*C. difficile* toxin A (ToxA; ~300 kDa) is a potent enterotoxin responsible for pseudomembranous colitis (see Chapter 21 of this volume). In addition to the apparent actin-cytoskeleton alterations in enterocytes, ToxA probably uses a neural mechanism to increase intestinal secretion. Lignocaine, hexamethonium, and substance P inhibitors can block Tox A-induced ileal fluid accumulation, mucosal permeability, and inflammation (Castagliuolo *et al*., 1994). It is proposed that ToxA stimulates primary sensory neurons in the intestinal mucosa, causing subsequent release of substance P and CGRP, which then facilitates intestinal secretion and inflammation. These neuropeptides bind to macrophages in the lamina propria and activate the release of proinflammatory cytokines such as tumor necrosis factor (TNF) (Pothoulakis and Lamont, 2001). Thereby, ToxA stimulates intestinal macrophage expression of neurokinin-1 (NK-1), which is a high affinity receptor for substance P, and additionally NK-1 deficient mice are protected from ToxA-induced intestinal secretion and inflammatory diarrhea (Castagliuolo *et al*., 1998). Neurotensin, a gastrointestinal neuropeptide, is also involved since an inhibitor of neurotensin prevents the secretory and inflammatory responses following ToxA exposure (Castagliuolo *et al*., 1999). Furthermore, ToxA also suppresses noradrenaline release at sympathetic synapses of the enteric nervous system that play an inhibitory effect on secretomotor neurons, thus amplifying mucosal secretion (Xia *et al*., 2000).

Finally, in addition to the various enterotoxins from bacilli listed above, *Staphylococcus aureus* also produces a myriad of 25–30 kDa, single-chain proteins called the staphylococcal enterotoxins (SEs) (Krakauer and Stiles, 2003). These potent toxins cause a prevalent form of food poisoning found throughout the world, and these molecules also possess "superantigenic" properties (see Chapter 49 of this volume). By classic definition, this latter property involves binding to both major histocompatibility complex class II (MHC II) on antigen presenting cells and Vβ specific T-cell receptors, which ultimately causes massive T-cell proliferation with a concomitant production/release of various proinflammatory cytokines. To date, it is uncertain if superantigenicity plays a direct role in SE-induced food poisoning. However, levels of inflammatory mediators like prostaglandins and leukotrienes are increasingly evident in the circulatory system of nonhuman primates shortly after an oral dose of SEB (Jett *et al*., 1990). Mast cells may also play a role in SE-induced food poisoning, which perhaps involves not only inflammatory mediators but also stimulation by neuropeptides like substance P released from sensory neurons (Alber *et al*., 1989). Another study reveals that SEB-induced effects in mice (intraperitoneal injection) are abrogated by capsaicin, the active ingredient of hot chili peppers, which depletes peptidergic sensory nerve fibers and TNF production (Tiegs *et al*., 1999). An intraperitoneal injection of SEB into rats induces expression of Fos (a cell activator) throughout the brain via vagus nerve stimulation, thus suggesting that the peripheral presence of an SE has profound effects upon the brain (Wang *et al*., 2004). Similar results (capsaicin inhibition and vagal nerve stimulation) have also been reported for *E. coli* ST in rats (Rolfe and Levin, 1999). Exactly how an SE molecule communicates directly (or indirectly) with the vagus nerve is unknown, but MHC II-bearing cells found between fibrous vagus bundles in the abdomen may provide a clue that involves interleukin 1β (Goehler *et al*., 1999). All of this evidence indirectly suggests a role for the nervous system during SE enterotoxicity, but in our opinion, more definitive studies await.

## CONCLUSION

Is neurotoxicity a unique, inherent function of a bacterial toxin? Most bacterial proteins with demonstrable "toxic" activity, such as those presented in this chapter, interact with various cell types. For example, more than one-third of all bacterial toxins are pore-formers that recognize ubiquitous membrane components as receptors, such as cholesterol, gangliosides, and proteins. These toxins can indiscriminately damage membranes from different cells, including those of neuronal origin. Among them, *C. perfringens* epsilon toxin has the fundamental structure of a pore-forming toxin, is cytotoxic for kidney epithelial cells, and also possesses specific neurotoxic activity. However, a specific neurotoxic mechanism of action and trafficking pattern targeting neuronal cells by epsilon toxin during the natural course of disease still remains undetermined. Other toxins have developed various internalization processes, therefore specifically modifying an intracellular target. Thus, several bacterial proteins like the large clostridial toxins (i.e., *C. sordellii* LT and *C. difficile* ToxA/ToxB) have the ability to bind/enter various cell types that include those of neuronal origin. Large clostridial toxins inactivate intracellular targets like Rho and/or Ras GTPases, which are involved in multiple signaling pathways. Among them, Rac controls the neuroexocytosis process. Thereby, large clostridial toxins efficiently block neurotransmitter release, although they do not specifically target neuronal cells. Involvement of their neurotoxic activity during disease, which is often overcome by toxic effects upon other cell types in natural pathology, is also a function of a toxin's opportunity to enter neuronal cells near the infection site. Finally, two unique classes of neurotoxins, the BoNTs and TeNT, have evolved as specific inhibitors of the neuroexocytosis machinery. These bacterial proteins recognize specific receptors on neuronal cells and only interfere intracellularly with highly specialized molecules, like the SNARE proteins, which play a pivotal role in evoked release of neurotransmitter. It is intriguing that toxins produced by environmental bacteria, which are not normally adapted for a commensal life with higher organisms and only interact accidentally with them, possess such specific and highly sophisticated tools. What is the underlying selective pressure for such evolution from a bacterial protease to a neurotoxin? Perhaps neurotoxins simply result from an evolutionary process independent of the host. What is the inherit benefit derived by an environmental bacterium to produce a neurotoxin, which apparently does not recognize other bacterial or environmental substrates? Clearly, we approach this from a scientist's (human) perspective, and with such an inherent bias it may be difficult and virtually impossible to truly understand this natural curiosity.

During their evolution, clostridial pathogens have developed a potent arsenal of noxious proteins that affect the central and peripheral nervous system of various vertebrates. These commonly named neurotoxins specifically target some key functions, or cellular processes, of eukaryotic cells, which subsequently cause a wide array of life-threatening diseases in humans and animals. These neurotoxins bind to specific receptors in the plasma membrane of susceptible host cells and translocate their enzymatically active domains/subunits into the cytosol, where finally they elicit the deleterious effects commonly associated with the holotoxins. Modes of action for the neurotoxic proteins reviewed in this chapter have been deciphered during the last decade, and now a clearer picture of their intracellular substrates is emerging. The specificity of these toxic proteins has enabled them to become useful tools to elucidate and characterize crucial processes for eukaryotic cells, which include neurotransmitter release, physiological signaling pathways, and constitutive cellular mechanisms. However, additional studies are needed to completely identify their specific membrane-receptors, as well as comprehend the mechanisms and structures involved in toxin routing throughout the nervous system. Thus, multidisciplinary approaches integrating molecular microbiology, membrane biology, biochemistry, physiology, proteomics, and pharmacology will further advance our understanding of the transport mechanisms required for directing molecules to specific locations within the nervous system of eukaryotes. Clearly, specificity of action for the BoNTs has made them very useful therapeutic agents for many human neurological syndromes caused by hyperactivity of cholinergic nerve terminals (see Chapter 58, in this volume). It is expected that future pharmacological developments will employ the inherent capabilities of various clostridial neurotoxins to deliver biologically active substances into nerve cells.

CHAPTER

# 20

# Uptake and transport of clostridium neurotoxins

*Stephanie Bohnert, Katrin Deinhardt, Sara Salinas, and Giampietro Schiavo*

## INTRODUCTION

Over the last 100 years the causative agents of tetanus and botulism and the molecules responsible for their symptoms, the clostridium neurotoxins (CNT), have been studied intensely. Despite their recent fame, the clinical effects of CNT have been known since the beginning of medical literature. Hippocrates described for the first time the symptoms of a sailor affected by hypercontraction of skeletal muscle, which he termed $\tau\varepsilon\tau\alpha\nu o\sigma$ for tension. Tetanus was considered a neurological disease until the end of the nineteenth century, when a potent neurotoxin produced by *Clostridium tetani*, named Tetanus Neurotoxin (TeNT), was identified as the sole causative agent of the spastic paralysis characteristic of tetanus, which is often fatal due to cardiovascular or respiratory failure. The same period also saw the first description of botulism, a general muscle weakness, followed by the isolation of *Clostridium botulinum* and its neurotoxins (Botulinum Neurotoxins, BoNTs).

The isolation of *C. tetani* and *C. botulinum* toxigenic strains in the late 1980s and studies on their intracellular activity and their synaptic targets in the 1990s have revealed important insights into a complex protein machinery able to recognize neurons, enter the cytosol, and modify synaptic function. The description of CNT and the study of their molecular mechanism of action are central to several disciplines, including microbiology, pharmacology, physiology, biochemistry, and medicine. Furthermore, these neurotoxins have been used as molecular tools to dissect regulated secretion and intracellular trafficking in a variety of cells. Recently, BoNTs have been used increasingly in human therapy, mainly for pathologies caused by synaptic hyperactivity and as cosmetic agents.

## CLOSTRIDIUM NEUROTOXINS

CNT are the most toxic substances known, with mouse Lethal Dose 50% ($LD_{50}$) ranging between 0.1 and 1 ng $kg^{-1}$ of body weight. Different animals show a great range of sensitivity to TeNT and BoNTs. Mammals, except rats, are among the most receptive species, whereas birds, reptiles, and amphibians are resistant to CNT to different extents (Gill, 1982). The time of onset of paralysis after CNT intoxication is dependent on the species, dose, and route of application. However, a delay ranging from several hours up to days is always present between infection with CNT and manifestation of the earliest clinical symptoms.

After entering the general circulation, CNT bind to the presynaptic membrane of the neuromuscular junction (NMJ) (Figure 20.1). This binding is highly specific and at high affinity, contributing together with the enzymatic activity of CNT to the very low $LD_{50}$ values and the limited spreading around the site of injection observed *in vivo*. Following binding, CNT are internalized into the neuron. BoNTs remain at the NMJ and block the release of the excitatory neurotransmitter acetylcholine (ACh), causing a flaccid paralysis (Figure 20.1b). In contrast, TeNT is retrogradely transported to

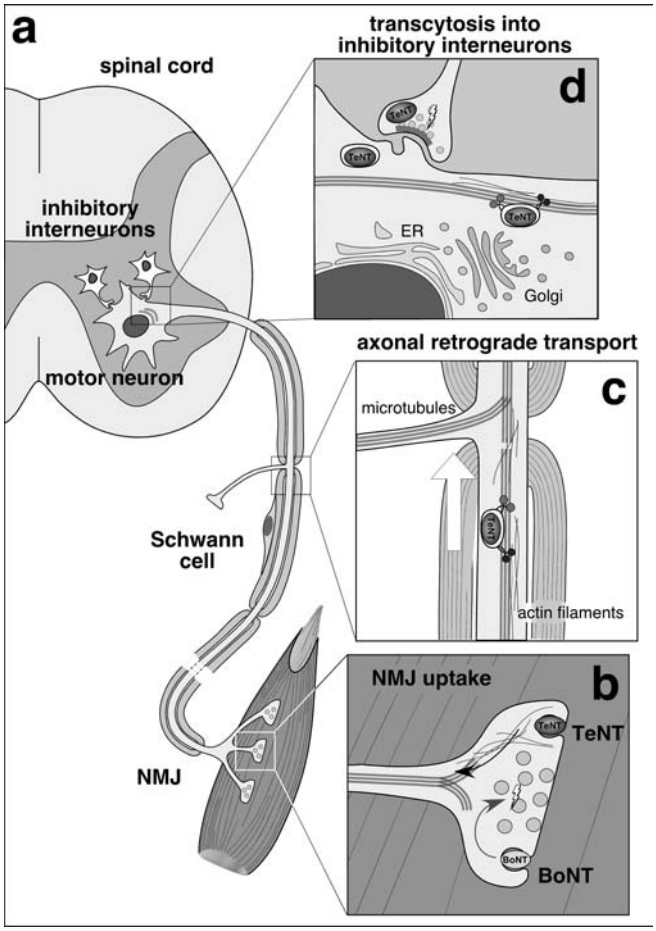

**FIGURE 20.1** Distinct trafficking of TeNT and BoNT *in vivo*. (**a**) Scheme of the anatomical connections between skeletal muscles, spinal cord, motor neurons (MN), and their afferent cells. MN control skeletal muscles with a specialized synapse termed *neuromuscular junction* (NMJ). The MN axon, which is wrapped by a myelin sheet produced by Schwann cells, can reach a length of a meter or more in large mammals. The MN soma is located in the spinal cord, where it forms contacts with adjacent interneurons. (**b**) NMJ uptake. After entering the general circulation, CNT reach the NMJ where they bind to the presynaptic terminal and are internalized. BoNTs remain at the NMJ, where they cleave SNARE proteins, thereby blocking the fusion of synaptic vesicles (SV). The consequent inhibition in ACh release causes a flaccid paralysis. In contrast, upon endocytosis TeNT enters specialized transport carriers directed towards the MN soma located in the spinal cord, where it accumulates in the ventral horn of the gray matter. (**c**) Axonal retrograde transport. Crucial elements of the axonal transport machinery are motor proteins that use ATP to perform mechanical work. Microtubule-based motors (cytoplasmic dynein and kinesins) play a major role in axonal transport and are MT-based. However, actin-dependent motors are also relevant for this process, indicating a functional connection between MT and actin-based transport. (**d**) Transcytosis into inhibitory interneurons. Once in the spinal cord, TeNT is released into the extracellular medium and internalized into adjacent inhibitory interneurons, where it cleaves VAMP, thereby blocking inhibitory neurotransmission. This impairs the balance between inhibitory and excitatory afferents on the MN, which ensures coordinated muscle contraction and causes spastic paralysis.

the motor neuron (MN) soma located in the spinal cord, where it accumulates in the ventral horn of the gray matter (Figure 20.1c). Once in the spinal cord, TeNT is released into the extracellular medium and internalized into adjacent inhibitory interneurons, where it blocks the release of inhibitory neurotransmitters (Figure 20.1d). This impairs the balance between inhibitory and excitatory afferents on the MN, which ensures coordinated muscle contraction and causes spastic paralysis. Despite their different clinical symptoms and intracellular targeting, the mode of action of TeNT and BoNTs is therefore similar. All CNT block neurotransmitter release and this inhibition is due to specific cleavage of soluble NSF attachment protein receptors (SNARE) involved in neuroexocytosis.

TeNT can bind sensory as well as adrenergic neurons, which exhibit a similar retrograde uptake. Although excitatory synapses appear not to be compromised in the early stages of the disease, they may be inhibited at later periods of TeNT intoxication. This preference for inhibitory versus excitatory synapses is maintained when TeNT is applied directly into the central nervous system (CNS) and may underlie the neurodegenerative and epileptogenic effects of TeNT, which result from unopposed release of glutamate from excitatory central synapses.

## STRUCTURE-FUNCTION RELATIONSHIP

As expected from their similar mechanism of action, toxins from the CNT family share a high degree of sequence and structural homology. CNT are produced as a single-chain inactive polypeptide of 150 kDa, which will be cleaved by endogenous or exogenous proteases (DasGupta, 1994; Weller *et al*., 1989) (Figure 20.2). This specific cleavage produces two chains, a 100 kDa heavy chain (H chain) and a 50 kDa light chain (L chain). These chains remain associated via non-covalent protein-protein interactions and a conserved inter-chain disulphide bond, which is essential for neurotoxicity (de Paiva *et al*., 1993; Schiavo *et al*., 1990a). The H chain can be further subdivided into two different fragments, the 50 kDa amino-terminal part ($H_N$) and the 50 kDa carboxy-terminal part ($H_C$) (Bizzini *et al*., 1977; Helting and Zwisler, 1977; Neubauer and Helting, 1981) (Figure 20.2b).

The existence of these three functional domains was confirmed by the crystallization and structural determination of BoNT/A (Lacy *et al*., 1998; Stevens *et al*., 1991) (Figure 20.2a), BoNT/B (Swaminathan and Eswaramoorthy, 2000), and the L chain and $H_C$ domain of TeNT (Umland *et al*., 1997; Rao *et al*., 2005) (Figure 20.2c). At a 3.3

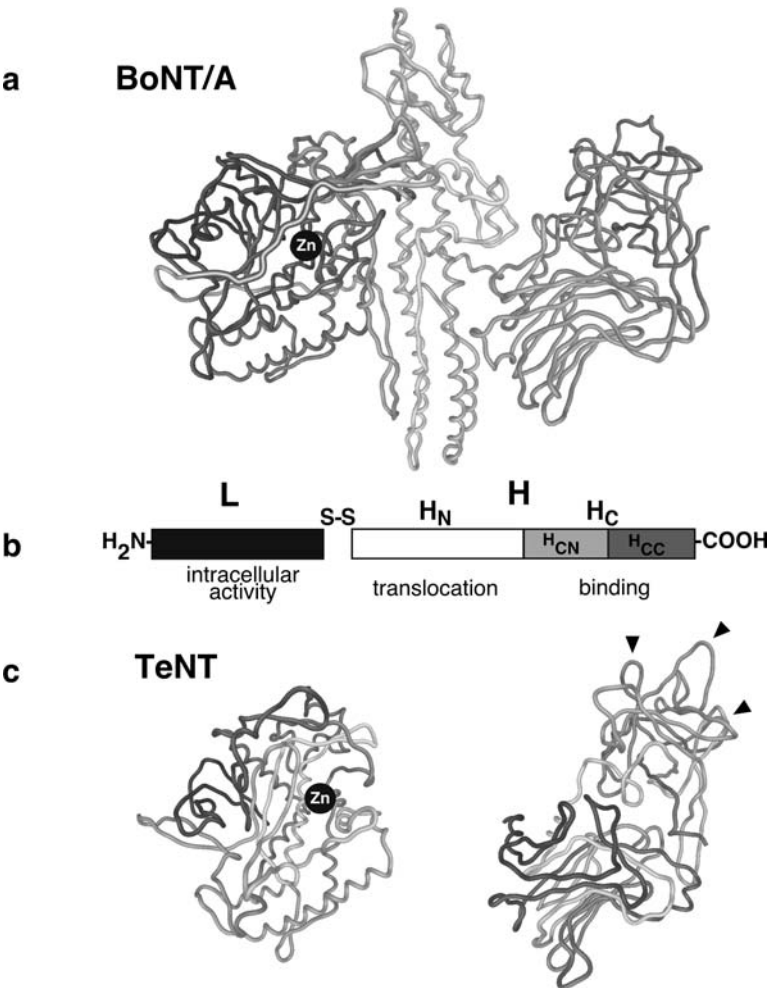

**FIGURE 20.2** Structure of CNT (**a**) Crystal structure of BoNT/A. The binding domain is highlighted in gray, the translocation domain in light gray and the catalytic domain, coordinating a zinc atom (large dark sphere), in dark gray. The catalytic domain is formed by a mixture of β-strands and α-helices. The translocation domain consists of two long α-helices and a long belt wrapping around the catalytic domain, here highlighted in white. The amino terminal part of $H_C$ displays two seven-stranded β-sheets ($H_{CN}$), whereas the carboxy-terminus adopts a modified β-trefoil fold ($H_{CC}$; PDB: accession number 3BTA) (Lacy *et al*., 1998). (**b**) Schematic representation of CNTs. The active holotoxins are formed by a 50 kDa L chain linked via a disulfide bond to a 100 kDa H chain. The carboxy-terminal portion $H_C$ (50 kDa) is responsible for neurospecific binding, whereas the amino terminus $H_N$ (50 kDa) is involved in the translocation of the catalytic domain into the cytosol. Structurally, $H_C$ can be subdivided in two 25 kDa domains, $H_{CN}$ and $H_{CC}$. $H_{CN}$ has structural analogies to the carbohydrate binding moiety of plant lectins and other oligosaccharide-binding proteins. $H_{CC}$ adopts a modified β-trefoil fold, which is present in several proteins involved in recognition and binding functions such as trypsin inhibitors. (**c**) Crystal structure of TeNT L chain (PDB accession number: 1YVG)(Rao *et al*., 2005) and $H_C$ chain. (PDB accession number: 1AF9) (Umland *et al*., 1997). Direct comparison between the L chains of TeNT, BoNT/A, /B, and /E suggest that their overall structure is very similar, differing only in terms of stringent substrate specificity. Similarly, the $H_{CN}$ domains of TeNT and BoNT/A display an overall identical fold, whereas the $H_{CC}$ of different CNT vary in their gangliosides interaction loops (arrowheads).

Å resolution, BoNT/A was found to be an elongated molecule, presenting a linear arrangement of three domains (Lacy *et al*., 1998; Stevens *et al*., 1991). These domains are structurally distinct with the exception of a large loop in the amino-terminal part of the H chain, which is wrapped around the perimeter of the L chain.

The $H_C$ domain, which is responsible for the neurospecific binding of CNT (Bizzini *et al*., 1977; Halpern and Neale, 1995; Herreros *et al*., 2000a), is composed of two distinct subdomains, rich in β-stucture and of roughly the same size. The amino-terminal subdomain ($H_{CN}$) has structural analogies with the carbohydrate binding moiety of plant lectins and other oligosaccharide-binding proteins. The carboxy-terminal portion ($H_{CC}$) of the H chain adopts a modified β-trefoil fold, which is present in several proteins involved in recognition and binding functions such as trypsin inhibitors. The entire $H_C$ domain remains completely isolated from the rest of the molecule, such that all the surface loops are accessible and therefore available for binding. Comparison of the crystal structures of different $H_C$ domains showed that the major differences between CNT resides in the loops of $H_{CC}$, where the sequence is poorly conserved (Umland *et al*., 1997). The removal of the amino-terminal portion $H_N$ of the H chain does not affect toxin binding, whereas the deletion of only a few residues from the carboxy-terminus abolishes toxin binding (Halpern and Loftus, 1993).

Studies with native and recombinant TeNT have shown that $H_C$ contains ganglioside- and cell-binding sites (Figueiredo *et al*., 1997). Two binding sites in $H_C$ have been found, which account for their interaction with gangliosides (Rummel *et al*., 2003). The identified interaction sites in gangliosides of the $G_{1b}$ series are absent in $G_{M1}$, which is consistent with its very low binding affinity to $H_C$.

The amino-terminal part of the H chain ($H_N$) is implicated in the pH-dependent membrane-penetration and translocation of the catalytic domain into the cytosol. It is composed of a loop interacting with the L

chain and a central body containing two very long α-helices as the main structural units. Although the function of this domain in the membrane insertion and L chain translocation has been well described (Donovan and Middlebrook, 1986; Shone *et al*., 1987), the exact mechanism(s) involved are still poorly understood. The amphipathic segment 659–681 of BoNT/A increased the permeability of lipid bilayers, implicating this fragment in pore formation (Oblatt-Montal *et al*., 1995). In the structure, the sequence corresponding to this peptide adopts a β-strand-like conformation and lies against the two main α-helices. This may suggest an involvement of this portion of the molecule in a pH-dependent conformational change, causing the exposure of previously hidden hydrophobic surfaces.

The L chain is the catalytic domain, responsible for the intracellular activity of the toxin (Ahnert-Hilger *et al*., 1989; Bittner *et al*., 1989; Mochida *et al*., 1989; Penner *et al*., 1986; Poulain *et al*., 1988; Weller *et al*., 1991). The L chain contains the catalytic zinc atom, essential for CNT endopeptidase activity. One zinc-atom is bound to the L chain of TeNT, BoNT/A, B and F (Schiavo *et al*., 1992a; Schiavo *et al*., 1992b; Schiavo *et al*., 1993a), while BoNT/C binds two atoms of zinc with different affinities (Schiavo *et al*., 1995). Heavy metal chelators are effective to remove the bound zinc and generate inactive apo-neurotoxins (Bhattacharyya and Sugiyama, 1989; Schiavo *et al*., 1992a).

The structure of BoNT/A, /B, and /E light chains suggest that substrate recognition cannot occur at the active sites of these CNT because their catalytic pocket organization and geometries are nearly identical (Agarwal *et al*., 2004; Lacy *et al*., 1998). The catalytic site is located deep in the structure of the protein, accessible only by a large channel, which accommodates the substrate. In the di-chain CNT, the entry to the channel is partially blocked by the large loop wrapping the L chain, and by the translocation domain itself (Lacy *et al*., 1998). Biochemical and mutagenesis studies have identified two critical residues in BoNT/A, $His_{222}$ and $His_{226}$, where the zinc atom is held in place. These residues are located in the sequence His-Glu-x-x-His, the characteristic zinc endopeptidase motif (Jongeneel *et al*., 1989; Schiavo *et al*., 1992a; Schiavo *et al*., 1992b; Wright *et al*., 1992). The glutamic acid residue in this motif coordinates the water molecule necessary for the catalysis (third ligand), whereas another glutamic acid ($Glu_{261}$ in BoNT/A) is the fourth ligand.

## Neurospecific binding

CNT binding has been examined using morphological and biochemical techniques in different systems like primary neuronal cultures, cell lines, and various membrane preparations (Halpern and Neale, 1995; Schiavo *et al*., 2000). CNT bind to the presynaptic membrane of cholinergic nerve terminals (Halpern and Neale, 1995). TeNT may also bind to sympathetic and adrenergic nerve fibres (Rossetto *et al*., 2001). *In vitro*, CNT are capable of binding to a variety of non-neuronal cells, but only at concentrations several orders of magnitude higher than those clinically relevant. In contrast, *in vivo* binding of CNT is absolutely neurospecific and requires concentrations in the subnanomolar range (Halpern and Neale, 1995; Simpson, 2000). The determinants of this high-affinity neurospecific binding are encoded within the $H_C$ domains, as recombinant $H_C$ fragments can counteract paralysis induced by the parental toxins (Lalli *et al*., 1999).

CNT bind to polysialogangliosides, in particular to members of the $G_{1b}$ series ($GD_{1b}$, $GT_{1b}$, and $GQ_{1b}$) (Halpern and Neale, 1995; Montecucco, 1986), with BoNTs containing one and TeNT two oligosaccharide-binding sites within the carboxy-terminal part of the $H_C$ domain (Rummel *et al*., 2003; Rummel *et al*., 2004b). The binding of CNT to polysialogangliosides is physiologically relevant, because mutations in the carbohydrate binding pockets decrease binding to the neuronal membrane (Louch *et al*., 2002; Rummel *et al*., 2003; Rummel *et al*., 2004b). Preincubation of NMJ preparations with $G_{1b}$ protects the NMJ from BoNT-dependent inhibition of neurotransmitter release and partially abolishes retrograde transport of TeNT (Stoeckel *et al*., 1977). Also, the removal of sialic acid residues from the membrane surface with neuraminidase decreases but does not abolish CNT activity (Bigalke *et al*., 1986). In addition, impairment of ganglioside biosynthesis leads to a reduced CNT activity *in vivo* (Kitamura *et al*., 1999; Williamson *et al*., 1999). Niemann (1991) suggested a model in which polysialogangliosides act as peripheral receptors for TeNT, mediating its retrograde transport to the CNS, where it binds to a second different acceptor (Niemann, 1991). Although appealing, this model suffers from the drawback of the low affinity and low specificity of polysialogangliosides as the only TeNT receptor in the periphery, where a high-affinity interaction is required to account for the extremely low doses of TeNT causing clinical symptoms *in vivo*. In addition, lack of binding competition between TeNT and BoNTs and their absolute neurospecificity make it unlikely that gangliosides are the unique binding determinant for CNT. Accordingly, specific protein co-receptors have been identified for some of the CNT. For example, BoNT/A, /B, /E, and /G interact with synaptotagmins I and/or II (Dong *et al*., 2003; Li and Singh, 1998; Rummel *et al*., 2004a; Yowler *et al*., 2002), which function as calcium-sensors at the synapse.

BoNT/B binds to the intraluminal portion of glycosylated synaptotagmin I and II (Nishiki *et al*., 1996) in a ganglioside-dependent manner. During neurotransmitter release, this region is exposed to the extracellular milieu, and it becomes accessible to large extracellular ligands. Thus, BoNTs might use synaptic vesicle (SV) endocytosis and recycling for their entry into MN. Moreover, the acidification of SV, which is necessary for their reloading with neurotransmitters, might mediate the acid-driven insertion of the heavy chain (Koriazova and Montal, 2003; Schiavo *et al*., 2000) into the SV membrane and the translocation of the L chain into the NMJ cytoplasm. However, the role of synaptotagmins as physiological BoNT receptors remains controversial because antibodies against this synaptotagmin domain fail to antagonize the binding and activity of BoNT/B at the NMJ (Bakry *et al*., 1997). Moreover, competition experiments clearly demonstrated that different BoNT serotypes do not share the same receptor (Evans *et al*., 1986; Habermann and Dreyer, 1986).

TeNT binds to one or more glycosylphosphatidylinositol (GPI)-anchored protein(s) of ~15 kDa (Herreros *et al*., 2000b). One of these proteins has been identified as Thy-1 in nerve growth factor (NGF) differentiated phaeochromocytoma (PC12) cells. However, it is unlikely to be the main protein receptor *in vivo* because Thy-1 knockout mice retain sensitivity to TeNT (Herreros *et al*., 2001). In contrast, pretreatment with a phosphatidylinositol-specific phospholipase, which cleaves the lipid anchor of GPI-anchored proteins, protects neurons from TeNT intoxication (Munro *et al*., 2001).

GPI-anchored proteins, cholesterol, gangliosides, and other sphingolipids are enriched in microdomains of the plasma membrane, termed *lipid rafts*. They act as platforms for signaling, ligand recognition, sorting, and endocytosis (Pike, 2003; Tsui-Pierchala *et al*., 2002). In addition, lipid rafts provide efficient and dynamic means for receptor clustering and ligand oligomerization. These include virulence factors, when locally concentrated on restricted domains of the plasma membrane (Abrami *et al*., 2003). Consequently, lipid microdomains are exploited by pathogens and virulence factors for their entry into host cells (Abrami *et al*., 2003; Duncan *et al*., 2002).

The complexity of the CNT receptors, which are composed of multiple lipid and protein components, together with the high affinity of CNT for the neuronal membrane has led to the recent proposal that arrays of presynaptic receptors (APRs) are involved in CNT binding (Montecucco *et al*., 2004). APRs are suggested to be dynamic entities that share several features with lipid rafts. Due to their high concentration at the NMJ and their lateral mobility, gangliosides are suggested to be the initial binding factors. They would act as "antennas" to capture CNT on the presynaptic membrane and allow subsequent clustering with the other molecules of the APR, thus leading to virtually irreversible binding. In addition to gangliosides, an APR would contain additional lipids, such as cholesterol, one or more GPI-anchored protein(s), and transmembrane protein(s). They may also include signaling molecules that upon binding trigger the internalization and/or sorting of CNT to specific synaptic structures. The APR recognized by BoNTs would guide them inside vesicles that acidify within the NMJ, whereas the APR binding TeNT would sort the neurotoxin into an endocytic vesicle undergoing retrograde transport along the axon. Upon sorting in the soma of the MN, TeNT will be released into the intersynaptic space, where it will enter inhibitory interneurons, possibly via SV endocytosis (Matteoli *et al*., 1996).

To reach its final site of action, TeNT has to bind to and enter two different neurons: a peripheral MN and an inhibitory interneuron of the spinal cord. In this regard, several proteins are taken up efficiently by MN when linked to recombinant TeNT $H_C$ (Coen *et al*., 1997; Fishman *et al*., 1990; Francis *et al*., 1995; Miana-Mena *et al*., 2002), as discussed in "Protein and gene transfer via TeNT." The identification of the receptors for TeNT present on MN will provide crucial information on this trafficking pathway leading from the NMJ to interneurons, offering new insights for the delivery of biologic and pharmacological agents into the spinal cord.

## INTERNALIZATION

Because the catalytic activity of the L chains is directed towards intracellular targets, this toxin domain must at least reach the cytosol. *In vivo*, CNT do not enter the cytosol directly via the plasma membrane but are endocytosed by the cell into vesicular compartments. Electron microscopic studies have shown that, after binding, CNT enter the lumen of vesicular structures in a temperature- and energy-dependent process (Critchley *et al*., 1985; Parton *et al*., 1987). In dissociated spinal cord neurons, gold-labeled TeNT is found first in coated pit structures at the cell surface, and then in a variety of vesicular and tubular structures as well as multivesicular bodies and, to a lesser extent, SV (Parton *et al*., 1987). In contrast, Montesano (1982) found that in liver cells TeNT accumulates in uncoated pits and non-clathrin coated vesicles. These discrepancies are difficult to reconcile and are probably a consequence of the different cell system and the high

concentration used by one group (Montesano *et al*., 1982).

It is well established that nerve stimulation facilitates intoxication by CNT (Habermann *et al*., 1980; Kryzhanovsky, 1958; Ponomarev, 1928; Schmitt *et al*., 1981; Wellhoner *et al*., 1973), and following membrane depolarization, TeNT colocalizes with SV markers in hippocampal neurons (Matteoli *et al*., 1996). In agreement with these findings, recent studies showed that TeNT uptake is dependent on presynaptic activity in MN *in vivo* (Miana-Mena *et al*., 2002), and that BoNT/A and /E enter neurons in a calcium- and stimulation-dependent manner (Keller *et al*., 2004). Generally, a high rate of neuroexocytosis correlates with a high rate of SV recycling via endocytosis, the two processes being tightly coupled (Murthy and De Camilli, 2003). Thus, a possible explanation for the shorter onset of paralysis induced by CNT under nerve stimulation is that they enter the synaptic terminal inside the lumen of SV. The accessibility of the internal lumen of SV to extracellular agents during neurotransmitter release has been demonstrated by the binding and uptake of antibodies specific for luminal epitopes of a SV protein (Kraszewski *et al*., 1995; Matteoli *et al*., 1992; Mundigl *et al*., 1995). According to this hypothesis, CNT might use SV as Trojan horses to gain entry to CNS neurons.

Several distinct mechanisms of endocytosis have been described (Conner *et al*., 2003), of which clathrin-mediated internalization is to date the best characterized. Additional pathways include caveolin-dependent endocytosis, as well as several clathrin- and caveolin-independent mechanisms. Though there may be additional ways of retrieval, the role of clathrin-mediated endocytosis in SV recycling is well established (Murthy and De Camilli, 2003). Therefore, it is likely that CNT exploit this pathway of clathrin-mediated endocytosis for their entry into the neuron in which they block release. This is an attractive model to explain the endocytosis of CNT in central neurons, but it is unlikely that SV recycling is responsible for the uptake of TeNT at the NMJ. In fact, three experimental findings contrast with this hypothesis. First, high frequency stimulation increases the rate of intoxication but not the binding of TeNT to the NMJ (Schmitt *et al*., 1981). If the toxin receptor is exposed during neuroexocytosis to allow the toxin to bind and then be endocytosed, an increase in the stimulation rate should also increase the total number of binding sites present at the NMJ. Second, TeNT is not active on a NMJ maintained at 18°C even in the presence of high-frequency stimulation and massive neurotransmitter release, whereas it is fully inhibitory at 25°C (Schmitt *et al*., 1981). Third, the uptake and retrograde transport of TeNT occur in NMJ intoxicated with BoNT/A, where neurotransmitter release is completely blocked (Habermann and Erdmann, 1978). The latter fact is in agreement with the notion that retrograde transport of various substances, including horseradish peroxidase, is not impaired in silenced NMJ (Kemplay and Cavanagh, 1983; Kristensson and Olsson, 1978). In addition, experiments performed in MN indicate that there is very limited co-localization between TeNT and SV markers (Lalli, 2002b), thus indicating that the pathway of internalization and intracellular trafficking of TeNT may be very different in peripheral and central neurons. Preliminary data suggest that in spinal cord MN, TeNT is also internalized via a clathrin-dependent pathway, which is, however, distinct from SV endocytosis (K.D., unpublished data).

## AXONAL TRANSPORT IN SPINAL CORD MOTOR NEURONS

Axons can reach a length of up to several meters. To overcome these distances, neurons have developed an exquisitely efficient and highly regulated transport system, which is essential for survival and growth, and for long-distance communication (Goldstein and Yang, 2000). Axonal transport was first observed in transected axons (Waller, 1852) and then confirmed in ligation experiments (Cajal, 1928; Weiss and Hiscoe, 1948). More recent metabolic radiolabeling studies clearly defined two types of transport systems, fast and slow. The fast component (0.1–5 μm/s) is mainly used for vesicle and organelle transport, and for secreted molecules like neurotrophins. The slow component (1–50 nm/s) is responsible for the transport of microtubules (MT), neurofilament components, cytoplasmic proteins, and metabolic enzymes (Vallee and Bloom, 1991).

Neurotrophins, their low affinity receptor ($p75^{NTR}$) (Lalli and Schiavo, 2002a), and several endocytic compartments use retrograde axonal transport from the synapse to the cell body to reach their final destination (Goldstein and Yang, 2000; Vallee and Bloom, 1991; Whitmarsh and Davis, 2001). Several pathogens, such as *Herpes* and *Polio* viruses, are targeted to the cell body, where the virus replicates or enters latency (Bearer *et al*., 2000; Satpute-Krishnan *et al*., 2003).

## TRANSPORT OF CLOSTRIDIAL NEUROTOXINS

In contrast to BoNTs, which remain at the synaptic site, TeNT carriers are recruited to the retrograde axonal

transport pathway towards the MN cell body located in the spinal cord (Stöckel *et al*., 1975). TeNT carriers are shared by both NGF and its low affinity neurotrophin receptor $p75^{NTR}$ (Lalli and Schiavo, 2002a). Despite the importance of these axonal compartments in health and disease, not much is known about their molecular and biophysical composition. Recently, we developed an assay based on fluorescently labeled TeNT $H_C$ to visualize and analyze the axonal retrograde transport in MN in real time (Figure 20.3a) (Lalli and Schiavo, 2002a).

Using this probe, three classes of TeNT carriers have been detected: round vesicles, tubules (Lalli and Schiavo, 2002a), and "vesicle clusters," which have a pearl-like morphology (S.B., unpublished results). Vesicles progress discontinuously with frequent pauses during their transport. In contrast, tubules and vesicle clusters display an overall faster and more continuous movement (Lalli and Schiavo, 2002a) (Figures 20.3b and 20.3c). Kinetic analysis revealed striking similarities between TeNT $H_C$ carriers and TeNT transport *in vivo* (0.8–3.6 μm/s) (Lalli *et al*., 2003b; Schiavo *et al*., 2000). These findings indicate that the non-toxic fragment TeNT $H_C$ can be used as a tool to dissect neuronal transport.

We have prepared chimeras of TeNT $H_C$ and ratiometric pHluorin, a pH sensitive green fluorescent protein mutant (Miesenbock *et al*., 1998), to determine the pH of retrogradely transported carriers in living MN. This issue is particularly interesting because acidic pH triggers a conformational change in TeNT and other CNT, which allows the active subunit to translocate through the carrier membrane into the cytosol (Montecucco *et al*., 1994; Williamson and Neale, 1994). During transport, TeNT $H_C$ carriers display neutral pH, whereas stationary TeNT $H_C$ organelles exhibit a wide spectrum of pHs, ranging from acidic to neutral. This distinct pH regulation is dependent upon a differential targeting of the vacuolar ($H^+$) ATPase, which is likely to be excluded from the majority of TeNT $H_C$-positive compartments (Bohnert and Schiavo, 2005). These findings suggest that TeNT $H_C$ exploits an endocytic transport pathway, which escapes acidification and targeting to degradative organelles.

Crucial components of the axonal transport machinery are motor proteins that use ATP to perform mechanical work. The main component of neuronal traffic is MT-based (Goldstein and Yang, 2000). However, actin dependent motors are also relevant for neuronal transport, suggesting a functional connection between

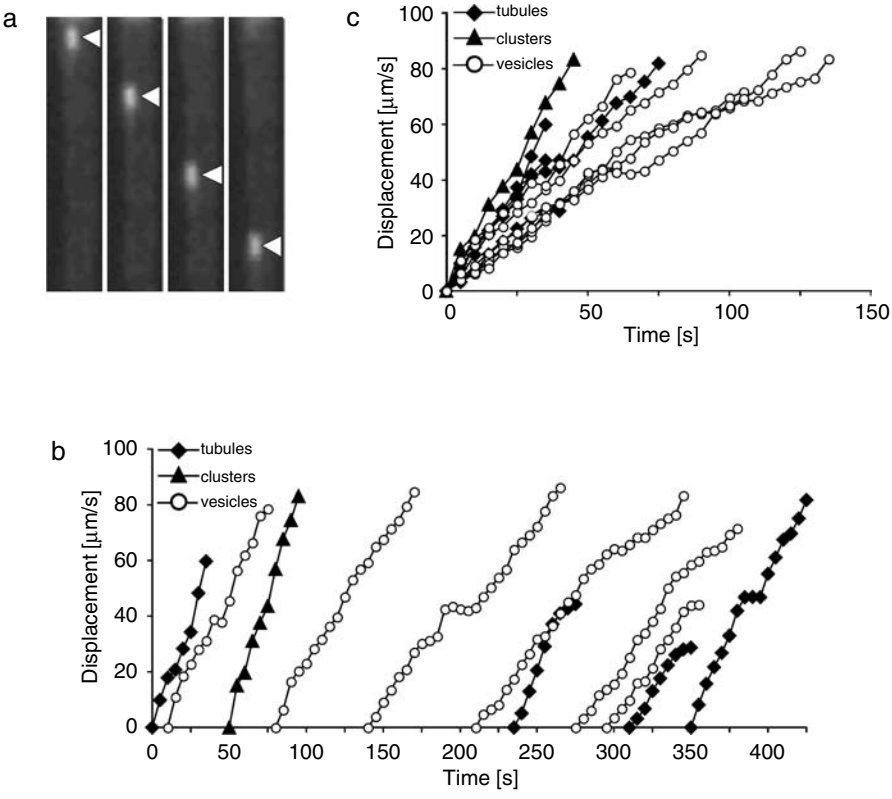

**FIGURE 20.3** Kinetics of axonal retrograde transport of TeNT $H_C$ carriers (**a**) TeNT $H_C$ containing organelles are retrogradely transported along a MN axon. Time series of a carrier containing fluorescently-labeled TeNT $H_C$ is shown. The cell soma is out of view located to the bottom. Frames have been taken every 5 s. (**b**) Displacement graph of TeNT $H_C$ carriers. The movements of one vesicle cluster (triangles), four tubules (diamonds), and six vesicles (empty circles) imaged during a representative experiment have been tracked and plotted versus time. Vesicular carriers display an overall slower and more discontinuous movement than the faster vesicle cluster and tubules. (**c**) The starting time for all carriers has been set as time = 0. The intervals between time points are 5 s.

MT and actin-based transport (Bridgman, 1999; Kamal and Goldstein, 2000).

Three families of force generating ATPases, myosins, kinesins, and dynein have been identified in neurons (Vale, 2003). Myosin I and II move along actin filaments from the minus to the plus end. Kinesins and dynein are ATPases, which are stimulated by binding to MT. Most kinesins move towards the MT plus end, whereas dynein moves in the opposite direction. Therefore, kinesins are thought to be responsible for anterograde transport (Griffin and Watson, 1988), and dynein for retrograde MT-based transport in axons (Schnapp and Reese, 1989; Vallee *et al*., 1989).

Dynein plays a main role in TeNT transport. For example, in *Loa* mice, a mutation in the motor protein dynein is associated with axonal transport defects and MN degeneration (Hafezparast *et al*., 2003). Cytoplasmic dynein binds directly to a fragment of neurofilament subunit M. Therefore, cytoplasmic dynein is thought to play a role in the short-duration retrograde movement of neurofilaments undergoing slow anterograde transport along axonal MT (Wagner *et al*., 2004). Dynein may also regulate other molecular motors because its inhibition affects the contribution of kinesins and myosins to retrograde transport (Lalli *et al*., 2003a).

Kinesins are a large superfamily of MT-dependent motor proteins. Three subfamilies have been identified: the Kin C family comprises kinesins with carboxy-terminal located core motor domain; Kin N kinesins have an amino-terminal core motor domain; and Kin I kinesins have an internal core motor domain. Kin N kinesins have been named "conventional kinesins" and Kin C and Kin I "unconventional kinesins." Kin N kinesins bind to MT and move from the minus-MT end towards the plus-MT end, whereas Kin C kinesins walk in the opposite direction. In nerve cells, conventional kinesins are responsible for the transport of organelles from the cell body to the nerve endings in both axons and dendrites. Interestingly, the presence of soluble kinesin and accessory factors is not required for anterograde movement (Schnapp *et al*., 1992). However, pharmacological inhibition of kinesin slows both anterograde and retrograde axonal transport (Brady *et al*., 1990; Lalli *et al*., 2003a). Moreover, mutations in kinesin heavy chain cause some forms of motor neuron disease, including amyotrophic lateral sclerosis, by disrupting fast axonal transport in both directions (Hurd and Saxton, 1996). The retrograde movement of TeNT $H_C$ carriers in MN treated with a potent kinesin inhibitor was strongly reduced (Lalli *et al*., 2003a).

Why does the disruption of a unidirectional motor system lead to bidirectional defects? The reason for this unexpected finding lies in the interdependence of anterograde and retrograde axonal transport systems, which is confirmed by the fact that dynein and kinesin share communal accessory factors, such as the dynactin complex (Martin *et al*., 1999). Therefore, dynein might not only be the main motor of fast retrograde axonal transport, but also a regulator of other motors associated with TeNT $H_C$ transport (Lalli *et al*., 2003a).

In addition to MT-dependent motors, the retrograde axonal transport of TeNT also requires axonal myosins, which move on F-actin (Cao *et al*., 2004). In particular, myosin Va has been shown to be important for retrograde transport of TeNT. MN from myosin Va-null embryos displayed a slower TeNT retrograde transport than wild-type cells (Lalli *et al*., 2003a).

## TRANSLOCATION OF CNT THROUGH VESICLE MEMBRANES

The different trafficking and targeting of TeNT and BoNTs indicate that neurotoxin internalization and translocation of the L chains are not directly linked. In order to display their catalytic activity, the L chains of CNT have to cross the vesicle membrane to reach the cytosol. CNT have to be exposed to a low pH to induce nerve intoxication (Matteoli *et al*., 1996; Simpson, 1982; Simpson *et al*., 1994; Williamson and Neale, 1994), even though the application of L chains to the cytosol is sufficient to block neurotransmitter release (Ahnert-Hilger *et al*., 1989; Bittner *et al*., 1989; Mochida *et al*., 1989; Penner *et al*., 1986; Poulain *et al*., 1988; Weller *et al*., 1991). It is therefore likely that an acidic pH is crucial to enable the active subunit to translocate through the vesicle's membrane into the cytosol (Montecucco *et al*., 1994).

Studies on model membranes (Montecucco *et al*., 1994) and in cell cultures (Beise *et al*., 1994) have shown that low pH induces a conformational change in CNT from a hydrophilic neutral to a hydrophobic acidic form. This transition enables both the H and L chains to penetrate into the hydrophobic core of the lipid bilayer (Boquet and Duflot, 1982; Cabiaux *et al*., 1985; Menestrina *et al*., 1989; Montecucco, 1986; Montecucco *et al*., 1989; Schiavo *et al*., 1990b). At low pH, CNT form a cation-selective ion channel in planar lipid bilayers with conductance of a few tens of picosiemens that are permeable to molecules smaller than 700 Da. CNT channels may be formed by oligomerization of the $H_N$ domain (Donovan and Middlebrook, 1986; Menestrina *et al*., 1989; Schmid *et al*., 1993; Shone *et al*., 1987), which is built by a pair of 105 Å-long α-helices buried at neutral pH. These helices are flanked by a short amphi-

pathic segment, which is able to form channels with similar properties to the holotoxin (Montal *et al*., 1992; Oblatt-Montal *et al*., 1995). It was proposed that the channel is formed by a toxin tetramer bringing four of these amphipathic segments into strict proximity with their hydrophobic residues lining the lumen of the pore (Montal *et al*., 1992; Oblatt-Montal *et al*., 1995). This is in agreement with the three-dimensional image reconstruction of the channel formed by BoNT/B in phospholipids bilayers (Schmid *et al*., 1993).

Both H and L chains are supposed to change conformation at low pH. The acidic toxin form may have the properties of a molten globule (Bychkova *et al*., 1988; van der Goot *et al*., 1991). The heavy chain forms a hydrophilic transmembrane cleft, nesting the passage of the partially unfolded L chain with its hydrophobic segments facing the lipids. The cytosolic neutral pH induces the L chain to refold and regain its water-soluble neutral confirmation following reduction of the interchain disulfide bond. Cytosolic chaperones may be involved in facilitating the exit of the L chain from the vesicle membrane and in promoting its cytosolic refolding (Ratts *et al*., 2003). The latter process is complicated by the absolute requirement of zinc for L chain catalytic activity. The protonation of the histidines coordinating the zinc ion at low pH is expected to release the metal atom, which has to be acquired again in the cytosol.

As the L chain is released into the cytosol, the transmembrane hydrophilic cleft of the H chain tightens up to reduce the amount of hydrophilic protein surface exposed to the hydrophobic core of the membrane. However, this process is not complete, leaving a channel across the membrane that is proposed to be the structure responsible for the ion conducting properties of CNT. Pore formation is therefore a consequence of membrane translocation, rather than its prerequisite (Schwab *et al*., 2000).

## INTRACELLULAR ZINC-ENDOPEPTIDASE ACTIVITY

The catalytic nature of CNT was discovered following the observation that the L chains contain the His-Glu-x-x-His binding motif of zinc-endopeptidases (Kurazono *et al*., 1992; Schiavo *et al*., 1992a; Schiavo *et al*., 1992b; Wright *et al*., 1992). Following this observation, it was soon demonstrated that TeNT was blocking ACh release at *Aplysia californica* synapses via a zinc-dependent protease activity (Schiavo *et al*., 1992a).

CNT are remarkably specific proteases. Only three targets, all members of the SNARE superfamily (Bock and Scheller, 1997), have been identified. TeNT and BoNT/B, /D, /F, and /G cleave VAMP (or synaptobrevin) but each at different sites (Figure 20.4) (Schiavo *et al*., 1992c; Schiavo *et al*., 1994; Schiavo *et al*., 1993b; Schiavo *et al*., 1993a; Yamasaki *et al*., 1994b; Yamasaki *et al*., 1994c); BoNT/A and /E cleave SNAP-25 at two different sites; and BoNT/C cleaves both syntaxin and SNAP-25 (Binz *et al*., 1994; Blasi *et al*., 1993a; Blasi *et al*., 1993b; Foran *et al*., 1996; Osen-Sand *et al*., 1996; Schiavo *et al*., 1993b; Schiavo *et al*., 1993c; Schiavo *et al*., 1995; Vaidyanathan *et al*., 1999; Williamson *et al*., 1996) (Figure 20.4).

SNARE proteins have been implicated as crucial components in most, if not all, intracellular membrane trafficking events (Chen and Scheller, 2001; Jahn and Sudhof, 1999). In eukaryotic cells, molecules need to be delivered to their correct intracellular destinations maintain the structural integrity of cellular compartments. To achieve this, transport vesicles bud from a donor organelle and then dock and fuse with a target membrane. SNARE were originally divided into v-SNARE and t-SNARE, based on their vesicle or target membrane location (Sollner *et al*., 1993). SNARE are currently classified into Q- and R-SNARE, depending on the presence of either glutamine or arginine in a

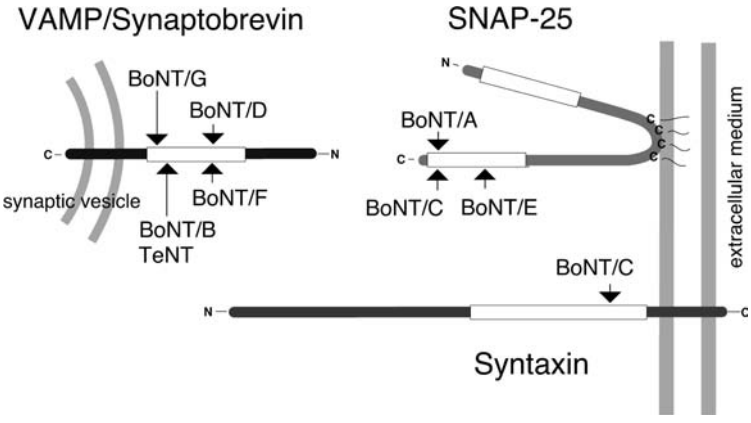

**FIGURE 20.4** Schematic structure of SNARE proteins cleaved by CNTs. VAMP is a type-II membrane protein anchored to SSV by a single transmembrane domain. VAMP is characterized by a short intraluminal domain, a conserved 60 residue-long cytosolic portion, which is able to form coiled coils, and a poorly conserved amino terminus. SNAP-25 is bound to the presynaptic membrane by several palmitoylated cysteines located in the middle of the molecule. Syntaxin is anchored by a single transmembrane domain to the neuronal presynaptic plasma membrane. The amino terminal part is cytosolic and only a few residues protrude into the intersynaptic cleft. The arrows indicate the sites of CNT cleavage.

central position of the SNARE motif (Jahn and Sudhof, 1999).

Studies on yeast and mammalian SNARE, anchored to liposomes, have reinforced the concept that the specificity of membrane fusion events relies on a precise pattern of v-SNARE–t-SNARE interactions (Bonifacino and Glick, 2004). Unique receptors of SNARE are found in different specific cellular compartments, suggesting that SNARE are functionally involved in all vesicle trafficking steps in endocytotic cells. Although the specificity of intracellular membrane fusion is associated with the biophysical properties of SNARE, a better spatial and temporal control of SNARE-mediated fusion is provided by additional regulatory systems, such as Rab GTPases and other proteins helping vesicle tethering and/or SNARE activation.

## CLOSTRIDIUM NEUROTOXIN TARGETS

### SNAP-25

SNAP-25 (synaptosomal-associated membrane protein of 25 kDa) was originally described as the major palmitoylated protein in the CNS (Hess *et al*., 1992; Oyler *et al*., 1989; Wilson *et al*., 1996). As shown in Figure 20.4, this protein lacks a classical transmembrane segment and its membrane binding is thought to be mediated by the palmitoylation of several cysteines in the middle of the polypeptide chain (Hess *et al*., 1992; Veit *et al*., 1996). SNAP-25 interacts with the other t-SNARE, syntaxin, and with VAMP to form the synaptic SNARE complex, which constitutes the core of the neuroexocytic apparatus (Sollner *et al*., 1993). The SNAP-25 family contributes two of the four α-helices that compose the SNARE complex. Upon interaction with syntaxin, SNAP-25 forms a three-helix bundle complex, which may act as a VAMP/synaptobrevin receptor on the plasma membrane (An and Almers, 2004). In addition, SNAP-25 forms a stochiometric complex with the SV calcium sensor synaptotagmin (Bai and Chapman, 2004), and this interaction is believed to be important in a late step of the calcium-dependent phase of neurotransmitter release (Banerjee *et al*., 1996; Schiavo *et al*., 1997).

SNAP-25 is required for axonal growth during neuronal development and in nerve terminal plasticity in the mature nervous system (Geddes *et al*., 1990; Osen-Sand *et al*., 1993) and is conserved from yeast to humans (Wilson *et al*., 1996). It is expressed in the nervous system in two developmentally regulated isoforms (SNAP-25A and B), with the B form predominating in the adult nervous tissue. Both a shorter (SNAP23) and a longer (SNAP29) isoform are also known that can partially vicariate for SNAP-25 function (Sorensen *et al*., 2003). In mast cells, SNAP-23 is required for exocytosis, implying a crucial role of this isoform in promoting membrane fusion (Guo *et al*., 1998).

### Syntaxin

Syntaxins are widely distributed throughout the cell and their function is required for a wide range of intracellular membrane fusion pathways (Teng *et al*., 2001). They belong to a family of proteins that are tail-anchored (also called type IV membrane proteins) (Salaun *et al*., 2004). Syntaxins have an amino-terminal cytoplasmic domain that is membrane bound by virtue of a single carboxy-terminal hydrophobic domain with no ectodomain (Borgese *et al*., 2003) (Figure 20.4). Syntaxins constitute a large protein family with homologues in yeast and plants. There are 15 members of the syntaxin family in the human genome, of which four are expressed in the plasma membrane. Syntaxin 1 is mainly located on the neuronal plasmalemma (Bennett *et al*., 1992; Inoue and Akagawa, 1992) and functions in regulated secretion and exocytosis. Syntaxin 2 and 3 are also functioning in exocytosis, whereas syntaxin 4 is involved in glucose transporter traffic in adipocytes.

Syntaxin 1 is associated with calcium channels in the active zones (Atlas, 2001; Stanley, 1997), but it is also present on most of the neuronal cell membrane (Garcia *et al*., 1995). It interacts in a calcium-dependent manner with some isoforms of the SV protein synaptotagmin (Sudhof, 1995) via a domain that is also responsible for the interaction with VAMP and α-SNAP (soluble NSF attachment protein) (Hayashi *et al*., 1995; Kee *et al*., 1995; Lin and Scheller, 1997). Together with SNAP-25, syntaxin 1 undergoes a recycling process in organelles indistinguishable from SV (Walch-Solimena *et al*., 1995). Syntaxins are essential for neuronal development and survival, because BoNT/C, unlike the other CNT, acts as a cytotoxic factor in neurons (Osen-Sand *et al*., 1996). Disruption of synaptic architecture by BoNT/C in central nervous system neurons activates distinct and independent neurodegenerative programs in the axo-dendritic network and in the cell bodies (Berliocchi *et al*., 2005). Several isoforms undergo a complex pattern of alternative splicing and expression during long-term potentiation, thus suggesting that syntaxins are involved in synaptic plasticity (Rodger *et al*., 1998). This differential expression could be important for a direct modulation of calcium entry via selective interaction with specific calcium channels, in addition to the formation of distinct SNARE complexes with different SNAP-25 and VAMP isoforms.

## VAMP

VAMP (vesicle-associated membrane protein or synaptobrevin) is a protein of 13 kDa localized to SV, dense core granules, and synaptic-like microvesicles, and is the prototype of vesicular SNARE (v-SNARE) (Sudhof, 1995). Several isoforms have been identified, which are present in all vertebrate tissues, their relative amount and distribution differing between tissues and cell-types (Rossetto *et al*., 1996; Rossi *et al*., 2004). Structurally, VAMP can be divided in to four functional domains (Baumert *et al*., 1989). The amino-terminal portion is proline rich and isoform specific, whereas the central portion of the cytoplasmic domain is very conserved through evolution and contains the coiled-coil region responsible for SNARE complex formation (Lin and Scheller, 1997; Sutton *et al*., 1998). The protein is anchored to the membrane by a single transmembrane domain, which is followed by a short and poorly conserved intravesicular portion (Figure 20.4). VAMP-2, the major SNARE protein of SV, is essential for two synapse-specific membrane trafficking steps, fast exocytosis for neurotransmitter release, and fast endocytosis that mediates rapid reuse of synaptic vesicles (Deak *et al*., 2004). Surprisingly, VAMP is not necessary for asynchronous neurotransmitter release, which is still present upon its cleavage by TeNT and BoNTs and in neurons derived from knockout mice (Humeau *et al*., 2000; Schoch *et al*., 2001).

Several experimental data support a direct correlation between CNT-induced proteolysis of SNARE and the inhibition of neurotransmitter release. Recombinant VAMP, SNAP-25, and syntaxin are cleaved at the same peptide bonds as the corresponding cellular proteins, indicating that no additional endogenous factors are necessary for the proteolytic activity of the CNT. Of the several isoforms of SNARE proteins identified in different species and tissues, only some of them are susceptible to proteolysis by CNT. In general, a SNARE protein may be resistant to a neurotoxin because of mutations at the cleavage site or in other regions involved in neurotoxin binding.

## BASIS FOR CLOSTRIDIUM NEUROTOXIN RECOGNITION OF SNARE PROTEINS

An inspection of the sequence of the three synaptic SNARE at the CNT cleavage sites reveals no conserved patterns that could account for the specificity of these zinc-proteases for their intraneuronal targets. Hence, whereas the overall architecture of the active sites of theses enzymes is expected to be similar, each CNT must differ in its detailed spatial organization in order to accommodate and hydrolyze such different peptide bonds.

Biochemical studies have uncovered several unique features of CNT. Short peptides encompassing the cleavage site are not cleaved, although they bind the toxin, while longer segments are cleaved (Foran *et al*., 1994; Yamasaki *et al*., 1994a). Strikingly, TeNT and BoNT/B cleave VAMP at the same peptide bond (Gln76-Phe77) (Schiavo *et al*., 1992c), yet when injected into the animal they cause the opposite symptoms of tetanus and botulism. This observation has been particularly relevant, because it clearly demonstrates that the distinct symptoms derive from different sites of intoxication rather than from a different intracellular mechanism of action. Even though TeNT and BoNT/B hydrolyze the same peptide bond of VAMP, they do have different requirements in terms of the maximal length of the peptide acting as a substrate. For example, the minimal VAMP segment cleaved by BoNT/B spans amino acids 44–94 but is extended to 33–94 for TeNT (Foran *et al*., 1994).

Some CNT hydrolyze a peptide bond, leaving identical sequences elsewhere in the substrate untouched. Other CNT have some degree of flexibility in terms of the peptide bond cleaved. BoNT/B cleaves Gln-Phe, present in the natural substrate VAMP, but is also able to hydrolyze peptides in which the above bond was substituted by Asn-Phe, Ala-Phe, or Gln-Tyr (Breidenbach and Brunger, 2004). BoNT/A and /C are poorly effective on isolated SNAP-25 and syntaxin, requiring the membrane insertion or their substrates for full activity (Blasi *et al*., 1993b; Schiavo *et al*., 1995). These findings indicate that the toxin-substrate interaction requires some other structural elements of the SNARE sequence serving as recognition motifs for the CNT.

Comparison of the sequence of synaptic SNARE proteins of different species shows the presence of a 10 residue-long motif, termed SNARE motif (Rossetto *et al*., 1994). This motif forms an α-helix with a negatively charged face flanked by a hydrophobic face (Rossetto *et al*., 1994; Washbourne *et al*., 1997). Multiple copies of this motif are present in syntaxin, SNAP-25, and VAMP and are proposed to act as CNT recognition sites. In fact, only peptides that include at least one SNARE motif are cleaved *in vitro* by CNT (Cornille *et al*., 1997; Foran *et al*., 1994). The SNARE motif is exposed on the protein surface on native non-assembled SNARE proteins, as shown by the binding of anti-SNARE motif antibodies. These antibodies cross-react among the three SNARE and inhibit the proteolytic activity of the neurotoxins (Pellizzari *et al*., 1996). CNT also cross-inhibit each other (Pellizzari *et al*., 1996), possibly by

interacting with the SNARE motif. Extensive site-directed mutagenesis of VAMP and SNAP-25 demonstrates that different CNT bind different SNARE motifs (Pellizzari *et al*., 1997; Pellizzari *et al*., 1996; Washbourne *et al*., 1997). Resistance to CNT *in vivo* is sometimes associated with mutations in the SNARE motifs or with deviations from the consensus. In fact, the drosophila VAMP lacks one of the three acidic residues in each SNARE motif, and is not cleaved by TeNT (Sweeney *et al*., 1995).

The molecular basis of the substrate recognition by CNT is however still under debate. The validity of a reported co-crystal structure of VAMP-2 bound to BoNT/B (Hanson and Stevens, 2000) has been questioned recently (Breidenbach and Brunger, 2004; Rupp and Segelke, 2001), mainly due to the lack of observed electron density for the substrate and the improbable ligand stereochemistry. Recently, Breidenbach and Brunger reported a novel high-resolution structure of a CNT L chain in complex with its SNARE substrate (Breidenbach and Brunger, 2004). To overcome the inability to co-crystallize wild-type BoNT/A L chain with SNAP-25, an inactive variant (E224Q, Y366F) has been used together with a truncated version (residues 141–204) of SNAP-25. This SNAP-25 fragment adopted three types of secondary structure in complex with BoNT/A: residues 147–167 formed a distorted α-helix, residues 168–200 were extended, whereas residues 201–204 were involved in a distorted β-sheet (Breidenbach and Brunger, 2004).

The amino-terminal helical region of the SNAP-25 fragment interacts with the L chain of BoNT/A along the hydrophobic patch formed at the interface of four α-helices, named the α-exosite. The carboxy-terminal portion of the SNAP-25 portion forms one strand of a distorted, three-stranded antiparallel β-sheet at a region that is referred to as β-exosite. For BoNT/A substrate recognition, SNAP-25 has to be bound to a presynaptic membrane via its linker domain. In the membrane bound, non-complexed SNAP-25, the amino- and carboxy-terminal domains are unstructured or flexible. The binding of BoNT/A is probably initiated by helix formation at the α-exosite. Two anchor points along the extended portion of SNAP-25, residues 170–172 and 192–193, and individual side chains in the nearby region are additional determinants of substrate specificity. These sites reduce $K_m$ and enhance binding of the β-exosite, inducing conformational changes at the active site, which make the endopeptidase competent to cleave its substrate.

BoNT/A can cleave small peptides (residues 192–206 of SNAP-25), which only bind to one anchor point in addition to the β-exosite, but at reduced $k_{cat}/K_m$ (Sukonpan *et al*., 2004). The lack of anchor points might therefore explain the different minimal residue segments of VAMP cleaved by BoNT/B (amino acids 44–94) and TeNT (amino acids 33–94) (Foran *et al*., 1994). Therefore, most of the enzyme-substrate interface serves to provide a substrate-specific boost to $k_{cat}/K_m$ by reducing $K_m$ (Breidenbach and Brunger, 2004). These findings also explain the inability of BoNT/A to cleave SNAP-25 when it is present in complex with other SNARE.

In conclusion, these studies suggest that multiple recognition sites on the SNARE proteins determine the specificity of the CNT for their targets. This binding is followed by interactions with other regions of the sequence that are different for each SNARE, including the segment containing the peptide bond to be cleaved. The relative contribution of these interactions for the specificity and strength of CNT binding to each SNARE remains to be determined.

## PROTEIN AND GENE TRANSFER VIA TENT

To date, the pharmacological treatment of brain diseases has been challenging because conventional drugs are mostly uneffective in crossing the blood-brain barrier (BBB). However, TeNT is able to enter the central nervous system by bypassing the BBB. This property makes TeNT a potentially exploitable resource for cargo delivery to the brain. The non-toxic carboxy-terminal $H_C$ fragment of TeNT is easy to handle, and it is the ideal transporter for proteins and DNA from the bloodstream to the CNS. However, a major drawback for the widespread use of TeNT in human therapy would be the immunity against tetanus due to standard vaccinations.

CuZn superoxide dismutase (SOD-1), an enzyme involved in the scavenging of superoxide free radicals, has been studied as a neuro-protectant to ameliorate oxidative injury. Increased levels of SOD-1 are cyto-protective in experimental models of neurological disorders associated with free radical toxicity, as found in strokes and traumas. A fusion-protein of SOD-1 and the non-toxic TeNT $H_C$ was internalized and retrogradely transported into cultured hippocampal neurons, and the hybrid protein remained enzymatically active after transport (Figueiredo *et al*., 1997; Francis *et al*., 2004b; Francis *et al*., 1995). Another hybrid protein, produced from a β-galactosidase gene (lacZ)-TeNT $H_C$ gene fusion can be retrogradely transported across a synapse *in vivo* (Coen *et al*., 1997). TeNT $H_C$ fused to the β-galactosidase enzyme reached second and higher-order neurons after injection in rat tongue (Miana-Mena *et al*., 2003). Furthermore, a fusion

construct of diphtheria toxin and TeNT $H_C$ has also been used to deliver passenger proteins to the neuronal cytosol (Francis *et al*., 2004a).

A somatic gene transfer approach based on TeNT $H_C$ was used to map muscle to MN projections in *Xenopus* spinal cord. DNA encoding the LacZ gene fused to TeNT $H_C$ could be produced from plasmid DNA injected into muscle, and the fusion protein was able to cross the NMJ and undergo retrograde transport *in vivo* (Coen *et al*., 1999). These results provided the first demonstration of the synthesis and transport of a TeNT $H_C$ fusion protein produced directly from exogenous DNA in a vertebrate system. Retrograde trans-synaptic transfer of a fusion protein of GFP and TeNT $H_C$, expressed in defined neurons in transgenic mice, was used to assess the genetic mapping of neuronal circuits (Maskos *et al*., 2002). Furthermore, TeNT $H_C$ has been shown to be suitable as targeting moiety for viral vectors, which indicates a potential for gene therapy of inherited neurodegenerative diseases, such as spinal muscular atrophy (Schneider *et al*., 2000). Taken together, TeNT $H_C$ chimeras could serve as effective tools to deliver important pharmacological cargoes to the CNS, providing an alternative therapeutical approach to neurological disorders.

## CLOSTRIDIUM NEUROTOXINS AND SIGNALING

Not all the clinical symptoms of tetanus intoxication can be attributed to the block of neurotransmission. Several symptoms such as insomnia, hyperactivity, and hyperthermia suggest the implication of different mechanisms, different neurons, and different areas of the CNS.

The binding of TeNT triggers the activation of specific signaling cascades (Gil *et al*., 2001), even before classical tetanus symptoms are evident (Aguilera *et al*., 1993; Gil *et al*., 1998). The $H_C$ fragment of TeNT activates different protein kinase C (PKC) isoforms as well as the Extracellular signal-Regulated protein Kinase/Mitogen-Activated Protein Kinase (ERK/MAPK) and the neurotrophin receptor TrkA (Gil *et al*., 2001). Furthermore, $H_C$ might enhance phospholipase C (PLC)γ-1 activity, an enzyme involved in calcium homeostasis, thus modulating intracellular calcium influx. In cultured cortical neurons, $H_C$ activates a signaling cascade involving Trk receptor, the survival pathway Akt, and the ERK1/2 pathway (Gil *et al*., 2003). TeNT has been shown to rescue cerebellar granule neurons from apoptosis by activating the PI3 Kinase/Akt pathway (Gil *et al*., 2003).

TeNT also specifically blocks $Na^+$-dependent serotonin (5-HT) uptake in rat-brain synaptosomes (Inserte *et al*., 1999; Najib *et al*., 1999). Serotonin transporter (SERT) is the sole molecule responsible for extracellular 5-HT transport (Borowsky and Hoffman, 1995). PKC has been implicated as a regulator of SERT activity via the phosphorylation of Ser/Thr residues responsible for re-uptake inhibition (Qian *et al*., 1997). This inhibition is independent of the metalloprotease activity of the L chain, and its potency is higher than 5-HT selective re-uptake inhibitors (Inserte *et al*., 1999; Najib *et al*., 1999).

TeNT-dependent signaling and its physiological consequences are still poorly understood. The fact that $H_C$ colocalizes with NGF and its low affinity receptor $p75^{NTR}$ in retrogradely transported carriers (Lalli and Schiavo, 2002a) raises the question of the physiological relevance of the signaling triggered by TeNT. Indeed, the neurotrophin signaling activated by TeNT is not restricted to the synapse but can also be propagated by retrograde transport within signaling endosomes (Kahn *et al*., 2002), which might contribute to the regulation of axonal transport (Chan *et al*., 2004; Mandelkow *et al*., 2004). Signaling molecules activated by TeNT might therefore act on different levels: internalization, transport, and/or sorting of the toxin.

## ACKNOWLEDGMENTS

We apologize to our colleagues whose work has been omitted due to space limitations. Work in the laboratories of the authors is supported by the European Molecular Biology Organisation (S.S.) and by Cancer Research UK.

CHAPTER

# 21

# Large clostridial cytotoxins modifying small GTPases

*Maja Rupnik and Ingo Just*

## INTRODUCTION

Large clostridial cytotoxins (LCTs) are a family of toxins similar in origin, primary structure, enzymatic glycosyltransferase activity, and sharing sequence similarities ranging from 42 to 96%. They are protein exotoxins produced by clostridia and possess cytotoxic activity that is characterized by cell rounding and formation of transient arborized morphology based on disaggregation of the actin cytoskeleton. The LCTs are single-chained proteins (range from 250–308 kDa) and composed of three functional domains (Figure 21.1) responsible for cell entry and intracellular inactivation of small regulatory GTPases by covalent modification (Just *et al*., 2000; Busch and Aktories, 2000; Just and Gerhard, 2004). Their major targets are the Rho-GTPases and to a minor extent the Ras-GTPases. The Rho-GTPases are the master regulators of the actin cytoskeleton, but beyond the regulation of cytoskeleton-dependent cell functions, they are also involved in the regulation of transcription, apoptosis, and transformation.

The family encompasses toxin A (TcdA) and toxin B (TcdB) from *Clostridium difficile*, the lethal (TcsL) and the hemorrhagic toxin (TcsH) from *Clostridium sordellii*, and the α-toxin (TcnA) from *Clostridium novyi* (Bette *et al*., 1991; von Eichel-Streiber *et al*., 1996). *C. difficile* toxins show high similarity with *C. sordellii* toxins in biological activities, as well as in cross-reactivity with the same polyclonal and monoclonal antibodies (Martinez and Wilkins, 1992). TcdA is a functional homologue of TcsH, and TcdB of TcsL. TcnA is only distantly related to the remaining four toxins and does not cross-react with *C. difficile* or *C. sordellii* specific antibodies (Ball *et al*., 1993). Recently, a unified nomenclature of LCTs was agreed to and will be adopted also in this chapter (Rupnik *et al*., 2005a).

The producing microorganisms cause intestinal infections in humans and animals (*C. difficile* and *C. sordellii*) or gas gangrene (*C. sordellii* and *C. novyi*) (Kelly *et al*., 1994; Bartlett, 1994; Kelly and LaMont, 1998; Hatheway, 1990). LCTs are their major virulence factors and responsible for the onset of symptoms. However, although toxins possess comparable activity at a cellular level, they differ in their *in vivo* effects and exhibit biological action at those sites at which they are delivered by their producing microbes. In addition to their clinical relevance, LCTs are used as tools in cell biology to study the role of Rho and Ras.

## MOLECULAR BIOLOGY OF LARGE CLOSTRIDIAL TOXINS

### Toxin genes and pathogenicity locus PaLoc

Genes have been sequenced for four of the five members of LCT: TcdA, TcdB, TcsL, and TcnA, and the results have confirmed previously known immunological and functional similarities within the LCT group (von Eichel-Streiber and Sauerborn, 1990; von Eichel-Streiber *et al*., 1990; Dove *et al*., 1990; Johnson *et al*., 1990; von Eichel-Streiber *et al*., 1992; Green *et al*., 1995; Hofmann *et al*., 1995). LCT toxins share similarity from

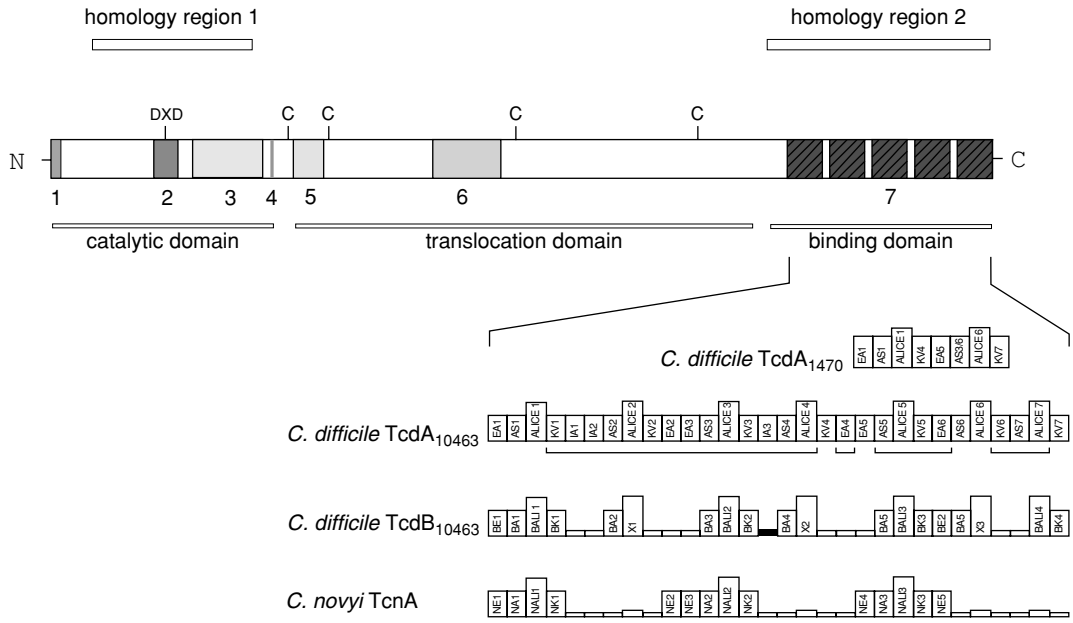

**FIGURE 21.1** Schematic presentation of a toxin from a LCT group. LCTs are large single-stranded proteins with three domains involved in enzymatic activity, translocation, and cell binding. The regions with known or putative functions are shown schematically and positions are given for TcdB (except for 1, which is described only in TcsL):
(1) binding site for phosphatidylserine (TcsL; aa 1 to 18);
(2) extended D-X-D motif (aa 264 to 296);
(3) GTPase specificity (aa 364–468, see text for discussion);
(4) cleavage site (aa 543/544);
(5) putative nucleotide (ATP) binding site (aa 651 to 683);
(6) highly hydrophobic region (aa 956 to 1128);
(7) repetitive sequences (from aa 1852 to 2366;)
DXD – glycosyltransferase motif; C – conserved cysteines (aa 595, 698, 1167, 1625)
Alignment of homologous repeats in TcdA, TcdB, and TcnA is presented. Repetitive domains are composed by 4 to 5 groups—long repeats have 49 to 52 aa (ALICE, BALI, NALI; X is a truncated form of BALI) and short repeats 20 aa (e.g., EA, AS, KV, and IA for TcdA). Additionally, deletions in $TcdA_{10463}$ (indicated by ???) leading to truncated repeats in $TcdA_{1470}$ in $A^-B^+$ toxinotype VIII are indicated.
Homology regions 1 and 2 mark two parts of LCTs that show amino acid sequence similarity with other microbial proteins (see text for discussion).

42 to 88% at amino acid sequence (Table 21.1); however, differences are mainly accumulated in the N-terminal catalytic domain, where the homology spans only from 28.8 to 78.6% (Thelestam *et al*., 1999; von Eichel-Streiber *et al*., 1995).

All LCT genes have similar structure with 3'-end repetitive regions coding for stretches of 20 to 52 amino acids, defined as clostridial repetitive oligopeptides, CROPs (von Eichel-Streiber *et al*., 1992), or repeating units (Dove *et al*., 1990) (Figure 21.1, Table 21.2). At the protein level in all four sequenced toxins, CROPs can be clustered according to the homology into four to five groups. Interestingly, the repeats are only conserved at the nucleotide level in the gene coding for TcdA, which results in frequent homologous recombinations resulting in deletions and insertions. A number of strains with shorter but still fully functional TcdA are described (Rupnik *et al*., 1998; Blake *et al*, 2004). No shorter variants of any other toxin from the LCT group have been reported so far.

TcdA, TcdB, TcsL, and TcsH are chromosomally encoded, whereas the gene for TcnA resides on a phage (Eklund, 1993). The toxin coding region is well characterized for TcdA and TcdB produced by *C. difficile*. It is defined as pathogenicity locus (PaLoc) and includes, besides two toxin genes *tcdA* and *tcdB*, three additional accessory genes (*tcdR, E,* and *C*) (Braun *et al*., 1996; Hammond and Johnson, 1995) (Figure 21.2). *tcdR* and *tcdC* are involved in the regulation of toxin production and will be discussed below. *tcdE* codes for a 170 aa hydrophobic protein homologous to phage holin protein, and was suggested to contribute to the release of the toxin from the bacterial cell (Tan *et al*., 2001).

