing off to leave extensive areas of raw, denuded, varnish-like skin. In young infants, loss of the protective epidermis can result in poor temperature control, excessive fluid losses, and secondary infection, which can be fatal (Korting, 1994; Hoffmann *et al*., 1994). They may also develop staphylococcal septic shock and present with hypotension, tachycardia, neutropenia, and respiratory distress (Finch, 1988; Loughead, 1992).

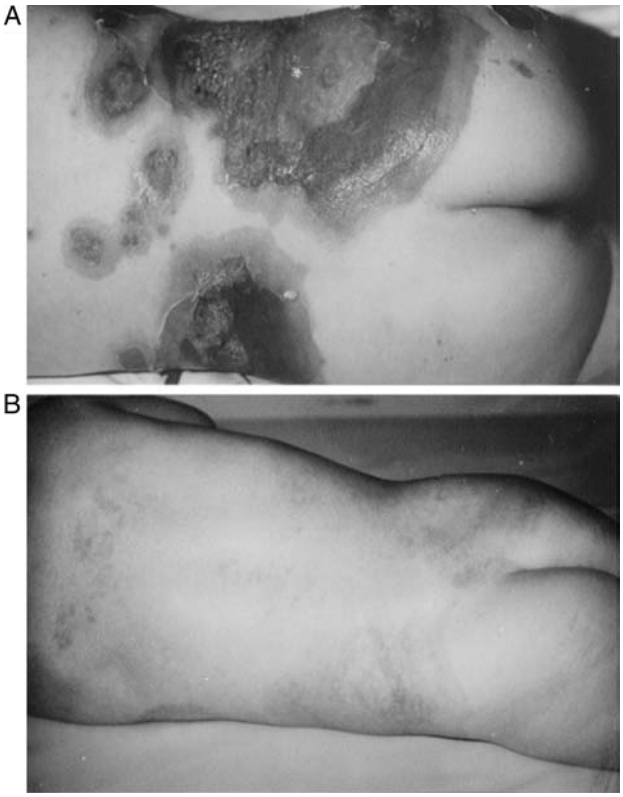

**FIGURE 56.1** (a) A two-year-old boy with generalized staphylococcal scalded skin syndrome. He presented with a 3-day history of fever and an erythematous rash, which evolved into well-demarcated superficial blisters that ruptured on slightest pressure to leave extensive areas of denuded skin. (b) The same boy one week after completing 5 days of intravenous antibiotic treatment. Note that the lesions have healed without scarring. ## THE ORGANISM

SSSS is caused by *Staphylococcus aureus*, an aerobic, nonspore-forming, Gram-positive coccus belonging to the Micrococci family that is found in air, fomites, and dust, and commonly colonizes humans and animals (Lowy, 1998). It can be distinguished from other staphylococcal species on the basis of the yellow pigmentation it produces, β-hemolysis on blood agar, and positive results of coagulase, mannitol-fermentation, and deoxyribonuclease tests. *S. aureus* causes disease in two main ways—local invasion and toxin production. The organism produces a host of proteins and enzymes that are useful for tissue destruction and spread of infection—such as protease, lipase, and hyaluronidase—as well as protection against antibiotics, such as β-lactamases and penicillin-binding proteins. Like other skin commensals, *S. aureus* does not usually cause infection in healthy individuals (Darmstadt, 1997). However, when local barriers are broken, *S. aureus* will cause skin infections and may invade into deeper tissues to cause serious systemic illness (Ladhani and Garbash, 2005). Skin and soft tissue infections are often described as either primary or secondary. Primary infections involve apparently healthy skin with no obvious site of skin break to explain the lesion, while secondary infections occur in diseased skin, such as atopic dermatitis or in previously healthy skin that has been traumatized by, for example, surgery, burns, or bites. *S. aureus* is the most common cause of skin and soft tissue infections, accounting for over half of all organisms isolated in large epidemiological studies (Darmstadt, 1997; Doern *et al*., 1999; Jones *et al*., 1999; Gales *et al*., 2000; Laupland *et al*., 2003). *S. aureus* is responsible for folliculitis, furunculosis, carbunculosis, and cellulitis (Failla and Pankey, 1994; Rhody, 2000; Sharma and Verma, 2001; Chiller *et al*., 2001; Stulberg *et al*., 2002; Mengesha and Bennett, 2002), as well as surgical and traumatic wound infections,

mastitis, and neonatal oomphalitis. Other skin and soft tissue infections may also be caused by *S. aureus*, but are often polymicrobial in origin. These include burns, decubitus ulcers, puncture wounds of the foot where *Pseudomonas aeruginosa* is often implicated, and mammalian bites, which are often co-infected with other multiple antibiotic–resistant organisms (Griego *et al*., 1995). In addition to local invasion, *S. aureus* can cause disease by production of exotoxins, such as enterotoxins, which cause gastroenteritis; toxic shock syndrome toxin-1, which causes the toxic shock syndrome; and the exfoliative toxins, which are responsible for the bullous impetigo and SSSS.

## Staphylococcal virulence factors

Like other major pathogens, *S. aureus* is adapted to identify changes in its environmental conditions and regulate expression of different factors that alter colonization, multiplication, invasion, spread, destruction of host immune defenses, and cause multi-organ failure (Archer, 1998). The pathogenicity of *S. aureus* is multifactorial and depends on a wide range of cell wall–associated (e.g., capsular polysaccharide, Protein A, and fibronectin binding protein) and extracellular virulence factors (e.g., coagulase, hemolysins, enterotoxins, epidermolysins, and synergohymenotropic toxins) produced by the organism (Novick, 2000). The *agr* gene locus controls the expression of most of the virulence factors (including the exfoliative toxins) by increasing the production of extracellular proteins and suppressing the expression of cell surface proteins (Ji *et al*., 1995; Jarraud *et al*., 2003). This locus encodes a two-component signaling pathway whose activating ligand is a bacterial density-sensing, auto-inducing octapeptide that is itself also encoded by the *agr* locus. Four major polymorphisms in the amino acid sequence of either the autoinducing peptide or its corresponding receptor have been described and termed *agr* I–IV, and some polymorphisms may be associated with a specific staphylococcal infection. Generalized exfoliation in the staphylococcal scalded skin syndrome, for example, is associated with *agr* group IV, while toxic shock syndrome is associated with *agr* group III (Ji *et al*., 1997; Jarraud *et al*., 2003).

*S. aureus* produces a range of different virulence factors that are associated with skin and soft tissue infections. One such virulence factor, known as epidermal cell differentiation inhibitor (EDIN), is associated with the exfoliative toxins and SSSS. At least three isoforms of staphylococcal EDIN, which are so called because EDIN-A was first discovered as an inhibitor of morphological differentiation of epidermal keratinocytes *in vitro*, have been reported (Sugai *et al*., 1992). The EDINs belong to the C3 family of bacterial Rho-specific mono-ADP-ribosyltransferases that specifically ribosylate and inactivate small eukaryotic GTPases belonging to the Rho family, which play a vital role in regulating the eukaryotic actin cytoskeleton (Sugai et al., 1992; Yamaguchi *et al*., 2001). The gene for ETB is located within the same pathogenicity island as EDIN-C (Yamaguchi *et al*., 2001), while ETD was discovered in a pathogenicity island that also encodes for EDIN-B (Yamaguchi *et al*., 2002). Pathogenicity islands are mobile DNA segments of variable sizes that encode various virulence genes in over 30 different bacterial species and can be transferred horizontally (Hacker *et al*., 2003; Novick, 2003; Schmidt and Hansel, 2004). LukE-LukD is another virulence factor that is produced by over 75% of *S. aureus* isolates from cases of impetigo, compared to less than a third of isolates from other primary skin infections, routine hospital isolates, or nasal carriers (Gravet *et al*., 2001). LukE-LukD is staphylococcal pore-forming leukotoxin that can induce dermonecrosis in rabbits (Gravet *et al*., 1998). The clinical significance of the association between the exfoliative toxins and such virulence factors and their role in the pathogenesis of SSSS is not clear and warrants further research.

## Epidemiology and risk factors for staphylococcal infections

*S. aureus* remains one of the most important causes of life-threatening bacterial infections in humans (Lowy, 1998; Laupland *et al*., 2004). Large epidemiological studies consistently identify *S. aureus* among the top five causes of bacteremia in all age groups (Reacher *et al*., 2000). Despite advances in the prevention and management of infections, the incidence of both community-acquired and hospital-acquired staphylococcal infections over the past 20 years continues to rise, with little change in mortality rates (Pittet and Wenzel, 1995; Ayliffe 1997; Kallman *et al*., 1997; Archer, 1998; Reacher *et al*., 2000; Laupland *et al*., 2003). This rise parallels more widespread use of invasive procedures, increasing severity of illness in hospitalized patients, poor compliance with infection control practices, increasing selection of antibiotic-resistant strains, intravenous drug abuse, and an increasing prevalence of diabetes (Lowy, 1998; Laupland *et al*., 2003). In the pre-war era, mortality due to invasive *S. aureus* infection was reported to be over 80% and, although the discovery of penicillin and other antibiotics resulted in a dramatic reduction in mortality, it still remains around 25%, with reported mortality rates of 11–43% over the past 25 years (Mylotte *et al*., 1987; Archer, 1998; Laupland *et al*., 2003). People who are colonized with *S. aureus* are at

higher risk for subsequent development of staphylococcal infections (Weinke *et al*., 1992; Wenzel and Perl, 1995; Weinstein, 1995; Kluytmans *et al*., 1995; von Eiff *et al*., 2001; Huang and Platt, 2003). Other predisposing factors for developing staphylococcal infections include immunodeficiency (including HIV), diabetes mellitus, chronic granulomatous disease, defects in the mucocutaneous barriers produced by trauma including surgery, foreign surfaces (sutures, shunts, intravascular catheters), burns, as well as frequent and/or multiple hospital admissions (Drews *et al*., 1995; Raymond and Aujard, 2000; Hudome and Fisher, 2001; Grohskopf *et al*., 2002).

### Commensal carriers of *S. aureus*

Humans are a natural reservoir of *S. aureus*, with 25–50% of the general population being nasal carriers and 10–20% being persistently colonized (Noble *et al*., 1967; Ladhani *et al*., 1999b). Individuals with primary skin disorders (such as atopic dermatitis, contact dermatitis, and psoriasis), underlying diseases (such as diabetes mellitus and acquired immunodeficiency syndrome), those undergoing hemodialysis, and surgical patients, have higher staphylococcal carriage rates of up to 100% (Lowy, 1998; Abeck and Mempel, 1998; Noble, 1998; Hussain *et al*., 2001; Nakamura *et al*., 2002; Arkwright *et al*., 2002). In neonates, *S. aureus* is also commonly found on the skin around the eyes, perineum, wound sites, circumcision wounds, and umbilical stumps (Annunziato and Goldblum, 1978; Opal *et al*., 1988; Dancer *et al*., 1988; Peacock *et al*., 2003). Inanimate objects such as stethoscope bells, ophthalmoscope and otoscope handles, laundry carts, nursery magazines, and ventilation shafts in hospitals may also harbor *S. aureus* and can be responsible for prolonged epidemics of staphylococcal infections in neonatal nurseries (Kaplan *et al*., 1986).

### Exfoliative toxin-producing *S. aureus*

The association between *S. aureus* and SSSS was made as far back as 1891 when Almquist isolated the organism from a patient with pemphigus neonatorum and initially called it *Micrococcus pemphigi neonatorum* (Almquist, 1891). In 1956, Lyell described a skin condition in adults and children that resembled scalded skin and called it toxic epidermal necrolysis (Lyell, 1956). He did not realize that he had described two unrelated conditions until 1967 when he reviewed 128 cases that fitted his diagnostic criteria for toxic epidermal necrolysis and found that almost a quarter—all children under 10 years of age—presented predominantly with staphylococcal infection (Lyell, 1967). Subsequent studies showed that the skin lesions associated with *S. aureus* infection in children occurred specifically within the midepidermal layer of the skin, while in adults the skin lesions were not associated with staphylococcal infection and occurred at the dermoepidermal junction (Lowney *et al*., 1967; Lyell *et al*., 1969; Lyell, 1979).

In Europe and the United States, most *S. aureus* strains responsible for SSSS belong to phage group II, particularly types 71 and 55/71 (Parker *et al*., 1955; Melish and Glasgow, 1970; Dajani, 1972), which account for 7–25% of human *S. aureus* isolates in the United Kingdom (Dancer and Noble 1991). Around 30–40% of phage group II *S. aureus* strains produce exfoliative toxin (Kapral, 1975; Fleurette and Ritter, 1980; Willard *et al*., 1982). In Japan, most strains causing SSSS belong to phage groups other than II (Kondo *et al*., 1974; Sarai *et al*., 1977; Murono *et al*., 1988), and one Nigerian study reported that almost 60% of toxin-producing staphylococcal strains were non-typeable, with phage group II strains accounting for only 18% (Adesiyun *et al*., 1991).

The lack of a suitable and standardized assay for the exfoliative toxins has meant that there is very little literature on the epidemiology of SSSS. One prospective study of 944 *S. aureus* isolates from 577 dermatological patients of all age groups reported a 5.1% carriage rate of exfoliative toxin-producing *S. aureus*, although only 32% of these patients presented with clinical features of SSSS, indicating that a large proportion were simply asymptomatic carriers (Elsner and Hartman, 1988). Another epidemiological survey revealed that 33% of 500 pregnant women attending an antenatal clinic carried at least one strain of *S. aureus* in the nose, axilla, and/or perineum and, of the 184 *S. aureus* isolates, 5 (2.7%) produced exfoliative toxin (Dancer and Noble, 1991). Other studies have reported toxin production in 6% of 2,632 *S. aureus* isolates from hospitalized adults and children (Piemont and Monteil, 1983), 4.4% of 194 isolates from human diarrhea and wounds (Adesiyun *et al*., 1991), 19% of 100 isolates from the mouths of children with dental disease (Miyake *et al*., 1991), and 40% of isolates from superficial skin infections (Arbuthnott, 1981). One Nigerian study reported that 3.9% of 666 *S. aureus* isolates from healthy animals also produced exfoliative toxin; however, their importance as reservoirs for human SSSS is not known (Adesiyun *et al*., 1991).

## THE EXFOLIATIVE TOXINS

Although the presence of a soluble toxin in the pathogenesis of SSSS was suspected as far back as the 1950s (Lyell, 1956), the first clue of its existence came only

after Melish and Glasgow (1970) showed that sterile fluid obtained from intact bullae and sterile supernatant from phage group II *S. aureus* cultures were able to reproduce the skin lesions of SSSS, with a positive Nikolsky sign in neonatal mice. Even intraperitoneal inoculation resulted in exfoliation, indicating that the toxin had its specific target in the skin. Within a year, the active component in the supernatant was isolated, purified, characterized, and termed exfoliatin or epidermolysin (Kapral and Miller, 1971; Melish *et al*., 1972; Arbuthnott *et al*., 1971). Soon after, it was realized that at least two different toxin serotypes existed (Kondo *et al*., 1974). The second serotype was isolated and characterized as a heat-labile toxin with a similar molecular weight to the original toxin. This second serotype, termed ETB, produced identical clinical and histological lesions in humans and newborn mice as the original serotype, ETA (Kondo *et al*., 1975b). Both toxins were soon isolated, sequenced, characterized, and cloned into other bacteria such as *Escherichia coli* (Kapral and Miller, 1971; Kondo *et al*., 1975a; Jackson and Iandolo, 1986; Sakurai *et al*., 1987; Ladhani *et al*., 2002). ETA consists of 242 amino acids, has a molecular mass of 26,950 Da, and is heat stable, while ETB consists of 246 amino acids, has a molecular mass of 27,274 Da, and is heat labile (Kondo *et al*., 1975a; Bailey *et al*., 1980). Like many other staphylococcal virulence factors, the toxins are encoded in pathogenic islands, which are capable of horizontal transfer between bacteria (Novick, 2003). The *eta* gene is chromosomally located within a 43 kb temperate phage ϕETA that is capable of converting a toxin-negative *S. aureus* strain into an ETA-producer, while the *etb* gene is located on a 38.2–38.5 kb plasmid (Lee *et al*., 1987; Yamaguchi *et al*., 2000). In the United Kingdom and Ireland, 32% of 116 *S. aureus* isolates from patients with suspected SSSS produced ETA, 27% produced both ETA and ETB, and 12% produced ETB only, with neither toxin being detected in 34 strains (De Azavedo and Arbuthnott, 1981). A large epidemiological study in Germany found 98% of the exfoliative toxin–producing isolates from dermatological patients produced ETA only (Elsner and Hartman, 1988). In France, most cases of childhood SSSS were associated with ETA alone (89%) with only a few cases due to both ETA and ETB (8%) or ETB alone (4%) (Piémont and Monteil, 1983; Willard *et al*., 1982). Similarly, a Nigerian study reported that ETA accounted for 91.1% of the 34 toxin-producing strains isolated from a range of human and animal sources (Adesiyun *et al*., 1991). In the United States, 40% of *S. aureus* isolates from SSSS patients produced ETA, 36% produced both, and 16% produced ETB only (Melish, 1982). On the other hand, ETB is more prevalent in Japan, with two studies reporting ETB, ETA, and ETB, and ETA production rates of 52, 23, and 25% of 61 isolates (Murono *et al*., 1988) and 35, 37, and 21% of 43 isolates from patients with SSSS (Kondo *et al*., 1975b), respectively.

At least two other antigenically distinct toxin serotypes produced by *S. aureus* have been identified more recently (Ladhani *et al*., 2003). ETC, which was isolated from a horse with skin infection and phlegmon, is a 27-kDa heat-labile toxin that produces intraepidermal splitting in both newborn mice and chicks (Sato *et al*., 1994). The role of ETC in human SSSS is not known. Recently, another 28-kDa serotype, termed ETD, with 40% sequence similarity to ETA, 59% to ETB, and 13% to ETC, was identified while screening the genome of clinical *S. aureus* isolates with probes for the *eta* and *etb* genes (Yamaguchi *et al*., 2002). ETD produces exfoliation in newborn mice but not in one-day-old chicks. Intriguingly, two of the three ETD-producing strains identified in this study were isolated from wound infections and not SSSS. In a parallel study of Japanese patients with impetigo, only one of 88 *S. aureus* isolates produced ETD (Yamaguchi *et al*., 2002). The authors speculate that ETD may have a wider pathogenic role in staphylococcal infections, such as disrupting the skin epithelial barrier and allowing the organism to spread or invade local tissues.

An extensive search for similar toxins among 461 human clinical isolates of 18 different staphylococcal species other than *S. aureus* using multiplex polymerase chain reaction did not identify any toxin genes (Becker *et al*., 2001). However, in piglets, certain strains of *S. hyicus* are able to produce exotoxins that are responsible for exudative epidermitis, a skin disease characterized by exudation, exfoliation, and blister formation with skin erosions (Tanabe *et al*., 1993). They are able to produce midepidermal cleavage in less than five-week-old piglets and one-day-old chicks, but not older chicks, mice, or guinea pigs (Tanabe *et al*., 1993; Anderson, 1998). Two toxin serotypes, designated SHETA and SHETB (Sato *et al*., 2000), have been isolated in Japan and four others, termed ExhA, ExhB, ExhC, and ExhD, have been isolated in Denmark (Ahrens and Andersen, 2004). The molecular sizes of the protoxins are approximately 30 kDa, while the mature toxins are 27 kDa in size and 816–834 bases in length (Ahrens and Andersen, 2004). They have a 45–70% homology to the *S. aureus* exfoliative toxins at DNA level and 49–54% homology at the protein level. There is no species-specific clustering of the amino acid sequences. Instead, ExhC is more similar to ETA than other *S. hyicus* exfoliative toxins, while SHETB has a higher similarity to ETD (Ahrens and Andersen, 2004). Interestingly, the aspartate residue constituting the active site of all serine proteases is replaced with glutamate in ExhD. However, this substitution is unlikely to

change the biochemical properties of the toxin, and histologically, the skin lesions produced by ExhD are identical to the other exfoliative toxins (Ahrens and Andersen, 2004).

## Risk factors for developing SSSS

SSSS is predominantly a disease of infants and young children. Initial animal studies that led to the discovery of the toxins showed that mice younger than five days old developed exfoliation after inoculation with a toxigenic *S. aureus* strain, while those over seven days old did not (Melish and Glasgow, 1970). Similar observations were made in baby chicks, piglets, and other animals (Ladhani *et al*., 2003), suggesting that there may be a specific maturation process that protects adults from developing generalized SSSS. However, anatomical differences in the skin are unlikely to explain this observation because immunosuppressed adults and those with renal failure can also develop generalized SSSS (Cribier *et al*., 1984). SSSS has also been reported in healthy, immunocompetent young adults (Opal *et al*., 1988), and intradermal injection of purified toxin into the forearm of a healthy adult will result in mid-epidermal splitting and blister formation (Wiley *et al*., 1974).

On the other hand, there is increasing evidence to show that renal function plays a critical role in determining susceptibility to generalized SSSS. An extensive literature review observed that over 75% of adults who develop generalized SSSS had impaired renal function (Cribier *et al*., 1984). Animal studies have shown that newborn mice excrete only one-fifteenth of a test dose of intravenous exfoliative toxin within three hours, compared to a third of the test dose by adult mice (Fritsch *et al*., 1976). Furthermore, nephrectomized, but not hepatectomized, adult mice will develop exfoliation when challenged with exfoliative toxin (Fritsch *et al*., 1976). Another recent study demonstrated that serum toxin levels peaked at 120 minutes after injection of a test dose and were still detectable in significant amounts at 16 hours in one-day-old mice. In 10-day-old mice, however, toxin levels peaked at 60 minutes and then dropped sharply to undetectable amounts by 6 hours—exfoliation was noted in the one-day-old mice at 2–4 hours post-injection but not in the 10-day-old mice (Plano *et al*., 2001). Furthermore, repeated hourly injections to maintain a maximal level of toxin for a sustained period of time resulted in exfoliation in 10-day-old and 21-day-old adult mice, suggesting that a critical amount of toxin is required in the epidermis to induce exfoliation. These findings suggest that poor renal clearance of exfoliative toxin in neonates and young children results in high levels of toxin in the bloodstream, thereby allowing a critical amount of the toxin to reach the epidermis and induce exfoliation. In adults, this may occur when patients are critically ill, immunocompromized, or have renal failure. However, other factors are likely to be important since only a small proportion of patients with renal failure develop generalized SSSS.

Immune function has also been considered to be an important risk factor for developing SSSS. One animal study showed that immunization with purified extracts of exfoliative toxin protected neonatal mice from exfoliation when inoculated with toxigenic *S. aureus* strains (Melish *et al*., 1981), while another showed that passive transfer of maternal antitoxin antibodies played an important role in protecting newborns from exfoliation following subcutaneous innoculation of exfoliative toxin (Machida, 1995). In humans, a significant proportion of adults who develop SSSS, for example, are immunocompromized (Cribier *et al*., 1984). Antibody studies have shown that 13 of 21 children (62%) with localized SSSS had antitoxin antibodies in the acute phase (within five days) of the infection and 100% in the convalescent phase (14 days after infection) (Melish *et al*., 1981). In contrast, none of the 10 children with generalized SSSS had antitoxin antibodies in the acute phase compared to 100% in the convalescent phase (Melish *et al*., 1981). However, a recent animal study reported that adult mice that were thymectomized at birth (and, therefore, lacking mature T cells) and adult mice with severe combined immunodeficiency (SCID) lacking both mature T and B cells (and, therefore, not able to produce protective antibodies) were not susceptible to exfoliation (defined as a positive Nikolsky sign and/or blister formation at 16 hours after subcutaneous toxin injection) (Plano *et al*., 2001). Furthermore, injecting adult spleen cells into neonatal mice did not protect against exfoliation when challenged with exfoliative toxin, suggesting that the adaptive immune response, which develops after the first week of life in mice, does not play a significant role in protection against exfoliation (Plano *et al*., 2001). Further studies are, therefore, required to elucidate the role of the host immune system in developing SSSS.

## Mechanism of action of the exfoliative toxins

In generalized SSSS, the exfoliative toxins are made during the post-exponential phase of bacterial growth (Bailey *et al*., 1995) and excreted from colonizing staphylococci before being absorbed into the systemic circulation (Melish *et al*., 1981). The toxins reach the zona granulosa of the epidermis by diffusing through dermal capillaries. Injection of $^{125}$Iodine-labeled toxin into neonatal mice has shown that, apart from the skin,

there is no significant binding of the toxins to any other body organ (Fritsch *et al*., 1976). The toxins are species specific—ETA and ETB, for example, only affect humans, monkeys, mice, and hamsters, but not rats, rabbits, voles, chickens, guinea pigs, or frogs (Kapral and Miller, 1971; Bailey *et al*., 1995; Elias *et al*., 1975). The lesions of localized and generalized SSSS are histologically identical, except that *S. aureus* is sometimes seen in localized forms of SSSS but rarely in generalized SSSS (Ladhani *et al*., 1998). *In vitro* studies have shown that addition of exfoliative toxin to human keratinocyte cultures obtained from plastic surgery or mouse organotypic skin cultures results in the disappearance of small vesicles that are usually present between the cells and formation of intercellular fluid-filled gaps between the zona granulosa and zona spinosum of the epidermis, followed by appearance of midepidermal splitting, which is characteristic of SSSS (Lillibridge *et al*., 1972; McCallum, 1972). There is no inflammatory response, cytolysis, cell degeneration, or necrolysis (Dedobbeleer and Achten, 1975; Elias *et al*., 1975; Wuepper *et al*., 1975; Hoffmann *et al*., 1994).

Despite discovery of the exfoliative toxins as the cause of SSSS in the early 1970s, it took another 30 years to identify the mechanism by which the toxins caused midepidermal splitting. The toxins do not have any significant *in vitro* enzymatic activity towards a wide range of non-specific substrates tested (Arbuthnott *et al*., 1974; Rogolsky *et al*., 1974; Kondo, 1976; Bailey *et al*., 1980; Wiley and Rogolsky, 1985), and exfoliation in newborn mice is not significantly affected by any of a wide range of metabolic inhibitors (Smith and Bailey, 1990; Bailey *et al*., 1995). Initial studies suggested that the toxins may have intrinsic lipase activity because a significant proportion of *S. aureus* isolates from patients with SSSS had lipolytic activity (Arbuthnott *et al*., 1969; Tait, 1973). In addition, incubation of purified toxin with egg yolk emulsion or bovine sphingomyelin resulted in a dose-dependent release of phosphate, suggesting that the toxin had intrinsic phospholipase activity (Wiley and Rogolsky, 1985), although other investigators were unable to detect any lipase activity towards triacylglycerol or phospholipids (Prevost *et al*., 1991).

The idea that the exfoliative toxins may act as atypical serine proteases came when sequence analysis studies showed that the exfoliative toxins had a 25% primary sequence homology with staphylococcal V8 protease (26% with ETA and 31% with ETB), a member of the trypsin-like serine protease family that does not possess any disulfide bridges and has an unusual specificity for cleaving the carboxyl-terminal side of acidic amino acid residues (Drapeau, 1978). Furthermore, the highly conserved serine-histidine-aspartate catalytic triad that forms the active site of all serine proteases was also present in the exfoliative toxins (Dancer *et al*., 1990). Mutation of any of the three amino acids forming the catalytic triad resulted in loss of exfoliative activity when injected into newborn mice (Prevost *et al*., 1991; Redpath *et al*., 1991). In addition, phenylmethylsulfonyl fluoride (PMSF), a specific serine protease inhibitor, delayed exfoliation by ETA in neonatal mice (Dancer *et al*., 1990). At around the same time, Bailey and Redpath (1992) tried to determine whether the toxins might have an esterolytic activity on the basis that proteases are always esterases and serine proteases tend to have a higher catalytic efficiency toward esters (Ferscht, 1985). They demonstrated that both ETA and ETB have very low but significant *N-t*-butoxycarbonyl L-glutamic acid α-phenyl (boc-L-Glu-*O*-phenyl) esterase activity, which was not present in a mutant form of ETA where the Ser-195 of the putative catalytic site was replaced by glycine (Bailey and Redpath, 1992). Furthermore, the pH dependence of both ETA and ETB in this reaction was typical of the histidine-associated $pK_a$ found with all serine proteases.

Takiuchi and colleagues (1987) initially showed that neonatal mouse epidermis incubated with exfoliative toxin at 37°C for 12 h produced a four-fold increase in caseinolytic activity in the supernatant after epidermal cells were removed by centrifuging at 1,000 *g* for 15 min, when compared to epidermis alone, ETA alone, or ETA boiled for 40 min at 100°C before incubation with epidermis. This activity was inhibited by $\alpha_2$-macroglobulin, indicating the activation of proteases or inhibition of protease inhibitors in the supernatant. Protease activity in the supernatant was also reported when exfoliative toxin was incubated for 20 hours with neonatal mouse epidermal extracts, formed by grinding neonatal mouse epidermis in liquid nitrogen, followed by suspension in buffer and high-speed centrifugation (Jaulhac *et al*., 1994). Incubation of exfoliative toxins with A431 cells (a human squamous cell line) was also shown to induce proteolytic activity in the supernatant, which could be abolished by pre-incubation with the specific serine protease inhibitor, PMSF (Ladhani *et al*., 1999b). A 20-kDa protease was subsequently reported to be responsible for the casein hydrolyzing activity in the supernatant (Ninomiya *et al*., 2000). This protease produced identical skin lesions when injected subcutaneously into newborn mice and cross-reacted with anti-exfoliative toxin antibodies, leading the authors to speculate that the exfoliative toxins were pro-enzymes and interaction with an epidermal component changed the structure or size of the toxins and converted them into active proteases.

A major step forward in our understanding of the toxins' possible mechanism of action came after

Barbosa and colleagues (1996) used the structures of known glutamate-specific, trypsin-like serine proteases to develop a computer model of the three-dimensional structure of ETA (Figure 56.2). They predicted that the toxins consist of two domains, each consisting of six-strand β-barrels common to all members of the trypsin family; an active site, formed by the serine-histidine-aspartate catalytic triad that is located on the interface of the two barrels; and a C-terminal α-helix, although the toxin had a larger N-terminal portion than the other members. The active site, formed by the serine-histidine-aspartate catalytic triad, is located on the interface of the two barrels and a C-terminal α-helix. The toxins additionally possess threonine-190 and histidine-213 (chymotrypsin numbering) in the core of the N-terminal S1 pocket that are conserved in all glutamate-specific serine proteases (Vath *et al*., 1997; Cavarelli *et al*., 1997). Homology to the *Streptomyces griseus* protease Glu-SGP suggested that ETA and ETB cleaved after a glutamic acid (or possibly aspartic acid) residue that would be stabilized in the active site by histidine-213, threonine-190, and lysine-216. Unlike other members of the trypsin family, however, the exfoliative toxins have a distinct, highly-charged (8 of 15 residues in ETA and 6 of 11 residues in ETB) N-terminal α-helix near the base of the S1 pocket. Furthermore, the proline-192-glycine-193 bond in ETA and its equivalent valine-183-glycine-184 in ETB are flipped 180° relative to other serine proteases. This allows the proline-192 in ETA and valine-183 in ETB to form a hydrogen bond with their respective active site serine residue, thus blocking the active site. This would explain why the toxins are inactive in their native state. Their computer predictions were soon confirmed by crystallographic data for both ETA and ETB (Vath *et al*., 1997; Cavarelli *et al*., 1997; Vath *et al*., 1999).

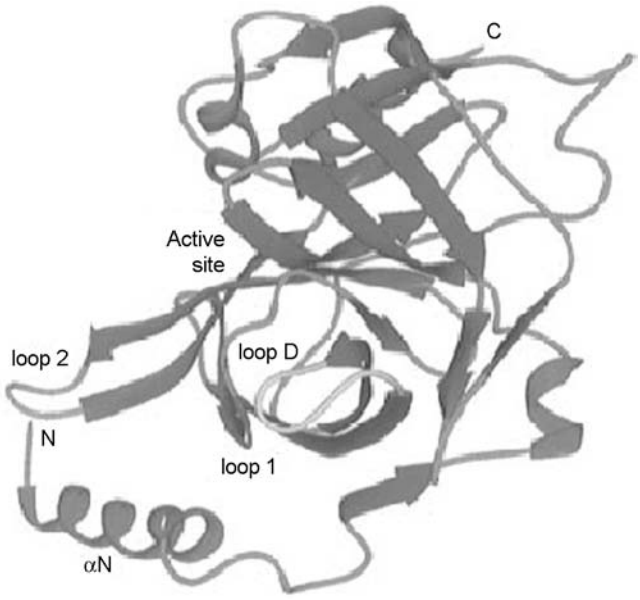

**FIGURE 56.2** Ribbon diagram of the structure of ETA. Like other members of the chymotrypsin-like family, ETA consists of two perpendicular domains, each made up of six antiparallel β-strands that form a β-barrel, and a carboxy-terminal helix. The active site, formed by the serine-histidine-aspartate catalytic triad, is located on the interface of the two barrels and the carboxy-terminal helix. However, the amino-terminal domain of ETA has a unique, highly charged, extended amphipathic 15-residue α-helix (αN) containing a four-turn helical loop. The αN helix is in contact with both loops 1 and 2 of the carboxy-terminal and prevents loop 2 from folding into the conformation seen in other serine proteases. Loop 2 is considered to be important for the proper positioning of substrate in the active site. It has been proposed that binding of the αN helix to a specific region on desmoglein-1 results in a conformational change that exposes the active site of the toxin, which can then bind and cleave the protein. (Reproduced from Vath *et al.* (1997) and by permission of *Biochemistry*, American Chemical Society)

It has been proposed that binding of the highly charged N-terminal α-helix to a specific epidermal receptor could flip the proline-glycine bond in ETA (and valine-glycine in ETB) to allow a conformational change that exposes the active site, which can then bind and cleave the substrate (Vath *et al*., 1997; Cavarelli *et al*., 1997; Vath *et al*., 1999). Free energy calculations suggest that it would require less than 3 kCal/mol of energy to cause this flip, and there are no steric hindrances to prevent the flip from occurring (Cavarelli *et al*., 1997). A similar mechanism has been identified in other proteases, including thrombin and hepatitis C virus NS3 protease (Cavarelli *et al*., 1997). Interestingly, the catalytic triad that forms the active site is not conserved in *S. aureus* ETC, *S. hyicus* exfoliative toxin A (SHETA), or the recently cloned exfoliative toxin from *S. intermedius*, although they are able to produce identical skin lesions in their respective animal models (Yamaguchi *et al*., 2002; Terauchi *et al*., 2003).

The target for the exfoliative toxins in the epidermis has only been identified recently. Previous studies had suggested that gangliosides may be the epidermal receptors for the exfoliative toxins (Sakurai and Kondo, 1979). Pre-incubation of ETA with a GM4-like—but not GM1-, GM2-, or GM3-like—glycolipid extract from the skin of one-day-old suckling mice for three hours resulted in loss of exfoliative activity when subcutaneously injected into neonatal mice, suggesting that the GM4-like glycolipids present in neonatal but not adult mice were possible receptors for the toxins and would account for the age and species specificity of the toxins (Sakurai and Kondo, 1979; Tanabe *et al*., 1995). On the other hand, another group showed that both ETA and ETB could cleave alpha- and beta-melanocyte-stimulating hormones, and this activity was not present with biologically inactive mutants of

the toxins, suggesting that these proteins may be the target for the toxins in the epidermis (Rago *et al*., 2000).

However, in a series of elegant experiments, the true epidermal target for the exfoliative toxins was identified following observations by Amagai and colleagues (2000) that the skin lesions of SSSS were clinically and histologically identical to pemphigus foliaceus (Figure 56.3), an autoimmune skin condition in which autoantibodies attack desmoglein-1, a transmembrane desmosomal glycoprotein in the cadherin gene superfamily, which plays an important role in maintaining keratinocyte cell-to-cell adhesion in the superficial epidermis (Angst *et al*., 2001). The group showed that injecting small quantities of purified exfoliative toxin into the neck of newborn mice produced identical blisters to pemphigus foliaceus, and using immunofluoresence staining and Western blot analysis, they were able to demonstrate that the blister formation was specifically due to degradation of desmoglein-1, with no reaction occurring when ETA was incubated with the closely related desomglein-3 or E-cadherin (Amagai *et al*., 2000; Hanakawa *et al*., 2002). Desmoglein-1 is found throughout the epidermis and mucous membranes, but blisters are only formed in the superficial epidermis in both SSSS and pemphigus foliaceus because desmoglein-3, which is found in the deep epidermis and in mucous membranes but not in the superficial epidermis, will compensate for desmoglein-1 and maintain the integrity of the structure if the function of the latter is compromised (the "desmosome compensation" hypothesis). This explains why the mucous membrane is not affected in SSSS (Mahoney *et al*., 1999).

Using wild-type ETA and mutant ETA that is able to bind but unable to cleave desmoglein-1, the dissociation constant of the reaction between ETA and desmoglein-1 has been estimated at 8μm, which is within the range of a hydrolytic reaction whose specificity is due to relatively strong binding in the catalytic site with a relatively low Km (Hanakawa *et al*., 2002). Co-immunoprecipitation studies between ETA and desmoglein-1 and between ETA and other closely related epidermal antigens, such as desmoglein-3 and E-cadherin, also confirm that ETA binds specifically to

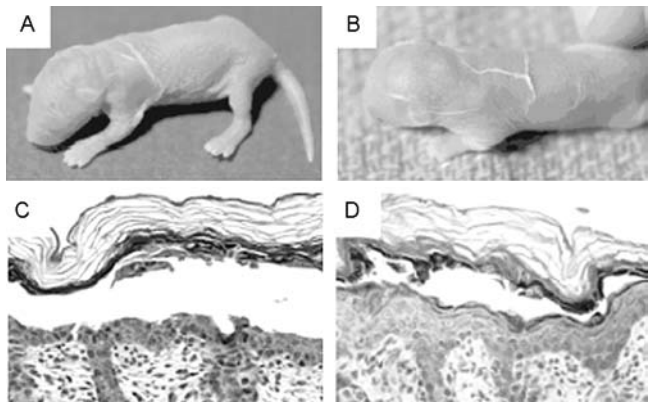

**FIGURE 56.3** Neonatal mice aged 1-2 days injected with pemphigus foliaceus autoantibodies against desmoglein-1 (a) and exfoliative toxin (b) showed identical superficial blistering and exfoliation. The histological appearance of the blisters showing midepidermal cleavage is also identical with both the antibodies (c) and exfoliative toxin (d). (Reproduced from Amagai *et al.* (2000) and by permission of *Nature Medicine*, Nature Publishing Group)

desmoglein-1 and dissociates after hydrolysis of the target peptide bond, consistent with enzyme recycling (Hanakawa et al., 2002). Kinetic studies show that the values for $K_{cat}/K_m$, which is a measure of enzyme efficiency, of $6.2 \times 10^4\ M^{-1}\ s^{-1}$ for ETA, $2.6 \times 10^4\ M^{-1}\ s^{-1}$ for ETB, and $1.9 \times 10^4\ M^{-1}\ s^{-1}$ for ETD, suggest very efficient proteolysis of a large substrate by the toxins (Hanakawa *et al*., 2004). These values are similar to those for the acidic amino acid-specific *S. aureus* V8 protease and glutamic acid-specific *Streptomyces griseus* proteinase (Hanakawa *et al*., 2004).