PaLoc region is inserted in an identical integration site in several *C. difficile* strains tested (Braun *et al*., 1996; Hammond and Johnson, 1995). In non-toxigenic

[a]D: *C. difficile*-like, S: *S. sordellii*-like ; () -minor substrate

[b]adapted from references: Just *et al*., 1995a,b and 1996 and 2004; Hofmann *et al*., 1996; Popoff *et al*., 1996; Chaves-Olarte *et al*., 1997; Chaves-Olarte *et al*. 1999; Genth *et al*., 1996; Selzer *et al*., 1996

strains PaLoc is substituted by 115 bp non-coding sequence. The border sequences are perfectly conserved in toxinogenic as well as non-toxinogenic strains, indicating that PaLoc is a distinct genetic element. However, PaLoc itself does not show any evidence of being a mobile element, as there is no homology with transposon-, phage-, or plasmid-like sequences, no typical direct or inverted repeats, and no tRNA sequences either within or near the PaLoc (Braun *et al*., 1996). Still, the possibility that PaLoc is a part of an even larger virulence-associated element was not excluded.

Toxin coding region is less well characterized in *C. sordellii* and *C. novyi*. In both species partial sequences of regions near the toxin genes revealed the presence of small ORFs (Figure 21.2C). In *C. sordellii,* sequence is known only for ORF downstream of *tcsL*, and it shows 73% identity and 93% similarity to *tcdE* (Green *et al*., 1995). Interestingly, the toxin coding region was sequenced in variant *C. sordellii* strain 6018, which does not produce TcsH (Green *et al*., 1996). *C. difficile* strains not producing TcdA, which is a structural and functional homologue of TcsH, are widespread, but they always have at least a truncated *tcdA* gene. In *C. sordellii* 6018, on the other hand, no *tcsH* sequences could be detected by PCR or hybridization (Green *et al*., 1996). In *C. novyi* no sequence data is available, but orientation of two small ORFs upstream and downstream of *tcnA* correspond to *tcdR*/*tcdE* and *tcdC* (von Eichel-Streiber *et al*., 1994).

## Genetic manipulations of toxin coding and associated PaLoc regions

Only a few methods have been developed for DNA manipulation of LCT-producing clostridia, and they are generally available only for *C. difficile*. For this reason, heterologous hosts were predominately used for the expression of recombinant holotoxins or their functional domains (Hofmann *et al*., 1997; Wagenknecht-Wiesner *et al*., 1996; Frisch *et al*., 2003; Faust *et al*., 1998; Kink and Williams, 1998; Burger *et al*., 2003; Ackermann *et al*., 2004) and regulation studies

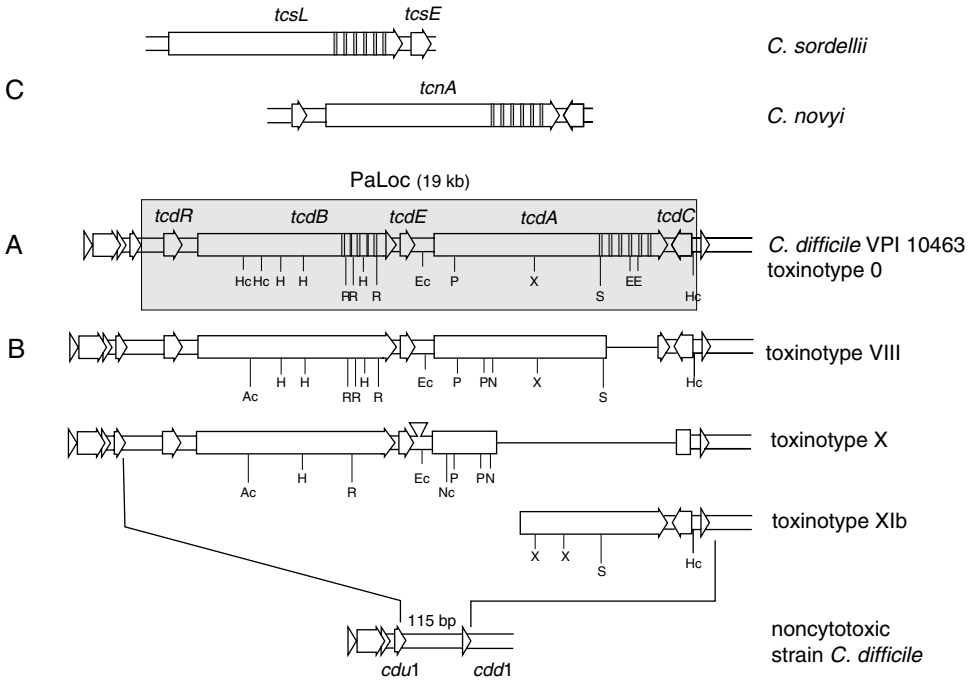

**FIGURE 21.2** Regions encoding the LCT toxins. **(A)** *C. difficile* pathogenicity locus PaLoc with two toxin genes, *tcdA* and *tcdB*, and three accessory genes, *tcdR, E, C*. Repetitive regions at 3'-end are hatched. Several restriction sites used in RFLPs analysis of variant strains are represented (Hc-*Hin*cII, H-*Hin*dIII, R-*Rsa*I, Ec-*Eco*RV, P-*Pst*I, X-*Xba*I, S-*Spe*I, E-*Eco*RI, Ac-*Acc*I, Nc-*Nco*I). **(B)** Variant PaLoc regions of some representative toxinotypes; note insertions (toxinotype X), changed restriction sites, and deletions in *tcdA*. In toxinotype XI only remnants of PaLoc are present and no functional LCT toxins are produced. In non-toxinogenic strains, PaLoc is replaced by 115 bp noncoding sequence. **(C)** Known toxin coding regions in *C. sordellii* and *C. novyi*; for *C. novyi* only position and orientation of two small ORFs is described in the literature, but no sequence data is available. Therefore, no similarities could be determined and ORFs are not named in this figure.

(see below), whereas only a few reports use *C. difficile* as a host (Tang-Feldman *et al*., 2002; Mani *et al*., 2002). For a review on early partial cloning and sequencing studies of the LCT toxin genes, the reader is referred to Moncrief and Wilkins (2000).

The complete *C. difficile* toxin genes were cloned and expressed in two different heterologous hosts: in *E. coli* (*tcdA:* Phelps *et al*., 1991; Ackermann *et al*., 2004; *tcdB*: Johnson *et al*., 1990) and *Bacillus megaterium* (*tcdA:* Burger *et al*., 2003). Expression in *E. coli* is very low, probably due to the different codon usage. Only the expression of TcdB (under its own promotor) was sufficient to allow mutagenesis studies (Barroso *et al*., 1994). The *B. megaterium* system resulted in a better yield of TcdA and enables a simple purification via His-tag (Burger *et al*., 2003). Tang-Feldman and co-workers (2002) have introduced a complete *tcdB* gene in non-toxigenic *C. difficile* strain; however, the transformation efficiency and the expression were again low and neither recombinant toxin nor the strain were used in further studies.

## Variability of LCT toxins and toxin coding regions

Variant toxins from *C. difficile* TcdB and *C. sordellii* TcsL with slight differences in substrate pattern are reported (Table 21.2), suggesting the divergence and variability in toxin coding regions. While variability in *C. novyi* is undocumented and in *C. sordellii* limited to a few examples (Green *et al*., 1996; Popoff *et al*., 1996; Hofmann *et al*., 1996), it is well recognized in *C. difficile* at the gene as well as at the protein level.

Toxin coding PaLoc region in *C. difficile* can display deletions, insertions, and numerous point mutations, resulting in changed RFLP patterns when compared to the reference strain VPI 10463 (Figure 21.2B). Such strains are defined as variant strains and are grouped into toxinotypes (Rupnik *et al*., 1998). Currently, 24 variant toxinotypes are described (I to XXIV), including about 10% of *C. difficile* strains, whereas strains identical to the reference VPI 10463 represent the most numerous toxinotype 0 (http://www.mf.uni-mb.si/mikro/tox/).

Deletions of various sizes are mostly limited to the repetitive regions of *tcdA*. Only in two toxinotypes, X and XI, is PaLoc significantly changed (Figure 21.2B). Gene *tcdC* was shown to frequently possess small deletions and nonsense mutations, but the possible modified function of truncated TcdC was not studied (Soehn *et al*., 1998; Spigaglia and Mastrantonio, 2002). Insertions in PaLoc are rare, and two examples include a 1.1 kb between *tcdE* and *tcdA* in strain 8864 (Figure 21.2B, toxinotype X) (Soehn *et al*., 1998; Song *et al*, 1999) and 2 kb in *tcdA* gene in strains of toxinotype XIV (Mehlig *et al*., 2001; Rupnik *et al*., 2001). The later insertion is a novel mobile genetic element, ISTron, which is precisely excised from mRNA. Therefore, TcdA produced by toxinotype XIV strains is of expected size and fully functional (Braun *et al*., 2000; Mehlig *et al*., 2001). Modified restriction sites are found throughout the PaLoc region, but they are predominate in the *tcdB* gene, while the *tcdA* gene seems to be more conserved (Rupnik *et al*., 1998).

The majority of variant toxinotypes produce both toxins ($A^+B^+$ strains), though variant $A^-B^+$ and $A^-B^-$ strains are also described. In fact, two groups of $A^-B^+$ *C. difficile* strains were the first variants to be recognized (Torres, 1991; Lyerly *et al*., 1992; Borriello *et al*, 1992; Depitre *et al*., 1993). The number is raised to five currently differentiated $A^-B^+$ toxinotypes (Johnson *et al*., 2003; Rupnik *et al*. 2003); however, the molecular mechanism underlying the lack of TcdA production is clarified only in two of them. In toxinotype VIII, it is due to a point mutation introducing a stop codon at amino acid position 47 of TcdA (von Eichel-Streiber *et al*., 1999). In toxinotype X, stop codon is introduced at amino acid position 699, but additional deletion and insertion in $PaLoc_{8864}$ both result in low levels of transcription of remaining *tcdA* and *tcdC*, making both gene products undetectable at the protein level (Soehn *et al*., 1998). Another representative group of strains with significantly changed PaLoc leading even to the absence of production of both toxins is toxinotype XI ($A^-B^-$), where only the remnants of whole length PaLoc are present (Rupnik *et al*., 2001) (Figure 21.2B).

Variations at the nucleotide level can result in production of LCT toxins with changed properties, such as immunoreactivity with different antibodies, minimal differences in size, different substrate patterns, and different cytopathic effects (Figure 21.8, Table 21.2). Only a couple of studies have described properties of variant toxins of $A^+B^+$ strains (Mehlig *et al*., 2001; Blake *et al*., 2003). Probably for historical reasons, the variant TcdBs produced by $A^-B^+$ strains, $TcdB_{1470}$ and $TcdB_{8864}$, are best characterized at the molecular and biochemical levels (Torres, 1991; von Eichel-Streiber *et al*., 1995; Rupnik *et al*., 1997; Soehn *et al*., 1998; Sambol *et al*., 2000; Kato *et al*., 1999; Chaves-Olarte *et al*., 1999). Unlike reference $TcdB_{10463}$, $TcdB_{8864}$ was reported to exhibit enterotoxic activity (Borriello *et al*., 1992) and had a lower lethal dose, similar to TcsL (6 ng; Lyerly *et al*., 1992). $TcdB_{8864}$ also showed minimal immunological differences and did not react with two mAbs specific for wild-type TcdB (Lyerly *et al*., 1992). $TcdB_{1470}$, the representative of the most widespread $A^-B^+$ group (toxinotype VIII), binds to the same receptors as $TcdB_{10463}$, but modifies similar targets as *C. sordellii* $TcsL_{1522}$ and was therefore postulated to be a hybrid toxin (Chaves-Olarte *et al*., 1999). $tcdB_{8864}$ and $tcdB_{1470}$ are similar to each other, but significantly different from $tcdB_{10463}$ in regions coding for catalytic domain (von Eichel-Streiber *et al*., 1995; Rupnik *et al*., 1997; Soehn *et al*., 1998). Correspondingly, both variant toxins differ from $TcdB_{10463}$ in recognizing GTPases and, as a consequence, in CPE (Chaves-Olarte *et al*., 1999; Chaves-Olarte *et al*., 2003) (Table 21.2, Figure 21.8). In addition to the two $A^-B^+$ toxinotypes mentioned, the same sordellii-like CPE is detected by several $A^+B^+$ toxinotypes (IX, XIV, XV, XVII) and is caused by variant TcdBs rather than by variant TcdAs (Blake *et al*., 2004; Rupnik *et al*., 2003).

In receptor binding repetitive regions, on the other hand, $tcdB_{8864}$ and $tcdB_{1470}$ differ one from another; $tcdB_{1470}$ is identical with the reference strain, whereas $tcdB_{8864}$ resembles some other variant strains (von Eichel-Streiber *et al*., 1995; Rupnik *et al*., 2001). No comparative studies on binding of both toxins were done, but similar changes at 3'-end of genes resulted in changed properties of the catalytic domain, and different properties of variant binding domains could be expected.

## Regulation of toxin production in C. *difficile*

Toxin production varies greatly among different toxigenic strains and is additionally influenced by culture conditions (temperature, atmosphere), as well as by the growth medium used (complex vs. defined medium, nutrients, addition of antibiotics). In all tested strains, toxin levels are up-regulated in complex glucose-deprived media but not in defined glucose-deprived media (Dupuy and Sonenshein, 1998, Karlsson *et al.*, 1999). Toxin levels are also up-regulated during biotin starvation (Yamakawa *et al.*, 1996), while the presence of cysteine and proline down-regulate the production (Karlsson *et al.*, 2000). The reports on the effect of other amino acids and sub-inhibitory levels of antibiotics are somewhat controversial, and seem to be strain and medium dependent (Onderdonk *et al*., 1979; Haslam *et al*. 1986; Barc *et al*., 1992; Osgood *et al*., 1993; Yamakawa *et al*., 1994; Karlsson *et al*., 1999; Drummond *et al*., 2003). Temperature regulation is observed only in

some tested strains, such as VPI 10463 and serogroup H, but not in serogroup A and C; however, temperature regulation is not medium dependent (Karlsson *et al*., 2003).

Regulation of toxin production at the molecular level is only partially understood, but recent advances in *C. difficile* genetics should facilitate further studies. Transcriptional studies have shown PaLoc genes to be organized in two distinct transcription units (Figure 21.3). Genes *tcdR, B, E, A* are found on polycistronic and monocystronic transcripts, and their expression is induced at the transition from the exponential to stationary phase (Hundsberger *et al*., 1997). *tcdA* and *tcdB* mRNAs reach their maximum values in the early stationary phase. At this stage, levels of *tcdA* mRNA are approximately twofold in comparison to *tcdB* (Dupuy and Sonenshein, 1998), which is in agreement with larger amounts of TcdA obtained after toxin purification (von Eichel-Streiber *et al*., 1987).

So far, two PaLoc accessory genes, *tcdC* and *tcdR* (also *tcdD* or *txeR*), are implicated in regulation. The role of TcdC as a negative regulator is based on the observation that transcription of *tcdR, B, E, A* is low during the high-level transcription of *tcdC* (Hundsberger *et al*., 1997). Moreover, TcdC specifically binds to TcdR, responsible for positive regulation (see below), and thereby decreases transcription from toxin promoters *in vitro* (B. Dupuy, personal communication).

TcdR (previously TcdD or TxeR), a 22 kDa protein, strongly activates expression from *C. difficile* toxin gene promoters when expressed in *trans* in *C. perfringens* (Mani and Dupuy, 2001) and *E. coli* (Moncrief *et al*., 1997) and was therefore suggested to be a positive regulator. However, Mani and Dupuy (2001) have shown that isolated TcdR acts by interacting with RNA polymerase core enzyme to stimulate its binding to the promoter region of *tcdA*, *tcdB* (Mani and Dupuy, 2001), and of *tcdR* (Mani *et al*., 2002) and therefore functions as an alternative sigma factor.

TcdR forms, together with TetR (regulation of tetanus toxin gene in *C. tetani*), BotR (regulation of BoNT in *C. botulinum*), and UviA (regulation of bacteriocin gene in *C. perfringens*) a new alternative sigma factor subgroup within $\sigma^{70}$ family (Mani and Dupuy, 2001; Raffestin *et al*., 2005; Dupuy *et al*., 2005). This new group is likely to represent a common regulatory mechanism for clostridial toxins and bacteriocins. All four regulators show high sequence similarity and are able to substitute for each other *in vitro* and *in vivo* (Dupuy). This functional complementarity correlates with a high conservation of -35 sequences of the promoters recognized by all four factors (Hundsberger *et al*., 1997; Hammond *et al*., 1997; Dupuy and Sonenshein, 1998; Raffestin *et al*., 2005).

TcdR mediates, at least partially, the temperature and glucose control of *C. difficile* toxin production (Mani *et al*., 2002; Karlsson *et al*., 2003). The presence of *tcdR* in *trans* increased expression from both toxin promoters at 37°C, but not at 22 or 42°C in *C. perfingens* system (Karlsson *et al*., 2003). In contrast, early studies on environmental effects on *Clostridium difficile* reported

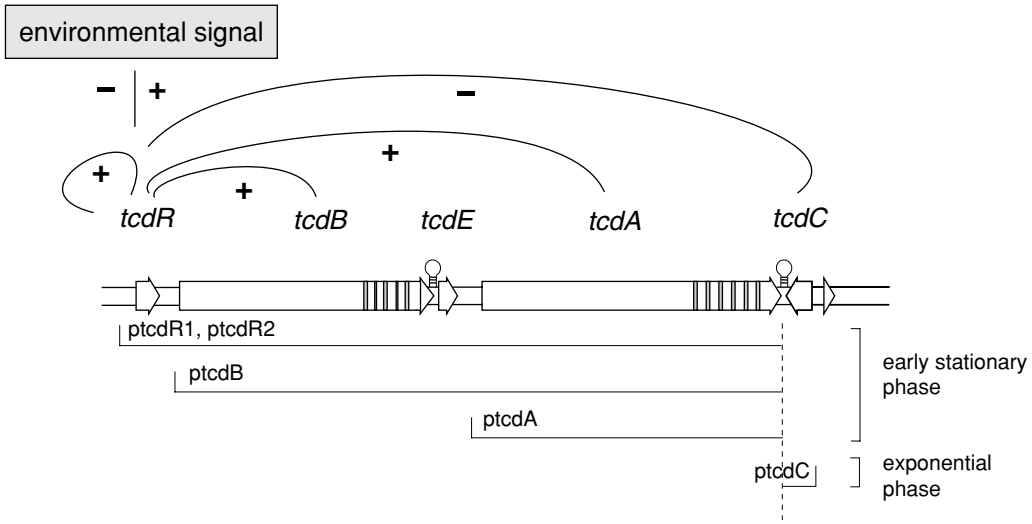

**FIGURE 21.3** Model for regulation of *C. difficile* toxin gene expression. The five PaLoc genes are transcribed in two discrete units: *tcdC* in exponential phase and *tcdR, B, E, A* as monocistronic or polycistronic mRNAs in stationary phase. Each PaLoc gene has own promoter (ptcd); however, transcription from *ptcdE* is not well documented. TcdR is transcribed from two promoters, which differ in sensitivity for the glucose. TcdR is a sigma factor and positively affects the transcription of itself and of both toxin genes. Environmental factors (e.g., temperature and glucose) act on TcdR transcription but could probably act also directly on the toxin genes.

increased toxin levels at 45°C in continous culture (Onderdoonk *et al*., 1979). During the studies of glucose effect on TcdR expression, it was discovered that *tcdR* gene has at least two promoters. One is glucose sensitive and is repressed by 1% glucose when tested in *C. perfringens* system (Mani *et al*., 2002). The second *tcdR* promoter is relatively weak, independent of TcdR, and insensitive on glucose, and provides a basal level of TcdR expression (Mani *et al*. 2002). Glucose could also act independently with the toxin promoters or via other regulatory mechanisms. However, the intermediate steps between environmental stimulus and transcription of PaLoc genes, including two component sensor/regulator systems or catabolite regulator protein (CcpA), remains largely unknown.

Unlike some other clostridial toxin genes (*C. perfringens* enterotoxin; Zhao and Melville, 1998), the production of *C. difficile* toxins A and B does not seem to be linked to sporulation (Kamiya *et al*., 1992). However, several other *C. difficile* proteins, such as enzymes involved in butyric acid production, electron carriers in oxidation-reduction reactions, and enzymes from purine biosythesis pathway are co-regulated with the toxin production in *C. difficile* (Karlsson *et al*., 2000; Maegawa *et al*., 2002; Karlsson *et al*., 2003).

Little is known about *in vivo* toxin expression and physiological relevance of toxin regulation. Glucose-dependent regulation could be an adaptation to the gut environment, as levels of free glucose are low in the large intestine (Karlsson *et al*., 2000). Association between amino acid limitation and increased toxin production may be of clinical relevance because protein malnutrition may be a risk factor for *C.Difficile*-associated disease (Karlsson *et al*., 2000).

## Related proteins from other organisms

There are several descriptions of a single toxin or highly conserved toxins being produced by different species, e.g., Shiga-like toxins or BoNTs. So far, only one report has described isolation of yet another clostridial species, *C. baratii*, producing a *C. difficile*-like toxin(s) (Ravizzola *et al*., 1998). The strain is no longer available, but the culture supernatant was cytotoxic and reacted with *C. difficile* commercial A/B kit.

However, LCTs show similarity with many other proteins, mainly putative glycosyltransferases. Interestingly, the C-terminal repeats and N-terminal enzymatic domain show homology with two different groups of proteins (Figure 21.1), suggesting a modular evolution of LCTs.

The C-terminal domain is similar to a number of nonrelated proteins with a common feature of binding saccharides, choline, or glucans (Wren, 1991): glycosyltransferases from oral streptococci *S. mutans* and *S. downei* and to lytic enzymes (amidases and muramidases) from *S. pneumoniae* and its bacteriophages (Wren, 1991; von Eichel-Streiber *et al*., 1992). In both *S. mutans* and *S. downei*, glycosyltransferases are extracellular proteins and are considered as virulence factors, contributing to dental plaque and caries formation (Wren, 1991).

The 500 to 700 aa N-terminal part of LCTs with glycosyltransferse D-X-D motif exhibit sequence similarity to gycosyltransferases involved in capsular polysaccharide synthesis, yeast OCH1 glycosyltransferases (Busch *et al*., 2000), and adhesion molecules. Most interesting, however, is the sequence homology of LCTs and several large putative toxic molecules, of which only one (LifA) was invariably linked with toxic action.

The homology to large plasmid-encoded protein in enterohemorrhagic *E. coli* (EHEC) was reported in 1998 (Burland *et al*., 1998), and the gene was designated *toxB* solely on the basis of similarity to LCTs. In addition to *toxB*, two other *E. coli* proteins are similar to *C. difficile* and *C. sordellii* toxins: Efa1 produced by some EHEC strains and LifA produced by enteropathogenic (EPEC) strains. LifA and Efa1 (both 3223 aa) are 97.4% identical to each other and 28% identical to *E. coli* ToxB. No enzymatic activity has yet been ascribed to ToxB, Efa1, and LifA (Stevens *et al*., 2004). Only LifA (lymphostatin) so far has been shown to have toxic properties. It inhibits lymphocyte proliferation and synthesis of proinflamatory cytokines, but unlike LCTs, does not cause changes in the cytoskeleton of HEp-2 cells (Klapproth *et al*., 2000).

Proteins similar to LCTs and Efa1/LifA were detected also in genomes of *Chlamidophyla caviae* and *C. muridarum*, whereas *C. trachomatis* possess only a truncated gene (Read *et al*., 2003). Both former species cause cytopathic effects on cells, but the mechanism is unclear. Putative toxins from *Chlamydophyla* and *Chlamydia* contain, besides LCT-like catalytic domain, also cysteine protease domain that could mediate proteolytic C-terminal cleavage of Rho (Shao *et al*., 2002). Other large uncharacterized proteins similar to LCTs are found in *C. acetobutylicum* and *P. fluorescens*.

# STRUCTURAL AND FUNCTIONAL PROPERTIES OF LCTS

LCTs are large, single-chained proteins with postulated three domain structure. Several functional motifs are recognized (Figure 21.1), whereby three of them are highly conserved and correlate with the three

functional domains: (i) D-X-D glycosytransferase motif within the catalytic domain, (ii) stretch of hydrophobic amino acids in putative translocation domain, and (iii) repetitive sequences forming the receptor binding domain.

All LCTs are cytotoxic and lethal, but only TcdA, TcdB, and TcsH possess enterotoxic activity. Cytotoxicity is primarily due to the glucosylation of Rho GTPases and subsequent effects on cell cytoskeleton and signaling pathways, whereas systemic effects of the toxins, such as lethality and enterotoxicity, are less understood.

## Cell entry

The LCTs act intracellularly and get access to their targets by receptor-mediated endocytosis and translocation to the cytoplasm from the endosomal compartment.

### *Receptor binding domain and cellular toxin receptor*

The first step of cell entry is the interaction with membranous structures to allow binding, which is thought to be mediated by the repetitive peptide elements (CROPs: combined repetitive oligopetides) located at the C-terminal part of each cytotoxin. The best studied prototype in this respect is TcdA. The previously discussed homology of repetitive peptide elements (about one-third of the TcdA molecule) with the carbohydrate-binding regions of glycosyltransferases from *Streptococcus mutans* (Von Eichel-Streiber and Sauerborn, 1990; Von Eichel-Streiber *et al*., 1992) indicates a structural hint that TcdA binds to cellular carbohydrate structures. This notion has been at least partially supported by various findings showing that treatment of cells with glycosidases, N-glycosylation inhibitor tunicamycin, or proteases reduce but do not abolish TcdA effects on cells (Pothoulakis *et al*., 1991; Pothoulakis *et al*., 1996; Smith *et al*., 1997). Furthermore, TcdA was shown to bind directly to the terminal carbohydrate structure Galα1-3Galβ1-4GlcNAc (Krivan *et al*., 1986; Tucker and Wilkins, 1991); however, this oligosaccharide is absent in humans (Larsen *et al*., 1990). Humans do have GalNAcβ1-3Galβ1-4GlcNAc-structure, to which TcdA also binds (Karlsson, 1995; Teneberg *et al*., 1996). The membranous sucrase-isomaltase glycoprotein was identified as a functional TcdA receptor in rabbit ileal brush border, but again, this receptor is not expressed in many toxin-sensitive tissues (e.g., human colon) (Pothoulakis *et al*., 1996). It is conceivable that TcdA recruits different receptors that are similar but not identical. The carbohydrate structure (containing at least Galβ1-4GlcN) seems to be the essential element for binding of TcdA to its cell receptor, but whether this carbohydrate is linked to proteins or lipids is unknown.

So far there are no data on the receptors of the other LCTs. Binding of TcsL to phosphatidylserine was reported for TcsL and the binding site is located at N-terminus (Mesmin *et al*., 2004) (Figure 21.1). However, phosphatidylserine is enriched on the cytoplasmic site of cell membranes, and this binding is thought to play a role in the docking of the catalytic fragment close to its membrane-associated GTPases substrate, rather than in the binding step of holotoxin.

That the C-terminal part of TcdA is, in fact, the receptor binding domain has been directly shown by competition studies testing the ability of different TcdA subfragments to block the cellular uptake of the holotoxin (Frisch *et al*., 2003). In this study, only the complete receptor binding domain of TcdA was shown to be functional, resulting in binding and endocytosis. Shortened receptor binding domain, although covering about 15 from 30 repetitive elements, showed no internalization. This finding does not argue against multiple receptor-binding subunits, but supports the view that at least the correct assembly and the correct folding of all CROPs are a prerequisite for receptor binding. Alternatively, it is conceivable that TcdA interacts with a single receptor molecule, meaning that despite the repetitive structure, only one unique cell receptor is recognized. The latter notion is supported by the finding that a monoclonal antibody that recognizes only two small epitopes in the 109 kDa receptor-binding domain completely blocks receptor binding and toxic effects (Lyerly *et al*., 1986; Frey and Wilkins, 1992).

### *Endocytosis and processing*

Subsequent to receptor binding, the toxins are endocytosed (Florin and Thelestam, 1983; Henriques *et al*., 1987) and the formed vesicles are acidified, which is a prerequisite for entering the cytosolic compartment (Figure 21.4). Inhibition of endosomal acidification by, e.g., bafilomycin A1 completely blocks cytotoxic effects, as shown for TcdA, TcdB, and TcsL. This inhibition can be bypassed by acidification of the culture medium (pH 5), allowing the translocation of the toxin directly across the cell membrane into the cytosol (Qa'Dan *et al*., 2000; Barth *et al*., 2001; Fiorentini and Thelestam, 1991).

At least TcdB is processed during the course of uptake (Pfeifer *et al*., 2003; Rupnik et al., 2005b). Only the enzymatically active fragment but not the holotoxin is detectable in the cytosol, and the translocation/binding domain remains in the endosomes (Pfeifer *et al*., 2003). The cleavage site $Leu_{543}/Gly_{544}$ was determined in $TcdB_{10463}$ after *in vitro* cleavage reaction (Rupnik *et al*., 2005b). The protease involved and the step where proteolytic cleavage takes place have not yet been identified. However, the *in vitro*

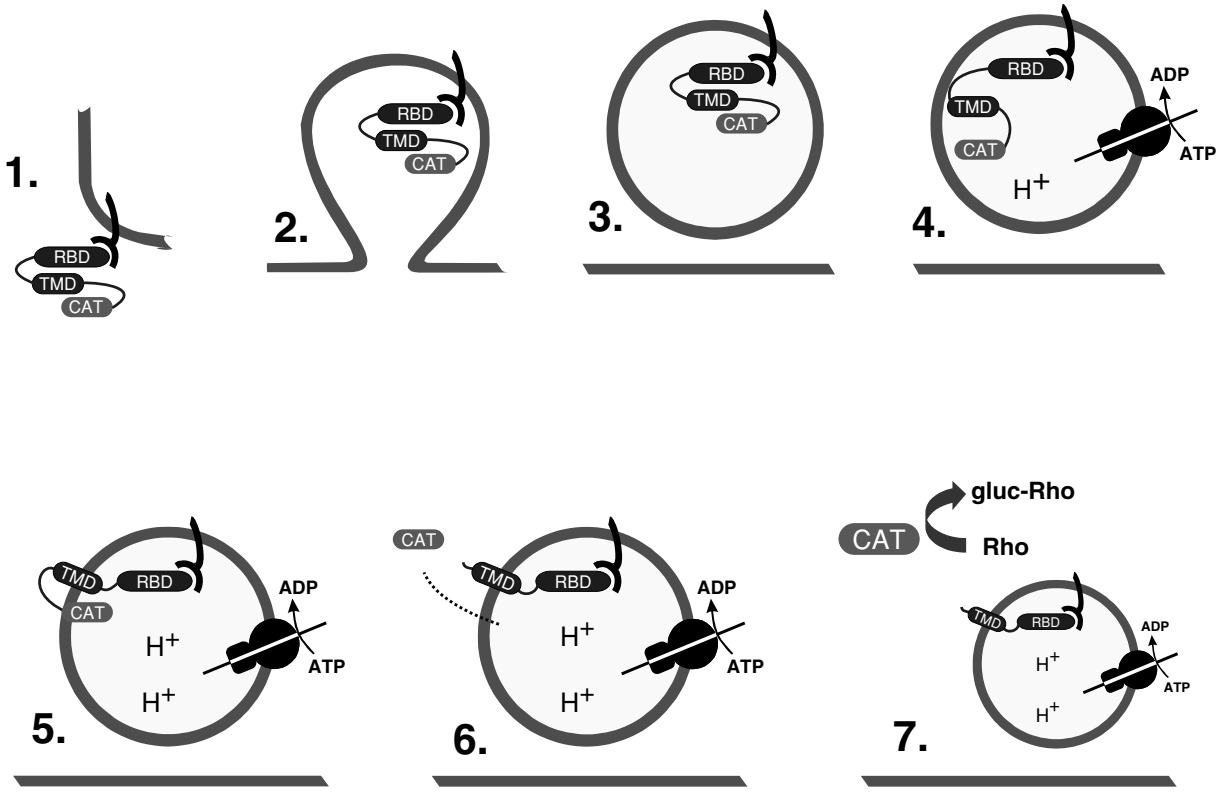

**FIGURE 21.4** Cell entry of LCTs exemplified for TcdB. 1. The C-terminal receptor-binding domain (RBD) of TcdB interacts with the putative cell receptor. 2. Toxin binding induces receptor-mediated endocytosis. 3. Endocytosed vesicle is processed to endosomes. 4. Vesicular-ATPase pumps protons into the endosomal lumen, resulting in a decreased pH (about 5.5). 5. Acidic pH induces refolding of the toxin, allowing the hydrophobic transmembrane domain (TMD) to form a pore into the endosomal membranes (shown only for TcdB.). 6. The catalytic domain (cat) is translocated through the pore into the cytoplasm. The proteolytically cleavage catalytic domain is released (shown only for TcdB). 7. The catalytic domain mono-glucosylates the Rho-GTPase targets in the cytoplasm.

proteolytic activity, which results in a specific cleavage of TcdB in two fragments, has been partially characterized (Rupnik *et al*., 2005b). Based on the comparable primary structure, it is likely that other LCTs are also processed. The same cleavage site as in $TcdB_{10463}$ was determined also for variant $TcdB_{8864}$, with the difference at position -2 (EGSL/GEDD vs. EGAL/GEDD). Cleavage site EGAL/GEDD is conserved also in TcsL and the toxin could be cleaved *in vitro*, but further characterization of cleavage reaction was not done. Cleavage site is changed in TcdA (GGSL/SEDN) and TcnA (GRTL/NYED).

All LCTs carry in the middle part a hydrophobic region (Figure 21.1), which is thought to be involved in translocation. This notion is based on the known uptake mechanism of other toxins using an endosomal pathway, where the acidic endosomal pH triggers conformational changes in the hydrophobic stretch, allowing membrane insertions and subsequent translocation of the catalytic domain into the cytosol. That this notion is also true for TcdB is shown by the finding that a decrease in the pH, in fact, increases hydrophobicity of TcdB, a conformational prerequisite for membrane insertion (Qa'Dan *et al*., 2000). A further support comes from the finding that TcdB and TcsL are able to form pH-dependent pores, allowing small cations such as $Rb^+$ to pass (Barth *et al*., 2001). This seems to be a general property of TcdB since it can be reproduced in an artificial lipid bilayer model. The function of the pore is assumed to transport the catalytic domain from the endosomal lumen into the cytosol.

This model of the cell entry of a single-chained toxin seems not to be true for *C. sordellii* TcsL because TcsL consists of a dissociable protease-resistant high-molecular complex (Voth *et al*., 2004). Dissociation of this complex is pH-dependently regulated; at pH 4, distinct proteins of 45–55 kDa appear, which are cytotoxic.

## Molecular mode of action

All LCTs are transferases that catalyze the transfer of a glucose (glcNAc in the case of TcnA) moiety to cellular

targets, the Rho- and Ras-GTPases. Toxins TcdA and TcdB mono-glucosylate Rho, Rac, Cdc42, RhoG, and TC10, all GTPases that are members of the Rho subfamily (Just *et al*., 1995a; Just *et al*., 1995b; Boquet and Lemichez, 2003; Just and Gerhard, 2004). TcdA was reported also to partially modifiy Rap (Chaves-Olarte *et al*., 1997). TcsL (various isoforms) and the variant TcdBs from *C. difficile* strains 1470 and 8864 predominantly modify Rac from the Rho subfamily and, in addition, Ras-GTPases, such as Ras, Rap, and Ral (Genth *et al*., 1996; Popoff *et al*., 1996; Just *et al*., 1996; Hofmann *et al*., 1996; Schmidt *et al*., 1998; Chaves-Olarte *et al*., 1999; Chaves-Olarte *et al*., 2003). The glucose moiety from the ubiquitiously present co-substrate UDP-glucose is covalently bound to a pivotal threonine residue residing in the effector region of the GTPases (also called *switch 1*). The acceptor amino acids are Thr-37 in RhoA and Thr-35 in Rac, Cdc42, and Ras. TcnA from *C. novyi* recruits UDP-N-acetyl-glucosamine (UDPglcNAc) and transfers the glcNAc to the same threonine residue in Rho, Rac, and Cdc42 as toxins TcdA/TcdB (Selzer *et al*., 1996) (Table 21.2).

### *The glucosyltransferase activity*

*Catalytic domain*

The catalytic activity resides in the N-terminal part of the toxins, convincingly demonstrated for TcdA, TcdB, TcsL, and TcnA (Faust *et al*., 1998; Hofmann *et al*., 1997; Wagenknecht-Wiesner *et al*., 1997; Hoffman *et al*., 1998; Busch *et al*., 2000b). The studies using recombinant domains have shown that N-terminal domain covering amino acid residues 1 to 546 exhibited full enzyme activity. This is the minimum size of the catalytic domain since further reduction of the size results in loss of activity (Hofmann *et al*., 1997; Wagenknecht-Wiesner *et al*., 1997). The exact size of catalytic domain in TcdB (543 aa) was now defined by the characterization of the cleavage site (Rupnik *et al*., 2005b). Furthermore, microinjection of the N-terminal domain caused the same morphological and cytoskeletal effects as do the holotoxins.

These data have been fully supported by the application of chimeric toxins using a heterologous delivery system: The N-terminal part of the lethal factor of anthrax is fused to the catalytic domain of TcdB (residues 1–556) and the cell entry is mediated by the protective antigen of anthrax toxin (Spyres *et al*., 2001). The same system is applied to deliver the catalytic domain of TcsL from *C. sordellii* to cells (Voth *et al*., 2004). The finding that a mutant Don cell line—deficient of the co-substrate UDP-glucose—is resistant to the cytotoxins and that resistance is reversed by microinjection of UDP-glucose further supports the notion of the glucosyltransferase-based cytotoxicity (Chaves-Olarte *et al*., 1996). In conclusion, all the data support the notion that the cytotoxic activity of the LCTs is mediated by their inherent enzyme activity.

Structure-function analysis of the active fragments of *C. difficile* TcdB, *C. sordellii* TcsL, and *C. novyi* TcnA has shown that the essential structural element for enzyme activity is the D-X-D motif, an amino acid sequence of aspartic acid-any amino acid-aspartic acid (Busch *et al*., 1998) (Figure 21.5). This D-X-D motif, which is conserved in all LCTs, is present in various pro- and eukaryotic glycosyltransferases. UDP-glucose binding within the catalytic cleft of several eukaryotic glycosyltransferases is based on divalent metal ion-dependent coordination, which structurally requires two adjacent aspartic acids, the D-X-D motif (Wiggins and Munro, 1998). None of the aspartic acids, however, is identified to directly act as a catalytic amino acid (Boix *et al*., 2002). From the 3D structures of rabbit N-acetylglucosaminyltransferase and bovine beta1.4-galactosyltransferase, it can be deduced that one aspartate directly interacts with $Mn^{2+}$ to further mediate UDP binding (Unligil and Rini, 2000; Unligil *et al*., 2000; Boeggeman and Quasb, 2002). Exchange of one of the aspartic acid residues results in a more than 1000-fold decrease in enzyme activity, which cannot be rescued by an excess of $Mn^{2+}$ (Busch *et al*., 1998). Furthermore, such mutant toxin loses its ability to bind to the co-substrate UDP-glucose, shown by failure to be labeled with azido-UDP-glucose. In addition to the D-X-D motif, tryptophan-102 is also involved in binding of the co-substrate UDP-glucose, and mutational exchange results in a dramatic decrease in transferase activity (Busch *et al*., 2000a). These findings are not only important for the understanding of the catalytic

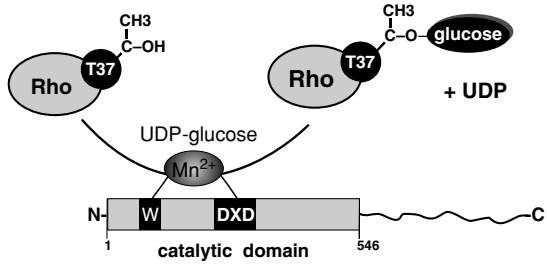

**FIGURE 21.5** Catalytic mechanism. The catalytic domain of the LCTs is located at the N-terminal part of the toxin molecule and recombinant functional proteins of 546 residues were used in the studies. The tryptophan-102 (W) and the D X D motif (residues 286–288) are involved in UDP-glucose co-substrate binding through $Mn^{2+}$ or $Mg^{2+}$. The C-terminal part (residues 408–468 in TcdB) covers the protein substrate recognition site. The catalytic domain forms together with the substrate Rho and the co-substrate UDP-glucose a ternary complex in which the glucose moiety is transferred to the acceptor threonine residue and covalently linked.

mechanism, but also serve as a basis for the generation of enzyme-deficient toxins.

*C. difficile* TcdA, TcdB, and the variant TcdBs, as well as TcsL and TcsH from *C. sordellii,* recruit the nucleotide sugar UDP-glucose as co-substrate; the glucose moiety is transferred to the protein substrate (Figure 21.5). *C. novyi* TcnA is an exception because it uses UDP-GlcNAc as a co-substrate. N-acetylglucosaminylation of small target GTPases, in fact, occurs in intact cells as it was deteced by specific [$^{14}$C]galactosylation of the cellular GTPase, which depends on the N-acetylglucosamine moiety attached (Selzer *et al*., 1996). Under artificial conditions, TcnA also utilizes UDP-glucose but the $K_m$ is about 340 μM compared to 17 μM for UDP-glucNAc and seems not to be of relevance (Busch *et al*., 2000b). In general, the $K_m$–value of the LCTs for nucleotide sugars is in the range 10–20 μM.

The catalytic mechanism implies a specific substrate recognition site for the Rho/Ras substrates. This site has been characterized by constructing chimeras of catalytic domains from toxins with different substrate specificities, such as TcdB and TcsL (Hofmann *et al*., 1998). Amino acid residues 408–468 in TcdB determine the specificity for Rho, Rac, and Cdc42, whereas residues 364–408 in TcsL determine for Rac and Cdc42 but not for Rho recognition. Interestingly, the substrate specificity of TcsL and TcdB is determined by different domains. The recognition of the Ras proteins in TcsL is mediated from the region aa 468–516, which is adjacent to the Rho recognition site (Hofmann *et al*., 1998; Busch and Aktories, 2000). It seems that the substrate recognition sites are modularly organized. However, the differing substrate specificities are in fact not understood. TcdA, TcdB, TcsH, and TcnA preferentially glucosylate Rho subfamily GTPases but not GTPases from other subfamilies (Table 21.2), whereas *C. sordellii* TcsL and the variant $TcdB_{1470}$ possess a different substrate specificity: They modify Rac but not Rho and, in addition, H-Ras, Rap, Ral, and R-Ras (Genth *et al*., 1996; Popoff *et al*., 1996; Just *et al*., 1996; Hofmann *et al*., 1996) (Table 21.2).

The acceptor residue threonine is highly conserved in Rho- and Ras-GTPase and plays an essential role in the GTP-driven switching of the effector region. Only in the GDP-bound form is the hydroxyl group accessible, and thus the inactive Rho-GDP is the preferred substrate for the cytotoxins (Just *et al*., 1995a; Herrmann *et al*., 1998).

*Catalytic mechanism*

The glucose is O-glycosidically bound in an α-anomerical configuration (Vetter *et al*., 2000; Geyer *et al*., 2003). Thus, the glucosylation reaction goes under retention of the configuration of the α-D-glucose at the C-1 position. Since 1.5-gluconolactone mimicking the transition state inhibits Ras glucosylation by TcsL, it can be concluded that the reaction mechanism includes a glucosyl oxonium transition state (Geyer *et al*., 2003). Retention of configuration and the glucosyl transition state exclude a single $S_N2$ reaction mechanism but rather argues for a binucleophilic substitution (double replacement) or a stereospecific $S_N1$ reaction, where structural constraints of the catalytic pocket prevent formation of a racemate (Vetter *et al*., 2000; Geyer *et al*., 2003).

In addition to the transferase activity, LCTs exhibit glycohydrolase activity in the absence of Rho substrates to hydrolytically cleave the co-substrate UDP-glucose into UDP and glucose (Just *et al*., 1995b; Chaves-Olarte *et al*., 1997; Ciesla, Jr. and Bobak, 1998; Busch *et al*., 2000a). The glycohydrolase activity is much slower than the transferase activity. Whether this hydrolase activity contributes to the biological activity of the LCTs is unclear. This activity, however, can be used for studying the requirement of the divalent cations for enzyme activity, because this a well-defined, two-component system merely exists of the enzyme (cytotoxin) and the nucleotide sugar but is not hampered by the $Mg^{2+}$ ion-requiring Rho GTPases. $Mg^{2+}$ or $Mn^{2+}$ ions are essential for enzyme activity but not for correct folding because the removal of bound divalent metal ions by treatment with EDTA or EGTA results in a complete inhibition of enzyme activity, which can be fully restored by the addition of the metal ions (Just *et al*., 1996; Ciesla, Jr. and Bobak, 1998). Divalent metal ions are necessary but not sufficient for glycohydrolase activity since in the absence of $K^+$ cations, no enzyme activity is detectable (Ciesla, Jr. and Bobak, 1998). The requirement for $Mn^{2+}/Mg^{2+}$ and co-activation by $K^+$ may reflect that the LCTs are optimally adapted to the metal ion condition of the intracellular milieu of the mammalian target cell, especially because all factors are removed during the uptake process, including acidification and translocation through endosomal membranes.

### *Functional consequences of glucosylation of Rho-GTPases*

*Cellular functions of the substrates of the toxins*

The major cellular targets of the LCTs, the Rho GTPases, also called *small Rho GTP-binding proteins*, are molecular switches in various intracellular signaling pathways (Bishop and Hall, 2000; Takai *et al*., 2001b; Etienne-Manneville and Hall, 2002). The function of the switch is regulated by an intrinsic GTPase cycle (Figure 21.6). The active GTP-bound state is reached by catalysis of GEFs (guanine nucleotide exchange factors). This conformation of the Rho-GTPase allows

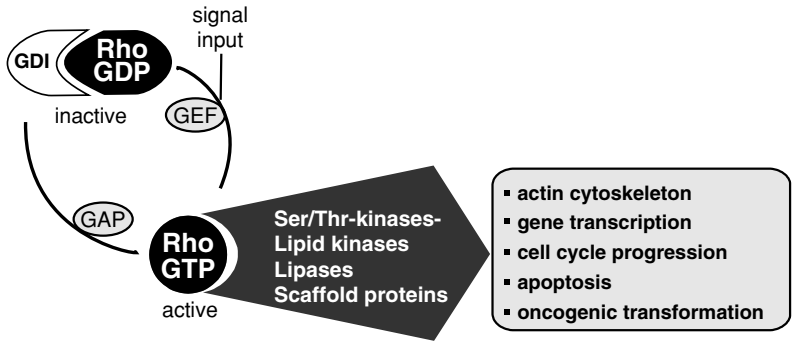

**FIGURE 21.6** Rho GTPase cycle. The small GTP-binding proteins are molecular switches, which are regulated by guanine nucleotide binding. The active GTP-bound state is reached by catalysis of GEFs (guanine nucleotide exchange factors), which are activated by external or internal signal input. The GTP-conformation allows binding to and activation of the effector proteins that amplify and execute the Rho signaling. Effector proteins are Ser/Thr-kinases, lipid kinases, lipases, and scaffold proteins. Inactivation is achieved by the intrinsic GTP-hydrolysing activity—triggered by GAPs (GTPase activating proteins) —resulting in an inactive GDP-bound Rho incapable of downstream signaling. Inactive Rho is cytosolically entrapped by GDI (guanine nucleotide dissociation inhibitor).

binding to and activation of the effector proteins, which amplify and execute the Rho signaling. Effector proteins are Ser/Thr-kinases, lipid kinases, lipases, and scaffold proteins (Van Aelst and D'Souza-Schorey, 1997; Hall, 1998; Zohn *et al*., 1998; Bishop and Hall, 2000; Ridley, 2001; Takai *et al*., 2001; Wettschureck and Offermanns, 2002; Etienne-Manneville and Hall, 2002). Inactivation is achieved by the intrinsic GTP-hydrolysing activity—triggered by other regulatory proteins such as GAPs (GTPase activating proteins)—resulting in an inactive GDP-bound Rho incapable of downstream signaling. Inactive Rho is cytosolically entrapped by GDI (guanine nucleotide dissociation inhibitor). This GTP-GDP cycle is governed by signal input through cell membrane-receptors and cross talk, respectively, and is accompanied by an additional spatial cycling from the cytosol (inactive state) to the membranes (active state) and back again (Figure 21.7A).

The family of Rho GTPases comprises Rho (A, B, C, D, G), Rac (1, 1b, 2, 3), Cdc42, Wnt-1, Chp, G25K, Rnd (1, 2, 3), TTF/RhoH, Rif, and TC10 (Van Aelst and D'Souza-Schorey, 1997; Mackay and Hall, 1998; Ridley, 2000). Best studied are RhoA, Rac, and Cdc42. RhoA induces formation of actin stress fibers and focal adhesions (Etienne-Manneville and Hall, 2002), Rac leads to formation of lamellipodia/membrane ruffles (Ridley *et al*., 1992), and Cdc42 induces formation of microspikes/filopodia (Kozma *et al*., 1995). Thus, Rho GTPases are essential for actin cytoskeletal-driven cell functions, such as cell migration, control of morphogenesis, and cell polarity. However, they are also involved in the regulation of cytoskeletal-independent cell functions, including cell cycle control, activation of transcription, apoptosis, and transformation (Bishop and Hall, 2000; Takai *et al*., 2001; Etienne-Manneville and Hall, 2002).

*Functional consequences of glucosylation of Rho GTPases*

The glucose moiety attached to the conserved threonine residue in the effector region causes various alterations of Rho functions (Figure 21.7): (i) Rho activation by exchange factors (GEFs) is reduced; (ii) intrinsic GTPase activity is reduced, but GAP-stimulated GTPase is completely inhibited; (iii) coupling to the effector proteins is completely blocked (Sehr *et al*., 1998; Herrmann *et al*., 1998). Inhibition of effector coupling is based on the effect of the glucose moiety to stabilize the inactive conformation of the effector region, although GTP can be bound (Vetter *et al*., 2000). In addition to the GTPase cycling, also the spatial cycling of the Rho-GTPases from cytosol to membranes is altered (Genth *et al*., 1999). Surprisingly, glucosylation renders Rho properties so that GDP-bound glucosylated Rho is bound to membranes, but cannot be complexed to GDI any more. Glucosylation blocks the cytosol-membrane cycling of Rho proteins, thereby leading to an entrapment at the membranes, which is thought to be the basis of the dominant negative effect of glucosylated Rho (Genth *et al*., 1999). Thus, glucosylation redundantly switches off Rho signaling to completely block all Rho-dependent signal pathways. The entrapment at the membranes, however, indicates a gain of function as a negative regulator rather than a mere inactivation of the GTPases.

The cytotoxic activity of the toxins caused by actin depolymerization can be fully explained by the inactivation of Rho-GTPases. RhoA is the upstream activator of the serine/threonine kinase ROCK (Rho-kinase), which in cooperation with the scaffold protein mDia regulate actin-myosin assembly and contractility, as well as actin polymerization, resulting in alteration of stress fiber formation and cell motility. Rac1

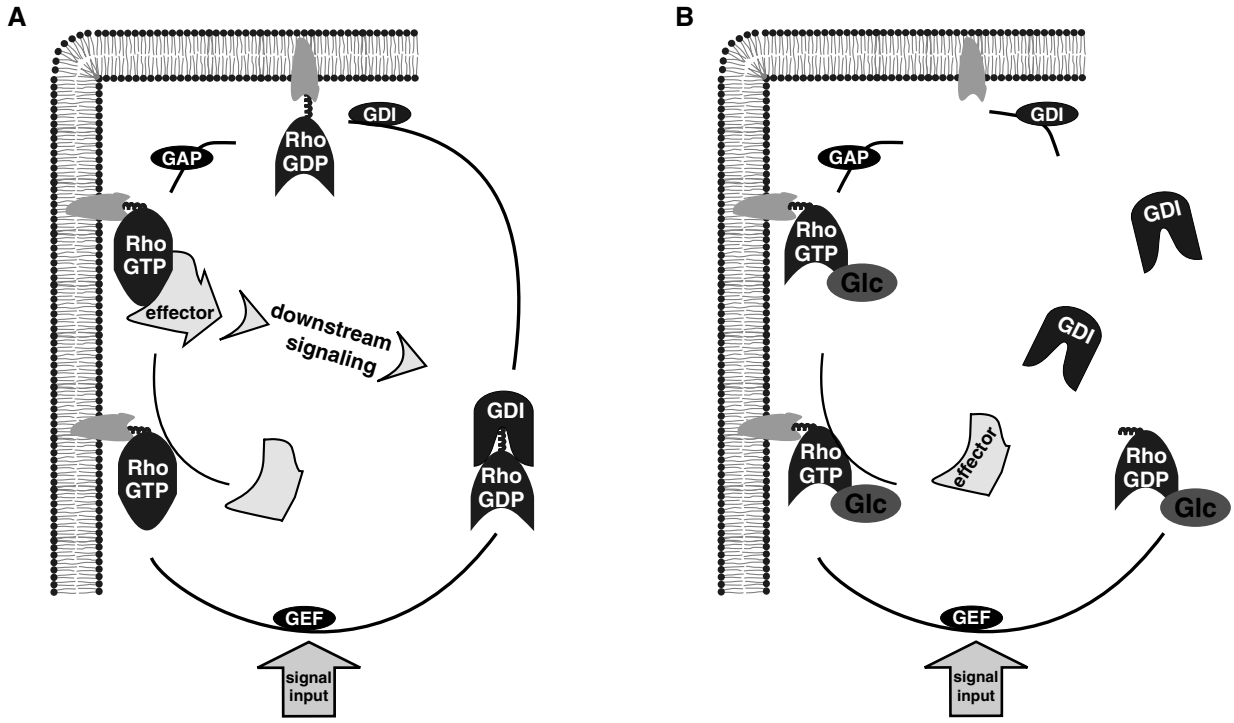

**FIGURE 21.7** Functional consequences of glucosylation. **A.** Cellular Rho signaling is governed by the GTP-GDP (GTPase)-cycle, which is driven by regulatory proteins such as GEFs, GAPs, and GDI. The GTPase cycle is accompanied by a spatial cycling from the cytosol (inactive state, complexed with GDI) to the membranes (active state) and back again. **B.** LCT-catalyzed mono-glucosylation alters the properties of Rho-GTPases. Glucosylated Rho is loaded with GTP and is translocated to membranous binding sites. Interaction with GAP and binding to GDI is blocked so that glucosylated Rho is entrapped at the membranes. However, glucosylated Rho is incapable of binding to effector proteins, resulting in a complete inhibition of Rho downstream signaling. Thus, the hallmark of glucosylated Rho is the enrichment of signaling incapable Rho at the membranes.

acts through PAK/WAVE/$PIP_2$, whereas Cdc42 acts through WASP. Their inactivation causes actin depolymerization in filopodia and lamellipodia, as well as de-inhibition of F-actin stabilization, resulting in inhibition of cell motility and phagocytosis. However, the molecular mode of action—glucosylation of Rho GTPases—implicates that all Rho-regulated cell functions are altered and, in fact, numerous cellular effects have been described to be based on inactivation of Rho GTPases: secretion (Prepens *et al*., 1996), phospholipase D activity (Schmidt *et al*., 1996), phagocytosis (Caron and Hall, 1998), neuronal axon formation (Bradke and Dotto, 1999), apoptosis (Subauste *et al*., 2000), deregulation of neurotransmitter exocytosis (Doussau *et al*., 2000), calcium mobilization (Djouder *et al*., 2000), muscarinic receptor signaling (Linseman *et al*., 2000), and chemoattractant receptor signaling (Servant *et al*., 2000).

Both TcdA and TcdB from the reference strain VPI 10463 cause morphological changes of fibroblasts, characterized by cell rounding and intermediate formation of "neurite-like" protrusions, but the intoxicated cells remain attached to the substratum. In contrast, variant TcdBs (e.g., $TcdB_{1470}$ and $TcdB_{8864}$) and TcsL from *C. sordellii* induce rounding with formation of some filopodia-like structures, however, accompanied by clustering of the cells followed by detachment (Chaves-Olarte *et al*., 2003) (Figure 21.8). The TcsL and the related variant TcdBs glucosylate Rac1 and Ras-GTPases but not RhoA. R-Ras, but not Rho, is involved in the control of cell adhesiveness through modulation of the integrin avidity (Zhang *et al*., 1996) and, thus, the difference in substrate specificity is responsible for different cytotoxic outcomes (Chaves-Olarte *et al*., 2003).

### *Enzyme-independent properties of* C. difficile *TcdA and TcdB*

Mitochondrial targeting of TcdA is currently under debate as an enzyme-independent activity important for the inflammatory activity of the cytotoxins (He *et al*., 2002). The release of interleukin-8 (IL-8) from colonocytes was reported to be related to the damage of mitochondria caused by TcdA. Toxin-induced damage resulted in a decreased ATP production and

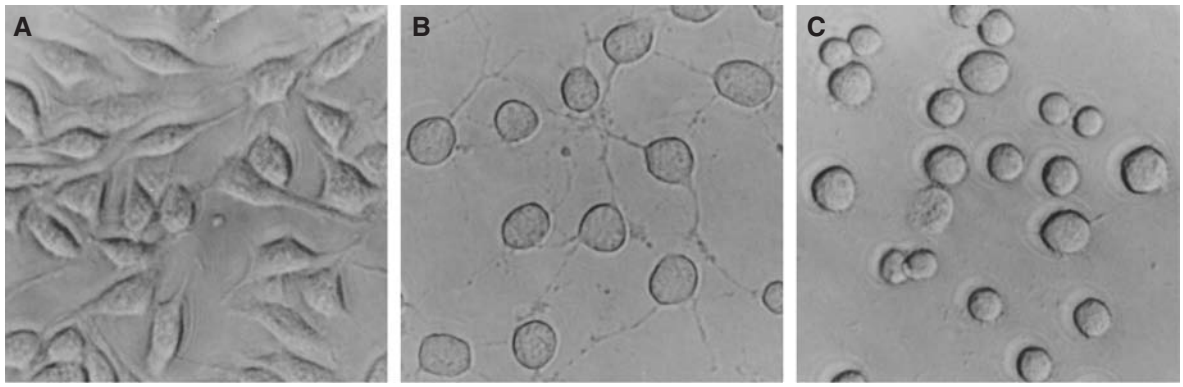

**FIGURE 21.8** Two morphological types of cytopathic effects (CPE) caused by LCTs. **(A)** Untreated control McCoy cells. **(B)** Difficile-like CPE with cells showing long protrusions; this CPE is obtained by toxins produced by the reference *C. difficile* strain and most of the variant *C. difficile* toxins (toxinotypes I–VII, XII–XIII, XV–XVI, XVIII–XXIV). **(C)** Sordellii-like CPE caused by TcdL and variant TcdBs of $A^-B^+$ toxinotypes (VIII, X, and XVII) and $A^+B^+$ toxinotypes (IX and XIV).

formation of reactive oxygene species (ROS), inducing a sequence of reactions involving activation of NFκB and eventually releasing the proinflammatory cytokine IL-8. Since this sequence takes place in a time window in which no glucosylation of Rho-GTPases were detectable, a Rho-independent effect of TcdA was postulated. This notion was supported by the finding that isolated mitochondria were directly affected by TcdA (He *et al*., 2000; He *et al*., 2002). However, the contrary finding has been reported, showing that mitochondrial damage as initiation of apoptosis started after 18–24 h of intoxication and was clearly dependent on the enzyme actitivity of the toxin (Brito *et al*., 2002). The effect of TcsL on mitochondria independently of the enzymatic effect on small GTPases was also reported (Petit *et al*., 2003)

A further Rho-independent effect is the rapid activation of the MAP-kinases ERK, p38-kinase, and JNK, starting 1–2 min after TcdA application to the monocytic THP-1 cell line (Warny *et al*., 2000). This early activation of kinase cascades clearly occurs before endocytosis of TcdA and the intracellular glucosylation of the Rho-GTPases, and it may be triggered through an interaction of the toxin with the host cell receptor. The p38-kinase activation resulted in monocyte activation and IL-8 production, thus offering an explanation of how TcdA may cause inflammatory processes.

The holotoxin TcdB is able to induce apoptosis in a caspase-dependent and caspase-independent manner. However, when the catalytic domain of TcdB—delivered as chimeric anthrax toxin or expressed in cells—was applied instead of the holotoxin, apoptosis was exclusively induced via a caspase-independent pathway (Qa'Dan *et al*., 2002). Thus, different TcdB domains should trigger apoptosis by two different mechanisms.

TcdA is able to induce a strong and long-lasting upregulation of the immediate early gene product RhoB at least partially through the p38-MAP-kinase signal pathway. Newly expressed RhoB is only partially inactivated by glucosylation, so that a significant portion of RhoB is active and capable of downstream signaling (Gerhard *et al*., 2005). Thus, the paradigm has to be challenged that the LCTs are specific inhibitors of the small GTPases.

In conclusion, it appears that especially TcdA and TcdB possess additional enzyme-independent biological activities that may contribute to pro-inflammatory effects in the course of the pseudomembranous colitis.

## LARGE CLOSTRIDIAL CYTOTOXINS IN PATHOGENESIS

Although all large clostridial cytotoxins possess glucosyltransferase activity to inactivate Rho- and Ras-GTPases, their *in vivo* effects differ from each other. They are major virulence factors causative for different diseases and clinical outcomes, respectively. TcdA and TcdB from *C. difficile* cause the antibiotic-associated diarrhea and the severe form, the pseudomembranous colitis (Kelly *et al*., 1994; Bartlett, 1994; Kelly and LaMont, 1998) is TcsL from *C. sordellii* involved in diarrhea and enterotoxemia in domestic animals and in gas gangrene in man (Hatheway, 1990), *C. novyi* TcnA has been identified as a causative agent for gas gangrene infections in man and animals (Hatheway, 1990). The difference between the comparable mode of action but different clinical features is likely based on the different organ targeting of the toxin-producing bacteria that colonize the gut or injured organs.

Additional strain-specific virulence factors are most likely involved in the pathogenesis.

Based on early animal studies, *C. difficile* TcdA, a biologically active enterotoxin, is thought to act primarily, whereas the effects of TcdB are secondary to TcdA (Lyerly *et al*., 1985). However, in human disease it appears that both toxins are of comparable relevance (Savidge *et al*., 2003). In about 5–7% of cases of *C. difficile*-associated diarrhea, so-called variant $A^-B^+$ strains are involved; these strains produce a variant TcdB, but no functional TcdA (von Eichel *et al.*, 1999; Kuijper *et al*., 2001; Barbut *et al*., 2002; Rupnik *et al*., 2003; Johnson *et al*., 2003). Despite lack of production of putative primary acting TcdA, the $A^-B^+$ strains are clearly associated with mild and severe forms of disease in humans. However, such strains are not able to induce diarrhea and PMC in animals (Depitre *et al*., 1993, Sambol *et al*., 2001), which further questions the relevance of the animal model to study the human disease.

The clinical symptoms of pseudomembranous colitis are characterized by secretory diarrhea and inflammatory processes of colonic mucosa. Toxin-induced fluid response and diarrhea may be explained by a decrease in barrier function of the colonocytes based on disruption of the actin cytoskeleton and inhibition of the function of tight junctions, resulting in a decreased transepithelial resistance allowing paracellular fluid loss (Hecht *et al*., 1988; Moore *et al*., 1990; Hecht *et al*., 1992; Riegler *et al*., 1995; Nusrat *et al*., 1995; Gerhard *et al*., 1998; Feltis *et al*., 2000; Nusrat *et al*., 2001; Liu *et al*., 2003).

The inflammatory response to the toxins is characterized by massive neutrophil infiltration and the production and release of various inflammatory mediators from mast cells and macrophages, such as prostaglandins and leukotriens, as well as IL-1, IL-6, IL-8, TNF-α, and IFN-γ (Pothoulakis *et al*., 1988; Mahida *et al*., 1996; Jefferson *et al*., 1999; Warny *et al*., 2000; He *et al*., 2002; Savidge *et al*., 2003; Ishida *et al*., 2004; Pothoulakis *et al*., 1998; Thelestam and Chaves-Olarte, 2000; Pothoulakis and LaMont, 2001). Furthermore, the enteric nervous system (ENS) is activated by the toxins through an unknown sequence of steps triggering secretory diarrhea and amplifying inflammation (Pothoulakis *et al*., 1998; Farrell and LaMont, 2000; Mantyh *et al*., 2000; Jones and Blikslager, 2002; Neunlist *et al*., 2003). However, the cellular and molecular mechanisms through which the toxins induce inflammatory processes are less clear and cannot be satisfactorily explained by their intracellular enzyme activity to inactivate small GTPases (Farrell and LaMont, 2000; Poxton *et al*., 2001; Bartlett, 2002; Stoddart and Wilcox, 2002).

## APPLICATION OF THE CYTOTOXINS AS TOOLS IN CELL BIOLOGY

Some of the large clostridial cytotoxins are applied as tools in cell biological research to study Rho-dependent signal cascades in intact cells. The basis for application is the cell accessibility (self-managed cell entry by receptor-mediated endocytosis) of the toxins and the notion that the cytotoxins possess a confined substrate specificity allowing the identification of the GTPase isoform involved in the cell function studied. Cell lines exhibit a broad spectrum of sensitivity towards the large clostridial cytotoxins. For example, CHO cells are highly sensitive to TcdB acting at femto-molar range, whereas HEp2 cells are quite insensitive; most fibroblasts and epithelial cells are insensitive to TcsL, but RBL (mast) cells are highly sensitive. TcdB is usually used, as it is much more potent than TcdA. To check whether Rac but not RhoA is involved or to check the participation of Ras-like GTPases, TcsL or the variant $TcdB_{1470}$ is applied because of their different target spectrum (Table 21.2). Although the canonical substrates of TcdA and TcdB are thought to be only Rho, Rac, and Cdc42, more Rho-GTPase isoforms are glucosylated than generally appreciated (Table 21.2). Especially RhoG and TC10 have to be considered.

The morphological changes (cell rounding and formation of arborized morphology) induced by the LCTs are an excellent readout to check cell sensitivity and to check whether the toxin applied has done its job in the special experimental setting. Non-adherent cells, however, escape the readout system of cell-shape changes. In this case, the only reliable method to check the effectiveness of the toxin is to perform a differential glucosylation. The principle of this assay is the fact that toxin-catalyzed glucosylation in intact cells prevents a second [$^{14}$C]glucosylation (co-substrate UDP-[$^{14}$C]glucose) of the lysates. A decrease in radioactive labeling of the Rho-GTPases in lysates compared to non-treated cells indicates previous glucosylation in the intact cell and thus proves the effect of the toxin. An alternative is the application of the C3-catalyzed [$^{32}$P]ADP-ribosylation using [$^{32}$P]$NAD^+$ as co-substrate, which, however, only proves modification of Rho but not of Rac or Cdc42. The differential glucosylation and ADP-ribosylation, respectively, are also applicable to assess the extent of inactivated (glucosylated) Rho-GTPases. However, one has to consider that membranous Rho is the active one, so that assessing glucosylation of membranous Rho is more relevant.

Since the Rho-GTPases are the master regulators of the actin cytoskeleton, the cytotoxins alter every actin-based cell function. To distinguish between mere

cytoskeletal and non-cytoskeletal effects, agents or toxins that directly interfere with actin polymerization should be applied for control. One such agent is latrunculin B, which enters cells by diffusion and sequesters G-actin. The second is the binary C2 toxin from *C. botulinum*, which ADP-ribosylates G-actin, thereby causing permanent depolmerization of the actin filaments (Aktories *et al*., 1997b; Barbieri *et al*., 2002; Aktories *et al*., 1997a).

Thus, the large clostridial cytotoxins should only be used for the initial orienting studies. The findings have to be confirmed by other methods, such as expression of dominant negative GTPases or application of siRNA, (Just *et al*., 1997; Bobak, 1999; Just and Boquet, 2000; Schiavo and van der Goot, 2001; Boquet, 2002).

CHAPTER

# 22

# *Pasteurella multocida* toxin

*Brenda A. Wilson and Mengfei Ho*

The major virulence factor of *Pasteurella multocida* responsible for atrophic rhinitis, pneumonia-like respiratory disease, and dermonecrosis is a monomeric 1285 amino acid protein toxin (PMT) produced primarily by capsular type D, some capsular type A, and a few non-typable strains. The *toxA* gene that encodes for PMT is located on a prophage pathogenicity island. While it is not known how PMT is released from the bacteria, purified PMT alone is sufficient to reproduce all the symptoms of atrophic rhinitis in swine and pneumonia-like disease in rabbits. Antibodies generated against PMT are protective toward atrophic rhinitis in animals. Experiments to define the molecular mechanisms of PMT action over the past 15 years have revealed that PMT binds to ganglioside-type receptors and enters mammalian cells via receptor-mediated endocytosis, where it then acts intracellularly to activate $G_q$-protein coupled signal transduction, Rho-protein-dependent actin cytoskeletal rearrangements, and mitogenesis. This chapter reviews what is currently known about the structure and molecular action of PMT, its role in pathogenesis, and its interaction with and effects on mammalian cells. Examples are also provided of the use of PMT as a powerful tool to study mitogenic, $G_q$-protein-, and Rho-protein-dependent signaling mechanisms.

## INTRODUCTION

### *Pasteurella multocida* and atrophic rhinitis

#### *Atrophic rhinitis and pasteurellosis*

Atrophic rhinitis is a disease of domestic and wild animals that is characterized by atrophy of the nasal turbinate bones, manifested by shortening, wrinkling, and twisting of the snout, sneezing, snuffling, nasal, discharge, teary eyes, and growth retardation. Depending on the severity of the disease, pathological changes can be mild and restricted to the snout with no overt clinical signs other than shrinkage of the ventral turbinates to severe and progressive disease with complete loss of all turbinate bone structures, septum deviation, respiratory distress, lung lesions, and generalized small stature and slow growth.

Atrophic rhinitis is an economically significant disease in swine, cattle, sheep, and rabbits, but it can affect other animals, such as small and large ruminants, poultry, cats, and dogs, as well as humans, and is therefore considered a zoonotic disease. In swine and rabbits, the primary disease manifestation is atrophic rhinitis (DiGiacomo *et al*., 1989; Foged, 1992), while in cattle, rabbits, and other animals other symptoms may be more pronounced, including respiratory distress or pneumonia (also referred to as pasteurellosis) and abscess formation (Kielstein, 1986; Deeb *et al*., 1990; DiGiacomo *et al*., 1991). An experimental mouse model of progressive atrophic rhinitis similar to the swine disease has been developed (Jordan and Roe, 2004).

#### *Atrophic rhinitis in swine*

Infection with *Bordetella bronchiseptica* or *Pasteurella multocida* alone or in combination can result in atrophic rhinitis in swine (reviewed in Chanter, 1990; Foged, 1992). After the first report in 1956 that intranasal inoculation of *B. bronchiseptica* could induce atrophic rhinitis in piglets (Switzer, 1956), it was generally believed that only *B. bronchispetica* could cause atrophic rhinitis. However, in the early 1980s, the correlation between severe clinical and pathological

symptoms of turbinate atrophic rhinitis and toxigenic isolates of *P. multocida* was firmly established (Kielstein, 1986; Foged, 1992). It is now well recognized that *B. bronchiseptica* alone causes a mild, transient form of atrophic rhinitis (Tornoe and Nielsen, 1976; Pedersen and Barfod, 1981; Rutter, 1981; Rutter *et al*., 1982; Rutter, 1985; Roop *et al*., 1987; Magyar *et al*., 1988), and while widespread, it has little impact on the productivity and health status of the animal. On the other hand, *P. multocida* infection is associated with moderate to severe progressive atrophic rhinitis (see Figure 22.1), which is also accompanied by growth retardation, and can have a significant health and economic impact (Pedersen and Barfod, 1981; Elling and Pedersen, 1985; Pedersen *et al*., 1988). Furthermore, it has been found that prior exposure to or co-infection with *B. bronchiseptica* predisposes piglets to colonization by *P. multocida* and to enhanced severity and progression of atrophic rhinitis and growth retardation (Harris and Switzer, 1968; Pedersen and Barfod, 1982; Rutter, 1983; Pedersen and Elling, 1984; de Jong and Akkermans, 1986; Nakai *et al*., 1986; Chanter *et al*., 1989; van Diemen *et al*., 1994a; Ackermann *et al*., 1996). Other predisposing infections can also exacerbate atrophic rhinitis by *P. multocida* (Brockmeier *et al*., 2001). In studies using non-toxigenic strains of *B. bronchiseptica* (i.e., lacking the *Bordetella* dermonecrotic toxin), it was found that colonization by toxigenic *P. multocida* was significantly reduced and hence atrophic rhinitis was much less severe (Magyar *et al*., 1988), suggesting that the toxin from *Bordetella* is a contributing factor for colonization.

**FIGURE 22.1** Atrophic rhinitis in swine. Shown are transverse sections of the nasal cavity of pigs exhibiting pathological changes of atrophic rhinitis ranging from mild (top panel) to moderate (middle panel) to severe (bottom panel) caused by infection with *Pasteurella multocida*. ### *Pasteurellosis in rabbits*

*P. multocida* is the primary etiological agent of atrophic rhinitis and respiratory disease (pasteurellosis or "snuffles") in rabbits (DiGiacomo *et al*., 1983; DiGiacomo *et al*., 1990; Deeb and DiGiacomo, 2000). Type A:12 strains are the most common in rabbits in the U.S., but A:3 and other A and D serotypes are found, with more severe disease being associated with A:3 and D strains (DiGiacomo *et al*., 1989; DiGiacomo *et al*., 1990; DiGiacomo *et al*., 1991). As for swine, co-infection with *B. bronchiseptica* increases the ability of *P. multocida* to colonize and cause disease (Deeb *et al*., 1990).

## Role of PMT in pathogenesis

Shortly after the demonstration that persistent turbinate atrophy could be induced by toxigenic strains of *P. multocida*, cell-free extracts from these strains were used to identify and isolate the toxin responsible for the symptoms of atrophic rhinitis (Il'ima and Zasukhin, 1975; Chanter *et al*., 1986). Early descriptions of assays used to monitor the activity of the toxin preparations included induction of turbinate atrophy after intranasal exposure in piglets (Elling and Pedersen, 1985; Chanter *et al*., 1986; de Jong and Akkermans, 1986; Dominick and Rimler, 1986; Elias *et al*., 1986; Foged *et al*., 1987; Dominick and Rimler, 1988; Kamp and Kimman, 1988; Elias *et al*., 1990); induction of atrophic rhinitis and other organ lesions after intramuscular, intraperitoneal, or intravenous injection (Rutter and Mackenzie, 1984; Chanter *et al*., 1986; de Jong *et al*., 1986; Cheville *et al*., 1988; Kamp and Kimman, 1988; Cheville and Rimler, 1989; Elias *et al*., 1990); induction of atrophic rhinitis and pneumonia in rabbits (Foged *et al*., 1987; Chrisp and Foged, 1991); guinea pig or rat dermonecrotic lesion assays (Nakai

*et al*., 1984b; Foged *et al*., 1987; Kamp *et al*., 1987; Elling *et al*., 1988); BALB/c mouse lethality assay (Rutter, 1983; Nakai *et al*., 1984b; Foged *et al*., 1987; Kamp *et al*., 1987); and cell culture assays of cytopathicity (Pennings and Storm, 1984; Rutter and Luther, 1984; Kimman *et al*., 1987; Chrisp and Foged, 1991). Results from these studies demonstrated that purified PMT alone could induce turbinate atrophy and other symptoms of disease, as well as lethality, dermonecrotic, cytopathic, mitogenic, and other biological effects. The primary systemic effects of PMT intoxication observed in laboratory animals were liver necrosis (Cheville *et al*., 1988; Cheville and Rimler, 1989; Lax and Chanter, 1990; Chrisp and Foged, 1991), spleen atrophy (Nakai *et al*., 1984a; Nakai *et al*., 1984b; Foged, 1988; Chrisp and Foged, 1991), hydronephrosis of the kidneys (Chanter *et al*., 1986; Lax and Chanter, 1990), pneumonia (Chrisp and Foged, 1991), and growth retardation (van Diemen *et al*., 1994a; Ackermann *et al*., 1996).

PMT appears to cause nasal turbinate atrophy through disruption of normal intramembranous bone biogenesis and degradation processes, mediated by the bone generating osteoblasts and macrophage-like osteoclasts, respectively (Kimman *et al*., 1987; Mullan and Lax, 1996; Mullan and Lax, 1998). PMT stimulates osteoclastic bone resorption *in vitro* (Felix *et al*., 1992; Mullan and Lax, 1996; Gwaltney *et al*., 1997; Mullan and Lax, 1998), stimulates the differentiation of preosteoclasts into osteoclasts (Martineau-Doize *et al*., 1993; Jutras and Martineau-Doize, 1996), and promotes osteoclast proliferation leading to bone resorption *in vivo* (Martineau-Doize *et al*., 1993). *In vitro*, PMT inhibits bone regeneration by osteoblasts (Sterner-Kock *et al*., 1995; Mullan and Lax, 1996; Mullan and Lax, 1998), as well as osteoblast differentiation (Harmey *et al*., 2004).

While atrophic rhinitis is strongly associated with infection by toxigenic capsular type D and A strains of *P. multocida*, the correlation between the presence of both atrophic rhinitis and pneumonic pasteurellosis is not always consistent with the presence of toxigenic strains. Unlike the case for rabbits (DiGiacomo *et al*., 1989; Chrisp and Foged, 1991; Suckow *et al*., 1991; DiGiacomo *et al*., 1993), pneumonic pasteurellosis in pigs, cattle, and poultry is most commonly associated with non-toxigenic capsular type A strains (Adler *et al*., 1999; Dowling *et al*., 2002; Davies *et al*., 2003; Davies *et al*., 2004; Dowling *et al*., 2004). However, there are reports of toxigenic capsular type A strains of *P. multocida* associated with pneumonic pasteurellosis and atrophic rhinitis (Kielstein and Elias, 1985; de Jong *et al*., 1986; Sakano *et al*., 1992). Indeed, immunization with bacterin-toxoid vaccine of *B. bronchiseptica* and toxigenic capsular type D *P. multocida* provides protection against challenge with both toxigenic serotype A and D strains (Sakano *et al*., 1997).