Based on the crystal structure of other cadherins, desmoglein-1 is predicted to form a rod-like structure with four highly conserved, homologous amino-terminal extracellular domains (EC1-4) of about 100 amino acids each that are stabilized and orientated by calcium-binding sites between these repeats, and a fifth extracellular region (EC5) intervenes between the repeats and the plasma membrane and is more variable in size and sequence (Figure 56.4). The primary amino acid sequence of the calcium-binding sites is also highly conserved and each site binds three calcium ions (Shapiro *et al*., 1995; Nagar *et al*., 1996; Tamura *et al*., 1998; Pertz *et al*., 1999; Boggon *et al*., 2002). The

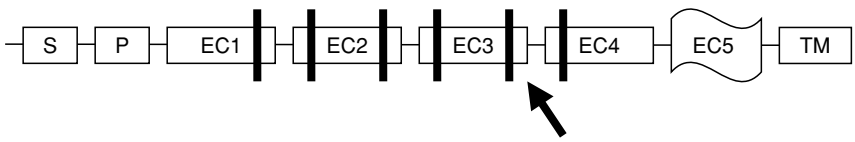

**FIGURE 56.4** Schematic diagram of desmoglein-1, showing the four homologous extracellular domains (EC1–4), a fifth juxtamembrane domain (EC5) that is not as well conserved within or among the cadherins and the putative calcium-binding sites (vertical bars). The exfoliative toxins disrupt cell-to-cell adhesion in the epidermis by hydrolyzing a single peptide bond between glutamic acid-381 and glycine-382 located between EC3 and EC4 of desmoglein-1 (arrow). S, Signal peptide; P, Propeptide; TM, Transmembrane domain.

toxins cleave desmoglein-1 between EC3 and EC4 after glutamic acid residue 381 (counting from the initiating methionine residue of both mouse and human desmoglein-1), precisely in one of the calcium-binding sites of desmoglein-1. This results in a conformation change in desmoglein-1, leading to dysfunction of the molecule and loss of intercellular adhesion within the epidermis (Hanakawa *et al*., 2003; Hanakawa *et al*., 2004).

The reaction between the exfoliative toxins and desmoglein-1 does not require any other factor—incubation of the toxins with recombinant extracellular domain of desmoglein-1 alone results in a dose-dependent degradation of the latter (Amagai *et al*., 2000; Amagai *et al*., 2002). Furthermore, when the serine residue of the active site is replaced with alanine, the toxins are still able to bind but unable to cleave desmoglein-1, supporting previous speculations that the toxins act as serine proteases. On the other hand, broad spectrum serine protease inhibitors such as diiopropylfluorophosphate (DFP), 3,4-dichloroisocoumarin (DCI), and α2-macroglobulin do not efficiently inhibit the toxins, suggesting that the catalytic site is either inaccessible or inactive. Current data suggest that the toxin must first bind to a very specific region on desmoglein-1 like a key in a lock, which in turn results in a conformation change (the proposed 180° flip of the proline-glycine bond in ETA and its equivalent valine-glycine bond in ETB) in the toxin that opens and/or correctly aligns the active site of the toxin with the cleavage site on desmoglein-1.

Using truncated mutants of desmoglein-1, Hanakawa and colleagues (2004) showed that the second and third extracellular domains of desmoglein-1, particularly sequences between amino acids 214–398, are essential for cleavage by the exfoliative toxins. Insertion of these sequences into the homologous human desmoglein-3, which the toxins are unable to hydrolyze, results in cleavage. The authors further showed that five amino acids on a loop in the third extracellular domain around 110 residues upstream from the cleavage site are essential for binding the toxin (Hanakawa *et al*., 2004). Substituting these five amino acids from human desmoglein-1 into canine desmoglein-1, which is not susceptible to the exfoliative toxins, resulted in hydrolysis of the latter (Figure 56.5).

However, unlike typical serine proteases, such as trypsin and chymotrpysin, the exfoliative are not only sequence-specific, but are also dependent on the three-dimensional structure of their substrate (Hanakawa *et al*., 2003). The toxins are unable to hydrolyze desmoglein-1 that has been heat-denatured at 56°C or 80°C for 1 hour or preincubated at low or high pH. Similarly, depletion of calcium from desmoglein-1 by

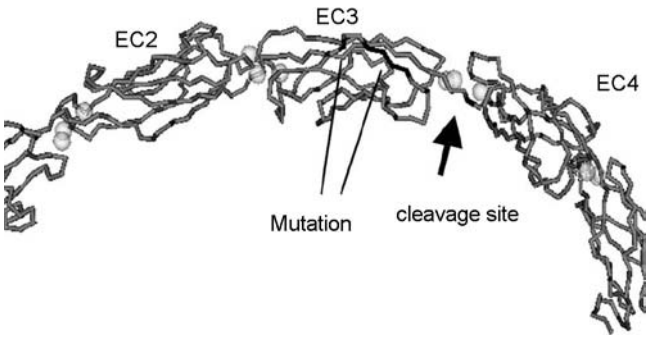

**FIGURE 56.5** Structure of canine desmoglein-1 based on the c-cadherin crystal structure. Canine desmoglein-1 is not susceptible to the exfoliative toxins. However, mutation of 5 critical amino acids between residues 271–277 on a loop proximal to the cleavage site in the third extracellular domain (EC3) to human sequences allows cleavage (thick arrow) of canine desmoglein-1 by the exfoliative toxins. (Reproduced from Hanakawa *et al.* (2004) and by permission of *Journal of Biological Chemistry*, American Society for Biochemistry and Molecular Biology)

preincubating with ethylenediamine tetra-acetic acid (EDTA) causes an irreversible conformational change in desmoglein-1, as demonstrated by antibodies that recognize specific conformational epitopes on desmoglein-1, immunofluorescence, circular dichronism, and tryptophan fluorometry (Hanakawa *et al*., 2003). The exfoliative toxins are unable to hydrolyze calcium-depleted desmoglein-1, even after calcium is added back into the assay. Together, these results suggest that the exfoliative toxins bind to a very specific region on desmoglein-1 that is dependent on both the primary amino acid sequence and the conformation of desmoglein-1, like a key in a lock. This results in a conformational change in the toxins (the proposed 180° flip in the proline-192-glycine-193 bond in ETA or its equivalent valine-183-glycine-184 in ETB) that will expose and/or align its active site with the specific cleavage site on desmoglein-1. This highly specific interaction explains both how the toxins are able to target one specific molecule within the body and why only certain species are affected.

## The toxins and the immune system

Whether staphylococcal exfoliative toxins possess superantigenic activity is currently under considerable debate. Superantigens are a group of bacterial and viral proteins that are able to bind directly to the Major Histocompatibility Complex (MHC) on the surface of antigen presenting cells outside the antigen binding groove (Dellabona *et al*., 1990) and cross-link with the variable Vβ region of the β-chain of the T cell receptor (Fields *et al*., 1996; Kappler *et al*., 1989), to potentially activate up to 20% of all T cells (Skov and Baadsgaard,

1995). *S. aureus* produces several superantigens, including toxic shock syndrome toxin-1 (Prasad *et al*., 1993; Acharya *et al*., 1994) and the staphylococcal enterotoxins (Baker and Acharya, 2004; Alouf and Müller-Alouf, 2003), and new superantigens continue to be discovered (Letertre *et al*., 2003; Omoe *et al*., 2004).

Initial reports indicated that the exfoliative toxins had mitogenic activity toward murine T lymphocytes (Morlock *et al*., 1980), and ETA was shown to preferentially stimulate Vβ2 human (Choi *et al*., 1990) and Vβ3 murine T cells (Herman *et al*., 1990). Furthermore, the toxins were able to activate murine macrophages to release high levels of tumor necrosis factor-α, interleukin-6, and nitric oxide to cause contact-dependent cytotoxicity in transformed embryo fibroblast cells, although the level of killing is lower than that for staphylococcal toxic shock syndrome toxin-1 and the enterotoxins (Fleming *et al*., 1991). However, others using recombinant ETA cloned into either a non-toxin producing strain of *S. aureus* (Fleischer and Bailey, 1992) or *Escherichia coli* (Plano *et al*., 2000) were unable to demonstrate any mitogenic activity towards human or murine T lymphocytes. The authors proposed that the superantigenic activity observed in previous studies was probably due to contamination by other staphylococcal enterotoxins at levels too low to be detectable by conventional biochemical methods (Fleischer and Bailey, 1992; Fleischer *et al*., 1995), as has been previously demonstrated with staphylococcal protein A (Schrezenmeier and Fleischer, 1987).

The authors further supported their argument with the following observations: (i) the characteristic symptoms of cytokines (including rash, fever, and hypotension) induced by the action on lymphocytes of other superantigens, such as toxic shock syndrome toxin-1 and the enterotoxins, is not seen with the exfoliative toxins; (ii) histological examination of skin from patients with SSSS does not show any recruitment of immune system cells; (iii) although the exfoliative toxins are similar to the other superantigens in that they are globular proteins and have similar molecular masses of 24 to 30 kDa, the degree of primary sequence and structural homology such as that seen between other superantigens is poor (Marrack and Kappler, 1990); (iv) none of the other known superantigens possess the protease activity of the exfoliative toxins; (v) ETA and ETB purified from *S. aureus* strains could stimulate spleen cells of transgenic mutant mice that were deficient in the expression of MHC class II antigens (Chapes *et al*., 1993), as well as MHC class II-deficient macrophages (Beharka *et al*., 1994); and (vi) it has not been possible to precipitate MHC class II molecules with commercial ETA, possibly because the toxins do not bind to the molecule.

On the other hand, there is some evidence that the exfoliative toxins possess a unique and specific superantigenic activity, which is separate from their enzymatic activity. Vath and colleagues (1997) cloned ETA into a superantigen-free strain of *S. aureus* and showed that the purified toxin had mitogenic activity toward T cells. The authors argued that since superantigenic activity could be demonstrated only after cloning ETA into the superantigen-free strain of *S. aureus*, ETA must be the source of the superantigenic activity and contamination by other superantigens was, therefore, unlikely. Also, recombinant ETA with a mutated active site, Ser195Cys-ETA, possessed a similar mitogenic activity but no exfoliative action when injected into newborn mice, indicating that the mitogenic activity was separate from the exfoliative activity. This dual action is also seen with the separate emetic activity and mitogenicity of the enterotoxins (Bohach *et al*., 1990) and with the lethality and mitogenicity of toxic shock syndrome toxin-1 (Murray *et al*., 1996). In contrast to other known superantigens, the superantigenic activity of the exfoliative toxins is considered to be unique because they induce selective polyclonal expansion of Vβs 3, 12, 13.2, 14, 15, and 17 (but not Vβ2), and only those murine Vβ T cells that are highly homologous to human forms are induced (Monday *et al*., 1999).

The exfoliative toxins are also able to stimulate the skin-associated lymphoid tissue (SALT), a part of the immune system that deals with antigenic challenges common to the skin and includes antigen-presenting Langerhans' cells, keratinocytes, and T cell subsets with skin-homing receptors (Streilein, 1989). *In vitro* studies have shown that the toxins can activate murine splenic T cells in the presence of Langerhans' cells and MHC class II-bearing keratinocytes to produce a range of cytokines, including IL-1 and tumor necrosis factor-α, capable of stimulating other accessory and immune system cells (Tokura *et al*., 1994). Furthermore, binding of the exfoliative toxins to Langerhans' cells results in dose-dependent depletion of these cells in cultured mouse skin, presumably due to migration of the cells to draining lymph nodes, where they may act as antigen-presenting cells for T lymphocytes (Pickard *et al*., 1994). The release of cytokines following activation of SALT may be responsible for the erythematous rash seen in SSSS, as has been proposed for the toxic shock syndrome toxin-1 in toxic shock syndrome (Leung *et al*., 1995a) and with the superantigens of group A streptococci in the development of the characteristic cutaneous swelling, erythema, and desquamation seen in streptococcal infections (Stevens *et al*., 1989). However, the lack of immune cells on histological specimens from patients

with SSSS cannot be easily explained and requires more research.

When compared to ETA, ETB is considered to be more pyrogenic and enhances susceptibility to lethal shock in rabbits (Monday *et al*., 1999). ETB is also more frequently isolated in generalized compared to localized SSSS and can cause generalized SSSS in apparently healthy adults (Opal *et al*., 1988). Furthermore, flow cytometry analysis showed that T cells stimulated by ETB show a corresponding population of T cell receptors on their surface bearing the appropriate Vβ (Monday *et al*., 1999). On the other hand, ETA appears to decrease the number of expected Vβ receptors on the surface of T cells, suggesting that ETA may down-regulate T cell receptors on the expanded set of T cells, a process also thought to occur with other superantigens (White *et al*., 1989). Despite these differences, both ETA and ETB produce identical skin lesions in humans and mice. There have been no studies on the superantigenic activity of other *S. aureus* or *S. hyicus* exfoliative toxins.

## FUTURE DIRECTIONS

Discovery of the mechanism of action of the exfoliative toxins and identification of their specific epidermal target has opened a whole new area for both academic and clinical research. Identification of a specific substrate means that a simple laboratory assay is now available to study different chemical and biological properties of the toxins without the need for live animal models. Such an assay could, for example, be used to determine how ETC from *S. aureus* and *S. hyicus* exfoliative toxin A (SHETA), which do not do not possess the serine-histidine-aspartate active site, are still able to induce exfoliation in their respective animal models.

Identification of desmoglein-1 as the substrate for the toxins should lead to the development of rapid, sensitive, and specific diagnostic assays that can be performed routinely in hospital laboratories and can detect and quantify the toxins in serum or other biological fluids from patients suspected with SSSS within a few hours. It should also be possible to develop new targeted anti-toxin therapies using analogues of desmoglein-1 that bind and inactivate the toxins before they reach the epidermis, as has been shown with *Listeria monocytogenes*, whose ability to invade epithelial cells can be inhibited by N-terminal fragments and recombinant peptides of E-cadherin (Lecuit *et al*., 1999). While such therapies may not be suitable for most uncomplicated cases of generalized SSSS, they may be lifesaving in high-risk patients, such as premature neonates and adults with serious underlying illnesses, and in cases due to multiresistant *S. aureus* (Yokota *et al*., 1996; Ackland *et al*., 1999), where antibiotic treatment alone may not be sufficient.

The exfoliative toxins may also play an important role in a wide range of other diseases where superantigens have been implicated. The ability of the exfoliative toxins to activate the SALT component of the immune system, for example, may have important consequences on various dermatological conditions, including cutaneous T cell lymphoma and atopic dermatitis. ETA is capable of inducing the proliferation of Vβ2.1-bearing cutaneous T cell lymphoma cells *in vitro*, and this proliferative response is enhanced by adding IL-1. This fits in with observations showing that activation of SALT by ETA results in IL-1 release (Tokura *et al*., 1994), and IL-1, along with IL-6, plays an important role in enhancing the activity of other superantigens (Kotb *et al*., 1990). Similarly, more than 90% of patients with atopic dermatitis are colonized with *S. aureus*, and their role in the pathogenesis of atopic dermatitis is supported by studies showing that eradication of *S. aureus* with antistaphylococcal antibiotics results in clinical improvement of the skin condition (Lever *et al*., 1988; Abeck and Mempel, 1998; Taskapan and Kumar, 2000; Zollner *et al*., 2000). Most *S. aureus* isolates from patients with atopic dermatitis release superantigens (Leung *et al*., 1993; McFadden *et al*., 1993; Zollner *et al*., 2000), and it has been speculated that superantigens bind to surface MHC class II molecules found on keratinocytes during inflammation and activate polyclonal T cells locally (Strange *et al*., 1994). Other conditions where staphylococcal superantigens may play an important role in pathogenesis include Kawasaki disease, a multisystem disorder in children that is characterized by fever, rash, conjunctivitis, mucosal inflammation, erythematous peeling of the hands and feet, and, rarely, coronary artery aneurysms (Melish, 1992; Leung *et al*., 1995b), hematogenously acquired staphylococcal nephritis (Koyama *et al*., 1995; Verba and Tarkowski, 1996), staphylococcal septic arthritis (Bremmel and Tarkowski, 1995; Zhao *et al*., 1996), rheumatoid arthritis (Paliard *et al*., 1991), multiple sclerosis (Brocke *et al*., 1994; Stinnisen *et al*., 1995), contact sensitivity (Saloga *et al*., 1995), nasal polyposis (Bachert *et al*., 2003; Bernstein *et al*., 2003), guttate and chronic plaque psoriasis (Lewis *et al*., 1993; Yokote *et al*., 1995), and sudden infant death syndrome (Blackwell *et al*., 1993; Lee *et al*., 1987; Morris *et al*., 1987). The role of the exfoliative toxins in these conditions, if any, needs to be established.

Understanding the action of the exfoliative toxins also has wider applications. For example, the toxins could be used in a controlled manner to induce localized exfoliation of offending superficial skin lesions

with minimal scarring. In addition, recent unpublished data show that the toxins preferentially concentrate in the skin of both susceptible (Balb/c mice) and non-susceptible (rats) newborn species, suggesting that the targeting and binding region of the toxins is different to the proteolytic region (Plano, 2004). Therefore, toxin analogues that bind but do not cleave desmoglein-1 could be used to stabilize the protein and protect it against, for example, destruction by autoantibodies in pemphigus foliaceus. Similarly, the targeting domain of the toxins could be used to deliver drugs, such as chemotherapy, to a localized region within the epidermis, with minimal systemic side effects.

Another area that requires further research involves identification of factors that lead to development of the disease. At least one-third of the general population carries *S. aureus* commensally and around 5% of these strains produce exfoliative toxin, but only a very small proportion of carriers develop SSSS. Polymorphisms in the desmoglein-1 gene may be one possible explanation. It is also possible that a triggering factor in either the organism or the host may be required for toxin production, or that the organism is constantly producing the toxins but protective mechanisms in the host, either locally or in the blood, prevent the toxins from reaching the epidermis. Of particular interest is the mechanism by which the toxins are able to cross the protective mucous membranes and endothelium to enter the bloodstream. A recent study using staphylococcal toxic shock syndrome toxin-1 and enterotoxins A and B has identified a highly conserved region that is essential for crossing the gut lining, and a synthetic peptide based on the conserved region (KKKV-TAQELD) was able to significantly reduce transcytosis (Shupp *et al*., 2002). The exfoliative toxins may also possess such a conserved region, which may provide a target for future vaccine development to prevent SSSS.

## CONCLUSION

Staphylococcal scalded skin syndrome is a relatively uncommon but potentially fatal blistering skin disorder, particularly in adults who have serious underlying disease and in young infants who are prone to secondary complications of exfoliation. The exfoliative toxins of *Staphylococcus aureus* are responsible for the condition and the mechanism by which they produce exfoliation is unique and highly specific. The toxins act as atypical serine proteases, which are inactive in their native state and require activation at their site of action. Binding to desmoglein-1, a transmembrane glycoprotein of desmosomes in the epidermis, produces a conformation change in the toxins, which exposes their active site and allows cleavage of desmoglien-1 at a critical site, resulting in exfoliation of the superficial epidermis and disruption of the skin barrier. There is also evidence that the exfoliative toxins possess a unique and specific superantigenic activity, which is separate from their enzymatic activity. Understanding the mechanism of action of the exfoliative toxins and identification of their epidermal target has not only helped us understand the pathogenesis of SSSS, but should also provide useful information on normal skin physiology and other toxin-mediated diseases. In the near future, the toxins will have other useful benefits in dermatology and therapeutics. However, many questions remain unanswered, and a lot more work needs to be done before we can close the chapter on the staphylococcal scalded skin syndrome.

CHAPTER

# 57

# Bacterial toxins as food poisons

*Per Einar Granum*

## INTRODUCTION

Food- and waterborne illness is a common, distressing, and sometimes life-threatening problem for people worldwide. People in developing countries suffer the most from these diseases. A significant proportion of cases of the estimated 1.5 billion episodes/year of diarrhea in children under five, including three million deaths, are of food- and waterborne origin. In many industrialized countries, despite all precautions, the incidence of foodborne infection has increased in recent years, although some have managed to reduce the numbers over the last few years. Surveys indicate that 5–10% of the population is affected annually, and in addition to the human suffering, food poisoning causes substantial economic loss. In the USA, costs are estimated to be US $5.8–10.7 billion/year, and between £231–331 million in England and Wales (Sockett and Todd, 2000). Although the two figures are not completely comparable, they indicate that food poisoning costs society about two to three times as much in the USA as in England and Wales after population adjustments. The ratio for bacterial infections were however 1.4:1 in 2000 between USA and England and Wales (Adak *et al.*, 2002). One single outbreak of cholera in Peru costs US $495 million in lost fish exports and in decreased tourism and local food sales (Sockett and Todd, 2000; WHO, 1997). Unfortunately, reliable/comparable figures from the developing world are not available.

The bacteria responsible for causing food poisoning have managed to adapt to the new niches presented to them with modern food processing. Much of the adaptation is through assimilation of new genes, including toxin- and invasion-related genes. The virulence factors that are responsible for the direct action on host tissues, and thereby development of disease, are dependent on the physical and genetic background of both the bacteria and the host. The toxins are, for some of the food poisoning diseases, the only cause of the symptoms but may for others only increase the severity of the disease. Many of the toxins described here are on mobile elements (plasmids, phages, and transposons), and can conceivably be transferred to bacteria that have not yet been identified as potential food pathogens. The presence of identical (or very similar) genes in different species of bacteria has caused confusion in terminology of the proteins and of the bacteria.

## THE FOOD-POISONING BACTERIA

There are a limited number of bacteria that are able to cause food poisoning, and they act through either intoxications or infections. For some of these species, the toxin(s) may be the only cause of the symptoms, while for others, the toxin(s) play(s) a moderate to minor role in pathogenicity. The role of the toxins along with the mechanisms of pathogenicity make it possible to divide the food-poisoning bacteria into five different groups according to the criteria given in Table 58.1. These five different groups are also illustrated in Figure 57.1. Group 1 contains the bacteria causing foodborne intoxications (toxins preformed in foods), while the remaining four groups comprise the species that have the ability to give us foodborne infections. For foodborne intoxications, the bacteria may or may not be present in the food at the time of consumption,

**TABLE 57.1** The different groups of bacteria causing food poisoning divided according to pathogenicity mechanisms

| Group[a] | Mechanisms of pathogenicity |
|---|---|
| 1 | Enterotoxin or neurotoxin preformed in foods |
| 2 | Enterotoxin produced in the intestine without bacterial adherence to epithelial cells |
| 3 | Enterotoxin produced in the intestine after bacterial adherence to epithelial cells |
| 4 | Bacterial invasion usually localized to the epithelium and intestinal immune system, with or without toxin production |
| 5 | Systemic infections |

[a]Bacterial intoxications: group 1, bacterial infections: group 2–5

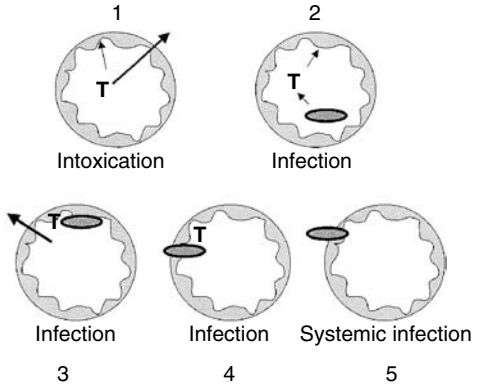

**FIGURE 57.1** Schematic illustration of the five different groups of foodborne pathogens. The circles indicate a cross-section of the intestine. The white area is the intestinal lumen, the dark gray a bacterium, and the **T** the toxin produced (see also the description in Table 57.1). The arrows pointing out of the intestine are for the botulinum toxin (group 1) and for the Shiga toxin of group 3.

and the bacteria can be killed by heat while the toxin survives (*S. aureus* and *B. cereus* emetic type). Taking a closer look at the species belonging to group 2 and 3 (Tables 57.1, 57.2, and Figure 57.1), we see that although they are by definition infections, the symptoms are almost entirely caused by toxin production in the host. In contrast, for the members of groups 4 and 5, which usually cause the most severe infections (frequently with fever), the toxins play a less important role in pathogenicity, mainly because these bacteria are able to invade the hosts cells, and the bacteria in group 5 cause systemic infections. From our present knowledge, it appears that protein toxins of the type discussed in this chapter do not play a direct role in virulence/pathogenesis for the bacteria in group 5, and these bacteria will not be discussed in this chapter.

Most of the foodborne diseases have been well characterized, and it is possible to summarize the knowledge on infective dose, incubation time, symptoms, and duration as seen in Table 57.2. For the intoxications caused by the members of group 1, the toxins are always preformed in the food (with an exception for infant botulism). The next group of bacteria produce the toxins (enterotoxins) in the small intestine of the host, but normally without any interaction with the host epithelial cells. Even for the members of group 3, the bacteria has little effect on the host, although colonization of the epithelial cells in usually necessary prior to enterotoxin formation. For the members of the first three groups, although the diseases might be severe (i.e., *C. botulinum*, EHEC, and *V. cholera*), fever is not a common symptom and is never high. In contrast, fever is usually a major symptom for infections caused by the members of groups 4 and 5 because of the bacteria's direct interaction and invasion of the host.

## THE TOXINS

The toxins involved in bacterial food poisoning mainly belong to three different groups of toxins: emetic toxins, neurotoxins, and enterotoxins (Table 57.3). Emetic toxins cause vomiting by binding specific receptors in the duodenum. Neurotoxins are proteins or small chemical substances (not relevant in this context) that act on the nervous system. Enterotoxins are defined as protein toxins that are active in the intestine and causediarrhea (fluid accumulation in loop tests). Enterotoxins can be divided into two groups: cytotoxic enterotoxins, which disrupt the cell membrane or other vital functions in the cell, thus causing cell death; and cytotonic enterotoxins, which enter the epithelial cell and cause diarrhea without direct membrane disruption or cell death. Table 57.4 shows some characteristics of the toxins of the different food-poisoning bacteria. Several of these toxins are described in detail in other chapters in this book, and will only be treated briefly here.

### *Staphylococcus aureus* enterotoxin

*Staphylococcus aureus* is a Gram-positive cocci, and the main reservoir is humans and warm-blooded animals. About 50–70% of strains have the ability to produce the *S. aureus* enterotoxins (SE) that are the cause of one of the most common types of food poisoning in the Western world. The enterotoxin is preformed in foods stored above 15–18°C, and it usually takes more than 3 h to produce enough enterotoxin to cause food poisoning. As little as 100–200 ng may cause emesis in man (Jablonski and Bohach, 2001). The enterotoxins are specific to primates and are also potent mitogenic superantigens (Marrack and Kappler, 1990). They consist of a family of seven different but related toxins (Alouf *et al*.,

**TABLE 57.2** The most important food poisoning organisms

| Species | Infective dose | Incubation time | Symptoms* | Duration |
|---|---|---|---|---|
| **Intoxications** | | | | |
| **Group 1** | | | | |

* A: Abdominal pain
B: Bloody diarrhea
D: Diarrhea
F: Fever
H: Headache
N: Nausea
V: Vomiting

[a]Symptoms in the order they usually appear

1991). Similar toxins are in rare cases found in other *Staphylococcus* spp. These toxins cause vomiting, yet they are called enterotoxins because of their ability to produce fluid accumulation in ileal loop tests. The SE also cause diarrhea, but not a severe type, and probably only at higher concentrations than needed for the cause of emesis. It has recently been shown that drugs blocking receptors for serotonin completely ablated the vomiting, diarrhea, and prostration induced by SEA or SEB in piglets (Hammamieh *et al*., 2003). Although these toxins are proteins (MW 26–28 kDa), the active part of the molecule is not influenced by heat treatment, so even autoclavation is not sufficient to reduce activity of preformed SE. Thus SE may be found in sterile heat-treated foods where it has been produced prior to heat treatment, i.e., canned foods.

**TABLE 57.3** Different types of toxins involved in food poisoning

| Types of toxins |
|---|
| Emetic toxins |
| Neurotoxins |
| Enterotoxins |
| Cytotoxic enterotoxins (kill cells) |
| Membrane active |
| Enzymatic active |
| Glycosidase toxins |
| Cytotonic enterotoxins (modify cells from inside) |
| Ribosylase toxins |

## *Clostridium botulinum* neurotoxin

Botulism is a rare but often fatal disease, caused by the spore-forming bacterium *Clostridium botulinum*. The main reservoir for this bacterium is soil. The different types of *C. botulinum* vary in potency and geographical locations. In Argentina, Brazil, China, and western parts of the USA, where the highly potent type A is the most frequently isolated type, fatality rates are higher than countries where other types are prevalent (Austin, 2001). *Clostridium botulinum* produces seven different neurotoxins (Hauschild, 1989). *C. tetani* neurotoxin is related, but not involved in food poisoning. Also, other *Clostridium* species may produce neurotoxins of the type found in *C. botulinum*. All the botulinum toxins are now known to be $Zn^{++}$ dependent endopeptidases, which split three different neuronal proteins at specific

**TABLE 57.4** Characteristics of toxins involved in food poisoning produced by different bacteria

| Species | Number of toxins | Toxin type* | Heat labile (L) stable (S) | Receptor | Mode of action | Enzyme activity |
|---|---|---|---|---|---|---|
| *Staphylococcus aureus* | Many different types | Emetic and CnEnt, protein | S | TCRVβ T-cells | Emesis: via nervus vagus and sympaticus | ? |
| *Bacillus cereus* (emetic) | 1 | Emetic cyclic peptide | S | $5\text{-HT}_3$ | Emesis: via nervus vagus | No |
| *Clostridium botulinum* | 7 (type A – G) closely related | Neurotoxin, protein | L | GT1b or GD1a | Split presynaptic membrane proteins | Zn++ dependent endopeptidase |
| *Bacillus cereus* (diarrheal type) | 3 (Hbl, Nhe and CytK) | CtEnt protein | L | Unknown | Membrane disruption | ? |
| *Clostridium perfringens* type A | 1 (CPE) | CtEnt protein | L | claudins 50 kDa protein | Membrane disruption | No |
| *Aeromonas* spp. | 1 (aerolysin) | CtEnt | L | GPI anchor | Membrane disruption | No |
| | many other types | CtEnt and CnEnt | L and S | ? | ? | ? |
| *Escherichia coli* | | | | | | |
| • ETEC (ST) | several | CnEnt, peptide | S | | cGMP accum. | ? |

*Ent-enterotoxin Cn-cytotonic Ct-cytotoxic

target sites (Montecucco and Schiavo, 1994). In contrast to *S. aureus* enterotoxins, the botulinum toxins are heat labile and are rapidly reduced in activity at 60°C (Hauschild, 1989). As expected, these toxins are usually produced in non-heat-treated foods stored above 3–10°C (differ for proteolytic and non-proteolytic strains) for longer periods of time, and only under anaerobic conditions. Occasionally recontaminations of cooked food products have been involved. As seen from Figure 57.1, the neurotoxins are not active in the gut, but only after transport into the blood, and further to the target cells. In infant botulism (only in children under one year of age), *C. botulinum* spores adhere to epithelial cells in the intestine, germinate, and colonize the intestine and produce the toxin there. Thus, this type of botulism belongs to group 3 (Table 57.1, Figure 57.1).

## *Bacillus cereus* toxins

*Bacillus cereus* is a Gram-positive, spore-forming, motile, facultative anaerobic rod. *B. cereus* causes two different types of food poisoning: the diarrheal type and the emetic type. The diarrheal type of food poisoning is caused by at least three different types of enterotoxins (Granum 2001), produced during vegetative growth of *B. cereus* in the small intestine (Granum, 1994), while the emetic toxin is produced by growing cells in the food (Kramer and Gilbert, 1989). The closely related *B. thuringiensis* is reported to produce enterotoxins (Jackson *et al*., 1995; Ray, 1991), and this could potentially cause serious problems, as spraying of this organism to protect crops against insect attacks has become common in several countries. There has been at least one confirmed *B. thuringiensis* outbreak of food poisoning (Jackson *et al*., 1995).

The dominating type of disease caused by *B. cereus* differs from country to country. In Japan the emetic type is reported about 10 times more frequently than the diarrheal type (Kramer and Gilbert, 1989), while in Europe and North America the diarrheal type is the most frequently reported (Kramer and Gilbert, 1989). The emetic toxin results in vomiting, while the diarrheal type, caused by enterotoxins, produces diarrhea (Granum, 2001). In a small number of cases, both types of symptoms are recorded (Kramer and Gilbert, 1989), probably due to production of both types of toxins. Counts ranging from $10^3$–$10^9$/g (or ml) *B. cereus* (Granum, 2001) have been reported in the incriminated foods after food poisoning, giving total infective doses ranging from about $10^5$–$10^{11}$. Partly due to the large differences in the amount of enterotoxin produced by different strains (Granum, 2001), the total infective dose seems to vary between about $10^5$–$10^8$ viable cells or spores. Thus, any food containing more than $10^3$ *B. cereus*/g cannot be considered completely safe for consumption.

The emetic toxin causes emesis (vomiting) only and its structure remained a mystery as long as the only detection system involved living primates (Kramer and Gilbert, 1989). The emetic toxin cereulide consists of a ring structure of three repeats of four amino and/or oxy-acids: $[D\text{-}O\text{-Leu-D-Ala-L-}O\text{-Val-L-Val}]_3$. This ring structure (dodecadepsipeptide) has a molecular mass of 1.2 kDa, and is chemically closely related to the potassium ionophore valinomycin (Agata *et al*., 1994). The emetic toxin is resistant to heat, pH, and proteolysis but is not antigenic (Kramer and Gilbert, 1989). The biosynthesis of the emetic toxin is through a large enzyme complex called a non-ribosomal peptide synthetase (NRPS) (Ehling-Schulz *et al*., 2005). It has been shown that it stimulates the vagus afferent through binding to the 5-$HT_3$ receptor (Agata *et al*., 1995).

*B. cereus* produces two different three-component enterotoxins (Beecher and Wong, 1997; Lund and Granum, 1997; Beecher and Wong, 1994; Beecher *et al*., 1995; Lund and Granum, 1996). They are called the hemolysin BL (Hbl) and the non-hemolytic enterotoxin (Nhe). Also a third one-component enterotoxin, cytotoxin K, has been described (Lund *et al*., 2000). This protein has a molecular mass of about 34 kDa and belongs to a family of β-barrel channel-forming toxins (Montoya and Gouaux, 2003). All these toxins are produced during the vegetative growth of *B. cereus* in the small intestine and are membrane active (Table 57.4).

## *Clostridium perfringens* enterotoxin

*Clostridium perfringens* are ubiquitous spore-forming, anaerobic, Gram positive, non-motile rods that grow well between 20 and 50°C (Hatheway, 1990). They are commonly found as a part of the intestinal flora of mammals. *C. perfringens* can produce at least 13 different toxins, though each individual isolate only produces a subset of these. The production of the four major lethal toxins is used to type isolates (A–E). The enterotoxin gene (*cpe*) has been found in all types. There are two major types of food poisoning, a diarrheal type caused by the *Clostridium perfringens* enterotoxin (CPE) and necrotic enteritis mainly caused by the β-toxin (β-barrel channel-forming toxin) in Type C strains.

*C. perfringens* type C can be involved in necrotic enteritis, known in Germany as "Darmbrand" and in New Guinea as "pig-bel." The symptoms are mainly caused by the β-toxin, although δ-toxin (hemolysin) and θ-toxin (perfringolysin O) contribute to the disease, which can be quite serious and has a mortality rate of 15–25%, even with treatment. The toxin is

trypsin sensitive and is normally inactivated by stomach enzymes. The disease is associated with individuals who have a low level of proteolytic enzymes in their intestinal tracts, most often caused by a low intake of protein. In New Guinea, pig-bel outbreaks coincided with traditional festivals where large amounts of spit-grilled pork were consumed while their staple diet, sweet potatoes, contains a trypsin inhibitor (Granum, 1990). The risk of *C. perfringens* type C food poisoning is minimal for healthy individuals with normal levels of proteolytic enzymes. Although the disease is not common, the danger of this type of food poisoning is real in immunocompromised individuals on special (vegetarian) diets. A relatively mild type of diarrhea is the most common form of food poisoning caused by *C. perfringens* and is one of the most common forms of human gastrointestinal illness in industrialized nations (McClane, 2001; Granum and Brynestad, 2002). Although the enterotoxin gene (*cpe*) has been found in all types of *C. perfringens*, only type A has been associated with CPE that caused food poisoning. After ingestion of food contaminated with large numbers (about $10^8$) of cells, CPE is produced by the bacterium during sporulation in the intestine and released upon lysis of the mother cell. CPE then binds to a protein receptor, after which a pore is formed, resulting in altered membrane permeability, which causes diarrhea.

CPE is a single, 319 amino acid polypeptide with a molecular weight of 35, 317 Da and an isoelectric point of 4.3 and is heat and pH labile (Kokai-Kun *et al*., 1997b). There is no significant homology to any known proteins. A two-domain structure has been proposed where the N-terminal is necessary for insertion/cytotoxicity and the C-terminal end (aa 290–319) contains the binding region, with specific binding necessary for toxicity (Kokai-Kun and McClane, 1997a). The binding also causes a change in secondary structure from mainly β-sheet to mainly α-helix (Granum and Harbitz, 1985). The removal of the first 25 to 34 aa increases activity (Granum *et al*., 1981; Granum and Richardson, 1991), and the first 44 aa can be removed without loss of activity (Kokai-Kun and McClane, 1997a). The observation that strains could lose the ability to produce enterotoxin and the fact that only 5–10% of naturally isolated strains carried *cpe* enterotoxin suggested that *cpe* was carried on some sort of mobile element. This possibility was confirmed when it was found that *cpe* is on a transposon, Tn*5565*, integrated between two housekeeping genes in human food poisoning strains (Brynestad *et al*., 1997). In animal isolates, the gene is carried on large plasmids with some strain-to-strain variation in the genetic structure (Cornillot *et al*., 1995; Miyamoto *et al*., 2002).

## *Aeromonas* spp. enterotoxin

Many different *Aeromonas* spp. have been suspected to cause gastroenteritis. They are Gram-negative motile rods, and the main reservoir is water. *Aeromonas* spp. have been suspected to be the cause of water- and foodborne (mainly seafood) gastroenteritis (Kirov, 2001), and outbreaks have been reported by several authors (Kirov, 2001). Three species, *A. hydrophila*, *A. caviae*, and *A. veronii* biovar sobria, have been suggested as a cause of human gastroenteritis (Kirov, 2001; Deohar *et al*., 1991). *Aeromonas* spp. is a potential serious food problem, as many of them can grow at refrigeration temperatures, at pH values from 4–10, under most atmospheres used to prevent bacterial growth in foods, and in the presence of high salt concentration (Kirov, 2001; Kirov, 1993). A variety of virulence factors and potential enterotoxins have been characterized (Kirov, 2001), and some strains have been shown to invade epithelial cells (Lawson *et al*., 1985; Watson *et al*., 1985).

The aerolysin and other hemolysins with closely related sequences seem to be the best candidates for the major enterotoxin (Granum *et al*., 1998; Kirov, 2001). These hemolysins are able to disrupt the membranes in epithelial cells and thereby cause diarrhea (Granum *et al*. 1998). It is not unlikely that more than one enterotoxin may be involved in food poisoning of humans, but addressing this question needs much more research, preferably on strains that have been involved in food poisoning. Although involvement of *Aeromonas* spp. in food poisoning is still controversial, an increasing number of papers point in the direction of direct involvement. The number of potential enterotoxins that has been suggested during the past few years (Kirov, 2001) may show the diversity of the different *Aeromonas* spp. strains. They are pathogenic to a variety of different animal species living under very different conditions (from fish to man).

## *Escherichia coli* enterotoxins

*Escherichia coli* is a Gram-negative rod with the intestine of warm-blooded animals as the main reservoir. The majority of the *E. coli* are non-pathogenic; still, there are at least five different types of *E. coli* that can cause food poisoning: enterotoxic (ETEC: two toxin types, ST and LT), enterohemorragic (EHEC: Shiga toxins), enteroinvasive (EIEC), enteropatogenic (EPEC), and enteroaggregative (EAaggEC) (Nataro and Kaper, 1998). The first two types produce enterotoxins (Table 57.2 and 57.4). Enterotoxic *E. coli* are probably the most common cause of travelers' diarrhea, and are an important cause of food poisoning

throughout the world. The main *E. coli* concern for the food industry is EHEC, because of the low infective dose (Table 57.2) and the severity of the disease, especially for the infirm and children, who are susceptible to the development of kidney failure (hemolytic-uremic syndrome: HUS).