## Immunity and vaccine development

The importance of the toxin in *P. multocida* pathogenesis and its potential as a vaccine target was first demonstrated by protection against atrophic rhinitis in pigs challenged with *B. bronchiseptica* and toxigenic *P. multocida* through vaccination of pregnant sows with filtrates from cultures of toxigenic *P. multocida* (Pedersen and Barfod, 1982). PMT does not appear to be released sufficiently by the bacteria such that it is efficiently presented to the immune system during infection. Naturally occurring atrophic rhinitis is characterized by a lack of immune response against PMT (van Diemen *et al*., 1994b; van Diemen *et al*., 1996). Initial studies using only bacterin of toxigenic *P. multocida* resulted frequently in low levels of toxin neutralizing antibodies (Rutter *et al*., 1984; Rutter, 1985; Chanter *et al*., 1989; Thurston *et al*., 1991; Thurston *et al*., 1992), even though immunization with toxoid alone afforded protection (Pedersen and Barfod, 1982; Foged *et al*., 1989; Frymus *et al*., 1989; Foged, 1991; Nielsen *et al*., 1991; Pettit *et al*., 1993b). Parenteral immunization of pigs, rabbits, and mice with formaldehyde-treated crude (Pedersen and Barfod, 1982; Nakai *et al*., 1984a; Nakai *et al*., 1984b; Bording and Foged, 1991) or purified (Foged *et al*., 1989; Frymus *et al*., 1989; Chanter and Rutter, 1990; Bording and Foged, 1991; Foged, 1991) preparations of PMT have been shown to produce protective, neutralizing antibodies against PMT effects. In addition, colonization of toxigenic *P. multocida* in piglets was reduced in piglets inoculated with porcine anti-PMT serum before or after exposure to bacteria (Chanter and Rutter, 1990). Most current vaccine formulations now consist of PMT toxoid alone (Nielsen *et al*., 1991; Petersen *et al*., 1991; Jarvinen *et al*., 1998) or PMT toxoid in combination with toxigenic *P. multocida* and/or *B. bronchiseptica* bacterins (Sakano *et al*., 1997; Suckow, 2000; Magyar *et al*., 2002; Riising *et al*., 2002; Rajeev *et al*., 2003).

Although protective immunity can be induced by intranasal immunization with PMT toxoid in rabbits (Suckow *et al*., 1995), rabbits generally develop little immunity after natural infection, and high levels of humoral antibodies (IgG) are not associated with clearance of infection, but rather with chronic infection (Deeb *et al*., 1990; DiGiacomo *et al*., 1990; Zimmerman *et al*., 1992). Pigs treated with PMT likewise show lower IgG antibody responses toward PMT and other antigens, including limpet hemocyanin, ovalbumin, and tetanus toxoid (van Diemen *et al*., 1996). In another

study, a reduction in the humoral response to ovalbumin antigen was also observed in pigs challenged intranasally with toxigenic *P. multocida* compared to non-infected control animals, suggesting that PMT might have contributed to suppression of the immune response to antigen (Hamilton *et al*., 1998). A possible role for PMT as an immunomodulator in pathogenesis was further supported in a subsequent study that showed intranasal challenge with toxigenic *P. multocida* or with PMT-containing cell-free extracts caused a significant reduction in the levels of anti-ovalbumin IgG in both pigs and mice (Jordan *et al*., 2003).

## PMT CHARACTERIZATION

### PMT pathogenicity island

The gene encoding for PMT, named *toxA*, was cloned from the chromosomal DNA of *P. multocida* by three independent laboratories (Petersen and Foged, 1989; Buys *et al*., 1990; Kamps *et al*., 1990; Lax and Chanter, 1990). The deduced sequence of the 3,855-basepair open reading frame of *toxA* corresponded to a protein of 1285 amino acids and a predicted molecular mass of 146.3 kDa (Buys *et al*., 1990) or 146.5 (Petersen and Foged, 1989), with the molecular weight differences being attributed to the small number of amino acid changes in the sequences from the different isolates. Sequence analysis revealed that a ribosome-binding site preceded the start of the *toxA* open reading frame and that a stem loop followed the stop codon. There was no evidence for a signal sequence. The promoter region is different from that of an *E. coli* consensus promoter, yet expression under its own promoter in *E. coli* is constitutive and comparable to that found in *P. multocida* (Petersen and Foged, 1989; Lax and Chanter, 1990; Hoskins and Lax, 1996).

The *toxA* gene and its flanking region had a low G+C content (34.6%), which differed from the rest of the *P. multocida* genome (40.7%), as recently confirmed by whole genome sequencing of a non-toxigenic strain of *P. multocida* (May *et al*., 2001). When the chromosomal DNA was exhaustively digested with the restriction enzyme *Hpa*II, which recognizes the 4-basepair GGCC sequence, the *toxA* gene was located on a prominent 15-kilobasepair *Hpa*II DNA fragment (Lax and Chanter, 1990). This suggested that the gene might reside on a transmissible element, presumably a prophage (Andresen, 1989; Buys *et al*., 1990; Lax *et al*., 1990; Petersen, 1990). In support of this possibility, a set of 24 bacteriophages, recovered after mitomycin C treatment of isolates associated with atrophic rhinitis, was used to develop an epidemiological typing system to discriminate between toxigenic and non-toxigenic *P. multocida* strains (Nielsen and Rosdahl, 1990).

Recently, further DNA sequencing of the region flanking *toxA* revealed the presence of additional genes with similarity to bacteriophage tail protein genes and a bacteriophage anti-repressor, as well as a restriction/modification system (Pullinger *et al*., 2004), supporting that *toxA* was located on a prophage. Analysis also indicated that the bacteriophage had integrated into a conserved tRNA-Leu-3 gene in the chromosome. The presence of a bacteriophage was also observed in the spent medium from *P. multocida* culture induced with mitomycin C, and hybridization indicated that the bacteriophage contained the *toxA* gene (Pullinger *et al*., 2004).

### PMT production and release

PMT does not have a signal sequence and appears to be mostly cell associated during *in vitro* culture, although small amounts can be detected in the culture filtrate after overnight incubation (Rutter and Luther, 1984; Nakai and Kume, 1987). Ultrastructural studies of toxigenic *P. multocida* showed that PMT was localized in the cytoplasm of the bacteria (Nakai *et al*., 1985; iDali *et al*., 1991). Although it is known that PMT is expressed under non-inducing conditions, it is possible that phage induction results in PMT release from cells during infection. The possibility that PMT expression is regulated by the phage life cycle has not been investigated.

### PMT protein purification and characterization

#### *Purification of native PMT*

Native PMT has been purified from cell-free extracts of *P. multocida* by a variety of methods, including ammonium sulfate precipitation, gel filtration, anion exchange chromatography, hydrophobic interaction chromatography, and preparative PAGE (Nakai *et al*., 1984b; Chanter *et al*., 1986; Foged *et al*., 1987; Kamp *et al*., 1987; Chrisp and Foged, 1991; Ward *et al*., 1998). Unlike most bacterial proteins, PMT is retained on anion exchange columns in neutral phosphate or Tris buffers and is eluted with relatively high salt concentrations (e.g., 400 mM NaCl). The final step of most purification protocols involves preparative PAGE, which yields highly purified toxin, but is also accompanied by significant loss in biological activity (Nakai *et al*., 1984b; Chanter *et al*., 1986; Foged *et al*., 1987; Kamp *et al*., 1987; Chrisp and Foged, 1991; Ward *et al*., 1998). Later methods for obtaining higher purification of the native protein from cell-free extracts involve affinity chromatography using monoclonal antibodies against PMT (Foged, 1988; Felix *et al*., 1992).

### *Purification of recombinant PMT*

The recombinant protein (rPMT) expressed in *E. coli* has been purified and extensively characterized by a number of laboratories (Petersen and Foged, 1989; Buys *et al*., 1990; Kamps *et al*., 1990; Lax and Chanter, 1990; Rozengurt *et al*., 1990; Wilson *et al*., 1999). rPMT was found to be indistinguishable in physical properties, biological activity, and antigenicity to that of native PMT. The only apparent difference is that the native PMT protein is posttranslationally modified at the N-terminus, whereas rPMT from *E. coli* is not. More recent strategies for obtaining highly purified rPMT preparations involve affinity purification using hexahistidine- or GST-tagged fusions, in which the affinity handle is then usually removed (Wilson *et al*., 1999; Pullinger *et al*., 2001; Orth *et al*., 2003).

### *Stability of PMT*

PMT can be completely inactivated by a number of protein-denaturing conditions, including by heating at 56˚C for 30–60 minutes or 70˚C for 5–10 minutes, or by treating at 20˚C with 0.37% formaldehyde for 1 hour or at 37˚C with 0.07% formaldehyde for 18 hours (Rutter, 1983; Nakai *et al*., 1984a; de Jong and Akkermans, 1986; Foged *et al*., 1987; Rozengurt *et al*., 1990; Foged, 1991). Unlike many bacterial protein toxins, PMT does not require or undergo additional processing, such as partial proteolytic cleavage at sensitive sites, in order to exhibit biological activity on cells. Compared to other bacterial protein toxins, full-length PMT is highly resistant to proteolytic cleavage by a number of proteases (Smyth *et al*., 1995; Smyth *et al*., 1999), but becomes susceptible at low pH, suggesting that reduced pH causes structural changes in the protein that make it more accessible to cleavage (Smyth *et al*., 1999). However, while this step may be important for translocation across cellular membranes, it is apparently not necessary for PMT to exhibit its intracellular activity, as evidenced by the rapid cellular response to PMT upon direct microinjection into cells (Wilson *et al*., 1997).

## PMT INTERACTION WITH AND ENTRY INTO MAMMALIAN CELLS

### Receptor binding

The initial step for internalization of many bacterial toxins is the binding to cell surface receptors, followed by receptor-mediated endocytosis into early endocytic vesicles. Once internalized, the toxin cannot be removed by extensive washing or neutralized by addition of antibodies. The cytotoxic effect of PMT on cultured fibroblasts could be blocked by polyclonal antiserum against the toxin, but only if the antiserum was added early, and not late, during the treatment with PMT (Rozengurt *et al*., 1990). PMT can act on multiple cells types, suggesting that the receptor(s) are ubiquitously expressed. Receptor-mediated binding and internalization of PMT conjugated to 20-nm colloidal gold particles into canine osteosarcoma and monkey kidney (Vero) cells was examined ultrastructurally (Pettit *et al*., 1993a). In these studies, preincubation of the cells with phospholipase C, trypsin, pronase, or neuraminidase had little effect on the association of gold-labeled PMT with the cells, but binding was blocked in a dose-dependent manner by addition of bovine brain mixed gangliosides, strongly suggesting that PMT interacts with ganglioside-type receptors (Pettit *et al*., 1993a). This finding was substantiated further by another study in which preincubation of PMT with the gangliosides GM1, GM2, or GM3 inhibited the PMT-mediated effects on 3T3 fibroblast cells (Dudet *et al*., 1996).

### Cellular uptake

Very little is known about the cellular uptake mechanisms of PMT. There is a notable lag period between initial exposure to PMT and observation of cellular effects, with earliest events usually seen after about one hour (Rozengurt *et al*., 1990, Wilson *et al*., 2000). Inhibition of endocytosis by incubation at 4˚C also prevented PMT-mediated effects on Swiss 3T3 fibroblast cells (Rozengurt *et al*., 1990).

Colloidal gold-labeled PMT was found bound at the cellular surface and in coated and non-coated membrane invaginations shortly after addition to cells, and in endocytic vesicles upon longer incubation (Pettit *et al*., 1993a). Fluorescein-labeled PMT was also used to observe cell binding and entry into bone cells (Gwaltney *et al*., 1997). However, when primary porcine bone marrow cell cultures were treated with fluorescein-labeled PMT, the fluorescence was found primarily on the surface and within the cytoplasm of lymphoid-like mononucleated cells, suggesting that toxin was translocated to the cytoplasm (Gwaltney *et al*., 1997). The difference in observations between these two studies is likely due to the gold particles being too large for transport or translocation to occur, whereas the fluorescein label did not hamper translocation.

After binding receptors at the cell surface, subsequent transport and/or membrane translocation of PMT from the endocytic vesicle to its target site of action appears to involve a low pH-dependent event, since addition of weak lysosomotrophic bases, such as methylamine, blocked PMT action (Rozengurt *et al*., 1990). Involvement of a low pH-dependent membrane

translocation event in PMT action was further supported by a recent study in which PMT cellular activity could be mimicked at the cell surface by a low pH pulse after PMT was bound to cells at 4°C in the presence of the endocytosis inhibitor bafilomycin A1 (Baldwin *et al*., 2004).

## MOLECULAR AND CELLULAR MECHANISMS OF PMT ACTION

### PMT effects on $G_q$-PLC signal transduction

#### *PMT and PLC signaling*

PMT stimulates hydrolysis of inositolphospholipids to increase the total intracellular content of inositol phosphates (Staddon *et al*., 1991a) and diacylglycerol (DAG) (Staddon *et al*., 1990); mobilization of intracellular $Ca^{2+}$ pools (Staddon *et al*., 1991a); and activation of protein kinase C (PKC)-dependent and independent phosphorylation (Staddon *et al*., 1990; Lacerda *et al*., 1996). These effects suggested the involvement of a cellular phosphatidylinositol ($PIP_2$)-specific phospholipase C (PLC) in PMT action on cultured fibroblasts and osteoblasts (Staddon *et al*., 1990; Staddon *et al*., 1991a; Lacerda *et al*., 1996; Mullan and Lax, 1998), which results in activation of the $IP_3$ pathway and causes $Ca^{2+}$ mobilization and PKC-dependent phosphorylation (Berridge, 1993).

Voltage-clamped *Xenopus* oocytes were used as a model system to demonstrate direct PMT-mediated stimulation of PLC activity and subsequent $IP_3$-induced intracellular $Ca^{2+}$ mobilization by monitoring the endogenous $Ca^{2+}$-dependent $Cl^-$ current evoked upon microinjection with PMT (Wilson *et al*., 1997). In addition, PMT activation of the PLC-$IP_3$ pathway in this system was found to be transient, but irreversible. Repeated microinjection of PMT did not elicit additional responses after the first injection, although subsequent injection with $IP_3$ still gave a response, supporting that the target of PMT action is upstream of $IP_3$ release (Wilson *et al*., 1997).

#### *Involvement of $G_q$-protein in PMT-induced PLC activation*

Receptor regulation of the $IP_3$ pathway is mediated either through protein tyrosine phosphorylation of PLCγ or G-protein activation of PLC β-isoforms. There are at least two G-protein-regulated $IP_3$ pathways that can be distinguished by their sensitivity to ADP-ribosylation by pertussis toxin (PTx) (Berstein *et al*., 1992, Camps *et al*., 1992, Wu *et al*., 1993). The βγ subunits of PTx-sensitive $G_{o/i}$-proteins preferentially stimulate PLCβ3 > PLCβ2 > PLCβ1. The α subunits of the PTx-insensitive $G_q$ family, including $G\alpha_q$ and $G\alpha_{11}$, stimulate PLCβ1 ≥ PLCβ3 » PLCβ2. Since PMT action results in the activation of a cellular $PIP_2$-specific PLC, it was possible that PMT-induced activation of the PLC-mediated $IP_3$ pathway could occur through one of these pathways. In keeping with this, PMT was found to facilitate PLC activation by G-protein-coupled receptor ligands such as bombesin, vasopressin, and endothelin (Murphy and Rozengurt, 1992).

To identify the intracellular signaling pathway involved in PMT-induced $IP_3$ signaling, specific antibodies against $G\alpha_{pan}$, $G\alpha_{q/11}$, $G\alpha_{i/o/t/z}$, $G\alpha_{s/olf}$, $G\beta_{pan}$, PLCβ1, PLCβ2, PLCβ3, or PLCγ1 were tested for their ability to block the PMT-induced $Cl^-$ currents in the oocyte system (Wilson *et al*., 1997). Only antibodies directed against PLCβ1, $G\alpha_{pan}$, or the C-terminus of $G\alpha_{q/11}$ blocked the PMT-mediated response in oocytes. GDPγS, a known inhibitor of Gα subunit-mediated signaling pathways, likewise blocked the PMT-induced response. The specific role of $G\alpha_q$ was further confirmed by over- and underexpression of mouse $G\alpha_q$ in *Xenopus* oocytes (Wilson *et al*., 1997). Overexpression of $G\alpha_q$ increased the PMT-induced response, whereas treatment with anti-sense $G\alpha_q$ RNA inhibited the response. These results established the direct involvement of $G\alpha_q$ protein in PMT-activation of PLCβ1. Studies using mouse knockout cell lines confirmed that PMT-induced PLC activation was exclusively dependent on $G\alpha_q$, and not other $G_q$ family members, such as $G_{11}$, $G_{12}$, or $G_{13}$ (other $G_q$ family members, $G_{14}$ or $G_{15/16}$, were not examined) (Zywietz *et al*., 2001).

Antibodies against Gβ subunit did not block but rather enhanced the PMT-induced response (Wilson *et al*., 1997), substantiating that Gβγ subunit activation of PLCβ2 by a $G_{i/o}$-dependent pathway was not involved in PMT action, and supporting that the anti-Gβ antibodies caused the dissociation of $G\alpha_q$ subunit from the heterotrimeric Gαβγ complex, such that $G\alpha_q$ could then be acted upon by PMT. The PMT-induced response was likewise enhanced by the release of $G\alpha_q$ subunit through sequestration of Gβγ subunits by PTx treatment. From these results, it was concluded that the monomeric $G\alpha_q$ subunit is the preferred target of PMT action on the PLC pathway. Based on these results, a model was proposed for PMT intracellular action on $G_q$-PLC-$IP_3$ signaling (see Figure 22.2).

#### *PMT interaction with $G_q$-protein*

Using a series of chimeras between $G\alpha_q$ and the closely related $G\alpha_{11}$ in $G\alpha_{q/11}$-knockout cells, a region of the helical domain was identified that is important for PMT-induced PLC activation (Orth *et al*., 2004). Within

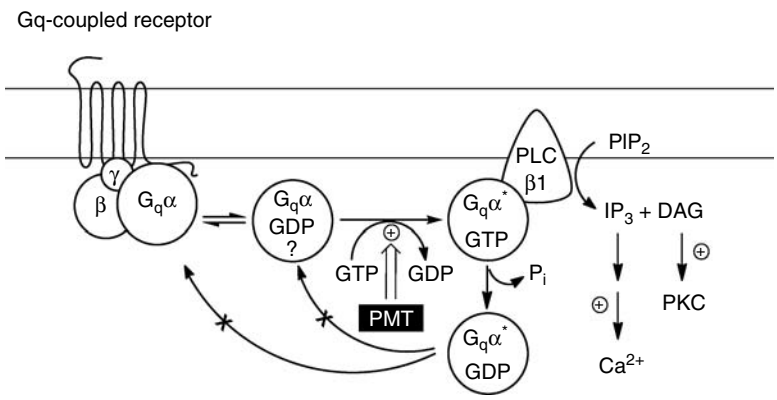

**FIGURE 22.2** Proposed model for PMT action on $G_q$-PLC signaling. Shown is a schematic representation of a proposed mechanism for PMT intracellular action, in which PMT acts on free GDP-bound $G\alpha_q$ and converts $G\alpha_q$ into an active form, presumably GTP-bound, which in turn stimulates PLCβ1. The activated PLCβ1 causes $PIP_2$ hydrolysis, leading to release of $IP_3$ and DAG and subsequent $Ca^{2+}$ mobilization, PKC activation, and downstream signaling. The PMT-induced response is transient due to the still-intact GTPase activity of $G\alpha_q$, which is stimulated by interaction with PLCβ1. The presumably modified $G\alpha_q$ can no longer be acted upon by PMT or be reassociated with the receptor-Gβγ complex.

the helical domain, exchange of Glu-105 or Asn-109 of $G\alpha_{11}$ with the corresponding His residues of $G\alpha_q$ resulted in a mutant $G\alpha_{11}$ protein that was able to mediate PMT-induced activation of PLC. However, the reciprocal exchange of the His residues in $G\alpha_q$ with the corresponding $G\alpha_{11}$ residues did not prevent PMT activation of PLC, suggesting that the differential activation of PLC mediated by these two proteins in response to PMT may be more complicated than a simple difference in recognition of the proteins by PMT.

Tyrosine phosphorylation of $G_{q/11}$ has been reported to regulate activation of $G_{q/11}$ signaling (Umemori *et al*., 1997; Umemori *et al*., 1999). Consistent with this, PMT appears to stimulate tyrosine phosphorylation of $G\alpha_q$; however, a mutant of PMT that was previously reported not to activate $G_q$ was also found to cause tyrosine phosphorylation of $G\alpha_q$ (Baldwin *et al*., 2003). Thus, the role of tyrosine phosphorylation in PMT action on $G_q$ is not clear.

### *PMT as a tool for studying $G_q$-PLC signaling*

PMT has been used as a selective activator of $G_q$-PLC signaling to demonstrate that $G_q$-coupled adrenergic receptor signaling in cardiomyocytes can differ between closely related animal species, such as mice and rats. For example, PMT was used to show that the $G_q$-PLC signaling pathway was still present and functional in mouse cardiomyocytes, even though α1-AR and endothelin receptors, which are known to selectively couple to PLC through $G_q$ in rat cardiomyocytes, were not functional as $G_q$-PLC regulators in the mouse cardiomyocytes (Sabri *et al*., 2000).

In neonatal rat cardiomyocytes, noradrenaline-stimulated $\alpha_{1A}$AR receptors were found to couple specifically to $G_{q/11}$ and not $G_{12/13}$, since overexpression of $G_{q/11}$-specific RGS4, but not $G_{12/13}$-specific Lsc-RGS, blocked $\alpha_{1A}$AR activation of PLCβ, which subsequently activated PLD through $Ca^{2+}$-independent PKC isoforms δ and ε (Gosau *et al*., 2002). PMT was used in this study to demonstrate the importance of $G_q$ and not $G_{11}$ in $\alpha_{1A}$AR activation of both PLC and downstream PLD.

PMT was used to show that histamine-induced catecholamine secretion from bovine adrenal chromaffin cells occurs through a PLC-independent membrane depolarization (Donald *et al*., 2002). In this study, PMT treatment caused an additive increase in basal and histamine-stimulated inositol phosphate levels, but not an increase or inhibition of adrenaline or noradrenaline secretion. The results obtained with PMT were consistent with other data, which showed that catecholamine secretion was not blocked by the PLC inhibitor ET-18-OCH3, by thapsigargin-depletion of intracellular $Ca^{2+}$ stores, or by $IP_3$-receptor inhibitors such as 2-aminoethoxydephenylborate or ryanodine plus caffeine (Donald *et al*., 2002).

Okada *et al*. used PMT to discriminate between $G_q$-dependent and $G_q$-independent $IP_3$ signaling induced by saccharin in frog rod taste cells (Okada *et al*., 2001). PMT treatment did not induce a response in the frog taste cells, suggesting the involvement of a Gβγ-coupled PLCβ2 isoform rather than a $G\alpha_q$-coupled PLCβ1 or PLCβ3 isoform in saccharin taste transduction.

PMT was recently used to demonstrate the involvement of $G_q$-PLC and $Ca^{2+}$ signaling in dendritic cell (DC) maturation (Bagley *et al*., 2004). In this study, the involvement of $Ca^{2+}$ release in PMT-stimulation of DC maturation was demonstrated by using xestospongin, an inhibitor that blocks $Ca^{2+}$ release from $IP_3$-gated intracellular stores.

PMT has also been used to study the role of $Ca^{2+}$ release in the cholinergic regulation of the circadian clock in the hypothalamic suprachiasmatic nucleus (SCN) of the rat brain. Muscarinic regulation of the SCN clock occurs through $G_q$-coupled M1 mAChR, with sensitivity exhibited only during the night phase of the 24-hour clock cycle (Gillette *et al*., 2001). PMT treatment advanced the clock phase (i.e., caused the

clock to reset) in the same direction as activation of muscarinic receptors, such as carbachol-stimulated M1 mAChR, and $IP_3$-mediated $Ca^{2+}$ release in early night (L. Artinian, W. Yu, B. A. Wilson, E. Gratton, M. U. Gillette, unpublished data). Inhibitors of $IP_3$-mediated $Ca^{2+}$ release, such as xestospongin, blocked the PMT-induced phase shift.

### *PMT as a tool for studying GIRK signaling*

Since the initial observation that prolonged treatment with PMT uncouples $G_q$-PLC signaling such that no further activation occurs through $G_q$ (Wilson *et al*., 1997; Wilson *et al*., 2000), several investigators have demonstrated the effectiveness of using prolonged PMT treatment to down-regulate $G_q$-mediated inhibition of G-protein-coupled inward rectifying $K^+$ (GIRK) channels. Bunemann *et al*. and Lei *et al*. used prolonged PMT treatment to shut down $G_q$-mediated inhibition of GIRK channels in human embryonic kidney HEK-293 cells (Bunemann *et al*., 2000, Lei *et al*., 2001). They were able to demonstrate the existence of two different regulatory pathways for PTx-insensitive inhibition of GIRK channels: one involving PMT-insensitive $G_{i/o}$-coupled $M_2$ mAChR muscarinic or 5-$HT_{1A}$ serotonin receptors and the other involving PMT-sensitive $G_q$-coupled $\alpha_{1A}$AR or thyrotropin-releasing hormone (TRH) receptors. Meyer *et al*. further showed that PMT is superior to the commonly used aminosteroid PLC inhibitor U73122 for down-regulating $G_q$-mediated inhibition of GIRK channels in cardiomyocytes (Meyer *et al*., 2001).

## PMT effects on Rho signal transduction and cytoskeletal function

### *PMT and Rho signaling*

PMT has been shown to indirectly induce Rho-dependent tyrosine phosphorylation of focal adhesion kinase ($p125^{FAK}$) and paxillin, which results in complex formation of $p125^{FAK}$ with the Src tyrosine kinase, actin stress fiber formation, and focal adhesion assembly (Lacerda *et al*., 1996; Ohnishi *et al*., 1998; Thomas *et al*., 2001). How PMT-mediated activation of the PLC-$IP_3$ signaling pathway promotes cytoskeletal rearrangement is not clear. However, tyrosine phosphorylation of $p125^{FAK}$ and paxillin is dependent on Rho, but appears to be independent of PKC activation or $Ca^{2+}$ mobilization (Lacerda *et al*., 1996; Ohnishi *et al*., 1998), two events resulting from PMT action on the PLC pathway. Inhibitors of serine/threonine protein kinases of the p160/ROK (Rho-associated coiled-coil-forming protein kinase) family, which are downstream targets of GTP-bound Rho, blocked PMT-induced phosphorylation of $p125^{FAK}$ (Thomas *et al*., 2001).

### *PMT and endothelial permeability*

PMT-induced Rho activation results in cell retraction and increased endothelial permeability (Essler *et al*., 1998). As shown in Figure 22.3, PMT disruption of endothelial integrity involves Rho-dependent activation of Rho kinase (ROK$\alpha$), which then inactivates myosin light chain (MLC) phosphatase PP1 and increases MLC phosphorylation and actin reorganization. This PMT-induced actin rearrangement was blocked by microinjection of the Rho inhibitor clostridial C3 transferase or by microinjection of the Rho-binding domain (RBD) or pleckstrin homology (PH) domain of ROK$\alpha$, which inhibits ROK$\alpha$ interaction with its regulators (Essler *et al*., 1998). PMT-mediated Rho activation has been speculated to be responsible for the observed vascular effects of PMT in dermonecrotic lesions from bite wounds (Aepfelbacher and Essler, 2001).

### *PMT and $G_q$-independent signaling*

PMT was shown to associate with vimentin (Shime *et al*., 2002), a component of intermediate filaments in cells, suggesting that this interaction may be involved in promoting cytoskeletal rearrangements. Another possibility is that PMT acts on the actin cytoskeleton indirectly through its action on Rho via $G_q$ or another yet unidentified $G_q$ family member (Katoh *et al*., 1998; Chikumi *et al*., 2002; Dutt *et al*., 2002; Vogt *et al*., 2003). In $G\alpha_q$- or $G\alpha_q/G\alpha_{11}$-deficient cells, PMT could still stimulate other cellular effects independent of $G_q$ or $G_{11}$, including Rho activation, Rho-dependent actin rearrangements and focal adhesions, and JNK and Erk mitogenic signaling (Zywietz *et al*., 2001). $G\alpha_{12/13}$ interaction with Rho-specific guanine nucleotide exchange factors can induce Rho-dependent responses (Sah *et al*., 2000). It may be that in the absence of $G_q$ or $G_{11}$, PMT acts on other related G proteins such as $G_{12}$ or $G_{13}$, both of which are known to activate Rho (Hart *et al*., 1998; Kozasa *et al*., 1998; Fukuhara *et al*., 1999; Gratacap *et al*., 2001; Kurose, 2003).

## PMT effects on mitogenic signal transduction

### *PMT and mitogenic signaling*

PMT acts on different cell types to initiate intracellular signal transduction events that result in DNA synthesis. PMT activates mature osteoclasts and induces proliferation and differentiation of periosteal (fibroblastic, osteogenic, and adipogenic) cells (Rozengurt *et al*., 1990; Mullan and Lax, 1996; Mullan and Lax, 1998). PMT stimulates the differentiation of preosteoclasts into osteoclasts and promotes osteoclast proliferation leading to bone resorption, while apparently inhibiting

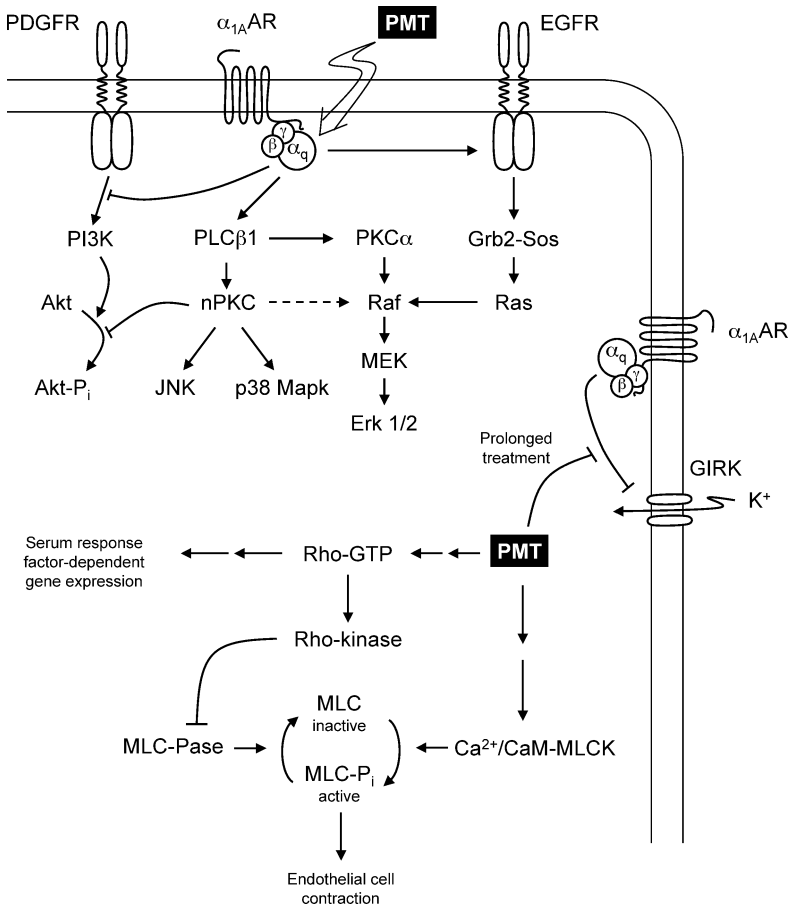

**FIGURE 22.3** Proposed model for PMT action on downstream signaling pathways. Shown is a schematic representation summarizing the proposed signaling pathways involved in PMT action. In this model activation of $G_q$ protein by PMT or $G_q$-coupled receptors, such as $\alpha_{1A}$AR, results in activation of PLCβ1, as well as transactivation of the EGF receptor via $G\alpha_q$ and inhibition of the PDGF receptor. In HEK-293 cells and cardiac fibroblasts, subsequent activation of the Erk1/2 kinase cascade is mediated by $G\alpha_q$ transactivation of the Ras-dependent EGF receptor tyrosine kinase pathway, with no significant contribution from the PLC-PKC pathway. In cardiomyocytes, PMT stimulates both the PLC-dependent $Ca^{2+}$ pathway and PKCα and novel nPKCs (PKCδ and PKCε), which in turn leads to activation of Erk1/2, as well as p38MAPK and JNK cascades. PMT both inhibits PDGF receptor-dependent PI 3-kinase (PI3K) activation and prevents subsequent activation of the Akt-dependent survival pathway. Release of $Ca^{2+}$ leads to activation of $Ca^{2+}$/calmodulin-dependent myosin light chain kinase ($Ca^{2+}$/CaM-MLCK), which then phosphorylates and activates MLC. PMT also stimulates the activation of Rho GTPase, stimulating Rho kinase to phosphorylate and thereby inactivates MLC phosphatase (MLC-Pase), which in turn prevents dephosphorylation of MLC, keeping it in its active state and causing cell contraction and endothelial permeability. Prolonged treatment with PMT down-regulates $G\alpha_q$-mediated signaling, including $G\alpha_q$-dependent inhibition of GIRK channels.

bone regeneration by osteoblasts (Sterner-Kock *et al.*, 1995; Mullan and Lax, 1998). In cultured epithelial cells, such as calf and monkey (Vero) kidney cells, calf testis, and bovine embryonic lung cells, PMT appears to cause morphological changes and cytopathic effects (Pennings and Storm, 1984; Rutter and Luther, 1984; Pettit *et al.*, 1993a; Sterner-Kock *et al.*, 1995; Dudet *et al.*, 1996). In cultured mesenchymal cells, such as murine, rat, and human fibroblasts, PMT action is mitogenic and initiates DNA synthesis and cell division (Rozengurt *et al.*, 1990; Mullan and Lax, 1996), which can promote anchorage-independent cell growth in soft agar (Higgins *et al.*, 1992), leading to the speculation that it can promote cell transformation and even cancer (Lax and Thomas, 2002). In agreement with these findings, flow cytometry analysis revealed that PMT stimulates fibroblast cells to move from the $G_1$ phase into and through the S phase without triggering apoptosis (Wilson *et al.*, 2000).

While PMT induced confluent Swiss 3T3 cells to increase in cell number up to three-fold, forming dense monolayers over the course of 4–6 days, cell cycle analysis revealed, however, that after the initial mitogenic response to PMT, cells subsequently arrested primarily in $G_1$ and became unresponsive to further PMT treatment (Wilson *et al.*, 2000). Consistent with these findings, PMT initially up-regulated the expression of a number of cell cycle markers, including the protooncogene c-Myc; the cyclins D1, D2, D3, and E; p21; PCNA; and the Rb proteins p107 and p130, yet continued expression of these markers, and hence continued proliferation, was not sustained (Wilson *et al.*, 2000). On the other hand, PMT exhibited a differential effect on epithelial-like cells. In confluent Vero cells, PMT induced rapid, dramatic morphological changes, but there was no increase in cell numbers or in the rate of DNA synthesis. Furthermore, PMT failed to up-regulate PCNA or cyclins D3 and E, markers critical for driving cells from $G_1$ into S phase; and hence, little or no cell cycle progression occurred in confluent Vero cells, which was further substantiated by flow cytometry analysis (Wilson *et al.*, 2000).

Mitogenic signaling stimulated by PMT appears to be different for different cell types. In some cells, PMT stimulation of Erk signaling occurs via $G_q$-dependent transactivation of epidermal growth factor (EGF)

receptor in a Ras-dependent manner, whereas in other cells, it occurs via a PKC-dependent, Ras-independent pathway (see Figure 22.3). In HEK-293 cells, both PMT and endogenous $G_q$-coupled α-thrombin receptors induced Ras-dependent Erk activation via PKC-independent transactivation of the EGF receptor (Seo *et al*., 2000). Expression of a dominant-negative mutant of the G-protein-coupled receptor kinase (GRK2) or a C-terminal peptide of $G\alpha_q$ ($G\alpha_{q305\text{-}359}$) blocked Erk activation by PMT and α-thrombin in these cells. In addition, PMT-stimulated Erk activation was blocked by dominant-negative inhibitors of mSos1 and Ha-Ras, as well as by an EGF-receptor-specific inhibitor tyrphostin (AG1478), but not by a PKC-specific inhibitor (GF109203X). PMT was similarly found to stimulate Erk activation via EGF receptor transactivation in cardiac fibroblasts; however, in cardiomyocytes novel PKC isoforms mediated PMT activation of Erk, p38MAPK, and JNK independently of the EGF receptor (Sabri *et al*., 2002).

PMT-mediated transactivation of tyrosine kinase signaling via $G_q$ activation was also reported for the generation of inositol phosphoglycans, which are second messengers of insulin signaling (Sleight *et al*., 2002). In this study, PMT stimulated the production of inositol phosphoglycans and interaction between the $G_q$ signaling pathway and the insulin receptor tyrosine kinase pathway, as evidenced by immunogold-labeling showing co-localization of the insulin receptor β subunit (IRβ) and $G\alpha_{q/11}$ in partially purified rat liver membranes, enriched in PLCβ1, clathrin, and caveolin-1.

### *PMT and apoptosis*

In neonatal rat cardiomyocytes, PMT and norepinephrine similarly induced cardiac hypertrophy, as evidenced by cellular enlargement of the cardiomyocytes, enhanced sarcomeric organization, and increased atrial natriuretic factor expression (Sabri *et al*., 2002). In these cells, PMT activated Erk, p38MAPK, and JNK via activation of PLC and novel PKC isoforms. PMT also decreased basal Akt activation by preventing Akt phosphorylation through the activation of EGF or insulin-like growth factor-1 (IGF-1), which led to cardiomyocyte susceptibility to apoptotic agents such as $H_2O_2$. This effect of PMT is reminiscent of what occurs upon intense, prolonged stimulation of cardiomyocytes by $G_q$-coupled receptors (Adams *et al*., 1998), where $G_q$-coupled receptor (or PMT) activation of $G_q$ stimulates cardiac hypertrophy, while inhibiting the Akt survival pathway and thereby promoting cardiomyocyte susceptibility to apoptosis. It is not known if PMT might cause similar effects in other cells, such as osteoblasts.

## PMT STRUCTURE AND FUNCTIONAL ORGANIZATION

### Sequence analysis

When the *toxA* gene was first isolated, cloned, and sequenced, no significant homologies to the primary sequences of any other proteins were found (Buys *et al*., 1990; Lax and Chanter, 1990; Lax *et al*., 1990; Petersen, 1990). However, shortly thereafter, additional members of the PMT dermonecrotic toxin family were reported, including the cytotoxic necrotizing factors type 1 and 2 (CNF1 and CNF2) from pathogenic *E. coli* (Falbo *et al*., 1993; Oswald *et al*., 1994), the dermonecrotic toxin (DNT) from *Bordetella* species (Walker and Weiss, 1994; Pullinger *et al*., 1996), and more recently the CNF homologue from *Yersinia pseudotuberculosis* ($CNF_Y$) (Lockman *et al*., 2002). CNF1 and CNF2 share 85% sequence identity (Oswald *et al*., 1994), and $CNF_Y$ shares ~65% homology with the *E. coli* CNFs (Lockman *et al*., 2002). PMT and CNF1/2 share 46% sequence similarity in their N-terminal 500 amino acids (Falbo *et al*., 1993; Oswald *et al*., 1994). Limited sequence similarity (<25%) between PMT and DNT (Walker and Weiss, 1994; Pullinger *et al*., 1996) can also be found in their N-terminal regions (Wilson *et al*., 1999). In addition, DNT and the CNFs share 55% similarity in their C-terminal 300 amino acids (see Figure 22.4).

### Localization of functional domains

Because PMT has cell binding, membrane translocation, and intracellular activities, it is believed to be composed of multiple functional domains and to belong to the family of AB toxins, as exemplified by diphtheria toxin. When the sequences of PMT and the related CNFs and DNT were first reported, there were no other matches in the databases that could provide clues about the functional domain structure of these proteins, although limited similarities in the C-terminus to putative metal-binding sites (Petersen, 1990), a

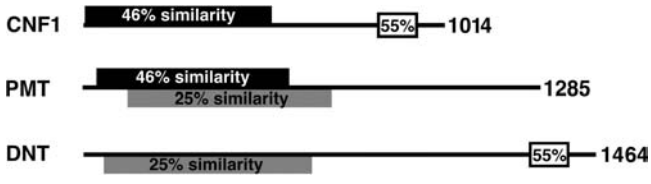

**FIGURE 22.4** Sequence comparison of the dermonecrotic toxins. Shown is a schematic representation indicating the regions of sequence similarity between PMT, CNF1, and DNT.

hydrophobic region between residues 380–470 (Lax *et al*., 1990), two amphipathic α-helices (Petersen, 1990), and a putative ADP-ribosyltransferase active-site His-Glu-Trp motif in the N-terminus (Lax *et al*., 1990) were described.

Single and double Ala substitution of the His and Glu residues of the putative ADP-ribosylation motif in PMT (His-29, Glu-155, and Trp-160) failed to diminish biological activity of the mutant proteins compared to wild-type PMT (Ward *et al*., 1994). Another study designed to detect toxin-catalyzed ADP-ribosylation in intact cells, in which the cellular pool of $NAD^+$ was metabolically labeled with [2-$^3$H] adenine, likewise failed to demonstrate PMT-mediated ADP-ribosylation of cellular proteins (Staddon *et al*., 1991b).

In a study to identify nontoxic, immunogenic vaccine candidates of PMT, four deletion mutants were expressed in *E. coli,* and the purified recombinant proteins were tested for biological activity and protective immunity (Petersen *et al*., 1991). Deletion of residues 175–247 generated an unstable recombinant protein that was found primarily in inclusion bodies. Deletion of residues 507–567 yielded a recombinant protein with 0.2% wild-type biological activity in the EBL cell assay and with 2% wild-type activity in dermonecrotic lesion and mouse lethality assays. Deletion of residues 28–149 resulted in a non-toxic protein that was able to provide protective immunity, while deletion of residues 1130–1285 resulted in a non-toxic protein that was unable to provide protective immunity. These results suggested that the C-terminus contains important immunological determinants required for neutralization of toxin and for providing protective immunity.

Specific antibodies against peptides derived from the N-terminus ($ToxA_{28\text{-}42}$), but not the C-terminus ($ToxA_{1239\text{-}1253}$), of PMT blocked the PMT-induced $Ca^{2+}$-dependent $Cl^-$ current in *Xenopus* oocytes (Wilson 1997). Consistent with this, microinjection of purified recombinant N-terminal (1–568, 1–505), but not C-terminal (505–1285, 1059–1285), deletion fragments of PMT into oocytes elicited toxin-induced responses (Wilson *et al*., 1999). However, other studies suggest that it is the C-terminus of PMT that has intracellular activity and that the N-terminus is the receptor-binding domain. In one of these studies, electroporation was used to introduce PMT fragments directly into EBL cells, and results indicated that C-terminal (581–1285), but not N-terminal (1–483, 1–1130), deletion fragments elicited morphology changes similar to intact PMT (Busch *et al*., 2001). In another study, fusion proteins of N-terminal (1–506) and C-terminal (681–1285, 849–1285) fragments of PMT with GST affinity tags at the N-terminus were microinjected into Swiss 3T3 cells and compared to intact PMT for morphology changes and biological activity (Pullinger *et al*., 2001). Results from this study suggested that the GST-fusion with residues 681–1285 induced morphology changes and mitogenesis similar to intact PMT, while the GST-fusion with the N-terminal fragment did not. The reason for the discrepancy between the results from these studies is not yet clear, but may be due to the nature of the properties of the recombinant PMT fragments and fusion proteins under the different experimental conditions used or may reflect that PMT has multiple binding and/or activity determinants.

PMT contains eight Cys residues at positions 26, 113, 230, 257, 793, 905, 1159, and 1165. Mutation of each of these residues revealed that there are probably no essential disulfide bonds and that only mutation of Cys-1159 and Cys-1165 resulted in reduced biological activity of PMT (Ward *et al*., 1998), with the Cys-1159-Gly mutant being about 10-fold reduced in mitogenic activity and the Cys-1165-Gly and Cys-1165-Ser mutants being greater than 10,000-fold reduced in activity. Although the role of the Cys-1165 residue in PMT activity was not determined in this study, another study in which wild-type and mutant proteins were electroporated directly into cells revealed that the Cys-1165-Ser mutant was unable to cause an increase in inositol phosphate levels (Busch *et al*., 2001).

Pretreatment of PMT with diethyl pyrocarbonate (DEPC), which covalently modifies His residues, inhibited the biological activity of PMT (Orth *et al*., 2003). DEPC-treated C-terminal fragment (581–1285) delivered by electroporation into EBL cells was blocked in its ability to stimulate PLC activity, as evidenced by reduced inositol phosphate accumulation. Consequently, the eight His residues located in the C-terminus of PMT (at positions 622, 635, 804, 1001, 1202, 1205, 1223, and 1228) were mutated to Ala or Leu, and their biological activities were compared with intact PMT (Orth *et al*., 2003). All but three of the mutants were fully active. The mutants His-1205-Leu and His-1223-Leu, and to a lesser extent His-1228-Leu, were significantly reduced in activity, suggesting the involvement of these His residues in PMT biological activity. In keeping with the earlier suggestion that this region contains a putative metal-binding motif (Petersen, 1990), it was suggested that these His residues might be involved in metal binding (Orth *et al*., 2003).

Recently, the involvement of the two predicted hydrophobic helices (residues 402–423 and 437–457) and the connecting hydrophilic loop (residues 424–436) in membrane translocation of PMT was tested by substitution of the acidic residues in the loop (Asp-425, Asp-431, Glu-434) with Lys (Baldwin *et al.,* 2004). Individual mutation of each of these residues caused up to a six-fold reduction in toxin translocation into

cells after binding to the surface in the presence of endocytosis inhibitor and then pulsing with low pH. On the other hand, mutation of Asp-401, which is outside of the predicted helix-loop-helix motif, completely abolished PMT activity. The reason for this observation was not determined, and it is not clear how this fits into the proposed model for translocation. Interestingly, comparison of the results for mutation of these residues in PMT with the results for the corresponding residues in CNF1 (Pei *et al*., 2001) suggested that if these regions are involved in membrane translocation then the mechanisms of translocation differ between PMT and CNF1 (Baldwin *et al*., 2004).

## Comparison with related toxins

### *Sequence comparison with DNT and CNF*

For DNT and the CNFs, the intracellular activity occurs through constitutive activation of the small G-protein RhoA (Oswald *et al*., 1994; Fiorentini *et al*., 1997; Flatau *et al*., 1997; Horiguchi *et al*., 1997; Schmidt *et al*., 1997), which regulates actin cytoskeletal function and is responsible for the formation of actin stress fibers and other cytoskeletal rearrangements. This activity is localized to the C-terminal 300 residues of DNT and the CNFs (Lemichez *et al*., 1997). However, PMT does not share this C-terminal sequence similarity. PMT also does not deamidate or polyaminate RhoA (Ohnishi *et al*., 1998) and does not act directly on RhoA (Lacerda *et al*., 1997; Ohnishi *et al*., 1998; Horiguchi, 2001). Thus, it is unlikely that PMT has a deamidase domain similar to that found in CNF or DNT.

Both CNFs are proteins of 1014 amino acid residues that share 85% sequence identity and 99% similarity (Falbo *et al*., 1993; Oswald *et al*., 1994). Because of the high homology between the two CNFs, it is believed that CNF2 has similar intracellular properties to that of CNF1. CNF1 has been shown to deamidate Gln-63 of RhoA (Flatau *et al*., 1997; Schmidt *et al*., 1997), a residue essential for the GTPase activity. The RhoA-deamidase domain also possesses transglutaminase activity and can incorporate alkylamines into RhoA at the Gln-63 position (Schmidt *et al*., 2001). This activity involves two essential C-terminal residues, Cys-866 and His-881 (Schmidt *et al*., 1998). The crystal structure of the Rho-activating domain of CNF1 is available (Buetow *et al*., 2001). Recent evidence suggests that the receptor-binding domain is located at the N-terminus (Fabbri *et al*., 1999; Meysick *et al*., 2001; Pei *et al*., 2001).

DNT is a 1464 amino acid protein produced by various *Bordetella* species (Walker and Weiss, 1994). The DNTs produced by *B. bronchiseptica, B. pertussis*, and *B. parapertussis* are nearly identical (>99% homology). DNT causes dermonecrosis in mice, forming hemorrhagic lesions at the site of inoculation. In osteoblast-like MC3T3-E1 cells, DNT changes cell morphology and inhibits differentiation into osteoblasts (Horiguchi *et al*., 1993). In fibroblast cells, DNT, like the CNFs, stimulates actin stress fiber formation and cytoskeletal rearrangements via Gln-63 deamidation and constitutive activation of RhoA (Horiguchi *et al*., 1995; Horiguchi *et al*., 1997; Ohnishi *et al*., 1998). DNT has also been shown to modify the Rho-related GTPases Rac1 and Cdc42 (Horiguchi *et al*., 1997; Masuda *et al*., 2002). Evidence suggests that the receptor-binding domain is located at the N-terminus (Matsuzawa *et al*., 2002).

### *Activity comparison with DNT and CNF*

One question of interest is the relationship between the structural similarities and the activities of the three toxins. PMT, DNT, and the CNFs cause dermonecrotic lesions at the site of injection in animal skin assays. How the molecular activity of these toxins translates into dermonecrotic lesions is not clear. Considering that PMT has been shown to induce IL-6 production in certain cells (Rosendal *et al*., 1995), it is possible that an inflammatory response contributes to dermonecrosis. On the cellular level, they all appear to cause similar, but not identical, effects on the cytoskeleton in cultured cells (Dudet *et al*., 1996; Lacerda *et al*., 1996; Horiguchi *et al*., 1997; Lacerda *et al*., 1997; Ohnishi *et al*., 1998). All three toxins stimulate DNA synthesis and actin cytoskeletal rearrangements, although through different mechanisms (Ohnishi *et al*., 1998).

CNF1 induces macropinocytosis in epithelial cells (Fiorentini *et al*., 2001) and phagocytic behavior in HEp-2 cells through activation of membrane ruffling (Falzano *et al*., 1993), which can trigger entry of noninvasive bacteria into cells and may contribute to its role in pathogenicity. Unlike PMT, the CNFs and DNT do not induce PLC activation, PKC activation, or $Ca^{2+}$ mobilization (Ohnishi *et al*., 1998). DNT and the CNFs stimulate DNA synthesis, but cell division does not occur; instead, cytokinesis is blocked during mitosis, resulting in large bi- and multinuclear cells. On the other hand, PMT stimulates DNA synthesis, but without adversely affecting cell division, and instead causes cell proliferation. Whereas PMT was shown to activate the MAPK pathway (Seo *et al*., 2000; Wilson *et al*., 2000), CNF1 and DNT did not (Lacerda *et al*., 1997). All three toxins have been shown to induce cytoskeletal changes through Rho-dependent tyrosine phosphorylation of p125FAK and paxillin; however, CNF and DNT do so by direct activation of Rho, whereas PMT appears to do so through indirect activation of Rho (Horiguchi *et al*., 1995; Lacerda *et al*., 1996; Lacerda *et al*., 1997; Thomas *et al*., 2001).

## CONCLUSION

Compared to the current knowledge of the structure and function of other bacterial protein toxins, particularly for the ADP-ribosylating, α-hemolysin-like, anthrax, and neurotoxin families of toxins, our understanding of PMT structure and activity is at a much earlier stage, and a number of outstanding questions remain about its functional organization, additional intracellular targets, and biochemical activity. Yet, because of its unique action on $G_q$, PMT is already being used as a potent research tool in deciphering cellular signal transduction pathways involving $G_q$-proteins. PMT facilitation of $G_q\alpha$-protein coupling to PLCβ1 causes the same cellular responses elicited by $G_q$-protein-coupled receptors. Down-regulation of $G_q$-PLC signaling upon prolonged PMT treatment also allows for distinguishing between PTx-sensitive and PTx-insensitive signaling pathways that involve $G_q$. Understanding the biochemical mechanism of PMT action may thus afford unique insight into the molecular signaling events involved in regulation of cell function, growth, and differentiation.

CHAPTER

# 23

# Cytolethal distending toxins

*Monica Thelestam and Teresa Frisan*

## INTRODUCTION

The first cytolethal distending toxin (CDT) was reported in 1987 as a novel type of toxin activity produced by pathogenic strains of *Escherichia coli*. The major hallmark of the observed cytotoxic effect was a remarkable cell distention, evident 3–5 days after addition of bacterial culture supernatants to cells growing *in vitro*, and resulting after a few more days in cell death (Johnson and Lior, 1987a). The same authors later identified a similar activity in *Shigella* (Johnson and Lior, 1987b) and *Campylobacter* spp (Johnson and Lior, 1988a), and they designated this putative toxin as "cytolethal distending toxin" (CDT), based on the conspicuous morphological effect (Figure 23.1).

It is now clear that the CDTs are produced from three linked genes, which are designated *cdtA*, *cdtB*, and *cdtC* and encode the proteins (CdtA, CdtB, CdtC) (Figure 23.2) with predicted molecular masses of around 25, 30, and 20 kDa, respectively. Several Gram-negative bacteria have been shown to produce CDTs, such as *Shigella spp* (Okuda *et al*., 1995), *Campylobacter jejuni* (Pickett *et al*., 1996), *Haemophilus ducreyi* (Cope *et al*., 1997), *Actinobacillus actinomycetemcomitans* (Mayer *et al*., 1999; Sugai *et al*., 1998), and several *Helicobacter spp* (Chien *et al*., 2000; Kostia *et al*., 2003; Taylor *et al*., 2003; Young *et al*., 2000b). So far no Gram-positive bacterium is known to produce CDT. The CDT-producing bacteria are listed in Table 23.1.

The CDT gene products have no immediate resemblance to any other known proteins, but using the PSI-BLAST search technique, a DNase I–like enzymatic activity could be identified in the CdtB component of CDTs from *E. coli* and *C. jejuni*, respectively (Elwell and Dreyfus, 2000; Lara-Tejero and Galan, 2000). The proposed DNA damaging effect was consistent with parallel observations on the *Haemophilus ducreyi* CDT, as the cellular responses to this CDT were identical to the cell cycle checkpoint responses evoked by ionizing radiation (IR), a well-known DNA damaging agent (Cortes-Bratti *et al*., 2001b). Indeed, we could show later that the *Haemophilus ducreyi* CDT (HdCDT) induces DNA double-strand breaks (DSBs) upon natural intoxication of mammalian cells (Frisan *et al*., 2003), thus attaining direct proof for the CDT attack on DNA. Moreover, the recently solved crystal structure of the HdCDT holotoxin revealed that this toxin consists of an enzyme belonging to the DNase I family (CdtB), which is associated with two ricin-like lectin domains (CdtA and CdtC) (Nesic *et al*., 2004).

Even though all CDTs have the same enzymatic activity, the CDT variants produced by different bacterial species might vary with regard to receptor specificity and internalization pathway. Therefore, we have proposed a nomenclature to avoid a confusing flora of different names in the literature on CDTs (Cortes-Bratti *et al*., 2001a). A particular CDT is specified exactly by indicating the initials of the producing bacterium before CDT and, if necessary, the strain number or other common designation after CDT (e.g., HdCDT: *H. ducreyi* CDT or EcCDT-III: *E. coli* CDT type III), as indicated in Table 23.1.

All previously known bacterial protein toxins attack either the plasma membrane or various targets located in the cytosol. The CDTs represent a completely novel concept among bacterial toxins, as they act instead on DNA. Therefore, this exciting family of toxins raises interesting questions that are novel to the field of toxinology. For instance, how does the active subunit of CDT reach its target, i.e., which is the molecular

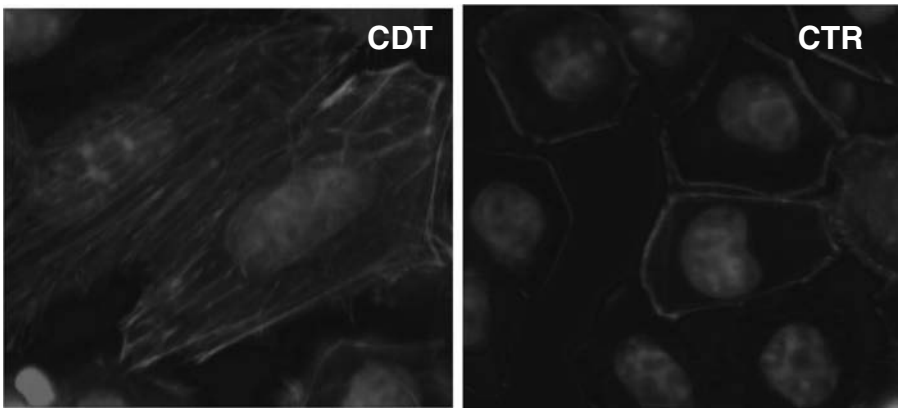

**FIGURE 23.1** CDT intoxication induces cell distention and promotion of actin stress fibers. HeLa cells were either left untreated (CTR) or exposed to HdCDT (CDT, 2μg/ml), and further incubated for 24h. F-actin was stained with FITC-phalloidin, and nuclei were counterstained with Hoechst 33258.

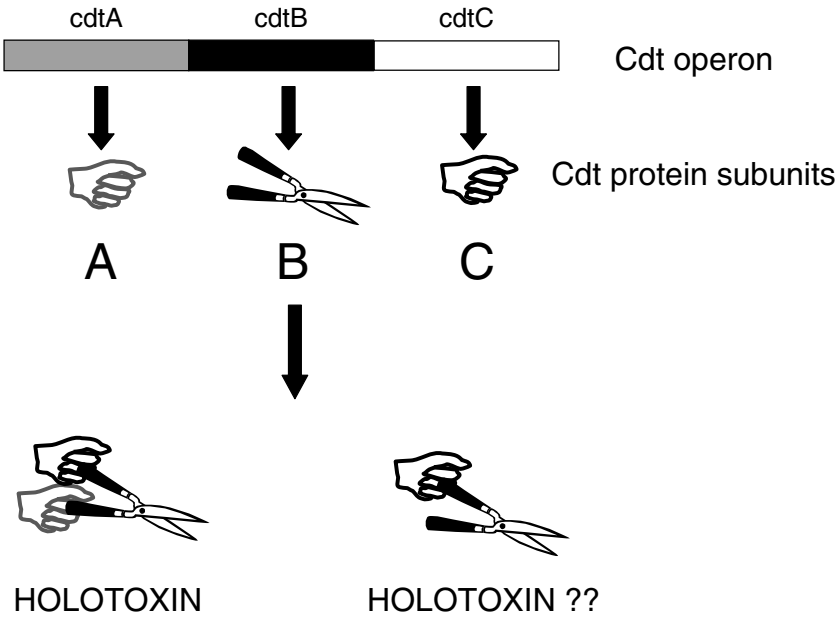

**FIGURE 23.2** Schematic representation of the three linked CDT genes and the respective protein subunits. CdtB is the active subunit, which causes DNA damage. CdtA and CdtC are required for binding the holotoxin to the plasma membrane of the target cell. Although the tripartite holotoxin (CdtA+CdtB+CdTC) has been found to be the most potent inducer of cellular intoxication, some doubts still exist as to whether this is the only possible subunit combination. This issue is discussed in the text.

mechanism for the transport of CdtB to the nucleus? Which are the molecular details for the action of CDT on DNA and which are the cellular responses, both immediate and long-term, to this unusual action of a bacterial protein toxin? Because of the genotoxic activity, the possibility exists that CDT could be disease related, not only as a cytotoxic agent in the pathogenesis of infections, but also in the long term as a potentially carcinogenic agent. However, the same genotoxic activity also makes this family of toxins particularly interesting as a basis for immunotoxins with good potential for anti-tumor activity.

This chapter will deal with several aspects of CDTs, but since this toxin family is relatively young, the main focus will be on their molecular action on mammalian cells. We will follow the toxin from the moment it meets the plasma membrane of a target cell until it reaches its target, and we will discuss how various types of cells respond to the toxin attack. The possible pathogenic roles of CDTs will also be discussed briefly, as well as potential practical applications of CDTs in the biomedical field.

## ACTION OF CDT ON MAMMALIAN CELLS

### The players: functions of the three different CDT subunits

Early genetic studies demonstrated that all three *cdt* genes need to be expressed in the producing bacterium for the generation of active (cytotoxic) CDT (Cope *et al.*, 1997; Pickett *et al.*, 1994; Pickett *et al.*, 1996; Sugai *et al.*, 1998; Young *et al.*, 2000b). However, the difficulty in

obtaining highly purified separate subunits from bacteria, which possess the entire *cdt* operon, created some confusion regarding the roles of the different subunits. Current studies are usually performed with recombinant CDT, but some discrepancies still remain and clarifying the roles of the subunits in cellular intoxication by CDT constitutes one of the most important frontiers in current CDT research. Therefore, we will start with a brief discussion of each subunit to set the scene for the ensuing journey from plasma membrane to nuclear target.

### *CdtB*

As stated previously, CdtB is definitely the most important active subunit showing DNase activity *in vitro* and *in vivo*. CdtB of various origins is cytotoxic after microinjection (Lara-Tejero and Galan, 2000) or electroporation/facilitated entry into cells (Elwell *et al.*, 2001; Mao and DiRienzo, 2002; Yamamoto *et al.*, 2004). In contrast, extracellularly added CdtB is not able to bind to most target cells and consequently is not cytotoxic by itself. Although the CdtB subunit of the AaCDT alone could cause G2 arrest in PHA-activated human T cells (Shenker *et al.*, 2000; Shenker *et al.*, 1999), the same authors later demonstrated that the presence of both the CdtA and CdtC subunits was required to achieve maximum cell cycle arrest in Jurkat cells (Shenker *et al.*, 2004). A holotoxin comprised of CdtABC was more than 50,000-fold more toxic to these cells than preparations containing either CdtAB or CdtBC. Thus, there is general consensus today that all three subunits must be added together for extracellularly induced maximal intoxication (Lara-Tejero and Galan, 2001; Lee *et al.*, 2003).

### *CdtA*

Shenker and coworkers (Shenker *et al.*, 2004) reported that a monoclonal antibody against CdtC co-precipitated CdtA and CdtB from extracts of CDT-producing *A. actinomycetemcomitans*. Interestingly, only a truncated form of CdtA (18 kDa) was detectable within this complex, suggesting that CdtA may undergo processing during the holotoxin assembly. The expression of two immunoreactive CdtA proteins corresponding to 25 and 18 kDa has been observed also for the HdCDT (Frisk *et al.*, 2001). CdtA seems to be able to bind to target cells, but alone it lacks cytotoxic activity (Lee *et al.*, 2003; Mao and DiRienzo, 2002). Also, the combination

of only CdtA and CdtB was without cytotoxicity on HeLa cells (Lara-Tejero and Galan, 2001; Lee *et al*., 2003). It is unclear whether the CdtA in these cases was in the truncated form or not.

### *CdtC*

CdtC has also been reported to be somehow processed in the holotoxin environment. The isoelectric point (pI) of the HdCdtC component was 1.5 pH units higher in recombinant strains expressing all three components than in recombinant strains expressing the CdtC protein alone (Frisk *et al*., 2001). A similar change of pI occurred after mixing the three individual recombinant components *in vitro*. Thus, it was suggested that HdCdtA/B may exert some kind of processing activity on HdCdtC, rendering it active (Deng *et al*., 2001; Frisk *et al*., 2001). Recently, however, the purified recombinant His-tagged AaCdtC alone, delivered to the cytosol with a lipid protein carrier, was found able to induce cell distention and eventually the death of CHO cells (Mao and DiRienzo, 2002). The specific mechanism of this putative CdtC cytotoxicity has not been elucidated.

### *Cytotoxicity of combined CdtB and CdtC*

Mao and DiRienzo (Mao and DiRienzo, 2002) also found an additive cytotoxic effect exerted by the combination of AaCdtB and AaCdtC when delivered into the cytosol together. We previously observed cytotoxicity with an extracellularly added, highly purified preparation of HdCDT in which we were not able to detect CdtA by Western-blot analysis (Li *et al*., 2002). This is consistent with the observation that extracts from *H. ducreyi* producing CDT in which the *cdtA* gene was mutated still had some cytotoxic activity (Lewis *et al*., 2001). Also, other workers reported the combination of purified HdCdtB with HdCdtC to be slightly cytotoxic (Wising *et al*., 2002). Likewise, a mixture of recombinant AaCdtB and AaCdtC could induce cell cycle arrest in HEp-2 cells, as measured by FACS analysis 72 h after toxin exposure (Akifusa *et al*., 2001). Similarly, the combined recombinant subunits CjCdtB and CjCdtC were able to induce G2 arrest in HeLa cells upon extracellular addition (Lee *et al*., 2003). On a microgram basis, however, this combination was only about 25% as effective as the tripartite CjCDT holotoxin. It would be of interest to determine the toxin amount produced by the bacteria *in vivo*, in order to understand whether the CdtB/C combination could have any physiological relevance.

In conclusion, the most reasonable interpretation of the combined current data on the CDT subunits is that CDT functions as an AB-toxin, where the DNase CdtB constitutes the active subunit, and a CdtAC heterodimer constitutes the optimal cell membrane-binding subunit. This tripartite holotoxin is the subunit combination with maximal activity in all tested cell systems. Apparently, the CdtC subunit alone can also function as a binding subunit, facilitating the cellular entry of CdtB, albeit with a much lower efficiency than the heterodimeric binding unit. That the AaCdtB alone can act on Jurkat cells (Shenker *et al*., 2004; Shenker *et al*., 2000) may have to do with specific properties of T cells, which in contrast to epithelial cells or fibroblasts appear able to bind and take up CdtB. The CDT binding process will be discussed in more detail in the next section.

## Pathway for the cellular internalization of CDT

Since CDT acts on DNA, it is conceivable that this toxin, like other intracellularly acting toxins, after binding to the cell surface has to be internalized and transported inside the target cell to the nucleus before it can act. In this section, we will discuss some recent studies relevant for both the binding and the internalization processes.

### *Cell surface binding of CDT subunits*

Different CDTs have a documented ability to intoxicate cells even after exposure times as short as 2 to 15 minutes (Aragon *et al*., 1997; Cortes-Bratti *et al*., 1999), and HdCDT could be absorbed out from the medium by repeatedly passing the same toxin solution over fresh HEp-2 cell cultures (Frisk *et al*., 2001). Such functional studies indirectly suggested that CDTs bind to cells rapidly and irreversibly, although no specificity of the binding could be demonstrated. It was earlier pointed out that a region in the CjCdtA, encompassing the amino acids 160 through 220, exhibits a lectin fold, which is also present in the binding subunits of the plant toxins ricin and abrin (Lara-Tejero and Galan, 2001). The recently determined crystal structure of HdCDT reinforced this observation and underscored the presence of a ricin-like lectin domain also in HdCdtC.

When recombinant HdCdtA and HdCdtC were produced from two plasmids and expressed in the same *E. coli*, a non-covalent CdtA-CdtC complex was formed in the absence of CdtB (Deng and Hansen, 2003). This CdtA-CdtC complex after association with HeLa cells (30 min, 4°C) was able to bind subsequently added CdtB, leading to cell killing within 72 h. Moreover, HeLa cells pretreated for 30 minutes at 37°C with the CdtA-CdtC complex were reported to become resistant to the cell killing induced by high concentrations of subsequently added HdCDT holotoxin (*H. ducreyi* culture supernatant). Surprisingly, however, such treated

cells turned out not to be resistant to the cell distention induced by lower amounts of the holotoxin (Deng and Hansen, 2003). This observation suggests that the cellular intoxication was not completely prevented.

Another recent piece of work considerably advanced our knowledge about binding of the CjCDT subunits to the HeLa cell surface (Lee *et al*., 2003). By competitive experiments, Lee and coworkers demonstrated that both the CdtA and CdtC subunits, but not CdtB, could bind specifically to the HeLa cell surface as detected by an enzyme-linked immunosorbent assay on living cells (CELISA). In unlabeled form, these subunits were able to reduce the binding of the corresponding biotinylated subunit. Interestingly, they could also compete with each other, suggesting that CdtA and CdtC were binding to the same receptor on the cell surface (Lee *et al*., 2003). Indeed, these two subunits of the CjCDT share about 40% sequence similarity with each other. McSweeney and Dreyfus recently noted the same binding competition between the CdtA and CdtC subunits of the EcCDT-II (McSweeney and Dreyfus, 2004).

Lee and coworkers (Lee *et al*., 2003), in addition, produced in-frame deletion mutants of CdtA and CdtC from which 43 and 22 amino acids, respectively, were deleted. Since the CdtA subunit from different bacteria shows several regions of homology, the authors chose to delete one of these regions from CjCdtA (amino acids 126–168). The amino acids 115–136 were deleted from the CjCdtC subunit because they were located in the region of highest homology between CdtCs from different bacteria. Both these mutant subunits in biotinylated form were still able to bind HeLa cells. Moreover, each mutant subunit was able to compete with the binding of both wild-type subunits, as well as that of the holotoxin. The binding of the CDT holotoxin decreased nearly fivefold in the presence of the CdtA mutant subunit and almost threefold in the presence of the CdtC mutant subunit. These interesting findings suggest that the deleted regions in each Cdt subunit do not play any significant role in cell surface recognition. On the other hand, the mutant subunits were unable to interact with CdtB and/or each other to reconstitute an active holotoxin, indicating that the deleted regions were instead critical for effective holotoxin formation (Lee *et al*., 2003).

### *Receptor for CDT*

No specific receptor for any CDT subunit has yet been identified, although receptor studies are currently going on in several laboratories. We recently demonstrated by immunofluorescence microscopy for the first time the direct binding of a CDT to the HeLa cell surface, using GST-labeled or fluorescein-conjugated HdCDT (Figure 23.3). Interestingly, we also found that extraction of membrane cholesterol with methyl-β-cyclodextrin (mβCD) before adding the toxin prevented cell surface binding of HdCDT and consequent intoxication (Guerra *et al*., 2005). Thus, it is likely that the receptor, at least for this variant of CDT, will be found among components enriched in the membrane microdomains known as lipid rafts, whose integrity is disrupted by drugs that extract cholesterol. It is also interesting to note that we were unable to demonstrate any binding of HdCDT to BalbC 3T3 fibroblasts, which have been previously reported to resist intoxication by CDT (Figure 23.3 and Cortes-Bratti *et al*., 1999). Apparently, the reason for their complete resistance is the lack of a functional CDT receptor, and this information might be helpful in future receptor studies.

### *Internalization of CDT and transport of CdtB via the Golgi complex and the ER*

The internalization process occurring after CDT binding to the cell surface has been studied only for the HdCDT. This toxin was reported to enter HEp-2/HeLa cells by endocytosis via clathrin-coated pits (Cortes-Bratti *et al*., 2000). The cellular intoxication was completely inhibited at conditions that block the fusion of early endo-

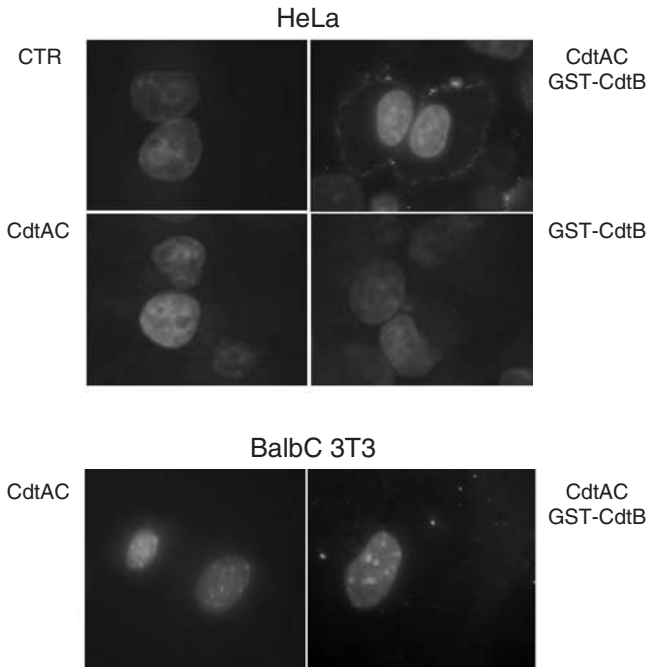

**FIGURE 23.3** Binding of CDT on the plasma membrane of sensitive cells. HeLa and BalbC 3T3 cells were left untreated (CTR) or exposed to the following subunit combinations: (i) CdtA+CdtC; (ii) GST-CdtB alone; (iii) CdtA+CdtC+GST-CdtB for 20 min on ice (the final concentration of each subunit was 0.2μg/μl). CDT binding was assessed by immunofluorescence staining, using a FITC-conjugated, anti-GST antibody. Nuclei were counterstained with Hoechst 33258.

somes with downstream compartments. Likewise, treatment of cells with agents that disrupt the Golgi complex (Brefeldin A, BFA, and Ilimaquinone) blocked the intoxication, suggesting that the toxin required transport in vesicles at least to the Golgi complex before its activity could be expressed (Cortes-Bratti *et al*., 2000). However, since BFA can affect also the transit through endosomes (van Dam *et al*., 2002), we have recently extended these observations by utilizing MDCK cells for which the Golgi complex, but not the endosomal compartment, has been shown to be BFA resistant (Hunziker *et al*., 1991). BFA did not induce any significant change in the HdCDT-induced intoxication of MDCK cells, in contrast to the results in HeLa cells, again supporting the involvement of the Golgi complex. Finally, a direct proof of CDT transit via the Golgi complex was recently obtained, since a CdtB genetically engineered to contain a sulfation site was shown to become sulphated, a reaction known to take place only in the Golgi complex (Guerra *et al*., 2005).

Several bacterial protein toxins have been shown to undergo retrograde transport from the Golgi complex to the ER. To clarify this aspect for HdCDT, we added also three N-glycosylation sites at the C-terminal of the CdtB subunit and were able to demonstrate its glycosylation. This finding indicated for the first time that HdCDT is also transported to the ER, the exclusive site for N-glycosylation reactions (Guerra *et al*., 2005).

***How does the CdtB subunit reach the nucleus?***

Toxins that are retrogradely transported to the ER and act on cytosolic targets, such as the ETA, ricin, and cholera toxin, are known to enter the cytosol only from the ER. The proposed mechanism for their transmembrane translocation involves the ER-associated degradation (ERAD) pathway (Simpson *et al*., 1999; Teter and Holmes, 2002), known to translocate misfolded secretory and ER membrane proteins into the cytosol for proteolytic degradation (Hampton, 2002). Several lines of evidence suggest that the ERAD pathway, using the Sec61p translocon, is essential for mediating cytosolic translocation of toxins that act in the cytosol, such as ricin and Shiga toxins. Both CHO (Teter and Holmes, 2002) and *S. cerevisiae* (Simpson *et al*., 1999) cells defective in various aspects of the ERAD pathway are resistant to ricin intoxication. Furthermore, sulfated and glycosylated ricin can be co-precipitated with anti-Sec61p–specific antibodies (Wesche *et al*., 1999). Also, cholera toxin is associated with and requires a functional Sec61p complex to be translocated from microsomes derived from porcine pancreas (Schmitz *et al*., 2000). In the case of the CDTs, there are two major options for reaching the molecular target: (i) CDT is translocated from the ER to the cytosol, perhaps as the toxins mentioned above, and then it enters the nucleus via nuclear pores or other transport mechanisms, or (ii) CDTs are directly translocated from the ER to the nucleus without any passage through the cytosolic compartment. Several groups are currently working on this interesting issue, as discussed below.

*Nuclear localization signals*

CdtB contains no known conventional nuclear localization signal (NLS). However, microinjection experiments in HeLa cells showed that a 76 amino acid stretch in the amino-terminal region (residues 48–124) in the AaCdtB constitutes an atypical NLS (Nishikubo *et al*., 2003). After microinjection, His-tagged CdtB-GFP entered the nucleus in 3–4 h. A lack of effect of leptomycin B on the speed of nuclear entry suggested that the relatively slow entry of the fusion protein was not due to CRM1-dependent nuclear export of the protein. An *in vitro* transport assay demonstrated that the nuclear localization of CdtB was mediated via active transport requiring ATP and physiological temperature. Moreover, cells treated extracellularly with a holotoxin containing mutant CdtB, with an 11-amino acid truncation in the identified NLS, were unaffected. This observation suggested that the identified amino-terminal NLS may be functional for nuclear localization of the toxin also when mammalian cells are naturally intoxicated with the holotoxin added extracellularly (Nishikubo *et al*., 2003). Subsequently, however, two NLS sequences, designated as NLS1 and NLS2, were identified in the carboxy-terminal region of the EcCdtB-II. Cell cycle arrest and nuclear localization were impaired in cells treated with CDT containing EcCdtB-II-ΔNLS mutants, while the *in vitro* DNase activity and the cell surface binding of the mutant holotoxins were not affected. Interestingly, fluorescence microscopy analysis showed a diffuse cytoplasmic distribution of the mutant CdtB in cells exposed to a CDT holotoxin containing the EcCdtB-II-ΔNLS2 subunit, while the EcCdtB-II-ΔNLS1 subunit localized preferentially in a perinuclear region upon internalization (McSweeney and Dreyfus, 2004).

*ERAD and Derlin-1 pathways are not required*

These interesting studies still do not tell us whether in natural intoxication the nuclear entry of CdtB takes place from the cytosol or directly from the ER. Therefore, we have recently studied HdCDT intoxication in mutant cell lines, defective in the only two ER-to-cytosol translocation machineries characterized so far—the ERAD and the Derlin-1 dependent pathways.

To assess whether the ERAD pathway is necessary for efficient translocation and intoxication of target cells by HdCDT, we used a set of Chinese hamster ovary (CHO) cell clones, which had been selected for resistance to ricin, ETA, and cholera toxins, due to an altered ERAD system (Teter and Holmes, 2002; Teter *et al*., 2003). These mutant cell lines are subgrouped in two classes: (i) one clone presenting a deficient translocation of proteins from the ER to the cytosol (CHO 16D), and (ii) two clones presenting an enhanced cytosolic degradation of retro-translocated proteins (CHO 23G and CHO 24D). Using the minimal toxin concentration able to induce cell cycle arrest in the parental CHO cells, we found that all three CHO mutant cell lines were equally sensitive to HdCDT intoxication as the parental cells, whether assessed by cell cycle arrest after 24 h or by a colony assay after two weeks (Guerra *et al*., 2005).

It has been shown recently that retro-translocation into the cytosol of a subset of proteins involves a human homologue of the yeast Der1 protein, named Derlin-1 (Lilley and Ploegh, 2004; Ye *et al*., 2004). To assess whether HdCDT internalization is Derlin-1 dependent, we investigated the sensitivity to HdCDT of HeLa cells expressing Derlin-$1^{GFP}$, which acts in a dominant negative manner, blocking the transport of proteins from the ER to the cytosol (Lilley and Ploegh, 2004). Interestingly, HeLa cells expressing the dominant negative Derlin-$1^{GFP}$ were found to be equally sensitive to HdCDT as the control cell lines were (Guerra *et al*., 2005).

Based on these observations, we were able to conclude that the trafficking of HdCDT at least does not involve any of these two ER-to-cytosol translocation pathways.

The data collected so far demonstrate that HdCDT and other toxins such as ricin, ETA, and cholera toxin follow a similar internalization pathway down to the ER. However, a major difference was observed when the requirement for the ER-associated degradation (ERAD) pathway was tested, since our results with HdCDT suggest that this toxin either does not need to transit to the cytosol before entering the nucleus, or alternatively that its translocation to the cytosol occurs via a different pathway. Since we also excluded a putative exit of HdCDT via the other known ER-cytosol translocation pathway (Lilley and Ploegh, 2004; Ye *et al*., 2004), we favor the hypothesis that HdCDT is transferred directly from the ER to the nucleus without passage through the cytosol.

As already mentioned, Mc Sweeney and Dreyfus (McSweeney and Dreyfus, 2004) noted that deletion of each of the C-terminal NLSs from the *E. coli* CdtB-II subunit produced a differential localization of the active toxin subunit. Cells intoxicated with a holotoxin containing the EcCdtB-II-ΔNLS1 displayed a perinuclear distribution of the active component, consistent with its trapping in the late endosome and/or ER compartment. On the other hand, a diffuse cytoplasmic staining was observed in cells exposed to the EcCdtB-II-ΔNLS2-containing toxin. Thus, the NLS1 might be crucial for ER-to-nucleus transport. An interesting possibility is that the NLS2 may act as scavenger motif to retrieve CdtB molecules that have escaped to the cytosol, similar to the suggested ER retention function of the KDEL sequence in cholera toxin (Lencer and Tsai, 2003). Also, the findings that the nuclear transport of wild-type AaCdtB required ATP and physiological temperature and was relatively slow (Nishikubo *et al*., 2003) are fully compatible with the hypothesis that CdtB is transported directly from the ER to the nucleus. It is more difficult, however, to reconcile the observations that the NLSs in the Aa-CdtB and Ec-CdtB-II, respectively, are located in entirely different parts of the CdtB molecules.

In conclusion, we hypothesize that the CdtB nuclear translocation requires an atypical mechanism, which has still not been characterized, but involves a direct translocation from the ER to the nucleus. Very recently, a new reticular network has been identified and designated as nucleoplasmic reticulum (Echevarria *et al*., 2003). This organelle is described as a fine, branching intranuclear network that is continuous with the nuclear envelope and the ER. A high degree of complexity of the ER network is further demonstrated by the fact that specific ER molecules can be found on phagosomes upon phagocytosis (Desjardins, 2003). Interaction between phagosomes and the ER might also explain how the *Salmonella typhi* CdtB (StCdtB), expressed only upon bacterial internalization and in the absence of CdtA and CdtC, could gain access to the nuclear compartment within 3–4 h after cellular infection (Haghjoo and Galan, 2004).

In a recent paper, Shenker and colleagues questioned whether the relevant activity of the CDT family of toxins is a DNase-like activity, and they suggested that the cytotoxic effects might be triggered upon toxin-induced transmembrane signaling from the cell surface (Shenker *et al*., 2004; Thelestam and Frisan, 2004). However, the studies cited previously demonstrate beyond any doubt that at least the active CdtB subunit has to be endocytosed and undergo intracellular transport to the nucleus before it can damage cells. Nothing has yet been reported regarding the cellular localizations and fates of the other two toxin subunits.

Figure 23.4 summarizes the internalization pathway of CDTs.

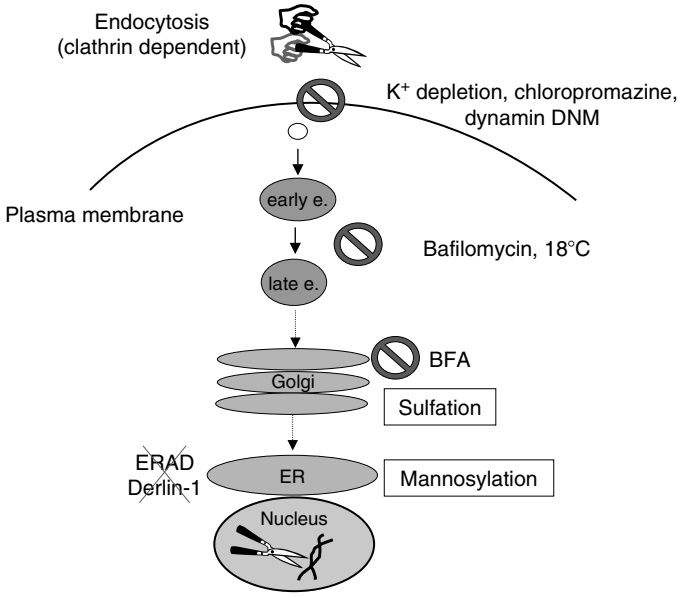

**FIGURE 23.4** CDT internalization pathway. CDTs are internalized via clathrin-dependent endocytosis into early and late endosomes. The CdtB subunit further transits to the Golgi complex (as assessed by sulfation experiments), and is then retrogradely transported to the endoplasmic reticulum (ER), as assessed by N-linked glycosylation. Further translocation from the ER does not require the ER-associated degradation (ERAD) pathway and is Derlin-1 independent.
The symbol Ø indicates that intoxication was abolished by the use of specific inhibitors or treatments.
Dynamin DNM: dynamin dominant negative mutant. BFA: Brefeldin A.

## Molecular mode of action of CDT

The next few sections will deal with the effect of CDTs on DNA, as well as the many cellular responses evoked by the CDT-induced DNA damage.

### *CdtB is a DNase*

On close analysis, all CdtBs turn out to have structural and functional homology to mammalian DNase I. The first description of position-specific homology between the CdtB subunit from EcCDT-II and mammalian DNase I was published by Elwell and Dreyfus (Elwell and Dreyfus, 2000). The homology pattern was found at specific residues that are involved in enzyme catalysis (Glu86, His154, Asp229, His261), DNA binding (Arg123, Asn194), and metal ion binding (Glu62, Asp192, Asp260). EcCdtB-II also contains a pentapeptide sequence (aa 259-263: Ser-Asp-His-Tyr-Pro) found in all DNase I enzymes. Shortly after, similar conserved residues were described for the *Campylobacter jejuni* CdtB (CjCdtB), and in fact identified in all known CdtBs (Lara-Tejero and Galan, 2000). The crystal structure of HdCdtB has been recently solved, and it shows the characteristic fold of the DNase I family: a central 12-stranded β-sandwich packed between outer α-helices and loops on each side of the sandwich (Nesic *et al.*, 2004).

The position-specific homology is associated with functional activity, since crude EcCDT-II preparations have DNase activity, as detected by *in vitro* digestion of the coiled pGEM-7zf plasmid (Elwell and Dreyfus, 2000). Transfection of HeLa cells with CjCdtB was shown to induce a slowly appearing nuclear fragmentation and a marked chromatin disruption (Lara-Tejero and Galan, 2000). Microinjected CjCdtB was also able to produce changes in the chromatin and enlargement of the nucleus. Both the DNase activity and the cytotoxicity were abolished by point mutations of conserved residues required for catalysis or for magnesium binding. Thus, the catalytic DNase activity is crucial for the cytotoxic activity of CDTs (Elwell and Dreyfus, 2000; Lara-Tejero and Galan, 2000).

### *CDT induces DNA double-strand breaks similar to ionizing radiation*

We recently provided direct evidence that intoxication of HeLa cells with the HdCDT holotoxin induces DNA double-strand breaks (DSBs) similar to IR (Figure 23.5a) (Frisan *et al.*, 2003). Moreover, mutation in the HdCdtB position 273, required for magnesium binding, completely abolished this effect (Figure 23.5a), as well as the cytotoxic responses. This first demonstration of CDT-induced DSBs in naturally intoxicated mammalian cells was made with a sensitive pulsed-field gel electrophoresis (PFGE) method. It contradicts an earlier report showing that EcCDT did not induce DNA strand breaks, as measured with the alkaline single cell gel electrophoresis (Comet) assay (Sert *et al.*, 1999). However, our findings agree with those of Hassane and coworkers who previously observed that yeast cells transfected with CjCdtB exhibited DSBs, also detectable by PFGE (Hassane *et al.*, 2001). Furthermore, this effect on DNA is fully consistent with the DNase activity of CdtB and the widely reported observations that CDT-treated cells exhibit cell cycle arrest and/or undergo apoptosis.

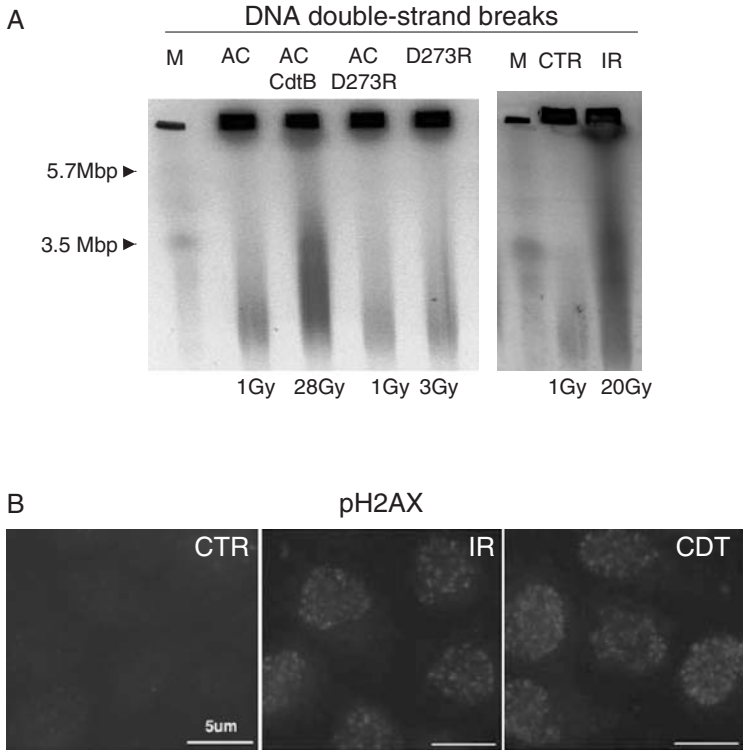

**FIGURE 23.5** CDT-induced DNA double-strand breaks (DSBs) and H2AX phosphorylation. A) Twenty-five thousand HeLa cells per well were cultivated in 12-well plates in complete medium containing 4,000Bq [methyl-$^{14}$C]-thymidine for 48h. The cells were then washed 3 times in PBS and chased for 2h in complete medium, and subsequently treated for 8h with: (i) CdtA+CdtC (negative control); (ii) HdCDT containing wild-type CdtB (at the concentration of 20µg/ml); (iii) HdCDT containing the mutated CdtBD273R (at the concentration of 20µg/ml); (iv) CdtBD273R alone (20µg/ml). Cells were processed for pulsed-field gel electrophoresis analysis. As control for DNA DSBs analysis, HeLa cells were left untreated or irradiated (20Gy, IR) and immediately processed for pulsed-field gel electrophoresis analysis.
M: molecular weight marker. Gy: equivalent radiation dose. **B)** HeLa cells were either incubated with medium alone (CTR), irradiated (20Gy, IR), or treated with HdCDT (2µg/ml, CDT) for 4h. Cells were fixed and stained with anti-phospho-H2AX specific rabbit serum, followed by FITC swine anti-rabbit serum.

### *CDT-induced cellular checkpoint responses*

We will first outline the cellular effects known to be elicited by DNA damaging agents in general and then present an overview of the cellular changes occurring specifically in response to various CDTs.

*Cellular effects of DNA damaging agents in general*

It is well known that cells exposed to agents causing DNA damage activate so-called "checkpoint responses" that arrest the cell cycle until the DNA damage has been repaired. These checkpoint responses can block cells in the G1, S, or G2 phases of the cell cycle (Elledge, 1996; Hartwell and Weinert, 1989). The protein kinase Ataxia telangiectasia mutated (ATM) and its homologue ATM and Rad3 related (ATR) play a central role in sensing DNA damage. ATM is activated in response to DNA DSBs induced by IR, and can in turn trigger all the different checkpoints. (ATR activation is mainly induced by other DNA-damaging agents, such as UV irradiation [Rotman and Shiloh, 1999]). Arrest in G1 is mediated by the tumor suppressor gene p53, which is stabilized in an ATM-dependent manner via phosphorylation on serine 20 by the chk2 protein kinase (Chehab *et al.*, 2000; Siciliano *et al.*, 1997). The G2 arrest depends on a loss of activation of the cdc2 complex. Normally, cdc2 activation is achieved via dephosphorylation at Thr-14 and Tyr-15 by the Cdc25C phosphatase (Jackman and Pines, 1997). The ATM-dependent protein kinases chk1 and chk2, activated in response to DNA damage, are able to inactivate Cdc25C (Matsuoka *et al.*, 1998; Sanchez *et al.*, 1997), and this leads to accumulation of the inactive phosphorylated cdc2 and arrest of cells in the G2 phase of the cell cycle.

*CDTs activate sensors of DNA damage*

We have demonstrated that HdCDT induces phosphorylation of the nuclear sensor of DNA damage, histone H2AX, as early as 1 h after intoxication (Figure 23.5b). Moreover, the DNA repair complex Mre11 was relocalized in the nuclei of HeLa cells with kinetics similar to those observed upon exposure to IR (Li *et al.*, 2002). Also, the CjCDT was reported to induce Rad50 foci in the nuclei of the CjCDT-treated primary human fetal fibroblasts (IMR-90 cells) (Hassane *et al.*, 2003). Thus, DNA-damage–associated molecules are activated as an early response to the DSBs induced by CDTs.

*CDT-induced cell cycle arrest*

Even before the toxin was known to damage DNA, cells exposed to various CDTs had been reported to accumulate the phosphorylated (inactive) form of cdc2, leading to arrest in the G2/M phase of the cell cycle (Comayras *et al.*, 1997; Cortes-Bratti *et al.*, 1999; Peres *et al.*, 1997; Whitehouse *et al.*, 1998). The inactive cdc2/cyclin B complex resulting after intoxication with

EcCDT-III could be reactivated *in vitro* with recombinant Cdc25C (Sert *et al*., 1999). Furthermore, overexpression of Cdc25B or Cdc25C could override the G2 arrest induced by this toxin, causing progression to a mitosis, which was abnormal, however (Escalas *et al*., 2000). Both results suggested that CDTs do not target specifically cdc2 but rather some upstream component, leading to inactivation of Cdc25C and consequent lack of cdc2 dephosphorylation as a secondary effect.

The cellular checkpoint responses induced by HdCDT were then shown to closely resemble those induced by IR. It also became clear that the CDT-induced cell cycle arrest is not limited to the G2/M phase, but that the checkpoint responses depend on the cell type (Cortes-Bratti *et al*., 2001b), as summarized in Table 23.2. In human fibroblasts, both IR and HdCDT treatment induced ATM-dependent early activation of the p53 gene and the cyclin-dependent kinase inhibitor p21, which correlated with arrest in G1 (Cortes-Bratti *et al*., 2001b). In HeLa cells, both treatments induced chk2 kinase activation, accumulation of phosphorylated cdc2, and G2 arrest (Cortes-Bratti *et al*., 2001b). The checkpoint responses were already detectable 4 h post-intoxication.

*CDT-induced apoptosis*

In contrast to fibroblasts and epithelial cells, human lymphoblastoid cell lines treated with HdCDT did not arrest in either G1 or G2 at the toxin concentrations used. Instead, they rapidly underwent apoptosis, a phenomenon that was not further studied in these cells (Cortes-Bratti *et al*., 2001b). Instead, CDT-induced apoptotic cell death has been investigated in some detail in human T cells and T cell lines. Treatment of activated human T cells with the AaCDT (purified B subunit or recombinant holotoxin) was found to induce DNA fragmentation in 72–96h, and FACS analysis showed reduction in cell size and increased nuclear condensation (Shenker *et al*., 2001). Mitochondrial changes were evident as a decrease in transmembrane potential and an elevation of reactive oxygen species, and the caspases 8, 9, and 3 were activated after the G2 arrest. Overexpression of Bcl-2 decreased the CDT-induced apoptosis without inhibiting the G2 arrest (Shenker *et al*., 2001). A more recent report on AaCDT-induced death of human peripheral T lymphocytes and the Jurkat and MOLT-4 cell lines, however, suggested that AaCDT has the ability to induce human T-cell apoptosis through activation of the caspases 2 and 7 (Ohara *et al*., 2004). Thus, the exact

**TABLE 23.2** Mammalian cell sensitive to CDT[a]

molecular events on the pathway to the CDT-induced apoptotic cell death have not yet been fully elucidated, and they can be expected to depend on the particular type of target cell.

Figure 23.6 summarizes the checkpoint responses activated upon CDT intoxication.

### *CDT-induced Rho activation and stress response*

*Morphological effect of CDTs*

As already mentioned briefly, the most conspicuous morphological effect of CDT on cells growing as adherent monolayer is the cell distention leading within 72 h to a three- to fivefold increase of the cell size including a proportional nuclear enlargement. Along with this slowly developing distention, the actin cytoskeleton is strongly promoted, mainly noted as the appearance of prominent actin stress fibers (Figure 23.1). The stress fiber promotion has been reported for E. coli CDT (EcCDT-II) in CHO cells (Aragon *et al*., 1997), for HdCDT in HEp-2/HeLa cells, in Don hamster lung fibroblasts and human foreskin fibroblasts (Cortes-Bratti *et al*., 1999; Frisan *et al*., 2003), and recently also in HeLa cells treated with CDT from *Helicobacter cinaedi* (Taylor *et al*., 2003). After several days of toxin exposure, adherent cells begin to round up, show membrane blebbing in some cases, and then deteriorate completely. In contrast to fibroblasts and epithelial cells, T and B lymphocytes and dendritic cells do not distend but rather become rapidly apoptotic and fragmented after exposure to CDT (Cortes-Bratti *et al*., 2001b; Li *et al*., 2002; Shenker et al., 2004).

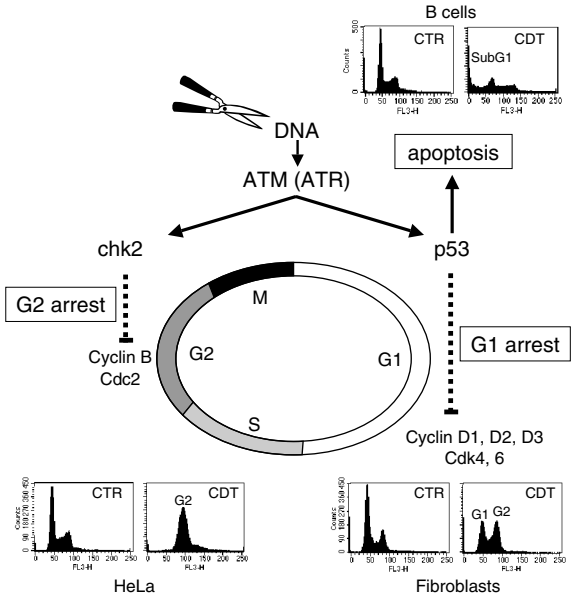

**FIGURE 23.6** Summary of the checkpoint responses activated upon CDT-induced DNA damage. The protein kinase ATM is activated upon CDT-induced DNA double-strand breaks. As a consequence of the DNA damage checkpoint responses, primary fibroblasts are arrested both in the G1 and G2 phases of the cell cycle, HeLa cells are exclusively arrested in G2, and B cells undergo apoptosis.

*CDT-induced stress fiber promotion depends on ATM-mediated activation of RhoA*

The reason that actin stress fibers are strongly promoted in certain CDT-treated cells was not understood in the early experiments (Aragon *et al*., 1997), although the possible involvement of small GTPases controlling the actin cytoskeleton was hypothesized (Cortes-Bratti *et al*., 1999). Later on, it became feasible to investigate this aspect of CDT intoxication with new tools that allow specific assay of the activated small GTPases Rho, Rac, and CDC42 (Benard *et al*., 1999; Ren *et al*., 1999). Thus, we could show that the HdCDT-activated stress fiber promotion in fibroblasts and HeLa cells depends on activation of RhoA, but not Rac or CDC42. This was observed both directly as activation of RhoA upon intoxication and as an inhibition of the stress fiber formation in CDT-treated cells transfected with a dominant negative mutant of RhoA (Frisan *et al*., 2003).

Interestingly, stress fiber promotion and cell distention were observed also in irradiated cells. However, the increased size of CDT-treated or irradiated cells was not connected to the stress fiber formation, since dominant negative RhoA inhibited the formation of stress fibers without affecting the distention of the treated cells (Frisan *et al*., 2003). The distention phenomenon instead appears to depend on activation of PI3-kinase and its downstream effector mTOR, whereas this enzyme had no clear effect on induction of stress fibers (Frisan *et al*., 2003). The activation of RhoA upon intoxication or irradiation was found to be ATM-dependent, thereby connecting the stress fiber promotion to the damaging action on DNA. Moreover, toxin-treated cells expressing a dominant negative form of RhoA detached and consequently died faster than cells expressing a functional RhoA (Frisan *et al*., 2003). Thus, the activation of RhoA was associated with prolonged cell survival, and it seems to represent an attempt of intoxicated cells to maintain cell adherence in order to stay alive while some time is given for DNA repair. The ATM-dependent activation of RhoA constitutes a previously unknown type of cell survival response to induction of DNA DSBs, which seems to occur regardless of the agent inducing the DSBs.

### *CDT-induced late cellular responses*

Only a limited number of studies have been devoted to responses occurring as secondary effects relatively late in cellular intoxication with CDTs. However, one study showed that each of the purified recombinant subunits

of AaCDT was individually able to induce production of the cytokines IL-1β, IL-6, and IL-8, but not TNFα, IL-12, or granulocyte-macrophage colony stimulating factor in human peripheral blood mononuclear cells (PBMC) as measured after 20 h incubation (Akifusa *et al*., 2001). CdtC was the most potent subunit, as 40 ng/ml CdtC was able to stimulate the production of nanogram quantities of IL-8. CdtB alone had only minimal cytokine stimulating activity, but it appeared to synergize with CdtA and CdtC to promote PBMC cytokine synthesis, and this synergy was most marked in inducing IFNγ production (Akifusa *et al*., 2001). The molecular mechanisms behind this effect are not clear, and the relation to DNA damage was not studied.

The effects of *Haemophilus ducreyi* and some of its antigens, such as HdCDT, were recently studied on human monocyte-derived dendritic cells (DCs), macrophages, and CD4+ T cells (Xu *et al*., 2004). While the whole bacteria induced antigen-presenting cells (APCs) to secrete TNF-α, IL-6, IL-8, and IL-12, the isolated toxin hampered both the induction of cytokine production by APCs and their ability to elicit T cell activation. DCs were shown to become slowly apoptotic, consistent with previous findings (Li *et al*., 2002). Thus, HdCDT is likely to inhibit the local immune responses in chancroid, besides delaying the healing of chancroid ulcers through the cytotoxic activity.

Both the AaCDT and HdCDT were recently reported to have a very interesting effect on periodontal connective tissue cells (Belibasakis *et al*., 2005). *A. actinomycetemcomitans* was shown by RT-PCR and protein determinations to induce the expression of Receptor Activator of NF-κB Ligand (RANKL) in human gingival fibroblasts and periodontal ligament cells. CDT was crucial for this effect as shown with (i) a CDT knockout mutant of the bacterium and (ii) a preparation where the CDT activity was neutralized with antibodies. Moreover, purified HdCDT (which has > 95% homology with the AaCDT) had the same RANKL-inducing effect. RANKL is known to induce osteoclast differentiation and activation (Teitelbaum and Ross, 2003). The authors speculate that CDT in this way might be indirectly involved in the pathological bone resorption process during localized aggressive periodontitis (Belibasakis *et al*., 2005).

### *CDTs act on several cell types*

As already discussed, CDTs act on various cell lines, and the outcomes differ depending on the cell type (Table 23.2). The most commonly reported end-points in CDT studies are cell cycle arrest and "cytotoxicity" based on morphological criteria. Cells reported until now to be sensitive to CDTs are summarized in Table 23.2. HEp-2, HeLa, CHO, Vero, and Don fibroblasts (Cortes-Bratti *et al*., 2001a; Pickett and Whitehouse, 1999), as well as human embryonic intestinal epithelial cells (INT407) (Hickey *et al*., 2000), a human colon carcinoma cell line (Caco-2), and a human keratinocyte cell line (HaCat) (Cortes-Bratti *et al*., 1999) are sensitive to CDTs. Human $CD4^+$ and $CD8^+$ T cells are highly sensitive to the AaCDT (Shenker *et al*., 1999), which also inhibits proliferation of the murine B-cell hybridoma cell line HS-72 (Sato *et al*., 2002), as well as periodontal ligament cells and gingival fibroblasts from humans (Belibasakis *et al*., 2002) and a human gingival squamous carcinoma cell line (Ca9-22) (Yamamoto *et al*., 2004). HdCDT affects normal human endothelial cells (HUVEC) (Svensson *et al*., 2002), foreskin keratinocytes and fibroblasts, embryonic lung fibroblasts, human B cells, and dendritic cells (Figures 23.6 and 23.7) (Cortes-Bratti *et al*.,

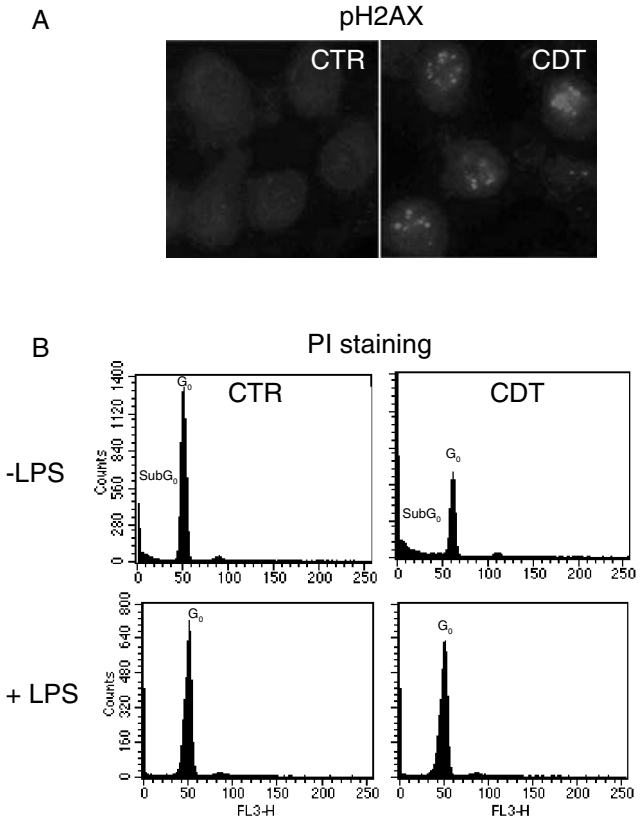

**FIGURE 23.7** CDT induces DNA damage and cell death in non-proliferating dendritic cells (DCs). **A)** Five days immature DCs were incubated with HdCDT (2μg/ml) for 5h and stained with histone H2AX phospho-specific rabbit serum (pH2AX). **B)** Effect on LPS-treated DCs. Five days immature DCs were incubated with or without LPS (1μg/ml) for 24h. Cells were further treated with HdCDT (2μg/ml) or left untreated for 48h. Cell cycle distribution was assessed by DNA staining with propidium iodide (PI) and flow cytometry (PI staining). The $G_0$ peak was arbitrarily set on the mean fluorescence intensity value of 50.

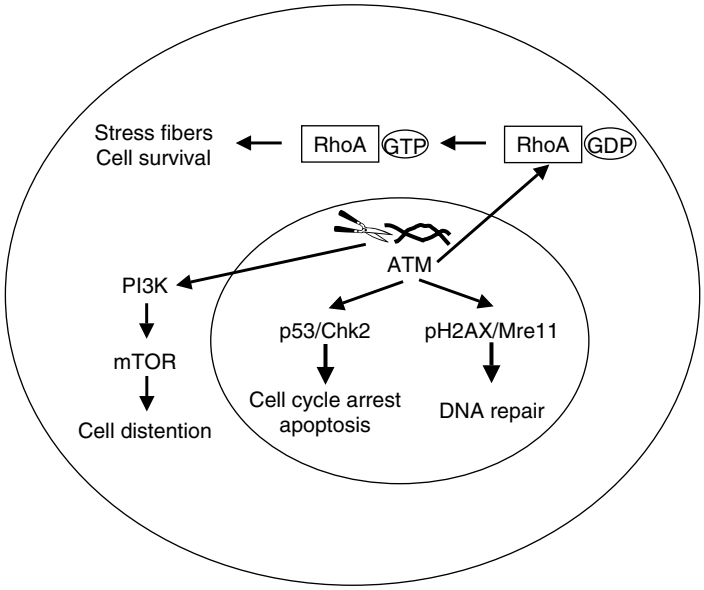

**FIGURE 23.8** Summary of the cellular responses activated by the CDT-induced DNA damage. CDT intoxication induces: (i) nuclear responses, leading to cell cycle arrest/apoptosis and activation of DNA repair complex; (ii) activation of cytosolic signaling pathways, important for prolonging cell survival.

2001b; Li *et al*., 2002). Primary human fetal fibroblasts (IMR-90) (Hassane *et al*., 2003), Cos-7 cells (McSweeney and Dreyfus, 2004), COS-1 (Sato *et al*., 2002), Jurkat, and MOLT-4 cells (Ohara *et al*., 2004) are also sensitive to CDT intoxication.

*CDTs act on non-proliferating cells*

It is noteworthy that CDTs attack also non-proliferating cells. Utilizing the focus formation assays of DNA repair enzymes, it was possible to establish that human dendritic cells (DCs) (Li *et al*., 2002), as well as serum-starved (i.e., non-proliferating) primary human fetal fibroblasts (Hassane *et al*., 2003), are sensitive to CDT. Phosphorylation of H2AX was detected in 50% to 60% of DCs exposed to HdCDT for 5h (Li *et al*., 2002; and Figure 23.7a). Cell cycle analysis shows that untreated DCs were in $G_0$ phase of the cell cycle, while a marked reduction of the cells in $G_0$ phase and a parallel increase of the sub$G_0$ population was observed in the HdCDT-treated DCs (Li *et al*., 2002; and Figure 23.7b). These findings contradict previous notions that cells need to pass through the S phase in order to become intoxicated (Alby *et al*., 2001; Lara-Tejero and Galan, 2000; Sert *et al*., 1999).

Interestingly, the effect of HdCDT on DCs was dependent on their stage of differentiation (Li *et al*., 2002), since LPS-treated DCs were resistant to HdCDT-induced cell death (Figure 23.7b). It is possible that upon DC maturation, the repertoire of surface molecules is modified in such a way that HdCDT is no longer able to bind and be internalized. This hypothesis is supported by the lack of DNA damaging activity observed in LPS-treated DCs exposed to HdCDT. Indeed, we could not demonstrate relocalization of the Mre11 complex or stabilization of the p53 protein in these cells, and H2AX phosphorylation was observed only in a small proportion of cells (Li *et al*., 2002).

In conclusion, most cultured cells that have been tested appear to be sensitive to CDT. The only cells so far reported to resist CDTs are the Y-1 adrenal cells and 3T3 fibroblasts of mouse origin (Cope *et al*., 1997; Cortes-Bratti *et al*., 1999; Johnson and Lior, 1988b). Since these cells were not able to bind HdCDT at all (Figure 23.3), the most probable reason for their resistance would be the lack of a cell surface receptor needed for binding of the toxin.

Figure 23.8 summarizes the intracellular responses activated by the CDT-induced DNA damage.

## CDTs AND DISEASE

Since CDTs are potent toxins produced by pathogenic bacteria, they have to be regarded as potential virulence factors. CDTs are detected in an increasing number of clinical isolates, but only a few experiments with CDTs in animal model systems have been reported.

### Occurrence of CDTs in clinical isolates

Several studies on *E. coli* isolates have been performed, especially concerning the possible association of CDT with enteropathogenic (EPEC) serotypes. The general conclusion from these studies is that EcCDT is produced in some, but not all, EPEC serotypes (Ansaruzzaman *et al*., 2000; Ghilardi *et al*., 2001; Janka *et al*., 2003; Okeke *et al*., 2000; Pandey *et al*., 2003). For example, only 1/200 children in Brazil (0.5%) with

acute diarrhea were infected with *cdt*-positive EPEC, while 1% of the non-diarrheic controls harbored *cdt*-positive isolates (Marques *et al*., 2003). CDT has been identified in urosepsis *E. coli* isolates (Johnson and Stell, 2000), in diarrhea isolates from dogs (Starcic *et al*., 2002) and from neonatal piglets (da Silva and da Silva Leite, 2002), in extraintestinal human and animal urinary tract infection (UTI) and non-UTI strains (Toth *et al*., 2003), and in 83% of bovine isolates of necrotoxigenic *E. coli* (Mainil *et al*., 2003).

Pickett and coworkers recently reported how the presence of *cdt* genes was related to a number of other virulence genes of *E. coli* (Pickett *et al*., 2004). Their study of a collection of 20 strains revealed that the CDT producers can be divided into three general groups with distinct differences in CDT type and in their complement of virulence-associated genes. Thus, *cdt* genes were found in: (i) a subset of uropathogenic *E. coli* strains; (ii) extraintestinal isolates of uncertain clonal identity; and (iii) in certain strains with characteristics in common with Shiga toxin–producing *E. coli* and EPEC (Pickett *et al*., 2004). CDT and the *cdt* genes were also identified in 17 out of 340 non-O157 Shiga toxin–producing *E. coli* (STEC) of serotypes that were all *eae*-negative (Bielaszewska *et al*., 2004). Among these *eae*-negative STEC, *cdt* was proposed to be disease associated, since it was significantly more frequent in isolates from patients with hemolytic uremic syndrome (3 of 7) and in isolates from patients with diarrhea (14 of 138) than in isolates from asymptomatic carriers (0 of 65).

The production of CDT has been detected in a few isolates of *Shigella dysenteriae*, *S. boydii*, and *S. sonnei* (Okuda *et al*., 1995). In contrast, almost all investigated *Campylobacter jejuni* and *C. coli* strains have been reported to produce CDT or to possess the *cdt* genes. For instance, the *cdtB* gene was detected in all investigated isolates from chicken carcasses, i.e., the primary source of *C. jejuni* and *C. coli* in human infections (Eyigor *et al*., 1999a; Eyigor *et al*., 1999b). *In vitro* assay showed that the *C. jejuni* isolates produced CDT at high toxin titers, whereas *C. coli* produced little or no toxin. Likewise, 100/101 *C. jejuni* and 7/10 *C. coli* isolates from Danish broilers had the *cdt* genes. Again the *C. coli* strains produced lower amounts of the toxin (Bang *et al*., 2001). CDT production was also demonstrated from *C. fetus*, and PCR experiments suggested the presence of *cdtB* sequences in other species of *Campylobacter* (Pickett *et al*., 1996). A study on several virulence genes, including the *cdt* cluster in *C. jejuni* and *C. coli* isolates from Danish pigs and cattle, demonstrated a high prevalence (83–95%) of *cdt* genes and CDT production (Bang *et al*., 2003). More recently, the same authors (Bang *et al*., 2004) reported that 90–97% of 117 *C. jejuni* isolates from Danish turkeys produced CDT, as detected by cytotoxicity in three different cell lines.

In contrast to the situation in *Campylobacter* spp, the *cdt* genes and CDT activity are not present in all species of *Helicobacter*. The three genes have been identified in *H. hepaticus* (Young *et al*., 2000a), and the *cdtB* gene was detected in human clinical isolates of *H. pullorum* (Young *et al*., 2000b) and in canine isolates of *H. flexispira* (Kostia *et al*., 2003), but no CDT homology was found in *H. pylori* (Chien *et al*., 2000). Interestingly, CDT was recently reported as the first putative virulence factor present in *H. cinaedi*, which is the most commonly reported enterohepatic helicobacter in humans (Taylor *et al*., 2003). The *cdtB* gene detected by PCR, as well as CDT production detected by cytotoxicity, was present in all 11 investigated isolates, 10 of which were clinical isolates.

Out of 50 periodontitis strains of *A. actinomycetemcomitans*, 86% had the *cdt* genes and expressed cytotoxic activity (Ahmed *et al*., 2001). A majority (39/40) of clinical isolates from Brazil, Kenya, Japan, and Sweden were also found to harbor the *cdt* genes and produce the AaCDT (Fabris *et al*., 2002). Although there was some variation in toxin production among the strains, no clear relationship between CDT activity and periodontal status could be found. CDT production and occurrence of the *cdtB* gene were also reported in 73 strains of periodontopathogenic bacteria (Yamano *et al*., 2003), and CDT activity was found in 40/45 tested *A. actinomyctemcomitans* strains. The remaining 28 strains of other bacteria did not have CDT. In another recent study *A. actinomycetemcomitans* was detected in 106/146 subgingival plaque samples isolated from periodontitis patients, and among these only 13 sites were positive for the *cdt* genotype (Tan *et al*., 2002). However, 10 of these 13 positive sites were obtained from patients diagnosed with aggressive periodontitis, and the authors speculated that the cytotoxicity and immunosuppression by CDT may contribute to the pathogenesis of aggressive periodontitis (Tan *et al*., 2002). The RANKL-inducing activity of AaCDT, reported more recently (Belibasakis *et al*., 2005), might also contribute in the pathogenesis of this disease.

Finally, 89% of a group of isolates of *H. ducreyi* from different parts of the world showed CDT activity on HEp-2 cells (Purvén *et al*., 1995). A later study identified the *cdt* genes and CDT production in 83% of 29 isolates of *H. ducreyi* from chancroid (Ahmed *et al*., 2001). Likewise, 87% of 45 strains of *H. ducreyi,* found in still more recent chancroid isolates from various parts of the world, produced the toxin (Kulkarni *et al*., 2003).

In conclusion, a majority of strains of *C. jejuni*, *A. actinomycetemcomitans*, and *H. ducreyi* appear to

Table 23.3 Summary of the CDT occurrence in clinical isolates

| Toxin | Bacteria/disease | Species infected |
|---|---|---|
| *E. coli* CDTs | EPEC | Human |
| | Urosepsis *E. coli* | Human |
| | Diarrhea isolates | Dog |
| | Diarrhea isolates | Pig |
| | UTI strains | Human/animal |
| | Non-UTI strains | Human/animal |
| | Necrotoxigenic | Bovine |
| | STEC | Human |
| *Shigella* CDTs | Few isolates | |
| *Campylobacte*r CDTs | *C. jejuni* | Chicken/human |
| | *C. coli* | Chicken/human |
| | *C. fetus* | |
| *Helicobacter* CDTs | *H. pullorum* | Human |
| | *H. flexispira* | Human |
| | *H. cinaedi* | Human |
| AaCDT | Aggressive periodontitis | Human |
| HdCDT | Chancroid | Human |

produce the CDT, while the presence of the *cdt* genes in other bacteria is more variable. Table 23.3 summarizes the data reported in the previous paragraphs.

## Effects of CDTs *in vivo*

An *E. coli* strain expressing the *S. dysenteriae cdt* genes was able to induce watery diarrhea in the suckling mouse model, and the partially purified CDT also had some effect. In addition, the toxin caused a certain tissue damage in the descending colon of these mice (Okuda *et al*., 1997). When *cdtB* negative strains of *C. jejuni* were administered to severe combined immunodeficient mice, no difference in enteric colonization was observed. However, the CDT-deficient strains showed an impaired invasiveness into blood, spleen, and liver tissues as compared to the wild-type bacteria (Purdy *et al*., 2000), implying that CDT might have a role in the pathogenesis (invasion) of *C. jejuni*. A more recent study of a *C. jejuni cdtB* mutant in NF-κB deficient mice suggested that CDT may contribute to the pro-inflammatory response, as well as the ability of *C. jejuni* to escape immune surveillance (Fox *et al*., 2004). The *cdtB* mutant was able to colonize the NF-κB deficient 3X mice to the same extent as the wild-type bacteria, but produced significantly less gastritis (Fox *et al*., 2004), suggesting that CDT may be important for the pathogenic process taking place after the colonization. The authors speculate that CDT may target the cells of the immune system in the lamina propria, therefore influencing the host's ability to clear bacterial pathogens. Young and coworkers recently provided further evidence for a potential pro-inflammatory activity of CDTs (Young *et al*., 2004). Strains of *H. hepaticus* expressing a functional CDT caused severe colitis in a murine model of inflammatory bowel disease, using C57BL/6 interleukin 10 (IL-10) deficient mice. In contrast, the CDT-negative isogenic mutants were without effect (Young *et al*., 2004).

An isogenic *H. ducreyi cdtC* mutant was equally virulent as the parent strain when tested in the temperature-dependent rabbit model for experimental chancroid, despite the fact that it was not cytotoxic to HeLa cells and keratinocytes (Stevens *et al*., 1999). Isogenic *H. ducreyi cdtA* and *cdtB* mutants also proved to be as virulent as the wild-type strain with regard to lesion production in the same rabbit model (Lewis *et al*., 2001). In human volunteers, expression of CDT also was not required for pustule formation by *H. ducreyi*, although CDT might still be relevant for induction or persistence of the ulcer stage, which is not testable in humans (Young *et al*., 2001). The purified HdCDT holotoxin induced dose-dependent pathologic skin reactions in rabbits (Wising *et al*., 2002). High levels of neutralizing antibodies against CDT were detected in only 22% and 2% of patients with chancroid and periodontitis, respectively. Moreover, a majority of healthy individuals also had HdCDT antibodies, and thus such antibodies may not be specific markers for chancroid infection (Mbwana *et al*., 2003).

In conclusion, the fact that CDTs are produced by diverse human pathogens suggests that these toxins might contribute to the development of different diseases. However, there is currently no absolutely clear association between toxins and specific disease symptoms, and one major problem is the lack of suitable animal models for these types of studies. Conceivably, CDT could have a role in all instances where cell proliferation is required. Thus, CDTs produced by intestinal pathogens could possibly contribute to gastroenteritis by blocking the proliferation of crypt cells, although there are no studies yet on this particular aspect of the *E. coli*, *Campylobacter*, or *Shigella* CDTs. The HdCDT could contribute to the very slow healing of chancroid ulcers. Furthermore, immunosuppression could be one important general effect of CDTs, as suggested by the recent studies cited previously and by the *in vitro* effect of CDT on DCs, which have a central role for induction of both cellular and humoral-mediated immunoresponses (Li *et al*., 2002). Targeting DCs could represent a strategy developed by several pathogens in order to avoid or delay the onset of immunoresponses. In fact, the AaCDT was originally isolated as the "immunosuppressive factor" (ISF) of *A. actinomycetemcomitans*, and it might possibly play such a role in the pathogenesis of aggressive periodontitis and other infections caused by this bacterium

(Shenker *et al*., 1999). Finally, the recent evidence that AaCDT can induce expression of the osteoclast-activating factor RANKL in periodontal connective tissue cells further supports a role for CDT in localized aggressive periodontitis.

## CONCLUSION

During the 10 years after the first cloning of CDT, this tripartite toxin has generated an increasing interest, and the development has advanced rapidly from mysterious cell distending activity to well-known toxin with defined mode of action and now even crystallized. CDT turned out to be unique in that it is the only bacterial toxin known to target DNA as a primary action, subsequently activating a number of important cellular stress responses designed to save the attacked cell while it attempts to repair its DNA. Although we know today so much more than a decade ago, there are many more questions waiting for their answers. In addition, there is reason to believe that CDT, like many other bacterial protein toxins, can be developed into a useful tool in cell biology and biomedicine.

### Action of CDT on cells

The receptor(s) for CDT has not yet been identified. This issue is complicated by the tripartite CDT structure with two separate binding subunits, CdtA and CdtC, which might bind to separate receptor structures, or to the same (as suggested in Lee *et al*., 2003; McSweeney and Dreyfus, 2004). The sequence homologies between the CdtA and CdtC subunits from different bacteria are much lower than between the different CdtB subunits. Thus, it is even possible that the receptor(s) for CDTs of different origins will turn out to differ despite the fact that the active CdtB subunit in all CDTs has the same DNase activity. That there are lectin-like regions in CdtA and CdtC similar to those found in the binding subunit of ricin might point to a galactose-containing receptor, although Mao and DiRienzo (Mao and DiRienzo, 2002) failed to inhibit the binding of AaCdtA to CHO cells with various galactosides and mannosides. Besides the binding to cell surface receptor(s), the three subunits must be able to interact with each other to form the fully active holotoxin. Obviously, this interaction must depend on specific amino acid stretches, some of which have already been identified. It would also be of interest to combine subunits of CDTs from different bacteria to see whether they can fully complement each other.

It is clear that CDT has to be internalized in cells so that the CdtB subunit can be transferred to the nucleus. Upon microinjection, CdtB is able to enter the nucleus from the cytosol, but the molecular events of this transfer process are not known. Moreover, it is not yet clear how the CdtB subunit is translocated from the ER to the nucleus upon natural intoxication. A passage through the cytosol seems less likely, according to the most recent observations that neither the ERAD-pathway nor Derlin-1 is necessary for the translocation. The cellular fates of CdtA and CdtC, after fulfilling their putative roles to facilitate entry of CdtB, have also not been clarified. Another unresolved issue is whether CdtC, if it really proves to be cytotoxic by itself, has an entirely different mode of action than CdtB.

### CDTs and disease

It will be interesting to see when CDTs will be more clearly demonstrated to cause or at least to contribute to the symptoms in infections caused by the bacteria producing them. Now that the mode of action of CDT is basically known, this aspect will probably become more attractive for study, even if the lack of really good animal models is still a problem. In any case, CDTs are likely to affect the immune response as well as other situations in which cell proliferation is needed, such as the healing of chancroid or periodontic ulcers. Another potentially important aspect is that CDTs, being genotoxic, might possibly constitute a contributing factor in long-term cancer development. Since CDT is produced by so many common pathogens, this is a rather disturbing perspective, which has not yet been studied at all. On the other hand, the action of CDT on DNA makes it a potentially good candidate for an anti-tumor agent.

### CDTs as tools in cell biology

Bacterial toxins have been extremely useful in the study of different aspects of cell biology. So far, CDTs are the only bacterial protein toxins known to induce a subtle DNA damage. In the field of cell and tumor biology, regulation of the cell cycle is currently one of the major issues, and CDT will probably be utilized as a tool in such studies. Toxins have also been very helpful in the study of endocytosis and intracellular transport in general. Studies with Shiga toxin showed for the first time that a molecule can be transported from the cell surface to the Golgi complex and the ER (Sandvig and Van Deurs, 2000). The ER appears to have a central role in regulation and execution of processes involving intracellular trafficking, some of which are still unknown. In this context, elucidation of the mechanism by which CdtB is translocated into the nucleus becomes an important issue.

Finally, the study of CDT has already led to the discovery of a novel cellular signaling pathway, transmitting survival signals from damaged DNA to the small GTPase RhoA (Frisan *et al*., 2003). CDT will be useful in the continued efforts to clarify all the molecular details from DNA damage to RhoA activation, as well as from the latter event to the downstream components involved in protecting the cells from immediate death.

## ACKNOWLEDGMENTS

Work from the authors' laboratory has been supported by the Swedish Research Council (grants # 05969 and 15012) and the Karolinska Institutet. T.F. was supported by the Swedish Cancer Society, the Swedish Society for Medical Research, and the Swedish Research Council.

CHAPTER

# 24

# *Helicobacter pylori* vacuolating toxin

*Mark S. McClain and Timothy L. Cover*

## INTRODUCTION

*Helicobacter pylori* is a Gram-negative, spiral-shaped bacterium that colonizes the human stomach (Warren and Marshall, 1983; Marshall and Warren, 1984; Dunn *et al*., 1997; Cover *et al*., 2001; Suerbaum and Michetti, 2002). It has been estimated that about 50% of the world's population is colonized by *H. pylori*, with this proportion reaching greater than 90% in certain parts of the world. Despite the fact that most hosts mount humoral and cellular immune responses against *H. pylori*, colonization commonly persists for decades in the absence of antimicrobial therapy (Everhart, 2000). Infection by *H. pylori* is associated with an increased risk for development of peptic ulcer disease, gastric adenocarcinoma, and gastric lymphoma (Dunn *et al*., 1997; Cover *et al*., 2001; Suerbaum and Michetti, 2002).

An exotoxin produced by *H. pylori*, VacA, was discovered in 1988 (Leunk *et al*., 1988). Substantial evidence indicates that the toxin plays a role as a virulence factor in the pathogenesis of *H. pylori*–induced gastric diseases. One of the most striking activities of this toxin is its capacity to induce formation of large cytoplasmic vacuoles in cultured epithelial cells (Leunk *et al*., 1988; Cover and Blaser, 1992). However, VacA also produces an assortment of other cellular effects. VacA contributes to the capacity of *H. pylori* to colonize the stomach in a murine model of infection. In addition, VacA interferes with the activation and proliferation of T lymphocytes, which might be a factor that enables *H. pylori* to resist clearance by host immune defenses. Many of the activities attributed to the toxin, including cell vacuolation, are associated with the capacity of the toxin to form anion-selective membrane channels. Current studies are aimed at understanding the molecular mechanisms by which the toxin interacts with cells to produce multiple effects. In addition to providing further insights into *H. pylori* pathogenesis, these studies have implications for diverse fields of cell biology, including the study of lipid rafts, endocytosis and intracellular trafficking, apoptosis, cell proliferation, signal transduction, and chloride channels.

*H. pylori* colonization of the stomach is a complex process that involves bacterial adaptation to the acidic gastric environment, motility, adhesion, and interactions with the gastric epithelium and with host immune defenses. The VacA toxin is one factor that *H. pylori* apparently utilizes to make the human stomach a hospitable niche (Montecucco *et al*., 1999; Atherton *et al*., 2001; Papini *et al*., 2001). This review discusses our current understanding of VacA, including its synthesis, genetic diversity, association with disease, activities, interaction with host cells, and structure.

## VacA SYNTHESIS AND GENETIC DIVERSITY

The VacA toxin is the product of a single chromosomal gene (*vacA*) that is present in all *H. pylori* strains (Cover *et al*., 1994; Phadnis *et al*., 1994; Schmitt and Haas, 1994; Telford *et al*., 1994). The gene is transcribed from its own promoter (Schmitt and Haas, 1994; Forsyth *et al*., 1998; Forsyth and Cover, 1999), and expression of *vacA* is regulated by a variety of environmental stresses that *H. pylori* might encounter in the human host. One study reported that transcription of *vacA* is increased in response to acidic pH via a mechanism requiring CsrA (carbon storage regulator A), an RNA binding protein involved in posttranscriptional regulation (Barnard

*et al*., 2004). Other studies have reported that *vacA* transcription is increased in response to the presence of cultured gastric epithelial cells (van Amsterdam *et al*., 2003) and in response to iron limitation (Szczebara *et al*., 1999; Merrell *et al*., 2003).

The *vacA* gene encodes for a ~140 kDa protein, which undergoes proteolytic processing at the amino terminus to remove a ~33 amino acid signal sequence and at the carboxy terminus to remove a ~50 kDa domain (Cover *et al*., 1994; Phadnis *et al*., 1994; Schmitt and Haas, 1994; Telford *et al*., 1994; Nguyen *et al*., 2001) (Figure 24.1A). The carboxy-terminal portion of this 50 kDa domain exhibits ~40% amino acid similarity to the IgAβ-core domain from the IgA-protease of *Neisseria gonorrhoeae* (Pohlner *et al*., 1987; Schmitt and Haas, 1994), a representative of the autotransporter family (type V secretion pathway) of secreted bacterial proteins (Henderson *et al*., 1998; Desvaux *et al*., 2004). This region of VacA also includes a carboxy-terminal amino acid motif ending in phenylalanine that is frequently found among outer membrane proteins of Gram-negative bacteria (Struyvé *et al*., 1991; Cover *et al*., 1994). Two cysteines, separated by 10 to 12 amino acids, are located near the C-terminus of the mature toxin, and a similar motif is found in several other members of the autotransporter family of secreted bacterial proteins (Yanagida *et al*., 1986; Pohlner *et al*., 1987; Gilmore *et al*., 1989; Poulsen *et al*., 1989; Carl *et al*., 1990; Benz and Schmidt, 1992; Cover *et al*., 1994). One study investigated the functional role of the carboxy-terminal portion of the VacA protoxin by fusing it to the cholera toxin B subunit and expressing this fusion protein in *E. coli* (Fischer *et al*., 2001). The CtxB-VacA fusion protein expressed in *E. coli* was localized to the outer membrane, and the CtxB domain was shown by protease digestion experiments to be exposed on the bacterial surface. This capacity of the VacA carboxy-terminal region to transport the cholera toxin B subunit provides evidence that the carboxy-terminal portion of VacA may serve as an autotransporter in *H. pylori*. In *H. pylori*, it remains to be determined whether the mature 88 kDa VacA toxin is cleaved from the autotransporter

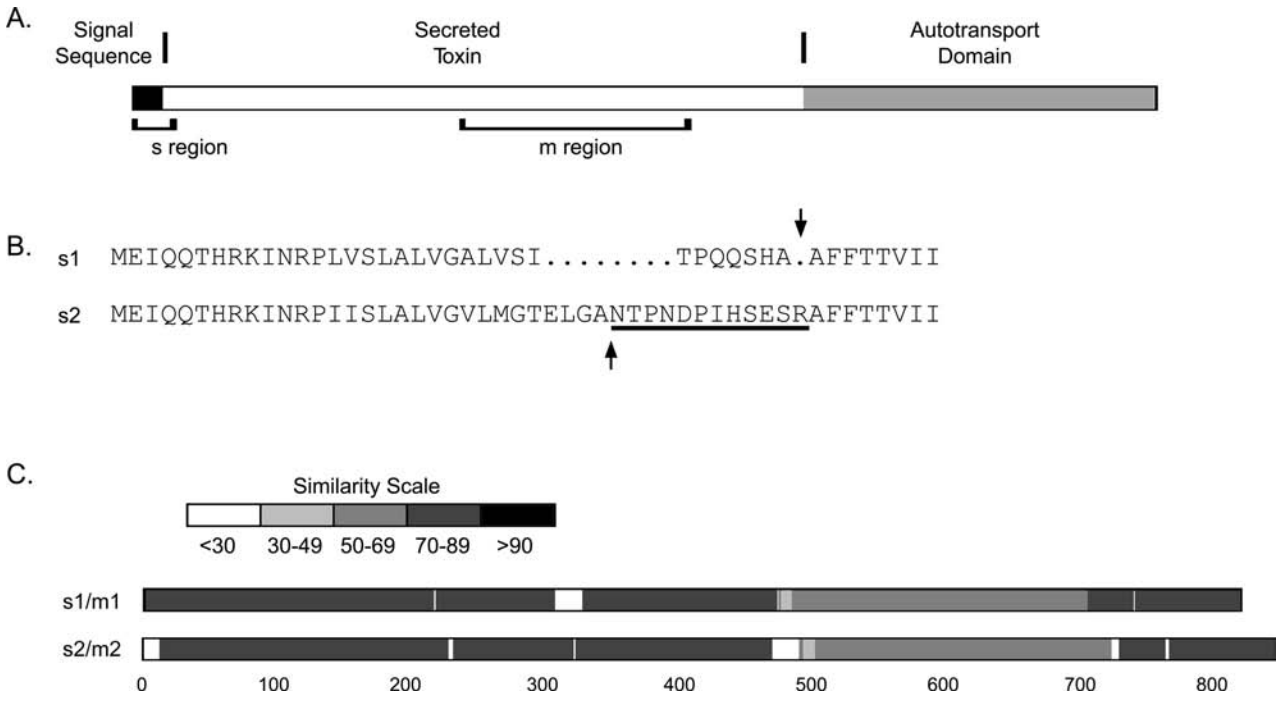

**FIGURE 24.1** VacA primary structure and amino acid diversity. A. The organization of the VacA protoxin is depicted. Proteolytic cleavage of an amino-terminal signal sequence and a carboxy-terminal autotransporter domain results in a mature, 88-kDa secreted toxin. Two regions of VacA diversity (s region and m region) are indicated. B. The "s" regions from prototypical s1 (*H. pylori* strain 60190, GenBank accession U05676) and s2 (*H. pylori* strain Tx30a, GenBank accession U29401) VacA toxins are shown. Arrows indicate the site at which the amino-terminal signal sequence is cleaved. The underlined residues correspond to a 12 amino acid extension located at the amino-terminus of s2-type VacA toxins. C. The amino acid sequences of prototypical s1-m1 (*H. pylori* strain 60190) and s2-m2 (*H. pylori* strain Tx30a) mature VacA toxins were aligned using the SIM local similarity program (Huang and Miller, 1991) and the similarity between the two sequences is depicted graphically (Duret *et al*., 1996). The numbering scheme represents amino acid positions. Several regions displaying less than 30% identity correspond to insertions or deletions in one of the two proteins.

domain by autoproteolysis or by the activity of an unidentified protease. A 33 kDa protein corresponding to the carboxy-terminus of the VacA autotransporter domain remains localized with the bacteria (Telford *et al*., 1994; Fischer *et al*., 2001), and a ~12 kDa fragment is secreted into the culture supernatant, suggesting that an additional proteolytic event removes this fragment (Bumann *et al*., 2002).

Following removal of the amino-terminal signal sequence and carboxy-terminal autotransporter domain, the mature 88 kDa VacA is secreted into the culture medium, though a significant fraction of the 88 kDa toxin may remain associated with the bacterial cell surface (Telford *et al*., 1994). The toxin that remains associated with the bacterium can be delivered to eukaryotic cells either via membrane blebs (Fiocca *et al*., 1999; Keenan *et al*., 2000) or through a contact-dependent mechanism (Ilver *et al*., 2004). The primary amino acid sequence of the mature VacA toxin resembles little else in GenBank. A BLAST search of the full-length VacA sequence reveals relatedness to three paralogous proteins from each of the two sequenced *H. pylori* genomes (Tomb *et al*., 1997; Alm *et al*., 1999) and a pair of proteins from *H. bilis* (Feng *et al*., 2002) (Figure 24.2). The similarity, however, is largely limited to the carboxy-terminal autotransporter domain of VacA (Figure 24.2). In addition, sequences have been found in two *H. acinonychis* isolates that exhibit 84% nucelotide identity to *vacA* from *H. pylori*, but these sequences contain numerous insertions, deletions, and translational stops (Dailidiene *et al*., 2004).

There is considerable variation among different *H. pylori* strains with respect to the levels of toxic activity found in broth culture supernatants (Leunk *et al*., 1988; Cover *et al*., 1993a; Atherton *et al*., 1995). Some strains appear to harbor inactive genes containing deletions or other mutations within the *vacA* open reading frame (Ito *et al*., 1998). Among strains that contain active genes, both the level of *vacA* transcription and the efficiency of VacA secretion may differ (Cover and Blaser, 1992; Cover *et al*., 1993a; Forsyth *et al*., 1998). However, differences in the quantity of secreted toxin do not wholly account for the differences in toxin activity observed in culture super-

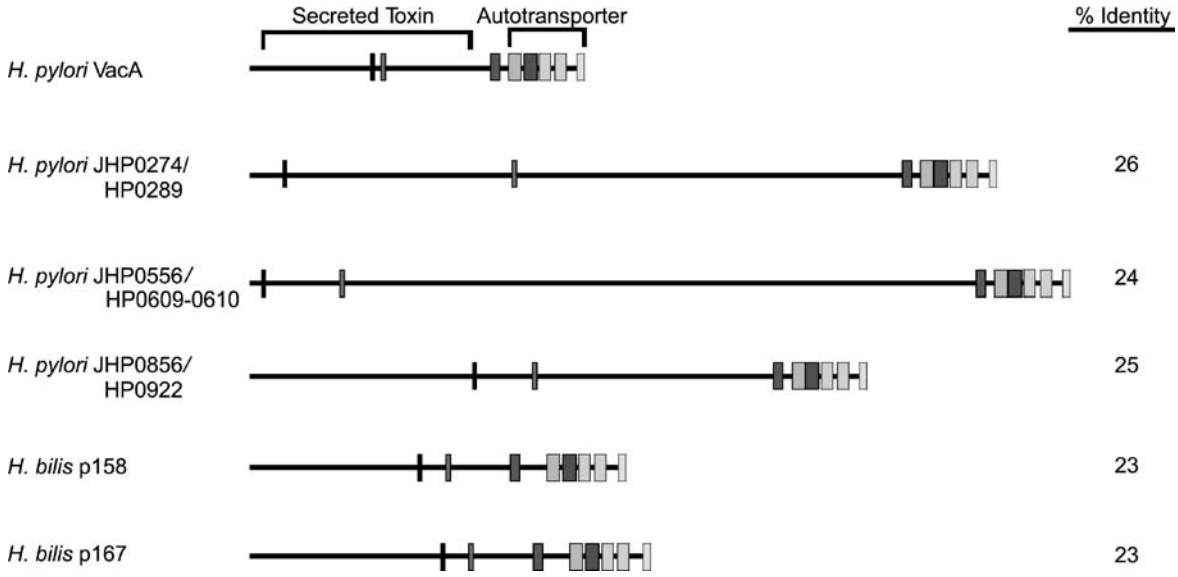

**FIGURE 24.2** VacA and related proteins. The amino acid sequence of the VacA protoxin from *H. pylori* strain 60190 was analyzed using the BLAST local alignment search tool (Altschul *et al*., 1990). Other than additional VacA sequences, the only other similar proteins ("Expect" score $<7\times10^{-7}$) were three paralogous proteins from each of the two sequenced *H. pylori* genomes, JHP0274 (accession C71953) and HP0289 (accession A64556), JHP0556 (accession D71917) and HP0609/0610 (accession A64596 and B64596), and JHP0856 (accession H71879) and HP0922 (accession B64635). HP0609 and HP0610 were identified as two adjacent open reading frames in the genome sequence of *H. pylori* strain 26695 (Tomb *et al*., 1997) and correspond to the single, larger open reading frame JHP0556 identified in strain J99 (Alm *et al*., 1999). In addition to these proteins from *H. pylori*, two proteins from *H. bilis*, designated p158 (accession AA039266) and p167 (accession AAQ14336) also exhibit similarity to VacA. A non-redundant set of proteins was compiled, and was then used as input into the Block Maker program (Henikoff *et al*., 1995), which finds "blocks" (short multiple aligned ungapped segments corresponding to the most highly conserved regions of proteins) within a group of related proteins. Related blocks are identified by shading, and the relative positions of the identified blocks in each related protein are depicted. The percent amino acid identity between VacA and each related protein, within the indicated regions corresponding to the carboxy-terminal autotransporter β-core domain, are listed. Less similar proteins were excluded from the Block Maker analysis.

natants from individual *H. pylori* strains. Another contributing factor is the high level of sequence diversity among different *vacA* alleles, resulting in VacA proteins with different amino acid sequences (Atherton *et al*., 1995). Analyses of VacA sequences from numerous *H. pylori* isolates have led to the recognition of several families of *vacA* alleles (Atherton *et al*., 1995; Strobel *et al*., 1998; van Doorn *et al*., 1998). Two families (s1 and s2) are recognized based on sequence variability at the 5′ end of the *vacA* gene, including the portion that encodes the VacA amino-terminal signal sequence (Figure 24.1B), and two additional families (m1 and m2) are recognized based on variability of *vacA* "midregions" (Figure 24.1C). Various s1, m1, and m2 subfamilies of *vacA* alleles have also been described. Among *H. pylori* isolates, s1/m1, s1/m2, and s2/m2 *vacA* alleles are relatively common and exhibit a worldwide distribution, whereas s2/m1 alleles are only rarely observed (Letley *et al*., 1999; Van Doorn *et al*., 1999). Surprisingly, the main families of *vacA* sequences (s1, s2, m1, and m2) have remained relatively intact despite evidence that recombination among *vacA* alleles from different strains has occurred commonly (Suerbaum *et al*., 1998; Atherton *et al*., 1999; Ji *et al*., 2002; Aviles-Jimenez *et al*., 2004). This suggests that various *in vivo* selective forces favor preservation of these structures.

VacA proteins that induce vacuolation of mammalian cells *in vitro* are expressed from s1-type alleles, whereas s2-type VacA proteins lack detectable vacuolating activity. The differences between s1- and s2-type VacA proteins are found both in the signal sequences (removed from the mature toxin) and in the amino-termini of the mature toxins. In comparison to s1-type toxins, s2-type proteins contain an additional 12 amino acids at the amino terminus (Atherton *et al*., 1995) (Figure 24.1B). Multiple studies have analyzed chimeric proteins in which an active s1-type VacA toxin was converted to a s2-type protein or vice versa (Letley and Atherton, 2000; McClain *et al*., 2001b; Letley *et al*., 2003). The results from these studies indicate that the 12 amino-acid extension found in s2-type VacA proteins confers a vacuolation-negative phenotype.

Mid-region diversity in *vacA* alleles has been linked to differences among VacA proteins in cell tropism (Pagliaccia *et al*., 1998; Ji *et al*., 2000; Wang *et al*., 2001). m1-type VacA toxins produce vacuolating cytotoxic effects in a wide variety of different cultured cell lines, including HeLa cells, which are commonly used to assess vacuolating cytotoxic activity. In contrast, m2-type VacA toxins appear to exhibit vacuolating activity toward a narrower range of cells (if they exhibit any activity) and are relatively inactive against HeLa cells (Pagliaccia *et al*., 1998). m2-type VacA toxins bind poorly to HeLa cells (Pagliaccia *et al*., 1998; Wang *et al*., 2001), which suggests that distinct cellular receptors for m1- and m2-type VacA toxins may account for the observed differences in cell tropism (Wang *et al*., 2001). Analysis of a series of m1/m2 chimeras has led to the identification of a stretch of 148 amino acids within the VacA m region that may determine cell specificity (Ji *et al*., 2000).

Based on the high level of genetic diversity among *vacA* alleles, it is not surprising that there is considerable antigenic variability among VacA toxins as well. Monoclonal antibodies produced against s1-m1 VacA failed to recognize s2-m2 VacA proteins (Vinion-Dubiel *et al*., 2001). This result is not completely unexpected because mature s1-m1 and s2-m2 VacA proteins are only about 75% identical in amino acid sequences overall and exhibit even greater amino acid diversity in the VacA m-region. More notable was the inability of various monoclonal antibodies to consistently recognize s1-m1 toxins from multiple different strains (Vinion-Dubiel *et al*., 2001). s1-m1 toxins produced by different *H. pylori* strains are typically about 90% identical in amino acid sequences. These data suggest that amino acid diversity among VacA proteins from different *H. pylori* strains may occur disproportionately in surface-exposed epitopes.

## ROLE OF VacA *IN VIVO*

### Mice and other model animals

Several studies have examined the role of VacA *in vivo* by using animal models for *H. pylori* infection. In one study, the *vacA* allele type of wild-type *H. pylori* isolates did not influence the ability of *H. pylori* to colonize mice, i.e., a variety of *H. pylori* strains were found to colonize independently of the *vacA* allele carried by each strain (Ayraud *et al*., 2002). This is consistent with the capacity of *H. pylori* strains containing various types of *vacA* alleles to colonize humans. However, the presence of VacA does appear to influence *H. pylori* colonization. When mice were co-infected with a mixture of *vacA*-positive and isogenic *vacA*-negative strains, the *vacA* knockout mutant did not colonize mice as efficiently as the wild-type parental strain (Salama *et al*., 2001). It is worth noting that the *H. pylori* strain, SS1, used in this study (Salama *et al*., 2001) has been reported by other investigators to contain an s2/m2 *vacA* allele (van Doorn *et al*., 1999a), which encodes a VacA protein with little if any cytotoxic activity *in vitro*. This suggests that critical functions of VacA remain to be determined. In a gerbil model, the colonization efficiency of a *vacA* mutant strain was slightly less than that of the parental

strain (Wirth *et al*., 1998), and no effect of VacA on colonization efficiency was detected in a gnotobiotic piglet model (Eaton *et al*., 1997).

Oral administration of purified VacA to mice causes gastric ulceration and inflammation (Telford *et al*., 1994; Fujikawa *et al*., 2003), accompanied by infiltration of both mast cells and monocytes (Supajatura *et al*., 2002). Based on the capacity of VacA to induce ulceration in mice when administered intragastrically, it has been suggested that VacA contributes to the pathogenesis of gastric ulceration in humans. However, the intragastric concentration of VacA in these experiments is likely to be substantially higher than that which is encountered in the context of human *H. pylori* infection.

### *H. pylori* infection of humans

In an effort to determine whether or not VacA plays an important role in *H. pylori* pathogenesis in humans, many studies have examined the relationship between *vacA* allele types and the development of gastroduodenal disease. Among *H. pylori*–infected individuals, infection with *H. pylori* strains containing an m1-type *vacA* allele is associated with an increased risk for gastric carcinoma compared to infection by strains containing an m2-type allele (Figueiredo *et al*., 2002). Additionally, strains containing an m1-type *vacA* allele are associated with more pronounced epithelial damage, neutrophilic and lymphocytic infiltration, atrophic gastritis, and intestinal metaplasia (Nogueira *et al*., 2001). Thus, in comparison to strains containing m2-type *vacA* alleles, strains containing m1-type *vacA* alleles appear to be associated with more severe disease outcome.

Studies have also found that infection with *H. pylori* strains containing *vacA* s1-type alleles seems to correlate with more severe clinical disease. Numerous studies have concluded that peptic ulceration occurs more commonly among patients infected with *H. pylori* strains containing an s1-type *vacA* allele than among patients infected with strains containing an s2-type *vacA* allele (Atherton *et al*., 1995; Han *et al*., 1998; Rudi *et al*., 1998; Strobel *et al*., 1998; Gerhard *et al*., 1999; Kidd *et al*., 1999; Van Doorn *et al*., 1999; De Gusmao *et al*., 2000). Similarly, s1-type VacA alleles are associated with an increased risk for gastric carcinoma (Figueiredo *et al*., 2002). These associations are less apparent in many Asian countries than in Europe and the Americas (Pan *et al*., 1998), perhaps because in many Asian countries, nearly all *H. pylori* isolates contain s1-type *vacA* alleles (Van Doorn *et al*., 1999). The correlation between vacA s-types and development of peptic ulcers in humans is consistent with studies linking s1-type VacA to gastric epithelial damage in animal models and with studies indicating that s2-type toxins lack activity in cell culture assays (Letley and Atherton, 2000; McClain *et al*., 2001b; Letley *et al*., 2003). Strains that contain s1-type *vacA* alleles more frequently contain the *cag* pathogenicity island and more frequently express the BabA adhesin than do strains that contain s2-type *vacA* alleles (Rudi *et al*., 1998; Gerhard *et al*., 1999), which suggests that multiple bacterial factors contribute to ulcerogenesis.

## *IN VITRO* ACTIVITIES

### Vacuole formation

One of the most striking activities of VacA is its capacity to cause formation of numerous, large cytoplasmic vacuoles in intoxicated cells (Leunk *et al*., 1988; de Bernard *et al*., 1998b) (Figure 24.3). VacA induces formation of vacuoles in many different transformed cell lines and also in primary cultures of human gastric epithelial cells (Smoot *et al*., 1996; de Bernard *et al*., 1998b). Vacuoles also have been observed in gastric epithelial cells in gastric biopsies from patients infected with *H. pylori* (Tricottet *et al*., 1986; Fiocca *et al*., 1992), but it is not clear whether these vacuoles are caused by VacA. VacA-induced vacuole formation *in vitro* is inhibited by monensin (an ionophore that dissipates intracellular proton gradients) (Cover *et al*., 1992c) and inhibitors of the vacuolar ATPase (v-ATPase), including bafilomycin A1 and an antibody specific to the v-ATPase (Cover *et al*., 1993b; Papini *et al*., 1993; Papini *et al*., 1996), indicating that the v-ATPase is required for VacA-induced vacuole formation. The lumen of VacA-induced vacuoles is acidic, as indicated by the ability of the vacuoles to sequester neutral red and acridine orange (Cover *et al*., 1991, Catrenich, 1992). The accumulation of neutral red is the basis for a widely-used

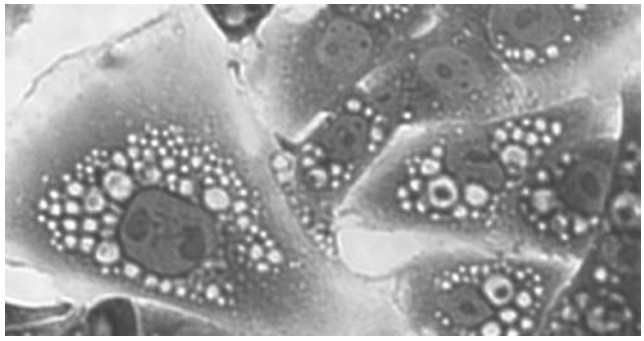

**FIGURE 24.3** VacA-induced vacuolation of HeLa cells. HeLa cell monolayers were treated with acid-activated VacA toxin purified from *H. pylori* culture supernatant in the presence of 5 mM $NH_4Cl$ and the cells were stained with crystal violet.

quantitative assay of the toxin's vacuolating activity (Cover *et al*., 1991). The formation of vacuoles in response to purified VacA is markedly stimulated by weak bases, such as ammonium salts, which enter acidic intracellular compartments in an uncharged state, become protonated, and may contribute to vacuole enlargement by inducing osmotic swelling (Cover *et al*., 1992c). *In vivo*, $NH_4^+$ ions may be supplied by the action of *H. pylori* urease, an essential enzyme required for the bacterium to survive in the acidic environment of the stomach, as well as by other pathways (Tombola *et al*., 2001). VacA-induced vacuoles possess characteristics typically associated with late endosomes and lysosomes, including the presence of rab7 (Papini *et al*., 1994), Lgp110 (Molinari *et al*., 1997), and Lamp1 (Li *et al*., 2004b) in the vacuole membrane, suggesting that VacA-induced vacuoles arise from these structures. Markers for other structures, including Golgi and early endosomes, have not been reported as components of VacA-induced vacuoles.

It is unlikely that increased osmotic pressure inside endocytic compartments can fully explain the swelling of VacA-induced vacuoles, as the increasing pressure would likely result in rupture of these compartments unless additional membrane were added to the growing vacuoles. It is likely that membrane fusion between nascent vacuoles and preexisting membrane-bound compartments contributes to vacuole biogenesis. Consistent with this model, vacuole formation was found to require the small GTP-binding protein Rab7 (Papini *et al*., 1997), which regulates fusion events between vesicles in the late endocytic pathway (Mohrmann and van der Sluijs, 1999). In addition, a recent study reported that syntaxin 7 is required for VacA-induced vacuole formation (Suzuki *et al*., 2003). Syntaxin 7 localizes to both late endosomes and lysosomes, and plays a crucial role in the fusion between late endosomes and lysosomes (Mullock *et al*., 2000; Nakamura *et al*., 2000). A requirement for syntaxin 7 and Rab7 is consistent with a model in which VacA-induced vacuole formation involves the docking and fusion of membrane vesicles via SNARE proteins.

In contrast, another study reported that microinjection of anti-syntaxin 7 antibodies into cells did not inhibit vacuole formation (de Bernard *et al*., 2002). This study also reported that cells transfected with a plasmid encoding dominant-negative α-SNAP did not vacuolate in response to exogenously added VacA, whereas, in contrast, these cells became vacuolated when cotransfected with a VacA-expressing plasmid. α-SNAP is an accessory protein that is essential for the recycling of SNARE protein complexes, allowing SNAREs to reform complexes that will drive subsequent rounds of membrane fusion (Whiteheart *et al*., 2001; Bonifacino and Glick, 2004). These results suggest that endocytosis of VacA requires α-SNAP, but that vacuole formation induced by intracellular VacA toxin does not require vesicle fusion via SNARE proteins. An alternative source of additional membrane for the nascent vacuoles may be found within late endosomes. Based on electron microscopy studies showing the lack of internal membrane structures within vacuoles (Catrenich and Chestnut, 1992; Cover *et al*., 1992b; Ricci *et al*., 1997; de Bernard *et al*., 2002), and on the apparent lack of lyso-bisphosphatidic acid (LBPA, a component of the internal membrane structures within endosomal and lysosomal membranes) in the lumen of VacA-induced vacuoles (de Bernard *et al*., 2002), it was proposed that the vacuoles may form by the addition of membrane from the extensive network of intracompartmental membranes within late endosomes (de Bernard *et al*., 2002).

If the process of vacuole formation involves fusion among preexisting membrane-bound compartments, how might VacA contribute to membrane fusion? VacA may function as a fusogenic protein in a manner analogous to a variety of viral fusion proteins (Nieva and Agirre, 2003; Li *et al*., 2004b). In this model, VacA is expected to become localized in the membrane of late endocytic compartments and function to promote docking or fusion of these compartments. In support of this hypothesis, VacA is internalized by cells and localizes in association with vacuole membranes (Sommi *et al*., 1998; Li *et al*., 2004b), and recombinant VacA fragments were shown to promote fusion of small unilamellar vesicles *in vitro* (Moll *et al*., 1995). Alternatively, VacA may modulate the activity of cellular proteins involved in intracellular pathways normally used for membrane fusion. Addition of purified VacA to cells in the absence of supplemental weak bases reveals a redistribution of several markers for late endocytic compartments to perinuclear clusters without the development of large cytoplasmic vacuoles (Li *et al*., 2004b). The membrane markers that undergo clustering and redistribution in response to VacA are the same as those that localize to the vacuole membrane in vacuolated cells, and experiments indicate that there is a structural relationship between VacA-induced perinuclear clusters and VacA-induced vacuoles (Li *et al*., 2004b). This VacA-induced clustering of late endocytic compartments resembles the clustering of late endocytic compartments observed following overexpression of constitutively active Rab7 (Bucci *et al*., 2000), RILP (a putative Rab7 effector) (Cantalupo *et al*., 2001), or Vam6p (the human homolog of a yeast protein that acts in conjunction with the yeast rab7 homolog in vesicle fusion in mammalian cells) (Nakamura *et al*., 1997; Caplan *et al*., 2001). Thus, VacA may act by modulating

the activity of Rab7 or related effector molecules, resulting in increased membrane fusion activity.

In addition to v-ATPase and Rab7, several other cellular constituents are required for the process of VacA-induced vacuole formation. These include dynamin and Rac1 (Hotchin *et al*., 2000; Suzuki *et al*., 2001). Disruption of microtubules by treatment with colchicine or nocodazole (Papini *et al*., 1994) and disruption of the actin cytoskeleton by treatment with cytochalasin D (Ricci *et al*., 2000) each result in at least partial inhibition of VacA-induced vacuolation (Li *et al*., 2004b). Overexpression of PIKfyve kinase (which produces phosphatidylinositol-3, 5-bisphosphate) inhibits VacA activity, which suggests that phosphatidylinositol derivatives may play an important role in VacA-induced cellular vacuolation (Ikonomov *et al*., 2002). In addition, cholesterol-rich lipid rafts, glycosylphosphatidylinositol (GPI)-anchored proteins, and the receptor protein tyrosine phosphatases (RPTP) RPTPα and RPTPβ have also been implicated in the process by which VacA induces vacuolation, and each is discussed in greater detail below (Yahiro *et al*., 1999; Ricci *et al*., 2000; Patel *et al*., 2002; Schraw *et al*., 2002; Kuo and Wang, 2003; Yahiro *et al*., 2003; Gauthier *et al*., 2004). The precise roles of all these cellular constituents in the process of VacA-induced vacuolation have not been completely elucidated. It seems likely that several of these factors may be required for binding, internalization, and intracellular trafficking of VacA, and other factors may be required for the process of vacuole biogenesis.

## Anion-conductive channels

VacA can form low-conductance, voltage-dependent, anion-selective channels in planar lipid bilayers (Czajkowsky *et al*., 1999; Iwamoto *et al*., 1999; Szabo *et al*., 1999; Tombola *et al*., 1999a). Anions such as $Cl^-$, $HCO_3^-$, and small organic molecules are conducted by VacA channels (Iwamoto *et al*., 1999; Tombola *et al*., 1999a). Evidence obtained from whole-cell, patch-clamp techniques indicates that VacA is able to form anion-selective channels in the plasma membrane of cells, leading to a partial depolarization of the membrane potential (Szabo *et al*., 1999). There is a correlation between the ability of VacA mutant proteins to form channels in lipid bilayers and the extent to which these proteins induce membrane depolarization of intact cells (McClain *et al*., 2003). These results support the conclusion that the plasma membrane channels formed in response to VacA are indeed directly due to the toxin, as opposed to the activation of a cellular channel in response to the toxin. The channels formed by VacA in the plasma membrane can lead to the diffusion of small ions, including $Cl^-$, $HCO_3^-$, and urea, across the cell membrane (Szabo *et al*., 1999; Debellis *et al*., 2001; Tombola *et al*., 2001).