Both types of ETEC are relatively mild diseases, and the symptoms are caused only by the enterotoxins. The heat-labile enterotoxin (LT) is among the best-characterized enterotoxins, and it is very similar to the cholera toxins (and an identical mode of action). This toxin consists of six subunits (5B and 1 A) and is an ADP-ribosylating toxin (Table 57.3). The heat-stabile toxins are peptides/small proteins with molecular mass below 10 kDa (18–72 amino acids) and act by activating guanyl cyclase and increasing cyclic GMP. The Shiga toxins produced by EHEC (O157:H7, among other serotypes), which are also found in other related bacteria, are closely related to the Shigella toxin, and with an identical mechanism of action (Table 57.3). There are two types of *E. coli* Shiga toxins (STI and STII), and strains can produce both or only one of them. The Shiga and Shigella toxins also consist of six subunits (5B and 1A), and the enzymatically active A unit is active after entering the target cells, where it modifies the ribosomes (glycosidase, Table 57.3). The genes are phage mediated and seem to be transferred from one bacteria to another. It is almost impossible for the food industry to control the problem of the presence of these types of *E. coli*, as all meat is a potential source of infection, and thus a specific problem in ground meat products.

## *Vibrio* enterotoxins

*Vibrio* spp. are motile, faculatively anaerobic, Gram-negative rods, where eight of the species are known food-associated pathogens. *V. cholera* and *V. parahaemolyticus* are the most common and have the best characterized virulence mechanisms, and are the only two included here. *Vibrio* spp. are found in estuarine waters throughout the world. They can be found in essentially all seafood and raw, undercooked, or recontaminated seafood are the major sources of food poisoning. *Vibrio* has been shown to survive for extended periods of time at refrigeration temperatures and can grow rapidly at room temperature (non-refrigeration) (Oliver and Kaper, 2001).

*Vibrio cholera* can cause an explosive, potentially fatal dehydrating diarrhea caused by ingestion of serotypes (01/0139) that carry the cholera enterotoxin (CT). The majority of infections involving *V. cholera* 01 are mild, and volunteer studies showed large differences in the susceptibility between individuals. Strains without CT can, in some cases, still cause diarrhea, but without the typical "rice water" stools. Additional toxins such as Zot, Ace, hemolysin/cytolysin are suspected to be involved in the pathogenesis of the disease. Genetic factors other than CT would seem to be important, as other bacteria, such as *E. coli*, carry a gene coding for a toxin comparable to CT, but these bacteria have not been shown to give cholera-like symptoms (Oliver and Kaper, 2001). The main source of infection is contaminated water, but also seafood has been involved.

*Vibrio parahaemolyticus* can cause a disease, mainly involving diarrhea, that is linked to the ability to produce the homo dimeric thermostable direct hemolysin (TDH) or the similar hemolysin TRH (Oliver and Kaper, 2001). However, Park *et al*. (2004) have just constructed *tdh*-deletion mutants by homologous recombination and analyzed their phenotypes. Although the deletion of both copies of *tdh* completely abolished the hemolytic activity of the wild-type strain, the deletion did not affect the cytotoxicity to HeLa cells. Enterotoxicity, assayed by the rabbit ileal loop test, was lowered by *tdh* deletion, but the mutant still showed partial fluid accumulation in rabbit intestine. These results indicate that the cytotoxicity and enterotoxicity of TDH-producing *V. parahaemolyticus* are not explained by TDH alone, and unknown virulence factor(s) could be involved in these pathogenic activities (Park *et al*., 2004). TDH is only partially inactivated at 100°C for 30 min. at pH 6.0. TDH produces edma, erythema, induration in skin, and lyses erythrocytes from many animals, excepting horses. More relevant for food poisoning is the ability to alter transport in the intestinal tract and thereby induce diarrhea. Studies using Ussing chambers demonstrated that TDH induces intestinal chloride ion secretion with the ganglioside GT1 or GT1b as the cellular receptor. TDH uses $Ca^{2+}$ as an intercellular second messenger, instead of cAMP or cGMP, and is the first bacterial enterotoxin where changes in intercellular calcium and secretory activity have been shown to be directly linked (Oliver and Kaper, 2001). However, the induction in a human embryonic cell line of a $Ca^{2+}$-independent cytotoxicity due to the hemolysin has also been reported (Tang *et al*., 1995). There is however no doubt that TDH is a membrane active toxin with the ability to form pores in phospholipid bilayers (Hardy *et al*., 2004). The main source of food poisoning is seafood from warm seawater.

## *Campylobacter jejuni/coli* enterotoxins

*Campylobacter jejuni* and *C. coli* are Gram-negative microaeropholic S-shaped motile spiral rods only growing between 30°C and 47°C. They can survive at 4°C for extended periods, and have a viable but not

culturable coccoid form. Reservoirs include water, domestic animals (notably poultry) and pets, and wild birds. Most outbreaks occur in the summer months. Camphylobacteriosis has been the most frequent cause of foodborne outbreaks in some European countries in the nineties (Wassenaar, 1997). Suspected food sources include raw milk, poultry, eggs, beef, and water. Even though *Campylobacter* spp. are susceptible to low pH, heat, and don't grow at low temperatures, the low dosage needed to cause sickness makes it difficult to avoid in food, and it will probably continue to be one of the most common food poisoning agents in industrialized nations. Patients can be unsymptomatic to severely ill. Symptoms include fever, cramping, and diarrhea, with or without leukocytes, that last several days to over a week. Infections are usually self-limiting, but extraintestinal infections and sequelae do occur, including bacteremia, reactive arthritis, and Guillain-Barré syndrome (GBS) (Nachamkin, 2001).

*C. jejuni* has been reported to produce a toxin with cholera-like enterotoxin activity elevating cAMP levels in rabbit ileal loop tests. However, genetic probing using CT probes proved negative, indicating that the sequence must be quite different. Shiga toxins, cytolethal distending toxin, and hepatoxins have also been described. Genetic studies have been difficult to perform in *Campylobacter*, and the lack of suitable animal models has hindered the study of the contribution of the different toxins in pathogenicity (Wassenaar, 1997). The wide range of symptoms seen during *Campylobacter* spp. infections suggests that different strains of *Campylobacter* spp. carry one or a number of different virulence genes, and the severity of the sickness is a result of the expression of the combination of genes found in the infecting bacteria (Poly *et al*., 2004).

## *Salmonella* spp. enterotoxin

*Salmonella* spp. is one of the most common food poisoning organisms in industrialized nations. They are resilient organisms that adapt to extreme environmental conditions, and there are strains that can grow at 54˚C, and others that can grow at 2–4˚C and tolerate pH values from 6.0 to 9.0. These bacteria are a major problem in poultry and egg products and other meat products. Salmonella infections can cause sickness ranging from uncomplicated diarrhea to serious systemic infections. The bacteria has a number of genes that facilitate the attachment to and invasion of host cells, and attachment is necessary for pathogenesis. Although many of the details of invasion of the host cells are known, the contribution of toxins produced by the bacteria in the total pathogenicity picture has not been completely elucidated (Bailey and Maurer, 2001).

Although the enterotoxin is not necessary for development of salmonellosis, it contributes to the disease. One enterotoxin is a thermolabile protein encoded by a 6.3kb operon (*stx*), which encodes three genes. The toxin increases the level of cAMP in cells, which leads to fluid exsorption and to diarrhea. Although genetic studies show that STX and cholera toxin are not closely related, functional studies show that the toxins share a similar mode of action with A and B components, and probably use the same GM1 ganglioside receptor (D'Aoust *et al*., 2001). *Salmonella* also produce a thermolabile cytotoxic protein localized in the bacterial outer membrane. This cytotoxin inhibits protein synthesis, apparently using the same mechanisms as Shiga toxins, although genetic studies show that the toxins are not identical (D'Aoust *et al*., 2001).

## *Shigella* enterotoxin

*Shigella* spp. are Gram-negative, non-motile rods, which are the cause of bacillary dysentery (a human-specific disease). The clinical picture ranges from watery diarrhea to severe dysentery (bloody diarrhea), and complications such as reactive arthritis and kidney failure (HUS) are seen. The infective dose is very low, and that facilitates the infectious spread of the bacteria through food and water. Most of the foodborne incidents are caused by infected food handlers, but the largest outbreaks are after natural or man-made disasters (war) where sanitation and water supply lines are broken down. Attachment and invasion genes are the primary virulence factors, while the production of Shiga toxins (glycosidase, Tables 57.3 and 57.4) seems to play a role in the progression of the disease, as dysentery is not seen in strains without the toxin (Lampel and Maurelli, 2001). The Shiga toxin (Stx) region of *Shigella dysenteriae* 1 lies on a defective prophage homologous to lambdoid bacteriophages in Stx-producing *Escherichia coli* (Greco *et al*., 2004). The Shigella toxin has the same structure and mechanism of action as the Shiga toxins of EHEC.

## *Yersinia enterocolitica* enterotoxin

*Yersinia* is a Gram-negative, facultative anaerobe rod that can grow between 0 and 44˚C. Watery to mucoid diarrhea is the most common symptom, while bacteremia and reactive arthritis are the most common complications. It is not a common form of food poisoning, and is most often seen in northern climates. Pigs are often carriers of *Yersinia*, but raw milk is the most commonly implicated food source. As with *Salmonella* and *Shigella*, invasiveness is the major virulence factor, and these genes are homologous in all three bacteria.

Most strains of *Yersinia* secrete a heat-stable enterotoxin, Yst (three different types), which is homologous to the heat-stable toxins from enterotoxigenic *E. coli* and *Vibrio cholera* non-01. The mechanism of action is elevation of intercellular cGMP levels, which affects the fluid transport pathways and results in diarrhea. The role of the toxin here, as in other invasive bacteria, is uncertain, but it appears that toxins can either worsen the clinical symptoms or assist in the attachment to the host cell (Robins-Browne, 2001). The Yst-b has recently been described as the major contributor to diarrhea produced by biotype 1A strains of *Y. enterocolitica* (Singh and Virdi, 2004).

## CONCLUSION

Only a few species of all known bacteria are involved in foodborne illness. It is not sufficient for bacteria to possess genes that can encode for toxins or other virulence factors. The bacteria must also be able to survive one or a number of detrimental and changing environmental factors, including dehydration, heat, cold, low pH values (stomach), competing flora, and other intestinal defense mechanisms. There are many bacteria that carry the same or equivalent virulence genes as bacteria known to cause foodborne illness that have not yet been fully recognized as cause of a human gastroenteritis, i.e., *Bacteroides fragilis* and *Citrobacter* spp. The modes of action for different groups of toxins are becoming clear, but the full importance of these toxins in the clinical picture is still somewhat unclear in all but the first two groups of toxins and some members of group 3 (Tables 57.1, 57.2, and 57.4). Even in these groups, genetic characterization of the different toxins and their prevalence among the strains of the species has just started. Equivalent toxins in different, and even the same, bacterial species can give very different symptoms, apparently due to the genetic background in which the toxins are found. It would be beneficial to the field if the nomenclature of the protein toxins (Granum *et al*., 1995) and the tests used to determine their action, preferably using available cell lines such as Vero, Caco, and HeLa, were standardized. Research on the role of toxins, their movement between bacteria, and regulation of expression is needed in order to effectively monitor and prevent unwanted bacteria in our food, and possibly prevent the rise of new pathogens.

# Medical applications of botulinum neurotoxins

*Eric A. Johnson, Gary E. Borodic, and Martin A. Acquadro*

## INTRODUCTION

Since the introduction of botulinum toxin complex (BTX) for the treatment of strabismus in 1980 (Scott, 1989, 2004), the utility of BTX has expanded to many indications across medical specialties. During the past decade, the pharmaceutical utility of BTX has further extended to a variety of disorders that do not have an apparent origin in hyperactive synaptic cholinergic activity. These include various pain disorders, inflammatory conditions, and autonomic syndromes. Important pharmacological attributes of this drug include specificity for cholinergic presynaptic nerve membranes, long duration of action (3–4 months), and the ability to contain the biologic effects within an injected anatomic region. Drawbacks and side effects to BTX use are formation of antibodies in a subset of patients and undesirable spread from the targeted area. Systemic complications have been rare. BTX consists of non-toxic proteins non-covalently linked with the biologically active botulinum neurotoxin (BoNT). Various preparations and immunotypes of BTX have been evaluated in humans with varying results, depending on the toxin serotype, its purity, formulation, potency, and the neurological condition being treated. Advances in understanding of the biochemistry, structure, and cellular biology of BoNTs have provided leads to improve the efficacy of BoNT as a drug and application to new indications. This chapter describes the scientific basis for BTX and BoNT as pharmaceuticals and describes clinical aspects of the toxin.

## NEUROTOXIGENIC CLOSTRIDIA AND BOTULISM

Clostridial neurotoxins (CNTs) are biologically active proteins that are antigenic in animals and can be neutralized with antisera raised against toxoids or against recombinantly expressed toxin fragments (Hatheway, 1988, 1990; Kozaki *et al*., 1989). CNTs, including tetanus neurotoxin (TeNT) and botulinum neurotoxin (BoNT), are produced by various species of neurotoxigenic clostridia (Hatheway 1989, 1990), and are well-known to cause the spastic and paralytic diseases tetanus and botulism (Bleck 1991; Cherington 1998, 2004). Neurotoxigenic clostridia synthesize TeNT and seven immunologically distinguishable serotypes of BoNTs, designated A through G (Hatheway 1988, 1989). BoNTs can be neutralized by polyvalent antitoxins obtained by immunization of animals with toxoids or recombinant BoNT fragments (Hatheway, 1988; Kozaki *et al*., 1989), or by combinations of monoclonal antibodies generated against BoNTs (Marks, 2004). A specific serotype of BoNT is neutralized by polyvalent antisera to the causative toxin type, but retains toxicity on incubation with antisera raised against a heterologous serotype (Hatheway, 1998).

Botulism is a distinct paralytic disease traditionally caused by the consumption of contaminated food (van Ermengem, 1895). The hallmark of botulism is a descending bilateral weakness and paralysis with an extremely long duration of illness of months to years in severe cases (Cherington, 1988, 2004). Botulism in

humans can weaken or paralyze every skeletal muscle in the body. BoNT inhibition of acetylcholine exocytosis affects parasympathetic and sympathetic systems at neuromuscular synapses. The clinical presentation of severe botulism has been reviewed (Cherington, 1998, 2004). Although the sensory system and CNS mentation are generally unaffected, there have been sporadic reports of sensory abnormalities, which may be associated with an unrelated illness (Cherington, 1998, 2004). Patients with signs of botulism must be monitored for respiratory difficulties. Botulism is quite rare in incidence and may be misdiagnosed as more common paralytic diseases, such as Guillain-Barré syndrome, myasthenia gravis, tick paralysis, diphtheritic neuropathy, Lambert-Eaton syndrome, or certain nervous system infections (Cherington, 1998, 2004). No specific antidote is currently available for preventing botulism or reversing paralysis once receptor binding and internalization ensues. Early administration of antibodies during onset of the disease can decrease the severity and slow its progression, resulting in a shorter hospital stay and more rapid recovery (Centers for Disease Control and Prevention 1998). Complete recovery requires the regeneration and restoration of functional neuromuscular junctions with resumption of neurotransmission.

## BOTULINUM NEUROTOXIN STRUCTURE AND FUNCTION

BoNTs and TeNT are produced as single-chain protein molecules of about 150 kDa that achieve their characteristic high toxicities of $10^7$ to $10^8$ $LD_{50}$s per mg by posttranslational proteolytic cleavage to form a dichain molecule composed of an L chain (about 50 kDa) and a heavy (H) chain (about 100 kDa) linked by a disulfide bond (Habermann and Dreyer, 1986; DasGupta, 1989; Sugiyama, 1980). Most BoNTs produced by strongly proteolytic strains of *C. botulinum* (type A) achieve full activation to the dichain form during culture, while less proteolytic strains of *C. botulinum* (serotypes B–G) produce incompletely nicked BoNTs, and complete activation to the dichain form can be attained in toxin extracts with trypsin or other suitable proteolytic enzymes. Following initial cleavage into the H and L chains, more extensive proteolytic modification may occur, including degradation to inactive forms (Antharavally *et al*., 1998; DasGupta *et al*., 2005). BoNTs can also undergo proteolytic degradation and other modifications during handling and storage, including autocatalytic cleavage and aggregation (Schantz and Johnson, 1992; DasGupta, 2005). Formulations and methods are required to retain the initial high specific toxicity of BoNTs.

BoNT occurs naturally in toxin complexes, commonly referred to as progenitor toxins. In these complexes, BoNT is associated with non-toxic proteins and RNA (Sugiyama, 1980; Sakaguchi, 1983; Schantz and Johnson, 1992; Johnson and Bradshaw, 2001). The full complement of components and structures for these toxin complexes has not been fully elucidated. Progenitor complexes have been referred to as the M complex (about 300 kDa) consisting of BoNT associated with an NTNH protein of 120 to 140 kDa, or as the L complexes (about 450 kDa), in which the M complex associates with hemagglutinin proteins, and the LL (about 900 kDa), where the L complex is thought to form a dimer (Sugiyama, 1980; Sakaguchi, 1983; Schantz and Johnson, 1992). The non-toxic proteins in the complexes have been demonstrated to provide protection during experimental manipulations and during passage through the gastrointestinal tract (Sakaguchi, 1983; Schantz and Johnson, 1992).

The biochemistry, structure, and cell biology of BoNTs have been reviewed (Montecucco and Schiavo, 1995; Schiavo *et al*., 2000; Turton *et al*., 2002; Lalli *et al*., 2003; Simpson, 2004) and is only summarized here as it relates to medical uses of BTX and BoNT. BoNTs and TeNT consist of three basic functional domains: (i) L chain ($L_c$), the catalytic domain that has endopeptidase activity on neuronal substrates; (ii) $H_N$, the translocation domain residing in the N-terminal region of the H chain that enables passage of the $L_c$ from endosomes into the nerve cytosol; and (iii) $H_C$, the receptor-binding domain located in the C-terminal region of the H chain. The gene and amino acid sequences of BoNT and TeNT have been analyzed for a limited number of strains (Niemann, 1991; Lacy and Stevens, 1999; Minton, 1995). The amino acid sequences of all seven BoNTs and TeNT have been deduced from the corresponding genes. The overall amino acid identity is about 40% for the eight CNTs whose genes have been sequenced, and as expected, BoNTs have regions of homology, particularly in the residues defining the catalytic active site, in the translocation domain, and in the two cysteine residues forming the disulfide bond connecting the H chain and the L chain (Niemann, 1991; Lacy and Stevens, 1999). The least degree of homology is in the carboxyl region of the H chain, which is involved in neurospecific binding and probably is the region that determines the serotype. Recent studies have demonstrated that subtypes of BoNTs occur within certain serotypes, in which the 150-kDa proteins differed by 5–20% in amino acid sequence and associated properties such as immunogenicity and neutralization by antitoxins (Dineen *et al*., 2004; Smith

*et al*., 1995; EAJ's laboratory, umpublished data). These findings suggest different evolutionary lineages of CNTs within serotypes leading to distinct BoNT structures, and this finding expands the repertoire of BoNTs available for fundamental studies and evaluation as therapeutics.

Early experiments showed that BoNT and TeNT act at the neuromuscular junction and prevent the release of acetylcholine (Schiavo *et al*., 2000), but the mechanism of action remained enigmatic for many years. During the past decade, it has been revealed that TeNT and BoNTs comprise a unique group of zinc proteases (Montecucco and Schiavo, 1995; Schiavo *et al*., 2000; Breidenbach *et al*., 2004). Their endopeptidase activity was initially suspected by analysis of the gene sequences, in which a highly conserved 20-residue segment contained the zinc-binding motif (His-Glu-Xaa-Xaa-His) characteristic of zinc endopeptidases (Schiavo *et al*., 2000). The identification of the cytosolic substrates for the BoNTs showed that the catalytic $L_c$s specifically cleaved synaptic proteins. BoNTs and TeNT were found to be extraordinarily specific proteases with activity on proteins of the SNARE apparatus (SNAP-25—serotypes A, E, and $C_1$; VAMP/synaptobrevin—serotypes B, $C_1$, D, F, and G; syntaxin—serotype $C_1$) (in Schiavo *et al*., 2000). BoNTs and TeNT cleave the target substrates at different residues, further contributing to their specificity. This high specificity for neuronal substrates is essential for utility of BoNT as a therapeutic, as they do not show general cytotoxicity. Recombinantly expressed $L_c$s also efficiently cleave the substrates *in vitro*, indicating that cytosolic factors are not necessary for activity.

Solving the crystallographic structures of BoNT/A, /B, and /E, as well as BoNT and TeNT domains has led to considerable insight into the cellular biology of these neurotoxins and their utility as pharmaceuticals (Lacy *et al*., 1998; Schiavo *et al*., 2000; Lalli *et al*., 2003; Hanson and Stevens, 2004; Swaminathan *et al*., 2004). The three-dimensional structures of CNTs have been found to be in agreement with the mechanism of intoxication proposed by sequence analysis and biochemical and cell biology experiments (Schiavo *et al*., 2000; Simpson 2004). Lacy *et al*. (1998) demonstrated that BoNT/A holotoxin is composed of domains of different evolutionary origins. The ganglioside-binding C-terminal subdomain has structural homology with proteins known to interact with sugars, such as the $H_C$ fragment of TeNT, serum amyloid P, sialidase, various lectins, and the cryia and insecticidal-$\delta$-endotoxin, which bind glycoproteins and create leakage channels in membranes (Lacy *et al*., 1998; Hanson and Stevens, 2004). Regions of thermolysin and leishmanolysin showed high homology to the catalytic $L_c$ domain. The translocation domain ($H_N$) differed in structure from bacterial pore-forming toxins and showed more resemblance to coiled-coil viral proteins, such as HIV-1, gp41/GCN4, influenza hemagglutinin, and the Moloney murine leukemia virus transmembrane fragment (Lacy *et al*., 1998; Hanson and Stevens, 2004). Interstingly, BoNT consists of a chimera of varied structural motifs that evolved by combination of functional subunits to generate a highly toxic molecule. Recent structural studies for other serotypes of BoNTs, as well as domains of the holotoxin, have shown similarity to BoNT/A and revealed interesting features that provide insight to their high toxicity (Lacy *et al*., 1998; Schiavo *et al*., 2000; Lalli *et al*., 2003; Hanson and Stevens, 2004; Swaminathan *et al*., 2004). Collectively, the biochemical, physiological, and structural studies have led to a pathway for mechanism of action (Montecucco and Schiavo, 1995; Schiavo *et al*., 2000; Simpson, 2004): (a) specific binding of BoNT to the presynaptic membrane of cholinergic neurons; (b) endocytosis of BoNT within vesicles into the nerve cytosol; (c) pH-dependent translocation of the catalytic domain ($L_c$) through the membrane of the endocytotic vesicle into the cytosol; and (d) catalytic cleavage of the specific nerve protein substrates (SNAP-25, VAMP, syntaxin).

The observation that BoNTs are chimeric molecules comprised of distinct protein domains suggests that designed chimeric neurotoxins could be constructed with enhanced or distinct therapeutic utility (Li *et al*., 2001; Goodnough *et al*., 2002; Bade *et al*., 2004). For example, exploitation of the binding and translocation domains to deliver enzymes that kill target neurons could lead to an increased duration of action. Further studies of BoNTs, TeNT, and their domains will undoubtedly lead to increased understanding of the biology of these toxins, as well as providing a strategy for improved vaccines and therapeutic agents.

## PHARMACEUTIC BASIS OF BOTULINUM AND TETANUS TOXINS AS THERAPEUTIC AGENTS

The success of BoNT as a therapeutic derives from certain important attributes of the toxin (Scott, 1989; Johnson, 1999): (a) exceptionally specific binding to the presynaptic membrane of cholinergic terminals; (b) extremely high potency; (c) remarkable specificity for catalytic cleavage of SNARE proteins involved in neurotransmitter trafficking and exocytosis; (d) minimal spread from the injection site; (e) limited and mild adverse effects and; (f) extraordinarily long duration of action.

The exceptional specificity and binding of BoNTs involves a multicomponent binding process to the presynaptic membrane (Montecucco *et al*., 2004). The receptor binding domain of BoNTs lies in the $H_c$ portion of the molecule (Lacy *et al*., 1998; Hanson and Stevens, 2002; Montecucco *et al*., 2004; Swaminathan *et al*., 2004). The presynaptic receptor systems for BoNTs have been postulated to involve an initial capture step mediated by a lipid- or a protein-linked oligosaccharide on the peripheral nerve terminals. This initial capture is followed by interactions with arrays of receptor molecules located in the neuronal membrane (Montecucco *et al*., 2004). These receptor array molecules have not been fully elucidated, but it appears that BoNT/B and BoNT/G interact with synaptotagmin I and II (Dong *et al*., 2003; Rummel *et al*., 2004; Montecucco *et al*., 2004). The possible involvement of dynamic arrays of presynaptic receptors involves more complexity than seen for most hormones and other signaling proteins that bind to receptors. This mechanism also increases the complexity of the ganglioside-protein double-receptor model for TeNT and BoNT that was postulated for many years. The presence of multiple receptor molecules could account for the high affinity of binding, and involvement of different receptors for various serotypes would explain in part the differential specificity for BoNTs. Montecucco *et al*. (2004) have suggested the interesting possibility that binding to the arrays of the presynaptic receptor could trigger a signaling cascade to induce pit formation, capture of BoNTs within a region of limited accessibility (Di Fiore and De Camilli, 2001), including reactivity to antibody molecules and inhibitors. The model proposed (Montecucco *et al*., 2004) is also consistent witht the increase in rate of BoNT internalization on nerve-ending stimulation and small synaptic vesicle (SSV) recycling (Schiavo *et al*., 2000). Since the degree of uptake of BoNTs into nerves is coupled to SSV recycling, the uptake of the toxins, as well as delivery of drugs or inhibitors attached to the receptor-binding domain, would be limited by synaptic neuronal activity. The elucidation of the mechanisms of receptor binding and internalization could lead to improved clinical protocols for BoNT as a therapeutic, as well as novel methods for therapy against botulism intoxication following the internalization process, which are unavailable at this time.

The exceptional toxicity of BoNT is essential for its therapeutic efficacy. BoNT is the most potent toxin known and is biologically active at femtomolar concentrations (Lamanna, 1959; Gill, 1982; Schantz and Johnson, 1992). BoNTs have an estimated lethal intravenous dose of 0.1–1 ng per kg body weight (Lamanna, 1959; Gill, 1982; Schantz and Johnson, 1992; Arnon *et al*., 2001). Experiences with commercial preparations of type A BoNTs in humans as well as non-human primate exposure studies have demonstrated that the intramuscular lethal dose is approximately 39 U/kg body weight for humans (Scott and Suzuki, 1988). Assuming that a mouse $LD_{50}$ of BTX is approximately 30 pg, and monkey susceptibility is equal to that of humans, then the i.m. lethal dose for a 70 kg human would be approximately 0.2 μg (the actual estimated dose is 1–2 μg (Schantz and Johnson, 1992)). When in its native complex form (BTX) (Sugiyama, 1980; Sakaguchi, 1983; Schantz and Johnson, 1992), BoNT is also extremely poisonous by the oral route, with an estimated lethal dose of 70 μg per kg for type A (Arnon *et al*., 2001). Due to the extreme toxicity of CNTs, careful handling and safety measures are extremely important in working with these toxins (Schantz and Johnson, 1992; Centers for Disease Control and Prevention, 1998; Malizio *et al*., 2000).

The specific toxicity of BTX preparations is an important consideration in efficacy and utility of BTX/BoNT as a pharmaceutical. The preparations used in medicine today consist of progenitor toxins, where the active BoNT component exists in large protein complexes. When present in these complexes, the BoNT generally accounts for about 30% of the protein mass, and thus the specific toxicity ($MLD_{50}$ per ng = U) is lower (about 10–40 U per ng) compared to purified neurotoxin (about 80–200 U/ng). It would be expected that the complexes with higher protein mass will have higher immunogenicity than purified BoNT. Furthermore, the biological activities of the non-toxic complexing proteins are not well known, and could have undesirable bioeffects in humans.

A third important attribute of BoNT as a therapeutic is the long duration of action. The longevity of action depends on serotype, and has usually been found to provide durations of paralysis in the order BoNT/A ≥ /C1 > /B> /F> /E in cultured primary neuronal cells (Bergey *et al*., 1987; Keller *et al*., 1999), animal models (Adler *et al*., 2001; Foran *et al*., 2003), and in humans (Eleopra *et al*., 2004). The biological mechanisms for the differences in serotype persistence is currently not understood, but probably involves differences in half-life and degradation of the CNTs in neurons, as well as their effect on neuronal regeneration (Keller and Neale, 2001; Foran *et al*., 2003). Differences in half-life have been inferred from activity measurements of BoNT/A in cultured primary hippocampal cells (Keller *et al*., 1999). The influence of synapse regeneration was inferred by the observation that truncated SNAP-25 modified by BoNT/A (cleavage at $Gln^{197}$-$Arg^{198}$; removal of only eight residues) was shown to remain in the neuronal terminus, while cleavage by BoNT/E

($Arg^{180}$-$Ile^{181}$; greater perturbation by removal of 26 residues) was removed from the neuron with accompanying repletion (Schiavo *et al*., 2000). BoNT/E-truncated SNAP-25 was more rapidly synthesized, presumably leading to more rapid recovery of neuromuscular activity (Eleopra *et al*., 1998). Since SNAP-25 cleaved by BoNT/A was not rapidly removed, it retained (nonfunctional) synaptic structure (Schiavo *et al*., 2000). BoNT/B and /F also have a shorter duration of activity in humans (Ludlow *et al*., 1992; Eleopra *et al*., 2004). The location of the $L_c$s in the nerve cytosol may also contribute to longevity (Dong *et al*., 2004; Fernández-Salas *et al*., 2004), possibly by avoiding proteolysis and removal. Sprouting and formation of new synaptic connections, as well as neuronal plasticity, could also contribute to nerve-muscle connections (Schiavo *et al*., 2000). The elucidation of the mechanisms leading to establishment of productive synaptic connections could provide a basis for BoNT pharmaceuticals with shorter or longer durations of action.

## HISTORICAL DEVELOPMENT OF BOTULINUM TOXIN AS A PHARMACEUTICAL

The background and development of botulinum toxin as a pharmaceutical has been described (Scott, 1989, 2004; Schantz and Johnson, 1992, 1987; Johnson, 1999). The general principle in the development of botulinum toxin as a drug followed the concept of "graded selective denervation" for control of involuntary muscle activity and with retention of voluntary muscle function. The concept of using botulinum toxin as a selective chemodenervating agent was probably considered for many years by neurologists (Scott, 2004). However, Drachman's provocative studies on the effects of botulinum toxin in developing chicken embryos at Johns Hopkins University in Baltimore provided conclusive experimental proof that botulinum toxin A induced selective denervation, muscle weakening, and muscle atrophy (Drachman, 1971). Following injection of enormous quantities (30 μg or approx. 1000 U) of BTX, the thighs and legs of the chicks were markedly shrunken, devoid of muscle tissue, and showed signs of degeneration and fat accumulation. The cardiac muscle of the chicks appeared normal, indicating that botulinum toxin did not have a generalized toxic effect on striated muscle but preferentially poisoned skeletal muscle. In these studies, Drachman obtained "crystalline" BTX preparations from Ed Schantz, who also supplied many researchers with toxin complex for basic and clinical studies (Scott, 2004). Drachman (1971) proposed the characteristics of an "ideal (nerve) blocking agent" in terms of its: (a) **mode of action** in selectively blocking cholinergic transmission (b) **specificity** in blocking only cholinergic transmission; (c) **reversibility** in not permanently impairing function or structure of nerve or muscle; (d) **generality of action** in blocking exocytosis from all motor neuron terminals of striated skeletal muscle; (e) **convenience of use** in requiring simple injection of a soluble toxin preparation into desired muscle regions; (f) **safety** if used with appropriate precautions and proper doses and; (g) **absence of systemic or CNS effects.**

The development of BTX as a therapeutic involved the collaboration of Alan B. Scott and Edward J. Schantz (Johnson, 1999). Scott's initial goal was to provide a pharmacologic alternative to surgery in patients with strabismus (crossed eyes) by injection of extraocular muscles. Compared to other agents tested including ethanol, bungarotoxin, and other substances, accurate injection of graded quantities of crystalline BTX altered ocular alignment. Transient ptosis in the vicinity of the monkeys' eyes cleared within a few days to weeks. Three and one-half months following injection, the EMG recorded from the injected muscle was of normal amplitude and eye movement was also normal. In these experiments, permanent ocular alignment changes after temporary muscle paralysis was the clinical outcome without any need for incision or direct exposure of the muscle. The quantity of toxin needed to induce ocular alignment was approximately 700-fold less than the estimated lethal dose for a 70 kg human (estimated as 1–2 μg; ~1,400 U). Scott predicted that botulinum toxin could be used as a denervating agent in humans for treatment of many conditions characterized by hyperactive neuromuscular activity.

The Food and Drug Administration approved one batch of crystalline botulinum toxin in 1989 produced in 1979 by Schantz at the Food Research Institute, University of Wisconsin - Madison (batch 79–11) for use in the United States for strabismus, blepharospasm, and hemifacial spasm. Schantz (and EAJ) later prepared several batches of crystalline BTX at the University of Wisconsin Food Research Institute using the Schantz strain (Hall A-*hyper*), tested media, fermentation conditions, and purification procedure (Schantz and Johnson, 1992, 1987; Johnson, 1999). According to Scott (personal communication), certain of these batches differed in potency and efficacy on injection into humans. During this period in the mid-late 1980s and extending into the late 1990s, botulinum toxin was increasingly being experimentally used for many other disorders and this single batch of toxin (79–11; ~150 mg) eventually was used for more than 250,000 injections in humans for an increasing number of syndromes.

Scott outlined the following principles and characteristics of botulinum toxin based on his monkey and human studies: (a) it showed no known focal or systemic effects apart from muscle paralysis; (b) it apparently did not elicit antibody production in the small doses that were used; (c) it diffused slowly and to a limited degree out of the injected muscle region into adjacent muscles; (d) the toxin acted for several weeks to months; (e) and the paralytic intensity was strongly correlated with the dose injected. As Scott predicted in 1973 (Scott *et al*., 1973), the utility of botulinum toxin A in medicine has greatly expanded to other neuronal disorders. Undoubtedly, the varieties of disorders treated with botulinum toxin will continue to grow, particularly as we learn more of its basic effects on nerve-muscle physiology.

## EFFECT OF BOTULINUM TOXIN COMPOSITION AND FORMULATION ON PHARMACEUTICAL EFFICACY

Purification of 900-kDa botulinum type A toxin complex (BTX) was refined and perfected in the 1940s–60s at Fort Detrick by Duff, Lamanna, Schantz, and collaborators (see Duff *et al*., 1957; Schantz and Johnson, 1992; 1997). In 1971, Schantz went to the University of Wisconsin, where he developed formulations for stabilization of pg quantities (femtomolar) of type A complex (Schantz and Johnson, 1992). The primary factors investigated were the roles of protein excipients, pH, and sodium chloride. It was decided that flash-dried or freeze-dried preparations were desired to prevent potential contamination and to provide a long shelf-life (Schantz and Johnson, 1992, 1997; Scott, 2004). The primary formulation developed contained human serum albumin (HSA) as a stabilizer (Schantz and Johnson, 1992). Under most drying conditions, the presence of physiological concentrations of NaCl led to BoNT inactivation (Goodnough and Johnson, 1992). Although BoNT was most stable at lower pHs (e.g., 5–6), it was felt that injection of acidic compositions into people could be painful, and thus physiological pH of 7.3 was chosen for the formulation.

Although batch 79–11 (produced in November 1979) was used with excellent results for many years (until 1998), like most proteins it showed degradation over time and specific activity declined to about 4 U per ng (Schantz and Johnson, 1987; Johnson, 1999; Scott, 2004). The decrease in specific toxicity meant that considerable inactive protein was present in the preparation, which probably acted as a toxoid upon injection into humans. This was reflected in the development of antibodies in a proportion of the patients, which then became refractory to further treatment (Hatheway and Dang, 1994; Borodic *et al*., 1996; Atazzi, 2004; Dressler, 2004). In the mid-late 1980s and 1990s, Schantz and I prepared fresh batches with the desired specific toxicity of 30–35 U per ng (Schantz and Johnson, 1992, 1987), which were turned over to Scott and used successfully for treatment of patients (A. B. Scott, personal communication).

During this period in the late 1980s and early 1990s, we were concerned that the complex proteins in the complex form of the toxin could promote immunity in humans based on the early literature that these nontoxic proteins were more immunogenic in animal studies and human trials (Kozaki, *et al*., 1989). Furthermore, experiments at Fort Detrick and elsewhere suggested the non-toxic complex proteins, including the hemagglutinins, could have undesirable biologic properties in humans (M. Crumrine, personal communication). Thus, our laboratory began to investigate the potential of using the pure neurotoxin component (BoNT/A) as the therapeutic agent. One possible concern to the use of BoNT/A instead of BTX was that being a smaller molecule (150 kDa) compared to the crystalline complex (900 kDa), it might diffuse to a greater extent and cause detrimental tissue reactions (Schantz and Johnson, 1987). However, recent experiments in animals (Tang *et al*., 2004; Borodic, unpublished data) and in human clinical trials indicated that tissue spread is not greater than the complex. Methods were developed to formulate and prepare dried preparations of purified BoNT/A, and to provide stability at elevated temperatures. As expected, preliminary experiments indicated that pure BoNT/A was less immunogenic than the large complex (M. Goodnough, thesis, University of Wisconsin). The single protein component in bulk material also enabled more precise analysis of purity and composition, including using SDS-PAGE, and more recently mass spectroscopy, which can be highly discriminating for evaluating the purity of toxin preparations (Barr *et al*., 2005). Thus, current data indicates that pure BoNT/A (and other serotypes) could have advantages in use as a therapeutic for human treatment.

## SAFETY IN WORKING WITH BoNTS AND TeNT

BoNTs and TeNT are extremely toxic molecules and are considered the most potent poisons known. Toxicity of BoNT/A has been estimated as 0.2 ng/kg of body

weight in humans, and the lethal dose is 1 $\mu$g or less. Because the consequences of an accidental intoxication are so severe, safety must be a primary concern of scientists studying these toxins. The CDC recommends biosafety level 3 primary containment and personnel precautions for facilities making large quantities of the CNTs. Selected personnel who work in the laboratory should be immunized with a pentavalent (A–E) toxoid available from the CDC. A biosafety manual should be posted in the laboratory and should contain the proper emergency phone numbers and procedures for emergency response, spill control, and decontamination. When performing steps in which aerosols may be created, special precautions need to be taken. A class II or III biological safety cabinet or respiratory protection should be used. The use of needles and syringes for bioassays requires extreme caution. Beginning in 1997, *C. botulinum* cultures and toxins were included in a group of select agents whose transfer has been controlled by the CDC. To transfer these agents, both the person sending and the person receiving them must be registered with the CDC and exchange the appropriate approval forms (Centers for Disease Control and Prevention, 1998; Malizio *et al.*, 2000).

## CLINICAL ASPECTS

BTXs and BoNTs can be injected transcutaneously into superficial or deep muscles without anesthesia or significant discomfort, through topically anesthetized mucous membranes, or through endoscopes to achieve regional denervating effects. Repeated injections over many years have been used to treat chronic diseases, with few side effects. Few injections over short time periods can be used to treat transient disorders. Placement of agents into appropriate regions is critical to success in treating neuromuscular disease. Diffusion of these agents is a function of dose and composition. Higher dose point injections can traverse fascial barriers causing regional complications within targeted areas, such as dysphagia (difficulty swallowing after anterior neck muscle injections) and diplopia and ptosis (after periorbital muscular injection). Appropriate anatomic placement is also critical to efficacy, as distribution of neuromuscular junctions has been known to vary between different muscle groups. Injection methods that maximize botulinum toxin delivery homogenously throughout the motor axons terminal distribution enhances response (Borodic *et al.*, 1988, 1991, 1994, 1998, 2002). Muscles with parallel fiber orientation tend to have neuromuscular junction distributed to the mid belly, whereas sphincter muscles tend to have diffuse distribution of neuromuscular junctions (Borodic *et al.*, 1988, 1991). For the former muscle type, injections would be most effective if applied to the mid belly, whereas for the sphincter muscle configuration, injections need to be applied within multiple regions. Long muscles such as paraspinal *longissimus dorsi* contain bands of innervation zones corresponding to each spinal nerve root segment (Figure 58.1) (Borodic *et al.*, 1988b, 1990, 1993, 1994). An animal model using multiple muscle biopsies at increasing distance from a point injection has been devised to assess diffusion potential at varying $LD_{50}$ doses (Figure 58.2 and 58.3 B). Such animal models have been used to compare properties of various botulinum toxin preparations for suitability for human use. Use of acetyl cholinesterase staining characteristics and muscle fiber size alterations are significant pathologic markers of botulinum effect, as they are direct structural consequences of neurogenic muscular atrophy (Figures 58.1, 58.2, and 58.3A) (Borodic *et al.*, 1988b, 1990, 1991, 1993, 1994).

The current dose unit is the $LD_{50}$ for the 18–22 g mouse. Such units have proven to be applicable to a particular dose formulation, but cannot be used as a universal standard. Differences in $LD_{50}$ dose requirements in various botulinum toxin preparations have been well documented. Variations in methodology between laboratories can perhaps explain a small degree of deviation in $LD_{50}$ determinations; however, clearly most differences relate to intrinsic pharmacologic properties of a given preparation.

Current research and speculation implicates direct sensory nerve effects from BTX injections ("third bioeffects") (Acquadro and Borodic, 1994; Borodic *et al.*, 2001, 2002a, 2002b; Dressler *et al.*, 2005), which may explain expanded uses of these pharmaceutical agents.

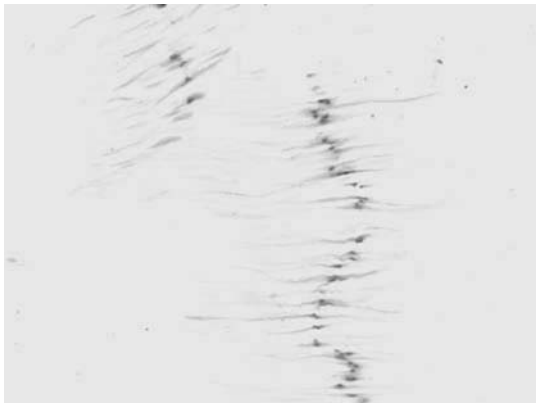

**FIGURE 58.1** Innervation zone of *longissimus dorsi* demonstrated as a band of neuromuscular junctions stained darkly for acetylcholinesterase using histochemistry. Each band of neuromuscular junctions correspond to each spinal segment in the rabbit back.

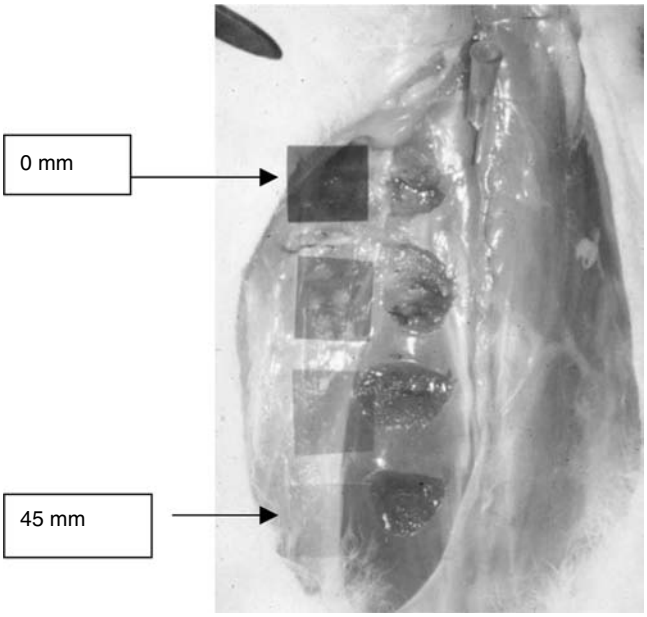

**FIGURE 58.2** Animal model devised to assess diffusion kinetics of botulinum toxin–based pharmaceuticals. Shaded areas corresponded to acetyl cholinesterase staining intensity after point botulinum toxin injections made at the upper segment of the paraspinal muscles (*longissimus dorsi*).

Although sensory nerve effects have been demonstrated in cell culture media (Borodic *et al*., 2002a, 2002b), binding to sensory nerves and definitive sensory nerve changes induced by BoNT remains to be demonstrated. Current research has suggested that secretion and/or intracellular expression of neuropeptides may be influenced by botulinum toxin injections, effecting sensitization and stimulation thresholds. Work in the sensory effects of botulinum toxin is a contemporary topic for basic science investigation. An example of suppression of inflammatory mediators is demonstrated in the skin of a patient treated with involuntary blepharospasm (Figure 58.4). In this example, cholinergic urticaria is suppressed within the denervation-diffusion field around forehead injection sites.

Immunologic resistance has been reported to be clinically significant in the past and continues to be a concern for long-term applications for any preparation (Borodic *et al*., 1996; Dressler, 2004). Upon repeated injections, formation of neutralizing antibodies can occur and highly sensitive methods to test for secondary resistance are still not readily available. Differences in preparation and formulations, such as specific activity, protein load per effective dose cycle, excipients, and immunotype (Borodic and Pearce, 1994; Borodic

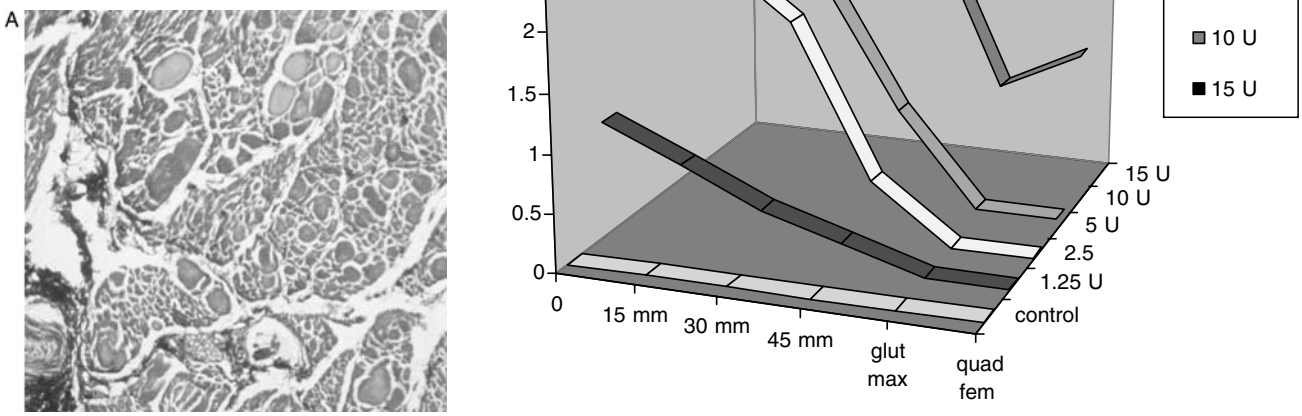

**FIGURE 58.3** (**a**) Muscle fiber size and size variability indicate neurogenic atrophy, a totally reversible phenomenon after botulinum toxin injection. Neurogenic atrophy remains contained to targeted anatomic region based on dose, placement, and composition of materials used. (**b**) Diffusion analysis of a botulinum-based pharmaceutical measured by fiber size variability and spread and intensity of acetyl cholinesterase staining in the rabbit *longissimus dorsi* muscle at increasing distances from injection. The vertical axis represents the degree of denervation using histochemistry and muscle fiber morphometrics; the horizontal axis represents distance from a point injection of varying LD 50 units. Remote location from point injections are gluteus maximus and quadriceps femoris muscles. Note that at 10–15 LD 50 units, the animal's minimum lethal dose, the remote muscles start to become denervated.

**FIGURE 58.4** "Third bioeffects" are terms related to neither neuromuscular nor autonomic effects of injectable botulinum toxin. Here, a patient demonstrates evidence of such effects on cholinergic urticaria (neurogenic hives) on the forehead. The effect is highlighted by white patches corresponding to the diffusion fields after injected botulinum neurotoxin.

*et al*., 1996) are distinguishing characteristics of available agents. Secondary immune response can render the therapy permanently ineffective. Incidence of antibody formation is an important criterion for assessing suitability of a given preparation for human use. Tachyphylaxis, that is, reduced effectiveness after many injections, occurs, but the role of immunity in this situation is uncertain. Whether this phenomenon is antibody-mediated or caused by another biologic process requires further investigation.

Various methods for measuring botulinum toxin antibodies have been used, including but not limited to neutralization bioassays (mouse neutralization assay), inhibition of Lc catalytic effects on cells in culture, ELISA, immunoprecipitation, and others (Sesardic, 2004; Jankovic *et al*., 2003). The mouse protection assay (MPA) is the standard for measuring antibodies, and the results of this assay have been determined to have consistent predictive value for clinical response (Borodic, 1999; Jankovic, 2004). Other assays, such as mouse hind limb paralysis (Pearce *et al*., 1995), have not been validated against clinical response. ELISA tends to be more sensitive, demonstrating consistently higher positive results compared to mouse neutralization. However, ELISA measures both non-neutralizing and neutralizing antibodies. Other methods for testing for the presence of antibodies are under investigation, using regional denervation models or cell cultures. Ideally, an antibody test should evaluate the entire biological events involved in intoxication, i.e., receptor binding, endocytosis, entry of Lc into the cytosol, and cleavage of neuronal substrates. Several antibody assays have been developed that measure inhibition of the catalytic activity of $L_c$ (Anne *et al*., 2001; Sesardic, 2004). However, these assays only determine one step in BoNT action. Furthermore, it is well-established that the H chain of BoNT contains the majority of epitopes that on immunization lead to neutralizing antibodies (Marks, 2004). Thus, assay systems that involve the $H_c$ and desirably the entire BoNT, such as primary neuronal cell culture methods (Keller *et al*., 1999; Keller *et al.,* Neale, 2004; Sesardic, 2004; Dong *et al*., 2004), the MPA (Pearce *et al*., 1995), and others would provide the optimum test for neutralizing antibodies.

Among current pharmaceutical preparations, more information is needed regarding antigenicity, as patients being treated with these agents often need repeated injections over many years. The current preparation of BOTOX has been reported to have less tendency to cause secondary resistance (Jankovic, 2004), although immunity still can occur, including in low-dose applications such as blepharospasm (Dressler, 2004; Dressler and Saberi, 2005). The original preparation of BOTOX (Allergan) (lot 79–11) was associated with an immunity rate of 10–20% over 3–5 years for large-dose applications (spasmodic torticollis) (BOTOX® package insert). MYOBLOC® (Botulinum immunotype B) has been reported to cause a positive MPA rate of 18% and ELISA positive rate of 50% over 18 months (WE MOVE Internet site).

Duration of action of type B and type F immunotypes has been shown to be significantly shorter than type A at equivalent $LD_{50}$ doses. Some argue that higher doses of type B can result in an almost equivalent duration of action (Lew, 2004). Experience with other immunotypes in human trials has not been reported in significant scale. The mouse $LD_{50}$ unit is not interchangeable and is specific for only one preparation. Generally, the conversion of $LD_{50}$ units between BOTOX/DYSPORT is approximately 4:1, whereas BOTOX /MYOBLOC is 1:100 (Ranoux *et al*., 2002).

The chronology of botulinum toxin injections for the treatment of human disease is presented in Table 58.1. The following represents an overview of indications listed in Table 58.1 with comments on contemporary developments regarding future medicinal utility.

**Ophthalmic Applications (1981)** (Mauriello, 1985, 1987; Elston, 1987; Borodic and Cozzolino, 1989; Snir *et al*., 2003)

In 1980–81, Alan Scott (Smith Kettlewell Eye Institute), with the scientific assistance of Dr Edward Schantz (University of Wisconsin), made a quantum leap in medical discovery by initiating clinical trials studying the application of botulinum toxin for the treatment of deviated ocular alignment in children

**TABLE 58.1**

| Disease | Date therapy initiated | Doses (U) | Case reports/ Open label trials | Randomized controlled studies | Regulatory approval |
|---|---|---|---|---|---|
| Strabismus/related applications | 1981 | 1.25–5 | + | | + |
| Essential blepharospasm | 1982 | 20–80 | + | + | + |
| Hemifacial spasm/facial nerve disorders | 1982 | 15–25 | + | + | + |
| Spamsodic torticollis | 1983 | 100–300 | + | + | + |
| Cerebral palsy | 1985 | | + | | − |
| Spasticity/occupation hand disorders | 1985 | 30–80 | + | + | − |
| Hyperhydrosis | 1988 | | + | + | + |
| Spasmodic dysphonia | 1984 | 2.5–5.0 | + | | − |
| Achalasia/esophageal stricture | 1990 | | + | − | − |
| Sinus secretion/coryza | | | + | | |
| Myofascial pain/headache | 1992 | 50–200 | + | + | − |
| Migraine | 1994 | 20–100 | + | +/− | − |
| Cosmetic (frown lines) | 1993 | 15–50 | + | + | + |
| Tension headache | 1992 | 15–50 | + | +/− | − |
| Post surgical pain | 1994 | 50–100 | + | − | − |
| Temporal mandibular joint syndrome | 1994 | 20–80 | + | + | − |
| Low back pain | 1997 | 100–200 | + | +/− | − |
| Trigeminal neuralgia | 2001 | 30–100 | + | − | − |

+/− indicates conflicting data

(strabismus). Although of substantial historic significance, the initial application for the treatment of strabismus has fallen out of favor as a first line therapy for these conditions due to difficulty with comfortable and effective placement of the pharmaceutical, even with electromyographic injection tip control. Weakness outside the targeted area can lead to vertical eye deviations when horizontal recti muscles are injected. The agents do provide backup options for more difficult surgical situations as an adjunctive measure, such as muscle transposition operations for sixth cranial nerve palsies.

The second and enduring ophthalmic application was neurologic involuntary blepharospasm. This disorder is associated with involuntary facial movements with relentless closure of eyelids, causing not only facial distortion but functional blindness. Botulinum toxin has become the treatment of choice for essential blepharospasm, as well as other related conditions causing involuntary eyelid closure. Blepharospasm was the first movement disease treated with botulinum toxin and the prototype condition from which dosing, principles of injection placement, and diffusion concepts were formulated (Borodic and Townsend, 1988; Borodic *et al*., 1991; Borodic *et al*., 1988, 1993, 1994). Dosing ranges from 15U to 100U of BOTOX® are used for these conditions. Injection placement is important to both efficacy and safety. Multiple injections points are preferred for the treatment within the orbicularis oculli, the major muscle involved with involuntary movement disorders of eyelids. The anatomic distribution of neuromuscular junctions is often diffuse throughout the muscle proper. Multiple injections spread the neurotoxin throughout the muscle, facilitating bringing the neurotoxin to innervation zones. This method has been compared to single-point injections and previously been shown to be superior (Borodic *et al*., 1988, 1991). Furthermore, placement of the material is important in preventing complications associated with this application. Avoiding the midline of the upper lid and medial portion of the lower eyelid help avoid the ptosis and diplopia complications associated with periocular injection. Avoiding placement of the drug away from the lateral canthal tendon avoids toxin diffusion into the lateral orbit structures, including the lateral rectus muscle. Avoiding the medial lower lid mitigates against diplopia from diffusion into the inferior oblique muscle.

The nature of morbidity associated with bilateral blepharospasm is primarily visual loss. Patients with bilateral blepharospasm suffer impairment in routine activities such as driving and reading. Involuntary movement can spread to other regions of the face, causing disfigurement. The extended syndrome has become known as Meige syndrome (previously described as Breugel's syndrome, see Figure 58.5). Prior to the institution of botulinum toxin for these conditions, surgical procedures such as bilateral facial neurectomy and aggressive myectomy surgery would be employed. Despite such procedures, many patients experienced return of involuntary movement with motor nerve regeneration and often became chronically disabled. Botulinum toxin has served to provide the best long-term therapy for this afflictions, as application is sim-

**FIGURE 58.5** Case of *benign essential blepharospasm* with facial dyskinesia (*Meige syndrome*). This was the prototype disease for the application of botulinum toxin for movement disorders, including dystonia, spasticity, and reactive and painful spasms. These patients lose vision and become disabled, based on involuntary eyelid closure.

**FIGURE 58.6** Adult onset spasmodic torticollis (cervical dystonia) was the first large-dose indication treated in injectable botulinum toxin-based pharamceuticals. The condition is characterized by pain, posture deformity (tilted, twisted, rotated neck), involuntary movement and tone, decreased range of motion, muscle hypertrophy, and disability. This condition was the prototype for the application of botulinum toxin for human pain disorders and syndromes.

ple, more effective, and safer to repeated surgical interventions.

Other disorders causing involuntary eyelid closure where botulinum toxin treatment has been documented include hemifacial spasm, apraxia of eyelid opening, myokymia, and synkinetic eyelid closure associated with aberrant regeneration of the seventh cranial nerve. Aberrant facial movement remote from periocular location has been effectively treated using botulinum injections throughout other facial regions.

Open label and double-blinded controlled studies have demonstrated efficacy, and regulatory approval had been granted for these indications. These conditions have provided the longest experience for the use of repetitive muscle injections for the treatment of a human affliction.

**Adult Onset Spasmodic Torticollis (Cervical Dystonia) (1983) (Figure 58.6)** (Tsui *et al*., 1986; Brin *et al*., 1987; Stell *et al*., 1988; Gelb *et al*., 1989; Borodic *et al*., 1990, 1991; Jankovic, 2002)

Botulinum has become the therapy of choice for cervical dystonia. This condition is characterized by pain, involuntary movement with distorting and twisting postures of head and neck, decreased range of motion of cervical spines, and hypertrophied sternomastoid muscles (anterior neck muscles). Pain is the most responsive syndrome component for this condition. Injections are usually given in multiple locations, mainly directed at painful regions within the posterior cervical region. Dosing for this indication ranges from 100–300 U with botulinum type A toxin (BOTOX®-OCULINUM) and botulinum toxin immunotype B-(5,000–10,000 U MYOBLOC®). The indication has most commonly been associated with secondary resistance with reported incidence between 4–20% with original botulinum A toxin preparation (79–11). This incidence is probably reduced with more recent preparations of BOTOX® (Jankovic, 2004). Open and double-blinded controlled studies have been reported and U.S. FDA has issued licenses for this indication for both BOTOX and MYOBLOC.

**Spasmodic Dysphonia (1985)** (Benninger *et al*., 2001; Boutsen *et al*., 2002; Pearson *et al*., 2003; Rubin *et al*., 2004)

This condition has been effectively treated with EMG-guided injection into the vocal cords through the cricothyroid membrane. The condition exists in several forms, adductor-abductor types and global muscular involvement, which respond differently to the treatment. The adductor subtype is the most responsive. Doses required are small, ranging from 1.25–5 U BOTOX®. Long-term repeated injections are often necessary. The botulinum injections replaced more destructive neurectomy procedures for this condition.

**Spasticity and Occupational Limb Dystonia (1991)** (Borodic *et al*., 1992; Bakheit *et al*., 2004; Brashear *et al*., 2004; Gordon *et al*., 2004; Swartling *et al*., 2004; Tamura *et al*., 2004)

Spasticity is increased muscle tone with unstable reflex movement caused by injury to the motor cortex and corticospinal tracts within brain and spinal tracts as a result of stroke, cerebral palsy, birth injury (cerebral palsy), head injury, or demyelinating and degenerative nervous system diseases. The clinical morbidity results from upper motor neuron–related weakness and unstable control of movement. Open label trials demonstrating efficacy have been reported for many indications in this category. Placement can require use of EMG stimulating electrodes for correct muscle placement. Doses will vary, depending on size and location of muscle abnormalities. Post-stroke spasticity has been studied with beneficial results demonstrated in double-blinded, placebo-controlled study designs.

**Autonomic Disorders / Hyperhidrosis (1989)** (Hoefflin, 1998; Lowe, 1998; Matarasso; Fagien *et al*., 1999; Naumann and Jost, 2004).

Use of botulinum toxin to reduce sweating and reflex tearing depends on blockage of autonomic cholinergic transmission. Blockage of reflex tearing in patients with aberrant facial nerve regeneration had been initially demonstrated with early experience for periocular injections. Other applications deal with primary hyperhidrosis syndromes, which result in sweating in hands and feet. Doses for these afflictions range from 15 U–100 U (BOTOX)® and regional effects can last for the order of 3–6 months. Double-blinded studies have confirmed efficacy for this indication and U.S. regulatory approval has been issued this past year for this indication.

**Cosmetic Applications (Figure 58.7) (1993)** (Borodic, 1996; Hoefflin 1998; Carruthers *et al*., 2004)

Currently, this is the most common use of botulinum toxin and has affected the general public's perception of BTXs as "serious medicinal agents" because of enormous publicity and promotion given to this treatment. The indication grew out of the observation that periocular lines and frown lines were depressed when the agent was used to treat blepharospasm patients. Masculine-appearing frown lines, forehead lines, and crow's-feet (smile lines), which can give an impression of age, can be effaced by relaxing the resting muscle tone and facial muscle contraction associated with human facial expression. Double-blinded controlled studies were generally simple in intent and design and have demonstrated efficacy for this condition. U.S. FDA approved this indication in 2002. The agents are widely used by healthy individuals for cosmetic purposes.

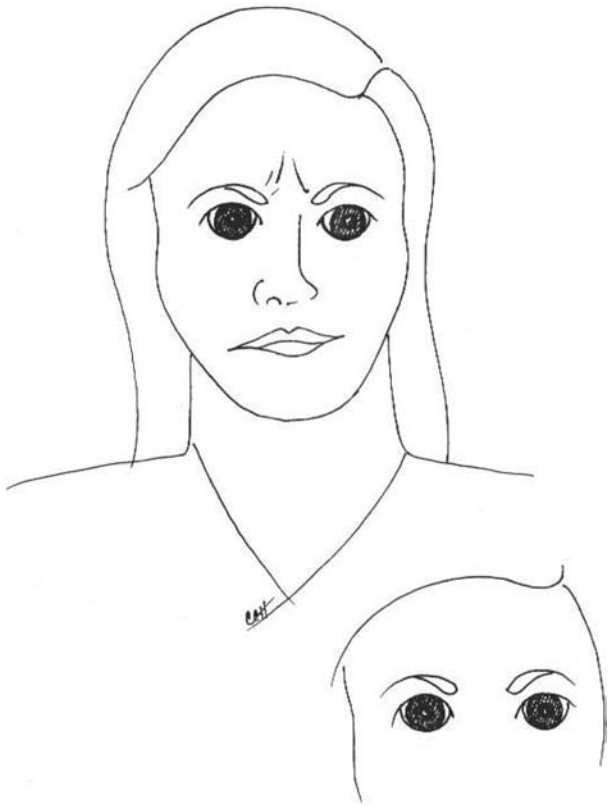

**FIGURE 58.7** The application of botulinum toxin for the reduction of rhytides (wrinkles) has become widespread throughout the world, because of low doses needed to achieve this effect and favorable safety record for this agent. The rhytides targeted include glabellar lines (frown lines between brow, as depicted), crow's-feet (smile lines), forehead creases, as well as neck bands and nasolabial fold flattening.

**Pain (not associated with dystonia)** (Tepper *et al*., 2004; Caputi, 2004; Blumenfeld, 2004; Evers *et al*., 2004; Borodic, 2001; Acquadro, 1993)

The pain component of the spasmodic torticollis-cervical dystonia syndrome was so responsive to botulinum toxin injection that the notion to use botulinum toxin for the treatment of pain emerged (Acquadro 1993). Botulinum was utilized as an agent for the primary treatment of muscle-based pain, without cervical dystonia, that is, myofascial pain. Myofascial pain is a general condition commonly associated with trauma, such as whiplash, surgery, and tension, and essential headaches based on an interaction with the sensory nervous system within various muscular regions. The condition can be non-traumatic in origin. Other overlapping and related medical conditions include fibromyalgia, temporal mandibular joint disease, and stress-related muscle pains. The use of botulinum toxin has rapidly expanded throughout the world for muscle-based applications (Borodic, 2001). Furthermore, observation on possible efficacy in migraine gave further impetus to investigate these indications (Caputi, 2004; Blumenfeld, 2004).

To date, a number of open label studies have suggested efficacy for application of botulinum toxin therapy for headaches (Blumenfeld, 2004). Although an initial industrial sponsored, randomized, double-blinded placebo-controlled study did show efficacy for the treatment of migraine, efforts have failed to reproduce these initial findings and have produced inconsistent results (Evers *et al.*, 2004). Furthermore, double-blinded studies for chronic tension headache have not to date confirmed initial observations (Evers *et al.*, 2004). Many issues relating to confounding data exist in the clinical literature. Endpoints in various studies are different, numbers in controlled studies have been small, no careful subset analysis of response exists, and predictive factors have not been evaluated. The use of retrospective global assessment scales, which have shown efficacy in open label trials and blinded trials, appear to be yielding different outcomes using the diary method of recording symptoms. Headache indications also notoriously are associated with placebo rates as high as 35%, and possibly even higher. An effort to resolve this issue is being conducted with a large multi-institutional double-blind placebo-controlled trial for migraine. Selection criteria for subgroups have also been advocated by the authors at this point in development history. At the time of preparation of this manuscript, more definitive data are expected to be released from large industrial supported, blinded, controlled studies involving the migraine indication.

In summary, pain applications can be a major area for future botulinum toxin use; however, more rigorous randomized controlled clinical studies will be needed to establish absolute scientific proof of efficacy. These studies are difficult because of the inherent high rate of placebo effect associated with migraine/other headache and pain indications and difficulty associated with blinding the treatment groups because of obvious facial and other muscular weakness created by botulinum injections.

### Urologic Applications (Cruz et al., 2004; Smith et al., 2004)

Botulinum toxin was initially applied in the bladder of patients with spinal neurogenic detrusor overactivity and urinary incontinence, or in the urethra in cases of detrusor external sphincter dyssynergia. In addition, the application of botulinum toxin was extended to the treatment of other urological disorders, including non-neurogenic detrusor overactivity, non-relaxing urethral sphincter, and detrusor underactivity. Interesting reports on the injection of botulinum toxin into the prostate of patients with benign prostatic hyperplasia have been reported. Bladder injection of botulinum toxin is not yet an approved treatment for lower urinary tract dysfunction. Nevertheless, available data suggest that in the near future the toxin will become a standard therapeutic option in incontinent patients with neurogenic and non-neurogenic forms of overactive bladder, who do not respond to or do not tolerate anticholinergic medication.

### Other indications

As botulinum toxin has been thought possibly to suppress neurogenic inflammation, other applications through the medical field are possible. Early development case studies are being compiled for interstitial cystitis, dermatosis, internal, and other inflammatory disorders. Cholinergic urticaria has been suppressed over the diffusion field in several patients (Borodic *et al.*, 2001). Experimental evidence in cell sensory cultures suggests botulinum toxin may block neuropeptide secretion, such as substance P, CGRP, and histamine. Despite scattered *in vitro* studies, it still is not clear that botulinum toxin preparations can bind to sensory nerve terminals or the degree that these agents can suppress inflammation.

## CONCLUSION

Botulinum neurotoxin has several desirable properties as a pharamceutical, including exceptional specificity for striated skeletal muscle, localized action and relative absence of systemic effects, remarkably high potency requiring extremely low doses, an uncommonly long duration of action for a single dose, and lack of immunogenicity when manufactured and used properly. It also presently has some disadvantages, such as spread to neighboring muscles, requirement for repeated injections, lack of consistency of biological activity, and antibody formation with improper use. It is likely that many of these disadvantages will be overcome as we better understand the physiology in relation to the human body and new generation botulinum drugs are developed. Despite its current shortcomings, it has benefited thousands of humans and allowed them to live normal and healthy lives.

# Toxins as tools

*Klaus Aktories*

## INTRODUCTION

Protein toxins are biological instruments, which help bacteria to prevail in a hostile environment defined by the innate or acquired immune system of the host organism. Usually the "classical" toxins are released from the microbes into the environment and, thereafter, act on or in target cells in a manner independently of the presence of the bacteria. To do so, bacteria eveloped fascinating mechanisms to attack the host organism by these microbial instruments, which are outlined in other chapters in detail. These properties of protein toxins are frequently exploited to use them as pharmacological tools to study the cell biology of eukaryotic cells. Among them are toxins, which act on the cell surface to cause pore formations; others act exclusively in the cytosolic fraction of cells and possess elaborate mechanisms to enter cells. Pore formation and uptake mechanisms of toxins are frequently utilized as protein delivery systems to translocate proteins into the cytosol. Many "classical" toxins covalently modify their eukaryotic targets and affect the functions of their targets in a persistent manner, which often results in a permanent inhibition or stimulation of the activities or functions of target proteins, and eventually allows important conclusions about the eukaryotic toxins' targets. Thus, the primary intention of using bacterial protein toxins as tools is to learn more about the biological roles of the eukaryotic targets of microbial toxins. However, very often this inversely results in an increase of our knowledge about the toxins and their structure-function relationships.

### General properties of protein toxins as pharmacological tools

Several properties qualify protein toxins as pharmacological tools (Table 59.1). The toxins are highly specific, extremely potent, and extraordinarily efficient. Moreover, although large in size, many protein toxins are able to translocate into the cytosol without major damage of the cell membrane of the target cells.

The high specificity of toxins is most important for the application of toxins as tools. Evolution of protein toxins resulted in a remarkable specificity for eukaryotic targets. Many toxins are able to differentiate between highly related and structurally similar members of eukaryotic protein families. For example, this is true for signaling proteins of the superfamily of GTP-binding proteins. Certain toxins are able to differentiate between related GTPases of the Rho family or between heterotrimeric GTP-binding proteins. Even more remarkable is the specificity of actin-ADP-ribosylating clostridial toxins to differentiate between α- and β/γ-actin isoforms, which are more than 95% identical in their amino acid sequence (see below, Table 59.2). Noteworthy, many toxins that modify target proteins appear to be more specific in intact cells or tissues than *in vitro* when the substrate specificity is studied under artificial *in vitro* conditions. A typical example for this is cholera toxin, which ADP-ribosylates many proteins in cell lysates (Gill, 1977), whereas no really good evidence exists that the toxins attack other targets than the eukaryotic $G_s$ protein involved in signal transduction via heptahelical receptors (see below). Nevertheless, one has to keep in mind that the

**TABLE 59.1** Advantages of toxins used as tools

| |
|---|
| **1. High specificity** |
| as compared to "synthetic" chemicals used as pharmacological tools action via specific receptors |
| **2. High potency** |
| caused by catalytic mechanisms of many toxins |
| **3. High efficiency** |
| caused by irreversible catalytic mechanism and eukaryotic targets with essential cellular functions |

toxins' specificity may not be "absolute," and it is highly recommended to take the findings obtained with a toxin as *one* important indication that should be corroborated by another toxin or even better by a different method.

High potency of protein toxins means that the toxins act at extremely low concentrations. For example, botulinum neurotoxins are the most potent biological agents ever known, with a minimal lethal dose in mice in the range of 10 picogram (Payling-Wright, 1955). These high potencies of toxins are achieved by at least two properties. First, many toxins are enzymes and act in a catalytic manner. They are, for example, proteases, ADP-ribosyltransferases, glucosyltransferases, N-glycosidases, or deamidases. Therefore, only few molecules may be necessary to modify target proteins by a catalytic reaction. Even more, it has been estimated that only one molecule of the ADP-ribosyltransferase diphtheria toxin, which inhibits protein synthesis by modification of elongation factor 2, is sufficient to intoxicate a target cell (Yamaizumi *et al*., 1978). Second, by high-affinity interaction with specific cell surface receptors, the toxins may target preferentially cells that are particularly sensitive towards the toxins' actions.

The high efficiency of bacterial toxins is caused by reasons already mentioned. Of course, the catalytic activity, which is the basis for the mode of actions of many toxins, is particularly important. However, similarly important for high efficiency is the toxins' choice of eukaryotic substrates. Generally, the toxins attack functionally important eukaryotic substrates, which play pivotal roles in the biology of the target cell. These toxins' targets are often crucial switch proteins of cellular signaling like heterotrimeric G proteins. For example, this is true for the activation of the $G_s$ proteins, which are ADP-ribosylated by cholera toxin, and also for the Gi proteins, which are inhibited by pertussis toxin-catalyzed ADP-ribosylation. Perhaps an even more impressive example is the targeting of Rho GTPases by various bacterial protein toxins, including Rho-inhibiting C3 ADP-ribosyltransferases and clostridial glucosylating toxins (see below). These signaling proteins are not only inhibited but also activated by toxins like the deamidating cytotoxic necrotizing factors (CNF 1 and 2) and the transglutaminating dermonecrotic toxin DNT.

It is important to mention that not only the "classical" protein toxins, which may be defined by their ability to act on target cells independently of the presence of the producing bacteria, are employed as pharmacological tools. Recently, bacterial effector proteins, whose cell entry depends on the presence of the bacteria and which are microinjected by type-III secretion system (TTSS) into the target cells, also are used as toxins. In this case, the complete bacteria must be used, which has many drawbacks, e.g., the specificity of the action.

## PORE-FORMING TOXINS AS TOOLS

Different types of bacterial protein toxins are known that affect target cells by formation of pores, thereby causing imbalance of cellular electrolytes, depletion of nucleotides, or other essential low molecular mass cellular factors. These toxins are widely used as pharmacological tools to permeabilize eukaryotic cells with the intention to change the cytosolic content in a well-defined manner; for example, to introduce small molecules, which are membrane impermeable (e.g.,

nucleotides and ions). The pore-forming toxins are used to introduce peptides or proteins, such as antibodies, into target cells

Streptolysin O from *Streptococcus pyogenes* is probably the best established pharmacological tool in this group (Ahnert-Hilger *et al*., 2000). However, many other pore-forming toxins are known that are used as cell biological tools, including tetanolysin, *Escherichia coli* hemolysin, and *Staphylococcus aureus* α-toxin (van der Goot, 2001). Interestingly, usage of pore-forming toxins as delivery devices appears not to be an artificial application of these toxins. It was reported recently that streptolysin O functions as a delivery system to allow other bacterial proteins that lack a cell transportation device to enter host cells. Therefore, usage of pore-forming toxins as a pharmacological tool to deliver membrane impermeable factors into the cytosol might mimic their biological function (Madden *et al*., 2001).

Streptolysin O is an approximately 60-kDa protein, which belongs to the family of cholesterol-dependent cytolysins, indicating that its action depends absolutely on the presence of cholesterol (Bhakdi *et al*., 1997). Streptolysin O and related toxins (e.g., perfringolysin O) interact with membrane cholesterol and homo-oligomerizes to form a prepore. Then the toxin oligomers convert to a pore-forming complex by membrane insertion of two transmembrane β-hairpins per monomer and form large aqueous β-barrel pores with an internal diameter of up to 30 nm. About 50 monomers take part in oligomerization and pore formation. The toxin does not bind to membranes, which do not contain cholesterol. Moreover, the number of binding sites and the binding affinity appear to depend on the amount of cholesterol in the membrane (Palmer, 2001).

Because the pores of streptolysin O are very large, they are permeable for large molecules (over 100 kDa). Probably, this is the reason why streptolysin O also interacts with internal membranes. When the toxin is applied as a tool, the extent of cell damage and the alteration of intracellular membranes are reduced by dissociation of the binding event from the pore-forming process by a temperature shift. First, streptolysin O binding is carried out at low temperature (0°C). Then surplus streptolysin O is removed by washing. The permeabilization is initiated by increasing the incubation temperature to 37°C. Usually, the permeabilization by streptolysin O is lethal for the cell. However, recently it was shown that a reversible membrane permeabilization is possible with streptolysin O. This depends on calcium-calmodulin and intact microtubules and allows the transport of up to 100-kDa proteins into the cytosol (Walev *et al*., 2001).

Pore-forming toxins have been widely used in studies on exocytosis from various secretory cells, on calcium regulation, on signal-contraction coupling in smooth muscle cells, and on intracellular membrane trafficking (Ahnert-Hilger *et al*., 2000). Researchers using pore-forming toxins must consider that these toxins induce a wide spectrum of biological effects, many of which are explained by changes in cellular ion fluxes and appear to be triggered by monovalent ion fluxes and by $Ca^{2+}$ influx (e.g., secretion, generation of lipid mediators, and cytoskeletal redistribution). However, some of the effects of pore-forming toxins cannot be explained in this way. Examples of the latter effects are activation of G-protein signaling and proteolytic shedding of membrane proteins. All these effects must be considered when interpreting data obtained with pore-forming toxins as tools.

Other members of this large toxin family are perfringolysin O from *C. perfringens*, and tetanolysin from *C. tetani*.

*S. aureus* alpha-toxin, which is also frequently used as a pharmacological tool, is a hydrophilic polypeptide of 293 amino acids, whose crystal structure was analyzed recently (Song *et al*., 1996). The model derived from the crystallographic data shows a mushroom-shaped, homo-oligomeric heptamer with a transmembrane domain composed of a 14-strand antiparallel β-barrel with a pore diameter of 2.6 nm. The pore formation caused by alpha-toxin is limited to the cell membrane because the toxin monomers (about 33 kDa) are not able to pass through the pore.

### Pore-forming toxins used as pesticides

It should be mentioned that some pore-forming toxins have an enormous commercial importance as pesticides against insects. For this purpose especially, members of the large family of pore-forming toxins (Cry families) from *Bacillus thuringiensis* are used. These toxins kill insect larvae, but apparently are not harmful to mammals, and spraying plants with spores of *B. thuringiensis* seems to be environmentally safe. Importantly, the various toxins are specific for certain insects only. Recently, the genes for toxins were introduced into many crop plants in an effort to protect them from insect attack (Schnepf *et al*., 1998; Aronson and Shai, 2001).

## PROTEIN TOXINS TO STUDY GTP-BINDING PROTEINS

Several ADP-ribosylating toxins target GTP-binding proteins, which belong to related GTPase families.

While diphtheria toxin and *Pseudomonas* exotoxin A modify the eukaryotic GTP-binding protein elongation factor 2, cholera toxin, the related heat-labile toxins from *E. coli*, and pertussis toxin modify the α-subunits of heterotrimeric G-proteins from Gs and Gi, respectively. In addition, several low molecular mass GTPases of the Ras superfamily are targets of ADP-ribosylating toxins, including C3-like transferases from *C. botulinum*, *C. limosum*, and *S. aureus*.

## Cholera toxin and pertussis toxin

Cholera toxin and pertussis toxin have been extremely valuable tools in studies on signal pathways involving heterotrimeric G proteins (Figure 59.1).