VacA mutants that exhibit defects in the capacity to form membrane channels in planar lipid bilayers invariably lack vacuolating cytotoxic activity (Tombola *et al*., 1999a; Vinion-Dubiel *et al*., 1999; McClain *et al*., 2001b; McClain *et al*., 2003). Furthermore, a variety of chemicals that inhibit chloride channel activity also inhibit the ability of VacA to form channels and to induce vacuolation (Iwamoto *et al*., 1999; Szabo *et al*., 1999; Tombola *et al*., 1999b).The relative strength of the VacA channel inhibitors correlates with the ability of the chemicals to inhibit vacuolation (Tombola *et al*., 1999b). In addition, the histidine-modifying reagent diethylpyrocarbonate (DEPC), which inhibits vacuolating activity, was also found to inhibit VacA channels (Tombola *et al*., 1999a). Taken together, these data support the hypothesis that VacA channel activity is required for vacuole formation. However, channel formation alone does not appear to be sufficient to induce vacuole formation, as certain dominant-negative mutants interfere with the vacuolating activity of wild-type VacA, but do not appear to interfere with channel activity (McClain *et al*., 2001b).

Tombola *et al*. (Tombola *et al*., 1999a) proposed a model to account for the relationship between VacA channel activity and vacuolation (Figure 24.4). This model proposes that VacA is internalized by cells and localizes to the membrane of endocytic compartments, and that VacA channels are formed in this site. The formation of VacA channels in the membrane of

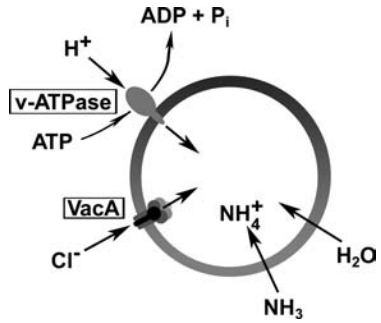

**FIGURE 24.4** VacA channel activity is required for vacuolation. In this model (Tombola *et al*., 1999a), the VacA toxin inserts into the membrane of endosomes to form anion-selective membrane channels. The influx of $Cl^-$ through the VacA channel presumably activates the v-ATPase (Al-Awqati, 1986), leading to an increase in the lumenal concentration of $H^+$. Weak bases such as $NH_3$ diffuse across the vacuole membrane and become protonated and sequestered, leading to an osmotically driven influx of $H_2O$, and resulting in an increased osmotic pressure within the vacuole. The increased pressure is presumed to help drive enlargement of the vacuolar compartment.

v-ATPase–containing vesicles is expected to lead to an influx of $Cl^-$ into the vesicle lumen. The increased intralumenal $Cl^-$ concentration is expected to stimulate the v-ATPase (Al-Awqati, 1986), resulting in an increase in lumenal $H^+$. This acidification of the vesicle leads to the influx of weak bases (such as $NH_3$), which become protonated and accumulate within the vesicle, resulting in the influx of water to counteract the increased tonicity. In support of this model, vacuolation is accompanied by and requires uptake of $Cl^-$ from the medium, and vacuolation can be inhibited by hyperosmotic medium (Morbiato *et al*., 2001).

Endogenous chloride channels are found in a variety of intracellular organelles, including endosomes and lysosomes, where the channels are believed to function as an electrical shunt for the v-ATPase (al-Awqati, 1995; Szewczyk, 1998). Proton pumping by the v-ATPase involves the transfer of both acid equivalents and electrical charge across the vesicle membrane, and $H^+$ entry into the lumen must be accompanied by anion entry (or cation exit) in order to dissipate the electrical potential across the membrane. Acidification of endosomes by the v-ATPase is accompanied by significant increases in both intralumenal $Cl^-$ concentrations and in endosome volume (Sonawane *et al*., 2002). Overexpression of the intracellular chloride channel ClC-3 in human hepatoma (Huh-7) cells and in Chinese hamster ovary (CHO-K1) cells induces the formation of large cytoplasmic vacuoles with characteristics of late endosomes or lysosomes, including the presence of Lamp-1 on the vacuole membranes (Li *et al*., 2002). Furthermore, the formation of the ClC-3–induced vacuoles requires the channel activity of the ClC-3 protein, and is inhibited by bafilomycin A1, suggesting a role for the v-ATPase (Li *et al*., 2002). Thus, overexpression of ClC-3 results in cytoplasmic vacuolation that is remarkably similar to the vacuolation induced by the VacA toxin. This similarity is consistent with the hypothesis that membrane channels play an important role in VacA-induced vacuole formation.

## Effects on mitochondria and apoptosis

Addition of VacA to cells results in perturbations to mitochondria, as evidenced by a decrease in cellular ATP levels (Kimura *et al*., 1999), a decrease in the mitochondrial membrane potential (Kimura *et al*., 1999; Willhite and Blanke, 2004), and the release of cytochrome c (Galmiche *et al*., 2000; Willhite *et al*., 2003). The VacA-induced effects on mitochondria appear to depend on VacA channel activity, as both the VacA-induced reduction in mitochondrial membrane potential and the release of cytochrome c are inhibited by chemicals that block VacA channels (NPPB and DIDS) (Willhite *et al*., 2003) and by a channel-inhibiting, dominant-negative mutant VacA protein (Vinion-Dubiel *et al*., 1999; Willhite *et al*., 2003). Furthermore, VacA mutants that lack channel activity do not cause release of cytochrome c from mitochondria (Willhite *et al*., 2003). The effects of VacA on mitochondria seem to be independent of vacuolating activity, as mitochondrial damage is not inhibited by bafilomycin A1 (Willhite *et al*., 2003), and the VacA-induced mitochondrial effects occur at higher toxin concentrations and at later time points than are required to induce vacuolation (Willhite *et al*., 2003; Willhite and Blanke, 2004).

VacA expressed within transfected cells or added exogenously to cultured cells has been observed to associate with mitochondria (Galmiche *et al*., 2000; Willhite and Blanke, 2004). In experiments in which VacA was incubated with isolated mitochondria, the toxin was found to remain free within the matrix or associated with the inner mitochondrial membrane (Galmiche *et al*., 2000). Just as the formation of channels by VacA in the endocytic membrane could lead to vacuole formation, the formation of channels by VacA in the inner mitochondrial membrane might contribute directly to a decrease in the mitochondrial membrane potential and the release of cytochrome c. Thus, VacA might act in a manner analogous to the mitochondrial permeability transition pore (PT) (Chang and Yang, 2000; Willhite and Blanke, 2004). Opening of the PT pore causes swelling of the mitochondrial matrix (due to the high osmolarity of the matrix), leading to rupture of the mitochondrial outer membrane and the release of cytochrome c. The disruption of the inner mitochondrial membrane potential has also been associated with opening of the PT pore. It is not clear how endocytosed VacA finds its way to the mitochondria. It has been suggested that some VacA protein might undergo trafficking from the endocytic pathway retrograde through the Golgi to the cytoplasm (Argent *et al*., 2004), and could thus gain access to the mitochondria. However, mechanisms by which VacA might cross the outer mitochondrial membrane remain unclear.

Exogenously added VacA, as well as various VacA fragments that are expressed in transiently transfected HeLa cells, induce cleavage of poly(ADP-ribose) polymerase (PARP), a substrate of activated caspase-3 (Tewari *et al*., 1995; Galmiche *et al*., 2000; Cho *et al*., 2003). Caspase 3 is one of the effector caspases, which cleave various cytoplasmic and nuclear proteins (including PARP), thereby triggering apoptosis (Chang and Yang, 2000). One pathway leading to the activation of caspase-3 is the release of cytochrome c from mitochondria. Cytosolic cytochrome c forms a complex with procaspase-9 and apoptotic protease activating

factor 1 (APAF-1), leading to activation of caspase-9, which in turn activates the effector caspases, including caspase-3 (Chang and Yang, 2000).

Consistent with the findings that VacA induces perturbations in mitochondria and cleavage of PARP, analyses of wild-type and *vacA* mutant *H. pylori* strains have indicated that VacA contributes to the ability of *H. pylori* to induce apoptosis of cultured cell lines (Peek *et al*., 1999; Kuck *et al*., 2001; Menaker *et al*., 2004). Further experiments have demonstrated that purified VacA can induce apoptosis in the absence of other *H. pylori* factors (Kuck *et al*., 2001; Cover *et al*., 2003). A mutant VacA protein that lacks channel-forming activity failed to induce apoptosis (Cover *et al*., 2003), which suggests that VacA-induced apoptosis is a process that requires the formation of VacA channels.

## Immune-modulating activities

In addition to stimulating the formation of cytoplasmic vacuoles and contributing to apoptosis, VacA interferes with the activation and proliferation of T lymphocytes. VacA is able to inhibit T lymphocyte activation and proliferation by a variety of different mechanisms. First, VacA blocks activation of nuclear factor of activated T cells (NFAT), a key transcription factor required for optimal T lymphocyte activation (Boncristiano *et al*., 2003; Gebert *et al*., 2003). This effect has been attributed to abrogation of calcium influx, thereby blocking the activity of the $Ca^{2+}$-calmodulin-dependent phosphatase calcineurin (Gebert *et al*., 2003). Second, VacA inhibits IL-2-dependent cell-cycle progression and proliferation via a mechanism that is independent of VacA effects on NFAT activation (Sundrud *et al*., 2004). Both of these mechanisms appear to depend on VacA channel-forming activity, as mutant VacA toxins that lack channel activity do not inhibit T cell proliferation (Boncristiano *et al*., 2003; Sundrud *et al*., 2004), and the inhibition of cell cycle progression by wild-type VacA is blocked by a channel-inhibiting, dominant-negative mutant VacA (Vinion-Dubiel *et al*., 1999; Sundrud *et al*., 2004). Finally, VacA can interfere with T cell activation through a channel-independent mechanism that involves activation of intracellular signaling through the mitogen-activated protein kinases MKK3/6 and p38 and the Rac-specific nucleotide exchange factor, Vav (Boncristiano *et al*., 2003).

VacA has been demonstrated to produce several additional effects on immune cells. *H. pylori* strains expressing VacA, in contrast to isogenic *vacA* null mutants, inhibit phagosome-lysosome fusion in macrophages (Zheng and Jones, 2003). Phagosomes containing VacA-expressing *H. pylori* were found to retain EEA1, a marker of early endosomes, and had low levels of LAMP1 (a lysosomal marker), whereas the phagosomes containing a *vacA* mutant strain had lower levels of EEA1 and higher levels of LAMP1 (Zheng and Jones, 2003). The phagosomes containing the VacA-expressing *H. pylori*, but not phagosomes containing the mutant *H. pylori*, also retained the tryptophan aspartate-containing coat protein (TACO) (Zheng and Jones, 2003), retention of which has been linked to defective trafficking of phagosomes containing *Mycobacterium bovis* (Ferrari *et al*., 1999). VacA was also shown to inhibit antigen presentation using a model system consisting of tetanus-toxoid-specific human $CD4^+$ T cells and autologous B cells (Molinari *et al*., 1998b). Specifically, antigen presentation via newly synthesized class II MHC molecules was inhibited by VacA, but VacA did not inhibit presentation relying upon recycled MHC class II molecules. Peptide-class II complexes are assembled in endocytic, lysosome-like compartments, where newly synthesized class II molecules are targeted from the trans-Golgi network (TGN) (Hiltbold and Roche, 2002).

The ability of VacA to inhibit both phagosome-lysosome fusion and antigen presentation suggests that the toxin induces a generalized defect in endocytic trafficking in cells exposed to the toxin. In support of this hypothesis, VacA-treated HeLa cells exhibit a variety of defects related to altered endocytic trafficking, including inhibited maturation of procathepsin D and inhibition of epidermal growth factor degradation (Satin *et al*., 1997). The observed defects in endocytic trafficking are associated with a partial neutralization of the pH inside endosomes and lysosomes (Satin *et al*., 1997).

VacA also produces pro-inflammatory effects on several cell types, including mast cells. *In vivo*, significant numbers of mast cells are observed in the gastric mucosa of patients infected with *H. pylori* (Nakajima *et al*., 1997; Nakajima *et al*., 2004), and similar mast cell infiltration is observed in mice experimentally colonized with *H. pylori* (van Doorn *et al*., 1999b). Within three minutes after the addition of VacA to a cultured mast cell line *in vitro*, the cytoplasmic $Ca^{2+}$ concentration was observed to undergo rapid oscillations that lasted in excess of two hours, and similar results were reported using primary, bone-marrow derived mouse mast cells (de Bernard *et al*., 2004). VacA induces mast cell degranulation (de Bernard *et al*., 2004), and stimulates mast cells to secrete pro-inflammatory cytokines, including tumor necrosis factor $\alpha$ in a $Ca^{2+}$-dependent mechanism (Supajatura *et al*., 2002; de Bernard *et al*., 2004). Furthermore, VacA has been reported to stimulate the production of the pro-inflammatory enzyme cyclooxygenase 2 (Cox-2) in the MKN-28 gastric cancer

cell line (Caputo *et al*., 2003) and in human neutrophils and macrophages (Boncristiano *et al*., 2003).

### Other activities

Human gastric epithelial cell lines treated with VacA exhibit decreased thymidine incorporation (Ricci *et al*., 1996; Pai *et al*., 2000; Tabel *et al*., 2003) and an increased percentage of cells in the $G_0/G_1$ phase of the cell cycle compared with untreated control cells (Kimura *et al*., 1999). VacA has also been shown to inhibit the migration of cells into wounds introduced in cultured monolayers (Tabel *et al*., 2003). The reduced wound healing observed in monolayers treated with the toxin correlates with the ability of VacA to disrupt the actin cytoskeleton (Pai *et al*., 1999; Ashorn *et al*., 2000; Tabel *et al*., 2003). Thus, the ability of VacA to inhibit cell migration and proliferation, both of which are required for maintenance of the gastric epithelium and for ulcer healing, may directly impact ulcerogenesis.

When added to polarized epithelial monolayers, VacA increases the trans-epithelial resistance (TER) and the paracellular permeability to small molecules, including $Fe^{3+}$ and $Ni^{2+}$, that are essential for *H. pylori* survival *in vivo* (Papini *et al*., 1998). Significantly, these effects of VacA were also observed when *H. pylori* strains expressing m2-type VacA proteins, which do not induce vacuoles in the cell line tested, were added to polarized monolayers, but were not observed when *vacA* null mutant strains were added (Pelicic *et al*., 1999). The ability of VacA to increase TER does not require the addition of weak bases and is not blocked by inhibitors of the v-ATPase, but is inhibited by the chloride channel inhibitor NPPB. This suggests that VacA channels might be mechanistically involved in this phenomenon via a pathway distinct from that which leads to vacuole formation.

Purified VacA induces phosphorylation of the MAP kinases Erk1/2 and p38 in a gastric epithelial cell line (Nakayama *et al*., 2004), and phosphorylation of p38 in the Jurkat T-cell line and in human macrophages and neutrophils (Boncristiano *et al*., 2003). VacA-induced phosphorylation of p38 was shown to lead to activation of p38 kinase activity, leading to the activation of downstream effectors in several of these cell types (Boncristiano *et al*., 2003; Nakayama *et al*., 2004). Among cells treated with a specific inhibitor of p38 kinase activity, VacA continued to induce vacuolation and led to a decrease in mitochondrial membrane potential and the release of cytochrome c (Nakayama *et al*., 2004). Thus, these phenomena occur via mechanisms that are distinct from the p38 signaling pathway. In addition to effects of VacA on MAP kinase signaling pathways, VacA has been reported to alter several additional signaling pathways in various cell types (Pai *et al*., 2000; Asahi *et al*., 2003; Boncristiano *et al*., 2003; Caputo *et al*., 2003; Fujikawa *et al*., 2003; Suzuki *et al*., 2003; Yuan *et al*., 2004).

## VacA STRUCTURE AND FUNCTION

### Formation of oligomeric structures

Early studies of VacA indicated that the toxin could assemble into high molecular mass structures (Cover and Blaser, 1992). Imaging of purified VacA by deep-etch electron microscopy (EM) indicates that VacA monomers assemble into flower-shaped oligomeric structures comprised of 6 to 14 subunits (Lupetti *et al*., 1996; Cover *et al*., 1997; Lanzavecchia *et al*., 1998) (Figure 24.5). The predominant oligomer appears to be two hexamers stacked to form a dodecamer. These structures are about 30 nm in diameter, and consist of a central ring surrounded by peripheral "arms" or "petals." Imaging of VacA in a vitrified aqueous environment by EM with cryonegative staining (Adrian *et al*., 2002) has permitted visualization of side views of these structures, in which the petals are slightly separated from each other, and the closest contact between the two hexamers appears to occur between the central rings. This suggests that the central ring is the most hydrophobic portion of the complex, while

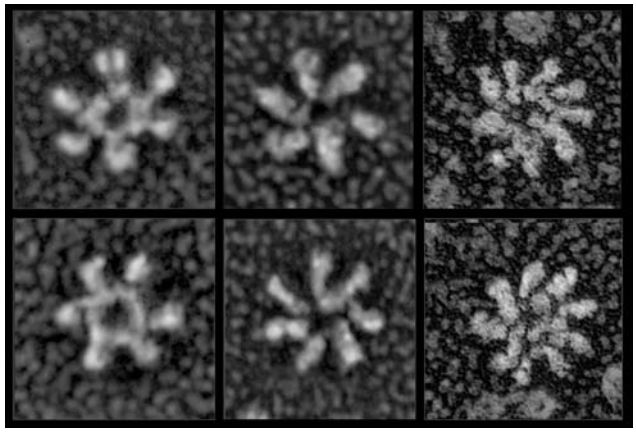

**FIGURE 24.5** Deep-etch electron micrographs of purified oligomeric VacA absorbed to mica flakes. Several studies have examined the organization of VacA oligomers by electron microscopy (Lupetti *et al*., 1996; Cover *et al*., 1997; Lanzavecchia *et al*., 1998; Adrian *et al*., 2002). Left column: Radially symmetric "flowers" exhibiting a prominent central ring. Middle column: Flatter forms lacking a prominent central ring. Right column: VacA oligomers absorbed to mica were treated with pH 3.5 glycine buffer to reveal dissociation into monomeric components.

the petals may be relatively hydrophilic (Adrian *et al*., 2002).

The structure of VacA oligomers associated with a lipid membrane appears slightly different from the structure of VacA oligomers observed in solution. Imaging of VacA bound to lipid membranes by both deep-etch EM and atomic-force microscopy (AFM) reveals that VacA assembles predominantly into single-layered hexameric rings with a central pore (Czajkowsky *et al*., 1999; Iwamoto *et al*., 1999; Adrian *et al*., 2002). Correspondingly, the kinetics of VacA channel formation in planar lipid bilayers suggests that VacA forms hexameric structures (Iwamoto *et al*., 1999).

In cells transfected with genes expressing CFP- and YFP-tagged VacA, the toxin was shown to assemble into oligomeric complexes, based on fluorescence resonance energy transfer (FRET) analysis (Willhite *et al*., 2002). Additional studies have shown a correlation between the formation of VacA oligomeric complexes and VacA activity. First, an analysis of mutant toxins indicated that toxins that fail to oligomerize also do not induce vacuolation (Vinion-Dubiel *et al*., 1999). Second, certain inactive mutant VacA toxins, when expressed together inside transfected cells, complement each other to induce vacuole formation (Ye and Blanke, 2002). Finally, certain inactive mutant toxins exhibit a dominant-negative phenotype when mixed with wild-type VacA (Vinion-Dubiel *et al*., 1999; McClain *et al*., 2001b). Evidence suggests that this dominant-negative activity is due to the formation of mixed-oligomeric complexes containing both wild-type and mutant VacA proteins (McClain *et al*., 2001b). It remains to be determined whether VacA binds to cells as an oligomeric "prepore" that subsequently inserts into the membrane, or whether the active toxin oligomer assembles from monomers that have already bound to cells or inserted into the membrane.

The oligomeric VacA toxin purified from *H. pylori* culture supernatant exhibits relatively little vacuolating cytotoxic activity, but its activity can be greatly enhanced if the purified protein is first acidified or alkalinized before it is added to cells (de Bernard *et al*., 1995; Yahiro *et al*., 1999). Acid- or alkaline-activation of the VacA toxin results in structural changes as evidenced by changes in circular dichroism, fluorescence spectra, and labeling with the hydrophobic probe 1-anilino-8-naphthalenesulfonate (ANS) (de Bernard *et al*., 1995; Molinari *et al*., 1998a). These structural changes are accompanied by a disruption of the VacA oligomeric structure into component monomers (Cover *et al*., 1997; Molinari *et al*., 1998a; Yahiro *et al*., 1999). The disrupted monomers are able to reassemble into oligomeric structures if the pH is returned to neutrality (Cover *et al*., 1997). Thus, it is believed that activated VacA monomers may reassemble into toxin oligomers when added to the neutral pH medium overlying cells in culture (though it is unclear whether such reassembly occurs in solution or on the cell surface). VacA in crude culture supernatants does not require activation to exhibit vacuolating cytotoxic activity, which suggests that the striking effect of these pH shifts may be limited to experiments involving purified oligomeric VacA. Nevertheless, the phenomenon of activation has contributed significantly to our understanding of VacA structure-function relationships. For example, compared with non-activated purified VacA, activated toxin exhibits increased binding to the cell surface, and only activated VacA is internalized by cells (McClain *et al*., 2000; Schraw *et al*., 2002).

## VacA domains

The 88-kDa VacA monomer can be proteolytically processed into an amino-terminal 33-kDa (p33) and a carboxy-terminal 55-kDa (p55) fragment (Nguyen *et al*., 2001). The reported masses of these fragments vary considerably in the literature, and these differences may be due to sequence variation among *vacA* alleles in different *H. pylori* strains. It has been suggested that the p33 and p55 fragments represent two domains of VacA. The cleavage of 88-kDa VacA into 33- and 55-kDa fragments can be detected in highly purified VacA preparations, but it is not known whether the cleavage results from an autoproteolytic activity of VacA or from a contaminating protease. Cleavage of 88-kDa VacA into these two fragments has no detectable impact on vacuolating activity, and the two fragments remain physically associated (Lupetti *et al*., 1996; Torres *et al*., 2004). Co-transfection of cells with genes encoding both p33 and p55 leads to vacuolation, whereas each fragment, individually, is inactive (Ye *et al*., 1999); this suggests that at least a portion of each fragment is required for toxin activity. Evidence indicates that independently expressed recombinant p33 and p55 fragments, when mixed together, can physically interact. The p33 and p55 fragments were shown to interact inside transfected cells by co-immunoprecipitation and by FRET analysis (Willhite *et al*., 2002; Ye and Blanke, 2002). Further studies of these two fragments by yeast-two hybrid analysis revealed interactions between p33 and p55, but interactions between p33 and p33 or between p55 and p55 were not detected in this system (Torres *et al*., 2004).

By transfecting the *vacA* gene into cultured cell lines, researchers have been able to define portions of the VacA toxin that are essential for vacuolating activity (de Bernard *et al*., 1997; de Bernard *et al*., 1998a; Ye *et al*.,

1999; Ye and Blanke, 2002). Such transfection studies have clearly indicated the importance of the amino-terminal portion of VacA. Deletion of as few as five amino acids from the amino terminus of VacA is sufficient to eliminate vacuolating activity (de Bernard *et al*., 1998a). The minimal fragment of VacA that is able to induce cytoplasmic vacuolation when expressed inside cells comprises the amino-terminal 422 amino acids of the toxin (Ye *et al*., 1999). This portion of VacA corresponds to the entire p33 fragment and the first 111 amino acids of the p55 fragment. Whereas intracellular expression of the p33 VacA fragment did not induce vacuolation, this fragment was active when co-expressed with a fragment corresponding to amino acids 312 to 478 (the amino-terminal 167 amino acids of p55) (Ye *et al*., 1999).

Amino acid sequences near the amino terminus of VacA play an important role in both vacuolation and membrane channel formation (de Bernard *et al*., 1998a; Ye *et al*., 1999; Letley and Atherton, 2000; Ye and Blanke, 2000; McClain *et al*., 2001b; Letley *et al*., 2003; McClain *et al*., 2003). The amino terminal end of s1-type VacA toxins is predicted to be hydrophobic, and appears to be the only contiguous stretch of hydrophobic amino acids long enough to span a membrane (Figure 24.6). The ability of this region to insert into a membrane has been shown using the TOXCAT system (designed to detect transmembrane helix association in a biological membrane) in *E. coli* (Russ and Engelman, 1999; McClain *et al*., 2001a). Based on this result and on the analysis of VacA toxins containing single amino acid substitutions within the hydrophobic region, it seems likely that this amino-terminal hydrophobic region of VacA either forms part of the VacA channel or plays an indirect role by stabilizing the structure of the channel (McClain *et al*., 2003). An important feature of the VacA amino-terminal hydrophobic region is the presence of GXXXG motifs, which are associated with packing interfaces among protein transmembrane domains (Russ and Engelman, 2000; McClain *et al*., 2003). The significance of the GXXXG motif has been most widely studied using glycophorin A as a model transmembrane protein (Lemmon *et al*., 1992; Lemmon *et al*., 1994; MacKenzie *et al*., 1997; Brosig and Langosch, 1998; Russ and Engelman, 2000). In addition, the importance of GXXXG motifs has been reported in a variety of other transmembrane proteins (Asundi and Carey, 1995; Williams *et al*., 1995; Hebert *et al*., 1996; Mendrola *et al*., 2002; Arselin *et al*., 2003; Lee *et al*., 2004; Li *et al*., 2004a; Polgar *et al*., 2004) and in soluble proteins as well (Kleiger *et al*., 2002). The VacA hydrophobic region contains three tandem copies of the GXXXG motif (Figure 24.6A). One copy in particular, comprised of glycines at positions 14 and 18, has been shown to be important in the packing interface of this putative VacA transmembrane domain as determined by the TOXCAT system, and is essential for both vacuolating activity and membrane channel formation (McClain *et al*., 2003). A recent theoretical model of the VacA amino terminus is consistent with the $G_{14}XXXG_{18}$ repeat assembling into the most closely packed region of the structure (Figure 24.6 B and C) (Kim *et al*., 2004).

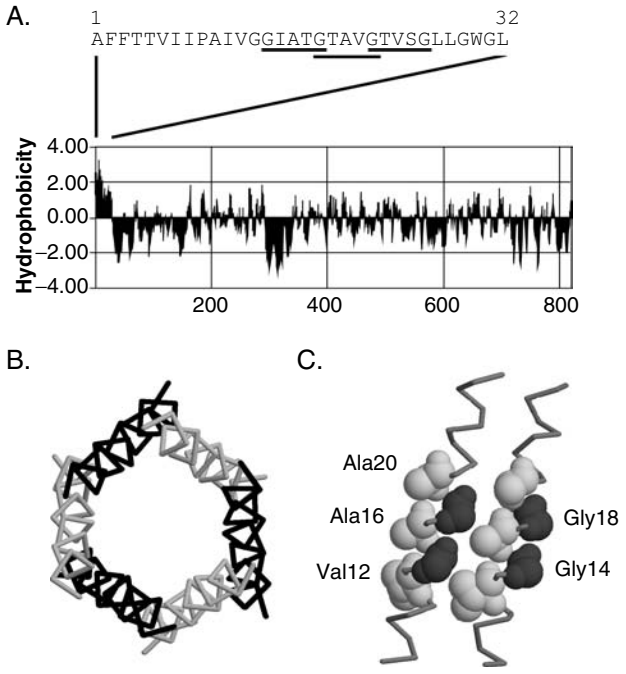

**FIGURE 24.6** The amino terminus of s1-type VacA**.** A. Based on a hydrophobicity plot of the amino acid sequence of VacA from *H. pylori* strain 60190, the amino terminal 32 amino acids of VacA are predicted to form a hydrophobic region. Three tandem copies of a "GXXXG" motif ($G_{14}XXXG_{18}$, $G_{18}XXXG_{22}$, and $G_{22}XXXG_{26}$) are found within this hydrophobic region. B and C. A theoretical model proposes that the amino terminal hydrophobic regions from six individual VacA monomers adopt an α-helical configuration and pack together to form a six-membered ring (Kim *et al*., 2004). This structure is shown from the top in panel B. Two adjacent helices from the proposed structure are shown in a side view (i.e., in a cross section of the membrane) (panel C) with space-filling representations of glycines 14 and 18 (dark shaded) and valine 12 and alanines 16 and 20 (light shaded) forming the most closely packed region.

Whereas much of the intracellularly active domain of VacA appears to reside within the p33 fragment, the p55 fragment appears to play a significant role in binding of the toxin to cells. Antibodies raised against the p55 fragment, but not antibodies against the p33 fragment, block binding of VacA to cells (Garner and Cover, 1996), and a p55 fragment expressed in *H. pylori* is able to bind to cells (Reyrat *et al*., 1999). Curiously, this p55 fragment was not internalized by cells (Reyrat *et al*., 1999), suggesting a need for the p33 domain for toxin internalization. VacA proteins of the m1 and m2

types (which differ in amino acid sequences mainly within the p55 domain) exhibit distinct cell tropisms, which are due (at least in part) to differences in binding to cells (Pagliaccia *et al*., 1998; Wang *et al*., 2001). One region of the p55 domain important for binding was mapped by analysis of recombinant GST-VacA fusion proteins (Wang and Wang, 2000). This study concluded that the last 100 amino acids of VacA are critical for the ability of VacA to bind to cells. This region is distinct from sequences reported to be responsible for the cell tropism of m1- and m2-type VacA proteins (Ji *et al*., 2000).

## INTERACTIONS WITH HOST CELLS

### Interactions at the cell surface

Several previous studies have provided evidence for saturability and specificity of VacA binding to cells (Massari *et al*., 1998; Wang and Wang, 2000; Wang *et al*., 2001). In contrast, studies with radiolabeled VacA have not provided convincing evidence of a saturable binding process, and the binding of radiolabeled VacA was only partially inhibited by excess unlabeled VacA (McClain *et al*., 2000; Ricci *et al*., 2000; Patel *et al*., 2002). At least five different putative receptors for VacA have been reported, including receptor protein tyrosine phosphatase β (RPTPβ) (Yahiro *et al*., 1999), RPTPα (Yahiro *et al*., 1997; Yahiro *et al*., 2003), the epidermal growth factor receptor (Seto *et al*., 1998), heparan sulfate (Utt *et al*., 2001), and various lipids (Moll *et al*., 1995; Molinari *et al*., 1998a; Czajkowsky *et al*., 1999; Geisse *et al*., 2004).Thus, at present, there is considerable confusion about which cell surface components are most relevant for VacA binding and cytotoxicity. It remains unclear whether VacA cytotoxicity is dependent on binding of VacA to one specific receptor, or whether cytotoxicity results from specific or nonspecific binding of VacA to multiple cell-surface components.

The most thoroughly characterized interaction between VacA and a putative receptor is the interaction between the toxin and RPTPβ (Yahiro *et al*., 1999; Padilla *et al*., 2000; Fujikawa *et al*., 2003). This interaction was initially characterized by observing that acid- or alkaline-activated VacA, but not the inactive oligomeric form of the purified toxin, could associate with RPTPβ expressed on the surface of AZ521 gastric epithelial cells (Yahiro *et al*., 1999). An important set of experiments was subsequently performed using HL60 cells (Padilla *et al*., 2000). This cell line is normally relatively resistant to VacA but becomes sensitive following differentiation into macrophage-like cells (de Bernard *et al*., 1998c). Both induction of VacA sensitivity and expression of RPTPβ mRNA were directly dependent on the concentration and time of exposure of cells to the differentiating agent phorbol 12-myristate 13-acetate (PMA) (Padilla *et al*., 2000). Treatment of HL-60 cells with RPTPβ antisense oligonucleotide before incubation with PMA led to a dose-dependent decrease in VacA sensitivity. In this same study, RPTPβ cDNA was stably expressed in BHK-21 cells, a cell line that is normally resistant to VacA (Padilla *et al*., 2000). BHK-21 cells expressing RPTPβ showed greater sensitivity to VacA than did control cells or cells transfected with vector only. Compelling evidence that RPTPβ plays a significant role in VacA intoxication was provided by studies using transgenic RPTPβ −/− mice (Fujikawa *et al*., 2003). In wild-type C57BL/6 mice, oral administration of either VacA or the endogenous RPTPβ ligand pleiotrophin induced disruption of the gastric epithelium, whereas neither VacA nor pleiotrophin disrupted the epithelium in RPTPβ −/− mice. Furthermore, primary gastric cells from wild-type mice detached from a reconstituted basement membrane following VacA treatment, whereas cells from the RPTPβ −/− mice did not detach (Fujikawa *et al*., 2003). However, VacA causes vacuolation of cells that do not express RPTPβ, including primary gastric cells from RPTPβ−/− mice and the human kidney cell line G401, indicating that RPTPβ is not the only receptor for VacA (Fujikawa *et al*., 2003; Yahiro *et al*., 2003).

A second VacA-interacting protein, p140, was detected in the gastric cell lines AZ-521 and AGS, as well as in the monkey kidney line COS-7 (Yahiro *et al*., 1997). Internal amino acid sequence analysis and time of flight-mass spectrometry analysis of p140 identified this protein as RPTPα (Yahiro *et al*., 2003). Treatment of G401 cells (which do not express detectable RPTPβ) with RPTPα-antisense oligonucleotide before exposure to VacA inhibited vacuolation (Yahiro *et al*., 2003). These results support the involvement of RPTPα in VacA-induced vacuolation in G401 cells.

Most RPTPs, including RPTPα and RPTPβ, contain two cytoplasmic protein tyrosine phosphatase (PTP) domains, a single transmembrane segment, and an extracellular domain (Beltran and Bixby, 2003). Though the cytoplasmic PTP domains are highly conserved, the extracellular domains of RPTPs are quite variable. Similarity between the extracellular domains of RPTPα and RPTPβ is limited to a short segment of each protein (less than 30% amino acid identity over a stretch of about 50 amino acids) (Yahiro *et al*., 2003), but a recent study implicates an unrelated region of RPTPβ as being critical for the interaction with VacA (Yahiro *et al*., 2004).

Multiple studies have documented that VacA associates with cholesterol-rich microdomains (rafts) on the surface of epithelial cells (Patel *et al*., 2002; Schraw *et al*., 2002; Kuo and Wang, 2003; Gauthier *et al*., 2004). VacA interactions with lipid rafts have also been detected *in vitro*, based on AFM imaging (Geisse *et al*., 2004). The association of purified VacA oligomers with rafts requires activation of the toxin by exposure to acidic pH (Schraw *et al*., 2002). Depletion of cholesterol from cells by treatment with methyl-β-cyclodextrin disrupts raft integrity and also inhibits VacA-induced vacuolation (Patel *et al*., 2002; Schraw *et al*., 2002; Kuo and Wang, 2003). Specifically, cholesterol depletion partially inhibits VacA binding to cells and blocks VacA internalization or intracellular trafficking (Patel *et al*., 2002; Schraw *et al*., 2002; Kuo and Wang, 2003). However, cholesterol depletion does not appear to inhibit the ability of VacA to form channels within the plasma membrane as determined by measuring membrane depolarization (Schraw *et al*., 2002). The inhibition of vacuolating activity by cholesterol depletion is also observed in cells pretreated with VacA, as well as in cells in which the *vacA* gene is transfected, suggesting that cholesterol also plays an important role after VacA has been internalized (Patel *et al*., 2002). Cholesterol-rich rafts can be isolated from late endosomes (Fivaz *et al*., 2002), where cholesterol modulates the rab7 activity cycle (Lebrand *et al*., 2002), possibly accounting for the role of intracellular cholesterol in VacA-induced vacuolation (Patel *et al*., 2002).

Cholesterol-rich membrane rafts are enriched in glycosylphosphatidylinositol (GPI)-anchored proteins, and treatment of cells with phosphatidylinositol-specific phospholipase C (PIPLC) removes GPI-anchored proteins from the cell surface (Sharom and Lehto, 2002). Cells treated with PIPLC have been found to be relatively resistant to VacA-induced vacuolation (Ricci *et al*., 2000; Kuo and Wang, 2003; Gauthier *et al*., 2004). However, the role of GPI-anchored proteins in VacA toxicity is unclear. Removal of GPI-anchored proteins by PIPLC treatment has no detectable effect on VacA binding to cells or on VacA localization to rafts (Kuo and Wang, 2003; Gauthier *et al*., 2004). Additionally, mutant CHO cells that are unable to synthesize GPI anchors (and hence lack GPI-anchored proteins) and their wild-type counterparts exhibit similar sensitivity to VacA-induced vacuolation (Schraw *et al*., 2002). Nonetheless, removal of GPI-anchored proteins from the cell surface reduced the ability of VacA to form channels in the plasma membrane as determined by measuring chloride flux (Gauthier *et al*., 2004).

## Internalization

After incubation of VacA with cells at 37˚C for several hours, VacA can be detected inside cells by a variety of immunological techniques (Garner and Cover, 1996; Sommi *et al*., 1998; Fiocca *et al*., 1999; Schraw *et al*., 2002; Li *et al*., 2004b), and the toxin becomes resistant to exogenously added proteases (McClain *et al*., 2000; Patel *et al*., 2002). Evidence implicates an active cellular process in the internalization of activated VacA, as internalization does not occur at 4˚C and is inhibited by depleting cells of ATP (McClain *et al*., 2000). Furthermore, VacA does not become protease resistant when incubated with rabbit erythrocytes, suggesting that VacA internalization does not occur spontaneously after binding to membranes (McClain *et al*., 2000). Once internalized, the 88-kDa protein persists inside the cell for hours with little noticeable degradation (Sommi *et al*., 1998; McClain *et al*., 2000). Multiple lines of evidence indicate that internalization of the toxin is required for many of the effects of VacA. Several studies have shown that transfecting the *vacA* gene into cells results in vacuolation, cytochrome c release, and apoptosis (de Bernard *et al*., 1997; Ye *et al*., 1999; Galmiche *et al*., 2000), suggesting that these activities result from actions of VacA at intracellular sites.

The cellular pathways by which VacA is endocytosed have not yet been clearly delineated. Two well-studied pathways utilized by cells to internalize ligands involve clathrin-coated pits or caveolae (Pelkmans and Helenius, 2003). VacA-induced vacuolation was observed among cells transfected with inhibitors of clathrin-mediated endocytosis (dominant-negative Eps15, or GFP-linked five tandem SH3 domains of intersectin) (Ricci *et al*., 2000), suggesting that VacA can be internalized via a clathrin-independent process. In support of this conclusion, cells treated with chlorpromazine, which inhibits assembly of clathrin-coated pits, exhibited an increase in vacuolation in response to VacA (Patel *et al*., 2002). Similarly, VacA appears to be internalized via a caveolae-independent process, as filipin blocks caveolae-mediated endocytosis (Orlandi and Fishman, 1998; Norkin *et al*., 2001), but did not affect VacA-mediated vacuolation (Patel *et al*., 2002). Dynamin, originally viewed as a protein involved in the formation of endosomes from the plasma membrane but subsequently implicated in a variety of steps involving endocytic trafficking inside cells (Kirchhausen, 1998; Schmid *et al*., 1998), has been shown to be required for VacA-induced vacuolation, but is not required for VacA internalization (Suzuki *et al*., 2001). Taken together, these results suggest that VacA is internalized by a dynamin-independent macropinocytotic pathway (Pelkmans and Helenius, 2003).

### Interactions with intracellular targets

Using VacA as bait in yeast two-hybrid screening of host cell libraries, two groups identified proteins that interact with VacA. One such protein is VacA-interacting protein of 54 kDa (VIP54) (de Bernard *et al*., 2000). VIP54 was isolated from a HeLa cell cDNA library, using a two-hybrid screen, as a protein that interacted with the amino-terminal portion of the VacA p55 domain. To validate the yeast two-hybrid results, a recombinant GST-tagged VIP54 was shown to interact with purified VacA. Confocal immunofluorescence microscopy with anti-VIP54 affinity-purified antibodies showed a fibrous pattern, suggesting that VIP54 associates with intermediate filaments. In support of this conclusion, immunofluorescence microscopy and immunoprecipitations indicated that VIP54 interacts with vimentin (either directly or indirectly). VIP54 is expressed in cultured cells and many tissues, including brain, muscle, kidney, and liver. Little is known at this time about VIP54, but the amino acid sequence of VIP54 is highly similar to SPIN90 (implicated in maintenance or assembly of the cytoskeleton in cardiac myocytes) (Lim *et al*., 2001) and to AF3p21 (found only in the nucleus) (Hayakawa *et al*., 2001). Potentially, these three proteins may represent alternate splice variants transcribed from a single gene. The functional significance of potential interactions between VacA and VIP54 is unknown.

An interaction between VacA and RACK1 was found using a yeast two-hybrid screen of a human gastric mucosa cDNA library (Hennig et al., 2001). The VacA fragment found to interact with RACK-1 consisted of the carboxy-terminal portion of the p33 domain and six residues from the p55 domain (amino acids 170–317). The interaction was confirmed by demonstrating an interaction in vitro between a recombinant RACK-1 and recombinant GST-tagged VacA. RACK1, a 36-kDa homologue of the b subunit of G proteins, belongs to a large family of regulatory proteins made up of highly conserved repeating WD40 units (Neer et al., 1994). RACK1 is composed of seven such WD-repeats. The cDNA inserts of two-hybrid positive clones encoded for the three carboxy-terminal WD motifs of RACK1 protein, suggesting that they are sufficient for interaction with VacA (Hennig et al., 2001). WD-repeats are involved in protein-protein interactions (Yaffe and Smerdon, 2004), and RACK1 has been reported to interact with a variety of cellular proteins (McCahill et al., 2002). The functional significance of potential interactions between VacA and RACK1 is unknown.

## VacA AS A VACCINE ANTIGEN

Oral immunization of mice with purified VacA protects mice from subsequent infection with *H. pylori* (Marchetti *et al*., 1995; Marchetti *et al*., 1998). Immunization with purified VacA conferred protection against subsequent challenge by *H. pylori* strains that produced vacuolating toxin activity *in vitro*, but such an immunization failed to protect against challenge with a wild-type strain that lacked detectable toxic activity for HeLa cells (Marchetti *et al*., 1995; Marchetti *et al*., 1998). One study reported that eradication of VacA-producing *H. pylori* from chronically infected mice can be achieved by therapeutic vaccination with VacA, and mice from which *H. pylori* were eradicated by the therapeutic vaccination were protected from subsequent challenge (Ghiara *et al*., 1997).

Many challenges remain in the development of an effective vaccine against *H. pylori. H. pylori* infection persists in the absence of antibiotic treatment, even though antibodies against numerous *H. pylori* antigens (including VacA) may be found in serum and gastric juice from the majority of *H. pylori*-infected humans (Cover *et al*., 1992a; Cover *et al*., 1993a; Perez-Perez *et al*., 1999). Thus, the immune response to VacA that is elicited in humans in response to *H. pylori* infection does not lead to clearance of the infection. Whether immune responses to natural *H. pylori* infection confer some measure of protection against subsequent *H. pylori* infection has not been investigated in detail. In animal studies, the failure of an s1-m1 VacA antigen to induce protective immunity against a non-toxigenic strain is likely due to antigenic diversity among different VacA proteins. In particular, it seems clear that many antibodies that are reactive with s1-m1 VacA fail to recognize s2-m2 VacA and may even fail to recognize s1-m1 from other *H. pylori* isolates (Vinion-Dubiel *et al*., 2001). Therefore, a vaccine based on multiple *H. pylori* antigens, including VacA, is likely to prove more effective than a vaccine based solely on a single VacA protein (Ghiara *et al*., 1997; Rossi *et al*., 2004).

## CONCLUSION

The activities attributed to VacA are numerous, and additional activities are likely to be discovered as researchers continue to investigate this toxin. Several VacA activities, including vacuole formation and effects on mitochondria, may be attributed to the channel-forming properties of VacA. In this sense, VacA resembles a pore-forming toxin that acts on intracellu-

lar targets (e.g., late endosomes and lysosomes, or mitochondria). Interestingly, there are numerous VacA proteins (i.e., s2-type proteins) for which *in vitro* activities have not been identified. Further studies of s2-type proteins may lead to the identification of activities shared with s1-type VacA toxins that are highly relevant *in vivo*. Alternatively, the s1- and s2-type VacA proteins may have evolved divergent functions suited to the distinct lifestyles of different *H. pylori* isolates. Further investigations of VacA are likely to lead to findings that are relevant for diverse fields of biology, and should also provide important insights into how *H. pylori* interacts with the human stomach.

CHAPTER

# 25

# *Escherichia coli* heat-stable enterotoxin b

*J. Daniel Dubreuil*

## INTRODUCTION

Although most *Escherichia coli* strains live as symbiotic organisms in the intestine of animals including man, several pathogenic strains belonging to distinct groups are now defined on the basis of the production of specific virulence factors. Pathogenic strains belonging to different groups cause diarrhea via diverse mechanisms. Enterotoxigenic *E. coli* (ETEC) represents one of these groups. ETEC strains are important causes of traveler's diarrhea and diarrheal illnesses in children in developing countries. In addition to causing human diseases, specific ETEC strains are also responsible for severe diarrhea in domesticated and also in some wild animals (Beutin, 1999; Caprioli *et al.*, 1991; Sears and Kaper, 1996).

ETEC pathogenesis comprises two steps. First, the microorganism has to colonize the small intestine by means of specific adherence factors. Fimbrial or nonfimbrial adhesins that permit attachment to enterocytes of specific animal hosts and hence contribute to intestinal colonization are produced by ETEC. These adhesins enable ETEC to attach to receptors on the intestinal epithelium of susceptible hosts, to overcome physiological defenses such as peristaltism. Once established, ETEC strains produce one or more enterotoxins. Following interaction with specific receptors on the surface of the enterocytes, the enterotoxins will cause secretory diarrhea. Adherence of ETEC to intestinal epithelial cells is crucial for establishment of the pathogen and also for efficient delivery of toxins to their targets. Minimal histopathologic lesions are observed in the intestinal mucosa of animals infected by ETEC. In fact, microscopic observations reveal a layer of adherent bacteria covering uniformly the brush border epithelium of the small intestine with little or no visible alteration of the tissue.

ETEC cause diarrhea by production of two distinct types of enterotoxin, a heat-labile (LT) toxin with two subtypes (LTI and LTII) and a family of heat-stable (ST) enterotoxins. LT is a high molecular mass toxin (85 kDa) functionally and structurally related to *Vibrio cholerae* enterotoxin (Kaper *et al.*, 2004). STs are low-molecular mass toxins that share the property of retaining toxic activity after incubation at 100°C for 30 min, whereas the activity of LT is abrogated under the same conditions. Two types of ST, STa and STb (also known as STI and STII), based on solubility in methanol and activity in infant mice, were described. STa is soluble in methanol and active in infant mice, whereas STb is insoluble in methanol and not active in infant mice. STa has further been subdivided into STaH (or STIb) and STaP (or STIa), so named as they were isolated originally from a human or a porcine ETEC strain, respectively (see Chapter 48). These toxins are slightly different with respect to their sequence and number of amino acids. STb has no homology with STa enterotoxin at either the gene or the protein levels. This chapter will be devoted to *E. coli* heat-stable toxin b.

## STb POLYPEPTIDE

STb enterotoxins isolated from different animal species show the same nucleotide and amino acid sequences.

However, in a recent study, Fekete *et al*. (2003) isolated a swine ETEC strain that produced STb toxin where two amino acids were not conserved (His12-Asn, Lys23-Ile). The toxicity of this molecule was not determined. STb toxin has been observed in *E. coli* strains isolated principally from pigs but also from cattle (including water buffaloes), chickens, dogs, cats, ferrets, and humans (Beutin, 1999; Bradley *et al*., 2001; Dubreuil, 1997; Hammermueller *et al*., 1995).

The mature STb polypeptide comprises 48 amino acids containing four cysteine residues involved in disulfide bridge formation (Figure 25.1). The enterotoxin has a Mr of 5,200 Da. As already stated, STb bears no homology to STa enterotoxin (Dreyfus *et al*., 1992). The STb polypeptide is synthesized as a 71 amino-acid precursor comprising a 23 amino-acid signal sequence (Lee *et al*., 1983; Picken *et al*., 1983). Sukumar *et al*. (1995) indicated that the peptide spanning from Cys10 to Cys48 has full biological activity and that the first seven amino acids at the $NH_2$-terminus of the mature toxin are not involved in either the structure or toxicity of STb.

STb is a poorly immunogenic molecule, but antibodies can be produced against the mature toxin, provided numerous boosting injections are given. However, a better serological response can be obtained following immunization by either fusion proteins or proteins chemically coupled to STb (Dubreuil *et al*., 1996; Urban *et al*., 1990, 1991). In the later case, neutralizing antibodies can be obtained, but this occurs rarely when the native toxin is used for immunization. The anti-STb antibodies can neutralize STb toxicity, but are unable to neutralize STa or CT toxins (Hitotsubashi *et al*., 1992a). Yet, only one antigenic type of STb was observed.

## BIOCHEMICAL CHARACTERISTICS

For STb, the determined iso electric point of 9.6 corresponds to a highly basic protein (Handl *et al*., 1993). STb is insoluble in methanol, and the toxin loses biological activity following β-mercaptoethanol or trypsin treatment (Burgess *et al*., 1978; Dubreuil *et al*., 1991; Fujii *et al*., 1991). However, it resists acid (pH 2), alkaline (pH 12), and 8 M urea treatments (Dubreuil *et al*., 1991). STb is very susceptible to protease degradation, particularly by trypsin-like enzymes (Whipp, 1987; 1991). Out of 48 residues, the mature toxin contains 1 tyrosine, 2 phenylalanines, and no tryptophan; this results in a low absorbance at 280 nm (Handl *et al*., 1993).

### *estB* gene

The *estB* gene that encodes STb is found on heterogeneous plasmids that may also code for other properties, including other enterotoxins (i.e., LT, STa), colonization factors, drug resistance, colicin production, and transfer functions (Harnett and Gyles, 1985; Echeverria *et al*., 1985). The *estB* gene is part of a transposon of approximately 9 kb designated Tn*4521* (Lee *et al*., 1985; Hu *et al*., 1987; Hu and Lee, 1988). This transposon is flanked by defective IS*2* elements, but is nevertheless functional as the STb gene can transpose from one plasmid to another (Lee *et al*., 1985; Hu and Lee, 1988). The structural gene for STb from different clinical isolates appears to be uniform in size, but the flanking sequences are heterogeneous, suggesting that *estB* could be found on different transposons (Lee *et al*., 1985). Thus, it seems that transposition of *estB* is a mechanism by which this virulence factor is disseminated among ETEC. Spandau and Lee (1987) reported that the promoter for *estB* expression was weak. The promoter did not conform to the consensus sequence as one important base in the Pribnow box (–10 region), the final invariant T, is replaced by a G. However, the –35 region is highly homologous to the –35 consensus sequence. Thus, the STb promoter is capable of binding RNA polymerase, but seems to be a poor transcription initiator and hence very little STb is produced. Lawrence *et al*. (1990) indicated that cloning the *estB* gene into a high-expression vector downstream to the strong bacteriophage lambda $p_L$ promoter increased by 10- 20-fold the mRNA produced, but the amount of STb enterotoxin was not increased. STb synthesis by wild-type *E. coli* strains varies with the composition of the culture medium used (Busque *et al*., 1995). A repressive effect of glucose on STb production and a reversal of this effect upon addition of cAMP were noted.

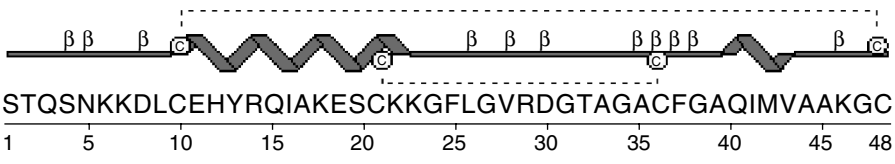

**FIGURE 25.1** Primary sequence of STb toxin showing the position of the disulfide bonds. Alpha-helices are present between Cys10-Lys22 and Gly38 and Ala44. Beta turns are also indicated.

Catabolite repression of STb was confirmed using mutant strains for adenylate cyclase and the catabolite activator protein. A DNA homology search revealed a sequence with 72% identity with the cAMP receptor protein (CRP)-binding site located 26 bp upstream of the –35 region of the transcriptional start site. The *estB* gene appears to be quite stable as laboratory strains can be studied many years (more than 15 years) without loss of the genetic trait (Dubreuil, unpublished data).

## DISULFIDE BOND FORMATION AND SECRETION OF STb

STb intramolecular disulfide bonds must be correctly formed in order to produce an active molecule. The pathway by which these bonds are formed has been established (Figure 25.2). STb polypeptide is synthesized as a 71 amino acids precursor (Lee *et al.*, 1983;

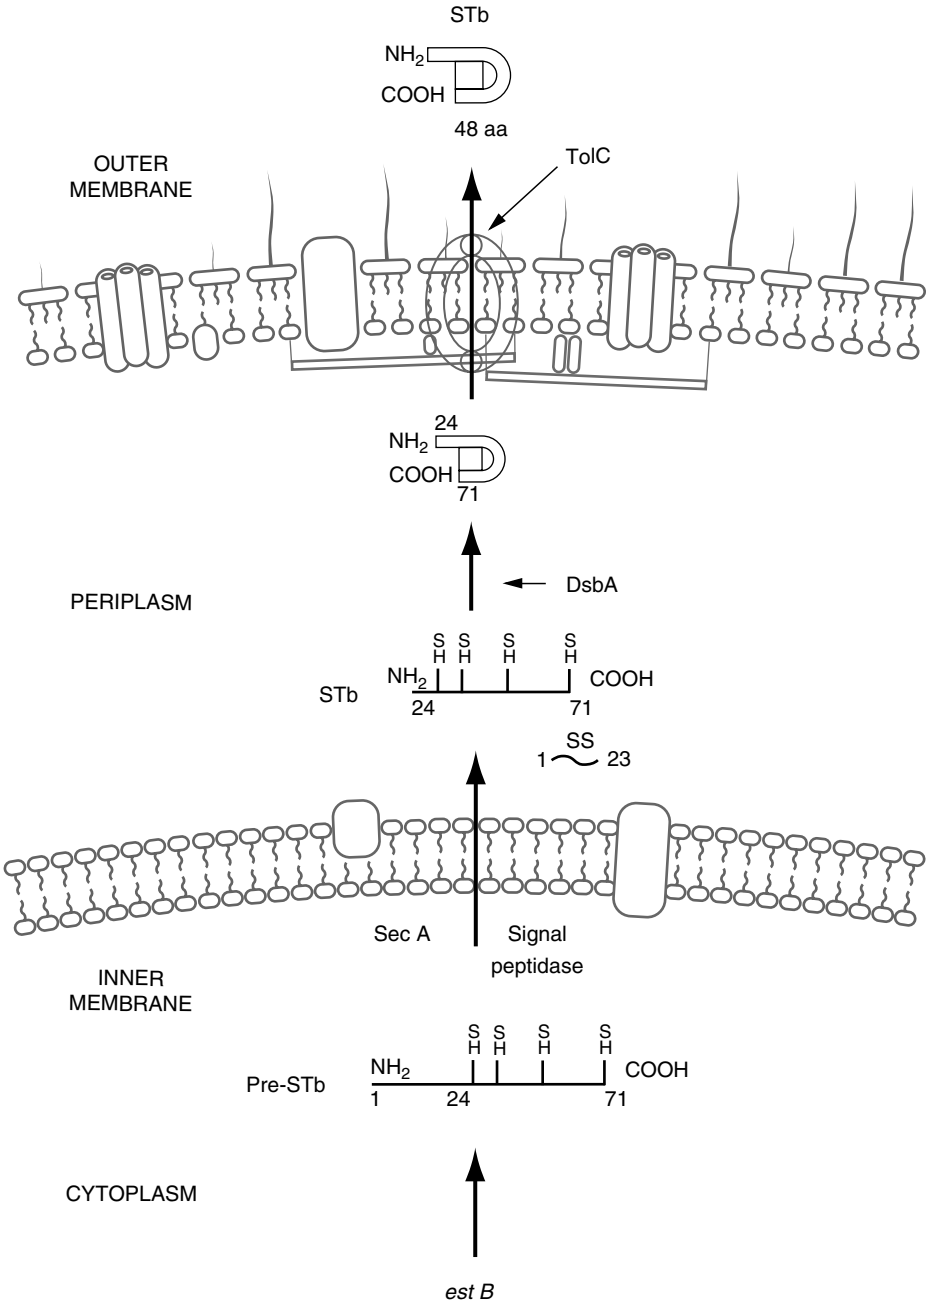

**FIGURE 25.2** Disulfide bond formation and secretory pathway for STb toxin.

Picken *et al*., 1983). The $NH_2$-terminus of pre-STb (residues 1–23) has characteristics of a signal sequence that is cleaved by a signal peptidase during export to the periplasm (Kupersztoch *et al*., 1990). Thus, an 8.1-kDa precursor (pre-STb) is converted to a transiently cell-associated 5.2-kDa form consisting of 48 amino acids. Conversion of pre-STb to cellular STb depends on the *secA* gene product. For STb, like STa, translocation of the precursor to the periplasm requires energy (Kupersztoch *et al*., 1990). These data indicate that export of STb relies on the general export pathway of *E. coli*. After STb is detected as a cell-associated molecule, an indistinguishable extracellular form becomes apparent, indicating that no proteolytic processing occurs during mobilization of STb from the periplasm to the culture supernatant. Conversion of cellular to extracellular STb does not depend on membrane potential or oxidative phosphorylation.

Foreman *et al*. (1995) obtained secretion-deficient mutants using a synthetic transposon. In *dsbA* and *tolC* defective mutants, STb was absent from the culture supernatant, indicating that these genes were required for secretion of STb. STb is effectively secreted out of the cell through the secretory system, including TolC, an outer membrane protein. Dreyfus *et al*. (1992) explored the role of the four cysteine residues in STb secretion. Cysteines were separately substituted with serine. These resulting peptides were exported to and degraded in the periplasm, suggesting that formation of disulfide bonds protected STb from protease activity. Therefore, as observed by Foreman *et al*. (1995), a *dsbA* mutant that formed disulfide bonds at a slower rate yielded a STb-negative phenotype, as the reduced form of the toxin was degraded. Similarly, Okamoto *et al*. (1995) transformed a *dsbA* mutant with a plasmid harboring *estB*. STb was not detected either in the cells or in the culture supernatant. STb production was restored by introducing the wild-type *dsbA* gene into the mutant strain, thus confirming that DsbA is involved in forming the disulfide bonds in STb and that its absence results in degradation during the secretory process. Using oligonucleotide-directed site-specific mutagenesis on the four cysteine residues, it was established by Arriaga *et al*. (1995) that the two intramolecular disulfide bonds must be formed for the efficient secretion of STb. Elimination of either one of the bonds renders the toxin susceptible to periplasmic proteolysis. Circular dichroism studies have also indicated that the integrity of the disulfide bonds is crucial for the structure and function of the toxin, as reduced STb adopted a random-coiled conformation (Sukumar *et al*., 1995). Mature STb is not associated with the cellular fraction, but found preferentially in the culture supernatant (Kupersztoch *et al*., 1990). Okamoto *et al*. (2001) studied the interaction of STb with TolC. Using deletion mutants, they analyzed the efficiency of secretion of these altered molecules into the culture supernatant. Their observations indicated that the central region of STb from amino acid 19 to 36 is involved in the secretory process, corroborating previous results showing that DsbA is necessary for STb to adopt a structure that can then cross the outer membrane.

## STb RECEPTOR

The presence and nature of the STb receptor on different tissues of various animals was investigated soon after the toxin was identified. For example, a study by Weikel *et al*. (1986b) examining the response of human adult ileal mucosa to STb in a Ussing chamber, in contrast to the piglet jejunum, which responded electrogenically to STb, indicated that human tissue showed no response. Based on these observations, the authors inferred that the adult human ileum could lack the receptor for STb. Dreyfus *et al*. (1993) suggested that a STb receptor was present on cell types of both intestinal and non-intestinal origin, as Madin-Darby canine kidney, $HT29/C_1$ human intestinal epithelial cells and primary rat pituitary cells all responded to STb. They showed that human intestinal epithelial cells did possess a receptor for STb, as a dose-dependent calcium increase was observed due to the action of STb. Hitotsubashi *et al*. (1994) identified a 25 kDa protein from the membranes of mouse intestine to which STb bound. The specificity of the interaction was corroborated by competition experiments between radiolabeled ($^{125}$I) and unlabeled toxin. Preliminary characterization of the molecule suggested that it was not a glycoprotein. The study also indicated tissue specificity, as the STb-binding protein was not found in mouse tissues such as liver, lung, spleen, and kidney. More recently, Chao and Dreyfus (1997) studied the interaction of STb with cultured human intestinal cell lines. $^{125}$I-STb bound specifically to T84 and HT-29 cells with low affinity ($\leq 10^5 M^{-1}$) to a high number of binding sites ($>10^6$ per cell), reaching equilibrium within 5–10 min at either 4, 22, or 37°C. Approximately half of the bound molecules were stably associated with the plasma membrane and/or internalized into the cytoplasm because an acidic saline treatment could not remove them. Binding and subsequent internalization were not affected by treatment of cells with trypsin, endoglycosidase F/peptide N-glycosidase F, *Vibrio cholerae* neuraminidase, tunicamycin, or sodium chlorate, indicating that protein, glycoprotein, or sulfated proteoglycans were not involved in the process. It was also shown that STb internalization was independent

of temperature, cytoskeleton rearrangement, energy, or hypertonic conditions. Overall, their results indicated that STb was probably binding to membrane lipids of the plasma membrane. The same conclusion was obtained when rat intestinal epithelial cells were studied (Chao and Dreyfus, 1999). Nevertheless, STb appeared to interact selectively with plasma membranes since STb was binding with lower affinity to CHO cells and fibroblasts than to intestinal epithelial cells. From their study, Chao and Dreyfus (1997) inferred that STb becomes stably associated with the lipid bilayer and possibly penetrates the bilayer or disrupts it sufficiently to activate directly a protein $G_{i3}$ that seems to be implicated in the mode of action of STb (Dreyfus *et al*., 1993). This hypothesis is based on the fact that the amphipathic $NH_2$-terminal helix of STb possesses a strong membrane-association potential (Segrest *et al*., 1990; Sukumar *et al*., 1995). In addition, the study of Chao and Dreyfus (1997) shed new light on the 25-kDa protein previously identified by Hitotsubashi *et al*. (1994) as the STb receptor. Based on their experimental data, the 25-kDa protein represented not a surface-specific receptor for the enterotoxin, but rather a cytoplasmic protein or a protein associated with the inner leaflet of the plasma membrane to which STb binds.

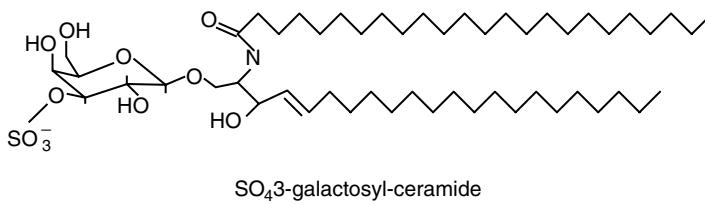
Rousset *et al*. (1998a) developed a semi-quantitative binding assay based on indirect fluorescence microscopy using biotinylated biologically active STb. The binding characteristics and the chemical nature of the molecule responsible for STb binding to the pig jejunum, the natural host tissue, were determined. The cellular complexity of sections of the pig intestinal tissue, although presenting some experimental limitations, was taken into consideration since it could lead to significantly different results from those of *in vitro* cultured intestinal epithelial cells, especially if they originated from other animal species. Using frozen sections of pig jejunum, it was demonstrated that biotinylated STb attached to microvilli. As in the study of Chao and Dreyfus (1997), binding was rapid, reaching saturation in 10 min, and the process was temperature-independent. However, binding was pH-dependent, being optimum at a pH of 5.8, which is comparable with the situation found *in vivo* for the small intestine. All pig tissues tested (including duodenum, ileum, caecum, colon, liver, lung, spleen, and kidney) showed binding toward STb, suggesting that a molecule common to these tissues could be acting as the STb receptor.

The chemical nature of the molecule involved in STb binding was studied using chemical and enzymatic treatments of the jejunum sections. Together, the data suggested that the molecule seems to be composed of a ceramide moiety comprising a terminal neuraminic acid and/or alpha-linked terminal glucose residue(s). Thus, a glycosphingolipid present in high number in the plasma membrane could specifically be recognized by STb. A high number of receptor was inferred from the fact that a 100-molar fold excess of STb could not effectively compete for binding with biotinylated STb. Chao and Dreyfus (1997) had also indicated that competition was limited, reaching approximately 50% in the presence of either 5-, 100-, or 1000-fold excess of STb. These two studies suggested that a molecule of lipidic nature present in high number in plasma membrane could represent the STb receptor.

Pursuing forward the investigation, Rousset *et al*. (1998b) evaluated the binding of STb to commercially available glycosphingolipids using a microplate-binding assay. STb binding varied greatly, depending on the molecule tested. Sulfatide ($SO_4$3-galactosyl-ceramide) was the molecule to which STb bound with greatest affinity (Figure 25.3). The reaction was dose-dependent and saturable. $GM_3$ (NeuAcα2-3GalβGlcβ1Cer) also did bind STb at approximately 55% of the level observed with sulfatide. Total lipid extraction of pig jejunum epithelium and thin-layer chromatographic analysis revealed that sulfatide is present at the surface of this tissue, as the lipid band to which STb bound was revealed with either an anti-sulfatide monoclonal antibody recognizing the $SO_4$3-galactose epitope or laminin, which specifically binds sulfated glycolipids. It thus appears that STb could bind to the pig jejunum through interaction with sulfatide. The functionality of sulfatide was also shown in the rat ligated loop assay (Rousset *et al*., 1998b). A comparative and quantitative binding assay of STb to glycolipids in microplate confirmed STb-sulfatide as a high-affinity interaction (Beausoleil and Dubreuil, 2001). As well, STb bound to $SO_4$3-lactosyl-ceramide at 76% compared to sulfatide. STb thus seems to possess a lectin-like property where molecules with terminal β-galactose are preferred for binding and the epitope recognized by STb was more specifically $SO_4$3-galactosyl. Competitive assay using $^{125}$I-labeled STb and cold toxin indicated, following a Scatchard analysis of the data, a Kd= 2-6± $1{,}5\times10^{-6}$M. This value is similar to what was determined by Chao and Dreyfus (1997) for STb binding to cells in culture ($\leq 10^{-5}$M).

To confirm the chemical structure of the STb receptor, a mass spectrometer analysis was done on the lipids islolated from pig jejunum following the method of Folch (Beausoleil *et al*., 2002b). These lipid extracts were separated on high-performance thin layer chromatographic plates, and the band migrating at the same distance as commercial sulfatide and also binding STb in overlay method were recuperated from the silica plates. The samples analyzed by mass

**FIGURE 25.3** Chemical structure of sulfatide.



spectrometry in electrospray negative-ionization mode indicated that the most abundant ions observed had *m/z* values of 779, 795, 879, and 906. Confirmation of the structure of these ions was performed using collision-induced dissociation (CID) of these ions. All the CID spectra showed a very intense 97 ion characteristic of the $HSO_4^-$ ion, along with lower intensities of the 241 ion arising from dehydration of the galactose-sulfate moiety. In comparison, to commercial bovine brain sulfatides (used as a control), ions of 795, 879, and 907 have been attributed to hydroxylated sulfatides with saturated fatty acid chain containing 16, 22, and 24 carbons, while the 779 ion corresponded to a saturated fatty acid chain of 16 carbons (Hsu *et al*., 1998). Thus, the major sulfatide ion found in pig intestine corresponding to the 795 are hydroxylated sulfatides harboring a ceramide comprising 16 carbons.

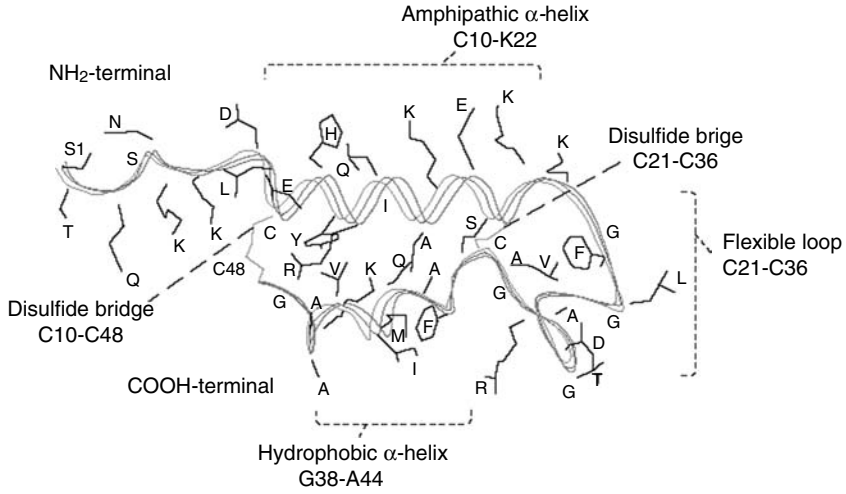
## TOXIC DOMAIN AND 3D STRUCTURE OF STb

Sukumar *et al*. (1995) determined the solution structure of STb by two- and three-dimensional NMR methods. The NMR-derived structure showed that STb is helical between residues 10 and 22 and residues 38 and 44 (Figure 25.4). The helical structure in the region 10–22 is amphipathic, exposing several polar residues to the solvent. The loop region between residues 21 and 36 contains a cluster of hydrophobic residues. Circular dichroism studies confirmed that the integrity of the disulfide bonds is crucial for the structure and function of the toxin. STb is a highly organized molecule with 73 ± 2% α-helix, 4 ± 2% β-structure and 22% remainder.

As the isoelectric point of 9.6 indicates, the side-chain of some of the basic amino-acid residues project outside the molecule. Studies have been conducted to determine the role of selected amino acids and, in particular, of the basic residues on STb toxicity. It is peculiar that, among the 48 amino acids composing mature STb, 9 are basic (one histidine, two arginines, and six lysines).

A loop defined by the disulfide bond between Cys21 and Cys36 and containing 14 amino acids (Figure 25.4), including four glycines residues and four of the nine charged residues, suggested the presence of an extended coil region based on secondary structure predictions (Dreyfus *et al*., 1992). The location of an Arg29 and Asp30 charged pair inside this loop is such that it is highly exposed in a hydrophilic environment. The authors speculated that these two

**FIGURE 25.4** NMR-derived 3D structure of STb toxin (Sukumar et al., 1995).



amino acid residues would probably be involved in receptor recognition. Using site-directed mutagenesis, amino-acid substitutions were performed on these two residues. When Arg29 was changed to serine to eliminate the charge, a significant reduction in specific activity of the mutant molecule was noted, whereas a smaller reduction of toxicity was associated with the substitution of Asp30. No alteration in the stability of the mutated molecule was noted in the intestinal loop model. Fujii *et al*. (1994) likewise investigated the role of basic amino-acid residues on STb enterotoxicity. Studies involving chemically modified STb indicated that lysine residues play an important role in STb toxicity and that the contribution of other basic residues to toxicity is relatively low. These results were confirmed using oligonucleotide-directed mutagenesis. In fact, when Lys residues at positions 18, 22, 23, and 46 were replaced by neutral amino acids, the toxicity of the molecule was reduced. Mutations of Lys22 and Lys23 resulted in a substantial alteration of the biological activity.

Based on the STb NMR structure (Sukumar *et al*., 1995), an extensive study in which amino acids were mutated in order to delineate the binding site of STb with sulfatide and the region responsible for the toxic activity was conducted (Labrie *et al*., 2001b). The focus was put on basic residues in the loop and those present in the hydrophobic α-helix that are facing the solvent. Seventeen single- or double-point mutations were produced, purified by high-pressure chromatography and analyzed by circular dichroism to assure a proper 3D structure of the molecules before testing for binding to sulfatide and toxicity. Binding to sulfatide was evaluated using a microplate binding assay, and enterotoxicity was determined, *in vivo*, using the rat loop assay (Labrie *et al*., 2001b). The results obtained indicated that hydrophobic and electrostatic interactions are important for STb attachment to sulfatide. Mutations in the hydrophobic α-helix (F37K, I41S, and M42S) decreased, as well, the binding and toxicity by more than six-fold. Basic residues in the loop defined by Cys21 and Cys36, when mutated (K22, K23, and R29), also reduced the binding and toxicity, confirming the results obtained previously by other research teams (Dreyfus *et al*., 1992; Fujii *et al*., 1994). For all STb mutants constructed and analyzed, when a reduction in binding to sulfatide was noted, a concomitant reduction in toxicity equivalent or greater was noted. Overall, this indicated that binding to sulfatide represented a prerequesite step preceding fluid secretion.

The study on delination of the binding and toxic domains of STb has established that, besides basic residues in the loop, F37, I41, and M42 are important in the expression of toxicity. As numerous toxins need to form oligomers to act on target cells, the possible implication of these hydrophobic residues in such a process for STb toxin was inferred. A study using a chemical cross-linker, [bis (sulfosuccinimidyl) suberate], and gel electrophoresis permitted the observation of protein-protein interaction of STb molecules (Labrie *et al*., 2001c). Under these conditions, STb was forming hexamers and heptamers in solution, and the process was temperature-independent. Oligomerization was observed in the absence or presence of the STb receptor, and this process was not observed in the presence of β-mercaptoethanol, indicating that STb 3D integrity is required. Interestingly, mutations in the COOH-terminal region (F37, I41, and M42) of STb, corresponding to the hydrophobic α-helix, prevented the interactions between STb molecules.

Taken together, the data suggested that the binding between STb and sulfatide is done via basic residues present in the flexible loop, while the hydrophobic α-helix is the region of the molecule involved in the STb-STb binding. The propensity of hydrophobic groups to associate due to their repulsion from the aqueous solvent could compel STb molecules to interact. This could explain the decrease in binding to sulfatide observed with polar mutants located in the hydrophobic α-helix. These mutants when tested *in vivo* showed low toxicity, indicating that oligomerization could be necessary for the expression of toxicity. These studies have demonstrated the importance of positively charged amino acids (K22, K23, and R29) in attachment to sulfatide. Thus, the initial force involved in STb-sulfatide binding could rely on electrostatic interactions. Mutating the glycines in the loop (G24, G27, G31, and G34) also decreases the attachment to sulfatide. The reduced binding could be due to the alteration of the loop flexibility for which the glycines are responsible.

## MECHANISM OF ACTION/ MEDIATORS OF SECRETION

STb is a rapidly acting toxin but of moderate action. In mouse intestinal loops, purified toxin elicits a response in 30 min and fluid accumulation reaches a maximum after about 3 h (Hitotsubashi *et al*., 1992b). Kennedy *et al*. (1984) first reported, using crude culture filtrates of STb-positive ETEC strains, that STb induced fluid secretion after 3–6 h and that the toxin did not disrupt intestinal histology. STb stimulated a cyclic nucleotide-independent secretion. Thus, STb appeared as a cytotonic toxin with properties and a mechanism of action different from that of STa. Weikel and Guerrant (1985) showed that, relative to controls, significant accumulation of $Na^+$ and $Cl^-$ occurred

intraluminally *in vivo*. Measurements of the electrolytes' content of ligated intestinal segments *in vivo* further suggested that STb stimulated bicarbonate ($HCO_3^-$) secretion. This $HCO_3^-$ secretion was also observed by other researchers (Argenzio *et al*., 1984; Weikel *et al*., 1986a). Contradictory observations were reported in different studies. For example, Whipp *et al*. (1986) observed that exposure of swine jejunum to a culture supernatant containing STb induced microscopic alterations of intestinal mucosa, in particular the loss of villous absorptive cells and partial atrophy of villi, which are consistent with the loss of absorptive capacity. The toxin was capable of causing partial villous atrophy in pigs after only 2h (Whipp *et al*., 1987; Rose *et al*., 1987).

Using light microscopy, Hitotsubashi *et al*. (1992b) observed that exposure of mouse jejunum to purify STb for 3 h caused a dilation of capillaries of the submucosa and a decrease in the thickness of the lamina propria. No cellular damage or inflammation was observed. Thus, it appears that damage to the epithelium does not occur, or rarely, with pure toxin but does when STb-containing supernatants are used (Whipp *et al*., 1987; Rose *et al*., 1987). Using the mouse intestinal loop assay model and purified toxin, Hitotsubashi *et al*. (1992b) confirmed that STb did not alter cGMP or cAMP levels in intestinal mucosal cells, indicating that the mechanism of action of STb in inducing fluid secretion differs from that of STa and of the cholera toxin (CT).

The level of prostaglandin $E_2$ ($PGE_2$) in the intestinal intraluminal fluid increased as a result of STb action, and prostaglandin synthesis inhibitors significantly reduced the response to STb. This report was the first to involve $PGE_2$ in the mechanism of action of STb. Fujii *et al*. (1995) confirmed that the quantity of $PGE_2$ produced by intestinal cells was directly related to the dose of STb administered to the mouse. In addition, the quantity of $PGE_2$ correlated with the volume of fluid released into the intestinal lumen. Levels of arachidonic acid and phosphatidic acid were also elevated by STb, indicating that arachidonic acid metabolism is stimulated by STb, possibly through phospholipase $A_2$ activity. Phosphatidic acid is also produced, from membrane phospholipids, through phospholipase C activity (Dubreuil, 1999).

Two groups have reported independently that both $PGE_2$ and 5-hydroxytryptamine (5-HT or serotonin), the latter being regarded as another secretagogue, were released into the intestinal fluid following STb administration (Harville and Dreyfus, 1995; Peterson and Whipp, 1995). Peterson and Whipp (1995) compared the secretory effects of CT, STa, and STb using the pig intestinal loop model and measured the effects of these toxins on the synthesis of cAMP, cGMP, and $PGE_2$, as well as the release of 5-HT from intestinal enterochromaffin cells. A combination of maximal doses of STa and STb yielded additive effects on fluid accumulation, suggesting different mechanisms of action. A similar additive effect on fluid accumulation and luminal release of 5-HT was noted with a combination of CT and STb. A cAMP and cGMP response to STb could not be demonstrated in either mucosal tissue or luminal fluid. Treatment of rats with ketanserin, a 5-HT receptor antagonist, reduced intestinal secretion induced by STb (Harville and Dreyfus, 1995; 1996). Nonetheless, the mode of action of STb may be somewhat similar to that of CT since the latter toxin stimulates the release of both $PGE_2$ and 5-HT, suggesting a potential effect on the enteric nervous system. Interestingly, a study by Eklund *et al*. (1985) using an *E. coli* strain producing both STa and STb showed that, at least in rats and cats, these heat-stable enterotoxins evoke secretion, in part, via activation of the enteric nervous system, as drugs influencing nervous activity significantly diminished the secretory response. Furthermore, a study using isolated mouse ileum indicated that STb could also act directly on the muscle cells of the ileal serosa increasing the spontaneous motility of the intestine and resulting in contractions (Hitotsubashi *et al*., 1992b). These contractions were not induced when the toxin was applied to the mucosa. The spontaneous motility was not inhibited by atropine, indicating that it was not the result of the excitation of cholinergic nerves. In addition, papaverine, which causes relaxation of smooth muscle, had an inhibitory effect on STb, implying that STb acts directly on muscle cells.

*In vitro* experiments suggested that STb functions by opening a G-protein–linked ($G_{i3}$, a pertussis toxin-sensitive G-protein), receptor-operated calcium channel in the plasma membrane (Dreyfus *et al*., 1993). A dose-dependent increase in intracellular $Ca^{++}$ linked to extracellular $Ca^{++}$ was observed. This process could be blocked by agents that impair GTP-binding regulatory function. Elevated intracellular $Ca^{++}$ activates phospholipases and result in the release of arachidonic acid from membrane lipids. It thus appears that the initial action of STb in the induction of diarrhea is the uptake of $Ca^{++}$ into cells. Subsequently, synthesis of $PGE_2$ and other secretagogues is stimulated, leading to diarrhea.