Cholera toxin is produced by *Vibrio cholerae* and the cause of the watery diarrhea of cholera. The ~85-kDa toxin is composed of an enzyme subunit of about 28 kDa (A-subunit) and a binding component consisting of five identical B subunits of about 11.6 kDa. The enzyme part consists of a ~21-kDa A1 and a ~6-kDa A2 subunit. A1 and A2 are linked by a disulfide bridge. A1 is the ADP-ribosyltransferase, whereas A2 links the enzyme to the B component. The B subunit binds to the ganglioside receptor GMI, which leads to internalization of the toxin and retrograde transport to the ER and translocation of the enzyme subunit via the sec61p into the cytosol (Kaper *et al*., 1995). The ADP-ribosyltransferase targets the α-subunit of heterotrimeric Gs proteins. It ADP-ribosylates arginine 201 of $G_{s\alpha}$ or equivalent arginine residues in splice variants of the α subunit of the $G_s$ protein. The modification of $G_{s\alpha}$ blocks its intrinsic GTPase activity, prevents the endogenous switch-off mechanism, and renders the α subunit persistently active (Cassel and Pfeuffer, 1978). In the intestinal mucosa, persistently active $G_{s\alpha}$ stimulates adenylyl cyclase, increases intracellular cyclic AMP levels, and activates cAMP-dependent kinase A (PKA), which phosphorylates numerous proteins. It is suggested that phosphorylation of $Cl^-$ channels (e.g., CFTR) finally results in electrolyte and fluid misbalance typical for cholera. *In vitro*, cholera toxin also ADP-ribosylates other G proteins such as transducin and, under specific conditions, even $G_i$ (Gierschik *et al*., 1989). In addition, potential *in vitro* substrates include many cell proteins with a suitable arginine residue. Also, small arginine derivatives like agmatine are *in vitro* modified. Finally, the toxin itself is modified by an auto-ADP-ribosylation reaction. Thus, in *in vitro* experiments, the specificity of CT is not very impressive. By contrast, in intact cells, $G_{s\alpha}$ seems to be the preferred substrate of the toxin (Van den Akker *et al*., 2000). Like many other ADP-ribosyltransferases, CT has NAD glycohydrolase activity. It splits NAD into ADP-ribose and nicotinamide in the absence of a protein

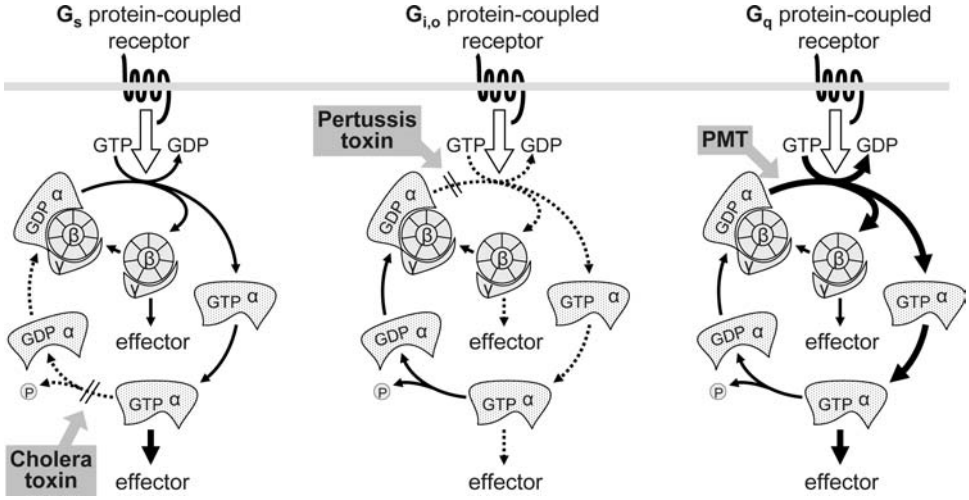

**FIGURE 59.1** Mode of action of toxins affecting heterotrimeric G-proteins.
Left panel: Cholera toxin ADP-ribosylates the α-subunits of Gs proteins. This blocks the GTPase activity and inhibits the switch-off mechanism of the Gs protein.
Middle panel: Pertussis toxin ADP-ribosylates $G_{i,o}$ proteins. Thereby, the interaction of the G protein with the receptor is blocked. The G protein cannot be activated by the receptor and remains in the inactive state.
Right panel: *Pasteurella multocida* toxin (PMT) activates $G_q$ proteins. Although the precise mechanism is not known at present, it is suggested that the activation step is facilitated by the toxin. This causes enhanced activation of $G_q$ signaling.

substrate. NAD glycohydrolase activity is low as compared with the ADP-ribosyltransferase activity. ADP-ribosylation by CT is stimulated by the presence of ADP-ribosylation factors, which are members of a subfamily of small GTPases (ARF subfamily of GTPases). In addition to application of CT as a tool to manipulate signal pathways via $G_s$ protein or to label $G_{s\alpha}$ protein, the toxin is frequently used as an adjuvant to stimulate mucosal immune responses (Plant and Williams, 2004). Moreover, CT is successfully used as a tracer for retrograde transport in neuronal cells (Hayakawa *et al*., 2004).

Pertussis toxin (PT) is a major exotoxin of *Bordetella pertussis*, the causative pathogen of whooping cough. PT is a hexameric toxin of 105 kDa, consisting of the enzyme subunit S1 (about 26 kDa, A subunit) and the binding pentamer (B subunit) formed of S2 (about 22 kDa), S3 (about 22 kDa), two S4 subunits (about 12 kDa), and S5 (about 12 kDa). PT ADP-ribosylates the $G_\alpha$ subunits of the heterotrimeric $G_{i/o}$ proteins (e.g., $G_{i1\text{-}3}$, $G_{o1,2}$, and $G_t$) (Figure 59.1). The toxin selectively ADP-ribosylates a cysteine residue located at the C-terminus (four amino acid residues before the carboxy-terminal end) of the Gα proteins. In the 1980s, PT was most important for identification of $G_i$ as inhibitory G proteins besides the stimulatory $G_s$ protein. A consequence of PT-catalyzed ADP-ribosylation is uncoupling of G proteins from their membrane receptors with subsequent blockade of the G-protein-transduced signal pathways. Importantly, G proteins of the $G_s$, $G_{q/11}$, $G_{12/13}$, and $G_z$ subfamilies and a splice variant of $G_{i2}$ [$G_{i2}$(L)] are not modified by pertussis toxin. Therefore, the toxin is a well-established tool to test whether a signaling pathway involves "PT-sensitive" G proteins or not (Nürnberg, 1997).

## *Pasteurella multocida* toxin

Recently, *Pasteurella multocida* toxin was employed for studies involving $G_q$ proteins. PMT is a ~ that 150-kDa protein that causes atrophic rhinitis and turbinate bone atrophy in pigs (Lax *et al*., 2004; Wilson and Ho, 2004). It is an extremely potent mitogen. One prominent toxin effect is stimulation of phospholipase Cβ (Murphy and Rozengurt, 1992). So far, the precise molecular mechanism of toxin is not known. However, recent studies indicate that PMT activates $G_{\alpha q}$ proteins (Wilson *et al*., 1997) (Figure 59.1). Therefore, PMT is applied in signal transduction studies to investigate the role of $G_q$. Interestingly, PMT is able to differentiate between $G_q$ and $G_{11}$. Gq stimulates $G\alpha_q$, but not the highly related $G\alpha_{11}$. In addition PMT interferes with Rho signal pathways (see below) (Zywietz *et al*., 2001). Rho proteins are most likely activated by $G_q$, but also by the $G_{12/13}$ subfamily proteins. Therefore, it might be that the effect of PMT is not as specific as previously suggested and also $G_{12/13}$ proteins are activated by the toxin.

## Studying small GTPases with bacterial protein toxins

Various low-molecular-mass GTP-binding proteins are targets of bacterial protein toxins, which cause inhibition or stimulation of these switch proteins. Well-studied examples of the toxins are the ADP-ribosylating C3-like transferases, the clostridial glucosylating toxins, and deamidating and/or transglutaminating toxins. All these toxins were frequently used as cell biological tools and were of major importance in elucidating the functional role of the small GTPases.

Small GTPases are usually grouped in at least five families, including the Ras, Rab, Arf, Ran, and Rho subfamilies, which have about 30% sequence identity. Members within each GTPase subfamily are at least 50% identical in their amino acid sequence. Similar to heterotrimeric G proteins, the low molecular mass or "small" GTP-binding proteins are regulated by a GTPase cycle. They are inactive in their GDP form and active after GDP-GTP exchange. Hydrolysis of bound GTP terminates the active state of the GTPases (Van Aelst and D'Souza-Schorey, 1997; Bishop and Hall, 2000). Especially Rho subfamily GTPases are targets for bacterial protein toxins. This family comprises about 20 GTPases (e.g., RhoA, RhoB, RhoC, RhoD, RhoE, RhoG, Rac1, Rac2, Rac3, Cdc42Hs, G25K, and RnD/RhoE). At least three groups of regulatory proteins control the function and activity state of Rho proteins. Guanine nucleotide exchange factors (GEFs) activate Rho GTPases by facilitating the GDP-GTP exchange. GTPase-activating proteins (GAPs) stimulate and catalyze the GTP hydrolysis, thereby inactivating the GTPases and, finally, guanine nucleotide dissociation inhibitors (GDIs). The latter regulators block nucleotide exchange, extract Rho proteins from membranes, and keep them in the cytosol. Most likely, they are involved in presentation of the GTPases to effectors or other regulators.

Rho GTPases (Rho, Rac, and Cdc42) are master regulators of the actin cytoskeleton. They are crucially involved in adhesion and migration of cells. They play a pivotal role in endocytosis, secretion, and phagocytosis. Moreover, Rho GTPases act as molecular switches in numerous vital cellular processes, including cell polarity, cell cycle progression, transcriptional regulation, transformation, and apoptosis (Nobes and Hall, 1995).

# INACTIVATION OF RHO GTPases BY BACTERIAL PROTEIN TOXINS

## C3-like ADP-ribosyltransferases

C3-like ADP-ribosyltransferases are basic proteins (IP > 9) with molecular masses of about 25 kDa, having a sequence identity of 30 to 70%. Seven isoforms produced by *Clostridium botulinum, Clostridium limosum, Bacillus cereus*, and *Staphylococcus aureus* have been described. C3 transferases ADP-ribosylate RhoA, RhoB, and RhoC at asparagine 41, thereby blocking the biological activity of Rho (Figure 59.2). The underlying mechanism is most likely inhibition of activation of Rho GTPases by GEFs, release from membranes into the cytosol, and formation of a tight inactive Rho-GDI complex after ADP-ribosylation (Sehr *et al*., 1998; Genth *et al*., 2003). Although asparagine 41 is located in the so-called effector region of the Rho protein, ADP-ribosylated Rho is still able to bind to its effectors' protein kinase N and Rho-kinase. C3 modifies Rac by up to 5% *in vitro*. However, all experimental evidence indicates that in intact cells, C3-like transferases ADP-ribosylate RhoA, RhoB, and RhoC, but not Rac and Cdc42. This is most important because C3 has been widely used to study the cell biological role of Rho. There is an exception: C3stau (also called EDIN) additionally ADP-ribosylates RhoE/(Rnd3) (Wilde *et al*., 2001). Recent studies suggest that some C3 isoforms possess additional properties, that might be of relevance for using the toxins as tools. For example, it was shown that C3 from *C. botulinum* and *C. limosum* interacts with high affinity (about 15 nM) with the small GTPase Ral without ADP-ribosylating the protein. This interaction, however, blocks the ADP-ribosylation of Rho by C3 (Wilde *et al*., 2002). Because Ral functions are also altered by C3 binding (at least *in vitro* activation of phospholipase D by Ral is blocked by C3), it is feasible that high concentrations of C3, which are used for microinjection studies, affect Ral signaling.

C3 transferases lack any specific binding and translocation subunit and their cell accessibility is rather poor. This is probably the reason why C3 shows low toxicity compared with other protein toxins. For example, the intraperitoneal injection of 100 µg of C3 into mice has no obvious consequences. To circumvent the problem of poor cell accessibility, several approaches are possible. First, various techniques to permeabilize cells can be applied to allow C3 uptake. Osmotic shock, electroporation, and pore-forming toxins like streptolysin O were used for this purpose. Many studies applied microinjection techniques (Paterson *et al*., 1990). Other approaches are based on chimeric toxins. A fusion toxin, consisting of C3 and the receptor-binding and translocation subunits of diphtheria toxin, was employed (Aullo *et al*., 1993). Another chimeric toxin was constructed of *C. botulinum* C2 toxin and C3 transferase. C3 was fused to the N-terminal part of the enzyme component of C2I, which is apparently involved in the interaction of C2I with C2II (Barth *et al*., 1998). This C2I-C3N fusion toxin could be introduced into cells via the binding and translocation component C2II (Figure 59.4). Similarly,

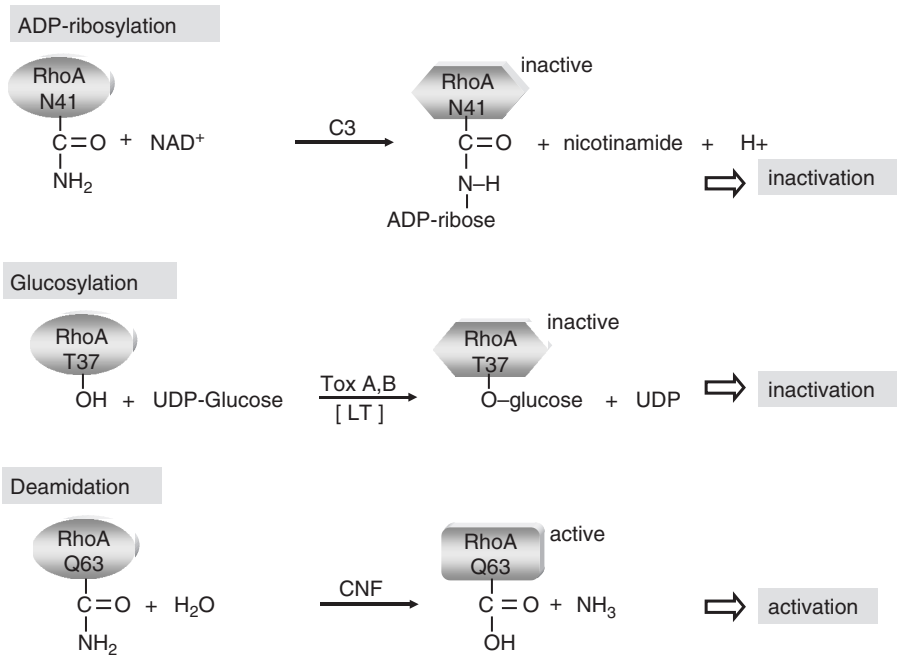

**FIGURE 59.2** Inactivation and activation of low molecular mass GTPases of the Rho family by various toxins often used as tools.

C3 exoenzymes specifically ADP-riboylate RhoA, B, and C. Thereby, Rho proteins (RhoA) are inactivated. Clostridial glucosylating toxins, e.g., *C. difficile* toxin A and B (ToxA, B) glucosylate many Rho proteins, including RhoA, Rac, and Cdc42. *C. sordellii* lethal toxin (LT) glucosylate Rac but not RhoA. In addition, Ras subfamily proteins are modified. Glucosylation blocks the biological activity of Rho GTPases.

*E. coli* cytotoxic necrotizing factor (CNF) deamidates Rho GTPases at glutamine63/61. This causes constitutive activation of the Rho proteins.

as observed with the diphtheria toxin-C3 fusion protein, in intact cells, the Rho-ADP-ribosylating activity of C2I-C3 was increased several hundredfold compared with that of the native C3 transferase. After removal of the chimeric toxin from the medium, cells recover rapidly after a few hours, most likely by neosynthesis of Rho, because the toxin is degraded rapidly (Barth *et al*., 1999). C3 from *C. botulinum* is translocated into cells by adding short peptides to the C-terminal end of the exoenzyme. For this purpose, short sequences of the human immunodeficiency virus transcription activator Tat are used (Sauzeau *et al*., 2001; Park *et al*., 2003). Moreover, the transport of C3 into cells can also be accomplished by fusing the third helix of the *Antennapedia* homoedomain protein from *Drosophila* to C3. In addition, short proline-rich peptides and highly basic arginine-rich peptides were C-terminally fused to C3 exoenzyme to facilitate the uptake of the transferase (Winton *et al*., 2002).

The intracellular expression of the C3 gene is another method to use C3-specific inhibition of Rho GTPases (Hilal-Dandan *et al*., 2004). Transgenes based on the thymocyte specific lck promoter have been used for expression of C3 in thymus (Henning *et al*., 1997). Recently, a transgenic mouse model expressing C3 exoenzyme in a lens-specific manner was utilized (Maddala *et al*., 2004). Under transcriptional control of the lens-specific alpha A-crystallin promoter, mice, expressing the C3 exoenzyme transgene, exhibited selective ocular defects (Rao *et al*., 2002).

As mentioned above, the use of C3 was most important in elucidating the functions of Rho proteins. Inhibition of a specified signaling pathway by using C3 was taken as an indication that Rho is involved in the signaling process. Thereby, pioneering work on the role of RhoA was performed showing that RhoA specifically controls stress fiber formation and induction of cell adhesions (Ridley and Hall, 1992). C3 was frequently used as a tool to study the role of Rho in regulation of the actin cytoskeleton, in cell motility, migration, and cell invasion. For example, C3 was used to study the role of Rho in translocation of aquaporin-2 into the apical membrane of renal cells induced by vasopressin (Klussmann *et al*., 2001). The toxin was successfully applied in studies on the regulatory function of Rho GTPases in neurite outgrowth, branching, and neuroregeneration (Lehmann *et al*., 1999; Wahl *et al*., 2000). Similarly, the role of Rho GTPases in the control of phospholipase D and in phospholipid metabolism was successfully studied with C3 (Meacci *et al*., 1999). Functions of Rho GTPases in transcriptional activation were another important topic, which was frequently addressed by applying C3 as a tool (Alberts and Treisman, 1998). Moreover, C3 was successfully employed in delineation of the role of Rho in the signaling of various heptahelical receptors to the actin cytoskeleton, phospholipases, and the nucleus via heterotrimeric G proteins. Especially important was C3 in studies on the functions of $G\alpha_{12/13}$ (Mao *et al*., 1998). Finally, C3 was studied in cell division and apoptosis (Kishi *et al*., 1993; Fiorentini *et al*., 1998).

## Clostridial glucosylating cytotoxins

Rho proteins are the targets of various clostridial cytotoxins, which modify the GTPases by glucosylation (Just *et al*., 1995; Just and Gerhard, 2004). Having molecular masses between 250 and 308 kDa, these toxins have been termed "large" clostridial cytotoxins. However, the name *clostridial glucosylating toxins* appears to be more informative and will be used here. *C. difficile* toxins A and B, which are the major virulence factors in antibiotic-associated diarrhea, are the most important members of this toxin family. Toxin B is termed cytotoxin, because it is several hundredfold more potent in inducing cytotoxic effects *in vitro* than toxin A. Whether the difference in potency is related to different cell membrane receptors is not clear. Both toxins have very similar lethal dose in mice (minimum lethal dose in mice about 50 ng i.p.).

*C. difficile* toxins A and B glucosylate Rho GTPases by using UDP-glucose as a second substrate (Figure 59.2). Not only RhoA, RhoB, and RhoC, but also other members of the Rho subfamily, like Cdc42 and Rac, are substrates. By contrast, small GTPases like Ras, Rab, Arf, or Ran are not substrates. The toxins glucosylate Thr37 of RhoA (Thr35 of Rac and Cdc42), which is involved in coordination of the magnesium ion and binding of nucleotides. Threonine 35/37 is located in the so-called switch-I region of the GTPases, which participates in effector coupling. This means that the region is responsible for the switch function of the GTPase in signaling. Toxin-catalyzed glucosylation inhibits the RhoA-effector interaction. This explains the functional inactivation of the GTPase after toxin treatment (Sehr *et al*., 1998). Notably, the acceptor amino acid residue for glucosylation is located very close to the site of ADP-ribosylation catalyzed by C3-like transferases (Asn41 in RhoA). This explains why glucosylated Rho is not modified by C3 and ADP-ribosylated Rho is not Substrate for clostridial glucosylating toxins.

*C. difficile* toxins A and B are often used as cell biological tools to screen the involvement of various Rho GTPases in a specific cellular process. For example, toxin B was used to study the involvement of Rho proteins in signal transduction of the FcεRI receptor and in histamine or serotonin secretion from mast cells or RBL cells (Prepens *et al*., 1996) (Figure 59.3). However, one

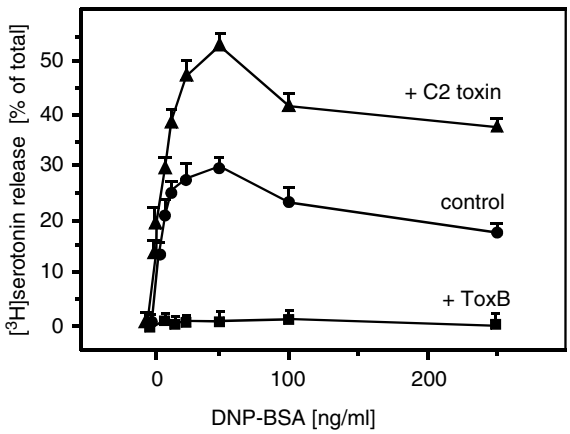

**FIGURE 59.3** Effects of *C. difficile* toxin B and *C. botulinum* C2 toxin on serotonin release from rat basophilic leucemia (RBL) cells. Serotonin release is induced by stimulation of the high-affinity antigen receptor (FcεRI) of RBL cells by increasing concentrations of the antigen DNP-BSA. Treatment with toxin B inhibits serotonin release, indicating the involvement of Rho GTPases in the degranulation response. The effect of toxin B is not caused merely by destruction of the actin cytoskeleton, because C2 toxin, which depolymerizes the actin cytoskeleton, does not block but increases serotonin release. (Data from Prepens *et al*., 1996)

has to consider that Rho proteins are involved in various signaling pathways, including regulation of the actin cytoskeleton. In the above-mentioned example, it is important to test whether the inhibitory effect of the toxin on secretion is a primary effect or secondary to depolymerization of the actin cytoskeleton. Another agent or toxin that selectively depolymerizes the actin cytoskeleton without having major effects on Rho proteins, such as cytochalasin or *C. botulinum* C2 toxin (see below), could be employed. In respect to histamine or serotonin secretion from RBL cells mentioned above, it was shown that C2 toxin increased receptor-induced secretion. This indicated that the inhibitory action of toxin B on secretion was not caused by disturbing the actin cytoskeleton.

The other members of the family of clostridial glucosylating toxins differ in cosubstrate or protein substrate specificity from toxins A and B; however, the conserved Thr35/37 residue of the GTPases is modified in each case. *C. novyi* alpha-toxin modifies Rho subfamily proteins like *C. difficile* toxin, but catalyzes N-acetylglucosaminylation by using UDP-GlcNAc as a co-substrate. *C. sordellii* lethal toxin, which is about 90% similar to *C. difficile* toxin B, also uses UDP-glucose as a co-substrate, but differs in its protein targets. Whereas Rac is a very good substrate for this toxin, Rho is poorly modified (most probably not at all in intact cells). In addition, lethal toxin glucosylates and inactivates Ras subfamily proteins like Ras, Rap, and Ral (Popoff *et al*., 1996). In recent years, several toxin B isoforms have been described that show substrate specificity similar to lethal toxin from *C. sordellii* (Mehlig *et al*., 2001). All these toxins are used as tools to get hints about the involvement of specific types of Rho proteins in signaling processes.

## RHO-ACTIVATING TOXINS

Hydrolysis of bound GTP is the switch-off mechanism of Rho GTPases. Mutation of amino acid residues involved in GTP hydrolysis is a well-established method to construct constitutively active (also called "dominant active") Rho GTPases, which possess no or marginal GTP hydrolysis activity. Transfection of mutated genes or microinjection of mutant proteins are frequently used in studies to elucidate the physiological role of Rho or related GTPases (Paterson *et al*., 1990). Interestingly, bacterial protein toxins exist that are capable of forming persistently active Rho mutants by posttranslational modification. These toxins are CNF1, 2 from *E. coli* and CNFy from *Yersinia*. CNFs catalyze the deamidation of glutamine 63 of RhoA to glutamic acid (Schmidt *et al*., 1997; Flatau *et al*., 1997) (Figure 59.2). Because glutamic acid is not able to fulfill the function of glutamine, the intrinsic and GAP-stimulated GTPase activity of Rho is blocked. CNF not only deamidates Rho, but also deamidates Cdc42 and Rac. Due to Rho GTPase activation, CNFs cause stress fiber, microspikes, and lamellipodia formation. Multinucleation is another typical feature of CNF-treated cells. Similarly to CNFs, dermonecrotic toxin (DNT; 154 kDa) causes activation of Rho proteins. However, DNT does not only deamidate the crucial glutamine (e.g., Gln63 of Rho) residue, but causes attachment of polyamines onto this residue, and therefore acts like a transglutaminase (Masuda *et al*., 2000). Because DNT is more unstable than CNFs, the latter is more often used to activate Rho proteins (Chaves-Olarte *et al*., 2002; Hopkins *et al*., 2003). Effective activation of Rho GTPases by the toxins can be monitored by different migration of deamidated RhoA in SDS-PAGE. By contrast, deamidated Rac and Cdc42 do not show altered migration behavior in SDS-PAGE. Activation of Rho GTPases is also tested in pull-down experiments performed with Rho GTPase effectors (or the GTPase-binding domains of the effectors), which only bind to the activated forms of the GTPases. Recently, it was observed that activation of Rac (less of RhoA and Cdc42) by CNF causes increased proteasomal degradation of the GTPase (Doye *et al*., 2002). Therefore, signal pathways, which depend on active Rac, may be stimulated by CNFs for a limited period of time only and not persistently. This has consequences for the monitoring of the toxin effects on cells. Whereas treatment of cells

with CNFs results in a Rac-like phenotypes after 2–4 h, which is characterized by membrane ruffling and lamellipodi formation, after 8–24 h toxin-treated cells exhibit morphological features characterized by RhoA activation (e.g., strong stress fiber formation). This change in morphology is accompanied by a decrease in the amount of Rac protein determined by Western-blotting.

## ADP-RIBOSYLATING TOXINS TO STUDY ACTIN

Actin is a major structural protein of the cytoskeleton. It is an essential part of the contractile apparatus of skeletal muscle and is vital for all kinds of motile processes, including migration, phagocytosis, endocytosis, secretion, and intracellular transport. Actin and the actin cytoskeleton are targeted by various bacterial protein toxins. The toxins directly modify actin by ADP-ribosylation or indirectly alter the regulation of the actin cytoskeleton by interfering with switch proteins of the Rho family, which control the cytoskeleton. In the latter case the above-mentioned Rho proteins, which are also preferred targets of bacterial protein toxins, play a crucial role.

### *Clostridium botulinum* C2 toxin

Actin is ADP-ribosylated by *Clostridium botulinum* C2 toxin, *C. perfringens* iota toxin, *C. spiroforme* toxin, and the ADP-ribosylating toxin from *C. difficile* (Barth *et al*., 2004). All these toxins consist of a separate enzyme and cell-binding/translocation subunit. These components are not linked by either covalent or noncovalent bonds. The binding components are proteolytically activated and form heptamers.

Most often, C2 toxin from *C. botulinum* and iota toxin from *C. perfringens* were used as pharmacological or cell biological tools (Figure 59.4). Studies require activation of the binding component by trypsin (Ohishi *et al*., 1980). Thereby, the ~80-kDa binding component (C2II) of C2 toxin is cleaved into the ~65-kDa active fragment (C2IIa), which forms heptamers (Barth *et al*., 2000). Membrane receptors of the heptamers on eukaryotic target cells are complex and hybrid carbohydrate structures, which, so far studied, have been found on all types of mammalian cells (Eckhardt *et al*., 2000). Cellular uptake of the enzyme component (C2I, 50 kDa) occurs from acidified endosomal compartments via C2IIa that insert into the membrane and form pores. In the cytosol, C2I ADP-ribosylates actin at arginine-177. All other toxins, including SpvB, appear to modify the same residue of actin. C2I ADP-ribosylates nonmuscle β/γ–actin but not α-actin isoforms. In contrast, *C. perfringens* iota toxin catalyzes the ADP-ribosylation of all mammalian actin isoforms known (Mauss *et al*., 1990). The modification by the toxin is highly specific. Neither G proteins, which are substrates for the arginine-modifying CT, nor other cytoskeletal elements, such as tubulin, are ADP-ribosylated.

ADP-ribosylation of actin has major functional consequences. ADP-ribosylation blocks polymerization of G-actin. Arg177, which is modified by the toxins, is located at an actin-actin contact site, and the attachment of ADP-ribose appears to hinder actin interaction. This also explains why G-actin but not polymerized F-actin is substrate for ADP-ribosylation. Surprisingly, ADP-ribosylated actin acts as a capping protein, which binds to the plus ends of actin filaments (Wegner and Aktories, 1988). At this site of the polar actin filaments, usually filament growth occurs. Thus, by binding to the plus ends, ADP-ribosylated actin is able to inhibit the polymerization of unmodified G-actin onto preformed filaments. The minus ends of actin filaments are not affected by ADP-ribosylated actin. Therefore, dissociation of monomers, which preferentially occurs at these ends of filaments, is not altered. Monomeric actin released is subsequently ADP-ribosylated by the toxin and trapped in the non-polymerizable form. ADP-ribosylation also affects interaction of actin with actin-binding proteins (e.g., nucleation activity of the gelsolin actin complex), which are important for actin dynamics. Altogether, ADP-ribosylation causes destruction of the cytoskeleton and major morphological changes of targeted cells, which are reflected by rounding up of cells, which is accompanied by depolymerization of F-actin and an increase in the amount of G-actin. Thus, the actin ADP-ribosylating toxins are powerful tools to depolymerize actin filaments in intact cells. Accordingly, the toxins are used to study the functions of actin in intact cells. Alternatively, cytochalasins are often employed to study cellular consequences of actin depolymerization (Cooper, 1987). A tool to induce actin polymerization is phalloidin, which, however, is hampered by its poor cell accessibility. Recently, jasplakinolide (Holzinger, 2001) and latrunculin (Spector *et al*., 1999), both low-molecular-mass toxins from marine sponges, emerged as new tools to polymerize actin and depolymerize actin, respectively.

The actin-depolymerizing C2 toxin was employed in many studies to investigate the role of actin in exocytosis. In many types of culture cells, C2 toxin causes an increase in hormone or neurotransmitter-stimulated exocytosis. This was shown for the release of steroids in Y-1 adrenal cells (Considine *et al*., 1992), for serotonin release in RBL cells (Prepens *et al*., 1996), for

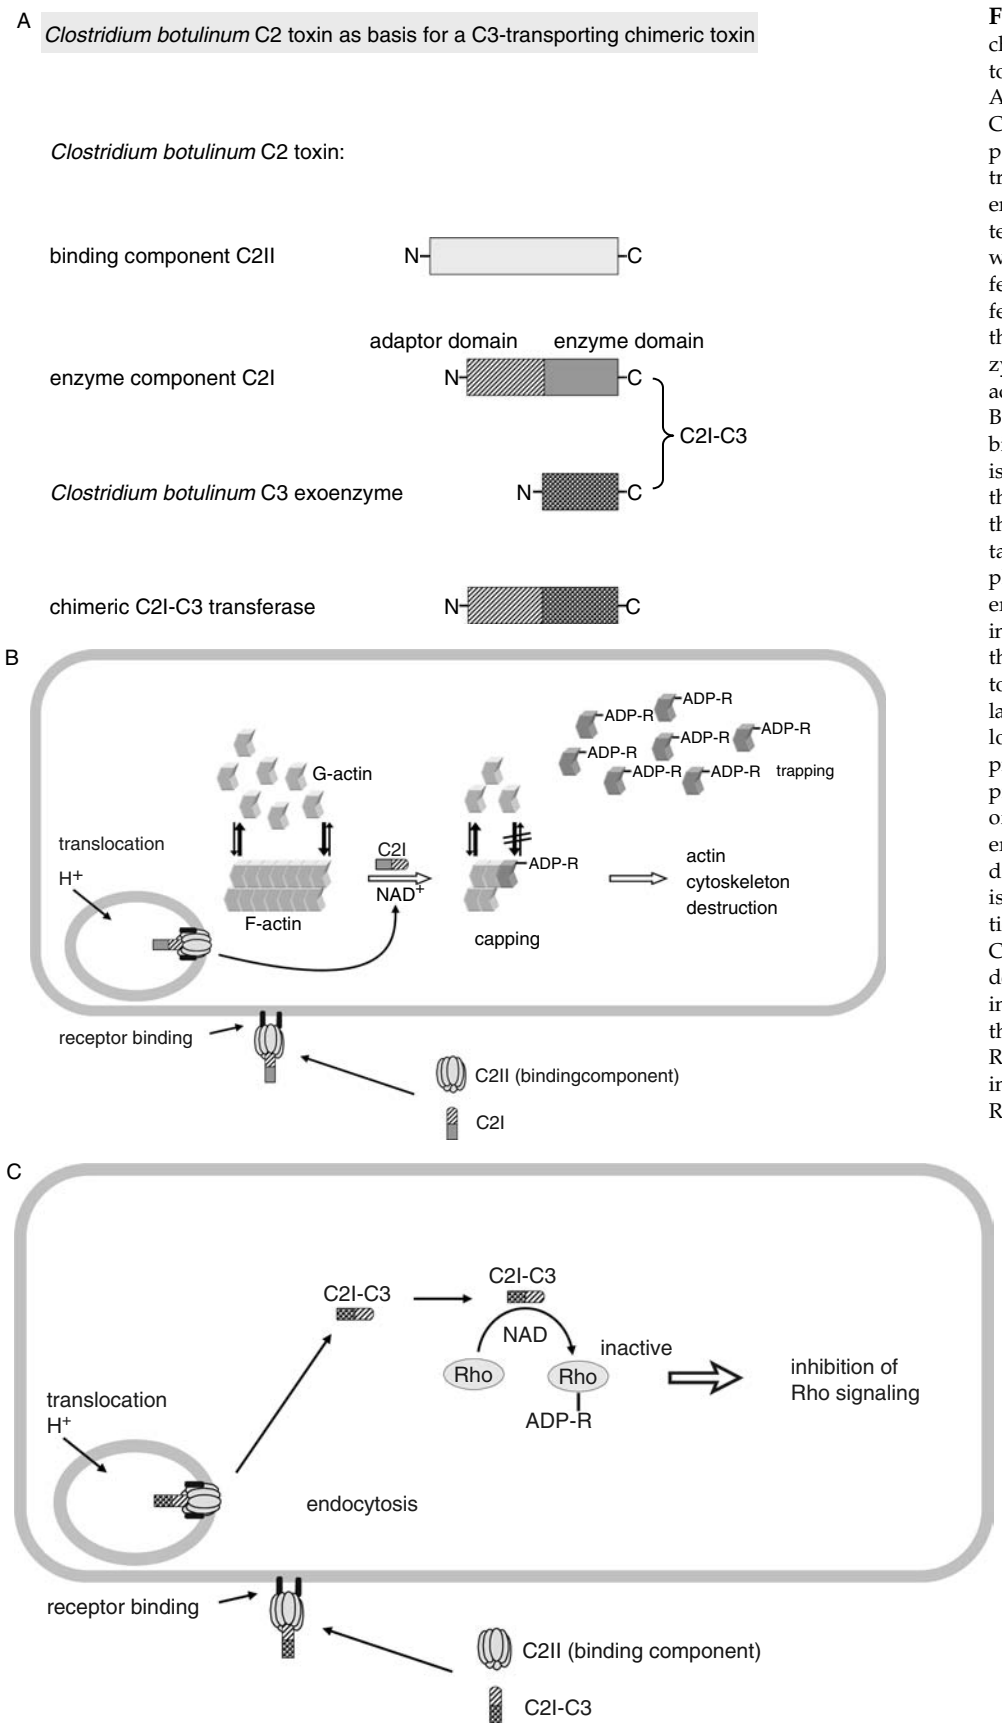

**FIGURE 59.4** Construction of a chimeric C3 toxin on the basis of C2 toxin.
A. The binary actin-ADP-ribosylating C2 toxin consists of the enzyme compoment (C2I) and the binding/translocation component C2II. The enzyme component of C2I has an N-terminal adaptor part for interaction with C2II and the C-terminal transferase part. The C-terminal transferase part of C2I is exchanged with the Rho-ADP-ribosylating exoenzyme C3, which possesses poor cell accessibility.
B. Action of C2 toxin in cells. The binding component C2II of C2 toxin is activated by trypsin treatment and then forms heptamers, which bind to the cell receptor. C2I binds to the heptamer and the receptor-toxin complex is endocytosed. In low pH endosomes, the binding component inserts into the membrane and allows the translocation of C2I into the cytotosol. In the cytosol C2I ADP-ribosylates actin. ADP-ribosylated actin has lost its ability to polymerize (trapping). Moreover, it acts like a capping protein to block the polymerization of G-actin at the fast growing "plus-ends" of actin filaments, while the depolymerization at the minus ends is not affected. This causes destruction of the actin cytoskeleton.
C. The chimeric C2I-C3 protein is delivered into the cytosol by the binding component C2II (see above). In the cytosol, C2I-C3 ADP-ribosylates Rho (e.g., RhoA). Thereby, Rho is inactivated, resulting in inhibition of Rho signaling pathways.

insulin release in isolated rat islets (Li *et al*., 1994), and for calcium-regulated exocytosis from adrenal chromaffin cells (Gasman *et al*., 1999). Usually, C2 toxin does not affect the basal release of mediators. Biphasic effects of the toxin were reported for the release of noradrenaline from PC12 cells (Matter *et al*., 1989). Short-term treatment (1 h) of the cells with C2-toxin increased noradrenaline release, whereas longer incubation decreased mediator release induced by depolarization or by carbachol. C2 toxin was used to study the role of actin in recycling of synaptic vesicles in the lamprey giant reticulospinal synapse (Shupliakov *et al*., 2002). It was found that C2 toxin inhibited endocytosis and changed the feature of clathrin-coated pits engaged in endocytosis. The data suggested that actin plays a role not only in vesicle transport at the synapse but also in the fission process.

In hamster insulinoma HIT-T15 cells, C2 toxin treatment inhibited insulin release by about 50%. Inhibition of insulin release was more pronounced in the second phase of the biphasic insulin release. These findings can be interpreted to indicate that actin filaments are involved in the recruitment of vesicles to the releasable pool and that C2 toxin blocks this action (Li *et al*., 1994). The toxin was employed to show the involvement of actin microfilaments in the retrograde transport from the Golgi to the endoplasmic reticulum (Valderrama *et al*., 2001). Also, in suspended mast cells (Prepens *et al*., 1998), C2 toxin inhibited regulated mediator release. In these cells, however, the inhibitory effect of C2 toxin turned into a stimulatory effect after adhesion of the mast cells, suggesting a complex role of actin, which cannot be explained simply by a barrier function or vesicle recruitment.

The actin-ADP-ribosylating C2 toxin was used to investigate the activation of neutrophils by chemotactic agents. In neutrophils, cell shape change, adhesion, migration, degranulation, and phagocytosis are induced by complement C5a, *N*-formyl peptides, or leukotriene $B_4$. It was shown by using the toxin that all these events depend on the redistribution of the cytoskeleton and on changes in actin polymerization (Norgauer *et al*., 1988). By using C2 toxin, it was shown that redistribution of the actin cytoskeleton largely affects the activity of superoxide anion-producing NADPH oxidase of neutrophils.

C2 toxin was used to investigate the role of actin in regulation of the serum responsive factor (Sotiropoulos *et al*., 1999). Quite often, C2 toxin was employed to study Rho signaling. In these cases, C2 toxin was used to distinguish effects merely caused by depolymerization of the actin cytoskeleton (e.g., caused by glucosylation of RhoA) from effects induced by Rho independently of the cytoskeleton. Appropriate controls of the specific action of C2 toxin are necessary in all these studies. Usually, the single toxin components (C2I or C2II) can be applied, which should not induce any effects in the system studied. It is also important that the toxin effects should occur with some delay of at least 15 to 30 min. This time is required for uptake of the toxin. It is recommended to test whether actin is actually ADP-ribosylated by the toxin. Moreover, the actions of C2 toxin should be compared with the effects of other actin-targeting agents, such as cytochalasins and latrunculin.

## CLOSTRIDIAL NEUROTOXINS AS TOOLS TO STUDY EXOCYTOSIS

Botulinum neurotoxins and tetanus toxin consist of a light chain (about 50 kDa), which is biologically active and harbors the enzyme activity, and a heavy chain (about 100 kDa), which is responsible for binding and membrane translocation. The chains are linked by a disulfide bond. The clostridial neurotoxins function as metalloendoproteases. The toxins selectively cleave synaptic proteins (synaptobrevin/VAMP, syntaxin, SNAP-25, and their respective isoforms), which are involved in the late steps of exocytosis and block neurotransmitter release from presynaptic nerve endings. One isoform of tetanus toxin (TeNT) and at least seven different serotypes of botulinum neurotoxins (BoNT/A, B, C1, D, E, F, and G) are known. Most importantly for the application as tools, the toxins differ in their protein substrate specificity, e.g., synaptobrevin is cleaved by tetanus toxin and BoNT/B, D, F, and G; SNAP25 is cleaved by BoNT/A, C, and E; and syntaxin is cleaved by BoNT/C. Moreover, most toxins cleave the synaptic proteins at different sites. Although TeNT and botulinum neurotoxins act on the molecular level in a very similar manner, their actions differ on the anatomic level. This is the reason why they cause completely different symptoms and diseases. Whereas botulinum neurotoxins act on peripheral nerves and cause flaccid paralysis, tetanus toxin acts on the central nervous system and induces spastic paralysis (tetanus) (Schiavo *et al*., 2000a; Rossetto *et al*., 2001).

Notably, the clostridial neurotoxins were of extreme importance for the elucidation of processes involved in neuronal exocytosis and vesicle-cell membrane fusion processes (Schiavo *et al*., 2000b). Moreover, in combination with permeabilization methods (e.g., usage of pore-forming toxins), clostridial neurotoxins are also used in studies on signal secretion coupling of non-neuronal cells (e.g., insulin-secreting cells) (Sadoul *et al*., 1995). These cells are otherwise insensitive toward neurotoxins because they lack the specific membrane

receptor. TeNT is also applied to induce experimental epilepsis (Bagetta and Nistico, 1994) and neuronal degeneration (Bagetta *et al*., 1991). Botulinum neurotoxins, which are the most potent toxic agents known, are now used as therapeutics. They are used, for example, to treat blepharospasm, strabism, and many different types of dystonias (Munchau and Bhatia, 2000), but also hyperhidrosis (Heckmann *et al*., 2001), pain from muscle spasm (Porta, 2000), and migraine headaches (Silberstein *et al*., 2000). Recently, the toxin is even used as a cosmetic (Blitzer and Binder, 2002).

## TOXINS FOR INTRACELLULAR PROTEIN DELIVERY

Intracellularly acting toxins possess the ability to translocate into cells. Although we have exciting new information about toxin translocation, this property is still largely enigmatic for many toxins. This is especially true for agents belonging to the biggest toxins known (e.g., large clostridial glucosylating cytotoxins with molecular masses of 250 to 308 kDa). The capability of protein toxins to cross the lipid cell membrane without major damage of the cell integrity has been exploited for use as a carrier system for proteins. Usually, these AB-toxins consist of the biologically active component (A, enzyme component) and the binding/translocation component (B). Considering that the binding and translocation domains are functionally and structurally separate entities, the toxins are better described as three-domain proteins. These functional domains are on a single toxin chain (e.g., *Pseudomonas* exotoxin A), on different chains linked by disulfide bonds (e.g., diphtheria toxin, botulinum neurotoxins), or they are on specific components, which are not covalently associated (e.g., CT and PT). Another type is the group of binary toxins, which have no linked enzyme and binding/translocation components. To construct a protein delivery system, all three toxin components may be used. To target a specific cell type, it might be necessary to change the receptor-binding part of the toxin. This is exemplified for diphtheria toxin and Pseudomonas exotoxin A immunotoxins, which were constructed to selectively target tumor cells. In the case of diphtheria toxin, the receptor-binding domain was exchanged with interleukine 2 to kill tumor cells (e.g., non-hodgkin cutaneous T cell lymphoma), which are rich in IL-2 receptors (Kreitman, 1999). Such toxins are already in clinical studies. Other toxin constructs are used to transfer an enzyme that otherwise is not able to cross the cell membrane into the cytosol. In this case, the receptor and translocation domains of the toxins are fused to the enzyme. The above-mentioned constructs of C3 with diphtheria toxin or with C2 toxin are examples (Figure 61.4). Also, the light chain of tetanus neurotoxin has been introduced into cells by means of an anthrax toxin fusion protein (Arora *et al*., 1994). Transport by anthrax toxin was also used to deliver cytoxic T cell epitopes into target cells to eventually stimulate specific cytotoxic T lymphocytes via MHC-1 complexes (Ballard *et al*., 1996).

## CONCLUSION

The previously mentioned examples show that various bacterial protein toxins are frequently and successfully employed as pharmacological and cell biological tools. In many studies, they were decisive instruments to elucidate the physiological functions of their target and turned out to be extremely helpful to clarify the cellular role of their mammalian substrates. These studies revealed that many bacterial protein toxins, and especially those that were earlier classified as "cytotoxins" because they appeared to alter the cell morphology in a uniform and "unspecific" manner, elicit highly specific effects. Knowledge of these subtle actions in target cells will certainly increase the usage of toxins as tools. Without question, the great potential of toxins as tools in cell biology and pharmacology is not yet fully exploited. An increase in our knowledge in their structure-function relationships will open new possibilities to use the bacterial protein toxins as pharmacological and cell biological tools, as well as therapeutic agents.

CHAPTER

# 60

# Engineering of bacterial toxins for research and medicine

*Aurélie Perier, Alexandre Chenal, Aurélie Babon, André Ménez, and Daniel Gillet*

## INTRODUCTION

Bacterial toxins are proteins capable of achieving multiple remarkable tasks (Menetrey *et al*., 2005; Parker and Feil, 2005). They function as autonomous molecular devices, targeting specific cells in an organism, punching holes in their membranes, or modifying intracellular components. Intoxication processes involve highly specialized steps of great complexity. It is thus tempting for the biochemist, the protein engineer, the biotechnologist, or the medical scientist to exploit the sophisticated properties of bacterial toxins to design new toxin-derived molecules for research, biotechnology, or medical treatments. Some toxins or toxin subunits are used in their natural form as biochemical and cell biology tools or for the treatment of specific diseases. For instance, streptolysin O is used to punch transient holes into cells for the delivery of oligonucleotides (Broughton *et al*., 1997) or proteins (Fawcet *et al*., 1998; Walev *et al*., 2001) into their cytoplasm. Cholera toxin B pentamer is used as a marker of lipid rafts due to its binding specificity for gangliosides sequestered in these membrane microdomains (Harder *et al*., 1998). It is also used as an adjuvant for mucosal vaccines (Freytag and Clements, 2005). *Clostridium* toxins are used to study actin and G proteins (Richard *et al*., 1999); botulinum toxin is used in the treatment of dystonies (Jankovic, 2004). Also, natural bacterial toxins inactivated by chemical treatment are used as vaccines. These include diphtheria, tetanus, and pertussis toxins.

Besides the use of native toxins as tools, therapeutics, or vaccines, toxins or toxin fragments can be engineered or combined with other protein domains to build rationally new proteins with new defined activities. This review focuses on the vast possibilities offered by toxin engineering for the design of new tools and therapeutics. The applications of native toxins are described in other chapters of this book. Also, the mechanisms of action of the toxins used for engineering are not detailed here. The reader is invited to return to the corresponding chapters of this book to find all precisions on those mechanisms.

A brief overview of the properties of bacterial toxins helps to understand the fascinating possibilities they offer as building blocks to tailor new proteins with desired activities (Table 60.1). Toxins are usually secreted by bacteria in a soluble form. The toxins are then able to diffuse in the aqueous environment of body fluids such as digestive or respiratory secretions, interstitial fluid surrounding infected tissues, lymph, blood, etc. Some toxins are capable of crossing epithelial barriers or penetrating deeply inside organs. For instance, botulinum toxin crosses the digestive wall from the intestine lumen by transcytosis to the blood circulation, and tetanus toxin reaches inhibitory interneurons in the central nervous system by retrograde transport through peripheral neurons. Cell intoxication proceeds with a series of successive steps involving different domains or subunits of the toxin (Figure 60.1). Activation of the toxin by proteolytic cleavage of a terminal peptide, an interdomain loop, or even an intradomain site is necessary for many toxins. This process may involve bacterial or host proteases and may occur before or after binding of the toxin to the surface of target cells. It is likely that the need for an activation mechanism prevents the toxins from inter-

**TABLE 60.1** Properties of bacterial toxins that can be exploited for engineering

| Properties | Toxins concerned[a] |
|---|---|
| Diffusion in body fluids | Pore-forming[b] and intracellular[c] |
| Crossing of epithelial barriers | Botulinum toxins, some $AB_5$ toxins |
| Penetration into central nervous system | Tetanus |
| Proteolytic activation | Pore-forming[b] and intracellular[c] |
| Targeting of cell surface receptors | Pore-forming[b] and intracellular[c] |
| Action on the cell surface (permeabilization) | Pore-forming[b] |
| Translocation from the cell surface | *B. pertussis* adenylate cyclase |
| Internalization and intracellular trafficking | Intracellular[c] except *B. pertussis* adenylate cyclase |
| Conformational change upon oligomerization | Pore-forming[b], $A_nB_7$ toxins |
| Conformational change upon acidification | $AB_{RT}$ toxins, $A_nB_7$ toxins |
| Membrane penetration | Pore-forming[b], $AB_{RT}$, $A_nB_7$ toxins |
| Pore formation (large size, poor or no selectivity) | Pore-forming[b] (except RTX toxins) |
| Permeabilization | RTX toxins, some $AB_{RT}$ |
| Channel formation (small size, high selectivity, voltage gated) | $AB_{RT}$, $A_nB_7$ toxins and colicins |
| Translocation from cell compartments | Intracellular[c] except *B. pertussis* adenylate cyclase |
| Enzymatic activities (see Menetrey *et al*., 2005 for list) | Intracellular[c] |

[a]See Figure 60.1 and Menetrey *et al*., 2005 for nomenclature. [b]Pore-forming toxins. [c]Toxins with intracellular targets.

acting inappropriately with bacterial or host membranes. Bacterial toxins select their target cells by recognizing specific cell surface receptors. Most toxins recognize receptors found on any cell types, thus having a broad spectrum of targets, while others recognize receptors found on very specific cells, such as neurons (*Clostridium* neurotoxins) or dendritic cells of the immune system (*Bordetella pertussis* adenylate cyclase). Pore-forming toxins act directly at the cell surface, in most cases after oligomerization (Parker and Feil, 2005). Toxins with intracellular targets of the $AB_{RT}$ and $AB_5$ types act usually as individual molecules (monomers or preassembled oligomers), while toxins of the $A_nB_7$ type assemble as oligomers following binding to the cell surface (Menetrey *et al*., 2005). These toxins penetrate the cells by the internalization pathways

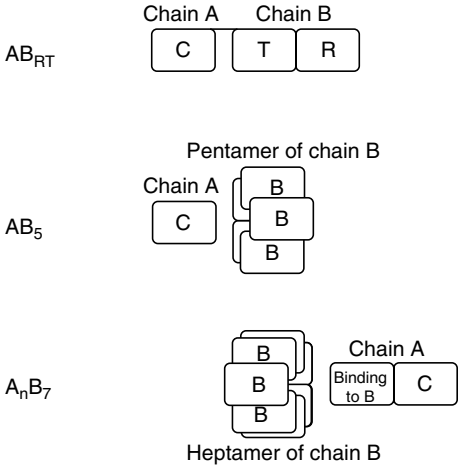

**FIGURE 60.1** Structure/function organization of toxins with intracellular targets (Ménétrey *et al*., 2005). In principle, each module (chain or domain) may be isolated and used for engineering in combination with other proteins. In all cases, chain A carries the catalytic domain (C) of the toxin. For $AB_{RT}$ toxins, chain B is formed of a receptor-binding domain (R) responsible for binding to the cell surface, receptor-mediated internalization, and intracellular trafficking and a translocation domain (T) responsible for passage of the C domain inside the cytoplasm. For $AB_5$ toxins, chain B is responsible for binding to the cell surface, receptor-mediated internalization, and intracellular trafficking. For $A_nB_7$ toxins, up to three A chains may bind to one B heptamer. Chain A contains a domain responsible for binding to the B heptamer and a C domain. Chain B is responsible for binding to the cell surface, receptor-mediated internalization, intracellular trafficking, and translocation of chain A into the cytoplasm. Among $AB_{RT}$ toxins are: diphtheria toxin *(C. diphtheria),* exotoxin A (*P. aeruginosa*), botulinum toxins (*C. botulinum*), tetanus toxin (*C. tetani*), large clostridial toxins (*C. difficile, C. sordellii, C. novyi*), and dermonecrotic toxins (*E. coli, B. pertussis*). The adenylate cyclase of *B. pertusis* resembles $AB_{RT}$ toxins, although its chain B is derived from an RTX toxin. Among $AB_5$ toxins are cholera toxin (*V. cholerae*), heat-labile toxins (*E. coli*), pertussis toxin (*B. pertussis*), Shiga toxin (*S. dysenteriae*), and Shiga-like toxins (*E. coli*). Among $A_nB_7$ toxins are anthrax toxin (*B. anthracis*), VIP toxin (*B. cereus*), C2 toxin (*C. botulinum*), iota toxin (*C. perfringens*), and actin-ADP-ribosylating toxins (*C. spiroforme* and *C. difficile*).

followed by their receptors. They are directed to given intracellular compartments depending on their receptors or on internal targeting sequences. Most toxins of both types (pore-forming or with intracellular targets) undergo major conformational changes involving one or several domains in order to interact with and penetrate into the membrane of the cell surface or of the intracellular compartments to which they are targeted. They create channels or pores, some with small sizes and narrow selectivity, some with very large sizes permeable to macromolecules. Toxins with intracellular targets translocate their catalytic domain (C) or subunit through the membrane of given cell compartments into the cell cytoplasm. This process involves major structural changes of the catalytic components (Falnes *et al*., 1994). Finally, these components refold in the cytoplasm and exert their enzymatic activities towards specific substrate molecules participating in key cellular processes (Menetrey *et al*., 2005).

All these steps, all these complex activities are frequently associated with individual domains, chains, or subunits of toxins (Figure 60.1). This is particularly true for toxins with intracellular activities. Many of these domains can be isolated from the rest of the toxin by recombinant DNA technology and used for their properties, isolated or combined with other proteins. Also, they can be modified by protein engineering. They may retain entirely or partially their original function, or even express new unexpected capabilities. Even genes encoding fragments of toxins or toxin receptors can be used to engineer cells or animals. Possibilities are infinite. This review intends to illustrate the concept of toxin engineering with a series of examples but it cannot be exhaustive. These examples are sorted according to the two principal types of bacterial toxins (toxins with intracellular activities and pore-forming toxins) and to the molecular functions or mechanisms that are exploited (Table 60.1). However, most examples of toxin engineering involve toxins with intracellular targets, especially diphtheria toxin, which is certainly one of the most extensively manipulated toxin (Chenal *et al*., 2002a) (Figure 60.2).

## ENGINEERING RECEPTOR-BINDING ACTIVITIES

### Tissue-specific cell ablation in mice by expression of a toxin receptor

Mice are not sensitive to diphtheria toxin, while humans are. This is due to differences in the sequence of the molecule acting as the receptor for the toxin in sensitive species (especially man and monkeys). The receptor for diphtheria toxin is a membrane precursor of an epidermal growth factor-like growth factor capable of binding heparin (proHB-EGF) (Naglich *et al*., 1992; Mitamura *et al*., 1995). Five residues of human proHB-EGF involved in toxin binding are mutated in the murine sequence, impairing recognition (Cha *et al*., 1998). Murine cells transfected with the simian gene for

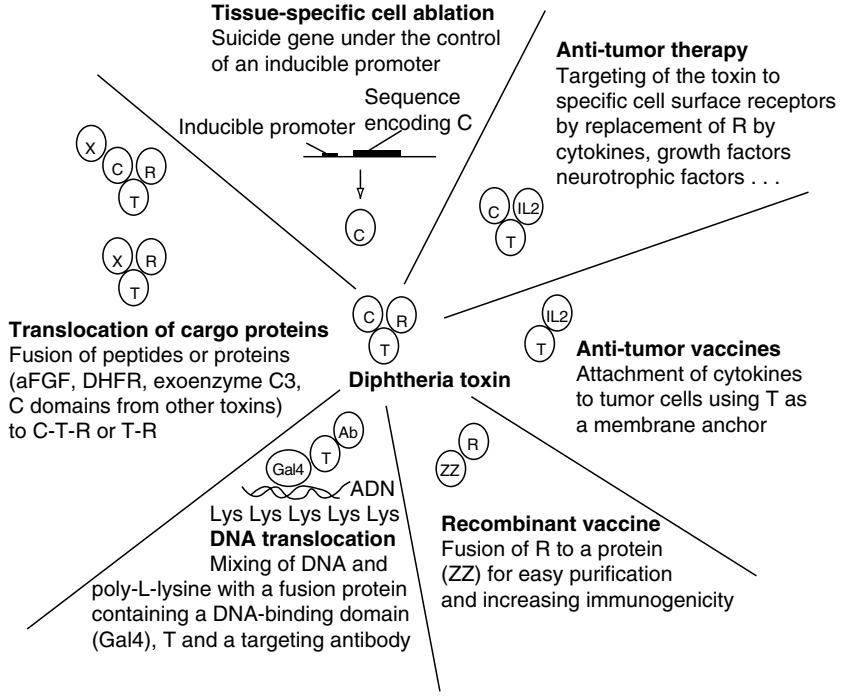

**FIGURE 60.2** Examples of diphtheria toxin engineering. See text for references.

proHB-EGF and expressing the receptor become sensitive to the toxin (Brown *et al*., 1993). On the basis of these data, Saito *et al*. (2001) demonstrated that human proHB-EGF can be used to sensitize specific cell types to diphtheria toxin in mice *in vivo*. This enables deletion of a given tissue or organ in order to study its function or treatments to supplement its loss. The gene for human proHB-EGF is placed under control of a promoter, whose expression is specific for the tissue to be deleted. The construct is introduced in mice embryos to produce transgenic mice. Only the tissue(s) corresponding to the tissue-specificity of the promoter expresses proHB-EGF. When needed, this tissue is destroyed by injection of diphtheria toxin to the mice. Using the liver cell–specific albumin promoter, mice developed fulminant hepatitis following administration of a small amount of diphtheria toxin (Saito *et al*., 2001).

## Toxoids based on receptor-binding domains of toxins

Vaccines against tetanus, diphtheria, and whooping cough are made of the corresponding toxins fixed with cross-linking agents such as formaldehyde. Anti-sera against tetanus or botulinum toxins are prepared by immunizing horses with such toxoids. Chemical cross-linking of residues separated in the primary sequence of the toxin but close in space due to the tertiary structure block the structural changes involved in the intoxication process (Paliwal and London, 1996). Large amounts of dangerous toxins must be produced to make toxoids. In addition, antibodies against toxoids could be of lesser quality than antibodies against the natural toxins. It has been proposed that protective antibodies are mostly directed against the receptor-binding domain of a toxin because they prevent the first step of intoxication, i.e., binding of the toxin to the target cells. As a consequence, several teams have used recombinant receptor-binding (R) domains of toxins as toxoids, in an isolated form, or fused to a protein increasing immunogenicity.

Recently, Tavallaie *et al*. (2004) defined the smallest part of botulinum toxin (type A) R domain (named fragment Hc) capable of generating a good protective immune response in mice. In fact, this part is the entire R domain itself. Each of the two subdomains defining the R domain is less efficient in generating a protective response, even when injected simultaneously. This indicates that the interface between both subdomains must carry important protective epitopes. Indeed, the structure of each isolated subdomain and of the entire R domain were studied by circular dichroism and fluorescence. The results show that the interface connecting the subdomains is highly structured, further suggesting that important epitopes defined by the tertiary structure of the interfacial region are necessary to elicit protective antibodies (Tavallaie *et al*., 2004). Overall, this work shows the potential of recombinant R domains as toxoids and the importance of conformational epitopes in generating a protective anti-toxin immune response.

In an attempt to make safe and easy-to-produce recombinant anti-diphtheria toxin vaccine, it has been proposed to link the R domain of diphtheria toxin to a protein that enables easy purification and that increases immunogenicity (Lobeck *et al*., 1998). The protein fused to R was ZZ, a derivative of the staphylococcal protein A made of two IgG-binding domains (Ljunberg *et al*., 1993; Jansson *et al*., 1998) (Figure 60.2). The presence of ZZ fused to R offers a simple and efficient means to purify the protein from bacterial extracts, using IgG affinity chromatography. Also, ZZ often increases immunogenicity of the fusion partner, presumably by enhancing its presentation to specific T cells. The fusion protein was able to generate antibodies inhibiting diphtheria toxin cytotoxicity. However, the antibody titers obtained with the recombinant protein were lower than with the formaldehyde-treated toxoid (Lobeck *et al*., 1998).

## Changing R domains of toxins to target toxicity to specific cell types

About a century ago Paul Erlich dreamed of ways to drive toxins to kill cancer cells while avoiding normal cells (Erlich, 1956). He called these targeted toxins "magic bullets." This idea started to concretize about 25 years ago when antibodies against cell surface markers were chemically conjugated to toxins (Trowbridge and Domingo, 1981). Exotoxin A from *Pseudomonas aeruginosa*, diphtheria toxin, and the plant toxin ricin were selected to build immunotoxins due to their high toxicity. For instance, one molecule of diphtheria toxin entering a cell is enough to kill it (Yamaizumi *et al*., 1978; Falnes *et al*., 2000). These immunotoxins were able to kill cells expressing the markers recognized by the antibodies. However, first-generation immunotoxins had many drawbacks. Full-size antibodies were used, leading to very large molecules diffusing poorly inside tissues. These antibodies from mice were highly immunogenic. The R domain of the toxin was not necessarily identified and removed, leading to unwanted killing of normal cells. The cloning of toxin genes and the increased knowledge of toxin structure progressively led to highly sophisticated engineered molecules (Kreitman and Pastan, 1995; Murphy and vanderSpek, 1995). Today, the same

three toxins are still used. In the case of diphtheria toxin (Figure 60.2) and *Pseudomonas* exotoxin A, the R domain is entirely eliminated. Only the C and T domains are kept, the later enabling the transfer of the former through the membrane of the compartment into which the toxin is internalized inside the cell cytoplasm. The C domains of both toxins ADP-ribosylate elongation factor 2, blocking protein synthesis of the cell. The R domain is replaced by a Fab, a single chain Fv fragment or a growth factor (Kreitman and Pastan, 1995; Murphy and vanderSpek, 1995). In most cases, whole immunotoxins are now prepared by gene fusion technology and recombinant protein expression. Chemical conjugation tends to be abandoned because recombinant proteins are more homogeneous, and orientation and accessibility of the binding site is easier to control. Growth factors or other receptor-binding ligands may be superior to antibody fragments when they have an affinity for their receptor higher than that of an antigen/antibody interaction. For instance, the dissociation constant of interleukine-2 for its high-affinity receptor is 10 picomolar, while that of an antibody for its antigen is rarely as good. In addition, recombinant single chain Fv fragments, which are fused to the toxin, are hard to produce and have frequently a reduced affinity for the antigen compared to the native antibody.

Since the publication in 1986 by John R. Murphy *et al*. of the first fusion protein connecting diphtheria toxin and a peptide hormone, the melanocyte-stimulating hormone (MSH), more than 20 diphtheria toxin-related fusion proteins have been described (Table 60.2). A whole set of cytokines and growth factors have been used that recognize a wide variety of cell types such as tumor cells, angiogenic cells, neurons, immune cells, etc. The derived immuno- or rather hormonotoxins are aimed at malignancies, autoimmune disease, pain, HIV infection, or graft-versus-host disease (Table 60.2). Two variants of a fusion toxin targeted to the receptor for interleukin-2 (IL-2) (Figure 60.2 and Table 60.2) have shown clinical activity in a variety of diseases, including cutaneous T cell lymphoma, B-cell non-Hodgkin's lymphoma, Hodgkin's disease, graft-versus-host disease, psoriasis, rheumatoid arthritis, and type I diabetes. The highest response rates were observed in cutaneous T cell lymphoma, leading to the approval of one of theses toxins by the United States Food and Drug Administration for the treatment of this disease as the drug denileukin diftitox (Ontak®) (Foss, 2000; Eklund and Kuzel, 2005). Clinical trials involving patients with acute myeloid leukemia have started to test a diphtheria toxin fusion protein targeted to the receptor for GM-CSF (Hall *et al*., 2001; Frankel *et al*., 2002). Other hormonotoxins derived from diphtheria toxin are under investigation for the treatment of various blood malignancies (Table 60.2). Although cutaneous T cell lymphoma, the target of Ontak, makes solid tumors, it is usually thought that circulating tumors should be more sensitive to immunotoxins because the toxins, which are administered intravenously, should reach the tumor cells more easily.

Unfortunately, the difficulties and costs linked to the development of such molecules and the clinical trials needed explain why only one fusion toxin already reached the pharmacy. Considering these difficulties, the experience gained during the development of Ontak helped to pinpoint critical points to address in order to make a drug from a targeted toxin. First, the fusion toxin must have a high affinity for its receptor, with $K_D$ close to picomolar values (Kiyokawa *et al*., 1989; Waters *et al*., 1990). This allows using low doses for the treatments, decreasing risks of side effects or non-specific toxicity. Second, the toxin must be devoid of residual binding to any normal tissue (Kuan *et al*., 1995; Siegall *et al*., 1997; Baluna *et al*., 1999). Third, the targeted cells must express high amounts of high-affinity receptors for the ligand linked to the toxin (Lakkis *et al*., 1991; vanderSpek *et al*., 1997), and these receptors must be efficiently internalized by the cells into the early endosomes, the compartment of translocation of diphtheria toxin (Lemichez *et al*., 1997). This may explain why Ontak is validated for cutaneous T cell lymphoma only and not for other lymphomas. Ideally, the efficacy of the treatment should be assayed *in vitro* on the tumor cells from each patient to assess good sensitivity of these cells.

In the late 1980s, a number of genetically engineered fusion toxins were described combining *Pseudomonas* exotoxin A and a series of targeting proteins such as IL-2, IL-4, IL-6, CD4, TGF alpha, and antibody Fv fragments (Chaudhary *et al*., 1988; Lorberboum-Galski *et al*., 1988; Siegall *et al*., 1988; Batra *et al*., 1989; Chaudhary *et al*., 1989; Ogata *et al*., 1989; Siegall *et al*., 1989). A toxin-Fv fragment fusion protein was targeted to CD25, one of the chains of the IL-2 receptor. Successive improvements were made to exotoxin A–derived immunotoxins (Brinkmann, 2000), and some encouraging responses were observed against lymphomas. Phase 2 trials are underway (Pastan, 2003). Many Fv fragments with other specificities targeting a variety of tumors were linked to exotoxin A. Among those is found an Fv fragment against CD22, a marker expressed on leukemia and lymphoma cells (Kreitman *et al*., 2001; FitzGerald *et al*., 2004). Unfortunately, immunotoxins derived from exotoxin A provoked vascular leak syndrome in patients, due to undesired toxicity toward endothelial cells (Kuan *et al*., 1995; Siegall *et al*., 1997; Baluna *et al*., 1999). In order to

circumvent this serious side effect, the region of the toxin responsible for recognition of the endothelial cells was identified (Baluna *et al*., 1999). It seems to implicate an (x)D(y) tripeptide motif. This finding opens the way to additional engineering for safer immunotoxins.

### Neuron targeting and neuron-to-neuron delivery

The R domain of tetanus toxin, known as fragment C or TTC, corresponds to the C-terminal half of the heavy chain of the toxin. It has a molecular mass of 50 kDa. It binds specifically to neurons and may be used as a vector to target soluble proteins to the central nervous system. Like native tetanus toxin, fusion proteins or conjugates in which TTC is linked to a soluble protein show enhanced uptake and transport by motor neurons following intramuscular or systemic administration (Beaude *et al*., 1990; Fishman *et al*., 1990; Figueiredo *et al*., 1997). In addition, like the whole toxin, TTC enables transynaptic passage of passenger proteins from motor neurons to presynaptic processes and neurons (Fishman and Savitt, 1989; Beaude *et al*., 1990; Kissa *et al*., 2002). The aim of these studies is to deliver neurotrophic factors such as cardiotrophin-1 (Bordet *et al*., 2001) or lysosomal enzymes to the central nervous system for the treatment of neurodegenerative disorders. Also, a fusion protein in which green fluorescent protein is linked to TTC enables the visualization of synaptic transfer and neuronal networks *in vivo* (Kissa *et al*., 2002). Finally, a fusion protein containing the diphtheria toxin C and T domains linked to TTC has been constructed to combine the neuronal targeting property of TTC and the translocation property of diphtheria toxin (Francis *et al*., 2000). The aim is to deliver passenger proteins to the cytoplasm of neurons.

## ENGINEERING TOXIN ACTIVATION

During the intoxication of a cell, diphtheria toxin is activated by cleavage of a proteolytic site in a loop connecting the C and the T domain (Chenal *et al*., 2002a). This loop of 14 amino-acid residues is located between Cys 186 and Cys201, which form a disulfide bond linking the two domains after cleavage. The loop contains the sequence Arg190 Val191 Arg192 Arg193, which corresponds to a consensus motif recognized by the cellular protease furin and other proteases such as trypsin and PACE4. Cleavage takes place between Arg193 and Arg 194 (Tsuneoka *et al*., 1993). As furin is ubiquitously expressed, engineering of a tissue-specific protease cleavage site in place of the native activation site should enhance the selectivity of fusion toxins targeted to growth factor receptors. This principle has been tested on a diphtheria toxin GM-CSF fusion toxin targeted to acute myeloid leukemia cells (Abi-Habib *et al*., 2004). The sequence RVRRSV of the connecting loop was modified to a urokinase plasminogen activator (uPA) cleavage site GSGRSA. As a consequence, the toxin was highly toxic to leukemia cells expressing receptors for both GM-CSF and uPA. Toxicity correlated with expression levels of both receptors. Leukemia cells expressing GM-CSF receptors only were sensitized to the toxin by the addition of pro-uPA. Thus, normal myeloid stem cells expressing only the receptor for GM-CSF should not be sensitive to this toxin.

## EXPLOITING MEMBRANE BINDING AND TRANSLOCATION

Toxins with intracellular targets of the $AB_{RT}$ type (Menetrey *et al*., 2005) have a T domain, which assists the passage of the C domain through the cell membrane into the cytoplasm. Diphtheria, *Pseudomonas* exotoxin A, tetanus, and botulinum toxins are found among these toxins (Figure 60.1). T domains of known structure are made of alpha helices. They react at the acid pH of the endosome following internalization of the toxin. They adopt a molten globule conformation with loss of tertiary constraints, conservation of secondary structures, looser packing, and exposure of hydrophobic surfaces. This provokes the interaction of T with the membrane, its penetration into the bilayer, and a major reorganization of the helices (Gress *et al*., 1994; Chenal *et al*., 2002a, 2002b, 2003; Koriazova and Montal, 2003; Mere *et al*., 2005). The T domains of diphtheria and botulinum toxins form ion channels into membranes and at higher concentrations can destabilize and permeabilize lipid vesicles. Several applications have been found for the T domain of diphtheria toxin on the basis of its properties.

### Membrane anchors applied to cancer vaccination

Our group has shown that the T domain of diphtheria toxin can be used as a membrane anchor to attach soluble proteins to the surface of cells (Figure 60.2). Fusion proteins have been constructed in which the antibody-binding protein ZZ or cytokines [human IL-2, murine IL-3, and the Flt3 Ligand (FL)] have been fused to the N- or C-terminus of T (Liger *et al*., 1998; Nizard *et al*., 1998, 2001 and unpublished results). Incubation of cells with the

fusion proteins at acid pH (pH 4.8) drives the T domain to interact irreversibly with the membrane of the cells. In most cell types, the anchored proteins are not internalized. They remain displayed on the surface for several days. They can be recognized by specific antibodies and by cells carrying the corresponding receptor. These receptor-bearing cells respond to the signal found on the carrier cell. This stimulation is due to cell-cell contacts but also to a slow shedding of the anchored molecules in the culture medium (Nizard *et al*., 2003 and unpublished results). Such device allows the manipulation of the surface of given cells to modify their relations with other cells. It can be an advantageous alternative to gene transfection techniques. Indeed, many cell types are impossible to transfect efficiently, and it is hard to master the levels of expression of the transfected genes. In contrast, when using recombinant proteins connected to a membrane anchor and added externally to cells, it is possible to control the amounts attaching to the cell surface.

The membrane anchor principle has been used for the design of cancer vaccines assayed in mice. The studies were performed with two models of tumors, the RMA T cell lymphoma and the B16 melanoma. The vaccines were prepared by anchoring human IL-2 (Nizard *et al*., 2002; 2003) or human FL (unpublished results) to the surface of the cells using the T domain. The cells were previously treated with mitomycine to block their proliferation. Seventy percent of mice vaccinated with the RMA-IL-2 vaccine were fully protected against tumor challenge (Nizard *et al*., 2002, 2003). Protection was mediated by cytotoxic T lymphocytes specific for a tumor antigen. In mice vaccinated with the B16 vaccine, tumor progression was delayed. This result is significant since this tumor is poorly immunogenic. Vaccine efficacy depended on the precise dosage of cytokines anchored at the surface of tumor cells. Vaccination with a mixture of RMA cells carrying IL-2 and FL had a synergistic effect (unpublished observations). Overall, these vaccines were as efficient as similar vaccines prepared by transfer of cytokine genes inside tumors (Schmidt *et al*., 1995). However, preparation of the cells is easier using the membrane anchor technology. Also, this procedure presents several advantages as compared to gene transfection. It does not require the culture of tumor cells from the patients and eliminates the safety problems connected with viral vectors while allowing control of the amount of cytokine delivered with the vaccine (Nizard *et al*., 2002, 2003).

## Adjuvant for DNA transfection

The T domain from diphtheria toxin has been used as an adjuvant for DNA transfection. Passage of DNA particles from the compartments where they are internalized into the cell cytoplasm is rather inefficient. The T domain has been used in combination with DNA particles as a means to escape from these compartments because its interaction with membranes at acid pH can destabilize them. In a first study, T was chemically coupled to the high molecular mass poly-L-lysine used to complex the DNA. An asialo-oromucoid-polycation conjugate was incorporated to the complex to achieve targeting (Fisher *et al*., 1997). In two other studies, a fusion protein was constructed, which cumulated successively the DNA-binding domain of the yeast transcription factor Gal4, T, and either an antibody fragment specific for the tumor-associated ErbB2 antigen (Figure 60.2), or the tetanus toxin TTC fragment for cell targeting (Uherek *et al*., 1998; Barati *et al*., 2002). These proteins were associated within a complex of plasmid DNA and poly-L-lysine. In all cases, the presence of the T domain increased transfection efficacy.

## Translocation of cargo peptides and proteins

The capacity of translocation of bacterial toxins offers the fascinating perspective of transporting cargo proteins and peptides into targeted cells (Figure 60.2). Many studies have been done on the subject, but unfortunately, translocation is more complex than it seems and any protein cannot be translocated into a cell by a bacterial toxin. Several principles can be drawn from these studies. The translocation machinery of many toxins can translocate peptides up to 100 residues when fused to the C domain of that toxin (Stenmark *et al*., 1991; Madshus *et al*., 1992). The C domain can be mutated in its catalytic site to abolish its toxicity. The translocation machinery of many toxins can translocate the C domain of other toxins. Hence, it was shown that the B heptamer of anthrax toxin (the protective antigen heptamer) can translocate efficiently the C domain (or A chain) of diphtheria, *Pseudomonas*, tetanus, Shiga, or cholera toxins when fused to the B chain binding domain of lethal factor, one of the two genuine A components of anthrax toxin (see Figure 60.1) (Arora *et al*., 1992; Arora and Leppla, 1993, 1994; Milne *et al*., 1995; Sharma *et al*., 2000). Similarly, the C3 exoenzyme, an orphan enzymatic A chain possessing ADP-ribosyltransferase activity, can be translocated by the B chain of diphtheria toxin (Aullo *et al*., 1993) and the B heptamer of C2 and iota toxins (Barth *et al*., 1998; Marvaud *et al*., 2002). Also, the B chain of diphtheria toxin or *Pseudomonas* exotoxin A has been linked with the enzymatic component from ricin and the resulting chimeric toxins efficiently translocate the ricin enzymatic moiety (Sundan *et al*., 1982; Pitcher *et al*., 1995). Diphtheria toxin can translocate proteins if they are

highly unstable or unfolded. This was shown for dihydrofolate reductase (Klingenberg *et al*., 1996) and acidic fibroblast growth factor (Wiedlocha *et al*., 1992). Once stabilized by a ligand, these proteins were not translocated anymore. Thus, the data suggest that most proteins are incompetent or too stable to be translocated by toxins.

### Delivery of peptide or protein antigens to dendritic cells for vaccination

Toxins are now widely used for the preparation of experimental vaccines. The principle of these toxin-based vaccines is to favor the uptake of viral or tumor antigens or their fragments by the dendritic cells of the immune system. In fact, toxins are used as vectors to deliver these antigen fragments inside the dendritic cells. These cells are responsible for the onset of an immune response. Their role is to engulf necrotic or apoptotic cells in tissues, including virally infected cells or tumor cells. Then they traffic to lymph nodes and present the antigens contained in these dead cells to T lymphocytes. As a result, the lymphocytes are stimulated against the virally infected cells or the tumor cells. They leave the lymph node through the circulation to reach the periphery where they find the sick cells and destroy them. Manipulating the uptake of antigens by dendritic cells directly *in vivo*, or *ex vivo* before re-infusion to the patient, to produce strong anti-tumor immune responses has become a major area of research in immunotherapy. Among the toxins used for these studies are diphtheria toxin, *Pseudomonas* exotoxin A, the adenylate cyclase from *Bordetella pertussis*, Shiga toxin, pertussis toxin, anthrax toxin (Smith *et al*., 2002a) (and also the plant toxin ricin (Smith, 2002b), and the insect toxin phospholipase $A_2$ from bee venom (Babon *et al*., 2005)). In most studies, the antigenic peptides or protein fragments are fused to the C domain (or A chain) of the toxin. The C domain is mutated on its catalytic site to prevent toxicity. In the case of Shiga toxin, the A chain can be removed and antigenic sequences can be fused (Lee *et al*., 1998; Haicheur *et al*., 2000) or chemically coupled (Haicheur *et al*., 2003) directly to the B subunit. Some of these toxins have an enhanced specificity for dendritic cells, allowing immunization *in vivo* instead of *ex vivo*. The adenylate cyclase from *Bordetella pertussis* targets specifically the marker CD11d/CD18 expressed on dendritic cells, which is the alpha (M) beta (2) integrin (Guermonprez *et al*., 2001). Direct injection of the toxin-derived vaccine *in vivo* allows efficient stimulation of cytotoxic T lymphocytes (Saron *et al*., 1997; Fayolle *et al*., 2001). The receptor for Shiga toxin is the ganglioside Gb3, which is found on the surface of various cell types, but in high amounts on dendritic cells. The non-toxic B pentamer of this toxin has been used successfully as a vector for tumor antigen peptides fused to it (derived from MAGE-1 or the mouse mastocytoma P815) (Lee *et al*., 1998; Haicheur *et al*., 2000) or for a chemically coupled, full-size model antigen (ovalbumin) (Haicheur *et al*., 2003). Vaccination of mice with these constructions primed specific cytotoxic T lymphocyte responses without the use of adjuvant.

### Translocation of drugs to the nuclei of receptor-targeted cells

The development of some anti-tumor drugs is precluded by the difficulty of these compounds to penetrate inside tumor cells and reach their target. Fusion proteins were constructed with the aim to deliver photosensitizing drugs to the nucleus of melanoma cells (Rosenkranz *et al*., 2003). These proteins contained MSH as a melanoma cell targeting sequence, an optimized nuclear localization sequence of the SV40 large T-antigen, an *Escherichia coli* hemoglobin-like protein as a carrier for photosensitizing drugs, and the T domain of diphtheria toxin as a translocator. These modular transporters delivered the drugs into the nuclei of murine melanoma cells, but not into cells devoid of MSH receptors, thereby enhancing the potency of the drugs.

## ENGINEERING C DOMAINS

### Suicide gene encoding a C domain

Suicide genes can be made from the DNA sequence encoding the C domain (or A chain) of toxins with intracellular targets placed under the control of an inducible promoter. Such a gene was constructed with the sequence encoding the C domain of diphtheria toxin (Figure 60.2) under control of a promoter regulated by HIV. The gene transfected in human T and promonocytic cell lines stopped the spread of HIV infection on cell cultures *in vitro* (Dinges *et al*., 1995). However, protection depended on the stock of virus used. More interestingly, hematopoietic CD34+ stem cells from human cord were transduced with the HIV-regulated diphtheria toxin C domain gene and were used to reconstitute a human immune system in SCID mice (Banda *et al*., 1998). The CD4+ T cells were protected from challenge with HIV 44 days after engraftment in mice. This may be a promising approach for the treatment of AIDS by toxin gene therapy of bone marrow stem cells.