A study by Fujii *et al*. (1997) suggested the involvement of a $Ca^{++}$-calmodulin–dependent protein kinase II (CaMKII) in the intestinal secretory action of STb. An increase in CaMKII activity in mouse intestinal cells was noted after addition of STb in intestinal loops. A calmodulin antagonist and an inhibitor of CaMKII both reduced the observed activity of STb. Worrell and Frizzell (1991) have previously shown that $Cl^-$ secre-

tion by $Ca^{++}$ is mediated by CaMKII in cultured colonic cell lines (T84). Thus, it was proposed that after an influx of $Ca^{++}$ in the cells and activation of CaMKII through the calmodulin pathway, there would be stimulation and opening of a $Cl^-$ channel followed by subsequent fluid secretion.

At this time, which $Cl^-$ channel is stimulated by CaMKII remains unresolved. The $Ca^{++}$ pathway in which a receptor-generated increase in intracellular $Ca^{++}$ activates multifunctional CaMKII leading to phosphorylation and opening of a $Ca^{++}$-dependent $Cl^-$ channel could be implicated (Wagner *et al*., 1991, 1992; Worrell and Frizzell, 1991). These $Cl^-$ channels are entirely independent of CFTR involved in the STa mechanism of action (Wagner *et al*., 1991). Interestingly, Seidler *et al*. (1997) reported that CFTR is also involved in electrogenic $HCO_3^-$ secretion in the small intestine of mice. Three intracellular signal transduction pathways, including cAMP, cGMP, and $Ca^{++}$, were shown to stimulate $HCO_3^-$ secretion. Since $HCO_3^-$ secretion was reported as a result of STb action, it is tempting to relate the $Ca^{++}$ influx as the first step in STb action leading to $HCO_3^-$ secretion.

## PORE FORMATION AND INTERNALIZATION OF STb

Recently, an *in vitro* test was developed to evaluate the toxicity of STb as it could represent an improvement over the time-consuming and expensive *in vivo* test using rats. Thus, a model for the evaluation of toxicity using the vital stain trypan blue and cells in culture was developed (Beausoleil *et al*., 2002a). Five cell lines (including A-549, human lung; CHO, Chinese hamster ovary; IEC-18, rat ileum; HT-29, human colon; and PK-1, pig kidney) were compared for their uptake of trypan blue when STb toxin was added. Of the tested cell lines, CHO, IEC-18, and HT-29 allowed entry of the vital stain. CHO and IEC-18 were the most sensitive cells tested. Stain uptake was dose-dependent with a maximal effect at 4 μg of STb for $10^6$ cells. Maximal stain uptake was observed after 2 h. Pre-treatment of CHO cells with sulfatase (removing the sulfate groups of cell surface-exposed molecules including sulfatide) completely inhibited trypan blue intake in presence of STb. Thus, it was concluded that sulfatide, the functional receptor for STb, must be present and not altered for the entry of the trypan blue into the CHO cells. When STb mutants (17 single- or double-point mutations) were tested for relative toxicity using trypan blue exclusion assay and the rat loop assay on CHO cells, a good correlation was observed between the two bioassays. In fact, the biological activity observed in the rat model was correlated to the trypan blue uptake assay in CHO cells ($R^2$=0.78) for STb toxin and mutants tested. The variance analysis statistical test indicated a significant correlation between the two bioassays ($Fc \geq F_{0.005}$). These results suggested that the trypan blue uptake bioassay could be used to evaluate the biological activity of STb toxin and mutants. Using a MTT viability test based on the activity of mitochondrial succinate-tetrazolium reductase system, it was clear that the metabolic activity of STb-treated cells was not significally altered, as the MTT assay did not indicate any cell mortality.

An electrophysiological study using planar lipid bilayers was conducted in order to elucidate the mechanism of entry of trypan blue inside STb-treated cells (Labrie *et al*., 2001a). The receptor for STb was reconstituted into large unilamellar vesicles made of PE, which were osmotically fused to PE:PC:cholesterol (7:2:1). Upon addition of STb, on both side of the membrane, well-resolved channel currents were observed when voltage was applied. The data indicated that under 1 KCl symmetrical conditions, the STb main conductance was 180 pS. STb channel activity appeared to be voltage-dependent, being mostly open at all voltages with a tendency to close for longer periods of time at higher negative voltages. Thus, STb may permeabilize eukaryotic cell membrane by disruption of the lipid bilayer, as was also suggested by Chao and Dreyfus (1999). The observation that STb forms oligomers (Labrie *et al*., 2001c) can indicate that STb may allow formation of pores that can alter the cellular membrane, permitting trypan blue intake.

The fate of STb injected in rat intestinal loops was followed using anti-STb gold labeled antibodies and transmission electron microscopy (Labrie *et al*., 2002). STb toxin was injected into rat intestinal loops and after 3h the animal was euthanized. The tissue was fixed and cut using an ultramicrotome. Toxin detection was done with anti-STb antibodies labeled with colloidal gold. Internalization of STb toxin and also of MBP-STb fusion protein was observed. Negative controls (without toxin or without antibodies) gave negative results. A mutant, I41E-M42R, with reduced hydrophobicity and unable to form oligomers but with residual toxicity (approximately 11% compared to STb) was not internalized. These results could mean that oligomerization of STb precedes and is required for internalization. No precise subcellular compartment could be determined as the final destination of the STb toxin.

## CONCLUSION

The heat-stable enterotoxin STb produced by ETEC *E. coli* induces intestinal fluid accumulation, resulting

in diarrheal illnesses and diseases in both humans and animals. From the recently acquired knowledge on STb toxin and on its receptor, we can propose a mechanistic view of the interaction of the toxin with the eukaryotic cell (Figure 25.5). Thus, STb toxin would form hexamers or heptamers in solution, the aqueous milieu compelling the interaction of hydrophobic α-helices together. These oligomers could be formed even in the absence of the receptor. Then oligomers would bind to sulfatide present on the cell surface. This interaction would involve basic residues (K22, K23, and R29) present in the loop (between C21–C36) and the galactose 3-sulfate moiety through initial electrostatic interactions. Then the STb oligomer or monomer would be inserted in the lipidic membrane bilayer. This process could destabilize momentarily the membrane, or pores could be produced, explaining the trypan blue uptake observed in cell in culture. Internalization would then be completed, and STb toxin would be found inside the eukaryotic cell as was observed by transmission electron microscopy (Labrie *et al.*, 2002). On the other hand, as in PLB, current channels were observed, pores could

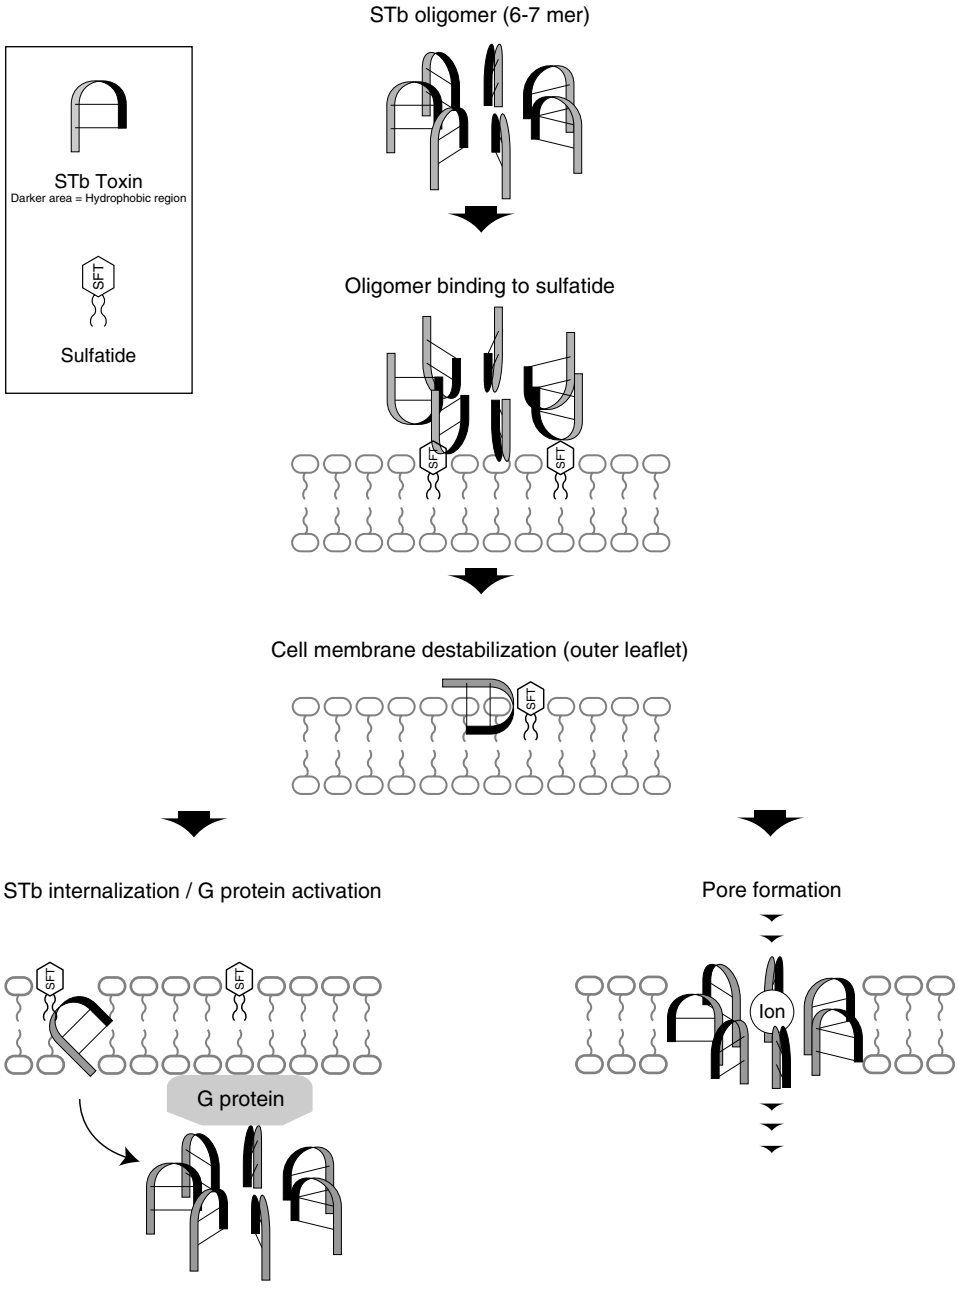


**FIGURE 25.5** Schematic illustration of the proposed mechanistic view of the interaction between STb and the eukaryotic cell based on racently acquired knowledge.

also be formed and selectively allow the passage of ions as $Ca^{++}$. Internalized toxin would now have a direct access to cytoplasmic components of the eukaryotic cell. For example, a direct access of STb to the already implied $G_{i3}$ protein would now be possible.

## ACKNOWLEDGMENTS

The author would like to acknowledge the contribution of graduate students and collaborators to the work presented in this review. In particular, É. Rousset, H.-É. Beausoleil, V. Labrie, J. Harel, F. Lépine, and J.-L. Schwartz. P. Sasseville realized the graphic work. The work has been supported by grants from the Natural Sciences and Engineering Research Council of Canada.

CHAPTER

# 26

# Paradigms and classification of bacterial membrane-damaging toxins

*Joseph E. Alouf*

## INTRODUCTION

The history of membrane-damaging toxins (MDTs) spans a period of about a century (Bernheimer 1996). To our knowledge, the first membrane-damaging activity of a bacterial culture fluid on erythrocytes was characterized by Paul Ehrlich (1888) and Alexandre Marmorek (1902) in the culture fluids of *Clostridium tetani* and *Streptococcus pyogenes*, respectively. The products involved were tetanolysin for the former and streptolysin S or O (or both) for the latter (see Chapters 36 and 42 in this volume). In this introductory chapter, some prominent features of MDTs are briefly outlined. A detailed description of these toxins is presented in (Chapters 27 to 47) of this volume.

## HISTORICAL BACKGROUND

MDTs were first identified by virtue of their lytic action *in vitro* on erythrocyte suspensions (in saline) of human or other animal species and the appearance of zones of hemolysis around bacterial colonies growing on blood agar plates (Alouf, 1977). This approach is still used for phenotypic characterization of hemolytic bacteria and consequently for the identification of relevant hemolytic toxins. However, it became clear from an early stage that many if not all bacterial hemolysins acted on cells other than erythrocytes. Many of them also caused tissue damage or death when injected into experimental animals, thereby justifying their status as "toxins."

The term "hemolysin," generally used in the literature until the 1970s (and sometimes even to date), appeared somewhat restrictive and inappropriate as a general term for MDTs. Certain members of this group are inactive on erythrocytes, while they damage other cells, such as leucocytes. This led to coining the term "leucocidin" for some of them, e.g., *S. aureus* leucocidins, *Pseudomonas aeruginosa* leucocidin also named cytotoxin, and the RTX leucotoxins of various Gram-negative bacterial species (Prevost *et al*. 2001; Xiong *et al*., 1994; Thumbikat *et al*. 2003). Therefore, Alan Bernheimer, a pioneer in the field of membrane-damaging toxins, proposed the terms "cytolysin" or "cytolytic toxin" in an attempt to describe more accurately the biological activity of MDTs (Bernheimer, 1970).

A new period in the study of bacterial cytolysins started at the turn of the 1970s. It concerned the mechanism of action of these proteins on various eucaryotic cells or cell lines, as well as on isolated cell membranes (ghosts) and artificial model membrane systems (phospholipid films and liposomes) investigated by a variety of biochemical, physical, and electron microscopic techniques. A considerable amount of literature is available for this important field (Alouf, 1977; Thelestam and Möllby, 1979; Alouf *et al*., 1984, 1989; Duncan, 1984; Bhakadi and Tranum-Jensen, 1988, 1991; Harshman *et al*., 1989; Sekiya *et al*., 1993, 1996; Walker

and Bayley, 1995; Morgan *et al*., 1994; Dobereiner *et al*., 1996; Palmer *et al*., 1996, 1998; Valeva *et al*., 1997; Vandana *et al*., 1997; Nakamura *et al*., 1998; Staali *et al*., 1998; Shepard *et al*., 1998; Gilbert *et al*., 1998; Rossjohn *et al*., 1998, 1999; Oscarsson, 1999; Jacobs *et al*., 1999; Alouf and Palmer, 1999; Menestrina, 2000; Billington *et al*., 2000; van der Goot, 2000; Hertle, 2000, 2002; Manteca *et al*., 2002; Heuck, 2003; Czajkowsky *et al*., 2004).

## GENERAL FEATURES OF THE MEMBRANE–DAMAGING TOXINS

MDTs are produced by a great number of both Gram-positive and Gram-negative bacterial species. To date, this superfamily of toxins comprises 122 toxins (about 36%) versus the repertoire of 339 bacterial protein toxins so far identified. Thus, the superfamily of MDTs constitutes the most important funtional group of bacterial protein toxins.

MDTs are characterized by their property to damage or disrupt the integrity of the cytoplasmic membrane of various eucaryotic cells (impairment of osmotic balance), reflected by cell swelling and subsequently cell lysis and the release of intracytoplasmic content, particularly hemoglobin in the case of erythrocytes and various macromolecules such as lactate dehydrogenases from various cells during the lytic process (Launay *et al*., 1984; Bhakdi and Tranum-Jensen, 1988; Menestrina and Vécsey-Semjén, 1999; van der Goot, 2003; Alouf, 1980, 2001).

Moreover, following the damage of the cytoplasmic membranes of target cells, many MDTs are able to disrupt the membranes of intracytoplasmic organelles, such as mitochondria, lysosomes, phagosomes, dense bodies, etc., leading to the release of a considerable array of pharmacologically active substances in the surrounding medium of the cells (enzymes, inflammatory factors, cytokines, serotonin) (Alouf, 1980; Launay and Alouf, 1979; Bhakdi *et al*., 1989).

### Toxin release and molecular features

The majority of PFTs are simple single-chain proteins secreted by the bacteria (extracellular toxins), but some of them may remain associated at the suface of these microorganisms. This is the case of the cell-bound form of streptolysin S (Calandra and Cole, 1981; and Chapter 42 of this volume), *Bordetella pertussis* adenylate cyclase-hemolysin (Locht, 1999). Other cytolysins remain strictly located in the cytoplasm, e.g., pneumolysin from *Streptococcus pneumoniae* (Johnson, 1977). This toxin is released in the surrounding medium after cell autolysis. Interestingly, *E. coli* ClyA cytotoxin is surface exposed and exported from bacterial cells in outer membrane vesicles (Wai *et al*., 2003).

The molecular weights of PFTs range from about 2.5 kDa for *S. aureus* δ-toxin (Freer and Birkbeck, 1982; Alouf *et al*., 1989; Dufourcq *et al*., 1999) up to about 177 kDa for *B. pertussis* adenylate cyclase-hemolysin (Locht, 1999). However, many PFTs show a broad diversity of molecular topology, genomic encoding, structural architecture, and functional originality, as described in subsequent chapters.

## PATHOGENIC EFFECTS OF MEMBRANE-DAMAGING TOXINS

Several lines of experimental evidence and clinical observations demonstrated (particularly by genetic deletions) that many MDTs play a pivotal role in bacterial virulence and pathogenesis. In experimental animal models, many toxins elicited the damage of host's cells, tissues, and organs, provoked apoptosis, organelle vacuolation, as well as the production of inflammatory mediators, including various cytokines. Animal death was also recorded (Bhakdi and Tranum-Jensen, 1991; Coote, 1996; Paton, 1996; Rubins *et al*., 1996; Schmiel and Miller, 1999; Ellemor *et al*., 1999; Jacobs *et al*., 1999; van der Goot, 2003; Oxhamre and Richter-Dahlfors, 2003).

### Lethal effects of MDTs

The lethality in humans of various MDTs is well established as dramatically illustrated by the tragedy (1928) in the small Australian town of Bundaberg in which 21 children died in the course of vaccination against diphtheria. The vaccine was contaminated with *Staphylococcus aureus*. The investigation of the cause of the fatalities established that death resulted from an overwhelming toxemia due to hemolyic factors (most probably α-toxin) at the early stage of the invasion of the organism (see Arbuthnott, 1970). Other typical examples among many others is the major involvement of *Clostridium perfringens* hemolytic α-toxin (phospholipase C) in the pathogenesis of gas gangrene (Bryant *et al*., 2000a, b; Stevens and Bryant, 2002; and Chapter 5 of this volume), *C. perfringens* β-2 toxin, and *C. septicum* α-toxin (Tweten, 2001; Manteca *et al*., 2002). RTX cytolysins from *Pasteurellaceae* and other species are also involved in animal and human diseases including lethality (Frey and Kuhnert, 2002; Thumbikat *et al*., 2003).

### Biological and pharmacological effects of sublytic concentrations of PFTs on target cells

The most important pathogenic effects of PFTs do not primarily concern the damage of host's erythocytes (hemolysis) as initially thought. They rather reflect the damage inflicted at sublytic doses to host's cells, which are very likely more representative of toxin concentrations *in vivo* (Billington *et al*., 2000; Oxhamre and Richter-Dahlfors, 2003). Many effectors are released by toxin-damaged cells, particularly immune system cells. These products among others are those of the cytokine network, nitric oxide, and certain key molecules in cell-signaling (Henderson *et al*., 1997; Kayal *et al*., 1999; Bryant *et al*., 2003). This is the case for:

1. *S. aureus* α-toxin (Bhakdi and Tranum-Jensen, 1991; Suttorp *et al*., 1993) and leucocidins (König *et al*., 1994b; Staali *et al*., 1998; Prévost *et al*., 2001)
2. Listeriolysin O (Nishibori *et al*., 1996; Tang *et al*., 1996; Weiglein *et al*., 1997; Tanabe *et al*., 1999; Sibelius *et al*., 1999; Jacobs *et al*., 1999)
3. RTX cytolysins, particularly *E. coli* α-hemolysin (Grimminger *et al*., 1991; König *et al*., 1994a; Coote, 1996; May *et al*., 1996; Lally *et al*., 1999; Oxhamre and Richter-Dahlfors, 2003)
4. *C. perfringens* α-toxin and perfringolysin O (Bryant *et al*., 2003; Rossjohn *et al*., 1999; Ellemor *et al*., 1999); *C. perfringens* β–2-toxin (Manteca *et al*., 2002)
5. Streptolysin O (Hackett and Stevens, 1992; Ruiz *et al*., 1998; Alouf and Palmer, 1999) and pneumolysin (Rubins *et al*., 1996; Alexander *et al*., 1998)
6. *Aeromonas hydrophila* aerolysin (Nelson *et al*., 1999; Buckley, 1999; Fivaz *et al*., 2001)
7. *B. cereus* cytotoxin K (Lund *et al*., 2000) and the *E. coli* cytolytic protein ClyA (Lai *et al*., 2000)

## CLASSIFICATION AND REPERTOIRE OF THE SUPERFAMILY OF MEMBRANE–DAMAGING TOXINS

The progress in the study of the mechanisms of membrane damage of target cells by this wide group of proteins allowed us to distinguish three families of MDTs (Arbuthnott, 1982; Bernheimer and Rudy, 1986; Rowe and Welch, 1994):

(i) The family of toxins exhibiting a detergent-like (surfactant) activity resulting in membrane "solubilization" and (or) partial insertion into the hydrophobic regions of target membranes. This appears to be the case for the 26-amino acid delta- and delta-like toxins of *Staphylococcus aureus, S. haemolyticus*, and *S. lugdunensis* (Freer and Arbuthnott, 1983; Alouf *et al*., 1989; Dufourcq *et al*., 1999), the heat-stable hemolysin from *Pseudomonas aeruginosa* (Rowe and Welch, 1994), and *Bacillus subtilis* cyclolipopeptides (surfactins, iturins, mycosubtilins, bacillomycins) (Bernheimer and Rudy, 1986; Sheppard *et al*., 1991; Maget-Dana and Peypoux, 1994; Menestrina and Vécsey-Semjén, 1999).

(ii) The family of toxins that enzymatically hydrolyze the phospholipids of the bilayer membrane of eucaryotic cells. This family comprises hemolytic and sometimes lethal phospholipases C, certain of them being zinc metallophospolipases. Other toxins exhibit sphingomyelinase or phospholipase D activities (Titball, 1999; and Chapter 27 in this volume). *C. perfringens* α-toxin (phospholipase C), *S. aureus* β-toxin (sphingomyelinase C), and *Vibrio damsela* hemolysin (phospholipase D) are among the most important members of this family. From a historical point of view, the first bacterial protein toxin whose molecular mechanism of action (phospholipase activity) was identified is *C. perfringens* α-toxin (Mac Farlane and Knight, 1941).

(iii) The family of the cytolytic pore-forming toxins (PFTs), which constitutes the majority of the members of MDTs' superfamily, characterized by its property to create channels (pores) through the cytoplasmic bilayer membrane (7–9 nm) of host's cells.

The PFTs family comprises roughly 85 proteins, whereas the enzymatic and tensio-active cytolysins comprise 27 and 10 proteins, respectively.

## THE CONCEPT OF TOXIN (PROTEIN)-INDUCED TRANSMEMBRANE PORES

This concept concerns a general process of disorganization of cytoplasmic cell membrane elicited by a great number of proteins of either procaryotic origin (bacterial toxins) or from eucaryotic organisms (complement, T lymphocytes, perforin, animal venoms, and toxins). This process involves the formation of hydrophilic pores (channels) in the cytoplasmic membrane of target cells provoked by the insertion of these proteins into the membrane, followed by the impairment of cell permeability and thereby cell destruction (lysis). Historically, the first proposal that proteins may create pores in cell membranes concerns the mechanism of erythrocyte lysis by insertion of the C5–C9 components ("membrane complex attack") of plasma complement (Mayer, 1972; Bhakdi and Tranum-Jansen, 1984).

This process was rapidly extended to an increasing number of cytolytic bacterial protein toxins since the

1980s, according to the following *modus operandi* (van der Goot, 2003).

## Pore formation

The toxins are released by the bacteria as water-soluble, generally monomeric proteins. The monomers diffuse toward the target membrane and bind often with great specificity onto various host cells' surface molecules. The surface-bound monomeric PFTs then encounter with other toxin molecules and undergo a series of remarkable changes. They form non-covalently associated oligomers organized into a ring-like structure called the prepore, at least for certain PFTs (Sellman *et al*., 1997; Heuck *et al*., 2003). A subsequent conformational change leads to an amphipathic state (β-barrel profile) of the oligomers, followed by insertion into the membrane and the formation of protein-lined pores of various sizes, depending on the toxin involved. In these pores, the hydrophobic surfaces of toxin molecules are exposed to the membrane acyl-chains and the hydrophilic sides line up the pore (Freer and Birkbeck, 1982; Bhakdi and Tranum-Jensen, 1988; Bhakdi *et al*., 1996; Parker *et al*., 1996; Bayley, 1997; Gouaux, 1997, 1998; Lesieur *et al*., 1997; Palmer *et al*., 1998; Shatursky *et al*., 1999; Gilbert *et al*., 1999; Menestrina *et al*., 2001; van der Goot *et al*., 2003).

## Toxin-binding sites receptors

The chemical nature of the receptors involved in the binding of toxin monomers on target cell surface are known for only a limited number of toxins:

1. Sugar moieties, such as the glycan core of glycosyl phosphatidyl (GPI)-anchored proteins in the case of aerolysin (Buckley, 1999; Fivaz *et al*., 2001; and Chapter 33 of this volume) and *C. septicum* α-toxin (Gordon *et al*., 1999)
2. Cholesterol for the family of "cholesterol-dependent" cytolysins (Alouf and Palmer, 1999; Heuck *et al*., 2001; Giddings *et al*., 2003; and Chapters 36 to 40 of this volume), and *V. cholerae* cytolysin (Zitzer *et al*., 1997; Palmer, 2004)
3. Human CD59 for the "cholesterol dependent" intermedilysin (Giddings *et al*., 2004)
4. Membrane phospholipids (Elias *et al*., 1966; De Azavedo, Chapter 42 of this volume)

## Electron microscopy of cell damage induced by pore-forming toxins

Since the pioneering electron microscopic studies of Dourmashkin and Rosse (1966) on erythrocyte damage by complement and streptolysin O, several investigations on PFTs have been reported. These authors and many others observed at the surface of target cells ring- and arc-shaped structures elicited by various cholesterol-dependent toxins, particularly streptolysin O, pneumolysin, listeriolysin O, and perfringolysin O (Bernheimer and Rudy, 1986; Bhakdi and Tranum-Jensen, 1988; Alouf and Palmer, 1999; Sekiya *et al*., 1993, 1996; Gilbert *et al*., 1999; Vazquez-Boland, 2001). Similar structures were obtained with *E. coli* α-hemolysin (Vandana *et al*., 1997). These structures reflect the oligomerization of the toxins and the formation of conducting pores at the surface of target cells (Gilbert *et al*., 1998, 1999).

## Sizes of the toxin-induced pores

The pores elicited by the toxins differ widely in size. The smallest pores formed in mammalian cell membranes have been sized to around 1–3 nm effective diameter. This is the case for *S. aureus* alpha-toxin (Bhakdi and Tranum-Jensen, 1988; Valeva *et al*., 1997; Fivaz *et al*., 2000), *E. coli* alpha-hemolysin (Lesieur *et al*., 1997; Menestrina and Vécsey-Semjén, 1999), and ClyA cytolytic toxin (Oscarsson *et al*., 1999), *Aeromonas* aerolysin (Buckley, 1999; van der Goot, 2003; Fivaz *et al*., 2001), and *Vibrio* El Tor hemolysin (Zitzer *et al*., 1997). The pores formed by streptolysin S are very small in diameter (Elias *et al*., 1966; Thelestam and Möllby, 1979). In contrast, the transmembrane pores formed by the cholesterol-dependent toxins create holes up to 35–40 nm in diameter corresponding to about 50 monomers of toxin molecules (Sekiya *et al*., 1993, 1996; Gilbert *et al*., 1999; Vazquez-Boland, 2001).

## Extension of the classical pore-forming concept

The classical concept concerns those soluble PFTs molecules that oligomerize at the surface of target cell and punch holes through the bilayer cytoplasmic membrane.

However, in certain cases (invading bacteria), other processes take place. Pores can also be generated once the bacterium has invaded the host cell (van der Goot, 2003). This is the case with listeriolysin O and ivanolysin O produced by the intracellular pathogens, *Listeria monocytogenes* and *Listeria ivanovii*, which grow and release these toxins inside the phagocytic vacuole (phagosome). These cytolysins provoke pore formation in the phagosomal membrane, thereby allowing the release of the bacteria in target cell cytosol (Dramsi and Cossart, 2002). In another situation observed with *Legionella pneumophila*, the production of IcmS by this intracellular pathogen leads to pore formation in the

host cell membrane from the cytoplasmic side, allowing local rupture and egress of the bacterium into the cell surroundigs (Burns, 2003; Molmeret *et al*., 2004). Interestingly, other non-cytolytic pore-forming protein toxins oligomerize to form pores as shown for the protective antigen (PA) of *Bacillus anthracis*, which forms heptamers in target cells (Petosa *et al*., 1997). The role of PA is to translocate the enzymatic moieties of anthrax toxin into cell cytosol.

## TYPOLOGY OF PORE-FORMING TOXINS

The cloning and sequencing of the majority of the structural genes of PFTs over the past 15 years, as well as the great progress of our knowledge of the mechanism of action of these cytolysins during the same period, allows a rational classification of these cytolysins into "congeneric" and "individualistic" toxins categories as initially suggested by Bernheimer and Rudy (1986) (Table 26.1). The former category comprises those PFTs that share close structural and (or) similar physicochemical and functional lytic properties and mechanisms of action, while the latter concerns PFTs exhibiting an appreciable degree of individuality or uniqueness.

### Congenering pore-forming toxins

Most PFTs that belong to this category of cytolysins are specifically produced by either Gram-positive or Gram-negative bacteria. However, certain congeneric toxins are produced by both *Clostridum septicum*

**TABLE 26.1** Representative congeneric pore-forming bacterial toxins sharing functional and (or) structural features

| |
|---|
| **Toxins from Gram-positive bacteria** |
| 1. The family of the cholesterol-dependent cytolysins (formerly SH-"activated" toxins):<br>22 toxins produced by 24 bacterial species from the genera: *Streptococcuss (4 species), Bacillus (6 species), Brevibacillus (1 species), Paenibacillus (1 species), Clostridium (9 species), Listeria (3 species), Arcanobacterium (1 species)* (Alouf, 2001; and Chapter 36 of this volume)<br>Eucaryotic organism-related toxin metridiolysin from the sea anemone *Metridium senile* |
| 2. The family of *S aureus* α-helix (α-toxin) and β-barrel pore-forming bicomponent leucocidins and γ-hemolysins sharing sequence homology: The bicomponent entities include 6 classes of S proteins and 5 classes of F proteins: LukS-PV / Luk F-PV / LukS-R / LukF-R / Luk-E / Luk-D/Luk-M /Luk-F'HlgA HlgB/ HlgC), proteins with 30 possible binary combinations (Prévost *et al*., 2001). The hemolytic γ-toxin comprises three components (Comai *et al*., 2002). *S. aureus* α-toxin and the bicomponent leucocidins are distant in sequence, but are similar in structure (Gouaux 1997). *S. intermedius* leucocidins S-I/F-I (Menestrina *et al*., 2001). |
| 3. *C. perfringens* β-toxin, *B. cereus* hemolysin II, and cytotoxin K (Hunter *et al*., 1993; Baida *et al*., 1999; Prévost *et al*., 2001). |
| 4. *S. aureus/S. epidermidis/S. lugdunensis* **δ**-toxin and many similar cytolytic amphipatic animal peptides: melittin (bee venom), mastoparans, etc. *(*Alouf *et al., 1989;* Dufourcq *et al., 1999).* |
| 5. Streptolysin S (SLS) and SLS-like cytolysins (Alouf and Loridan, 1988; Nizet *et al*., 2000; and Chapter 42 of this volume). |
| **Toxins from Gram-negative bacteria** |
| 1. The multigenic encoded RTX *(Repeats in Toxins)* family:<br>At least 27 hemolysins, leucocidins, enterohemolysins, and metalloproteases produced by 23 bacterial species from the genera *Escherichia, Proteus, Morganella, Pasteurella, Mannheimeia, Actinobacillus, Vibrio, Bordetella, Moraxella*, and *Enterobacter* (Welch, 2001; and Chapters 29 and 30 of this volume). |
| 2. The bicomponent A/B cytolysins from: *Serratia, Proteus, Edwardsiella, Haemophilus* species (Hertle, 2002; and Chapter 31 of this volume): Shl B/A (*S. marcescens)*, Hpm B/ A (*P. mirabilis, P. vulgaris)* Eth B/A *(E. tarda)*, Hhd B/A (*H. ducreyi*): Short sequence homologies of either A or B moieties with: *Bordetella pertussis,* filamentous hemagglutinin, *H influenzae,* hemopexin, and surface protein H. |
| 3. The family of cytolysins and cytotoxins of *V. cholerae* and other *Vibrio* species:<br>15 hemolysins related to El Tor and Nag hemolysins, Vmh (*V. mimicus*) and other species, hemolysins related to *V. parahaemolyticus,* and other hemolysins from four species (Zitzer *et al*, 1997; and Chapter 44 of this volume). |
| 4. The family of the enterobacterial cytolytic protein ClyA produced as outer membranes' vesicles by pathogenic *E. coli* and *Salmonella enterica* serovars Typhi and Parathyphi A (Wai *et al*., 2003; Oscarsson *et al*., 2002). |
| **Toxins from both Gram-negative and Gram-positive bacteria** |
| The family of *Aeromonas hydrophila, A. sobria* channel-forming toxins proaerolysin/aerolysin and *Clostridiun septicum* α-toxin (Fivaz *et al*., 2001). |
| Eucaryotic organisms' homologue of the plant cytolytic protein enterolobin (40% sequence identity) from the seeds of *Enterolobium contortisiliquum* (Fontes *et al*., 1997). The small lobe of aerolysin is almost identical to a fold in the S2 and S3 subunits of pertussis toxin. |

α-toxin and (*Aeromonas hydrophila* aerolysin) Ballard *et al*., 1995). The main features of congeneric PFTs are summarized in Table 26.1. For detailed data about these cytolysins, we refer the reader to the relevant specific chapters (Section III of this volume).

### "Individualistic" pore-forming toxins

Among many other PFTs, this wide group comprises *Enterococcus faecalis* and *Bacillus cereus* bi- and tri-component toxins, *Gardnerella vaginalis* toxin, *Legionella pneumophila* legiolysin, *Pseudomonas aeruginosa* leucotoxin (Xiong *et al*., 1994; Bhakdi *et al*., 1996; Menestrina and Vécsey-Semjén, 1999).

## CONCLUSION

Our knowledge on pore-forming toxins and more generally on other classes of membrane-damaging toxins has progressed considerably over the past decade as concerns their structure, genomic aspects, and structure-activity relationships. The study of the biological effects at the subcellular levels and the pathophysiological properties of these toxins also have witnessed remarkable developments. The involvement of some of them in the pathogenesis of various diseases is currently well established. However, the role of many other PFTs in acute and chronic infections remains to be elucidated.

CHAPTER

# 27

# Membrane-damaging and cytotoxic phospholipases

*Richard W. Titball and Ajit K. Basak*

## INTRODUCTION

Phospholipases have a special place in the history of bacterial toxinology because the α-toxin (phospholipase C) of *Clostridium perfringens* was the first bacterial toxin shown to have an enzymatic mode of action. This certainly explained the remarkable potency of this class of toxins, and of course since that time many bacterial toxins have been shown to be enzymes. As this chapter will highlight, enzymatic activity alone is not sufficient to confer toxic properties on a phospholipase C. Additionally, nowadays it is less clear what is meant by a toxic phospholipase. The idea that such proteins promote overt damage to the host, often leading to lethality, is still a valid concept. However, increasingly it is apparent that these bacterial enzymes might provoke more subtle but nevertheless detrimental effects on the host. Against this background this chapter considers bacterial phospholipases as toxins in the very broadest sense of the word and considers advances that have been made in understanding the molecular basis of toxicity alongside recent research that has identified new phospholipases that might play roles in disease.

## SUBSTRATES FOR PHOSPHOLIPASES

Phospholipids are ubiquitous in biological systems. They are key components of biological membranes and derivatives of phospholipids such as diacyglycerol and inositol triphosphates that serve as messengers within cells (Exton, 1990). The generalized structure of a glycerophospholipid (Figure 27.1) reveals a polar head group linked via a phosphate group and a glycerol backbone to non-polar hydrocarbon (fatty acyl) tails. Sphingolipids (such as sphingomyelin) contain a modified glycerol backbone, linked to fatty acyl tails. The length and degree of saturation of the hydrocarbon tails varies, and their non-polarity means that phospholipids are sparingly soluble in water. The majority of phospholipid in eukaryotes is found in cell membranes where it can adopt a bilayer configuration, with the tail groups embedded in the membrane and the head group's surface exposed.

Phospholipases hydrolyze phospholipids, and the location of the hydrolyzed bond is used to characterize phospholipases as types $A_1$, $A_2$, B, C, or D (Figure 27.1: $PLA_1$, $PLA_2$, PLB, PLC, or PLD; Möllby, 1978). Intriguingly, phospholipases may display concomitant hydrolytic and synthase activities. For example, the *Pseudomonas aeruginosa* PlcH phospholipase C can also function as a sphingomyelin synthase (Luberto *et al*., 2003). A wide variety of assays can be used to measure phospholipase activity. Colorimetric assays use water-soluble phospholipid derivatives (Kurioka and Matsuda, 1976). Other solution phase assays use phospholipid that has been emulsified with detergents to generate micelles (Waite, 1987) or use lipoproteins such as egg yolk lipoprotein (Waite, 1987). All of these assay systems are useful but reveal little about the ways in which phospholipases interact with membranes. Artificial membranes do allow these studies, but living cell membranes are complex mixtures of different phospholipids and proteins, and are able to repair

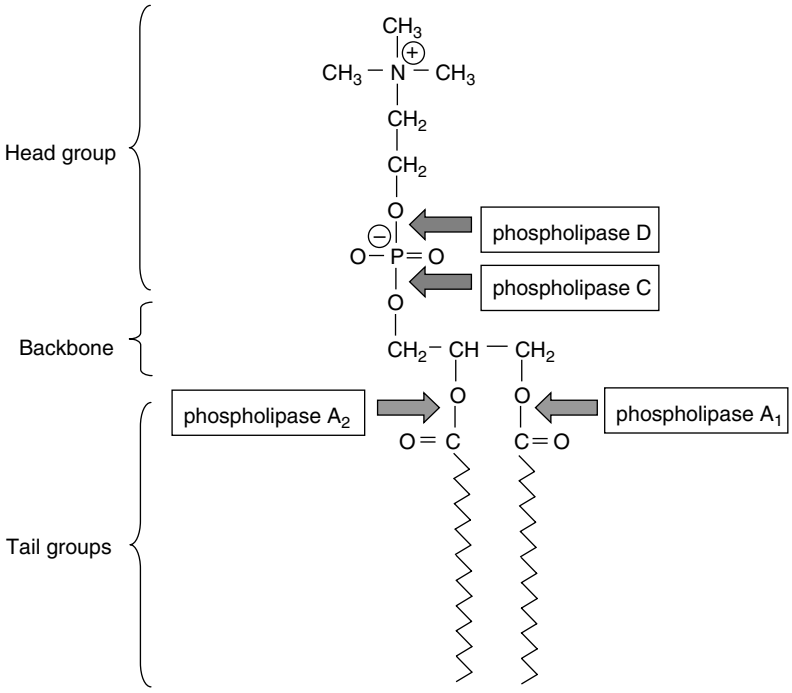

**FIGURE 27.1** Generalized structure of a phospholipid. An entire phosphatidylcholine molecule is shown. In other types of phospholipid, the head group may be inositol, serine, glycerol, or ethanolamine. In sphingomyelins, the backbone includes a $(CH_2)_{12}$. $CH_3$ fatty acyl chain and is termed a ceramide. In all phospholipids, the fatty acyl tails are typically 16–18 carbon chain lengths, but may be shorter or longer and may be unsaturated. The sites of phospholipid cleavage by $PLA_1$, $PLA_2$, PLC, or PLD enzymes are shown arrowed.

limited damage. The lysis of cells, such as erythrocytes, provides a measure of gross cell membrane damage and is easy to perform. However, there is evidence that cellular metabolism is modulated in phospholipase-treated cells and that gross effects on cell membranes (e.g., cell lysis) are only one manifestation of the effect of the enzyme on the cell. These different assay systems are of more than incidental significance: They can reveal the mechanisms by which different enzymes recognize and hydrolyze phospholipids.

## PHOSPHOLIPASES PRODUCED BY BACTERIA

The production of phospholipases by a variety of bacterial species has been reported, many of which are pathogens of man or animals. These enzymes have been grouped and classified as PLA, PLC, or PLD enzymes, based on the site of cleavage and preference for different types of phospholipid. For those proteins whose deduced amino acids sequences are known, the grouping of enzymes according to the above criteria coincides with grouping of enzymes according to amino acid sequence homology. Some of the bacterial phospholipases are lethal toxins, and this chapter considers membrane active bacterial phospholipases, the roles these enzymes play in the pathogenesis of disease, and the molecular basis of membrane interactions.

### Phospholipases A (PLAs)

PLAs are produced by a range of bacteria. Many of these enzymes are membrane bound, and in the case of *Escherichia coli*, they are known as detergent-resistant (DR) phospholipases (Homma *et al*., 1984). This group of PLAs are found in a wide range of Gram-negative bacteria including *Salmonella enterica*, *E. coli*, *Proteus vulgaris*, *Klebsiella pneumoniae*, *Helicobacter pylori* (Dorrell *et al*., 1999), and *Yersinia pseudotuberculosis*. There is no good evidence that these enzymes act as toxins, although the *Y. pseudotuberculosis* does appear to play a role in virulence (Karlyshev *et al*., 2001). A hemolytic cell surface PLA has also been reported from *Legionella pneumophila* (Flieger *et al*., 2004) and a surface bound $PLA_2$ is produced by Campylobacter sp (Istivan *et al*., 2004), but these enzymes do not appear to be closely related to the enterobacteriacae PLAs or to each other. Some bacteria are reported to produce secreted PLAs, and the *Yersinia enterocolitica* YplA (which is distinct from the surface associated PLA) appears to play a role in virulence (Schmiel *et al*., 1998). *L. pneumophila* also produces a secreted lysophospholipase A (Flieger *et al*., 2002), but neither of the *Legionella* enzymes appears to play a role in growth in host cells (Flieger *et al*., 2004). The *Vibrio parahaemolyticus* thermolabile hemolysin is reported to be an extracellular $PLA_2$ (Shinoda *et al*., 1991) and shows sequence similarity to the PLAs produced by *Vibrio cholera* (Fiore

*et al*., 1997) and by the fish pathogen *Vibrio mimicus* (Lee *et al*., 2002). These enzymes are related to the glycerophospholipid-cholesterol acyltransferases (GCAT) produced by *Aeromonas salmonicida* and *Aeromonas hydrophila* (Fiore *et al*., 1997), which can act as $PLA_2$s in the absence of acyl receptors (Thornton *et al*., 1988). The roles of these enzymes in virulence is not fully clarified, but some, like the *V. mimicus* PLA, are toxic towards cultured cells (Lee *et al*., 2002).

## Phospholipases B (PLBs)

There are some reports of PLBs produced by pathogenic bacteria such as *Moraxella bovis* (Farn *et al*., 2001). However, to date, there is no evidence that these enzymes are toxic or that they play roles in virulence.

## Phospholipases C (PLCs)

### *Gram-positive zincmetallophospholipases C*

All PLCs produced by the species *Clostridia*, *Bacillus*, or *Listeria* are zinc-dependent metallo-enzymes with molecular masses in the range 29–43kDa. The best characterized of these enzymes are the *C. perfringens* α-toxin (Titball *et al*., 1989) and the *Bacillus cereus* phosphatidyl choline-PLC (PC-PLC) (Johansen *et al*., 1988). The zincmetallophospholipases C can be divided into two groups: single domain proteins (e.g., *B. cereus* PC-PLC) with approximately 250 amino acids. The other protein (typified by *C. perfringens* α-toxin) possesses an additional carboxy-terminal domain.

Interestingly, *Bacillus anthracis* also possesses a homologue of the PC-PLC encoding gene, which is transcriptionally silent. However, it is possible that this gene is expressed under anaerobic conditions, which might be found in macrophages (Pomerantsev *et al*., 2003). The zincmetallophospholipases C are all active towards phosphatidyl choline, but individual enzymes have different activities towards other phospholipids. For example, some of the enzymes are also active towards sphingomyelin (Titball, 1993).

The crystal structures of *B. cereus* PC-PLC (Hough *et al*., 1989) and *C. perfringens* α-toxin (Naylor *et al*., 1998) both reveal that the active site contains up to three zinc ions. Crystallographic analysis of the *B. cereus* PC-PLC with substrate analogues (Hansen *et al*., 1993) suggests that the zinc ions form part of the substrate-binding pocket. These zinc ions also play a structural role by bridging helices in these proteins, and this might in part explain the high thermal stability of these proteins. The zinc-coordinating residues, identified from the crystal structures of PC-PLC (Hough *et al*., 1989) and α-toxin (Naylor *et al*., 1998), are conserved in all of the other zincmetallophospholipases for which deduced amino acid sequences are available (Titball, 1993), suggesting that these enzymes all have similar active site architectures. Substitution of the zinc-coordinating residues in α-toxin results in proteins that are devoid of PLC activity and are non-hemolytic and non-lethal (Guillouard *et al*., 1996). This finding confirms that the phospholipase activity is essential for all biological activities of α-toxin.

### *Gram-negative zinc-dependent phospholipases C*

PLC produced by *Pseudomonas fluoresecens* (Preuss *et al*., 2001) and *L. pneumophila* (Aragon *et al*., 2002; PlcA) appear to be members of a class of Gram-negative zinc-dependent PLC. These enzymes also require $Ca^{++}$ ions for activity and are not closely related to the Gram-positive zincmetallophospholipase Cs or to the *Pseudomonas aeruginosa* PC-PLCs (see below). These enzymes may also be structurally related to the recently discovered PlcB enzyme from *P. aeruginosa*, which is able to hydrolyze phosphatidylethanolamine and may be a zinc-requiring enzyme (Barker *et al*., 2004).

### *Gram-negative phosphatidyl choline phospholipases C (PC-PLCs)*

The PlcH phospholipase C produced by *P. aeruginosa* is considered to be the prototypic member of a superfamily of bacterial PLC and acid phosphatases (Stonehouse *et al*., 2002). This group of enzymes includes the phospholipases C of *Burkholderia pseudomallei*, *Burkholderia mallei*, *Bordetella pertussis*, *Mycobacterium tuberculosis*, and the acid phosphatase/phospholipase of *Francisella tularensis*. These proteins have molecular weights of 50–80kDa, and unlike the Gram-positive zinc-metallophospholipase C, they are not inhibited by D609 (Stonehouse *et al*., 2002). Several homologous genes have been identified in various other bacterial species. For example, there are two phospholipases in this superfamily in *P. aeruginosa*, typically three in *M tuberculosis*, and four in *B. pseudomallei*. All these enzymes share some sequence homology; they do not have similar properties. The *M. tuberculosis* proteins are truncated at the C-terminus and posses a C-terminal lipid-binding motif. Unlike the *Pseudomonas* enzymes, which are secreted from the cell via the twin arginine translocation system (Voulhoux *et al*., 2001), the *M. tuberculosis* enzymes appear to be bound to the cell surface (Johansen *et al*., 1996). This might explain the contact-dependent hemolytic activity that is associated with some virulent strains of *M. tuberculosis* (Leao *et al*., 1995).

The *P. aeruginosa* PlcH and PlcN enzymes have been studied most intensively. PlcH and PlcN show overall sequence homology of 59% (Ostroff *et al*., 1990), but

differ in their properties. PlcH is hemolytic and is able to hydrolyze phosphatidylcholine and sphingomyelin, whereas PlcN is non-hemolytic and able to hydrolyze phosphatidylcholine and phosphatidylserine. One of the most intriguing features of PlcH, which has not been reported for any of the other Gram-negative PC-PLCs, is the requirement for two chaperone proteins ($PlcR_{1,2}$) for full activity (Stonehouse *et al*., 2002). $PlcR_{1,2}$ appears to play a role in the export of PlcH, and $PlcR_2$ appears to remain complexed with PlcH such that enzyme purified from culture supernate is a 1:1 heterodimer termed $PlcHR_2$ (Stonehouse *et al*., 2002). $PlcR_2$ possesses an EF-hand motif, but paradoxically $Ca^{++}$ ions inhibit the hemolytic activity of PlcH and $PlcHR_2$ (Stonehouse *et al*., 2002). Therefore, it appears that the role of $Ca^{++}$ ions is different for PlcH activation in contrast to Gram-positive zinc metallo-phospholipase Cs, where $Ca^{++}$ ions are essential for the phospholipid recognition.

### *Other phospholipases C*

The relationship of other Gram-negative PLCs to the above enzymes is not known. Many of these enzymes are cell-associated and are produced by intracellular pathogens, although the significance of this relationship awaits clarification. The *L. pneumophila* enzyme ($M_r$ 50-54kD) requires divalent cations, and treatment with EDTA abolishes activity (Baine, 1988). However, the enzyme is not reactivated by treatment with $Zn^{++}$ ions, suggesting that it is not a zinc metallo-phospholipase C. The activity of the enzymes produced by *Ureaplasma urealyticum* (De Silva and Quinn, 1987) or by the oral spirochaetes, such as *Treponema denticola* (Siboo *et al*., 1989), has only been demonstrated using ρNPPC, so it is not possible to conclude whether these PLCs are phosphatidylcholine-preferring enzymes or are sphingomyelinases.

### *Sphingomyelinases C*

Some bacterial phospholipases C show a remarkable specificity for sphingomyelin. *B. cereus* sphingomyelinase (Yamada *et al*., 1988) and *Staphylococcus aureus* sphingomyelinase (β-toxin; Projan *et al*., 1989) show 56% amino acid sequence identity and have molecular masses of approximately 39kD. Both enzymes require $Mg^{++}$ or $Co^{++}$ ions for activity (Ikezawa *et al*., 1986). The sphingomyelinase produced by *Leptospira interrogans* is related to the *B. cereus* and *S. aureus* enzymes, but appears to be produced as a high molecular weight form (63kD), which is processed at the C-terminus to yield a 39kD mature protein (Segers *et al*., 1990). *B. anthracis* also possesses a homologue of the *B. cereus* sphingomyelinase gene (Pomerantsev *et al*., 2003), but like the PC-PLC gene (see above), it is transcriptionally silent. Also like PC-PLC, the gene may be expressed under some conditions (Pomerantsev *et al*., 2003).

### *Phosphatidylinositol-hydrolysing enzymes*

Several bacterial enzymes ($M_r$ ~ 34 kD) that are specific for phosphatidylinositol have been characterized. These type II soluble PI-PLC enzymes (*B. cereus* PI-PLC: Kuppe *et al*., 1989; *Bacillus thuringiensis* PI-PLC: Henner *et al*., 1988; *Listeria monocytogenes* PLC-A: Mengaud *et al*., 1991) possess similar primary structures, and are able to hydrolyze phosphatidylinositol and glucosyl phosphatidylinositol (GPI). It is possible that the *S. aureus* PI-PLC (apparent $M_r$ 20-33kD: Ikezawa, 1986) and the *C. novyi* PI-PLC (apparent $M_r$ 30,000: Ikezawa, 1986) are related to the *Bacillus* and *Listeria* enzymes. Unlike the mammalian enzymes, none of the bacterial PI-PLCs reported to date are metalloenzymes—in fact, $Zn^{++}$, $Mg,^{++}$ or $Ca^{++}$ ions inhibit the activity of the *B. cereus* and *S. aureus* enzymes (Heinz *et al*., 1998; Ikezawa, 1991). Also, unlike mammalian PI-PLCs (type 1 enzymes), the bacterial enzymes are not able to hydrolyze phosphatidylinositol phosphates to generate inositol triphosphate secondary messengers.

Significant insight into the relationship between the structures and functions of the bacterial (*B. cereus* PI-PLC) and mammalian enzymes (rat PI-PLC-δ1) has been obtained by comparing the crystal structures of these proteins (Figure 27.2; Heinz *et al*., 1998). The bacterial enzyme is a single domain that folds as a $\beta\alpha_8$ barrel, with the active site located in an open cleft at the C-terminus (Heinz *et al*., 1998). The crystal structure of the *L. monocytogenes* PLC-A (Moser *et al*., 1997) also reveals a single domain with very similar architecture to the *B. cereus* enzyme—even though these proteins show only 24% sequence identity. The mammalian enzyme also has a $\beta\alpha_8$ barrel domain, which contains the active site, together with a C2-fold domain, an EF-hand domain, and a PH domain (Figure 27.3; Heinz *et al*., 1998). The crystal structures of these proteins also confirm that only the mammalian enzymes bind a single catalytically essential $Ca^{++}$ ion within the active site cleft, and the residues in C2-domain take part in $Ca^{++}$-ion coordination (Heinz *et al*., 1998).

### *Phospholipases D (PLDs)*

The best-studied group of bacterial PLDs includes the enzymes produced by *Corynebacterium pseudotuberculosis*, *Corynebacterium ulcerans*, and *Arcanobacterium haemolyticum*, which show 64–97% sequence identity (Songer, 1997) and are related to the PLD in the venom of the brown recluse spider (Songer, 1997; Truett and King, 1993). These PLDs are hemolytic only in the

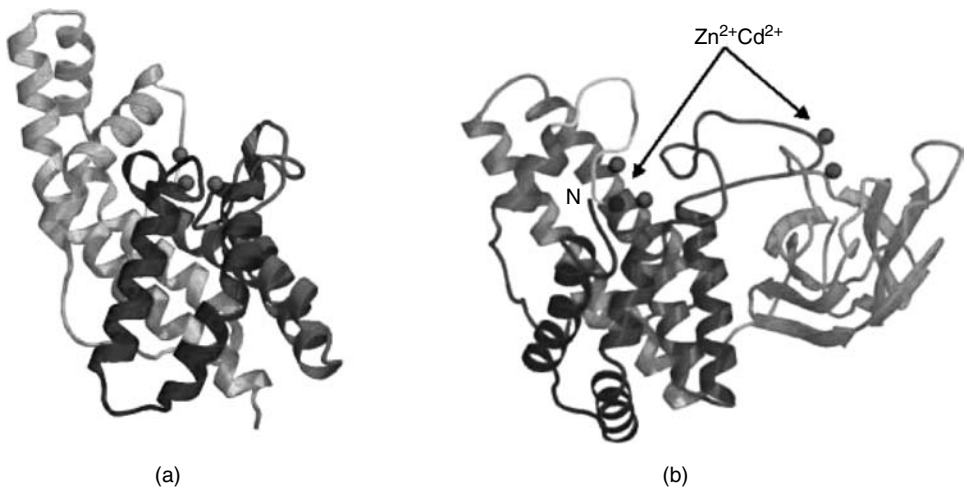

**FIGURE 27.2** Comparison of the crystal structures of the *B. cereus* PC-PLC (a: Hough *et al*., 1989) and the *C. perfringens* α-toxin (b: Naylor *et al*., 1998). Zinc residues found in the active site of the enzymes are shown as spheres. Calcium ions bound to the carboxy-terminal domain of *C. perfringens* α-toxin are also shown as spheres.

presence of the cholesterol oxidase of *Rhodococcus equi*, and pretreatment of erythrocytes with *C. pseudotuberculosis* PLD actually renders the cells resistant to lysis with *C. perfringens* α-toxin or *S. aureus* β-toxin (Soucek *et al*., 1971).

PLDs have also been reported to be produced by a variety of other bacteria, including *Haemophilus influenzae*, *S. enterica*, *Vibrio damsela* (Waite, 1987), *M. tuberculosis* (Johansen *et al*., 1996), *P. aeruginosa* (Wilderman *et al*., 2001), *Yersinia pestis* (Hinnebusch *et al*., 2000), *Neisseria gonorrhoeae* (Edwards *et al*, 2003), and *Rickettsia prowazekii* (Renesto *et al*., 2003). The latter enzyme might account for the activity previously ascribed to a $PLA_2$ produced by the bacterium (Renesto *et al*., 2003). Most of these enzymes have not been well studied. However, the *V. damsela* PLD is hemolytic, preferentially active towards sphingomyelin and able to degrade phospholipids in Madin-Darby canine kidney cells (Kothary and Kreger, 1985). The *R. prowazekii* PLD also appears to be active towards cultured cells, since antibody to PLD is able to reduce the cytotoxicity of the bacterium towards Vero cells (Renesto *et al*., 2003).

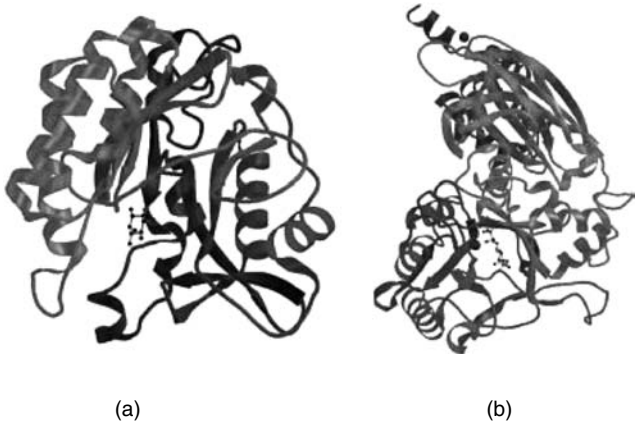

**FIGURE 27.3** Comparison of the crystal structures of the *B. cereus* PI-PLC (a) and rat PI-PLC-δ1 (b). Inositol is shown as a ball and stick molecule in the active site, and $Ca^{++}$ in the active site is shown as a sphere.

## ROLES OF PHOSPHOLIPASES IN DISEASE

In 1944, pioneering work by MacFarlane and Knight showed that the α-toxin produced by *C. perfringens* was an enzyme (MacFarlane and Knight, 1941). This finding stimulated interest in the roles of PLCs produced by other pathogenic bacteria, and even today new and more diverse roles of these enzymes are emerging in the pathogenesis of bacterial disease.

### *Colonization and invasion of host tissues*

Many of the mucosal surfaces of the body are covered by surfactant-like barriers, which are rich in phospholipids, such as phosphatidylcholine. Therefore, it is not surprising that bacterial phospholipases have attracted attention as a possible means of breaching this barrier. The degradation of lung surfactant has been demonstated, *in vitro*, using the α-toxin from *C. perfringens* (Holm *et al*., 1991), and there is no reason to suppose that phospholipases produced by respiratory tract pathogens would not be equally active. It is tempting to speculate that this would enhance the colonization of underlying tissues and while this may be true, the production of phospholipases by pathogens of the respiratory tract play additional roles. The *P. aeruginosa* PLCs are produced *in vivo* in

cystic fibrosis patients (Granström *et al*.,1984), and a PlcN/PlcH mutant was less able than the wild type to induce injury to alveolar epithelial cells (Saiman *et al*., 1992). One function of the *P. aeruginosa* enzymes might be to convert phosphatidylcholine to choline-betaine, which then protects against the high osmotic strength environment in the lung ( Shortridge *et al*., 1992). However, it is studies with the *P. aeruginosa* PlcB that have revealed one of the most remarkable roles of these enzymes. PlcB appears to play a key role in the generation of signaling molecules, such as diacylglycerol, which are then recognized by the bacteria as a chemoattractant (Barker *et al*., 2004). Thus, PlcB may promote the tropism of bacteria towards sites with the greatest potential for colonization. Clearly, the phospholipases of other pathogens of the respiratory tract might play similar roles.

Phospholipases might play similar roles in the case of pathogens that colonize the stomach. For example, the $PLA_2$ produced by *H. pylori* has been suggested to play a role in the degradation of the phosphatidylcholine-rich stomach lining, and thereby allow access to underlying tissues (Langton and Cesareo, 1992). This suggestion is supported by the finding that bismuth salts, which are often used to treat peptic ulcers, are potent inhibitors of the *H. pylori* $PLA_2$ activity (Ottlecz *et al*., 1993). The phospholipases produced by oral spirochaetes might perform similar functions (Siboo *et al*., 1989).

An additional possible role for phospholipases in the invasion of host tissues arises from a recent study with *B. cereus* PC-PLC, which has shown increased matrix metalloprotease production and enhanced permeability of monolayers after treatment of epithelial cell cultures with this enzyme (Firth *et al*., 1997). Whether this mechanism also operates *in vivo* and with PLCs produced by pathogenic bacteria awaits investigation. However, if demonstrated, this process could allow the release of nutrients onto the epithelial cell surface or allow the bacteria to gain access into the body. The *N. gonorrhoeae* PLD also appears to interact with host cells, promoting membrane ruffling and the invasion of cervical epithelial cells (Edwards *et al*, 2003). The molecular basis for this event is not fully clarified, but appears to involve the recruitment of the complement 3 receptor on the cervical cell surface (Edwards *et al*, 2003).

### *Growth and spread of infection in the host*

The production of *B. cereus* or *P. aeruginosa* PC-PLCs is induced under low $P_i$ conditions, suggesting that these enzymes form part of an enzyme cascade involved in phosphate scavenging (Gray *et al*., 1982; Guddal *et al*., 1989). It is worth noting that the PI-PLCs are able to release GPI-anchored proteins, such as alkaline phosphatase and alkaline phosphodiesterase, from the surfaces of eukaryotic cells (Ikezawa, 1986), and it is conceivable that these eukaryotic enzymes also contribute to phosphate scavenging. In addition to their possible role in phosphate acquisition, some phospholipases appear to play a direct role in the spread of infection in the host. Perhaps the most dramatic examples of this are seen with gas gangrene infections in man caused by *C. perfringens* and lymphadenitis or lyphangitis in ruminants or horses caused by *C. pseudotuberculosis*.

The development of gas gangrene is associated with two events. First, a traumatic injury to soft tissues, such as those sustained during road traffic accidents or during warfare that allows the entry of the bacterium (present in the soil or decaying organic matter) into the host. Second, disruption to the blood supply, which might occur following the severing of major blood vessels, results in anoxic conditions in tissues necessary for the growth of *C. perfringens*—an anaerobe. In the mouse model of disease, gas gangrene can be caused by the inoculation of a large dose of bacteria into the hind limb (Awad *et al*., 1995; Williamson and Titball, 1993). The infection progresses rapidly and can be fatal within just 18hr (Awad *et al*., 1995). Since the early 1900s, α-toxin has been suggested to be the major virulence determinant associated with the spread of the infection (McNee and Dunn, 1917). However, there was no evidence until 1995 when a *plc*-mutant of *C. perfringens* was tested in the murine model with little evidence of infection, minimal muscle necrosis, and no deaths of experimental animals (Awad *et al*., 1995).

Several recent studies have revealed the mechanisms by which α-toxin reduces the blood supply to tissues, which then become sufficiently anoxic to allow growth of the bacteria. The α-toxin appears to promote the contraction of the smooth muscle lining blood vessels (Fujii and Sakurai, 1989) and the formation of intravascular aggregates of platelets, leucocytes, and fibrin (Awad *et al*., 2001; Bryant *et al*., 2000). These events would reduce the blood supply to tissues. The formation of the intravascular aggregates appears to involve the up-regulation of a range of cell surface markers, such as platelet gpIIbIIIa (Bryant *et al*., 2003) and β2 integrins on neutrophils (Ochi *et al*., 2002). Initially, these aggregates are free-flowing, but later become bound to endothelial tissues (Bryant *et al*., 2000). Not only do these events reduce the blood supply, but they also modulate the influx of neutrophils into the site of infection (see below).

There is also increasing evidence that some phospholipases play key roles in the establishment of chronic infection. For example, the PLD produced by *C. pseudotuberculosis* appears to be essential for the formation of subcutaneous abscesses in sheep or goats

(Hodgson *et al*., 1992; McNamara *et al*., 1994). In contrast to *C. perfringens* α-toxin, which reduces the blood supply to infected tissues, the *C. pseudotuberculosis* PLD increases vascular permeability. This might allow bacterial spread from the primary sites of infection to the regional lymph nodes where chronic abscesses become established (McNamara *et al*., 1994). The *M. tubeculosis* PLCs appear to play quite a different role in the establishment of chronic disease—possibly because they release fatty acids from host cells as a carbon and energy source in the later stages of infection (Raynaud *et al*., 2002). Consequently, although *M. tuberculosis* PLC mutants are able to grow in macrophages, triple or quadruple mutants show a ten-fold reduction in the colonization of mouse lungs in the later stages of disease (Raynaud *et al*., 2002). This pattern of reduced colonization of lung tissues during the later stages of disease is remarkably similar to that reported for a *pldA* (PLD) mutant of *P. aeruginosa*, raising the possibility that this enzyme plays a similar role to the *M. tuberculosis* PLCs in establishing chronic disease (Wilderman *et al*., 2001).

The PLCs produced by *L. monocytogenes* (PLC-A and PLC-B) play yet a different role in the colonization of host cells by degrading the phagosome membrane and degrading the double membrane vacuole that forms when bacteria spread from cell to cell (Figure 27.4). PLC-A and PLC-B appear to have overlapping but distinct functions. Initial studies with single Δ*plcA* or Δ*plcB* mutants suggested that these enzymes played a minor role in host cell colonization. Further studies have shown that a *ΔplcA ΔplcB* double-mutant was 500-fold attenuated in the murine model of disease (Smith *et al*., 1995) and was markedly less effective in escaping from the phagosome and in spreading from cell to cell (Smith *et al*., 1995).

Other PLCs appear to play less important roles in the infection process. In the mouse model of mastitis, the level of tissue colonization by a β-toxin mutant of *S. aureus* was actually greater than that of the wild type (Bramley *et al*., 1989). While this suggests that β-toxin does not play a role in disease, it should be borne in mind that *S. aureus* causes a wide variety of different diseases in man and animals. It seems unlikely that the bacterium would retain a gene encoding a protein that was not required for survival or growth of the bacterium in any niche. Perhaps the enhanced colonization levels of the β-toxin mutant of *S. aureus* in the mastitis model indicate the role of β-toxin in the development of a stable host-pathogen relationship.

While most of this chapter is devoted to the consideration of the roles of phospholipases in the pathogenesis of diseases of mammalian hosts, it is also worth highlighting the possibility that these enzymes play a role in diseases of non-mammalian hosts. Perhaps the most dramatic example of this is seen in the case of the *P. aeruginosa* PlcH, which not only plays a role in disease of mammalian hosts but also in the growth of the bacterium in plant (*Arabidopsis thaliana*) tissues (Rahme *et al*., 1995). Whether the enzyme exerts similar effects in these markedly different host species awaits investigation.

### *Avoidance of host defense mechanisms*

The cytolytic properties of some PLCs extend to cells other than erythrocytes, and cytolytic activity towards host phagocytes has been reported (Titball *et al*., 1993). There is no evidence that lysis of phagocytic cells occurs on a large scale *in vivo*, but there is good evidence that PLCs can modulate the host response to infection in more subtle ways, thereby allowing the growth of bacteria. The usual host response to infection is to mount a dramatic inflammatory response with the migration of phagocytes into the infected tissues. It has been known for many years that gangrenous infected tissues were devoid of phagocytes (McNee and Dunn, 1917). This pattern is also seen in tissues taken from mice experimentally infected with wild-type *C. perfringens*, but not in tissues taken from mice infected with a Δplc mutant where the expected influx of phagocytes into infected tissues did occur (Stevens *et al*., 1997). In an elegant study, it was shown that α-toxin caused the

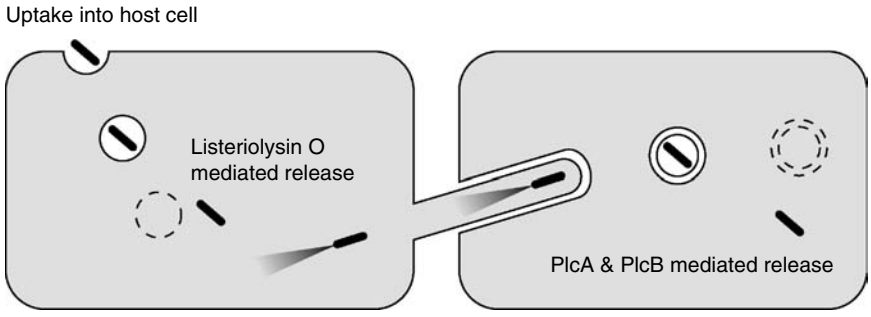

**FIGURE 27.4** Roles of membrane active proteins in the colonization of host cells by *Listeria monocytogenes*. After uptake by host cells, escape from the phagosome is mediated mainly by listeriolysin. Bacteria spread from cell to cell via double-walled vacuoles. Escape from these double-walled vacuoles is mediated mainly by the phospholipases PLC-A and PLC-B. Bacteria with mutations in *PlcA* and *PlcB* are able to infect cells, but are defective in cell-to-cell spread, resulting in small plagues in cell culture.

up-regulation of cell adherence markers (ICAM, ELAM, and p-selectin) on the surface of endothelial cells lining blood vessels (Bunting *et al*., 1997). Neutrophils treated with α-toxin appear to up-regulate β2-integrins, which mediate binding to fibrinogen and fibronectin (Ochi *et al*., 2002), and this might also contribute to neutrophil mistrafficking. Therefore, it appears that α-toxin causes mistrafficking of host phagocytes, allowing the bacterium to grow in host tissues. Whether other bacterial phospholipases also cause host phagocyte mistrafficking awaits investigation.

There are at least two examples where phospholipase play a role in resistance to killing in the host. The *Y. pestis* PLD is also known as the so-called murine toxin, which is reportedly highly toxic for mice. However, paradoxically, this enzyme does not appear to play a role in the pathogenesis of disease in mice (Hinnebusch *et al*., 2000), but rather in the colonization of the flea vector (Hinnebusch *et al*., 2002). The PLA of *H. pylori* appears to be required for survival of the bacterium in the acid conditions in the stomach (Dorrell *et al*.,1999). In both of these cases, the phospholipase appears to play a role in the remodeling of the bacterial membrane to allow the bacterium to survive in the host (Hinnebusch *et al*., 2002; Tannaes *et al*., 2001).

### *Damage to the host*

Early studies with PLCs focused on their cytolytic properties, and there was a general assumption that these enzymes caused widespread cell lysis in the host. Although lysis of erythrocytes does occur in experimental gas gangrene (evidenced as hematuria), there is little evidence that extensive hemolysis occurs during natural cases of gas gangrene or any other diseases involving phospholipase-producing bacteria. Speculatively, one might argue that phospholipases could also contribute to acute respiratory distress syndrome, which is associated with the breakdown of the lung surfactant layer, typically by host phospholipases (Murakami and Kudo, 2004). However, the current evidence indicates that bacterial phospholipases damage the host by subtly perturbing host cell metabolism and in some cases by inducing the production of pro-inflammatory cytokines (Wieland *et al*., 2002).

Many derivatives of phospholipids act as secondary messengers within eukaryotic cells (Exton, 1990). Diacylglycerol, which may be generated after cleavage of glycerophospholipids by phospholipases C, has profound effects on cellular metabolism (Exton,1990). Diacylglcerol lipase can convert diacylglycerol into arachidonic acid, which is then able to enter the arachidonic acid cascade (Samuelsson, 1993), with the resultant generation of prostaglandins, thromboxanes, and leukotrines (Figure 27.5). Treatment of cultured cells or isolated tissues with a variety of phospholipases, including *C. perfringens* α-toxin (Bunting *et al*., 1997; Fujii and Sakurai, 1989) or *P. aeruginosa* Plc-H (König *et al*., 1997), has been shown to result in the generation of these molecules. The diacylglycerol

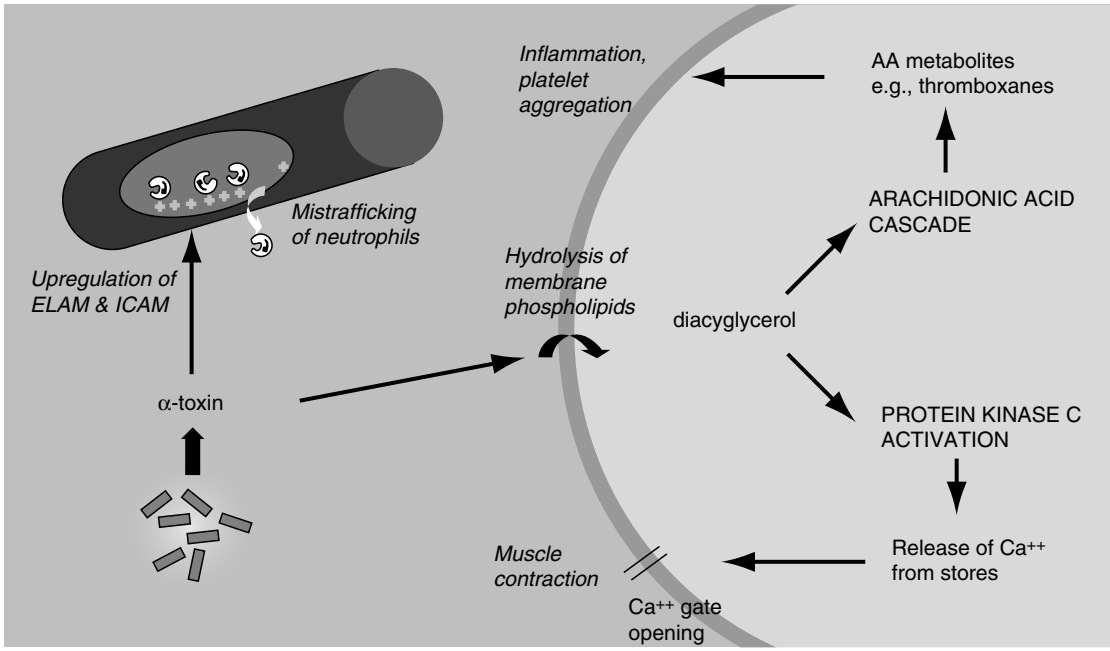

**FIGURE 27.5** Effects of *C. perfringens* α-toxin on mammalian cell metabolism

might also activate endogenous protein kinase C, which is essential for both short- and long-term effects on cellular metabolism (Bunting *et al*., 1997; Nishizuka 1992). The elevated production of matrix metalloproteases by cells treated with *B. cereus* PC-PLC is also thought to be due to activated protein kinase C (Firth *et al*., 1997), and the activation of protein kinase C is also implicated in the up-regulation of cell adherence markers on neutrophils treated with α-toxin (Ochi *et al*., 2002).

The effects of bacterial phospholipases on mammalian cells might be further potentiated as a result of activation of endogenous membrane phospholipases and especially phospholipases $A_2$, C, and D (Gustafson and Tagesson, 1990; Ochi *et al*., 1996; Sakurai *et al*., 1993). In studies with rabbit erythrocyte membranes, it has been shown that endogenous PLC is rapidly activated, followed later by the activation of PLD (Ochi *et al*., 1996; Sakurai *et al*., 1993). These activated mammalian enzymes might themselves generate further substrates for the arachidonic acid cascade. The mechanism by which the mammalian phospholipases are activated has been the subject of speculation. Some workers have suggested that activated protein kinase C is able to activate the mammalian enzymes, either directly or indirectly (Exton, 1990; Nishizuka, 1992; Waite, 1987). An alternative explanation is that the α-toxin mediates the effect via activation of GTP-binding proteins, which in turn activates mammalian phospholipases (Ochi *et al*., 2002) .

In addition to the further activation of the arachidonic acid cascade, mammalian PLCs are able to hydrolyze phosphatidylinositol diphosphate ($PIP_2$) to generate the secondary messenger inositol triphosphate ($IP_3$; Sakurai *et al*., 1993). The $IP_3$ would have a variety of effects on cells. For example, the release of calcium from the endoplasmic reticulum is triggered by $IP_3$, causing the opening of calcium gates in the cell membrane (Fujii *et al*., 1986). Boethius *et al*. (1973) showed that muscle cells treated with α-toxin become inexcitable, and this might explain the cardiotoxic effects of the α-toxin (Asmuth *et al*., 1995). The elevated intracellular calcium levels would also contribute to the activation of endogenous membrane phospholipases described in the previous paragraph.

The effects of α-toxin on eukaryotic cells might be further potentiated by the metabolic status of the cells. Cells deficient in UDP-glucose, a consequence of ischemia, are $10^5$ times more sensitive to *C. perfringens* α-toxin (Flores-Díaz *et al*., 1997). The molecular basis for this enhanced susceptibility has not been fully elucidated. However, UDP-glucose deficient cells contained normal levels of phosphatidylcholine, suggesting that alterations to the outer membrane leaflet were not responsible for the enhanced sensitivity. However, it is apparent that the products of sphingolipid hydrolysis (i.e., ceramide) by sphingomyelinases might also modulate cellular metabolism. Though the abilities of bacterial enzymes to activate these pathways have not been studied in detail, it is perhaps worth pointing out that ceramide is thought to play an important role in the induction of apoptotic responses (Spiegel *et al*., 1996).

In summary, these elegant studies tend to support the hypothesis that the bacterial enzymes are mimicking the effects of the mammalian enzymes and thereby modulating cellular metabolism to the detriment of the host. The effects that have been described above are all relatively short-term. It is also worth mentioning that long-term perturbation of cellular messengers such as protein kinase C has been linked with the transformation of cultured cells. Such effects might suggest a link between the development of cancers and the long-term exposure to bacterial phospholipases (Parkinson *et al*., 1987).

## INTERACTION OF PHOSPHOLIPASES WITH MEMBRANE PHOSPHOLIPIDS

A central feature of phospholipases, which play roles in the pathogenesis of disease, is their ability to interact with membranes, whether from outside the cell or from inside phagosomes. Bacterial phospholipases vary widely in their abilities to interact with membrane phospholipids, and this has resulted in the suggestion that those enzymes that play important roles in the pathogenesis of disease can be identified on the basis of their hemolytic activity. To some extent this proposal is supported by experimental evidence. Of the two related PLCs produced by *P. aeruginosa*, PlcH is hemolytic and able to induce the release of inflammatory mediators from granulocytes, whereas PlcN is devoid of both activities (König *et al*., 1997). A similar pattern is observed when the properties of *C. perfringens* α-toxin are compared with the *Clostridium bifermentans* PLC, *Clostridium sordellii* PLC, or *B. cereus* PC-PLC; the *C. perfringens* α-toxin has markedly higher hemolytic activity than the other enzymes (Jepson *et al*., 1999; Karasawa *et al*., 2003; Titball *et al*., 1991) and is able to cause release of inflammatory mediators from granulocytes (König *et al*., 1997) and is lethal when administered into animals.

The mechanisms that allow some enzymes to interact with membrane phospholipids have been the subject of various studies, and various theories have been developed to explain the mode of action of these

enzymes. One theory proposes that membrane active enzymes have structural features that allow their insertion into membranes. A second theory suggests that membrane active enzymes are able to hydrolyze both phosphatidylcholine and sphingomyelin. These theories are discussed in more detail below.