Suicide gene technology based on the C domain from diphtheria toxin can be applied to the ablation of

specific tissues in mice in order to provide models of degenerative diseases (Brockschnieder *et al*., 2004). A transgenic mouse strain was generated carrying a genetic construct for conditional expression of the C domain of diphtheria toxin. This construct is made by the introduction of the *lacZ* coding sequence flanked by *loxP* sites within the sequence of the C domain. The construct is introduced in a mouse locus ubiquitously expressed and as such expresses only beta-galactosidase as a control of expression. When this mouse strain is crossed with another transgenic mouse carrying a tissue-specific Cre recombinase gene, the recombinase excises the *lacZ* sequence from the C domain sequence through recognition of the *loxP* sites. This activation of the C domain sequence occurs only in the tissue expressing Cre. The C domain expression leads to destruction of the specific tissue. This system was applied to the specific ablation of hepatocytes, B cells, cortical neurons, and glial myelinating cells, respectively (Brockschnieder *et al*., 2004). Other studies using similar approaches exist. A model of basal ganglia disease has been described by expression of an attenuated form of the toxin gene in D1 dopamine receptor neurons (Padungchaichot *et al*., 2000; Wong *et al*., 2000). Transgenic mice expressing the C domain of diphtheria toxin under the control of the granzyme A promoter lead to specific ablation of CD8 T lymphocytes (Aguila *et al*., 1995).

### Double hybrid technology using the C domain of *B. pertussis* adenylate cyclase

*B. pertussis* adenylate cyclase may be considered as an $AB_{RT}$ toxin with a C domain located in the first 400 residues and a translocation and a receptor-binding activity carried by its 1,306 last residues. The region of the toxin carrying these two last functions is similar to RTX toxins. The C domain is activated by calmodulin, which binds with high affinity to the enzyme, but has a residual activity in the absence of calmodulin (Dautin *et al*., 2002). The C domain has a modular structure consisting of two complementary fragments: T25 (residues 1–224) and T18 (residues 225–399). Both fragments are necessary for enzymatic activity, but when co-expressed in *Escherichia coli*, they are unable to interact and have no activity. However, when T25 and T18 are fused to peptides or proteins able to interact, heterodimerization of the two hybrid polypeptides results in functional complementation of the two fragments of the C domain. The complex is able to synthesize cAMP. If expressed in a bacterial strain deficient for its endogenous adenylate cyclase, the enzymatic activity can be detected on an appropriate selective media. This bacterial double-hybrid screening system has been used successfully to detect a number of bacterial, yeast, viral, and human protein-protein interactions (see Dautin *et al*., 2002 for list). Similarly, this screening system can be used to study and select protease inhibitors in *Escherichia coli*. T25 and T18 can be connected together with a peptide linker carrying a proteolytic cleavage site, leading to a functional adenylate cyclase. In the presence of the protease, the enzymatic activity is lost. It is recovered in the presence of efficient protease inhibitors. This principle was tested with the human immunodeficiency virus protease and known inhibitors. It could distinguish wild-type protease from inhibitor-resistant proteases from infected patients resistant to antiretroviral therapy (Dautin *et al*., 2002).

## ENGINEERING OF ALPHA TOXIN FROM *STAPHYLOCOCCUS AUREUS*

Alpha-hemolysin from *Staphylococcus aureus* is a pore-forming toxin secreted as a 33-kDa monomer. After binding to the surface of cells, the monomers can self-assemble to form a heptamer. Then an important structural change occurs affecting a three-strand beta-sheet from each monomer, which reorganizes into a long two-strand beta-sheet plunging into the membrane (Song *et al*., 1996; Olson *et al*., 1999). Together, these beta-sheets from the seven subunits of the heptamer form a beta-barrel spanning the lipid bilayer, making a pore of about 2 nm in diameter and 10 nm long. The pore has a high conductance of about 700 pS and is permeable to molecules up to a molecular mass of 2,000. The group of Hagan Bayley at Texas A&M University has described ways to engineer this pore in order to use it as a device tunable by proteases or metal ions to control cell-membrane permeability, or as a sensor for organic molecules.

### Triggering of pore activity by a protease cleavage switch

Residue 131 of alpha-hemolysin is located at the tip of the long two-strand beta-sheet of each monomer forming the transmembrane stem of the pore. Fragments 1–131 and 132–293 of alpha-hemolysin can combine together and lead to a functional pore. If the C-terminus of fragment 1–131 or the N-terminus of fragment 132–293 is extended, the functional complementation is lost. A proteolytic site can be added between the peptide chain extension and the rest of the fragment to which it is connected. Cleavage by the corresponding protease restores complementation of both fragments, leading to a functional pore (Walker and Bayley, 1994). Thus, it is possible to generate pore-forming proteins

with a protease-activated trigger. Introduction of a combinatorial cassette allowed the selection of proteolytic cleavage sites that are highly susceptible to activation by cathepsin B, a protease that is secreted by certain metastatic tumor cells (Panchal *et al*., 1996). Toxins obtained by this procedure should be useful for the permeabilization of malignant cells, thereby leading directly to cell death or permitting destruction of the cells with drugs that are normally membrane impermeant.

### Control of pore activity by a metal ion switch

Residues 130–134 of alpha-hemolysin are located at the tip of the long two-strand beta-sheet of each monomer forming the transmembrane stem of the pore. When these residues are replaced by five histidines, the toxin retains its ability to form pores (Walker *et al*., 1994; Russo *et al*., 1997). However, this histidine stretch constitutes a divalent metal ion-binding site. Binding of $Zn^{2+}$ at a concentration of 10 μM completely blocks pore activity. Chelating agents such as EDTA restore pore permeability by removing free $Zn^{2+}$ in the solution. This permeabilizing system was applied to control the loading of cells by trehalose, a sugar used to improve the tolerance of mammalian cells to desiccation (Acker *et al*., 2003).

### Modulation of pore activity and sensing of organic compounds

The pore of staphylococcol alpha-hemolysin can accommodate deep inside its cavity a molecule of beta-cyclodextrin applied on its trans side (Gu *et al*., 1999). Beta-cyclodextrin is a ring-shaped cyclic molecule, comprising seven D-glucose units forming a hydrophobic cavity. The cavity can encapsulate organic molecules in aqueous solution. When beta-cyclodextrin (or other cyclodextrins) is lodged in the lumen of the alpha-hemolysin pore, the conductance of the pore is reduced from about 700 pS to 200 pS (depending on the membrane potential and ionic strength) (Gu *et al*., 1999), and the ionic charge and selectivity are modified (Gu *et al*., 2000a, 2000b). The cyclodextrin acts as a binding site for organic molecules, which further block the pore conductance to values and with residence times specific for each molecule, leading to specific signatures (Gu *et al*., 1999). The authors propose that the hemolysin-cyclodextrin complex can be used as a sensor for a variety of organic compounds. In addition, the selectivity of the pore formed by the hemolysin-cyclodextrin complex can be modulated by the use of different cyclodextrins of various chemical compositions (Gu *et al*. 2000a, 2000b).

The activity of the pore of alpha-hemolysin can also be controlled by introduction of mutations in the transmembrane beta-barrel. Depending on the mutations, the control of pore permeability may be specific for given molecules. Several mutants were constructed in which a ring of up to 14 arginines was introduced near the constriction in the transmembrane beta-barrel (Cheley *et al*., 2002). The permeability of one mutant was almost completely blocked by phosphate anions at pH 7.5, but not by other oxyanions. Another mutant had a high affinity for inositol 1,4,5-trisphosphate, an important cell-signaling molecule, second messenger for $Ca^{2+}$ mobilization, but not for other second messenger molecules. Such engineered pores can be useful components to build sensors of cell-signaling molecules.

## CONCLUSION

We have seen in this short overview the fascinating possibilities offered by bacterial toxins for the design of new proteins with new functions. We have seen also how animals expressing genes encoding a fragment of toxin or a toxin receptor can serve as models for degenerative diseases. The FDA has approved one engineered toxin targeted to an endogenous human receptor for the treatment of a lymphoma. New indications are under study and the number of patients who will benefit from this molecule should increase in the future. Many fusion toxins built on the same model and targeted to a variety of receptors are developed against a series of malignancies (Table 60.2). A few are now being evaluated in patients. There is little doubt that in the future, hospital pharmacies should possess complete sets of receptor-targeted toxins against a variety of leukemias, lymphomas, hopefully solid tumors, immunological disorders, etc. Toxins used as delivery vehicles for vaccines are starting to reach clinical trials. Many other engineered toxins are still in the test tubes. Some will remain as laboratory curiosities, while others may be future drugs. Some may become important biological tools for diagnostics, detectors, nano-technologies, or bioelectronics. A number of toxins are still undiscovered or poorly characterized and should offer new engineering possibilities. Important challenges are still in front of us: building of artificial channels and receptors; mastering injection of peptides, proteins, nucleic acids, or chemical compounds into cells; and targeting of substances to specific organs such as the central nervous system. Other possibilities are still "un-thought" of. However, the development of highly complex products from toxins for human applications is extremely long and costly. It took 15 to 20 years to

make a drug by engineering diphtheria toxin, about twice as long as for a conventional drug. It's just a beginning.

CHAPTER

# 61

# Engineered bacterial toxin vaccines and adjuvants

*Jan Holmgren and Ann-Mari Svennerholm*

## INTRODUCTION

There has been remarkable progress in the understanding of the molecular biology of bacterial toxins in recent years, linking the fairly detailed knowledge of the structure-function relationship of several bacterial toxins with an advanced understanding of toxin genes and the regulation of their expression as described in this volume. This has resulted in completely new possibilities to prepare detoxified yet immunologically active toxin derivates. In combination with the similarly rapid progress in biotechnology, dramatic improvements in the potentials for preparing rationally designed vaccine immunogens based on recombinantly produced, genetically engineered, detoxified toxins or non-toxic subunits now are at hand (Holmgren and Svennerholm, 1998; Del Giudice and Rappuoli, 1999).

Recently, engineered detoxified toxins or non-toxic subunits have also attracted much interest as vaccine carrier proteins, adjuvants, and/or immunomodulators, in some cases for parenteral use but especially for mucosal administration (Holmgren and Lycke, 1993; Lycke, 1997; Gagliardi *et al*., 2002). Mucosal immunization has for good reasons attracted much interest recently, mainly as a means to induce protective immunity against the many important infections, which either take place at and affect mucosal surfaces or have a mucosal surface as their portal of entry (Holmgren and Czerkinsky, 2005; Holmgren and Svennerholm, 2004). Much less well appreciated than vaccination against infections, mucosal immunization may also be used to induce peripheral tolerance to prevent or suppress the development of harmful immune responses to foreign proteins derived from ingested food or from commensal microorganisms, in case these antigens would reach the body interior in an undegraded, immunogenic form (Holmgren and Czerkinsky, 2005; Wu and Weiner, 2003). For both types of applications, it has been found that bacterial toxin derivatives can substantially influence the outcome in ways that give hope for further development toward practical medical use. Likewise, engineered bacterial toxin proteins have found a useful place as carrier proteins for various capsular polysaccharides in the development of conjugate vaccines against important infections with encapsulated bacteria (Vadheim *et al*., 1994; Lieberman *et al*., 1996). Yet a further potential area for use of engineered, and potentially even native, bacterial toxins is as adjuvants for dendritic cell vaccination, which is rapidly becoming a promising treatment complement in the clinical management of many cancer forms (George-Chandy *et al*., 2001; Gagliardi *et al*., 2002; Eriksson *et al*, 2004).

In this chapter, we will briefly describe the properties and clinical potential of various types of genetically engineered bacterial toxins and subunits in these different areas of vaccination, adjuvanting, and immunomodulation.

## CHOLERA TOXIN AND CHOLERA VACCINE DEVELOPMENT

Cholera toxin (CT) was the first toxin that was described in its detailed molecular structure and function, as well as in its complex immunological properties, both

as a protective immunogen and as a potent mucosal adjuvant and immunomodulator (Holmgren, 1981). This included the identification of the AB5 structure with different subunits being responsible for the cell, binding and the toxic activities; the identification of the GM1 ganglioside as the specific cellular receptor for the toxin; the clarification of the pathogenic toxic-enzymatic action of the toxin on the intestinal target cells (ADP-ribosylation of the Gs protein leading to adenylate cyclase activation and increased cyclic AMP formation); and the connection between these effects and the excessive salt and fluid losses characteristic of the cholera disease (Holmgren, 1981; Guerrant, 1985). It also included the identification of the completely non-toxic B subunit pentamer (CTB) rather than the toxic-active A subunit as the target for neutralizing antibodies, thus pointing to CTB as a rational protein to be used as a mucosal vaccine immunogen for inducing effective CT-blocking intestinal immunity that could protect against cholera disease (Holmgren and Svennerholm, 1998; Holmgren and Bergqvist, 2004). This notion was further strengthened by findings in animals showing that immunization with highly purified CTB gave rise to toxin-neutralizing antibodies, which could fully protect against disease not only after toxin challenge but also after challenge with live *V. cholerae* O1 bacteria in the gut (Holmgren *et al*., 1977). Furthermore, CTB has been found to be particularly well suited as an oral immunogen, because of its stability in the intestinal milieu and its high-affinity binding to the intestinal epithelium, including the M-cells of the Peyer's patches, properties that are very important for stimulating mucosal immunity and local immunological memory (Neutra and Kraehenbuhl, 1993).

Based on this knowledge and further work that showed also that antibacterial intestinal cholera immunity is important and that indeed the antibacterial and the antitoxic immune mechanisms cooperate synergistically in protecting against cholera infection and disease (Svennerholm and Holmgren, 1976), the oral CTB-whole cell cholera vaccine was developed (Holmgren *et al*, 1977). This oral cholera vaccine, which is now registered (Dukoral®) in more than 50 countries worldwide, thus represents one of rather few mucosal vaccines available for human use.

The first-generation oral cholera vaccine contained CTB purified from CT produced in a fermentor by the wild-type strain 569B (Tayot *et al*., 1981). This made the preparation of this extensively purified component laborious and relatively expensive. These drawbacks were overcome by the development of an efficient recombinant overexpression system for the large-scale production of CTB (Sanchez and Holmgren, 1989), systems that have since then been further improved upon (Lebens *et al.*, 1993). These latter procedures now yield well over one gram of highly purified CTB per liter of fermentor culture even in 1000-liter fermentations, which is approximately 100-fold better than with the early non-recombinant production and isolation of CTB. Since there is no CTA subunit gene present in the production strain used, no active toxin can be formed, which makes the purification processes further efficient and cheaper (Sanchez and Holmgren, 1989). No differences have been found in the function of recombinantly produced CTB and toxin-derived CTB as a vaccine component. Immunological and functional studies, including immunogenicity studies in both animals and humans, have not been able to demonstrate any differences in the two molecules or in the immune responses they evoke (Jertborn *et al*., 1992). Moreover, the results from an efficacy field trial in Peru with vaccine containing the recombinantly produced CTB (Sanchez *et al*., 1994) and most recently also those from a large effectiveness study in Mozambique (Lucas *et al.*, 2005) were fully consistent with the high efficacy results obtained in Bangladesh with first-generation vaccine containing native CTB (Clemens *et al*., 1988a).

Many studies have shown that the CTB-WC vaccine is safe and immunogenic in both children and adults in cholera-endemic as well as non-endemic countries, stimulating gut mucosal immune responses to the CTB and WC vaccine components (Holmgren and Svennerholm, 1998; Holmgren and Bergqvist, 2004). A high-level short-term and a good long-term protective efficacy of the vaccine has been demonstrated, being 85% for the first six months after vaccination in both endemic and non-endemic populations (Clemens *et al.*, 1986, Sanchez *et al.,* 1994), and remaining at or above 60% for at least two years in vaccinated adults and in children above age five years (Clemens *et al*., 1988a; Clemens *et al*., 1990). In children below age 5, the short-term efficacy is very high (100% for the first six months when tested in a field trial in Bangladesh), but of shorter duration than in older children and adults (Table 61.1).

Protection by the oral CTB-WC cholera vaccine is mediated by locally produced IgA antibacterial and antitoxic antibodies blocking bacterial colonization and cholera toxin action, respectively; for longer-term protection, mucosal memory for rapid induction of mainly anticolonization IgA antibodies is important since these antibodies can then block bacterial colonization and multiplication at the intestinal surface before the infection has progressed to cause disease (Holmgren and Svennerholm, 1998). The antitoxic immunity appears to be particularly important for high-level, early protection in previously immunologically, relatively naïve vaccines, such as represented by young children in cholera-endemic countries, or all

**TABLE 61.1** Evidence of high short-term protective antitoxic protective efficacy against cholera, especially in young children, by the CTB component of the B subunit (CTB)-killed whole cell (WC) oral cholera vaccine

| | | Protective efficacy % | | |

ages when outbreaks first occur in previously unaffected countries, or in travelers to endemic countries. This is illustrated by the data in Table 61.1, showing significantly higher short-term efficacy, especially in young children in Bangladesh, of the CTB-WC vaccine compared to the WC vaccine without CTB in a side-by-side comparison in the same trial (Clemens *et al*, 1986). The same notion is also supported by the much higher efficacy in previously cholera-spared adult Peruvians, and especially in children in a recent effectiveness study in Mozambique using rCTB-WC vaccine, than in both Bangladeshi and Vietnamese people vaccinated with only WC vaccine (Table 61.1). For long-term protection in endemic countries, antibacterial immunity, largely based on immunologic memory stimulation, appears to be most important.

The CTB-WC cholera vaccine also offers significant short-term cross-protection (through the CTB component) against diarrhea caused by enterotoxigenic *E. coli* (ETEC) producing the heat-labile enterotoxin (LT), which cross-reacts immunologically with CT (Table 61.2; Clemens *et al*., 1988b; Peltola *et al*., 1991; Scerpella *et al*, 1995). Currently there is no other vaccine available against ETEC. The CTB-WC cholera vaccine has also been shown to give rise to substantial herd immunity and has been found to substantially reduce overall diarrhea morbidity in areas where cholera and ETEC-diarrheas are common *et al*. A large effectiveness study to assess the role of the vaccine in public health control programs against cholera in Africa has recently been undertaken. Results show that protection even under these conditions and in a population where about 30% may be HIV infected is similar to the efficacy demonstrated in the previously cited phase 3 efficacy trials, being about 80% against cholera as presented to the local treatment centers and nearly 90% against more severe cholera disease associated with dehydration (Lucas *et al*., 2005).

A second type of oral cholera vaccine, based on a live attenuated *V. cholerae* strain deleted in its cholera toxin gene from the ability to make the toxic-active A subunit, is also registered in some countries for use in travelers (Levine and Kaper, 1995; Levine and Tacket, 1995). However, different from the CTB-WC vaccine, the live, attenuated cholera vaccine failed to generate significant protection when tested in a large field trial in Indonesia, and thus is not recommended by WHO for use in cholera-endemic countries (Richie *et al*., 2000; WHO, 2001). Although this vaccine strain may produce tiny amounts of B subunit, the antitoxic immune responses are meager and protection in volunteers appears to be exclusively mediated by mucosal antibacterial immunity. The same appears to hold true also for newer, live, attenuated oral cholera vaccine candidates, wherein the cholera toxin gene has been modified to render the strain non-toxic, such as the Peru-15 vaccine strain (Kenner *et al*., 1995), which currently is in phase 2 clinical testing (Cohen *et al*., 2002).

## TOXIN-BASED VACCINES AGAINST ENTEROTOXIGENIC *ESCHERICHIA COLI* (ETEC)

Enterotoxigenic *Escherichia coli* (ETEC) cause disease by colonizing the small intestine and elaborating LT or heat-stable enterotoxin (ST) or both toxins (Sack, 1980). The resulting illness usually lasts from 3–5 days and ranges from mild diarrhea without dehydration to severe cholera-like disease (Svennerholm and Steele, 2004). Though the illness is usually mild, it is occasionally cholera-like in its severity and causes an estimated 300–500,000 deaths per year, mostly in young children. This high incidence in developing countries and in travelers to these areas makes ETEC an important target

for immunoprophylaxis (Black, 1990, 1993). In regions of the world where ETEC is highly endemic, there is a decline in ETEC diarrhea incidence with age. This, together with the findings that the oral CTB-WC cholera vaccine induced highly significant protection against LT-producing ETEC, strongly supports the notion that an effective enterotoxin-based ETEC vaccine is achievable.

The critical virulence properties that contribute to the pathogenesis of ETEC diarrhea are the ability of bacteria to adhere to the mucosa of the proximal small intestine by means of specialized, usually fimbrial attachment proteins (so-called colonization factors, CFs) and to elaborate LT and/or ST enterotoxins (Gaastra and Svennerholm, 1996). Protective immunity against ETEC appears to be mediated by mainly secretory IgA antibodies directed against LT, CFs, and other surface antigens; ST, which is a low-molecular weight peptide, does not elicit neutralizing antibodies following natural infection (Holmgren and Svennerholm, 1998).

To provide broad spectrum protection, an ETEC vaccine should contain an appropriate "toxoid" together with fimbrial antigens representative of the most prevalent ETEC pathogens. In view of the fact that ST is not immunogenic in its own right, it is especially important that the CF antigens cover a broad range of ETEC strains producing ST. The most prevalent CF antigens on ST only or ST/LT producing human ETEC isolates are CFA/I, CS1-CS3 (CFA/II), and CS4-CS6 (CFA/IV). Thus, a multivalent ETEC vaccine containing an LT toxoid together with these CFs is estimated to be able to protect against about 80% of ETEC strains worldwide (Svennerholm and Savarino, 2004).

Different strategies have been taken to deliver ETEC toxin antigens and fimbriae to the human immune system to elicit protective immune responses in the form of inactivated or live candidate vaccines. An attractive approach seemed to be to prepare killed ETEC bacteria that express the most important CFs in immunogenic form on the bacterial surface and combine these cells with an appropriate toxoid for inducing LT-neutralizing antibodies, i.e., recombinantly produced CTB or LTB (Holmgren and Svennerholm, 1998; Ahren *et al*, 1993; Svennerholm and Savarino, 2004). Attempts to prepare a strongly immunogenic ST toxoid, either by preparing synthetic peptides coupled to a suitable carrier protein, e.g., recombinant CTB, or by producing recombinant ST-CTB fusion proteins, have not been successful, partly due to the small size and high content of cysteins of the ST molecule. Low-level antibody responses to ST have been possible to raise, but have been found to be insufficient for inducing protection in the gut.

An ETEC vaccine consisting of a combination of recombinantly produced CTB and formalin-inactivated ETEC bacteria expressing five of the most prevalent CFs (CFA/I, CS1-CS5) and common O-antigens (e.g., O6, O25, O78, O139) of ETEC has been produced and extensively studied in clinical trials (Svennerholm and Savarino, 2004). This rCTB-CF ETEC vaccine has been shown to be safe and give rise to significant IgA immune responses in intestinal fluid in 70–90% of vaccinated Swedish volunteers (Ahren *et al*., 1998). Phase I and II trials of the vaccine in Swedish, Bangladeshi, and Egyptian adult volunteers have all shown that it is well tolerated and gives rise to mucosal immune responses, i.e., peripheral blood antibody secreting cell responses against LT and the different vaccine CFs, in 70–100% of the volunteers (Svennerholm and Savarino, 2004; Åhrén *et al*., 1998; Savarino *et al*., 1998, Qadri *et al*., 2000). Analogous safety/ immunogenicity clinical trials with the CTB-WC ETEC vaccine in Egyptian and Bangladeshi children down to six months of age showed that the vaccine was equally immunogenic as in the adults and also well tolerated except in the youngest Bangladeshi infants. A dose finding study showed that a quarter of a full dose of rCTB-CF ETEC vaccine was equally safe and immunogenic in the youngest infants as a full dose in older children and adults (Qadri *et al*., to be published).

The protective efficacy of the rCTB-CF ETEC has been studied in adult travelers going from industrialized areas to different countries in Asia, Africa, and Latin America. In an initial pilot study in European travelers going to 20 different countries in Africa, Asia, and Latin America, the vaccine was shown to confer 82% protective efficacy ($p < 0.05$) against ETEC disease, but the number of cases fulfilling the inclusion criteria overall was low (Wiedermann *et al*., 2000). Clinical trials of the vaccine in European travelers going to Kenya or in Israeli soldiers have not allowed determination or the protective efficacy of the vaccine due to too few cases fulfilling the inclusion criteria (Svennerholm and Savarino, 2004). In a large placebo-controlled trial that was recently completed in nearly 700 American travelers going to Mexico and Guatemala, the rCTB-CF ETEC vaccine was effective (protective efficacy 77%, $p = 0.039$) against non-mild ETEC diarrheal illness, i.e., disease that interfered with the travelers' daily activity, whereas no significant protection was observed against ETEC diarrhea of any severity, including mainly mild cases (Sack *et al*., 2002).

The only pediatric study to assess efficacy of the rCTB-CF ETEC vaccine is a randomized, double-blind, control trial that was recently conducted in 350 6–18-month-old children in rural Egypt (Svennerholm and Savarino, 2004). Disease detection was based on active

surveillance through semi-weekly household visits and cultures of fecal specimens from children with diarrhea. No significant protection against ETEC disease was induced by the vaccine in this trial, but it should be noted that children with high immune responses were protected (Savarino *et al*., to be published). Based on these results from the testing of the vaccine in children in a developing country, there appears to be a need for improving vaccine efficacy.

Since not only LTB but also the immunologically closely related and strongly cross-reactive CTB are efficiently immunogenic, lack toxicity, are stable in the gastrointestinal milieu, and are capable of binding to the intestinal epithelium including so-called M cells on the Peyer's patch surface, both of these proteins are suitable to give rise to protective anti-LT immunity. Although CTB has afforded significant protection against *E. coli* LT disease (Clemens *et al*., 1988b; Peltola *et al*., 1991), an LT toxoid may be slightly more effective than CTB in inducing protective anti-LT immunity (Svennerholm and Savarino, 2004).

An intriguing finding, if it can be confirmed in humans, is that in mice transcutaneous immunization may induce a mucosal immune response.

Based on this, the possibility of immunizing transcutaneously with an *E. coli* colonization factor, CS6, alone or together with nonmutated LT, was evaluated in human volunteers (Guerena-Burgueno *et al*., 2002). No response to CS6 was observed in the absence of LT (which similar to CT is a strong adjuvant), whereas combined administration of the two antigens induced antibody secreting cell responses as well as serum antibody responses against CS6 in about half of the volunteers and anti-LT responses in serum in all of the vaccines (Guerena-Burgueno *et al*., 2002). The approach of giving recombinantly produced *E. coli* LT transcutaneously, either alone or following oral priming with LT antigen, will be further explored in volunteers in developed and in developing countries (Calderwood *et al*., personal communication).

Different strategies to construct live ETEC vaccines have also been attempted in which either attenuated *Shigella* or non-pathogenic *E. coli* are engineered to express different CS components alone or in combination with an LT toxoid. Considerable progress has been achieved recently in engineering strains of *Shigella* that are attenuated compared with their wild-type parent and in using these strains as live vectors to express ETEC CF and toxin antigens. Enlarging upon this strategy, different live multivalent *Shigella*/ETEC hybrid vaccines have been constructed, wherein the important fimbrial CFs are expressed along with mutated LT in attenuated *Shigella* (Altboum *et al*., 2001). Recently an attenuated *Shigella flexneri 2a* strain, CVD 1204, was used to individually express four different CFs, as well as a detoxified version of human LT (LThK63). Following mucosal immunization of guinea pigs with a mixture of two or more such *Shigella* strains, immune responses were observed against LT, the CF antigens, and O-antigen of the *Shigella* vector strain (Barry *et al*., 2003). Different Shigella-ETEC hybrid candidate vaccine strains are presently tested for safety and immunogenicity, both in guinea pigs and in monkeys. The ultimate goal is to produce five different *Shigella* strains that can express the most important CFs and an LT toxoid simultaneously in the gut.

While such developments of live ETEC vaccines may yield promising experimental vaccines, their usefulness in humans has yet to be established. It remains to be shown to what extent the safety and efficacy profiles established in animal models hold true in genetically diverse human subjects. Thus, humans in different geographic areas may differ significantly in their intestinal flora, nutritional status, and previous immunological experience, all of which are factors that have been found to affect mucosal vaccine efficacy. Indeed, several mucosal vaccines, including oral live cholera vaccine and rotavirus vaccine candidates, as well as oral polio vaccine, have been found to work less well in developing country settings than in industrialized countries. Furthermore, the pandemic HIV infection problem presents additional challenges with regard to both vaccine safety and efficacy, especially for live-attenuated vaccines.

## PERTUSSIS TOXIN AND DEVELOPMENT OF ACELLULAR PERTUSSIS VACCINE

Pertussis toxin (PT) is a major virulence factor of *Bordetella pertussis* and plays an important role in the pathogenesis of whooping cough. There are striking resemblances between the structure and function of PT and those described previously for CT and LT. Thus, similar to the latter toxins, PT has an AB5 subunit structure, wherein the A region (usually referred to as the S1 subunit) mediates ADP ribosylating enzymatic-toxic activity, and the B pentamer, the binding to target cells (Stein *et al*., 1994). However, different from the B homopentamers of CT and LT, the non-toxic B domain of PT is a heteropentamer consisting of one S2, one S3, two S4, and one S5 non-covalently linked subunits (Lobet *et al*., 1993). Binding to cell membrane receptors takes place mainly through the S2 and the S3 subunits, leading to translocation of the S1 subunit into the target cell where it can interact with the $G_i$ component of

adenylate cyclase and other GTP-binding proteins and block their activities.

In the last 20 years, there has been a progressive replacement of the efficacious but reactogenic whole-cell pertussis vaccines with different types of acellular vaccines. The latter vaccines usually contain several components, including detoxified forms of PT together with bacterial cell components, such as filamentous hemagglutinin (FHA) and one or more agglutinogens, such as pertactin and fimbrial antigens. Even vaccine containing exclusively PT toxoid has been used and found to be protective, although to a lesser extent than the more complex acellular vaccines (Edwards *et al*., 1995).

The general approach for detoxifying the bacterial antigens, including PT, present in these vaccine formulations has consisted of different chemical treatments, such as using formaldehyde, glutaraldehyde, or hydrogen peroxide (Edwards *et al*., 1995). Since all of these methods carry the risk of a small but significant rate of reversion to toxic activity of PT, it was attractive to develop a genetically engineered, fully stable, and non-toxic PT "toxoid," wherein the toxic-enzymatic activity of the S1 subunit had been eliminated by specific mutation. Among several such mutated PT molecules showing variable degrees of detoxification, one molecule having substitutions in two positions of the S1 subunit (at residues 9 and 129) was found to be totally devoid of toxic-enzymatic activity and thus selected for further testing towards the development of an acellular pertussis vaccine (Pizza *et al*., 1989; Nencioni *et al*., 1990).

Studies in animals confirmed that this mutant PT molecule appeared to be devoid of any of the classical toxic-active manifestations of wild-type PT, and also much better than previous chemically detoxified PT molecules that had preserved epitopes reacting with and inducing neutralizing antibodies. The safety and immunogenicity of the genetically inactivated PT has been extensively tested in clinical trials, both in adult volunteers and in infants and children (Podda *et al*., 1990, 1992, 1993). These trials, both using the mutant PT alone and in association with FHA and pertactin, showed that acellular pertussis vaccines based on engineered, non-toxic PT mutant were safe and induced high titers of anti-PT-neutralizing antibodies, as well as strong PT specific T cell proliferative responses. Further, in a double-blind, placebo-controlled phase III efficacy trial in 16,000 infants in Italy, a three-component acellular pertussis vaccine containing the genetically detoxified PT, FHA, and pertactin given together with diphtheria and tetanus toxoids showed a high level of efficacy (84%) against whooping cough with indirect evidence that the PT component contributed significantly to the efficacy (Pertussis Working Group, 1996).

## DIPHTHERIA TOXIN CRM 197 AS CARRIER IN CONJUGATE VACCINES

Diphtheria toxin (DT) is together with CT the best studied enterotoxin with regard to its structure and function. DT is a 58-kDa protein produced as a single polypeptide by lysogenic *Corynebacterium diphtheriae* strains. After reduction of disulfide bonds, DT consists of two fragments, A and B, responsible for enzymic-toxic and cell-binding properties, respectively (Van Ness *et al*., 1980; Bennett *et al*., 1994). Like the previous toxins discussed, DT ADP-ribosylates an intracellular target protein, for DT the elongation factor 2, which thereby becomes inactive, resulting in inhibition of cellular protein synthesis and cell death.

Already in 1971, Uchida and coworkers (1971) found that different non-toxic DT protein derivatives could be obtained following mutagenesis with nitrosoguanidin. These proteins were called cross-reacting material (CRM) since they were immunologically cross-reactive with DT. Among these mutant proteins, CRM 197, which is mutated in residue 52 in the A fragment, is being widely used as a carrier molecule for the production of conjugated vaccines containing capsular polysaccharides from bacteria (Decker *et al*., 1992; Del Giudice and Rappuoli, 1999). Thus, CRM197 is the carrier molecule for the protective polysaccharide antigen in a licensed *Hemophilus influenzae* conjugate vaccine (Vadheim *et al*., 1994), and is likely to be used also in future conjugate vaccines against pneumococcal and meningococcal infections.

## CT AND LT AND DERIVATIVES AS MUCOSAL ADJUVANTS

Besides being strong mucosal immunogens, both CT and LT are powerful mucosal adjuvants (Holmgren *et al*., 1993). They strongly potentiate the immunogenicity of most other antigens, whether these are linked to or simply admixed with the toxins, provided that the other antigen is given at the same time and at the same mucosal surface as the toxins. However, since both CT and LT are normally considered to be much too toxic for human use, great efforts have recently been made to define whether it would be possible to separate the adjuvant and toxic activities as a basis for development of mucosal adjuvants for human use.

### Adjuvant action of CT and LT

CT and LT can affect several steps in the induction of a mucosal immune response. These effects, which alone or in combination might explain their strong adjuvant action after oral immunization, include: (i) increased permeability of the intestinal epithelium leading to enhanced uptake of co-administered antigen; (ii) enhanced antigen presentation by various APCs; (iii) promotion of isotype differentiation in B cells leading to increased IgA formation; and (iv) complex stimulatory as well as inhibitory effects on T cell proliferation and cytokine production. In addition, CT and LT have been shown not only to avoid inducing oral tolerance, but also to abrogate otherwise efficient regimens for tolerance induction by oral antigen administration (Holmgren *et al*., 1993; Lycke, 1997).

Among these many effects, those leading to enhanced antigen presentation by various APC are probably of the greatest importance for the adjuvant activity. CT markedly increases antigen presentation by dendritic cells (DC), macrophages, and B cells and has also been found, at least *in vitro*, to make intestinal epithelial cells to become effective APC (Gagliardi *et al*., 2002). Consistent with this activity, CT upregulates the expression of MHC/HLA-DR molecules, CD80/B7.1 and CD86/B7.2 co-stimulatory molecules, as well as chemokine receptors, such as CCR7 and CXCR4 on both murine and human DC and other APC (Gagliardi *et al*., 2002; Eriksson *et al*., 2003). Importantly, CT also induces the secretion of IL-1 from DC (Eriksson *et al*. 2003), thus supporting similar observations made earlier for macrophages. IL-1 not only induces the maturation of DC, but is also by itself an efficient mucosal adjuvant when co-administered with protein antigens and might mediate a significant part of CT's adjuvant activity (Staats and Ennis, 1999).

It has been claimed that CT primarily induces Th2 type immune responses characterized by $CD4^+$ T cells producing IL-4, IL-5, IL-6, and IL-10 and by the production of IgA, IgG1, and IgE antibodies. LT, on the other hand, has been reported to induce a mixed Th1- and Th2-type immune response. However, other studies have shown that CT also can induce mixed Th1 and Th2 types of immune responses, in contrast to CTB, which appears to induce a more restricted Th2 type of immune response (Eriksson *et al*., 2003). Thus DC, which had been pre-treated *in vitro* with a protein antigen (ovalbumin, OVA) linked to or admixed with CT and then injected into mice in an antigen-specific manner, induced both Th1 and CTL responses in addition to a Th2 response. In contrast, DC pulsed *in vitro* with OVA linked to CTB only gave rise to a Th2 type of immune response.

## DEVELOPMENT OF NON-TOXIC DERIVATIVES AS MUCOSAL ADJUVANTS

To avoid toxicity, isolated CTB and LTB have been explored for their ability to augment immune responses also against co-administered antigens. However, their capacity as mucosal adjuvants has proved to be much less than that of the holotoxins. Indeed, both CTB and LTB are poor adjuvants when given to animals together with non-coupled antigens by the oral route, although they display a more significant adjuvant activity when administered via the nasal route. Mice vaccinated intranasally with the influenza virus HA vaccine PR8 H1N1 together with LTB had higher levels of anti-viral IgA and IgG, both in sera and in nasal and lung secretions compared to mice given the subunit vaccine alone, and were also protected against an intranasal viral challenge (Haan *et al*. 2001). Adjuvanticity of CTB or LTB is much improved when coupled to antigens, due to the increased uptake of coupled antigen across the mucosal barrier and the more efficient presentation of coupled antigen, as compared with uncoupled antigen not only by DC and macrophages, but also by naïve B cells (Eriksson *et al*., 2003; George-Chandy *et al*., 2001).

Recently, site-directed mutagenesis has permitted the generation of LT and CT mutants that have reduced toxicity but that retain significant adjuvanticity when given to animals by the nasal-mucosal route, or even though they then perform less well, by the oral-mucosal route (Pizza *et al*., 2001). Two such mutants, LTK63 and LTK72, are currently evaluated as adjuvants for intranasally administered influenza vaccine (A. Podda *et al*., to be published).

Another approach that has been used to circumvent the harmful drawbacks of CT or LT adjuvants is to link the enzymatically active A subunit domain of the toxin to a cell-binding moiety other than the natural B subunit, such as the cell-binding domain of *Staphylococcus aureus* protein A (CTA1-DD) (Ågren *et al*., 1999). CTA1-DD, like most other toxin derivates, functions when applied nasally but not when given orally. This limitation has recently been overcome by the incorporation of CTA1-DD fused to a short peptide into immune stimulating complexes (ISCOMS). Oral vaccination with the ISCOM-CTA1-DD complex induced systemic and mucosal responses with both Th1 and Th2 characteristics (Mowat *et al*., 2001).

To achieve detoxification of CT, yet another type of mutant was recently described in which peptides were added to the CTA1 amino end. The added peptides seemed to reduce both enterotoxicity and ADP-ribosylating activity by sterical hindrance with the

CTA1 active site (Sanchez *et al*., 2002). In general, in these detoxified constructs, adjuvanticity decreased with decreasing enterotoxicity/ADP-ribosylation. However, a mutant (eCT6), with 10- to 20-fold lower enterotoxicity, displayed a level of adjuvanticity comparable to that of the wild-type CT. Another mutant with a longer peptide linked to CTA1 (eCT23) and no detectable toxic activity, although being also much less potent in adjuvant activity than either CT or eCT6, was superior to CTB as both mucosal immunogen and as adjuvant for a co-administered antigen.

## CT AND CTB AS ADJUVANTS FOR DENDRITIC CELL VACCINATION

Dendritic cells (DC) are professional antigen (Ag)-presenting cells that act as sentinels throughout the body. Vaccination with autologous monocyte/bone-marrow-derived DC pulsed with an appropriate Ag together with a suitable adjuvant *ex vivo* represents a promising approach to immunotherapeutic vaccination in patients with cancer or severe infections. The fact that the *ex vivo*-pulsed DC are autologous and can be extensively washed free from any unprocessed Ag and adjuvant before being reinfused to the patient makes it promising to also be able to use even such strong (but toxic) adjuvants as unmodified CT for stimulating the DC to become maximally immunogenic without risks of causing toxic side effects *in vivo*.