### *Insertion into the membrane bilayer*

It is generally assumed that the surface of the phospholipid bilayer consists of tightly packed head groups, which mask the hydrophobic tail groups. This model would suggest that the bond susceptible to cleavage by the phospholipase is not exposed to the aqueous phase. In reality, the phospholipids adopt a "hockey stick" conformation in the bilayer, and the susceptible bond might be partially accessible to an enzyme in the aqueous phase (Figure 27.6). However, even with the "hockey stick" conformation of phospholipids, the active site of the enzyme could not be docked with the substrate without the phospholipase either becoming inserted into the membrane or having a mechanism that allowed retraction of the phospholipid out of the membrane. Evidence supporting the "insertion" hypothesis was originally reported by van Deenen *et al.*, (van Deenen *et al.*, 1976), who measured the activity of phospholipases towards phospholipid monolayers maintained at increasing lateral pressures. This showed (Table 27.1) that hemolytic phospholipases (e.g. *C. perfringens* α-toxin) were able to insert into monolayers maintained at lateral pressures above those found in erythrocytes. In contrast, non-hemolytic enzymes (such as *B. cereus* PC-PLC) were only able to hydrolyze phospholipids in monolayers maintained at low lateral pressures.

### *Surface-exposed hydrophobic amino acids might become buried in membranes*

Several regions on the surface of α-toxin have been identified as having possible membrane-binding functions (Naylor *et al.*, 1998). $Trp_{214}$ (in N-terminal domain), $Tyr_{331}$, and $Phe_{334}$ (in C-terminal domain) are surface exposed and are positioned in such a way that they could interact with the phospholipid tail groups on membrane binding (Figure 27.7). In *B. cereus* PC-PLC, $Trp_{214}$ is not exposed; instead, an insertion of a pair of antiparallel helices and $Tyr_{331}$ and $Phe_{334}$ are not present since there is no carboxy-domain in this enzyme. Other bacterial phospholipases might exploit similar mechanisms to allow insertion into the membrane. The *B. cereus* PI-PLC has a "ridge" of hydrophobic amino acids, which are thought to become inserted into the membrane (Heinz *et al.*, 1998). This region also appears to be important in the structurally related *Bacillus thuringiensis* PI-PLC, and two tryptophan residues ($Trp_{47}$ and $Trp_{242}$) have been shown to play a major role in membrane binding (Zhang *et al.*, 2004).

### *C2 domains might be involved in phospholipid recognition*

On comparing the structures of *B. cereus* PC-PLC (Hough *et al*., 1989) and *C. perfringens* α-toxin (Naylor *et al*., 1998), it is apparent that both enzymes possess structurally similar catalytic domains, but only *C. perfringens* α-toxin has a carboxy-terminal domain. If this domain is removed from α-toxin, the phospholipase C activity is retained, but hemolytic activity is lost (Titball *et al*., 1991; Nagahama *et al*., 2002). However, the isolated carboxy-terminal domain does not possess hemolytic (or indeed any detectable enzymatic) activity (Titball *et al*., 1993). When the two domains of α-toxin are mixed together in solution, hemolytic activity is restored (Titball *et al*., 1993; Nagahama *et al*., 2002). Even more dramatically, the fusion of the carboxy-terminal domain of α-toxin with the *B. cereus* PC-PLC results in a hemolytic hybrid protein (Nagahama *et al*., 2002). Collectively, these findings confirm that both the catalytic domain and the carboxy-terminal domain are required for membrane activity of the zincmetallophospholipases C.

For many years it has been known that calcium ions are essential for the hemolytic activity of α-toxin (MacFarlane and Knight, 1941) and for the hydrolysis of monomolecular films of phosphatidylcholine (Moreau *et al*, 1988). Three $Ca^{++}$ binding sites have now been identified in the carboxy-terminal domain of α-toxin, and these are located on the putative membrane-binding face of the protein. These $Ca^{++}$ binding sites are organized in a similar way to the calcium-binding sites in eukaryotic C2-fold domains (Naylor *et al*., 1998; Naylor *et al*., 1999). C2-fold domains have not previously been found in prokaryotes, and are typically found in proteins that are involved in lipid metabolism in higher eukaryotes, such as synaptotagmin and phosphatidylinositol-specific phospholipase C (Naylor *et al*., 1998).

The low-binding affinity of $Ca^{++}$ (Kd ~ 175-250 μM at pH 8.0) by the isolated carboxy-terminal domain of α-toxin and the incomplete and/or partial coordination of these ions in $Ca^{++}$ bound structure (Naylor *et al*., 1999) proves that the complete coordination of $Ca^{++}$ ions is partially dependent on membrane phospholipid headgroups (Naylor *et al*., 1999). Variant forms of α-toxin where $Ca^{++}$-binding residues are replaced show reduced activity (Table 27.2), providing further evidence for the role of the carboxy-terminal domain in membrane binding. The binding of $Ca^{++}$ ions by the carboxy-terminal domain appears to be accompanied by structural changes, which expose hydrophobic regions that are otherwise internalized (Naylor *et al*., 1999). This might be consistent with the insertion of these regions into the cell membrane and with the increased fluorescence of acrylodan-labeled α-toxin on binding to liposomes (Nagahama *et al*., 2002).

Does the presence of carboxy-terminal domain provide a simple way of identifying the toxic zincmetallophospholipases C? Unfortunately, the answer is no. The carboxy-terminal domains of the *C. bifermentans* and *C. sordellii* enzymes show approximately 50% sequence identity with the carboxy-terminal domain of *C. perfringens* α-toxin and are therefore likely to be C2-fold domains. Yet these enzymes are only weakly hemolytic and are considered to be non-toxic. To investigate the possibility that these carboxy-terminal domains have different properties, Jepson *et al*. (1999) constructed a hybrid phospholipase C. Removal of the carboxy-terminal domain of the *C. bifermentans* phospholipase C and replacement with the carboxy-terminal domain of α-toxin markedly enhanced hemolytic activity (Jepson *et al*., 1999). The reduced ability of the *C. bifermentans*

**TABLE 27.2** Calcium-binding ligands in the carboxy-terminal domain of *C. perfringens* α-toxin

| Calcium | Coordinating side chains | Mutagenesis | Phenotype of variant toxin compared to wild-type toxin | | | | | |

protein to interact with membrane appears to be due to the substitution of several key residues identified in α-toxin as playing a key role in membrane binding. For example, the substitution of $Tyr_{331}$ and $Phe_{334}$ in α-toxin with the counterparts in the *C. bifermentans* protein (Leu and Ile, respectively) markedly reduced hemolytic, cytotoxic, and myotoxic activities (Jepson *et al*., 2001). It is likely that other amino acid substitutions on the putative membrane-binding face also contribute to the reduced hemolytic and cytotoxic activity of *C. bifermentans* phospholipase C.

### *The active site may be opened on membrane interaction*

Although the models described previously can explain how phospholipases become partially inserted into the membrane, they do not explain how the enzyme adjusts the position of its active site to make a susceptible bond with the phospholipid. It is possible that the enzymes partially retract the phospholipid from the membrane. Analysis of the structure of the toxic phospholipase C produced by *Clostridium absonum* (structurally related to *C. perfringens* α-toxin) has revealed a hydrophobic channel, which might promote entry of the phospholipid into the active site (Clark *et al*., 2003). Alternatively, the phospholipase may undergo a conformational change that inserts the active site region into the membrane (Blow, 1991). It has previously been suggested that α-toxin might undergo structural changes on activation (Rosenthal and Pousada, 1968), and more recent data indicates that membrane binding is accompanied by structural changes in the protein, which result in the movement of two loops flanking the active site cleft (Naylor *et al*., 1999; Eaton *et al*., 2002). These structural changes may be a consequence of the binding of the carboxy-terminal domain, with the binding event communicated to the active site region via residues 60–90 (Naylor *et al*., 1999). Whatever the precise mechanism by which these structural changes occur, the overall result is the opening of the active site cleft (Eaton *et al*., 2002), and this provides a molecular explanation for long-standing observation of interfacial activation of α-toxin (Klein *et al*, 1975), which results in increased hydrolytic activity towards phospholipids, which are in a membrane-packed form.

## THE MOLECULAR BASIS OF SUBSTRATE SPECIFICITY

### *Substrate specificity and membrane phospholipid hydrolysis*

One of the striking features of the phospholipases is the wide variation in substrate specificity by proteins that

are structurally related. For example, although phosphatidylcholine is the preferred substrate for the zincmetallophospholipases, individual enzymes show differences in their abilities to hydrolyze other phospholipids. The molecular basis for these differences is becoming clearer as crystal structures of these proteins, in some cases complexed with substrate analogs, are becoming available.

One of the key mechanisms by which phospholipases recognize (and discriminate between) their substrates involves the interaction of the head group with the active site. The molecular mechanisms by which phospholipases bind to the head group have been investigated for *B. cereus* PC-PLC (Hanssen *et al*., 1993) and *B. cereus* PI-PLC (Heinz *et al*., 1998). *B. cereus* PC-PLC appears to recognize, primarily, the phosphate moiety that displaces water molecules and becomes coordinated to the three zinc ions in the active site cleft (Hansen *et al*., 1993b). Additional binding occurs via hydrogen bonds between various amino acid side chains and, especially, the choline head group and the carbonyl group (El-Sayed *et al*., 1985; Hansen *et al*., 1993). Remarkably, the substrate preference of the enzyme can be modified by replacing selected amino acids in the headgroup binding pocket (Antikainen *et al*., 2003). The active site of *B. cereus* PI-PLC is relatively wide, to allow entry of the bulky inositol head group, which is recognized primarily via the 4- and 5-hydroxyl groups and various polar and charged side chains of amino acids. In fact, the close interactions between these hydroxyl groups and the active site explain why the enzyme is not able to cleave inositol bisphosphate, since the additional phosphate groups cannot be accommodated within the active site cleft (Heinz *et al*., 1998).

The importance of the recognition of the fatty acyl tails of phospholipids is more variable between different bacterial phospholipases. The recognition of substrate by the bacterial PI-PLCs does not appear to be dependent on recognition of the fatty acyl tail groups (Bruznik *et al*., 1992). In contrast, the fatty acyl tails are recognized by zincmetallophopholipases, such as *B. cereus* PC-PLC and *C. perfringens* α-toxin. The fatty acyl tails must be at least $C_6$ in length for recognition by *B. cereus* PC-PLC (El-Sayed *et al*., 1985), and the recognition of phospholipids in liposomes by *C. perfringens* α-toxin is dependent on the presence of unsaturated fatty acyl tail groups, which are $C_{14}$ or less in length (Nagahama *et al*., 1996). Some of these apparent substrate recognition events might reflect changes in membrane fluidity, especially when liposome assay systems are used. However, it is clear that for some enzymes, recognition of this region of phospholipids is a key event. Since the head groups of sphingomyelin and phosphatidylcholine are usually identical (i.e., phosphorylcholine), the discrimation of these molecules must be dependent on recognition of the glycerol backbone and fatty acyl tail.

For some years it has been suggested that hemolytic phospholipases C were able to hydrolyze both phosphatidylcholine and sphingomyelin, which are major components of the outer leaflet of mammalian cell membranes, whereas non-hemolytic enzymes were able to hydrolyze only one type of phospholipid (Ostroff *et al*., 1990; Titball, 1993). For example, the hemolytic *P. aeruginosa* Plc-H enzyme can hydrolyze both phosphatidylcholine and sphingomyelin, while the related *P. aeruginosa* Plc-N enzyme is able to hydrolyze only phosphatidylcholine and is non-hemolytic (Ostroff *et al*., 1990).

One key difference between *B. cereus* PC-PLC and *C. perfringens* α-toxin is the ability of the latter to hydrolyze sphingomyelin and phosphatidylcholine (Krug and Kent, 1984) whereas the *B. cereus* enzyme is able to hydrolyze only phosphatidylcholine (Otnaess *et al*., 1977). Significantly, a mixture of *B. cereus* PC-PLC and *B. cereus* sphingomyelinase does cause hemolysis, and this mixture is termed cereolysin A-B (Gilmore *et al*., 1989 ; Beecher *et al*., 2000). Why is *B. cereus* PC-PLC active against erythrocyte membranes when combined with a sphingomyelinase, when it is apparently not able to insert into membrane bilayers? It is thought that in membranes, sphingomyelin can sterically obscure the phosphatidylcholine head group (Beecher *et al*., 2000). Therefore, one possibility is that the sphingomyelinase enzyme first hydrolyzes sphingomyelin, and that the resultant changes in membrane organization and lateral pressure allow the phosphatidylcholine hydrolyzing enzyme to act on membrane phospholipids (Beecher *et al*., 2000). Experimental evidence does lend some support to this suggestion. Sphingomyelin plays a key structural role in the outer leaflet of membranes, and erythrocytes incubated with *B. cereus* (or *S. aureus*) sphingomyelinase are not lysed unless they are subsequently exposed to an additional stress, such as cooling below the phase transition temperature (termed "hot-cold lysis") or treatment with divalent cation chelating agents (Bernheimer *et al*., 1974; Ikezawa *et al*., 1986). Viewed together, these findings tend to confirm that when sphingomyelin and phosphatidylcholine are hydrolyzed, the cell membrane is sufficiently weakened, which results in lysis.

### *Membrane-active enzymes may be non-hemolytic*

The above findings suggest that hemolytic activity is indicative of the hydrolysis of both sphingomyelin and phosphatidylcholine, and that hemolytic enzymes (or mixtures of enzymes) are able to penetrate membrane

bilayers. Hemolysis is certainly an extreme measure of cell membrane damage and remains a useful indicator of the interaction of an enzyme with mammalian cells. However, it should not be viewed as the sole indicator of membrane phospholipid hydrolysis. As noted above, bacterial sphingomyelinases are able to hydrolyze membrane sphingomyelin without cell lysis. In other cases non-hemolytic enzymes might act synergistically with other bacterial products to cause hemolysis. One example of this synergy is seen with the phospholipases C produced by *L. monocytogenes*. Although PLC-A and PLC-B are considered to be non-hemolytic (or at least very weakly hemolytic: Geoffroy *et al*., 1991), they play key roles in disruption of the phagosome and the double-membrane vacuole formed during cell-to-cell spread (Smith *et al*., 1995). It is significant that these phospholipases appear to act together, and with the pore-forming toxin listeriolysin O, to achieve these effects (Goldfine *et al*., 1995; Smith *et al*., 1995).

## VACCINES AND THERAPEUTIC APPLICATIONS OF PHOSPHOLIPASES

### Membrane probes

For many years phospholipases have been used as membrane probes—either to specifically hydrolyze different classes of phospholipids in membranes or to mimic the effects of eukaryotic phospholipases C. In the past, the use of phospholipases C in this way has been fraught with many problems; the enzymes were isolated from bacteria, which often produced other membrane-active toxins, and the difficulties of isolating "pure" phospholipases C meant that it was difficult to be certain that the effects observed were due to the bacterial phospholipases C. The availability of cloned gene products means that better defined preparations of phospholipases are now available to support these studies.

### Vaccines

Given the key roles that some phospholipases play in the pathogenesis of disease, it is not surprising that inactivated forms of the enzymes have been considered as components of vaccines. In this respect, *C. perfringens* α-toxin has attracted the most attention, but the toxic nature of this enzyme meant that early vaccination studies used formaldehyde toxoids, prepared from α-toxin isolated from the supernatant fluid of cultures of *C. perfringens* (Boyd *et al*., 1972; Kameyama *et al*., 1975). These toxoids induced protection against gas gangrene, but it was difficult to ensure that the vaccine did not contain other toxoided *C. perfringens* proteins, and therefore to be sure that the protective component in the vaccine was α-toxoid. Several approaches for the generation of genetically engineered toxoids have been reported. Either naturally occurring or laboratory-generated forms of the α-toxin have been reported with markedly reduced enzymatic and cytolytic activity (Guillouard *et al*., 1996; Schoepe *et al*., 2001). Immunization of mice with a naturally occurring non-toxic variant induced protection against subsequent challenge with wild-type α-toxin. These mutated proteins could, in principle, be developed as vaccines if reversion to toxicity were an unlikely event. Alternatively, the recombinant carboxy-terminal domain of α-toxin could be used as a non-toxic vaccine. Immunization of mice with this protein induced high levels of antibody, which protected mice against experimental gas gangrene caused by *C. perfringens* (Williamson and Titball, 1993).

The finding that the *C. pseudotuberculosis* PLD plays a key role in the pathogenesis of caseous lymphadenitis in sheep and goats has prompted suggestions that either a PLD mutant might itself be used as a vaccine (Hodgson *et al*., 1992) or that an enzymatically inactive form of the PLD might be used as a component of a subunit vaccine (Haynes *et al*., 1992).

The possibility that phospholipases produced by other bacteria might be used as components of vaccines has yet to be investigated. However, it should be borne in mind that in the case of intracellular pathogens, it may be difficult to induce an appropriate protective immune response. Remarkably, phospholipases C have also been exploited to solve this problem. In trials in humans, *L. monocytogenes* strains with mutations in the *actA* and *plcB* genes appear to be safe vaccine vectors, which might promote the induction of cellular responses to heterologous antigens (Angelakopoulos *et al*., 2002).

### Design of therapeutics

When bacterial phospholipases play key roles in the pathogenesis of disease, it is feasible that enzyme inhibitors could be used to treat these diseases. For example, bismuth salts, which can be used to treat gastric and duodenal ulcers, are thought to inactivate the *H. pylori* $PLA_2$, and it may be possible to design more effective enzyme inhibitors. The possibility that prokaryotic and eukaryotic phospholipases have similar structures or molecular modes of action suggests that the bacterial enzymes might be used to design and test drugs for use against eukaryotic phospholipases C or lipid-binding enzymes. Such drugs might be used to treat a variety of

inflammatory diseases in man. In this respect, it is interesting to note that the C-terminal domain of the *C. perfringens* α-toxin is folded as a C2-domain, which is found frequently in eukayotic enzymes, such as synaptotagmin, phosphatidylinositol PLC, and arachidonate-5-lipoxygenase (Naylor *et al*., 1998).

## Future directions for research

For many years, studies with bacterial phospholipases were limited to the enzymes produced by *C. perfringens* and *B. cereus*. More recently, studies have been carried out with phospholipases produced by other pathogens. However, there are still many phospholipases produced by pathogens that are poorly characterized and for which we have not determined their roles in the pathogenesis of disease. Why are some enzymes membrane bound and others exported from the cell, and, more generally, are the enzymes produced by intracellular pathogens specially adapted for this lifestyle?

In general, the interaction of phospholipases with membrane phospholipids is thought to be a key event, but we have limited knowledge of how this occurs. Hemolysis is an indicator of membrane interaction, but the hydrolysis of membrane phospholipids can occur without hemolysis. Why are some enzymes active towards liposomes but inactive towards erythrocytes? Why are mixtures of phosphatidylcholine hydrolyzing enzymes and sphingomyelinases hemolytic when the individual enzymes are not? Clearly, substrate specificity is one of the factors that determines the activity of enzymes, but how is this specificity achieved at a molecular level? In spite of research over the past 10 years, we do not fully understand how phospholipases exert their many effects on eukaryotic cells. What role do eukaryotic enzymes play in these processes? How do different enzymes exert different effects on different cell types?

The information that will be derived from these studies over the next decade is of more than philosophical significance. It will allow a variety of new approaches to the control of diseases. In some cases, vaccines will be devised and enzyme inhibitors could be used to treat bacterial diseases. These opportunities provide exciting new challenges to investigators in a rapidly expanding field.

CHAPTER

# 28

# *Bacteroides fragilis* toxins

*Cynthia L. Sears, Augusto A. Franco, and Shaoguang Wu*

## INTRODUCTION

*Bacteroides fragilis* are common colonic commensals comprising about 0.1% of the fecal flora in the majority, if not all, humans. Despite their small numbers in the fecal flora, *B. fragilis* are the leading anaerobes in intraabdominal and bloodstream infections (Polk and Kasper, 1996). Although the extraintestinal virulence of *B. fragilis* has long been ascribed to the capsule of the organism (Onderdonk *et al*., 1977; Tzianabos *et al*., 1993), recent data has begun to highlight both the genetic and molecular diversity of *B. fragilis* with the recognition that the organism expresses at least eight distinct capsular polysaccharides (Franco *et al*., 1999; Krinos *et al*., 2001; Obuch-Woszczatynski *et al*., 2004). The precise role of the unprecedented capsular diversity of *B. fragilis* in microbial survival, colonization, and disease remains to be defined.

In 1984, the landmark experiments of Myers *et al*. (1984) expanded knowledge on the pathogenic potential of *B. fragilis* and presented the first evidence that certain strains of *Bacteriodes fragilis* (termed enterotoxigenic *B. fragilis* or ETBF) were associated with diarrheal illnesses in young lambs. Subsequent studies revealed that culture supernatants of ETBF strains stimulated intestinal secretion in lamb ligated intestinal loops and that the biologically active factor was a heat-labile, about 20 kDa protein toxin, later termed the *B. fragilis* toxin (BFT) (Myers *et al*., 1984; Myers *et al*., 1985). Since these initial observations, ETBF have also been isolated from patients with extraintestinal *B. fragilis* infections and bacteremia (Chung *et al*., 1999; Claros *et al*., 2000; Kato *et al*., 1996; Pantosti *et al*., 1994a), as well as associated with diarrheal disease in livestock, children (over the age of one year), and adults (Kato *et al*., 2000; Zhang *et al*., 1999; Sears *et al*., 1995; Scotto d'Abusco *et al*., 2000; Sears, 2001). Most recently, in preliminary data, ETBF have been associated with active inflammatory bowel disease (Basset *et al*., 2004; Prindiville *et al*., 2000). The goal of this chapter will be to summarize the progress that has occurred over the last 20 years in understanding the genetics and mechanism of action of BFT.

## THE GENES AND PROTEIN STRUCTURE OF THE *BACTEROIDES FRAGILIS* TOXINS

Initially, the *B. fragilis* toxin (*bft*) gene was cloned and sequenced from three ETBF strains: lamb isolate VPI13874 (VPI-*bft* or *bft-1*), piglet isolate 86-5443-2-2 (86-*bft* or *bft-2*), and systemic isolate Korea 419 (Korea-*bft* or *bft-3*) (Chung *et al*., 1999; Franco *et al*., 1997; Kling *et al*., 1997). The terminology *bft-1*, *bft-2*, and *bft-3* recognizes the temporal sequence in which the alleles were identified. Subsequently, a new *bft* subtype was reported from Japan that is identical to *bft-3* (in amino acid sequence), making this the preferred terminology over Korea-*bft* (Kato *et al*., 2000). Available evidence indicates that ETBF strains and all three *bft* alleles are globally distributed. However, only limited investigations have characterized the epidemiology of the specific *bft* alleles of ETBF. For example, using a collection of 45 intestinal or extraintestinal ETBF strains isolated in the United States, the *bft-1* and *bft-2* alleles were identified in 58% and 42% of strains, respectively (Franco *et al*., 1997), but none was positive for the *bft-3* allele (Chung *et al*., 1999). In contrast, among 34 ETBF strains isolated in Seoul, Korea, 41%, 22%, and 32% contained

*bft-1*, *bft-2*, and *bft-3*, respectively (Chung *et al*., 1999), whereas, among 143 ETBF isolates in Japan, 63%, 24%, and 13% contained *bft-1*, *bft-2*, and *bft-3*, respectively (Kato *et al*., 2000). However, the *bft-3* allele is not restricted to East Asia, as it has been reported in ETBF strains from Europe (d'Abusco *et al*., 2000). Overall, available reports suggest that the *bft-1* allele is most common among human ETBF strains evaluated to date.

Although each of the three *bft* alleles identified and sequenced to date are distinct, all *bft* genes identified are chromosomal, have a guanosine plus cytosine content of 39%, and are predicted to encode a 397-residue holotoxin with a calculated molecular weight of approximately 44.5 kDa. These data, combined with identification of the *N*-terminal amino acid sequence of purified BFT-1 and BFT-2, suggest that ETBF strains synthesize BFT as a pre-proprotein toxin that is then processed by ETBF prior to secretion of the mature biologically active 20 kDa toxin (Figure 28.1) (Franco *et al*., 1997; Kling *et al*., 1997; Van Tassell *et al*., 1992; Wu *et al*., 2002). Consistent with this prediction, approximately 44 kDa and 20 kDa proteins are detected with anti-BFT antisera in lysates of ETBF strains (Franco *et al*., 1999; Franco *et al*., 2005). Fragilysin has been proposed as an alternative name for BFT (Obiso, Jr. *et al*., 1997a), although there is no evidence that BFT induces cell lysis (see Biologic and Physiologic Activities of BFTs, below).

The initial 18 amino acids of the predicted BFT holotoxin encode a signal peptide (preprotein domain) with a pattern typical of lipoprotein signal peptides, although there is no experimental evidence indicating that BFT is a lipoprotein (Franco *et al*., 1997). The proprotein toxin domain is predicted to be 211 residues in length. By analogy with data reported on the function of the proprotein region of the *Pseudomonas aeruginosa* elastase (McIver *et al*., 1995), the BFT proprotein region is hypothesized to be instrumental in proper protein folding and secretion of biologically active BFT (Franco *et al*., 1997). Consistent with these data, cloning and expression of the mature toxin domain without the proprotein domain in *Escherichia coli* yields a biologically inactive protein (Franco and Sears, unpublished data). The high degree of homology of the pre- and proprotein domains of all BFTs (see below and Figure 28.2) is consistent with the interpretation of conserved functions for these protein domains. Cleavage at the Arg-Ala site at the carboxy-terminus of the proprotein domain releases the mature toxin (Franco *et al*., 1997; Van Tassell *et al*., 1992; Wu *et al*., 2002).

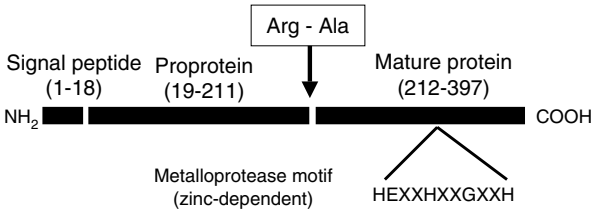

**FIGURE 28.1** Schematic of the protein structure of BFT. The amino acid sequences of BFT-1, BFT-2, and BFT-3 predict that each protein is a pre-proprotein toxin containing signal peptide, proprotein, and mature toxin domains. Intracellular cleavage at the Arg-Ala site by a, as yet unidentified, *B. fragilis* protease yields the mature protein toxin that is secreted by the organism. The mature protein domain of each protein contains a HEXXHXXGXXH motif, suggesting that BFTs are zinc-dependent metalloprotease toxins. Zinc-dependent proteolytic activity has been confirmed for BFT-1 and BFT-2.

The predicted mature toxin domain of each *bft* allele contains an extended zinc-binding metalloprotease motif, HEXXHXXGXXH, and a perfectly superimposable methionine residue close to the metalloprotease motif. This structural constellation predicts that BFTs are members of the metzincin superfamily of zinc-dependent metalloprotease enzymes (Moncrief *et al*., 1995; Obiso, Jr. *et al*., 1997b). BFTs possess the methionine residue 7 amino acids downstream of the zinc-binding metalloprotease motif, typical of the matrix metalloprotease subfamily (matrixins) (Moncrief *et al*., 1995; Obiso, Jr. *et al*., 1997b). Interestingly, limited homology exists between eukaryotic matrix metalloproteases and BFT, leading to the proposal that BFT may be the ancestral origin of these host tissue enzymes (Massova *et al*., 1998). Consistent with the structural predictions, BFT has been shown to be a protease *in vitro* (Moncrief *et al*., 1995) and *in vivo* on cells (Wu *et al*., 1998) and to contain 1 g-atom of $Zn^{2+}$ per toxin molecule (Moncrief *et al*., 1995). In addition, the biological activity of BFT is reduced by approximately 90% by zinc chelation of the purified protein (Koshy *et al*., 1996; Moncrief *et al*., 1995; Obiso, Jr. *et al*., 1995). Experimental proof of the importance of the metalloprotease motif to the biologic activity of BFT is provided by structure:function analyses in which point mutations to modify each of the conserved amino acids of the extended metalloprotease motif, as well as the conserved downstream methionine, reduce or eliminate the biologic activities of BFT (Franco *et al*., 2005). The reported *in vitro* substrates of BFT include G (monomeric)-actin, gelatin, azocoll, tropomyosin, collagen IV, human complement C3, and fibrinogen, although no biologic significance of these substrates has been identified to the cellular or intestinal mechanism of action of BFT (Moncrief *et al*., 1995; Obiso, Jr. *et al*., 1997b; Saidi *et al*., 1997). The only reported cellular (*in vivo*) substrate reported for BFT is E-cadherin (Wu *et al*., 1998). Although BFT has been reported to be autoproteolytic (Moncrief *et al*., 1995; Van Tassell *et al*., 1994a), mutations that inactivate the BFT metallopro-

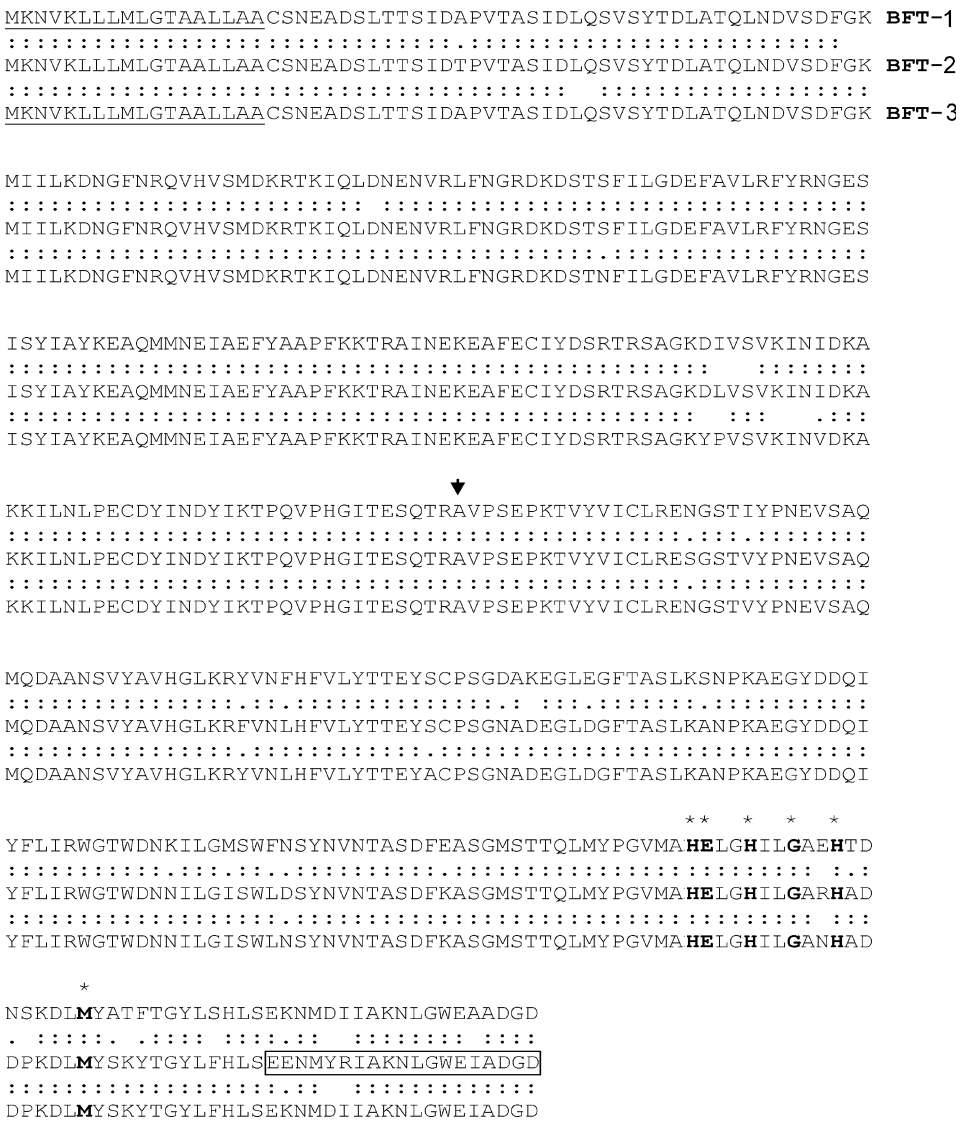

**FIGURE 28.2** Comparison of the amino acid sequences of BFT-1, BFT-2, and BFT-3. BFT-1 and BFT-2 are 95% similar and 92% identical in amino acid sequence. Of note, only two amino acid changes between the two proteins are present in the pro-protein domain, whereas 25 amino acid differences are clustered in the mature toxin domain. BFT-3 is 93% and 96% identical to BFT-1 and BFT-2, respectively. Underlined residues indicate the signal peptide domain. Arrow indicates the Arg-Ala cleavage site yielding release of the mature toxin. * and bold residues indicate the amino acids forming the $Zn^{2+}$-binding metalloprotease motif. Boxed amino acids indicate the predicted amphipathic domain specific to BFT-2.

tease motif do not alter the intracellular processing and secretion of BFT by *B. fragilis*, suggesting that other *B. fragilis* proteases are responsible for the intracellular processing of the toxin (Franco *et al.*, 2005). Protein modeling predicts the presence in BFT-2, but not BFT-1 or BFT-3, of a carboxy-terminus amphipathic domain (Franco *et al.*, 1997). Although this result suggests that the BFT-2 protein may oligomerize and insert into cell membranes, there is no experimental evidence that this occurs as yet.

A direct comparison of the predicted amino acid sequences of BFT-1 and BFT-2 reveals that the predicted proteins are 95% similar and 92% identical (Figure 28.2) (Franco *et al.*, 1997). BFT-3 is more closely related to BFT-2, being 93% and 96% identical with BFT-1 and BFT-2, respectively (Chung *et al.*, 1999). However, the degree of identity varies with the predicted protein domains of the toxins. Namely, comparison of the pre-proprotein domains indicates that these regions are highly conserved with only two to five amino acid changes between BFT-1, BFT-2, and BFT-3 (Chung *et al.*, 1999). In contrast, up to 25 amino acid changes are predicted in the mature toxin protein domain, with the greatest difference occurring between BFT-1 and BFT-2 (Chung *et al.*, 1999; Franco *et al.*, 1997). Detailed structure:function analyses to investigate the biologic importance, if any, of the amino acid heterogeneity in the mature toxin domain have not yet been performed.

Consistent with the protein diversity predicted by the gene sequence, BFT-1 and BFT-2 purify with distinct biochemical profiles and migrate differently when analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and two-dimensional gel

electrophoresis, confirming that the protein products of these *bft* alleles are unique proteins (Wu *et al*., 2002). Consistent with its greater homology to BFT-2, the purification profile of BFT-3 is similar to that of BFT-2 (Chung *et al*., 1999). BFT-2 exhibits modest, but consistently greater specific biologic activity than BFT-1 (Wu *et al*., 2002). The end point titer of biologic activity on HT29/C1 cells (cloned continuous human intestinal epithelial cell line) is 0.37 ± 0.06 ng/ml and 0.13 ± 0.02 ng/ml for BFT-1 and BFT-2 isolated from ETBF strains VPI13874 and 86-5443-2-2, respectively. However, this finding is not known to be important in disease pathogenesis. Both BFT-1 and BFT-2 are trypsin resistant and stable over a wide pH range (i.e., pHs 5-10) (Saidi and Sears, 1996; Van Tassell *et al*., 1992; Wu *et al*., 2002), suggesting mechanisms by which these toxins resist proteolysis in animal and human gut. Details on the properties of BFT-3 are not available as yet.

## MOLECULAR GENETICS OF ETBF

The chromosomes of all ETBF strains possess a unique 6-kb region of DNA not found in non-toxigenic *B. fragilis* strains (Franco *et al*., 1999; Moncrief *et al*., 1998b). This 6-kb DNA region has a guanosine plus cytosine (G + C) content of 35%, which differs from that of the native *B. fragilis* chromosome (about 42%) (Smith *et al*., 1998). Because of the strict association of this 6-kb region with ETBF strains and the G + C content that differs from the native *B.fragilis* chromosome, this DNA region has been named the *B. fragilis* pathogenicity island or islet (BfPAI) (Franco *et al*., 1999; Moncrief *et al*., 1998b). The BfPAI contains the *bft* gene plus about a 700 bp region upstream of *bft* that is required for maximal BFT production by ETBF strains (Franco *et al*., 1999). This 700 bp region contains five putative *B. fragilis* promoter consensus sequences (Bayley *et al*., 2000), although the precise functional promoter sequences have not yet been defined. Besides the *bft* gene, sequence analysis of this 6-kb region from ETBF strains containing *bft-1*, *bft-2*, or *bft-3* revealed one consistent additional open reading frame of 1180 bp with homology to zinc-dependent metalloprotease genes. This gene (termed *mpII* for metalloprotease II) (Moncrief *et al*., 1998b) is predicted to encode a 44.4 kDa protein (termed MPII). MPII has an overall predicted protein structure similar to the BFT proteins (Figure 28.1), namely a pre/signal peptide, proprotein, and mature metalloprotease domains; preliminary data suggest that MPII is also processed to an approximately 20kDa protein (Franco and Sears, unpublished data). However, MPII is only about 56% similar and 28% identical to the BFT proteins, and the lack of homology to the BFT proteins spans all the protein domains. In addition, unlike the BFT proteins, MPII is predicted to contain an ATP/GTP-binding site motif A (P-loop) (Franco *et al*., 1999), suggesting that MPII binds a nucleotide (Saraste *et al*., 1999). To date, no biological activity has been described for MPII, nor has it been completely purified (Franco *et al*., 1999; Moncrief *et al*., 1998a).

Initial studies of the DNA flanking the BfPAI revealed putative mobilization genes, suggesting that the BfPAI may be a mobile genetic element (Franco *et al*., 1999). Further examination of this flanking DNA led to the recognition that this DNA region had a G+C content (47–50%) that differed from the BfPAI (35%) and the *B. fragilis* chromosome (42%), suggesting the flanking DNA was also a distinct genetic element acquired from a different organism (Franco *et al*., 1999). Subsequently, using the Wellcome Trust Sanger Institute *B. fragilis* sequence database (http://www.sanger.ac.uk/Projects/B_fragilis/), the DNA element flanking the BfPAI has been identified to be a member of a new family of putative conjugative transposons (Franco, 2004). These putative conjugative transposons have also been detected in a subset of non-toxigenic *B. fragilis* strains (termed CTn9343 for the *B. fragilis* strain in which the new CTn was first characterized), as well as in ETBF strains (termed CTn86 for the ETBF strain in which the CTn has been partially characterized to date) (Franco, 2004). Distinctive features of these putative CTns are that they lack homology with CTnDOT (a *B. fragilis* CTn) or other described CTns; they lack the *tetQ* gene and tetracycline regulation of chromosomal excision (both features of CTnDOT); and, based on sequence analyses, the mechanism of chromosomal excision and transposition is predicted to differ from other known CTns (Salyers *et al*., 1995; Smith *et al*., 1998). However, neither CTn9343, CTn86, nor the BfPAI has been shown to be transmissible to other *Bacteroides* spp. *in vitro* to date. Intriguingly, using recombinant DNA techniques, *bft* expression appears to be regulated not only by its upstream promoter sequences, but also by one or more genes present on either CTn9343 or CTn86, suggesting that ETBF evolved from commensal, non-toxigenic *B. fragilis* by acquisition of two distinct genetic elements (the BfPAI and CTn86 or CTn9343) (Franco *et al*., 2002). In addition, ETBF strains vary significantly in the HT29/C1 cell biologic activity detected in the culture supernatants of the bacteria (Mundy and Sears, 1996; Myers *et al*., 1987; Van Tassell *et al*., 1994a; Van Tassell *et al*., 1994b; Weikel *et al*., 1992). The mechanisms by which ETBF vary in their secreted biologic activity are unclear, but initial data suggest that ETBF strain differences exist in *bft* gene number, *bft* transcription, and BFT secretion by the organisms (d'Abusco

*et al*., 2000; Wu *et al*., 2002) (unpublished data, Franco and Sears).

## BIOLOGIC AND PHYSIOLOGIC ACTIVITIES OF THE *BACTEROIDES FRAGILIS* TOXINS

Only the activities of BFT-1 and BFT-2 have been examined in any detail in animal models, cultured cells, and monolayers of polarized epithelial cells. Direct "head-to-head" comparisons of these proteins in different experimental models are not available. However, to date, all identified biologic and physiologic activities for BFT-1 and BFT-2 have been very similar, if not identical, except for the modestly higher biologic activity BFT-2 exhibits when tested on the cloned human colonic epithelial cell line, HT29/C1 (Wu *et al*., 2002). However, it is not clear that the observed difference in specific activity of these two proteins is important to the pathogenesis of ETBF disease. Thus, in this section, the biologic and physiologic activities of these proteins will be described without distinguishing between the two isotypes of BFT.

### *In vivo* studies

The activity of purified BFT has been demonstrated in ligated intestinal segments or loops of rats, rabbits, and lambs (Obiso, Jr. *et al*., 1995). These experiments revealed that: (a) histological changes precede the detection of intestinal secretion after treatment with BFT; and (b) BFT stimulates dose-dependent secretion in both ileal and colonic loops in all species examined, although there were species-specific differences in BFT potency in ileal vs. colonic loops (Obiso, Jr. *et al*., 1995). Consistent with these results, previous data in which ETBF organisms were fed to animals suggested that the primary sites of pathology in ETBF intestinal disease were the distal ileum and colon (Collins *et al*., 1989; Duimstra *et al*., 1991). Fluid secreted into the intestinal lumen after treatment with BFT revealed accumulations of sodium and chloride, as well as albumen and protein (Obiso, Jr. *et al*., 1995). At a higher dose of BFT, mildly hemorrhagic fluid and patchy mucosal wall hemorrhage were observed. Consistent with the hypothesis that BFT is an important virulence factor for ETBF *in vivo*, *bft* expression as well as detection of BFT and its biologic activity in feces of animals and humans has been identified (Myers and Weikel, 1992; Pantosti *et al*., 1994b; Pantosti *et al*., 1997; unpublished data, Wu and Sears).

Histological examination of ileal and colonic tissue treated with BFT in all species examined revealed villus blunting, crypt elongation, and neutrophil infiltration consistent with earlier reports of the histopathology of ETBF disease or intestinal tissue exposed to BFT-containing sterile culture filtrates (Obiso, Jr. *et al*., 1995; Sears *et al*., 1995). The inflammatory infiltrate is not always strictly neutrophils, but may be a mixed cell population, including plasma cells and lymphocytes. Extensive detachment and rounding of surface epithelial cells resulting in necrosis of villus tips were also observed. The ileal and colonic tissues of rats were the most severely damaged by BFT. The secretory and histologic effects of purified BFT were partially inhibited by zinc chelation of the toxin (Obiso, Jr. *et al*., 1995). Given that BFT is not a lethal toxin when epithelial cells are treated *in vitro* (Chambers *et al*., 1997; Donelli *et al*., 1996; Koshy *et al*., 1996; Obiso, Jr. *et al*., 1997a; Wells *et al*., 1996), the mechanism(s) leading to tissue damage and hemorrhage are unknown, but one possibility is that the inflammatory response contributes to the tissue damage. This inflammatory response is, at least in part, likely stimulated by BFT (Kim *et al*., 2001; Sanfilippo *et al*., 2000; Wu *et al*., 2004).

### *In vitro* studies of HT29/C1 cells

Early experiments attempting to define the biologic activity of BFT on tissue culture cells failed to identify any activity when crude BFT was tested on Chinese hamster ovary (CHO), Y-1 adrenal, and Vero cells (R.B. Sack, personal communication; Sears *et al*., 1995). However, in 1992, BFT was first reported to exhibit biologic activity on continuous human colonic carcinoma cell lines, HT29/C1, Caco-2, and T84 (Weikel *et al*., 1992). Subsequently, all epithelial cell lines examined to date with the capability of forming polarized monolayers *in vitro* (e.g., intestinal [HT29/C1, Caco-2, T84], renal [MDCK], and pulmonary [Calu-3] cell lines) developed morphologic changes in response to BFT (Figure 28.3). Other continuous colonic carcinoma cell lines, such as SW480 and HCT116, are also responsive to BFT (Wu *et al*., 2003; unpublished data, Wu and Sears). Subconfluent, uncloned HT29 or cloned HT29/C1 cell lines have been studied in the greatest detail and, in particular, cloned HT29/C1 cells have been shown to be exquisitely sensitive to BFT with a half-maximal effective toxin concentration of approximately 12.5 pM and as little as 0.5 pM altering cell morphology (Saidi and Sears, 1996). Using the HT29/C1 cell line, the key morphologic observation is that all BFTs cause rounding of the cells and disruption of cell-to-cell contacts, leading to dispersion of the cells from their normally tight cluster morphology (Figure 28.3a) (Chung *et al*., 1999; Mundy and Sears, 1996; Weikel *et al*., 1992). These changes in the light microscopic appearance of the cells

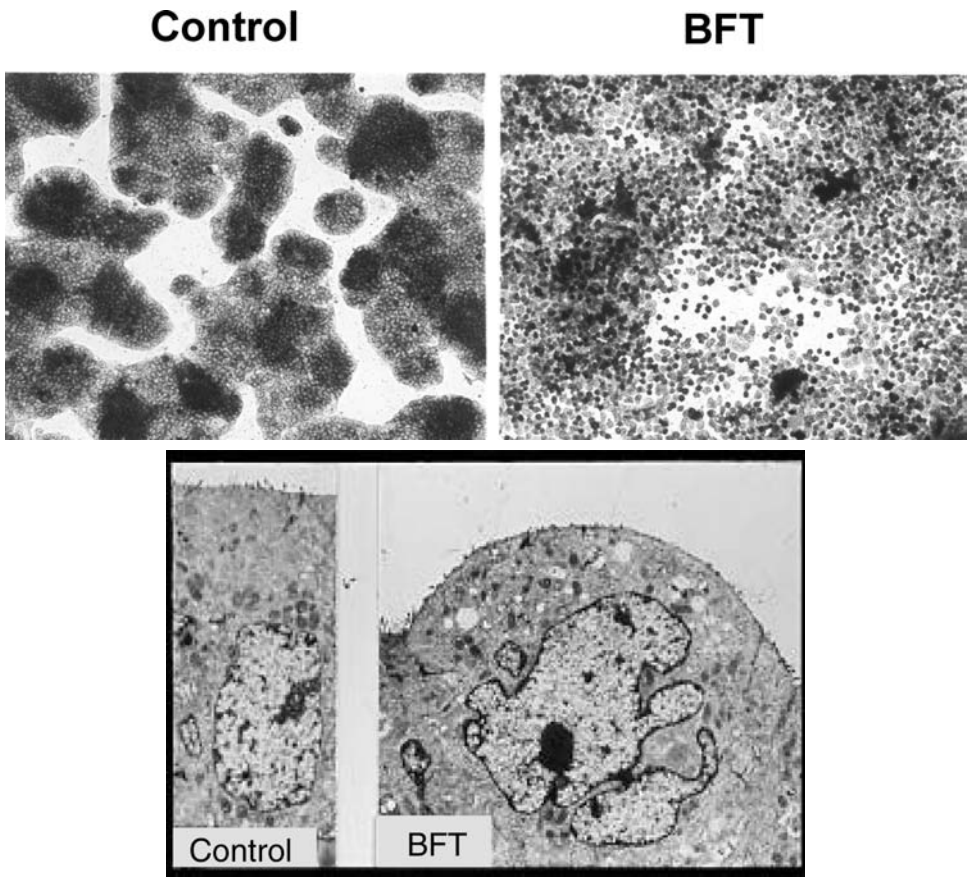

**FIGURE 28.3** Effect of BFT on intestinal epithelial cells *in vitro*. Light microscopic appearance of HT29/C1 cells after treatment with BFT (5 nM, 3 h). BFT-treated subconfluent HT29/C1 cells are rounded with loss of the tight cluster morphology when compared with untreated control cells (original magnification × 100). Transmission electron micrograph of a BFT-treated (5 nM, 2 h) polarized T84 cell. The BFT-treated cell reveals a dramatic increase in cell size and development of a domed apical membrane with loss of intact microvilli (original magnification × 3000). (Reproduced with permission from Chambers *et al*., 1997.)

are accompanied by time- and concentration-dependent changes in the F (filamentous)-actin structure of the cells, although the total F-actin content of the cells is unaltered (Donelli *et al*., 1996; Koshy *et al*., 1996; Saidi and Sears, 1996). Decreased stress fibers, cell surface blebs, and floccular F-actin staining with peripheral F-actin condensation are observed (Donelli *et al*., 1996; Koshy *et al*., 1996). The cellular morphologic changes stimulated by BFT require cellular ATP, indicating, not unexpectedly, that the BFT-stimulated changes in cell shape are energy-dependent events (Wu *et al*., 1998). However, further mechanistic details regarding how BFT modifies cell morphology and cellular F-actin structure are not yet known.

In studies of subconfluent HT29/C1 cells, BFT alters the morphology of HT29/C1 cells in a time-, temperature- and concentration-dependent manner (Saidi and Sears, 1996; Wu *et al*., 1998). BFT is inactive at 4°C, partially active at 20°C, and fully active at 37°C (Moncrief *et al*., 1995; Saidi and Sears, 1996). At 37°C, the onset of action of BFT is rapidly irreversible to washing. After treatment of HT29/C1 cells with 0.25 nM BFT for only 7 min or 2.5 nM for 2 min (followed by washing to remove the toxin), cells treated with BFT are destined to change shape. HT29/C1 cells will begin to develop altered morphology as early as about 10 min after BFT treatment, with 100% of subconfluent HT29/C1 cells exhibiting rounding by 30–60 min (Saidi and Sears, 1996; Wu *et al*., 1998). Changes in cell morphology become even more dramatic over the next 3 to 6 hours (Saidi and Sears, 1996; Weikel *et al*., 1992).

Despite the dramatic changes in morphology, HT29/C1 cells regain a normal appearance by light microscopy by 2–3 days after toxin treatment, indicating the biologic activity of BFT on HT29/C1 cells is reversible (Saidi and Sears, 1996; Weikel *et al*., 1992; Wu *et al*., 1998). It is unknown if this is due, for example, to loss of BFT biologic activity (BFT is a heat-labile protein), to proteolysis of BFT by host cells, or to other mechanisms of cell recovery. Further, most available evidence indicates that BFT is a non-lethal and non-cytotoxic protein. Namely, protein synthesis is not diminished in BFT-treated cells and, in fact, is stimulated beginning approximately 5 h after BFT treatment (Chambers *et al*., 1997; Koshy *et al*., 1996); LDH release from BFT-treated cells is not observed (Chambers *et al*., 1997; Koshy *et al*., 1996); BFT-treated cells exclude trypan blue and propidium iodide (Obiso *et al*., 1997a; Wells *et al*., 1996); DNA synthesis continues normally (Donelli *et al*., 1996); and no $^{51}Cr$ release from BFT-treated cells is observed (Obiso *et al*., 1997a). However, one report suggests that BFT induces cell death with

features of apoptosis by electron microscopy in cells released from plastic by BFT (Sanfilippo *et al*., 2000). Inhibitors of microtubules, and endosomal or Golgi trafficking do not alter BFT's activity (Donelli *et al*., 1996; Obiso, Jr. *et al*., 1997a; Saidi and Sears, 1996).

## HT29/C1 cells: molecular mechanism of action of BFT

Because BFT does not appear to enter cells (Donelli *et al*., 1996; Obiso, Jr. *et al*., 1997a; Saidi and Sears, 1996), and its biologic activity on intestinal epithelial cells is strikingly polar (Chambers *et al*., 1997; Obiso *et al*., 1997a), Wu *et al*. (1998) hypothesized that the cellular substrate for BFT was a cell surface protein present on the basolateral membrane of intestinal epithelial cells. Experiments to address this hypothesis revealed that BFT does not cleave the zonula occludens proteins, occludin or claudins (1 or 2), or the basal membrane protein, $\beta_1$-integrin, although these proteins have extracellular domains presumably accessible to BFT's proteolytic activity (Wu *et al*., 1998; unpublished data, Wu and Sears). Similarly, consistent with its proposed site of action at the cell surface, no quantitative changes in the intracellular proteins, $\beta$-catenin, $\alpha$-catenin, zonula occludens protein-1 (ZO-1), or actin, are identified by Western blot analysis during the first hour of BFT treatment of intestinal epithelial cells (Saidi *et al*., 1997; Wu *et al*., 1998). However, although these proteins are not BFT substrates, analysis of the cellular distribution of ZO-1, $\beta$-catenin, or occludin, for example, by confocal microscopy reveals redistribution of these proteins in the cells by one hour after treatment with BFT (Obiso *et al*., 1997a; Wu *et al*., 1998).

In contrast, the zonula adherens protein, E-cadherin (a 120 kDa transmembrane protein), is rapidly cleaved by BFT, as demonstrated by Western blot and confocal immunofluorescence analysis (Wu *et al*., 1998). This activity of BFT has been examined in greatest detail using HT29/C1 cells, although E-cadherin is also cleaved on polarized T84 and MDCK cells. Presentation of E-cadherin on an intact, living cell is required to detect E-cadherin cleavage stimulated by BFT, as *in vitro* cleavage of E-cadherin cannot be demonstrated in approaches tested to date (Wu *et al*., 1998). E-cadherin cleavage stimulated by BFT is time- and concentration-dependent. Onset of E-cadherin cleavage is detectable by 1 minute after treatment of intestinal epithelial cells (HT29/C1) with 5 nM BFT and yields 33 kDa and 28 kDa cell-associated E-cadherin fragments. By 1–2 hours after BFT treatment, there is a complete loss of intact cellular E-cadherin. The size of the proteolytic degradation products of E-cadherin combined with data indicating that BFT does not enter cells (Donelli *et al*., 1996; Obiso *et al*., 1997a; Saidi and Sears, 1996) and does not require cellular ATP for the initial cleavage of E-cadherin (Wu *et al*., 1998) suggest that BFT acts as a specific cell-surface protease toxin cleaving E-cadherin in its extracellular domain near the cellular plasma membrane. This finding has recently been confirmed using proteolytically inactive BFT mutants (unpublished data, Wu, Franco, and Sears). However, the exact site of E-cadherin cleavage has not yet been identified. Consistent with these data indicating that BFT cleaves E-cadherin, Wells *et al*. (1996) reported that treatment of HT29 cells with BFT resulted in decreased internalization of *Listeria monocytogenes* (but not other pathogenic enteric bacteria). E-cadherin is one ligand utilized by *L. monocytogenes* to enter epithelial cells (Mengaud *et al*., 1996). In contrast, further degradation of the 33 kDa and 28 kDa cell-associated E-cadherin fragments released by BFT treatment of cells requires cellular ATP, suggesting the recruitment of host cell proteases at this step in the mechanism of action of BFT (Wu *et al*., 1998). Consistent with this hypothesis, recent data suggest that presenilin-1/γ-secretase and proteasomal enzymes contribute sequentially to the degradation of the BFT-released 33 kDa and 28 kDa E-cadherin fragments (unpublished data, Wu and Sears). Cellular recovery after BFT treatment correlates with resynthesis of E-cadherin. However, transcriptional up-regulation of E cadherin synthesis has not been demonstrated (Wu *et al*., 1998).

Besides the critical role of its extracellular domain in intercellular adhesion, E-cadherin is complexed at its intracellular domain to β–catenin, a nuclear signaling protein involved in both normal and dysregulated cellular growth (Nelson and Nusse, 2004). Thus, the recognition that BFT induces proteolysis of E-cadherin led to the hypothesis that BFT may trigger β–catenin cellular signaling and cell proliferation. Indeed, BFT treatment of HT29/C1 cells induces β–catenin nuclear localization within 3 hours followed by induction of *c-myc* (a β–catenin-regulated gene) transcription and translation (Wu *et al*., 2003). By 48 hours after BFT treatment of HT29/C1 cells, cellular proliferation ensues and is stimulated by as little as 0.5 nM BFT (Wu *et al*., 2003). However, β–catenin signaling accounts for only about 30–40% of BFT-induced cellular proliferation, indicating that other, as yet unidentified, mechanisms contribute to cell growth stimulated by BFT (Wu *et al*., 2003). Of note, diminished E-cadherin on tumor cells is associated with enhanced metastatic potential and, consistent with this observation, BFT-treated HT29/C1 cells are highly mobile for up to 96 hours after treatment with BFT (unpublished data, Wu and Sears).

The pathology of ETBF-infected ileum and colon, as well as intestinal tissues treated with BFT, suggested

that BFT induces an inflammatory response (Obiso *et al*., 1995; Sears *et al*., 1995). Recently, BFT has been reported to stimulate secretion of the proinflammatory chemokine, interleukin-8 (IL-8), by human intestinal epithelial cells (HT29, HT29/C1, T84, and Caco-2) (Kim *et al*., 2001; Sanfilippo *et al*., 2000; Wu *et al*., 2004). Induction of IL-8 mRNA expression occurs rapidly and ceases by 6 hours after BFT treatment, whereas IL-8 secretion continues for at least 18 hours (Wu *et al*., 2004). Initial data indicate that multiple cellular signal transduction pathways contribute to BFT-induced IL-8 secretion, including the mitogen-activated protein kinases (MAPKs), p38 and extracellular signal-related kinase (ERK), tyrosine kinases, and Nuclear Factor-κβ (Kim *et al*., 2001; Wu *et al*., 2004). BFT induces an unusual supranuclear localization of Nuclear Factor-κβ that is dependent on activation of one or more tyrosine kinases; and simultaneous activation of MAPKs and Nuclear Factor-κβ appears necessary for induction of IL-8 secretion by BFT (Wu *et al*., 2004). Stimulation of IL-8 secretion *in vivo* is one potential mechanism by which ETBF, via BFT, may result in an intestinal inflammatory response. BFT has also been reported to induce increased expression of other chemokines important for the chemoattraction and activation of neutrophils, epithelial-neutrophil activating protein-78 (ENA-78), and growth-related oncogene-α (GRO-α), as well as transforming growth factor-β (TGF-β), an intestinal repair cytokine. However, the secreted TGF-β stimulated by BFT was largely in a biologically inactive form (Sanfilippo *et al*., 2000).

## *In vitro* studies with polarized epithelial monolayers

When polarized monolayers of epithelial cells (T84, MDCK, HT29, HT29/C1, Caco-2) are tested with BFT *in vitro*, the most striking observations are that: (a) BFT decreases the resistance of epithelial monolayers in a dose- and time-dependent manner; and (b) the activity of the toxin is polar; namely, BFT decreases resistance more rapidly and at lower toxin concentrations when placed on the basolateral membranes of the cell monolayers than when placed on the apical membranes of the monolayers (Chambers *et al*., 1997; Obiso *et al*., 1997a; Sears *et al*., 1995; Wells *et al*., 1996; unpublished data, Wu and Sears). Apical treatment of T84, MDCK, or HT29 monolayers with BFT (5 nM) results in an approximately 50% decrease in monolayer resistance after 3 to 6 hours (Chambers *et al*., 1997; Obiso *et al*., 1997a). In contrast, treatment of the basolateral membranes of T84 monolayers with BFT decreases monolayer resistance by 90% within 2 hours (Chambers *et al*., 1997). In addition, basolateral BFT rapidly increases the short circuit current (Isc; indicative of chloride secretion) in a concentration-dependent manner, a finding not observed with apical BFT (Chambers *et al*., 1997). The increase in Isc stimulated by BFT is self-limited, returning to baseline as monolayer resistance decreases further. T84 monolayers also secrete IL-8 in a polar manner when treated with BFT with predominant release of this chemokine across the basolateral membrane of the monolayers (Kim *et al*., 2001; Wu *et al*., 2004). This result suggests that BFT contributes to induction of the submucosal inflammatory response observed *in vivo* in response to ETBF infection.

Consistent with these physiologic results, apical BFT causes focal changes in the morphology of T84 monolayers, whereas basolateral BFT alters the morphology of all cells in the monolayer with development of a striking domed apical membrane on the cells (Chambers *et al*., 1997). Transmission and scanning electron microscopy reveal that cell swelling occurs with a loss of the microvilli of the apical membrane, resulting in the domed membrane structure (Figure 28.3b). Consistent with these observations, BFT stimulates a protracted increase in HT29/C1 cell volume, although the mechanism of this effect is unknown (Koshy *et al*., 1996). By transmission electron microscopy, the zonula occludens (tight junction) and zonula adherens, electron-dense structures that regulate the "barrier function" of epithelial monolayers, are observed to develop concentration-dependent morphologic changes. Initially, these structures become more dense and compact after BFT treatment, with subsequent complete loss of these structures between some cells. Sites where the zonula occludens and zonula adherens are noted to dissolve are typically associated with a complete loss of the apical membrane microvillus structure. These morphological changes explain the measured decrease in monolayer resistance ("barrier function"). Interestingly, the development of gaping junctions between HT29 cells treated with BFT has been shown to permit increased association and invasion of the basolateral membranes with pathogenic enteric bacteria (Wells *et al*., 1996). Despite the striking changes observed in the zonula occludens and zonula adherens, desmosomes remain intact after BFT treatment *in vivo* and *in vitro* (Chambers *et al*., 1997; Sears *et al*., 1995).

When F-actin is examined by confocal microscopy in T84 monolayers treated with basolateral BFT, the actin of the tight junctional ring and microvilli is nearly absent (Chambers *et al*., 1997). However, increased F-actin is demonstrated at the basal pole of the cells, consistent with the observation in HT29/C1 cells that total F-actin is unchanged in BFT-treated cells (Saidi *et al*., 1997). These results suggest that treatment of epithelial cells with BFT stimulates dissociation and

reassociation of F-actin, albeit in an entirely new cellular location. Interestingly, treatment of human colon *in vitro* with BFT confirms the polar activity of BFT on barrier function (tissue resistance) and the altered cellular F-actin architecture (Riegler *et al*., 1999). Morphologic changes in response to BFT have also been observed in organ cultures of human colonic biopsies, although heterogeneity in the response was observed, suggesting potential variable susceptibility to BFT and possibly ETBF disease in humans (Sanfilippo *et al*., 1998). Last, the ability of BFT to modify mucosal permeability has been proposed as the mechanism whereby BFT acts as a mucosal adjuvant to enhance the systemic antibody response to an intranasal antigen challenge in mice (Vines *et al*., 2000).

## Models of the mechanism of action of BFT and ETBF pathogenesis

Figure 28.4 shows proposed models of the molecular mechanism of action of BFT and the pathogenesis of ETBF-mediated intestinal secretion. Although these

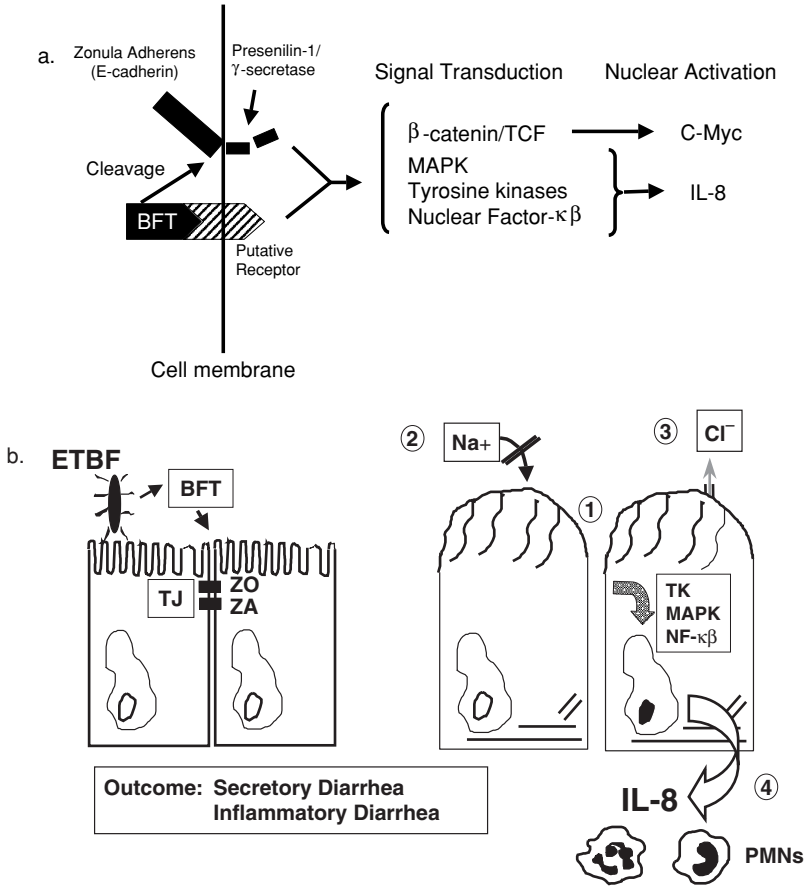

**FIGURE 28.4** Proposed models of BFT and ETBF pathogenesis. (a) Molecular mechanism of action of BFT. BFT binds to a specific cellular receptor (unpublished data, Wu and Sears) and cleaves the extracellular domain of the zonula adherens protein, E-cadherin, in an ATP-independent manner. Modification of the extracellular domain of E-cadherin triggers the ATP-dependent proteolysis of the intracellular domain of E-cadherin, probably by presenilin-1/γ-secretase and proteasomal enzymes. Loss of intact E-cadherin disrupts its linkages with catenin proteins and hence F-actin (not shown). These events may lead to the characteristic disruption of the apical cytoskeleton of polarized epithelial cells (Chambers *et al*., 1997; and Figure 28.3b. BFT also stimulates activation of multiple signal transduction pathways, resulting in nuclear activation and induction of new protein synthesis. Both C-Myc and interleukin-8 (IL-8) have been demonstrated to be induced in BFT-treated HT29/C1 cells (see text). TCF: T Cell Factor; MAPK: mitogen-activated protein kinases. (b) Pathogenesis of ETBF diarrheal disease. ETBF organisms attach to the apical membrane of intestinal epithelial cells and secrete BFT. BFT is proposed to diffuse through the zonula occludens (ZO) to reach the zonula adherens (ZA) where BFT cleaves its target protein E-cadherin. Cleavage of E-cadherin precipitates focal morphological changes and diminished barrier function (1). These events facilitate the delivery of BFT to the basolateral membranes of intestinal epithelial cells where further cleavage of E-cadherin may augment the apical morphological changes initially simulated by BFT. The dramatic changes in the apical morphology of BFT-treated intestinal epithelial cells are hypothesized to alter the function of one or more ion transporters (2,3), resulting in net intestinal secretion. Further, cellular signal transduction stimulated by BFT induces IL-8 synthesis and secretion (along with possibly other pro-inflammatory cytokines) into the submucosa resulting in an inflammatory response (4). 1 to 4 indicate proposed mechanisms by which ETBF, via BFT, stimulate intestinal secretion. TJ: Tight junction; TK: Tyrosine kinases; NF-κβ: Nuclear Factor-κβ; PMNs: polymorphonuclear leukocytes.

models build on the data on the biochemical, biologic, and physiologic sequelae of treatment of intestinal epithelial cells with BFT discussed in this chapter, many of the proposed steps require additional investigation for validation.

## FUTURE CHALLENGES IN ETBF AND BFT RESEARCH

The cleavage of E-cadherin by BFTs represents the first time that E-cadherin has been described as a bacterial toxin substrate. In addition, BFT is the first cytoskeletal-altering toxin predicted to act solely at the cell surface and without covalent enzymic modification of an intracellular substrate. Remodeling of cell-surface proteins by extracellular proteases is a mechanism yielding specific cellular responses and triggering specific cellular signal transduction pathways (Werb, 1997; Werb and Yan, 1998). The data available both on the dramatic cellular responses and cell signaling stimulated by BFT serve to illustrate this principle. Future studies to identify the mechanisms by which BFT induces cellular proliferation, inflammation, and actin cytoskeletal rearrangement are expected to contribute to the understanding of both normal and pathologic cell function. Importantly, the ability of BFT to induce cellular proliferation and inflammation suggests the hypothesis that prolonged mucosal colonization with ETBF may contribute to the pathogenesis of intestinal inflammatory and oncogenic processes. Consistent with this hypothesis, recent studies have suggested an association between ETBF colonization and active inflammatory bowel disease (Basset *et al*., 2004; Prindiville *et al*., 2000).

CHAPTER

# 29

# Structure and mode of action of RTX toxins

*Albrecht Ludwig and Werner Goebel*

## INTRODUCTION

Many bacterial pathogens produce protein toxins that are able to insert into the plasma membrane of eukaryotic cells and generate transmembrane pores, thereby causing cell death and osmotic cell lysis. At low, sublytic concentrations, several of these pore-forming cytolysins subvert physiological functions of host cells by inducing specific cellular reactions. Pore-forming cytolysins thus represent important virulence factors that play central roles in the pathogenesis of bacterial infections.

Several different families of genetically, structurally, and functionally related bacterial pore-forming cytolysins have been identified. The RTX toxins, which are found in a variety of Gram-negative pathogens, represent one of the largest of these toxin families. The designation "RTX toxins" thereby refers to the presence of a characteristic and functionally important tandem array of glycine-rich nonapeptide repeats in these toxins (RTX stands for repeats in toxin).

## GENERAL CHARACTERISTICS OF RTX TOXINS

The RTX toxins are distinguished from other groups of pore-forming cytolysins by a number of common traits:

1. RTX toxins are large, single-chain protein toxins with molecular masses typically around 100 to 120 kDa (e.g., *Escherichia coli* α-hemolysin, 110 kDa). Some more distantly related members of this toxin family, such as adenylate cyclase toxin (AC toxin) from *Bordetella pertussis* and RtxA from *Vibrio cholerae* (VcRtxA), are even considerably larger (AC toxin, 177 kDa; (VcRtxA), 484 kDa).
2. RTX toxins contain several characteristic structural and functional elements, namely (i) a conserved hydrophobic domain in the N-terminal half of the toxin protein; (ii) a series of glycine-rich nonameric repeats in the C-terminal half of the toxin protein (the "repeat domain"); and (iii) a C-terminal uncleaved secretion signal. The consensus sequence of the nonameric repeats is GGXGXDXUX, where U is a large hydrophobic amino acid (often L, I, or F) and X is any amino acid. The number of repeats varies among different RTX toxins between less than 10 to about 40.
3. RTX toxins are synthesized as inactive protoxins that require posttranslational activation (modification) prior to export from the toxin-producing bacteria. This activation is directed by a specific accessory protein that is co-synthesized with the protoxin. So far, two RTX toxins, *E. coli* α-hemolysin and *B. pertussis* AC toxin, have been shown to be activated by covalent fatty acylation of specific lysine residues. It is assumed that the other members of this toxin family are activated by a similar mechanism.
4. Export of RTX toxins through the cell envelope of Gram-negative bacteria proceeds via the type I secretion pathway. The RTX toxins are thereby translocated in a single step across both the inner

and the outer membranes, without any detectable periplasmic intermediate. This is accomplished for each RTX toxin by a specific export apparatus, an ABC exporter, that is typically composed of three protein components (i) an inner membrane transport ATPase belonging to the superfamily of ATP-binding cassette (ABC) transporters, which provides energy for the secretory process; (ii) an adaptor protein also anchored in the inner membrane, which complexes with the ABC protein to form an inner membrane translocase; and (iii) a channel-forming outer membrane protein of the TolC family that is transiently recruited by the toxin-engaged inner membrane translocase for RTX toxin export. Interaction of the large periplasmic domain of the adaptor protein with the periplasmic domain of TolC or of a TolC homologue thereby results in the transient formation of a completely proteinaceous conduit that connects the cell cytosol to the external environment and that permits export of the corresponding RTX toxin. RtxA from *V. cholerae* and several other unusually large, closely related RTX toxins, which represent a subclass within the RTX toxin family, appear to be secreted by atypical four-component type I secretion systems that require two distinct ABC transporters.

5. The activity of the RTX toxins is $Ca^{2+}$-dependent. The calcium ions bind to the repeat domain, which thereby most likely adopts a very stable parallel β-roll structure that is required for productive interaction with target cells. $Ca^{2+}$ binding most likely occurs after toxin export.
6. RTX toxins usually generate short-lived, cation-selective pores (channels) in lipid membranes. The effective pore diameter appears to be uniform for a given RTX toxin, but it may vary among different RTX toxins. The mechanism of pore formation is unclear. RTX toxin pores or pore-forming structures have not as yet been detected by electron microscopy. Pore formation in the plasma membrane of target cells may lead to colloid osmotic cell lysis, apoptosis, or subversion of cell functions.
7. The genes specifically involved in synthesis and secretion of an RTX toxin are clustered and usually organized in a single operon. RTX toxin operons typically contain four contiguous genes designated *rtxC*, *rtxA*, *rtxB*, and *rtxD* in transcriptional order. *rtxA* is the structural gene of the toxin protein (i.e., of the protoxin), *rtxC* encodes the protein mediating the activation (fatty acylation) of the protoxin, and *rtxB* and *rtxD* encode the ABC protein and the adaptor protein, respectively, of the cognate ABC exporter. The gene encoding the outer membrane component of this secretion apparatus is in most cases unlinked and located elsewhere on the bacterial chromosome, consistent with the finding that TolC is involved in several different transport systems. Nevertheless, transport, some RTX toxin determinants (e.g., those encoding *B. pertussis* AC toxin and the RTX toxin of *Moraxella bovis*) include this gene downstream from *rtxD*. Furthermore, some RTX toxin gene clusters show deviations from the typical operon organization: (i) In the *B. pertussis* AC toxin gene cluster, the *rtxC* gene (which is referred to as *cyaC*) is inverted relative to the other genes and transcribed from its own promoter. (ii) The closely related RTX toxin gene clusters of *V. cholerae, Vibrio vulnificus* and several other species are composed of two divergently transcribed operons. One of these operons contains *rtxC* and *rtxA* downstream from a conserved hypothetical gene. The adjacent operon comprises *rtxB*, *rtxD*, and a third gene, *rtxE*, which encodes an additional ABC transporter that is related to RtxB.

## MEMBERS OF THE RTX TOXIN FAMILY

RTX toxins are produced by a broad range of Gram-negative bacteria, including *E. coli*, members of the family *Pasteurellaceae* (*Mannheimia*, *Pasteurella*, and *Actinobacillus* species), *B. pertussis*, *V. cholerae*, and other pathogens. Table 29.1 lists the most extensively studied and also several of the less closely characterized members of this toxin family, and shows their salient genetic and functional characteristics. Some of the latter RTX toxins were discovered only recently. It is therefore likely that additional members of this toxin family will be detected in the future.

Based on their target cell specificity, most of the RTX toxins can be subdivided into two categories, namely hemolysins and leukotoxins. RTX hemolysins such as *E. coli* α-hemolysin (HlyA) and *Actinobacillus pleuropneumoniae* ApxI are active against a wide range of cell types (erythrocytes, leukocytes, and others) from various species. RTX leukotoxins, such as LktA from *Mannheimia haemolytica* and LtxA from *Actinobacillus actinomycetemcomitans*, on the other hand, are toxic only to certain cell types (particularly leukocytes) in a species-specific fashion. Some of the RTX hemolysins (e.g., enterohemorrhagic *E. coli* [EHEC] hemolysin and ApxII from *A. pleuropneumoniae*) show clear limits in their target cell spectra, but still act against wider arrays of cells than the leukotoxins.

It is remarkable that in addition to the RTX toxins, several proteins with other activities and functions are

**TABLE 29.1** RTX toxins

| Bacterium | RTX toxin | Hemolytic activity | Cytotoxic activity | Size of toxin protein (kDa) | Operon structure[a] | Reference |

| *Actinobacillus equuli* | AqxA | + | + | 110 | >*aqxCABD* | Berthoud *et al*. (2002) |
| *Actinobacillus actino-mycetemcomitans* | Leukotoxin (LtxA) | – | +[g] | 116 | >*ltxCABD* | Kraig *et al*. (1990) |
| *Bordetella pertussis* | AC toxin (CyaA) | + | + | 177 | *cyaC*< >*cyaABDE*[h] | Glaser *et al*. (1988) |
| *Vibrio cholerae* | RtxA (VcRtxA) | – | +[i] | 484 | *rtxArtxCchp*< >*rtxBDE*[j] | Lin *et al*. (1999) |
| *Vibrio vulnificus* | RtxA (VvRtxA) | n.d. | + | ~550 | *rtxArtxCchp*< >*rtxBDE*[j] | Boardman and Fullner Satchell (2004) |
| *Moraxella bovis* | Cytotoxin (MbxA) | + | + | 99 | >*mbxCABDtolC* | Angelos *et al*. (2003) |

[a]With exception of the *B. pertussis cya* and *M. bovis mbx* gene clusters, the gene encoding the outer membrane component of the toxin export apparatus is not linked to the corresponding *C*, *A*, *B*, and *D* genes, but located at a distant site. The transcriptional organization of the operons (5′ to 3′) is indicated by arrowheads.
[b]The gene cluster has not been sequenced.
[c]LktA from *M. haemolytica* is active only against ruminant leukocytes and platelets.
[d]*pllktB* and *pllktD* have not been sequenced.
[e]*apxIIB* and *apxIID* were apparently lost during evolution by deletion. Secretion of ApxII can, however, occur via ApxIB/ApxID.
[f]ORF1 appears to be required for activity of ApxIV, but it shares no significant homology with *rtxC* genes. Nothing is yet known regarding the secretion of ApxIV.
[g]LtxA from *Actinobacillus actinomycetemcomitans* is active only against human and primate leukocytes.
[h]*cyaC* is transcribed in opposite direction to *cyaABDE*; *cyaE* is homologous to *tolC* of *E. coli*.
[i]VcRtxA has no cytolytic activity, but causes depolymerization of F-actin by cross-linking G-actin.
jThe ORF provisionally named *chp* encodes a conserved hypothetical protein, and *rtxE* encodes an additional ABC transporter that is related to RtxB. *chp*, *rtxC*, and *rtxA* are transcribed in opposite direction relative to *rtxBDE*.
n.d., not determined.

also secreted from Gram-negative bacteria by type I secretion systems (i.e., by ABC exporters). These proteins do not share significant overall sequence similarity with the RTX toxins. However, most of them contain a series of glycine-rich $Ca^{2+}$-binding nonapeptide repeats that resemble those of the RTX toxins, and most of these proteins also possess an uncleaved C-terminal transport signal. Proteins exhibiting these features are classed with the RTX toxins in the superfamily of "RTX exoproteins." A large protein family belonging to the RTX exoproteins is the serralysin family of bacterial metalloproteases, which includes proteases from *Erwinia chrysanthemi* (Delepelaire and Wandersman, 1990), *Serratia marcescens* (Letoffe *et al*., 1991), *Pseudomonas aeruginosa* (Duong *et al*., 1996), and other bacteria. The RTX exoproteins further include related lipases from *S. marcescens* and *Pseudomonas fluorescens* (Duong *et al*., 1994; Akatsuka *et al*., 1995), surface layer (S-layer) proteins from *S. marcescens*, *Caulobacter crescentus*, and *Campylobacter rectus* (Awram and Smit, 1998; Kawai *et al*., 1998; Braun *et al*., 1999), the Fe-regulated proteins FrpA and FrpC of *Neisseria meningitidis* (Thompson and Sparling, 1993; Thompson *et al*., 1993), and the nodulation-signaling protein NodO from *Rhizobium leguminosarum* (Economou *et al*., 1990).

## PROPERTIES AND ACTIVITIES OF INDIVIDUAL RTX TOXINS

### *Escherichia coli* α-hemolysin (HlyA)

α-hemolysin (HlyA) from *E. coli* is the prototype member of the RTX toxin family. It is produced by a large percentage of the *E. coli* strains causing urinary tract and other extraintestinal infections, and contributes significantly to the virulence of these strains as shown in several animal models (Welch *et al*., 1981; Hacker *et al*., 1983; May *et al*., 2000).