Conjugation of Ag to either CT or CTB greatly facilitated MHC class II-restricted Ag presentation by DC associated with both an up-regulated secretion of IL-1β by the pulsed DC and increased expression of CD80 and CD86 on the DC surface (George-Chandy *et al*., 2001). DC pulsed with CT- or CTB-conjugated Ag were found to be superior to DC pulsed with free Ag at inducing CD4+ T cell and B cell responses *in vivo*. However, while CTB-Ag conjugates almost exclusively stimulated immune responses with a Th2 type profile, conjugates based on CT were shown to drive the *in vivo* responses toward a mixed Th1 and Th2 phenotype (Eriksson *et al*., 2003). Vaccination with Ag-CT-pulsed DC, but not DC pulsed with Ag-CTB or Ag alone, also induced Ag-specific CD8+ T cells that produced IFN and were cytotoxic for Ag(OVA)-expressing E.G7 tumor cells *in vitro* and were able to infiltrate and eliminate an already established OVA-expressing E.G7 tumor *in vivo* (Eriksson *et al*., 2004; Sun *et al*, 2004). We propose that the use of CT as a combined carrier-delivery system and adjuvant for DC vaccination represents a novel attractive strategy for therapeutic anti-tumor vaccination, at least for tumors that express sufficient amounts of MHC class I carrying tumor-specific peptide antigens.

## CTB::CPG – A NOVEL POTENT IMMUNO-MODULATING ADJUVANT

Bacterial DNA contains unmethylated CpG motifs, which distinguishes bacterial DNA from vertebrate DNA. Vertebrate genomes uniformly contain a lower frequency of CpG motifs, and these are usually methylated (Krieg, 2002). Vertebrate immune systems appear to have evolved TLR9, which distinguishes bacterial DNA from self DNA. Interactions between unmethylated CpG motifs in bacterial DNA or in synthetic oligodeoxynucleotide (ODN) and TLR9 rapidly activate DCs, splenocytes, monocytes, and macrophages through the Toll/IL-1-receptor signaling pathway (Wagner, 2002). This interaction results in production of Th1-polarizing cytokines such as IFN-γ, IL-1β, tumor necrosis factor-α (TNF-α), and IL-12, which up-regulate co-stimulatory molecules on APCs and activate B cells for proliferation and IL-6 secretion. *In vivo*, systemic administration of CpG DNA was demonstrated to promote NK cell activity, to increase the total number of B lymphocytes in the spleen, and to elevate plasma levels or tissue mRNA expression of IFN-γ, IL-12, and TNF-α. Altogether, CpG DNA induces a predominantly Th1-type immune activation (Krieg, 2002), and CpG DNA has been shown to enhance vaccine immune responses (Krieg and Davis, 2001).

Very strikingly, it has recently been shown that the immunostimulatory effect of CpG DNA is significantly enhanced when chemically conjugated to CTB (Harandi and Holmgren, 2004). When compared for their immunostimulatory effect on murine splenocytes, CpG ODN coupled to CTB induced much stronger chemokine responses than achieved with CpG alone, and when tested on human white blood cells, even more pronounced differences were found. Thus, *in vitro* treatment of human peripheral blood mononuclear cells (PBMC) with an optimal human CpG ODN did not give rise to any appreciable levels of CC chemokine responses, whereas CpG ODN coupled to CTB elicited strong CC chemokine responses by human PBMC. The corresponding optimal murine CpG conjugated to CTB when administered intravaginally also elicited stronger CC chemokine responses in the murine female genital tract mucosa than did the unconjugated CpG ODN. The mechanism(s) of the increased immunostimulatory property of CTB::CpG conjugate compared to CpG ODN alone remains to be defined, but could be due both to increased uptake of

CTB-coupled CpG ODN across the mucosal barrier, as well as directly by the target antigen-presenting cells to increased transport into endosomes in the latter cells, and possibly also to CTB/GM1-directed intracellular transport of CpG into ER not accomplished by the free CpG ODN (Adamsson *et al*., to be published).

CHAPTER

# 62

# Bacterial protein toxins as biological weapons

*Leonard A. Smith*

## INTRODUCTION: EVOLUTION OF BIOLOGICAL WEAPONRY

Naturally occurring diseases have plagued civilization longer than recorded history, as ancient civilization existed before primordial observations and accounts were transcribed and maintained. The impact of disease on civilization has influenced the course of history and continues to do so in many different ways. Since antiquity, the war fighters and designers of battlefield tactics seized upon nature's disease-causing microbes and viruses and used them as weapons to help defeat their enemies in war. Accounts of biowarfare date back centuries B.C. when the early Persians, Greeks, and Romans contaminated the water supplies of their enemies with poisons from plants, animal carcasses, cadavers, and any refuse available that could cause disease in their opponents (Warner, 1972; Kupperman and Smith, 1993; Barnaby, 1997; Eitzen and Takafuji, 1997; Christopher *et al*., 1997). Further examples of biowarfare are found throughout history and have continued into the 21st century. In 1346, the invading Tartar army catapulted plague-infected corpses into the Genoese-held city of Kaffa (present day Feodosia in the Ukraine) during their attack on the Crimean city in an attempt to cause an epidemic within enemy forces (Derbes, 1966; Geissler, 1986; Mee, 1990). This maneuver (i.e., hurling bodies of people who had died of bubonic plague) was repeated in 1710 when Russians attacked Swedish forces at Reval in Estonia (Barnaby, 1997). Smallpox was used as a biological agent during the French and Indian War (1754–1767) (Stearn and Stearn, 1945; Parkman, 1969; Cartwright, 1974; Geissler, 1986; Cole, 1988; Poupard *et al*., 1989; Wheelis, 1999), the American Revolution (1775–1783) (Eitzen and Takafuji, 1997; Fern, 2000), and World War II (1941–1945) (Harris and Paxman, 1982; Williams and Wallace, 1989). One example of smallpox's use as a biological weapon occurred in 1763 when the British military provided blankets and handkerchiefs contaminated with smallpox from British victims at Fort Pitt to Native Americans with the intent to spread the disease among them. During the French and Indian War, Fort Pitt (today Pittsburg), an outpost in western colonial Pennsylvania, was in danger of being seized by the local Indians, who had already attacked the nearby outpost and killed the inhabitants. The use of smallpox was a covert attempt to infect the Indian population and reduce their numbers.

During World War I, the Germans allegedly developed and used *Bacillus anthracis*, *Pseudomonas pseudomallei*, *Burkholderia pseudomallei*, and *Vibrio cholerae* to cause anthrax, glanders, and cholera. However, Germany denied these assertions and allegations were never proven (Eitzen and Takafuji, 1997). The use of biological agents as weapons against humanity took on new meaning before and during World War II when the Imperial Japanese Army under General Shiro Ishii initiated a massive program to develop, test, and employ biological warfare weapons (Williams and Wallace, 1989; Harris, 1994; Gold, 1996). In 1932, during the Japanese occupation of Manchuria, Ishii began the atrocious program of testing various

disease agents on human subjects in the provincial capital of Harbin, northeast China. In 1936, the secret biowarfare research Unit 731, operating under the guise of a water purification unit, was created 20 miles from Harbin, at Ping Fan. The capacious base situated on approximately six square kilometers included 150 buildings with five satellite camps, and some 300 Japanese scientists and 2,700 technical support staff (Harris, 2003). Their mission was to investigate, among other things, the effects of various pathogens on humans. Three of Unit 731's eight divisions were singly concerned with bacteriological research, warfare research, and the mass production and storage of bacteria. The Japanese military experimented with biological agents, including those that cause anthrax, botulism, brucellosis, dysentery, typhus, gas gangrene, cholera, meningococcal infections, bubonic plague, and smallpox, and their vectors (especially insects), along with potential antidotes and the effects of other drugs, chemical toxins, frostbite, and plant and animal diseases. The experiments used captives, disdainfully referred to as *marutas* or logs, to test the lethal potency of various pathogens in open areas. Victims were bound to stakes on a test site and exposed to cultures in experiments to evaluate the efficacy of biological weapons and delivery methods. In some cases, a disease pathogenesis would be assessed by performing surgery on prisoners exposed to an agent without anesthesia.

In Ping Fan (Unit 731) alone, it is believed that at least 3,000 prisoners of war were killed by biowarfare experimentation during 1941–1945 (Harris, 1997). Thousands more were murdered in the biowarfare death factories in Canton, Peking, Shanghai, Singapore, Mukden, Nanking, Changchum, and in a number of branch camps throughout Manchuria. Even after the war ended, plague epidemics erupted in and around Ping Fan and Harbin proper. In 1947, a major plague epidemic broke out in the same area, spreading through much of the northeast. More than 30,000 persons died from plague before the disease ran its course. A separate facility south of Chang-Chun in Manchuria, called the Army Military Horse Epidemic Prevention Department (Unit 100), adapted agents into delivery devices such as bombs, artillery shells, and spray tanks from aircraft.

From 1940 to 1943, the United Kingdom, the former Soviet Union, and the United States began an extensive research and development program into biological agents. Early in their programs, all three countries ascertained that anthrax could be a viable weapon against the Third Reich after open-field testing in which domestic animals died of pulmonary anthrax after being exposed to anthrax spores by aerosol delivery. These experiments were performed by the British on the Scottish island of Gruinard between 1942–43 and on Vozrozhdeniye Island in the Aral Sea by the Soviet Union around the same period. The Allies' position regarding the use of biological weapons was as a deterrent only to be used in retaliation for an enemy's employment of such a weapon, a policy of limitation said to be in line with the 1925 Geneva Protocol. Ironically, although the Japanese Imperial Army had developed biological weapons and used them against the Chinese and the Russians before and during World War II, the Germans had not devoted significant resources to developing biological weapons, and the U.S. and U.K. never resorted to using them during World War II.

After World War II, the biological weapons programs (both offensive and defensive) of the U.S., the U.K., and the Soviet Union continued to expand at an alarming rate. Finally, in July of 1969, responding to international political pressure, the U.K. proposed a prohibition on the development, production, and stockpiling of bacteriological and toxin weapons at the Conference of the United Nations Committee on Disarmament. Soon after, the Soviet Union proposed that the U.N. General Assembly convene a disarmament convention. In 1972, the U.N. Convention on the Prohibition of the Development, Production, and Stockpiling of Biological and Toxin Weapons and on Their Destruction, which banned the development, production, and stockpiling of biological weapons, was opened for signature (Wright, 1990). The convention entered into force with 43 parties on March 26, 1975, upon ratification by the three depositary states: the U.S., the U.K., and the Soviet Union. As of 2003, the Biological Weapons Convention (BWC) had 151 members who signed and ratified the articles of the BWC treaty and 16 other countries that have signed, but not yet ratified, the treaty. Before the 1972 BWC, the U.S. had stopped all offensive biological and toxin weapon research, development, and production as directed in President Richard M. Nixon's 1969 and 1970 executive orders to do so. Subsequently, all existing stockpiles of biowarfare agents in the U.S. were destroyed in 1971–72. Since 1972 however, the world has witnessed the continued development, stockpiling, and use of biological weapons from nation states and members of the BWC (e.g., the Soviet Union, Iraq) (Meselson *et al*., 1994; Zilinskas, 1997; Butler, 2000; Alibek, 2000), cults (e.g., Rajneeshees, Aum Shinrikyo) (Torok, *et al*., 1997; Carus, 2000, 2001; Sugishima, 2003), and individuals (e.g., Diane Thompson, Debra Green) alike (Carus, 2001; Kolavic, *et al*., 1997).

## POST 9/11 ERA: THE U.S. RESPONSE TO BIOLOGICAL TERRORISM

Events on September 11, 2001 ushered in an acute awareness in the U.S. that its people and homeland were vulnerable to catastrophic terrorist attacks. The recognition was further validated during the same month in 2001 when *Bacillus anthracis* spores were placed in at least four, and potentially seven or more, envelopes and mailed from Trenton, New Jersey, to New York, Washington, D.C., and Lantana, Florida. Two of these letters were addressed to Senators Daschle and Leahy (U.S. Senate) and two others were sent to icons within the media industry. The now infamous anthrax-containing, posted letters, resulted in 22 confirmed or presumed cases of anthrax infection. Of these, 11 cases were inhalation anthrax, and 11 cases of cutaneous anthrax (seven confirmed and four suspected). There were five fatalities among the victims diagnosed with inhalation anthrax. The Centers for Disease Control and Prevention (CDC) recommended that some 10,000 people potentially exposed to anthrax take antibiotics for 60 days. However, one study reported a dramatic increase in prescriptions in October 2001 for ciprofloxacin (up by 160,000 prescriptions or 40%) and doxycycline (up by 120,000 or 30%) over the previous year (Shaffer *et al*., 2003). The increased purchases of post-exposure prophylaxis appeared to reflect the mass panic among the medical community and the public. The cost for anthrax cleanup in Capital Hill offices was $27 million and over $100 million to decontaminate U.S. post offices in Brentwood and New Jersey. To date, there have been no arrests in connection with the anthrax letters, highlighting the difficulty in solving a biocrime of this kind even with today's state-of-the-art forensic capabilities.

## BACTERIAL PROTEIN TOXINS AS BIOLOGICAL WEAPONS

Biological weapons hold many attractions for terrorists, be they renegade groups or nation states, and it is extraordinarily difficult to control their development, manufacture, and delivery. However, there are obvious challenges to the production and successful use of biological weapons whether they are viruses, bacteria, rickettsia, or biological toxins. This chapter focuses on bacterial protein toxins and examines their potential as biological weapons. Biological toxins are molecules produced by living organisms that are poisonous to other species, such as humans. Toxins are not especially effective biological warfare weapons when delivered by aerosols in open-field battlefield situations. They are not infective and do not replicate in the human body as viruses and bacteria do. However, there are scenarios in which certain toxins could have a catastrophic impact on the public health if used in a bioterrorist attack. There are specific features of toxin weapons that make some better weapons than others. In general, an ideal toxin weapon will (i) have a vulnerable population that is unprotected or for which there is no or limited medical intervention available once the disease cause by the toxin has developed; (ii) possess a high specific toxicity or be virulent in low doses; (iii) have a short and predictable incubation period; (iv) be readily mass-produced; (v) remain potent during storage, transport, and dissemination; and (vi) be effectively delivered to its target(s). Although there are numerous bacterial protein toxins capable of causing disease, in many cases the pathogenic organisms or their spores are the most effective delivery vehicle for the toxins and therefore, the organisms or their spores constitute the biological weapon. For example, in the case of inhalational anthrax, *Bacillus anthracis* spores are typically the infective form in the bacterial life cycle. The infective dose by aerosol is 8,000 to 50,000 spores and the incubation period (i.e., time from exposure to symptomatology) is 1 to 5 days (Franz and Zajtchuk, 2000). The spores are able to colonize the human lower respiratory tract, and pulmonary macrophages transport them to the tracheobronchial or mediastinal lymph nodes where they germinate into vegetative cells. As the organisms grow and propagate, they produce anti-phagocytic capsules and at least three bacterial protein toxins (i.e., protective antigen, lethal factor, and edema factor) that play a major role in the anthrax disease. The protective antigen serves as the requisite chaperone molecule for the edema and lethal factors and enables these two toxins to be internalized into cells. These toxins cause necrosis of lymphatic tissue, resulting in the release of large numbers of *Bacillus anthracis* organisms into the circulation, causing a fatal septicemia with widespread hemorrhage and necrosis involving multiple organs.

The CDC through their Bioterrorism Preparedness and Response Office conducted a public health assessment of potential terrorism agents in 1999 (Rotz *et al*., 2002). Their objective was to identify the biological agents towards which preparedness and response efforts in the U.S. were to be initially directed. The assessment of potential terrorism agents was made based on the impact such specific biological agents would have on public health and the medical

infrastructure if they were to be used in a biological attack. Other criteria considered also included the delivery potential to large populations based on the stability of the agent and the ability to produce, transport, and disseminate the agent in quantities adequate to affect such populations, the potential for person to person transmission and/or the degree of infectivity associated with the agent, public perception as related to public fear and potential for civil disruption, and special health preparedness demands for vaccine and therapeutic drug inventories, enhanced surveillance, and diagnostic requirements. The military had previously made similar risk assessments to a multitude of chemical and biological agents based on battlefield vulnerability to its troops.

Based on the assessment study, the CDC categorized biological threat agents in three groups (A, B, and C). Agents in Category A are agents that present the greatest threat to the public health because they are capable of causing mass casualties and are highly contagious or relatively easy to disseminate. These include the etiologic agents causing smallpox (*Variola major*), plague (*Yersinia pestis*), tularemia (*Francisella tularensis*), viral hemorrhagic fever (filoviruses and arenaviruses), anthrax (*Bacillus anthracis*), and botulism (*Clostridium botulinum* neurotoxin). Agents in Category B cause moderate morbidity, result in low mortality rates, and are moderately easy to disseminate. Included in this category are *Coxiella burnetti* (Q-fever); *Brucella* species (brucellosis), *Burkholderia mallei* (glanders), *Burkholderia pseudomallei* (melioidosis); *Chlamydia psittaci* (psittacosis); *Rickettsia prowazekii* (typhus fever); food and water safety threats such as *Salmonella* species, *Shigella* species, *Escherichia coli* O157:H7, and *Vibrio cholerae*; viral encephalitis (e.g., alphaviruses); and three protein toxins: ricin from the plant *Ricinus communis*, enterotoxins from *Staphylococcus aureus*, and epsilon toxin from *Clostridium perfringens*. Category C agents include emerging infectious threats such as Nipah virus and hantavirus.

Three bacterial protein toxins are identified in the CDC select agent list and all three toxins originate from foodborne pathogens. They are botulinum neurotoxin (Category A), staphylococcal enterotoxin (Category B), and epsilon toxin from *C. perfringens* (Category B). Botulinum neurotoxin is the most potent toxin known, its production usually presents few unmanageable difficulties, and it is relatively stable during storage, transport, and various types of dissemination. For these reasons, botulinum neurotoxin has traditionally been the toxin of choice for nation states and terrorists seeking to develop and potentially employ toxins as biological weapons. Much of the remaining chapter will be spent on botulinum neurotoxin because it poses the greatest threat as a toxin weapon and is the only class of toxins classified as Category A threat agents.

## *Clostridium botulinum* neurotoxins

Botulism is a neuroparalytic disease caused by toxins elicited from the saprophytic bacteria *Clostridium botulinum*, *Clostridium baratii*, and *Clostridium butyricum* (CDC, 1998). *C. botulinum* elicits seven structurally similar, but immunologically distinct neurotoxins (about 150 kDa in mass), identified as serotypes A–G (Sugiyama, 1980; Hatheway, 1992). The unique strain *C. baratii* produces only serotype F (Hall *et al*., 1985) and the *C. butyricum* strain, serotype E (Aureli *et al*., 1986). The seven neurotoxins can be differentiated serologically by specific neutralization with antitoxin (Hatheway, 1992). Four of the seven neurotoxins (A, B, E, and F) cause naturally occurring human botulism (Arnon *et al*., 2001), but all seven are known to cause inhalational botulism in primates (Middlebrook and Franz, 1997; J. Anderson, manuscript in preparation), types C and D cause botulism in primates when ingested (Gunnison and Meyer, 1930; Dolman and Murakami, 1961; Smart *et al*., 1980), and type C toxin was shown to be very effective when used in human clinical trials treating patients for blepharospasm and cervical dystonia that had become resistant to treatment with type A neurotoxin (Eleopra *et al*., 2002). The seven neurotoxins have varying specific toxicities (Lamanna, 1959; Gill, 1982; Ohishi, 1984) and durations of persistence in the nerve cells (de Paiva *et al*., 1999; Foran *et al*., 2003), and it is reasonable to assume that all seven toxins can cause botulism in humans if the exposure level is high enough. Portals of entry for botulinum neurotoxin include the pulmonary tract (inhalation botulism), the gastrointestinal tract (foodborne and infant botulism), and mucus membranes of wounds (wound botulism). Once toxin is absorbed, the circulatory system transports the toxin to peripheral cholinergic synapses, primarily targeting neuromuscular junctions (Simpson, 2004). The toxin binds irreversibly to high-affinity receptors on motor end plates, is internalized into the nerve cell through receptor-mediated endocytosis, and functionally blocks neurotransmitter (acetylcholine) release, causing neuromuscular paralysis. The estimated human dose (assuming 70 kg weight) of type A toxin (extrapolated from non-human primate data) that is lethal to 50% of a population exposed (i.e., the $LD_{50}$) is approximately 0.09–0.15 μg by intravenous administration, 0.7–0.9 μg for inhalation exposure, and 70 μg by way of the oral route (Herrero *et al*., 1967; Scott and Suzuki, 1988; Schantz and Johnson, 1992; Franz *et al*., 1993).

As is the case with most naturally occurring illnesses, exposure to a disease-causing agent would go unnoticed in a bioterrorist attack. The first signs of an outbreak would occur when the hospitals and urgent care medical facilities began receiving victims. The initial diagnosis of botulism is clinical, with confirmatory laboratory findings days away. Neurological signs and symptoms resulting from a toxin-induced blockade of neurotransmission at voluntary motor and cholinergic junctions dominate the clinical manifestation of botulism (Merson and Dowell, 1973; Hughes *et al*., 1981; Wilson *et al*., 1982). Patients with botulism usually present with an acute onset of weakness in muscles innervated by the cranial nerves, leading to diplopia, dysphonia, dysphagia, and dysarthria. In mild cases, no other symptoms may develop. In more severe cases, symmetric weakness progresses in a descending manner, leading frequently to a flaccid paralysis. If the illness is severe enough, the respiratory muscles are paralyzed, leading to ventilatory failure and death unless intubation and mechanical ventilation assistance are initiated. In such cases, antibody therapy is also indicated to inactivate and clear toxin from the circulatory system before it can enter peripheral cholinergic nerve cells and cause further damage to neuromuscular junctions. Patients may also have evidence of autonomic dysfunction including dry mouth, blurred vision, orthostatic hypotension, urinary retention, and constipation. Sensory abnormalities are usually absent, as only motor and autonomic nerves are affected. Similarly, mental function is usually not affected and patients are afebrile. If botulism is a consequence of ingesting improperly preserved foodstuffs contaminated with bacteria and their pre-formed toxins, nausea, abdominal pain, vomiting, and diarrhea may often precede or accompany the neurological abnormalities. Paralysis from botulism can be long-lasting. Mechanical ventilation may be required for two to eight weeks with foodborne botulism, with paralysis lasting as long as seven months (Hughes *et al*., 1981). Symptoms of cranial nerve dysfunction and mild autonomic dysfunction may persist for more than a year (Maroon, 1977; Mann *et al*., 1981; Ehrenreich *et al*., 1989).

It is quite clear from the medical intervention required to assist patients with botulism that a successful bioterrorist attack on large numbers of the public with botulinum neurotoxin would overwhelm the public health system and impact its ability to respond to the victims of such an attack. In 1984, a cult known as the Rajneeshees carried out a successful large-scale biological attack on the citizens of The Dalles town in the U.S. state of Oregon. The plot was unsophisticated, requiring only acquisition and propagation of a common foodborne pathogen (*Salmonella typhimurium* in this case), and using it to contaminate self-service food bars at some 10–12 local restaurants in the area. A total of 751 persons with *Salmonella* gastroenteritis were identified as being associated with eating or working at area restaurants. Fortunately, there were no fatalities and only 6% of those affected required hospitalization (Torok, 1997; Carus, 2000; Miller *et al*., 2001). One has to ask, what the outcome would have been if a colorless, odorless, and tasteless solution of BoNT had been used in lieu of *S. typhimurium*.

*C. botulinum* bacteria are sporulating, obligate anaerobic, Gram-positive bacilli. The spores are ubiquitous and are widely distributed in soil and marine sediments worldwide (Ward, 1967; Smith, 1978; Sugiyama, 1980; Dodds, 1992; Popoff, 1995), and are quite frequently found in the intestinal tract of grazing domestic animals. Under appropriate environmental or laboratory conditions, spores can germinate into vegetative cells and growing vegetative cells will produce toxin. Examples where spores and conditions for promoting their germination and subsequent propagation of toxin-producing bacteria have been found include the improper preservation of foodstuffs (van Ermengen, 1897; Landman, 1904; Leuchs, 1910; Ball *et al*., 1979; Dodds, 1990; O'Mahony, 1990; Hatheway, 1992; Sobel *et al*., 2004; Varma *et al*. 2004), decaying vegetable matter, fish, birds, and other animal carcasses (Smart, 1980; Smart, 1987; Shaffer, 1990; Whitlock, 1997; McLaughlin, 2004), and microbiology laboratories (Lewis and Hill, 1947; Schmidt, 1964; Seigel and Metzger, 1979; Shone, 1995; Malizio, 2000). Because of its seemingly pervasive availability, it would appear to the trained microbiologist that acquisition of a *C. botulinum* strain would not be a limiting factor to the would-be terrorist who seeks to obtain such a strain and who has the expertise and resources to do so. In fact, Internet sites, libraries with scientific journals and books, and bookstores abound with information on how to isolate and culture anaerobic bacteria and specifically, how to produce botulinum neurotoxin. It is a wonder why there has not been a successful bioterrorist attack as yet employing botulinum neurotoxin, keeping in mind the simplest fact, that historically, the major cause of botulism was due to the ingestion of foodstuffs contaminated with *C. botulinum* and pre-formed toxin. The food supply remains our most vulnerable commodity to protect against a botulinum neurotoxin attack.

Botulinum neurotoxin was developed as a biological weapon by several countries, including Japan, Germany, Russia, Iraq, and the United States. The earliest modern use of botulinum neurotoxin as a weapon was by General Shiro Ishii, the head of the Japanese biological warfare command, Unit 731, who admitted to feeding cultures of *C. botulinum* to prisoners with lethal

effect during Japan's occupation of Manchuria in the early 1930s (Hill, 1947). The U.S. first produced botulinum neurotoxin during World War II in response to concerns that Germany had developed the toxin as a weapon to be used against Allied forces. The U.S. produced over 1 million doses of a botulinum toxoid vaccine for the Allied forces preparing to invade Normandy on D-Day (Cochrane, 1947; Bryden, 1989). Because of its lethal potency, the U.S. investigated the potential of botulinum neurotoxin as an offensive biological weapon during the 1940s (Bernstein, 1987; Bernstein, 1990; Franz *et al*., 1997a). The U.S. code name for botulinum neurotoxin was agent X. As noted above, the U.S. offensive biological program on botulinum neurotoxin and all other biological agents ended in 1969–1970 by executive orders from President Richard M. Nixon, and all stockpiles of toxin were destroyed.

Botulinum neurotoxin research, weapons development, and production were a part of the former Soviet Union biological warfare program (United Nations Security Council, 1995; Bozheyeva, 1999). The Soviet Union reportedly tested botulinum-filled weapons at the Soviet site Aralsk-7 on Vozrozhdeniye Island in the Aral Sea (Bozheyeva, 1999; Miller, 1999) and endeavored to use genetic engineering technology to transfer complete toxin genes into other bacteria (Alibek, 1999). Unlike the U.S., the former Soviet Union not only continued but significantly expanded their offensive biological weapons program after signing the BWC treaty in 1972 with ratification in 1975. By signing and ratifying the treaty, the Soviet Union thereby agreed to stop all offensive biological weapons development and destroy existing stockpiles of biological weapons. In April 1992, President Boris Yeltsin publicly declared that his country had continued what is now known to have been a massive offensive biological warfare buildup, which included developing BoNT for weapon use. That same year, the former deputy chief of Biopreparat (the Soviet agency whose primary function was to develop and produce weapons of mass casualties), Colonel Ken Alibek, defected to the U.S. and described the foreboding Soviet biological weapons program in great detail (Alibek, 1999).

Iraq's offensive biological weapons program significantly expanded in 1985, thirteen years after Iraq signed the BWC treaty. In 1995, Iraq admitted to the United Nations Special Commission (UNSCOM) inspection team to having produced 19,000 liters (L) of concentrated botulinum neurotoxin for use in specially designed missiles, bombs, and tank sprayers (United Nations Security Council, 1995; Zilinskas, 1997). Of the 19,000 liters of botulinum neurotoxin concentrate produced between 1989 and 1990 at Al Hakam and Al Manal, 10,000 liters were used to fill 13 Al Hussein SCUD missiles having a 600-km range and 100 400-lb (R-400) bombs (each bomb could hold 85 liters of toxin solution). Biological agents were never used by Iraq during the Gulf wars, and Iraq maintains all stockpiles were either destroyed by Iraq or by UNSCOM inspectors (Blik, 2004).

Aum Shirinkyo, a Japanese cult formed in 1987 by Chizuo Matsumoto (alias Shoko Asahara), obtained religious corporation status from the Tokyo Metropolitan Government in 1989. The cult strived to develop biological weapons after their political party (the Supreme Truth or Shinrito Party) was defeated in the Japanese Diet Election campaign of 1990. Botulinum neurotoxin was one of the first biological agents the cult attempted to produce. Senior followers of the cult obtained soil samples from northern Japan (Hokkaido) with the intent of isolating the *C. botulinum* bacterium. A production facility was constructed at the Aum Shinrikyo compound in the Kamiku-Isshiki village near Mt. Fuji for manufacturing the neurotoxin (Sugishima, 2003). The cult dispersed aerosols of what they thought contained botulinum neurotoxin at multiple sites in downtown Tokyo, Japan, and at U.S. military installations in Japan on at least three occasions between 1990 and 1995. These attacks all failed as there were no reports of a botulism outbreak in Japan during this period. Additionally, shortly preceding the sarin attack in the Tokyo subway, three attaché cases containing portable disseminating devices generating water vapor were found in the subway station. The cult's perpetrator for these devices said in testimony at Shoko Asahara's trial in 1996 that he believed those cases contained botulinum neurotoxin. It was reported that botulinum neurotoxin had not been detected in those devices. In 1995, the cult had some 50,000 followers worldwide and an estimated US$1 billion in financial resources (Sugishima, 2003). Thus, the cult had the resources to develop biological toxins for use as weapons, the intent to do so, and although they had no specialist in the development of biological weapons, among their followers were microbiologists, medical doctors, and other scientists. It is not completely clear why the biological assaults failed, but information placed in evidence at Asahara's trial indicated that the cult's scientists had difficulty overcoming the technical barriers in isolating and cultivating *C. botulinum* and may never have been successful in doing so (Sugishima, 2003).

## *Staphylococcus aureus* enterotoxins

*Staphylococcus aureus* bacteria are facultative anaerobic, non-sporulating, Gram-positive cocci. They pro-

duce a host of exotoxins that contribute to their ability to colonize and cause disease in mammalian hosts (Johnson *et al*., 1992; Monday and Bohach, 1999; Dinges *et al*., 2000). Staphylococcal enterotoxins are 23 to 29 kDa polypeptides in the bacterial superantigen family (Ulrich *et al*., 1995; Ulrich, 2000) and comprise at least 15 antigenically different enterotoxin serotypes (Balaban and Rasooly, 2000; Krakauer and Stiles, 2003). They are the most frequent cause of food poisoning (Holmberg and Blake, 1984; Tranter, 1990; Granum and Brynestad, 1999) and as little as 100–200 ng can cause emesis in humans (Jablonski and Bohach, 1997). Staphylococcal superantigens cause disease by binding to monocytes at major histocompatibility complex (MHC) type II receptors rather than the usual antigen-binding receptors (Johnson *et al*., 1992; Monday and Bohach, 1999). Conventional antigens are normally taken up and proteolytically processed by antigen-presenting cells (APC). They are then presented for recognition by multiple elements in the T cell receptor (TCR) in the binding cleft of MHC class II receptors. SE and other superantigens are not processed by APCs, but associate directly with MHC class II and the TCR complex outside of the typical binding cleft. This induces a cascade of pro-inflammatory cytokines (such as tumor necrosis factor, interferon, interleukin-1, and interleukin-2), with recruitment of other immune effector cells, and relatively little activation of counter-regulatory feedback loops. Released cytokines are thought to mediate many of the toxic effects of the enterotoxins.

During the 1960s, as part of its biological warfare program, the United States investigated staphylococcal enterotoxin B (then code-named PG) for its potential use as an incapacitating agent (Ulrich *et al*., 1997). Staphylococcal enterotoxin B was especially attractive as a biological agent because much lower quantities were needed to produce the desired incapacitating effect than were required with synthetic chemicals. The estimated human dose that is incapacitating for 50% of the population exposed (also called the effective dose [$ED_{50}$]) is 0.0004 μg/kg, and the estimated human dose that is lethal for 50% of the population exposed ($LD_{50}$) is estimated to be 0.02 μg/kg, both by the inhalation route (Ulrich *et al*., 1997; Franz and Zajtchuk, 1997). No data exist on the $LD_{50}$ and $ED_{50}$ in humans by other routes of exposure (Rusnak *et al*., 2004).

Like other biological threat agents, diagnosis of staphylococcal enterotoxin B intoxication is initially based on clinical and epidemiological findings. Clinical symptoms from intoxication with staphylococcal enterotoxins include non-specific flu-like symptoms, including fever, chills, headache, myalgia, and varying degrees of prostration. Additional symptoms are specific to the exposure route (Greenfield, 2002; Franz *et al*., 1997b; Zapor and Fishbain, 2004; Rusnak *et al*., 2004). The incubation period from oral intoxication is one to four hours after oral ingestion. Usual symptoms include nausea, vomiting, abdominal cramping, and diarrhea. Symptoms typically last up to 20 hours. With severe intoxication, there can be profound dehydration due to loss of fluids, shock, respiratory failure, and cardiovascular collapse. Approximately 15% of patients require hospitalization, with a 5% fatality rate, usually in the very young or the elderly. Treatment for staphylococcal enterotoxin B intoxication is supportive care, as no specific approved antitoxin or vaccine exists; however, experimental vaccines are under development.

Staphylococcal enterotoxin B inhalation exposure presents with different symptoms than seen with oral ingestion. Inhalation causes respiratory signs, including a non-productive cough, chest pain, and dyspnea. In severe cases, there may be pulmonary edema, respiratory distress syndrome, shock, and death (Mattix *et al*., 1995; Ulrich *et al*., 1997). Gastrointestinal signs may also be seen after an aerosol exposure and are postulated to result from secondary oral ingestion of staphylococcal enterotoxin B concomitant with the inhalation exposure. Recently, a review of 16 occupational exposures to staphylococcal enterotoxin B from 1989 to 2002 at the United States Army Medical Research Institute of Infectious Diseases was reported (Rusnak *et al*., 2004). Conjunctivitis with localized cutaneous swelling occurred in three persons within one to six hours after exposure to staphylococcal enterotoxin B; two of these persons also had gastrointestinal symptoms, which suggests that such symptoms occurred as a result of exposure by an indirect cutaneous or ocular route. This has been the first report of conjunctivitis and local facial swelling due to ocular exposure from staphylococcal enterotoxin B.

## *Clostridium perfringens* epsilon toxin

*Clostridium perfringens* are sporulating, anaerobic, Gram-positive bacilli and, like other clostridial species, their spores are ubiquitous. *C. perfringens* was one of the pathogenic bacteria manufactured and studied by Iraq as part of its biological warfare program (Zilinskas, 1997). *C. perfringens* strains (types A, B, C, D, and E) elicit toxins that cause gas gangrene in humans, necrotizing enteritis in humans and animals, and enterotoxemias in animals. *C. perfringens* type A produces a 35-kDa enterotoxin (CPE) that is responsible for the symptoms of common human food poisoning and acts by forming pores in plasma membranes,

allowing electrolytes and fluids to escape (Skjelkvale and Uemura, 1977; Olsen *et al*., 2000; Adak *et al*., 2002). *C. perfringens* types B and D produce epsilon toxin within the gut of infected animals, mainly lambs and goats, and cause fatal veterinary enterotoxemias after the toxin has been absorbed across the mucosal barrier of their gastrointestinal tract (Songer, 1996; Smedley *et al*., 2004). Although *C. perfringens* epsilon toxin is a Category B biothreat agent, there have been no reported cases of human disease with this toxin. Epsilon toxin (33 kDa) is synthesized as a relatively inactive precursor toxin that becomes activated by a post-translational processing step in which 13 N-terminal and 22 C-terminal amino acid residues are proteolytically removed (Hunter *et al*., 1992; Miyata *et al*., 2001). Epsilon toxin has been shown to form oligomeric pores in intestinal and extraintestinal target tissues (Petit *et al*., 2001; Miyata *et al*., 2001; Miyata *et al*., 2002; Petit *et al*., 2003). Studies investigating the distribution and localization of the toxin after systemic administration in mice found the toxin to localize primarily in nasal cavity, spinal cord, brain, and kidneys (Tamai *et al*., 2003), supporting the belief that the toxin's primary mechanism for toxicity is to cause edema and hemorrhage in various organs such as brain, kidneys, and lungs (Petit *et al*., 2003). Neurological disorders, including convulsions and opisthotonos, have been noted in rodents after epsilon toxin intoxication, signs believed to result from damage to brain vasculature and direct effects on hippocampal cells (Miyamoto *et al*., 1998; Miyamoto *et al*., 2000). The lethal dose of epsilon toxin for rodents is 100 ng/kg (Franz, 1997), and a comparable parental dose for a 70 kg human would be 7 μg. It is thought that a biothreat delivery would be via the aerosol/inhalation route, leading to pulmonary edema followed by central nervous system, renal, and cardiovascular damage (Greenfiled *et al*., 2002). There are no antidotes for this toxin.

## CONCLUSION

Before the terrorist attacks on the World Trade Center, the anthrax letters, and the rash of suicide bombings in the Middle East, there had been numerous warnings regarding the potential for terrorism and the realization that such aggression could be perpetrated with biological weapons (Dando, 1994; Danzig, 1997; Holloway, 1997; Takafuji *et al*.,1997; Falkenrath *et al*., 1998; Henderson, 1999; Kortepeter and Parker, 1999; Wilkening, 1999; Gurr and Cole, 2000). In fact, the U.S. Congress developed a comprehensive legal framework to prevent the illegitimate use of toxins and infectious agents and signed into law the Biological Weapons Act of 1989 and the Anti-Terrorism and Effective Death Penalty Act of 1996 (Ferguson, 1997). Of course, laws are usually not deterrents to bioterrorists and do not prevent them from committing acts of violence. Enactment of laws, however, does reflect the concern of the government towards the use of biological agents in acts of bioterrorism and biocrimes. Much of the attention in the1990s over bioterrorism was due to the violations of the 1972 BWC accord and the continued offensive biological warfare programs in the former Soviet Union and Iraq. The economic and political collapse of the Soviet Union heightened these concerns, including fears that scientists working in the Soviet biological warfare program would travel to Iraq, Iran, Syria, Libya, North Korea, and other countries to sell Soviet-produced biothreat agents (i.e., toxins, bacterial, and viral strains), as well as their scientific expertise (Alibek, 1999).

In response, a Trilateral Agreement between the U.S., the U.K., and Russia was signed in 1992, which was intended to build confidence that Russia would dismantle the former Soviet Union's offensive biological weapons program (Caudle, 1997). Additionally, it committed Russia to opening suspect facilities for inspection, converting biological warfare facilities to more productive uses, and ending all biological weapons projects except for defensive purposes. Before the anthrax letters in 2001, the U.S. government had begun preparing for a potential bioterrorist attack (Tucker, 1997; Stephenson, 1997). After the anthrax letters, the response was accelerated (Lane, 2001). Federal bioterrorism expenditures increased from $414 million in FY2001 to over $5.5 billion in FY2004 and are expected to increase by another $2.1 billion in FY2005. Between FY2001 and FY2005, it is estimated that the U.S. government will spend $22.1 billion on civilian biodefense (Schuler, 2004). Project BioShield, signed into law by President Bush on July 21, 2004, provided $6 billion over the next 10 years for the development and production of vaccines and drugs to be used in the event of another bioterrorist attack. The Presidential Directive "Biodefense for the 21st Century" signed April 28, 2004 by President Bush, reaffirmed the nation's commitment to protect its homeland and U.S. global interests against bioattacks. Historically, there have been relatively few biowarfare and bioterrorist attacks worldwide. However, as noted above, they do occur. Pathogens and toxins exist in nature and are potentially available to those who have a strong desire to acquire and employ them as weapons.

Opinions, interpretations, conclusions, and recommendations are those of the author and are not necessarily endorsed by the U.S. Army.