*E. coli* α-hemolysin is synthesized as a protein of 110 kDa (1024 amino acids) that is posttranslationally activated with the aid of the co-synthesized protein HlyC (20 kDa) by covalent, quantitative fatty acylation of two lysine residues, Lys-564 and Lys-690 (Issartel *et al*., 1991; Stanley *et al*., 1994; Ludwig *et al*., 1996; Lim *et al*., 2000). Secretion of the activated toxin from the *E. coli* cell is accomplished by a specific ABC exporter that is composed of the inner membrane proteins HlyB (80 kDa) and HlyD (55 kDa) and the outer membrane protein TolC (51.5 kDa) (Wagner *et al*., 1983; Wandersman and Delepelaire, 1990; Thanabalu *et al*., 1998). The structural gene of α-hemolysin, *hlyA*, is clustered with the genes encoding HlyC, HlyB, and HlyD in the *hlyCABD* operon, while TolC is genetically unlinked (Felmlee *et al*., 1985; Hess *et al*., 1986). Structural and functional elements identified in the HlyA protein include (i) the hydrophobic domain (amino acids 238–410), which contains three particularly hydrophobic stretches (residues 238–259, 299–327, and 366–410) and which is involved in pore formation; (ii) the $Ca^{2+}$-binding repeat domain (amino acids 724–852) comprising 13 consecutive nonameric repeats; and (iii) the uncleaved transport signal located within the C-terminal 50–60 amino acids (Gray *et al*., 1986; Ludwig *et al*., 1988, 1991; Koronakis *et al*., 1989; Boehm *et al*., 1990b; Jarchau *et al*., 1994) (Figure 29. 1).

*E. coli* α-hemolysin shows a broad range of biological activities. At higher concentrations, it efficiently lyses erythrocytes from many species and displays strong cytotoxic and cytolytic activity against a variety of nucleated cells, including polymorphonuclear leukocytes (neutrophils) and monocytes (Cavalieri and Snyder, 1982; Bhakdi *et al*., 1989, 1990), T lymphocytes (Jonas *et al*., 1993), and tissue cells (Mobley *et al*., 1990; O'Hanley *et al*., 1991). α-hemolysin may thus directly promote survival of *E. coli* in the host by killing immune cells involved in first-line defense mechanisms, and it may further promote *E. coli* infections by causing local tissue damage. At low (sublytic) concentrations, *E. coli* α-hemolysin induces a broad range of reactions in host cells. In particular, it triggers the release of inflammatory lipid mediators (leukotrienes, hydroxyeicosatetraenoic acids) from leukocytes and platelets (König *et al*., 1986, 1990; Grimminger *et al*., 1991a), stimulates the secretion of pro-inflammatory cytokines such as interleukin (IL)-1 and IL-6 from monocytes and other cells (Bhakdi *et al*., 1990; May *et al*., 1996; Uhlen *et al*., 2000), and induces an oxidative burst and degranulation in neutrophils (Bhakdi *et al*., 1989; Bhakdi and Martin, 1991; Grimminger *et al*., 1991b). Furthermore, α-hemolysin stimulates the arachidonate metabolism and production of vasodilatory agents in endothelial cells and causes increased permeability of endothelial cell monolayers (Suttorp *et al*., 1990; Grimminger *et al*., 1997). It is assumed that the host cell reactions elicited by sublytic doses of α-hemolysin significantly contribute to the pathogenesis of extraintestinal *E. coli* infections.

EHEC hemolysin (EHEC-HlyA, EhxA), an RTX toxin that is specifically produced by EHEC strains, is approximately 60% identical in amino acid sequence to *E. coli* α-hemolysin (Schmidt *et al*., 1995; Bauer and Welch, 1996b). It has hemolytic and leukotoxic activity, but exhibits a stronger target cell specificity than α-hemolysin (Bauer and Welch 1996b). Sublytic concentrations of EHEC hemolysin have been shown to induce the production of IL-1β in human monocytes (Taneike *et al*., 2002). The role of EHEC hemolysin in the virulence of EHEC strains is, however, unclear.

### Leukotoxin of *Mannheimia haemolytica*

*M. haemolytica* (formerly *Pasteurella haemolytica*), the etiological agent of bovine and ovine pneumonic mannheimiosis (pasteurellosis), produces an RTX leukotoxin, LktA, that shows a rather narrow host and target cell specificity. Biological effects of this toxin are largely restricted to ruminant leukocytes and platelets (Kaehler *et al*., 1980; Shewen and Wilkie, 1982; Clinkenbeard and Upton, 1991). Nevertheless, LktA exhibits also weak hemolytic activity (Forrestier and Welch, 1990; Murphy *et al*., 1995). Synthesis and secretion of LktA are directed by the *lktCABD* operon (Lo *et al*., 1987; Strathdee and Lo, 1989). The amino acid sequence of LktA (102 kDa) is 36% identical to that of *E. coli* HlyA. Most strikingly, LktA has a shorter repeat domain than HlyA, comprising only eight nonapeptide repeats (Strathdee and Lo, 1987).

The effects of *M. haemolytica* leukotoxin on ruminant leukocytes are concentration-dependent. Exposure to high concentrations of LktA causes rapid swelling and oncosis (cytolysis) of bovine alveolar macrophages and neutrophils (Clinkenbeard *et al*., 1989a & b, Thumbikat *et al*., 2005), preventing effective phagocytosis and

bacterial killing by these cell types. At sublytic concentrations, LktA has pleiotropic effects: It provokes an oxidative burst and degranulation in bovine alveolar macrophages and neutrophils (Czuprynski *et al*., 1991; Maheswaran *et al*., 1993); it causes functional impairment of bovine lymphocytes (Czuprynski and Ortiz-Carranza, 1992; Hughes *et al*., 1994); it induces synthesis and release of chemotactic eicosanoids, such as leukotriene $B_4$ ($LTB_4$) and 5-hydroxyeicosatetraenoic acid in bovine neutrophils (Henricks *et al*., 1992; Clinkenbeard *et al*., 1994; Wang *et al*., 1999); and it induces the expression and secretion of inflammatory cytokines (tumor necrosis factor-alpha [TNF-α], IL-1β) from bovine alveolar macrophages and peripheral blood neutrophils (Yoo *et al*., 1995; Leite *et al*., 2003). LktA may thus contribute to the severe inflammation that characterizes acute pneumonic mannheimiosis. Low concentrations of LktA can also induce bovine leukocytes to undergo apoptosis, which most likely plays a role in the initiation and persistence of *M. haemolytica* infections (Stevens and Czuprynski, 1996; Wang *et al*., 1998; Thumbikat *et al*., 2005). Several *in vivo* studies confirmed that LktA plays a central role in the pathogenesis of bovine pneumonic mannheimiosis (Petras *et al*., 1995; Tatum *et al*., 1998; Highlander *et al*., 2000).

LktA is also produced by strains of *Mannheimia glucosida* and *Pasteurella trehalosi*, but its role in infections caused by these species is less well documented (Davies *et al*., 2002). A leukotoxin related to LktA but exhibiting a broader species specificity has been identified in *Mannheimia varigena* (originally referred to as *Pasteurella haemolytica*-like bacterium) (Chang *et al*., 1993).

## RTX toxins of *Actinobacillus pleuropneumoniae* and closely related species

*A. pleuropneumoniae*, the causative agent of porcine pleuropneumonia, is extraordinarily versatile in the production of RTX toxins. Four different RTX toxins have been identified in this species. Three of these, ApxI, ApxII, and ApxIII, have been studied extensively. ApxI (110 kDa) is strongly hemolytic and strongly cytotoxic for phagocytic cells; its amino acid sequence is 56% identical to that of *E. coli* HlyA and 41% identical to that of *M. haemolytica* LktA (Frey *et al*., 1991, 1993b; Jansen *et al*., 1993b). ApxII (102.5 kDa) exhibits weak hemolytic and moderate cytotoxic activity, and is much more similar to *M. haemolytica* LktA (67% identity) than to ApxI (46% identity) and *E. coli* HlyA (47% identity); accordingly, ApxII contains only eight consecutive nonapeptide repeats (like LktA), while a series of 13 repeats is present in ApxI (Chang *et al*., 1989; Frey *et al*., 1991). ApxIII (113 kDa, 13 glycine-rich repeats in the repeat domain) shows strong cytotoxic activity against porcine alveolar macrohages and neutrophils, but it has no hemolytic activity. ApxIII is 50% identical to both ApxI and *E. coli* HlyA, and 41% identical to ApxII (Jansen *et al*., 1993a).

The different serotypes of *A. pleuropneumoniae* produce either ApxI plus ApxII (serotypes 1, 5, 9, and 11), ApxII plus ApxIII (serotypes 2, 3, 4, 6, and 8), only ApxI (serotype 10), or only ApxII (serotypes 7 and 12) (Kamp *et al*., 1991, 1994; Frey *et al*., 1992, 1993a; Jansen *et al*., 1993b, 1994). Interestingly, the virulence of these serotypes depends on which Apx toxins they synthesize (Frey, 1995). Serotypes secreting ApxI are exceptionally virulent and cause acute pleuropneumonia with high mortality, while those secreting only ApxII or ApxII plus ApxIII are usually moderately virulent and often cause chronic infections. Furthermore, serotypes that synthesize two different Apx toxins are generally more virulent than those producing just a single one, suggesting that these toxins synergize. Several studies confirmed that ApxI, ApxII, and ApxIII are major virulence factors of *A. pleuropneumoniae* and that ApxI particularly plays a critical role in the pathogenesis of acute pleuropneumonia (Cullen and Rycroft, 1994; Tascon *et al*., 1994; Jansen *et al*., 1995; Kamp *et al*., 1997).

While ApxI and ApxIII are encoded by conventional RTX toxin operons (*apxICABD* and *apxIIICABD*, respectively), the ApxII determinant is generally truncated in *A. pleuropneumoniae*, comprising only *apxIIC* and *apxIIA* (Jansen *et al*., 1992, 1993a, b, 1994; Frey *et al*., 1993a, b). *apxIIB* and *apxIID* were apparently lost during evolution. Nevertheless, all ApxII-producing *A. pleuropneumoniae* serotypes except serotype 3 can secrete this toxin via the ApxI exporter. In fact, with the exception of serotype 3, all serotypes that do not produce ApxI possess a truncated *apxI* operon comprising *apxIB* and *apxID*, and are consequently capable of producing the ApxI exporter which complements for secretion of ApxII (Jansen *et al*., 1992, 1993b; Frey *et al*., 1993a; Macdonald and Rycroft, 1993). The type I secretion system of ApxIII is apparently unable to export ApxII (Kuhnert *et al*., 2005).

ApxIV, the fourth RTX toxin of *A. pleuropneumoniae*, is encoded by a gene (*apxIVA*) that is apparently present in all *A. pleuropneumoniae* serotypes (Schaller *et al*., 1999). In contrast to ApxI–III, ApxIV is not produced in *A. pleuropneumoniae* cultures grown under various conditions *in vitro*, but serological data suggest that it is synthesized *in vivo*. ApxIV has weak hemolytic activity when expressed along with a putative gene referred to as ORF 1, which is located immediately upstream from *apxIVA*. ORF 1 shows, however, no significant homology to *rtxC* genes. Nothing is yet

known regarding the secretion of ApxIV. The ApxIV protein is unusually large (202 kDa in serotype 1, 170 kDa in serotype 3) and shows some variability in size due to differences in the $Ca^{2+}$-binding repeat domain (Schaller *et al*., 1999). The role of ApxIV in the pathogenesis of porcine pleuropneumonia remains to be elucidated.

Apx toxins have also been detected in *Actinobacillus* species that are closely related to *A. pleuropneumoniae*. *Actinobacillus suis*, an opportunistic pathogen that causes septicemia in young pigs, was shown to contain $apxICABD_{\text{var. suis}}$ and $apxIICA_{\text{var. suis}}$ gene clusters and to produce ApxI and ApxII (Burrows and Lo, 1992; Kamp *et al*., 1994; Schaller *et al*., 2000; Kuhnert *et al*., 2003). In *Actinobacillus rossii*, $apxIICA_{\text{var. rossii}}$ and $apxIIICABD_{\text{var. rossii}}$ were found, but only ApxII could be detected in cultures of this species (Schaller *et al*., 2000). *Actinobacillus lignieresii* was shown to contain an $apxICABD_{\text{var. lign.}}$ operon (Schaller *et al*., 2000), and a complete, functional *apxIICABD* operon was recently detected in *Actinobacillus porcitonsillarum* (Kuhnert *et al*., 2005). The equine pathogen *Actinobacillus equuli* produces, however, an RTX hemolysin referred to as Aqx (110 kDa) that is different from the Apx toxins (Berthoud *et al*., 2002; Kuhnert *et al*., 2003). PaxA (107.5 kDa) from *Pasteurella aerogenes*, on the other hand, shows high sequence similarity to ApxIII, and it appears also to be functionally similar to ApxIII since it is devoid of direct hemolytic activity (Kuhnert *et al*., 2000). Presence of the *paxCABD* operon and production of PaxA proved to be closely associated with *P. aerogenes* strains causing swine abortion and septicemia of newborn piglets, suggesting that PaxA is involved in the virulence of this species (Kuhnert *et al*., 2000).

## Leukotoxin of *Actinobacillus actinomycetemcomitans*

*A. actinomycetemcomitans* is the major pathogen in the etiology of aggressive periodontitis, especially of the localized form that affects young individuals, and has also been implicated in several other forms of periodontal disease, as well as in systemic infections. One of the putative virulence factors of this bacterium is the 116-kDa leukotoxin (LtxA), an RTX toxin exhibiting a unique specificity for human and some non-human primate leukocytes. In particular, LtxA selectively lyses primate monocytes/macrophages, neutrophils, and lymphocytes (Taichman *et al*., 1980; Tsai *et al*., 1984; Kelk *et al*., 2003). The monocytes and macrophages thereby proved to be most sensitive, and it has been suggested that these cells are lysed by a mechanism that involves activation of the cystein proteinase caspase 1 (Kelk *et al*., 2003). Primate neutrophils and lymphocytes are lysed only at 10-fold higher toxin concentrations. It has also been shown that LtxA can induce apoptosis in several cell types such as T lymphocytes (but apparently not in monocytes) (Mangan *et al*., 1991; Korostoff *et al*., 1998; Yamaguchi *et al*., 2001; Kelk *et al*., 2003). Due to these activities, LtxA may thus enable *A. actinomycetemcomitans* to evade detection by the host immune system. At low concentrations, LtxA triggers degranulation of neutrophils and induces production and secretion of IL-1β by human macrophages via activation of caspase 1 (Johansson *et al*., 2000; Kelk *et al*., 2005). It is remarkable that LtxA is more related to *E. coli* HlyA (51% identity) than to *M. haemolytica* LktA (43% identity) (Kraig *et al*., 1990).

The LtxA gene cluster, *ltxCABD* (also referred to as *lktCABD*), appears to be present in all *A. actinomycetemcomitans* strains, but the levels of LtxA expression vary considerably among different strains (Lally *et al*., 1989; Kraig *et al*., 1990; Hritz *et al*., 1996; Kolodrubetz *et al*., 1996). Localized aggressive and other forms of periodontitis are strongly associated with highly leukotoxic strains of *A. actinomycetemcomitans*, which is consistent with the hypothesis that LtxA plays an important role in the virulence of this bacterium (Zambon *et al*., 1983; Haraszthy *et al*., 2000).

Interestingly, LtxA expressed by rough (adherent) strains of *A. actinomycetemcomitans* remains associated with the bacterial cell, whereas smooth (nonadherent) strains secrete the toxin into the culture supernatants (Tsai *et al*., 1984; Lally *et al*., 1989; Kachlany *et al*., 2000). Ohta *et al*. (1993) suggested that retention of LtxA at the surface of *A. actinomycetemcomitans* may be due to electrostatic association of the toxin with nucleic acids bound to the bacterial cell surface. More recently, Kachlany *et al*. (2000) revealed that *tad* mutants of *A. actinomycetemcomitans* do not retain LtxA, but rather release it into the culture medium. The *tad* operon encodes long fibrils responsible for rough colony morphology and adherence to surfaces, which suggests that LtxA associates with a component of this adherence system, possibly the fibrils themselves (Kachlany *et al*., 2000). It has been shown that outer membrane vesicles secreted by *A. actinomycetemcomitans* are enriched in LtxA and that these vesicles can deliver the leukotoxin to target cells (Kato *et al*., 2002; Demuth *et al*., 2003).

## Adenylate cyclase toxin of *Bordetella pertussis*

*B. pertussis*, the causative agent of whooping cough, produces an RTX toxin known as adenylate cyclase toxin (AC toxin, CyaA) that is a major virulence factor required for the early stages of respiratory tract colonization

(Hewlett *et al*., 1976; Goodwin and Weiss, 1990; Gross *et al*., 1992; Khelef *et al*., 1994; Carbonetti *et al.,* 2005). AC toxin is expressed from the *cyaA* gene as a single 177-kDa protein (1706 amino acids), which is post-translationally activated by covalent fatty acylation through the co-synthesized protein CyaC (Glaser *et al*., 1988; Hewlett *et al*., 1989; Rogel *et al*., 1989; Barry *et al*., 1991; Hackett *et al*., 1994).

AC toxin is unique among the RTX toxins because it is a bifunctional toxin endowed with both cell-invasive adenylate cyclase activity and hemolytic (pore-forming) activity. The enzymatic and the hemolytic activity are thereby associated with different regions of the CyaA protein. In particular, the N-terminal about 400 amino acids of CyaA constitute the adenylate cyclase domain, while the amino acid sequence from position 400 to 1706 represents the hemolysin domain (Bellalou *et al*., 1990; Ehrmann *et al*., 1992; Sakamoto *et al*., 1992). Only the hemolysin moiety of CyaA exhibits sequence similarity to the other members of the RTX toxin family (Glaser *et al*., 1988), suggesting that the *cyaA* gene arose by fusion of an RTX toxin gene with an adenylate cyclase gene. The hemolysin domain of CyaA diverges significantly from the other RTX toxins (it is, for example, only 25% identical in sequence to *E. coli* HlyA), but it contains all structural elements typical of RTX toxins, namely (i) a hydrophobic domain suggested to be involved in channel formation (amino acids 500–700); (ii) a large $Ca^{2+}$-binding repeat domain (amino acids 1000–1600) containing almost 40 repeats with the consensus sequence GGXGXDXUX; and (iii) a C-terminal domain containing the secretion signal (amino acids 1600–1706) (Glaser *et al*., 1988) (Figure 29.1).

The principal pathophysiologic function of AC toxin is to cause rapid production of intracellular cyclic AMP (cAMP) following penetration of its catalytic domain into phagocytic cells, such as neutrophils and macrophages. This process is referred to as intoxication. In fact, relative to other RTX toxins, AC toxin is only weakly hemolytic (Bellalou *et al*., 1990; Rogel *et al*., 1991), which is consistent with the finding that it forms only very small pores in lipid bilayers (Benz *et al*., 1994b; Szabo *et al*., 1994). The hemolysin domain of CyaA is, nevertheless, required for the binding of AC toxin to target cells and for the subsequent translocation of the catalytic domain through the cell membrane into the host cell cytoplasm (Rogel *et al*., 1989; Bellalou *et al*., 1990; Bejerano *et al*., 1999). Once inside the cell, the AC domain is activated by binding of endogenous calmodulin, which enables it to catalyze the production of supraphysiologic levels of cAMP from host ATP (Wolff *et al*., 1980; Confer and Eaton, 1982; Rogel *et al*., 1991; Gray *et al*., 1998). Intoxication of immune effector cells leads to inhibition of chemotaxis, phagocytosis, and oxidative burst (Confer and Eaton, 1982; Friedman *et al*., 1987; Pearson *et al*., 1987; Weingart *et al*., 2000) and induces apoptosis of macrophages (Khelef and Guiso, 1995; Gueirard *et al*., 1998), thus allowing persistence of *B. pertussis* in the host and progression of the infection. Recently, it has also been reported that AC toxin induces the secretion of IL-6 by human tracheal epithelial cells (Bassinet *et al*., 2004).

The mechanism mediating the penetration of the catalytic domain into target cells has not been completely unraveled, but it is known that this process requires a negative membrane potential (Otero *et al*., 1995). In addition, several lines of evidence indicate that translocation of the AC domain and pore formation by the hemolysin domain of CyaA represent unrelated, if not mutually exclusive, events. Translocation of the catalytic domain through the target cell membrane depends, for example, on a conformational change of CyaA that is induced by $Ca^{2+}$ concentrations in the mM range (>200μM), while significantly lower $Ca^{2+}$ concentrations are required for membrane binding and hemolytic activity (Hewlett *et al*., 1991; Rogel and Hanski, 1992; Rose *et al*., 1995). In fact, the translocation-specific conformation of AC toxin inhibits its hemolytic activity (Gray *et al*., 2001). Furthermore, AC toxin induces intracellular cAMP production within

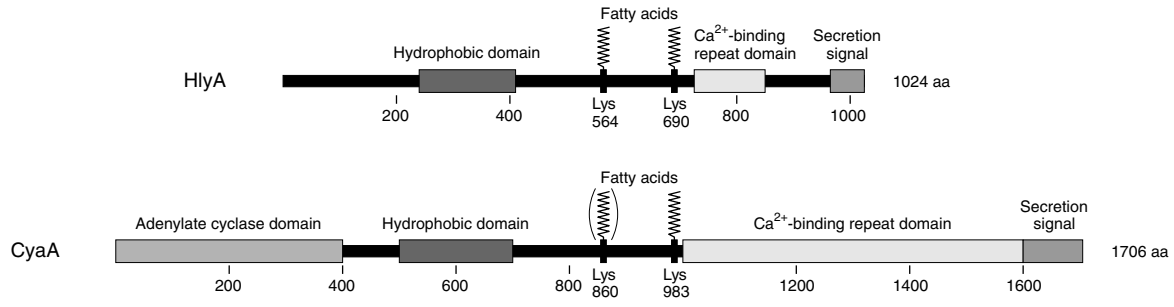

**FIGURE 29.1** Linear models of *E. coli* α-hemolysin (HlyA) and *B. pertussis* adenylate cyclase toxin (CyaA). Structural and functional domains are depicted as shaded boxes. aa: amino acids.

seconds to minutes after toxin addition, whereas hemolysis is observed only after much longer incubation times (Rogel *et al*., 1991; Otero *et al*., 1995; Gray *et al*., 1998). It has also been shown that AC toxin monomers are sufficient for intoxication, while hemolysis (pore formation) appears to be a highly cooperative event that likely involves oligomerization of membrane-embedded AC toxin molecules (Szabo *et al*., 1994; Gray *et al*., 1998; Osickova *et al*., 1999). Translocation of the AC domain into the host cell consequently cannot proceed through the transmembrane pore that is formed by the hemolysin moiety of CyaA. Khelef *et al*. (2001) suggested that internalization of AC toxin into endocytic vesicles contributes to macrophage cytotoxicity.

Unlike most other RTX toxins that are secreted into the extracellular milieu, AC toxin is not efficiently released by *B. pertussis* into the medium; the majority of the toxin rather remains associated with the bacterial surface after secretion (Hewlett *et al*., 1976). This is apparently due to physical interaction of AC toxin with the outer membrane filamentous hemagglutinin of *B. pertussis* (Zaretzky *et al*., 2002). Recently, Gray *et al*. (2004) revealed that the surface-bound AC toxin is unable to intoxicate target cells, and that only newly secreted AC toxin is responsible for intoxication. In addition, they found that delivery of the toxin requires close association of the bacteria with the target cells (Gray *et al*., 2004).

## RTX toxin of *Vibrio cholerae* and closely related RTX toxins of other bacteria

*V. cholerae* serotype O1 biotype El Tor produces an RTX toxin referred to as RtxA and VcRtxA that differs from all aforementioned RTX toxins with respect to both structure and mode of action. The protein deduced from the VcRtxA-encoding *rtxA* gene is 4,545 amino acids in length and has a predicted molecular mass of 484 kDa; VcRtxA is hence one of the largest single-polypeptide toxins known to date (Lin *et al*., 1999). Large regions of VcRtxA do not share sequence similarity with the typical RTX toxins. The presence of Gly- and Asp-rich (GD-rich), putatively calcium-binding repeats in the C-terminal region of VcRtxA, and the presence of genes located adjacent to *rtxA* that are related to the C, B, and D genes of other RTX toxin determinants indicated, nevertheless, that VcRtxA is indeed a member of the RTX toxin family. The GD-rich repeats of VcRtxA differ, however, from the nonameric repeats normally found in RTX toxins, because in the case of VcRtxA these repeats are elongated by nine additional residues. Hence, instead of the nonameric repeats, VcRtxA contains related GD-rich 18-residue repeats with the consensus sequence GGXGXDXX(V/I)XXGXXNXXX. Furthermore, unlike the typical RTX toxins, VcRtxA contains a series of glycine-rich 19-amino acid repeats with the consensus sequence GXAN(I/V)XT(K/H)VGDGXTVAVMX in its N-terminal region. These latter repeats do not show similarity to the GD-rich RTX repeats, and their function is unknown (Lin *et al*., 1999).

The gene cluster encoding VcRtxA differs from typical RTX toxin determinants in that it is composed of two divergently transcribed operons containing a total of six open reading frames (ORFs) (Lin *et al*., 1999; Boardman and Fullner Satchell, 2004). The first ORF in one of these operons encodes a 120-amino acid hypothetical protein. This ORF is followed by *rtxC* which encodes the protein that presumably mediates the maturation (fatty acylation) of the toxin, and the toxin structural gene *rtxA*. The adjacent operon encodes the type I secretion system for VcRtxA; it contains the genes *rtxB* and *rtxD*, which encode an ABC transporter (a transport ATPase) and an adaptor protein, respectively, and a third gene, *rtxE*, encoding another ABC transporter that is 60% similar in amino acid sequence to RtxB and that is required in addition to RtxB for export of VcRtxA (Boardman and Fullner Satchell, 2004). Interestingly, *V. cholerae* O1 strains of the classical biotype are unable to produce VcRtxA because they contain a 7.9-kb deletion within the *rtx* gene cluster that covers the 5′-terminal region of *rtxA*, all of *rtxC*, the hypothetical gene upstream from *rtxC*, and the 5′ end of *rtxB* (Lin *et al*., 1999).

In contrast to the conventional RTX toxins, VcRtxA is not associated with hemolytic or cytolytic activity (Lin *et al*., 1999). It rather causes depolymerization of F-actin stress fibers in a broad range of cell types, resulting in the rapid rounding of these cells in culture (Fullner and Mekalanos, 2000). VcRtxA accomplishes the F-actin depolymerization by cross-linking cellular actin monomers (G-actin) into dimers, trimers, and higher multimers, which suggests that disruption of the equilibrium between F-actin and G-actin, caused by the cross-linking of G-actin, might actually induce the depolymerization of the actin stress fibers (Fullner and Mekalanos, 2000). Recently, Sheahan *et al*. (2004) identified a 48-kDa domain within VcRtxA that covalently cross-links actin when transiently expressed within eukaryotic cells. Furthermore, they reported that deletion of this domain from VcRtxA completely abolishes the ability of the toxin to cross-link actin. These data suggested that VcRtxA inserts into the target cell plasma membrane and then, rather than forming a pore, delivers the actin cross-linking domain into the cell to either directly or indirectly catalyze the covalent cross-

linking of actin. Fullner *et al*. (2001, 2002) demonstrated that VcRtxA can disrupt the integrity of intestinal epithelial cell monolayers and that it stimulates pro-inflammatory immune responses, which may contribute to the pathogenesis of *V. cholerae* infections.

Recently, RTX toxins closely related to VcRtxA have been identified by genome sequence analysis in several other bacterial species, including the marine pathogen *Vibrio vulnificus* and the insect pathogens *Photorhabdus luminescens* and *Xenorhabdus bovienii* (Chen *et al*., 2003; Duchaud *et al*., 2003; Venter *et al*., 2004). The *rtxA*-like genes of all these bacteria encode toxins that are larger than 3500 amino acids and that share both the N-terminal 19-residue repeats and the atypical 18-residue RTX repeats. However, these toxins differ in central portions, suggesting that they may possess different cytotoxic activities (Sheahan *et al*., 2004; Boardman and Fullner Satchell, 2004). VcRtxA and RtxA from *V. vulnificus* (VvRtxA) are, for example, approximately 80 to 90% identical throughout most regions, but show extensive sequence divergence at two internal regions: (i) the VcRtxA sequence from residue 1963 to residue 2419, which contains the actin cross-linking domain, is absent in VvRtxA; instead, a different domain is present in VvRtxA at the same relative location; (ii) VvRtxA contains a domain at amino acid residue 3204 to 4095 that is missing in VcRtxA (Sheahan *et al*., 2004). Due to the presence of this latter domain, VvRtxA is even larger than VcRtxA (5,206 amino acids as deduced from the *V. vulnificus rtxA* gene). The absence of the actin cross-linking domain from VvRtxA indicates that this toxin does not cross-link actin. In fact, it has recently been shown that VvRtxA causes cell lysis (Sheahan *et al*., 2004).

An analysis of the DNA regions flanking the *rtxA*-like genes of the above-mentioned species revealed in all cases the presence of a gene cluster that resembles the *V. cholerae rtx* gene cluster (Chen *et al*., 2003; Duchaud *et al*., 2003; Boardman and Fullner Satchell, 2004; Venter *et al*., 2004). Thus, all of these bacteria carry two adjacent, divergently transcribed *rtx* operons with the toxin gene found in one of these two operons downstream from an *rtxC* homologue and a conserved hypothetical gene. The divergent operon generally comprises three genes encoding homologues of RtxB, RtxD, and RtxE. Interestingly, in the case of *P. luminescens*, five tandemly arranged *rtxA*-like genes were detected immediately downstream from the *rtxC*-like gene. Two of these toxin genes are intact while three are disrupted by frameshifts. Furthermore, three additional *rtxA* homologues (two complete genes and one disrupted by an insertion sequence) were found in another chromosomal region of *P. luminescens*. Thus, *P. luminescens* possesses eight *rtxA*-like genes, four of which are complete (Duchaud *et al*., 2003).

## SPECIFIC ASPECTS OF THE STRUCTURE AND MODE OF ACTION OF RTX TOXINS

### Posttranslational activation of RTX toxins

The activity of RTX toxins generally depends on a posttranslational activation (modification) that is mediated by the co-synthesized RtxC protein, as originally shown for *E. coli* α-hemolysin (HlyA) and *B. pertussis* AC toxin (CyaA) (Goebel and Hedgpeth, 1982; Barry *et al*., 1991; Hewlett *et al*., 1993). Issartel *et al*. (1991) revealed that *E. coli* HlyC activates α-hemolysin by catalyzing the acyl carrier protein (ACP)-dependent fatty acylation of the HlyA protein (pro-HlyA). Further studies demonstrated that pro-HlyA is covalently acylated at the ε-amino groups of two lysine residues, Lys-564 and Lys-690, and that the acylation at both sites is required for activity (Stanley *et al*., 1994; Ludwig *et al*., 1996). Under *in vitro* conditions, HlyC can acylate pro-HlyA with a range of fatty acids (Issartel *et al*., 1991). *In vivo*, however, HlyC exhibits a high selectivity for certain rather rare fatty acids. Mass spectrometric analysis of α-hemolysin produced by different *E. coli* strains particularly revealed that this toxin is heterogeneously acylated at both lysine residues with saturated 14-(68%), 15-(26%), and 17-(6%) carbon fatty acids (Lim *et al*., 2000).

Native AC toxin from *B. pertussis* strain 338 was shown to be covalently mono-acylated by a palmitoyl residue at Lys-983, which corresponds to Lys-690 of HlyA (Hackett *et al*., 1994). Furthermore, data from Basar *et al*. (2001) suggest that the acylation of Lys-983 is necessary and sufficient for the activation of this toxin. Nevertheless, recombinant AC toxin produced by *E. coli* in the presence of CyaC is acylated not only at Lys-983, but to some extent also at Lys-860, which is homologous to Lys-564 of *E. coli* HlyA (Hackett *et al*., 1995). In addition, recombinant AC toxin produced in *B. pertussis* strain 18323 was recently shown to be fully palmitoylated at both sites, Lys-983 and Lys-860, indicating that the extent of the acylation of Lys-860 depends on the strain and possibly its physiological state (Havlicek *et al*., 2001). Interestingly, *M. haemolytica* leukotoxin (LktA) contains only the lysine residue corresponding to Lys-564 of *E. coli* HlyA (Lys-554 in LktA), while a lysine residue homologous to Lys-690 of HlyA is missing. The acylation patterns of HlyA and LktA are consequently different, but the acylation process per se appears to be mechanistically similar for both toxins (Hormozi *et al*., 1998).

HlyC from *E. coli* has been shown to act as an acyltransferase that uses acylated ACP (acyl-ACP) as the fatty acid donor (Issartel *et al*., 1991; Trent *et al*., 1998;

Stanley *et al*., 1999). Furthermore, it has been demonstrated that HlyC binds the fatty acyl group from acyl-ACP to generate an acyl-HlyC intermediate, which subsequently transfers its fatty acyl group to pro-HlyA (Worsham *et al*., 2001, 2005). In the acylated HlyC intermediate, the fatty acid appears to be transiently bound to His-23 of HlyC (Worsham *et al*., 2001). Data from several laboratories indicate that the acylation of pro-HlyA by HlyC requires short amino acid sequences flanking the two acylation sites; these sequences most likely serve as independent HlyC recognition domains (Ludwig *et al*., 1996; Stanley *et al*., 1996; Langston *et al*., 2004). Other RtxC proteins show extensive sequence similarity to HlyC from *E. coli*, suggesting that they function in a similar way as HlyC.

## Secretion of RTX toxins

RTX toxins are secreted from Gram-negative bacteria via the type I secretion pathway. Toxin export thereby occurs in a single, energy-coupled step, resulting in direct passage of the toxin across both the inner and the outer cell membranes and the intervening periplasmic space. This is accomplished by the direct, reversible interaction of a toxin-specific inner membrane translocase, which is composed of two rotein components, with an outer membrane protein of the TolC family. When engaged by its export substrate (i.e., the corresponding RTX toxin), the translocase recruits TolC or a TolC homologue to form the active export complex containing all three proteins and the toxin. This assembly is transient: When the RTX toxin has been exported, the transport machinery disengages, and the components revert to their separate inner and outer membrane resting states (Thanabalu *et al*., 1998; Koronakis *et al*., 2000, 2004).

One of the components of the inner membrane translocase, the RtxB protein, belongs to the superfamily of ABC transporters (Higgins, 1992; Schmitt and Tampe, 2002), since it contains a nucleotide-binding domain that provides energy for the export process by hydrolysis of ATP. The other component of the translocase, the RtxD protein, is a member of the putative membrane fusion protein (MFP) family (Dinh *et al*., 1994) and functions as an adaptor protein that enables the translocase to interact in a reversible manner with TolC or a TolC homologue. Together, these three proteins form a secretion apparatus that is referred to as ABC exporter. Type I secretion of RTX toxins depends on the presence of an uncleaved secretion signal at the C-terminus of the toxin protein (Gray *et al*., 1986; Koronakis *et al*., 1989; Iwaki *et al*., 1995). The activation (fatty acylation) of RTX toxins is not required for secretion (Ludwig *et al*., 1987).

The *E. coli* α-hemolysin secretion apparatus has been studied in detail. HlyB, the inner membrane ABC protein of this ABC exporter, has been shown to contain an N-terminal integral membrane domain with six or eight predicted transmembrane segments and a C-terminal cytoplasmic nucleotide-binding domain (Wang *et al*., 1991; Gentschev and Goebel, 1992; Schmitt *et al*., 2003). HlyD, the adaptor protein, is anchored in the cytoplasmic membrane by a single transmembrane helix that links a small N-terminal cytoplasmic domain to a large C-terminal domain located in the periplasm (Wang *et al*., 1991; Schülein *et al*., 1992). This periplasmic domain which is predicted to contain long α–helices, most likely interacts with TolC to form the complete transport complex (Schlör *et al*., 1997; Thanabalu *et al*., 1998; Johnson and Church, 1999).

The analysis of the three-dimensional (3D) structure of TolC demonstrated that TolC is a trimeric outer membrane protein. In particular, the three TolC protomers assemble to form a 140-Å-long hollow continuous conduit, a "channel-tunnel," that spans both the outer membrane and the periplasmic space (Koronakis *et al*., 2000). This conduit consists of an α-helical barrel, which forms a 100-Å-long tunnel through the periplasm, and of a contiguous 12-stranded β-barrel, which forms a 40-Å-long channel through the outer membrane. The periplasmic α-helical barrel is a structure in which twelve α-helices (four from each TolC monomer) are packed in an antiparallel arrangement to form a hollow cylinder. The interior diameter of the central pore of the TolC trimer is 19.8 Å throughout the outer membrane channel and most of the tunnel, with the channel exit being constitutively open. In the resting state, the periplasmic entrance of the α-helical barrel is, however, constricted by three α-helices that are twisted inwards. Accordingly, TolC assembled in planar lipid bilayers causes only small conductance increases (Andersen *et al*., 2002a). When TolC is recruited for α-hemolysin export, the entrance of the α-helical barrel is opened for the toxin to gain access to the exit duct (Eswaran *et al*., 2003). This is apparently achieved by an iris-like realignment (untwisting) of the tunnel entrance helices (Andersen *et al*., 2002b). Interaction of the HlyA-engaged HlyB/HlyD complex with the TolC channel-tunnel thus results in the assembly of a continuous, completely proteinaceous conduit, that transiently connects the cell cytosol to the external environment and that specifically permits the export of α-hemolysin. HlyD has been shown to trimerize in the inner membrane, which is in line with the finding that this protein directly interacts with the TolC trimer (Thanabalu *et al*., 1998; Balakrishnan *et al*., 2001). HlyB, on the other hand, has been shown to act as a dimer (Benabdelhak *et al*., 2005; Zaitseva *et al*., 2005). The

number of HlyB dimers present in the HlyB/HlyD complex remains, however, to be determined.

The C-terminal secretion signal of *E. coli* α-hemolysin is apparently recognized by HlyB (Oropeza-Wekerle *et al*., 1990; Sheps *et al*., 1995). Moreover, it has recently been suggested that the C-terminus of HlyA is specifically recognized by the nucleotide-binding domain of HlyB and that the secretion is initiated by the subsequent displacement of HlyA from HlyB by ATP (Benabdelhak *et al*., 2003). Consistent with this, it has been shown that binding and hydrolysis of ATP by HlyB is directly coupled to the export of HlyA (Koronakis *et al*., 1995). Interaction of HlyA with HlyB alone is, however, insufficient to induce the export of HlyA. In fact, several studies suggest that HlyA must also bind to the cytosolic domain of HlyD to trigger recruitment of TolC and assembly of the type I export complex (Thanabalu *et al*., 1998; Pimenta *et al*., 1999; Balakrishnan *et al*., 2001). In addition, the proton motive force was found to be required at an early stage of HlyA secretion (Koronakis *et al*., 1991).

As noted above, it has recently been shown that the type I secretion system of the *V. cholerae* RTX toxin (VcRtxA) requires two distinct transport ATPases, namely RtxB and RtxE. Based on the finding that HlyB of *E. coli* acts as a homodimer, Boardman and Fullner Satchell (2004) suggested that RtxB and RtxE may function as a heterodimer. Furthermore, they speculated that the large size of VcRtxA may require multiple contact points within the structurally diverse regions of RtxB and RtxE to enhance specificity, thereby necessitating two distinct transport ATPases. Consistent with this hypothesis, other unusually large RTX toxins that are closely related to VcRtxA, such as the RTX toxins from *V. vulnificus, P. luminescens*, and *X. bovienii*, also appear to be exported by four-component type I secretion systems requiring two distinct ABC transporters in addition to an adaptor protein and an outer membrane protein of the TolC family.

The structural characteristics of the C-terminal secretion signals of RTX toxins are not entirely understood. In fact, RTX toxins generally show little sequence similarity in their C-terminal regions. Several studies indicated that the transport signals of RTX toxins are at least partially defined by higher-order structures (Hess *et al*., 1990; Stanley *et al*., 1991; Zhang *et al*., 1993, 1995), while others suggested that a small number of individual amino acid residues within the C-terminal region are critical for the interaction with the transport apparatus (Kenny *et al*., 1994; Chervaux and Holland, 1996). Recently, Hui and colleagues analyzed the functional elements of the *E. coli* α-hemolysin signal sequence using a combinatorial approach and revealed that the secondary structure and general biophysical properties rather than the primary sequence are important (Hui *et al*., 2000; Hui and Ling, 2002). In particular, they identified two functional domains within the secretion signal of HlyA. In the first domain (residues -49 to -28 with respect to the C-terminus), an amphiphilic α-helix extending from residue -49 to -38 was found to be critical, while in the second domain (last eight residues of HlyA), the relative lack of positively charged residues (i.e., hydrophobicity) proved to be important.

## Binding of calcium ions by RTX toxins

RTX toxins require $Ca^{2+}$ ions for activity, as shown first for *E. coli* α-hemolysin (Short and Kurtz, 1971) and *B. pertussis* AC toxin (Hewlett *et al*., 1991; Rogel and Hanski, 1992). Several studies revealed that the calcium ions bind to the nonapeptide repeats with the consensus sequence GGXGXDXUX in the C-terminal half of these toxins (Ludwig *et al*., 1988; Boehm *et al*., 1990b; Rose *et al*., 1995; Rhodes *et al*., 2001).

Analysis of the 3D structure of alkaline protease (AprA) from *P. aeruginosa* (one of the non-toxin RTX exoproteins) demonstrated that the consecutive nonameric repeats constitute a novel $Ca^{2+}$-binding structure called parallel β-roll, in which consecutive β-strands are wound in a right-handed helix (Baumann *et al*., 1993). The calcium ions are thereby bound within the turns connecting the β-strands. In particular, the first six residues of each repeat motif (GGXGXD) form a turn that binds a $Ca^{2+}$ ion, while the remaining three residues (XUX) build a short β-strand. One complete turn of the parallel β-roll thus consists of two consecutive nine-residue repeats (Baumann *et al*., 1993; Lilie *et al*., 2000). 3D structures of RTX toxins have not yet been determined, but it is assumed that their repeat domains likewise fold into parallel β-rolls upon binding of calcium ions.

The repeats in the extraordinarily large repeat domain of *B. pertussis* CyaA are organized in five cassettes (Glaser *et al*., 1988; Rhodes *et al*., 2001). Indeed, this repeat domain apparently folds into five parallel β-rolls (β-sheet helices), all of which appear to be required for cell intoxication (Rhodes *et al*., 2001). Interestingly, it has been shown that the repeat domain of CyaA contains a small number (three to five) of high-affinity $Ca^{2+}$-binding sites and about 35 low-affinity $Ca^{2+}$-binding sites (Rose *et al*., 1995; Rhodes *et al*., 2001). Rose *et al*. (1995) suggested that binding of calcium ions to the high-affinity sites might be required for the binding of CyaA to cell membranes and for lysis of erythrocytes, while binding of $Ca^{2+}$ to the low-affinity sites might induce the large conformational change that is required for entry of the catalytic domain into target cells.

Binding of the calcium ions to the repeats and formation of the parallel β-roll(s) most likely occurs after secretion of the RTX toxins, i.e., outside the toxin-producing bacteria, because the cytoplasmic $Ca^{2+}$ concentration ($[Ca^{2+}]_i$) in these bacteria is generally very low. In *E. coli*, for example, $[Ca^{2+}]_i$ is tightly regulated to a constant level of only about 0.1 μM (Gangola and Rosen, 1987). *E. coli* HlyA requires, however, $Ca^{2+}$ concentrations of >100 μM for full hemolytic activity (Ostolaza *et al*., 1995; Döbereiner *et al*., 1996). Thus, as long as HlyA is within the *E. coli* cell, its repeat domain is presumably flexible, which is probably a prerequisite for secretion through the *E. coli* cell envelope. After export, the calcium ions present in the extracellular medium may then bind to the repeat domain and thereby trigger the rapid formation of the stable β-roll structure, thus inducing the toxin to adopt a well-defined tertiary structure. The binding of calcium ions in the external medium may generally facilitate the folding of RTX exoproteins following secretion in an at least partially unfolded or extended conformation (Baumann *et al*., 1993).

## Binding of RTX toxins to target cells

The interaction of RTX toxins with eukaryotic cell membranes can be subdivided into two stages, namely (i) binding of the toxin to the membrane surface (adsorption), and (ii) membrane insertion resulting in pore formation. Significant progress has been made in the past years towards identifying cell surface receptors of RTX toxins. In particular, it has been repeatedly shown that $\beta_2$ integrins play an important role in binding of RTX toxins to leukocytes. $\beta_2$ integrins are leukocyte-specific, heterodimeric cell surface glycoproteins sharing the same $\beta_2$ subunit, CD18, but containing different α subunits. CD18 particularly associates with the α chains $\alpha_L$ (CD11a), $\alpha_M$ (CD11b), $\alpha_X$ (CD11c), and $\alpha_D$ (CD11d), to give rise to four distinct $\beta_2$ integrins: $\alpha_L\beta_2$ (CD11a/CD18), also known as lymphocyte function-associated antigen 1 (LFA-1); $\alpha_M\beta_2$ (CD11b/ CD18), also referred to as macrophage antigen 1 (Mac-1) and complement receptor 3 (CR3); $\alpha_X\beta_2$ (CD11c/CD18), also known as CR4 and p150/95; and $\alpha_D\beta_2$ (CD11d/ CD18) (Arnaout, 1990).

Lally and coworkers identified LFA-1 (CD11a/ CD18) as a receptor for *A. actinomycetemcomitans* leukotoxin (LtxA), as well as for *E. coli* α-hemolysin on the surface of human leukocytes (Lally *et al*., 1997). In addition, they suggested recently that LtxA recognizes a sequence or structure in the N-terminal β-propeller domain of human CD11a that is not present in the murine counterpart, which might explain the selective activity of LtxA against human (primate) leukocytes. AC toxin from *B. pertussis* has been shown to use the $\alpha_M\beta_2$ integrin (CD11b/CD18) as a specific host cell receptor, obviously by interacting with CD11b (Guermonprez *et al*., 2001). CD11b is exclusively expressed in immune cells such as neutrophils, macrophages, dentritic cells, and natural killer cells, which is consistent with the finding that phagocytes are the primary target cells of AC toxin *in vivo*. El-Azami-El-Idrissi *et al*. (2003) suggested that the main CD11b-interacting domain of CyaA is located within the glycine-rich repeat region, specifically between the amino acids 1166 and 1281. LktA from *M. haemolytica* apparently binds to bovine CD18, which enables this leukotoxin to use all $\beta_2$ integrins as receptors on bovine leukocytes (Wang *et al*., 1998; Li *et al*., 1999; Jeyaseelan *et al*., 2000; Deshpande *et al*., 2002; Dileepan *et al*., 2005). Leite *et al*. (2000, 2002, 2003) revealed that inflammatory cytokines secreted from bovine neutrophils in response to activation by LktA induce an up-regulation of LFA-1 in these cells, which in turn enhances LktA binding and consequently augments LktA cytotoxicity. In addition, they found that IL-1β (and perhaps other inflammatory cytokines) released from bovine peripheral blood mononuclear cells following infection with bovine herpesvirus-1 (BHV-1) can stimulate LFA-1 expression in these mononuclear cells and in bystander bovine neutrophils, thus enhancing LktA binding and LktA-mediated cytotoxicity (Leite *et al*., 2004, 2005). Consistent with these results, Yamaguchi *et al*. (2004) reported that TNF-α and IL-1 enhance *A. actinomycetemcomitans* LtxA-induced cell apoptosis by stimulating the expression of LFA-1.

Whether specific receptors are involved in or required for the binding of RTX toxins to erythrocytes is unclear. Bauer and Welch (1996a) found that the number of binding sites for *E. coli* HlyA on sheep erythrocytes is limited to a few thousand, which suggested that HlyA interacts with a specific cell surface component. Cortajarena *et al*. (2001, 2003) reported that glycophorin acts as a receptor for *E. coli* HlyA on red blood cells and that a region near the C-terminus of HlyA (amino acids 914–936) is essential for the toxin to bind to glycophorin. Nevertheless, other investigators did not observe saturability of the binding of HlyA to erythrocytes, suggesting that the binding is not receptor-dependent (Eberspächer *et al*., 1989). Furthermore, it has recently been suggested that erythrocytes do not contain specific receptors for *B. pertussis* AC toxin (Martin *et al*., 2004).

## Pore formation by RTX toxins

Osmotic protection experiments performed with *E. coli* α-hemolysin yielded first clues that RTX toxins may

damage target cell membranes by generating transmembrane pores (Bhakdi *et al*., 1986). Subsequently, biophysical studies such as planar lipid bilayer experiments and patch-clamp experiments demonstrated that RTX toxins form cation-selective membrane pores (channels) that have a defined size and a short lifetime of only a few seconds (Menestrina *et al*., 1987, 1996; Benz *et al*., 1989, 1994a, b; Szabo *et al*., 1994; Lear *et al*., 1995; Maier *et al*., 1996; Schmidt *et al*., 1996; Karakelian *et al*., 1998). Based on the single-channel conductance, an effective pore diameter in the range of 1 to 3 nm was calculated for *E. coli* α-hemolysin and several other RTX toxins, but some RTX toxins, such as *B. pertussis* AC toxin and *A. pleuropneumoniae* ApxIII, were found to generate considerably smaller pores. It is remarkable that, despite the large molecular mass of the RTX toxins, target membranes attacked by high doses of these toxins do not exhibit recognizable pore structures when examined by electron microscopy (Bhakdi *et al*., 1986; Soloaga *et al*., 1999). The reason for this is unclear, but the instability of the RTX toxin pores might play a role.

Structure/function analyses of several RTX toxins (*E. coli* HlyA, *B. pertussis* CyaA, *M. haemolytica* LktA) revealed that the highly conserved hydrophobic domain in the N-terminal half of these toxins is critical for their capability to generate transmembrane pores. In particular, it has been shown that deletions in this region and mutations altering their hydrophobicity specifically abolish or impair the cytolytic and pore-forming activity (Ludwig *et al*., 1987, 1991; Glaser *et al*., 1988; Cruz *et al*., 1990). In addition, it has been demonstrated that certain peptides representing parts of the hydrophobic region of *E. coli* HlyA are able to form pores in artificial lipid bilayers. One of these peptides also exhibited hemolytic activity (Oropeza-Wekerle *et al*., 1992). Two recent studies employing cystein-scanning mutagenesis and membrane insertion-dependent labeling, respectively, further confirmed that the hydrophobic domain of *E. coli* HlyA is the principal region of this toxin that inserts into the target membrane (Hyland *et al*., 2001; Schindel *et al*., 2001). Computer-assisted structure predictions suggested that the hydrophobic region of HlyA contains both hydrophobic and amphipathic α-helices that are long enough to span a lipid bilayer (Ludwig *et al*., 1991). Thus, this region appears to be directly involved in the generation of the pore. Insertion of *E. coli* HlyA and *B. pertussis* CyaA into target membranes has also been shown to be associated with a change in toxin conformation (Moayeri and Welch, 1997; Osickova *et al*., 1999).

Pore-forming exotoxins are usually synthesized as water-soluble (hydrophilic) molecules that have the intrinsic capability to spontaneously insert into target membranes and hence to adopt an amphiphilic structure. With respect to the mechanism of membrane insertion, two basic strategies have been recognized among membrane-inserting toxins:

(1) Toxins that do not contain extended hydrophobic sequences, such as *Staphylococcus aureus* α-toxin, the cholesterol-dependent cytolysins, and anthrax toxin protective antigen, must oligomerize after binding to the target membrane; subsequently, amphipathic sequences of the oligomerized toxin molecules associate with each other and insert as β-hairpins into the membrane, resulting in the formation of a stable β-barrel, which represents a transmembrane channel lined by antiparallel β-strands. In the β-barrel, the β-hairpins are arranged in such a way that their hydrophilic residues are oriented towards the lumen of the channel, while the intervening hydrophobic residues face the membrane lipids (Song *et al*., 1996; Petosa *et al*., 1997; Shatursky *et al*., 1999).
(2) Toxins such as the pore-forming colicins and diphtheria toxin contain hydrophobic and amphipathic α-helices long enough to span a lipid membrane. The hydrophobic α-helices are thereby buried within the toxin as long as it is in its water-soluble form. However, at the target membrane, partial unfolding of the toxin leads to a change in toxin conformation and insertion of the hydrophobic (and likely of amphipathic) α-helices as α-helical hairpins into the membrane, perhaps resulting in the generation of a transmembrane pore; membrane insertion thereby may or may not require toxin oligomerization (Lesieur *et al*., 1997; Stroud *et al*., 1998; D'Silva and Lala, 2000).

In the case of the RTX toxins, the mechanism of membrane insertion and pore formation is unknown. Nevertheless, based on the data described above, it is tempting to speculate that these toxins insert into membranes by a mechanism that might be similar to that employed by the latter group of toxins.

Whether pore formation by the RTX toxins is dependent on a toxin oligomerization is unclear. In fact, RTX toxins have been recovered only in monomeric form from target membranes, and it has been repeatedly suggested that these toxins act as monomers (Menestrina *et al*., 1987; Eberspächer *et al*., 1989; Stanley *et al*., 1993). On the other hand, dose-response analyses indicated that the lysis of target cells by RTX toxins is a highly cooperative event that likely involves toxin oligomerization (Cavalieri and Snyder, 1982; Simpson *et al*., 1988; Bhakdi *et al*., 1989; Taichman *et al*., 1991; Bauer and Welch, 1996b; Gray *et al*., 1998). In

the case of *E. coli* HlyA and *B. pertussis* CyaA, successful complementation between different inactive toxin mutants has been observed, which further argues in favor of the formation of toxin oligomers (Ludwig *et al*., 1993; Iwaki *et al*., 1995; Bejerano *et al*., 1999). In addition, the biophysical characteristics of RTX toxin pores are compatible with the hypothesis that these pores are generated by transiently formed (unstable) toxin oligomers (Benz *et al*., 1989).

Some investigators suggested that the cytolytic activity of RTX toxins might be due to a mechanism different from the generation of discrete-sized transmembrane pores. Moayeri and Welch (1994) proposed that *E. coli* HlyA creates membrane lesions that increase in size over time. Soloaga *et al*. (1999) suggested that HlyA inserts only into the outer leaflet of the lipid bilayer through a number of amphipathic α-helices, thereby causing destabilization of the membrane and transient bilayer breakdown.

## Role of fatty acylation and $Ca^{2+}$ binding for the activity of RTX toxins

RTX toxins require both the fatty acylation and the binding of calcium ions to the glycine-rich repeats for all known cytotoxic activities. The actual functions of these modifications are, however, not completely understood. Pore formation by *E. coli* HlyA in artificial lipid bilayers is apparently independent of $Ca^{2+}$ and not affected by deletions in the repeat domain (Ludwig *et al*., 1988; Döbereiner *et al*., 1996). In addition, nonacylated HlyA (pro-HlyA) forms pores in planar lipid bilayers, which have similar properties as those generated by the acylated toxin, although the pore-forming activity of pro-HlyA is considerably reduced compared to that of HlyA (Ludwig *et al*., 1996). Thus, $Ca^{2+}$ binding and acylation appear to be critical for the interaction between HlyA and eukaryotic cell membranes at some stage preceding pore formation. Several studies indicated that $Ca^{2+}$ binding and acylation are required for the binding of RTX toxins to target cell membranes (Ludwig *et al*., 1988, 1996; Boehm *et al*., 1990a, b; Issartel *et al*., 1991; Gray *et al*., 1999), even though this was not confirmed in some other studies (Bauer and Welch, 1996a; Soloaga *et al*., 1996; Bakas *et al*., 1998). Recent evidence indicates that nonacylated RTX toxins may loosely bind to target cells, but that the fatty acylation is essential for the tight and productive interaction that is required for cytotoxic effects to occur (Sun *et al*., 1999; El-Azami-El-Idrissi *et al*., 2003; Thumbikat *et al*., 2003). Lee *et al*. (2005) revealed that AC toxin from *B. pertussis* undergoes self-association in solution, and they suggested that this process requires the posttranslational acylation of the toxin, but not calcium.

## Role of LPS in RTX toxin structure and function

Preparations of active, extracellular RTX toxins typically contain substantial amounts of lipopolysaccharides (LPS). Indeed, some RTX toxins, such as *E. coli* α-hemolysin and *M. haemolytica* leukotoxin, have been shown to complex with LPS (Bohach and Snyder, 1985; Czuprynski and Welch, 1995; Li and Clinkenbeard, 1999). LPS is not required for the cytotoxic and cytolytic activity of RTX toxins (Welch, 2001). Nevertheless, the physical interaction between LPS and RTX toxins is functionally important, because LPS indirectly enhances RTX toxin activities. It has been particularly suggested that LPS is important for stabilizing the active conformation of *E. coli* HlyA and/or for protecting it from aggregation or degradation (Stanley *et al*., 1993; Bauer and Welch, 1997; Herlax *et al*., 2005). Consistent with this, it has been reported that complexation between LPS and *M. haemolytica* LktA results in enhanced and stabilized leukolytic activity of LktA, and that LPS also enhances inflammatory cytokine induction in bovine alveolar macrophages exposed to low doses of this leukotoxin (Li and Clinkenbeard, 1999; Lafleur *et al*., 2001). Recently, Ross *et al*. (2004) revealed that *B. pertussis* AC toxin synergizes with LPS to promote IL-10 production.

## Importance of calcium as a signaling molecule in the action of RTX toxins

Jorgensen *et al*. (1983) revealed that *E. coli* α-hemolysin causes changes in the selective permeability of the cytoplasmic membrane of erythrocytes, resulting in the rapid influx of extracellular $Ca^{2+}$ ions and in the efflux of $K^+$ ions. Subsequent studies showed that several other RTX toxins, such as *M. haemolytica* LktA and *A. actinomycetemcomitans* LtxA, also cause an unregulated $Ca^{2+}$ influx into target cells (Taichman *et al*., 1991; Sun *et al*., 1999). This calcium influx most likely plays an important role in the killing of host cells by RTX toxins. A popular hypothesis is that it initiates cytoskeletal destruction with multiple necrotic sequels that promote colloidal osmotic cell lysis (Welch, 2001).

Calcium is central as an intracellular second messenger and is involved in the regulation of a diverse array of cell functions (Berridge *et al*., 1998). Recent findings indicate that the $Ca^{2+}$ influx evoked by sublytic doses of RTX toxins is involved in the RTX toxin-mediated induction of inflammatory responses, particularly by causing activation of nuclear factor (NF)-κB. NF-κB is one of the major transcription factors required for induction of inflammatory responses in various cell types (Baeuerle and Baltimore, 1996). Several

pro-inflammatory cytokines, such as TNF-α, IL-1β, IL-6, and IL-8, are known to be regulated by this protein. In non-stimulated cells, NF-κB is bound to a cytoplasmic inhibitor protein, I-κB, which prevents its translocation into the nucleus. NF-κB activation results in degradation of I-κB, leaving NF-κB free to translocate into the nucleus and to induce the expression of genes involved in inflammatory responses (Guha and Mackman, 2001). Hsuan *et al*. (1999) observed that sublytic concentrations of *M. haemolytica* LktA induce nuclear translocation of NF-κB and expression of TNF-α, IL-1β, and IL-8 in bovine alveolar macrophages, and that elevation of the cytoplasmic $Ca^{2+}$ concentration ($[Ca^{2+}]_i$) is a prerequisite for NF-κB activation and expression of cytokine genes. The LktA-induced production of leukotriene $B_4$ by bovine neutrophils was also found to be dependent on a sustained and excessive increase in $[Ca^{2+}]_i$ (Cudd *et al*., 2003a). Elevation of $[Ca^{2+}]_i$ in LktA-stimulated bovine alveolar macrophages and neutrophils seems to be due to both influx of extracellular $Ca^{2+}$ through voltage-gated calcium channels (Ortiz-Carranza and Czuprynski, 1992; Hsuan *et al*., 1998) and release of calcium from intracellular stores within the endoplasmatic reticulum (ER) (Cudd *et al*., 2003b).

Uhlen *et al*. (2000) revealed that sublytic concentrations of *E. coli* α-hemolysin induce low-frequency $[Ca^{2+}]_i$ oscillations (periodicity: about 12 min) in renal epithelial cells, which stimulate the production of IL-6 and IL-8 in these cells. In addition, they observed that the calcium oscillations depend on the influx of $Ca^{2+}$ through voltage-operated L-type calcium channels in the plasma membrane, as well as on the release of $Ca^{2+}$ from stores within the ER through inositol trisphosphate receptor ($InsP_3R$) channels. A model based on these data suggests that interaction of HlyA with the cell membrane causes an influx of $Ca^{2+}$ through voltage-operated L-type calcium channels, and that an intracellular signal transduction pathway subsequently mediates activation of $InsP_3R$-gated $Ca^{2+}$ stores within the ER, resulting in the $[Ca^{2+}]_i$ oscillations (Söderblom *et al*., 2002). Although NF-κB activation by *E. coli* α-hemolysin has not yet been shown, it is likely that this transcription factor is involved in the α-hemolysin-induced IL-6 and IL-8 production in renal cells. In fact, Dolmetsch *et al*. (1998) demonstrated that expression of IL-8 is under control of artificially induced $Ca^{2+}$ oscillations due to frequency-modulated activation of NF-κB.

## CONCLUSION

A large quantity of new data regarding the structure and mode of action of RTX toxins has been compiled in the past years. Several things are, however, still poorly or incompletely understood. Examples are the mechanism of pore formation, the function of the fatty acylation and of the binding of calcium ions to RTX toxins, and the processes involved in the RTX toxin-mediated activation of host cells. Current work is aimed at further clarifying these issues.

CHAPTER

# 30

# Genetics and phylogeny of RTX cytolysins

*Joachim Frey*

## INTRODUCTION

RTX cytolysins represent a large family of bacterial, pore-forming protein toxins belonging to the type I exoprotein secretion system, which is present in a wide range of Gram-negative bacteria. *In vivo*, RTX toxins induce inflammatory mediators or exert cytotoxic effects, particularly to cells of the host's immune defense, thus provoking necrosis, apoptosis, inflammation, and consequently disease (Czuprynski and Welch, 1995; Welch, 2001). The designation RTX (repeats in the toxin) originates from the common feature, the glycine-rich repeated structures, mostly present in the form of multiple glycine-rich nonapeptides in the structural toxin peptide (Strathdee and Lo, 1989). These repeats have a strong $Ca^{2+}$-binding capacity and are involved in the binding to the host cell membrane. This feature is not only found in cytolysins and hemolysins of pathogenic bacteria, but also in particular in proteases, lipases, bactericides, and nodulation-related proteins, which are all involved in cytotoxicity of pathogenic bacteria or bacteria-host interactions of symbiotic bacteria (Table 30.1). Further common traits of RTX proteins are: (i) the fact that they are generally synthesized as inactive pretoxins and subsequently activated by a specific *cis*-located activator protein together with an acylase of the bacterial host (Hui *et al*., 2000; Issartel *et al*., 1991); and (ii) that they are secreted by particular, *cis*-located type I secretion systems. The close association of RTX cytolysins with type I secretion systems allows the export of the highly membrane-active proteins without damaging the membrane of the bacterial host. RTX cytolysins are therefore encoded on polycistronic operons, including the activator gene, generally termed C, the structural toxin gene termed A, as well as two genes of the type I secretion apparatus encoding the ABC transporter protein B and the export channel protein D. The order of these genes is most often encountered in the arrangement CABD and preceded by a promoter p, which characterizes the RTX operons as genetic entities in a broad spectrum of bacteria (Figure 30.1).

## OPERON STRUCTURES

The hemolysin (Hly) of *Escherichia coli* is the best-analyzed RTX cytolysin, and its operon serves as the archetype of RTX operons (Figure 30.1). The genes of the activator, *hlyC*, the structural hemolysin, *hlyA*, the ABC transporter protein, *hlyB*, and the export channel protein, *hlyD*, are ordered in the *hlyCABD* arrangement that is preceded by the promoter and regulatory genes (Figure 30.1). The *hlyCA* and *hlyBD* genes are separated by a rho-independent transcriptional attenuation sequence, and the *hlyD* gene is followed by a transcriptional stop signal that terminates the *hlyCABD* operon (Figure 30.1). Most hemolysins and leukotoxins, including those of *Actinobacillus actinomycetemcomitans* (*lktA*), *Actinobacillus equuli* (*aqxA*), *Actinobacillus pleuropneumoniae* (*apxIA*, *apxIIA*, *apxIIIA*), *Actinobacillus rossii* (*apxIIA*, *apxIIIA*), *Actinobacillus suis* (*apxIA*, *apxIIA*), Enterohemorrhagic *Escherichia coli* EHEC (*ehxA*), *Mannheimia* (*Pasteurella*) *hemolytica* (*lktA*),

**TABLE 30.1** Structural RTX toxin genes of Gram-negative bacteria

| Gene | Bacterial host | Function | Operon structure* | C+C content | |
|---|---|---|---|---|---|
| | | | | RTX | host |
| *apxI* | *A. pleuropneumoniae* | hemolysin | pCABD | 40 | 42 |
| *apxI* | *A. suis* | hemolysin | pCABD | 40 | 41 |
| *apxII* | *A. pleuropneumoniae* | hemolysin | pCABD | 36 | 42 |
| *apxII* | *A. rossii* | hemolysin | pCABD | 36 | 42 |
| *apxII* | *A. suis* | hemolysin | pCABD | 40 | 41 |
| *apxIII* | *A. pleuropneumoniae* | cytolysin | pCABD | 36 | 42 |
| *apxIII* | *A. pleuropneumoniae* | cytolysin | pCABD | 36 | 42 |
| *apxIV* | *A. pleuropneumoniae* | co-hemolysin, clip-and-link | pORF1A | 40 | 42 |
| *aqxA* | *A. equuli* | hemolysin | pCABD | 39 | 41 |
| *cyaA* | *B. pertussis* | adenylate cyclase-hemolysin | CppABDE | 67 | 68 |
| *cyaA* | *B. bronchiseptica* | adenylate cyclase-hemolysin | CppABDE | 67 | 68 |
| *ehxA* | *E. coli* EHEC | EHEC enterohemolysin | pCABD | 40 | 50 |

*The operon structure designation refers to Figure 30.1.

*Mannheimia varigena (lktA)*, *Moraxella bovis (mbxA)*, *Pasteurella aerogenes* (*paxA*), and *Pasteurella mairi* (*paxA*) show the *pCABD* operon structure (Figure 30.1, Table 30.1). A minor difference is found in the *A. pleuropneumoniae apxII* operon, which lacks the type I secretion genes B and D. These genes were probably lost during evolution, as indicated by the presence of a residual 300-bp fragment of a potential former *apxIIB* gene downstream from the *apxIIA* gene (Frey *et al*., 1993; Frey, 1995). This loss is, however, compensated by the presence of either a full *apxICABD* operon or a partial *apxIBD* operon in all pathogenic *A. pleuropneumoniae* strains that are able to *trans*-complement the necessary type I secretion functions (Reimer *et al*., 1995; Frey *et al*., 1993). Recently, a complete *apxIICABD* operon has been detected in *Actinobacillus porcitonsillarum*, which further supports the above-mentioned suggestion of a deletion event in *A. pleuropneumoniae* (Kuhnert *et al*., 2005). In addition to the above-mentioned ABC transporter protein B and the export channel protein D, type I secretion systems also require a host outer membrane protein, TolC, encoded by the gene *tolC*, which is located distantly and is genetically not linked to the cytolysin operons pCABD (Andersen *et al*., 2000; Balakrishnan *et al*., 2001; Thanabalu *et al*., 1998). The *tolC* function is also present in strains that are devoid of RTX cytolysins, and TolC proteins seem to be basic outer membrane components in most Gram-negative bacteria. Although *tolC* has not been identified in all bacterial species harboring RTX cytolysins and type I secretion systems, it is expected to be required for all type I secretion systems of the above-named bacteria. While most of the genes of the above-named RTX cytolysins are chromosomally located, it has to be noted that the *E. coli hlyCABD* operon can be both chromosomally and plasmid located (Hacker and Hughes, 1985) and that the EHEC *ehxCABD* operon is placed on the large plasmid of enterohemorrhagic *E. coli* 0157:H7 (Schmidt *et al*., 1996).

Besides the "classical" RTX cytolysins, which closely resemble the *E.coli* hemolysin Hly, several classes of RTX proteins have different biochemical and cytotoxic activities, but all contain glycin-rich repeats

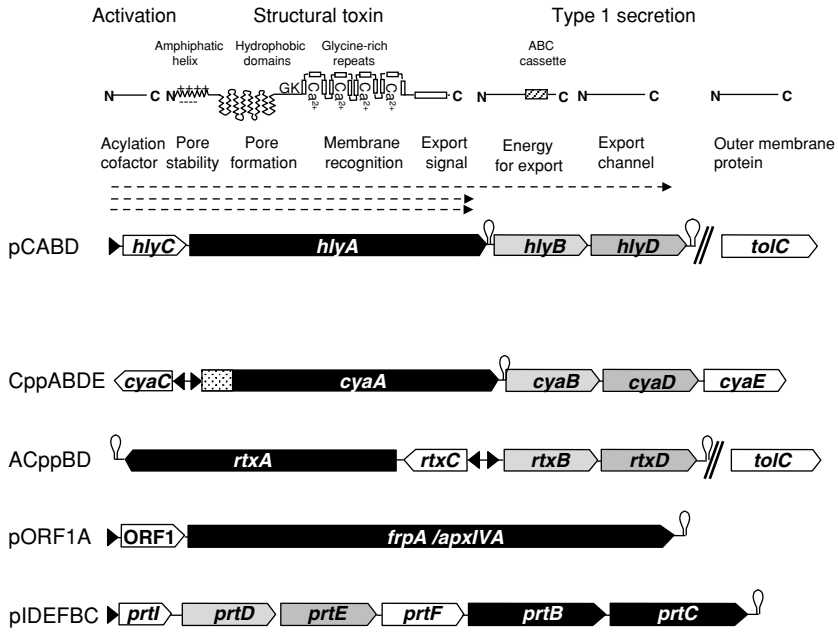

**FIGURE 30.1** Genetic organization and functional domains of RTX operons. The upper part of the figure represents the most common genetic and structural organization of RTX toxins, referred to as pCABD operon, and is mainly based on that of the *E. coli* hemolysin HlyA (Hughes *et al*. 1992; Ludwig *et al*., 1988). The basic functional activities are given on the top line, followed by a schematic statement of the gene products and their major structural characteristics. These domains are annotated. GK indicates the glycin-lysin acylation site. The ATP-binding cassette of the secretion protein B is abbreviated by ABC. N indicates the amino-terminal and C the carboxy-terminal end of the peptides. The four genes of the operon and the unlinked outer membrane gene *tolC* are represented by arrowhead boxes, which indicate the relative length and direction of the coding genes. Black triangles represent promoter sites, and the hairpins show the sites of *rho*-independent transcription termination signals. The dashed arrow above the *hly* gene map represents the direction and length of transcripts. The lower part of the figure shows the genetic organization of the other types of RTX operons, preceded by a short designation, which is reported in Table 30.1. Shading of the different arrowhead boxes was done in analogy to the *hlyC*, *hlyA*, *hlyB*, *hlyD*, and *tolC* genes of the *E. coli* RTX operon. The dotted part of the box of the *cyaA* gene represents the adenylate cyclase moiety.

with $Ca^{2+}$-binding activity. A particular RTX toxin is the calmodulin-sensitive adenylate cyclase-hemolysin CyaA of *Bordetella pertussis*. The *cyaA* gene of the structural toxin shows a significant difference between the guanine-cytosin (G/C) composition of the segment encoding the adenylate cyclase function and the hemolysin function, indicating that this composite protein evolved from a recombination event between two genes, each containing one of the above-named functions. The structure of the *cyaC-cyaABDE* operon shows the particularity that the activator gene C is transcribed on a separate cystron in the opposite direction to the other genes by promoters located between *cyaC* and *cyaA* (Westrop *et al*., 1996; Westrop *et al*., 1997). Moreover, the *TolC* analogue *cyaE* is part of the polycistronic (*cyaABDE*) operon (Figure 30.1).

A further single particular RTX operon is the hemolysin RtxA of *Vibrio cholerae*, which is tightly linked to the cholera toxin prophage (Lin *et al*., 1999; Chattopadhyay and Banerjee, 2003). The genetic organization of this determinant is bicystronic with the *rtxCA* and *rtxBD* type I secretion genes on two separated transcriptional units that are read in opposite directions from two adjacent promoters (Figure 30.1). While the genetic organization of the *V. cholerae* hemolysin determinant is characteristic for RTX cytolysins, this hemolysin lacks the canonical glycin-rich nonapeptide repeats and possesses instead an 18-residue glycine/aspartate-rich repeat that seems to be involved in $Ca^{2+}$-binding, similar to the alkaline protease ArpA of *Pseudomonas aeruginosa* (Baumann *et al*., 1993; Duong *et al*., 1992).

Several bacterial virulence attributes exhibit structural and functional features of RTX toxins, in particular, the glycine-rich nonapeptide repeats or glycine/aspartate-rich repeats with $Ca^{2+}$-binding capacity, yet with biochemical activities and genetic structures that are different from the hemolysins/cytolysins described above. Among them are the large, 200–300-kDa RTX proteins ApxIV of *A. pleuropneumoniae*, as well as FrpC and FrpA of *Neisseria meningitidis*. These proteins show both a novel calcium-dependent processing and cross-linking (clip and link) activity (Osicka *et al*., 2004), and they are known to induce high levels of

serum antibodies during infection (Thompson *et al*., 1993; Osicka *et al*., 2004; Schaller *et al*., 1999; Dreyfus *et al*., 2004). Recombinant ApxIV shows a co-hemolytic activity to porcine and ovine erythrocytes in synergy with sphyingomyelinase, similar to certain RTX cytolysins described above (Schaller *et al*., 1999). The genetic setup of this class of clip and link activity RTX proteins, however, strongly differs from the other RTX toxins and is characterized by a bicistronic operon, including a short, open-reading frame (ORF1) of about 450 base pairs (bp) followed by the structural RTX toxin gene A of 6000–7000 bp (Figure 30.1). The 450 bp ORF1 upstream *frpA*, *frpC*, and *apxIV* shows no similarity to the activator gene *hlyC* or other typical C-activators of RTX cytolysins, and the function of this potential co-factor is unknown. However, it has been shown that its presence is required for the co-hemolytic activity of ApxIVA (Schaller *et al*., 1999). The large RTX proteins FrpC, FrpA, and ApxIV carry a C-terminal 60 amino-acid structure, revealing several features that are conserved among secreted RTX proteins (Thompson and Sparling, 1993). FrpA can indeed be secreted by *E. coli* harboring *hlyBD* genes (Thompson and Sparling, 1993). However, no type I secretion genes have been evidenced in the vicinity of *frpA*, *frpC*, or *apxIV*, indicating that the corresponding type I secretion genes are unlinked in *N. meningitidis* and *A. pleuropneumoniae*.

A particular class of RTX proteins is constituted by a group of metalloproteases, including the PrtB and PrtC zinc metalloproteases of *Erwinia chrysanthemi* (Delepelaire and Wandersman, 1989), the zinc metalloprotease PrtA of *Photorhabdus luminescens* (Bowen *et al*., 2003), as well as the alkaline protease AprA of *Pseudomonas aeruginosa* (Duong *et al*., 1992) and the metalloprotease SrpA of *Serratia marcescens* (Suh and Benedik, 1992; Letoffe *et al*., 1991). The genetic structure of this class of RTX proteins is given in Figure 30.1. In *E. chrysanthemi*, this operon is composed by gene *prtI* encoding an inhibitor protein, which protects the bacterial host from detrimental effects of the protease, the three genes *prtD*, *prtE*, and *prtF* encoding transporter genes for secretion, and the two metalloprotease genes *prtB* and *prtC* (Figure 30.1). It has to be noted that the gene designations of these RTX protease operons are less consistent than those of the "classical" RTX cytolysins. Hence, in *P. luminescens*, the operon metalloprotease is named *prtA*, followed by the inhibitor gene *prtI* and then by type I secretion genes *prtB*, *prtC*, and *prtD*. Different gene designations are also used for three metalloprotease genes of *E. chrysanthemi* EC16, which are named *prtA*, *prtB*, and *prtC* (Dahler *et al*., 1990) and which all encode metalloproteases and not secretory functions.

## REGULATION OF GENE EXPRESSION OF RTX CYTOLYSINS

The regulation of expression of the *hlyCABD* operon has been investigated in detail (Bailey *et al*., 1997; Koronakis *et al*., 1989). It is important to consider that the *hlyCABD* operon contains two different groups of genes whose gene products are needed at completely different quantities. On the one hand, the *hlyA* product, which is secreted as HlyA hemolysin-cytolysin, and its activator, the *hlyC* gene product, are needed in high amounts at particular steps during the infectious process. On the other hand, the gene products of the type I secretion genes *hlyB* and *hlyD* are integral membrane components that, once inserted in the bacterial membranes, fulfill their function, and hence their gene expression does not need to be up-regulated at particular moments of the infection. Furthermore, the number of type I secretion pores or channels is expected to be limited in a bacterium in order to ensure its membrane integrity. In the *hlyCABD* operon, the structural toxin- and activator-genes *hlyA* and *hlyC* are contiguous and co-transcribed with the export genes *hlyB* and *hlyD* from promoters proximal to *hlyC*, but toxin synthesis and the export functions can be uncoupled by termination of the great majority of *hlyC* and *hlyA* transcripts within the intergenic poly U-sequence of a rho-independent terminator located between hlyA and the translation start of *hlyB* (Koronakis *et al*., 1989; Koronakis and Hughes, 1988; Welch and Pellett, 1988). Transcription of the *hlyCABD* operon requires the *rfaH* (*hlyT*) locus, a specific regulator of transcript elongation, and a 5′ *cis*-acting *ops* element, which is also involved in the regulation of transcription of genes of F-pilus and lipolysaccharide biosynthesis genes of *E. coli*, *Shigella flexneri*, *Yersinia enterocolitica*, *Vibrio cholerae*, *Klebsiella pneumoniae*, and *Pseudomonas aeruginosa* (Bailey *et al*., 1997; Bailey *et al*., 1992; Bailey *et al*., 1996). Uncoupling of transcription of the RTX toxin genes CA from the type I secretion genes BD by transcription attenuation by a rho-independent transcription termination locus has also been evidenced for the *apxICABD* operon in *A. pleuropneumoniae* (Gygi *et al*., 1992). Operon apxICABD, however, does not contain the 5′, *cis*-acting *ops* element. Expression of the *apxICABD* operon is strongly enhanced by extracellular free $Ca^{2+}$ ions at activities above 3mM, which increases ApxI production of *A. pleuropneumoniae* serotype 1 strains by a factor of 300 (Frey and Nicolet, 1988). The promoter of the *apxICABD* has been mapped by primer extension experiments. It revealed a particular ACAAAT (–44) box upstream the –35 sequence and an unusually long A+U rich leader sequence of the cor-

responding mRNA (Frey *et al*., 1994). While the promoter sequences of most of the RTX operons with pCABD structure seem to differ strongly, these operons all share the rho-independent transcriptional stop signal between the A and B genes, which seems to be crucial for an optimal repartition between the *CA* and the *CABD* transcripts.

Expression of the *frpA* and *frpC* genes in *N. meningitides* was shown to be iron-regulated, hence the designation *frp* (Fe-regulated protein) (Thompson *et al*., 1994). When *N. meningitidis* is grown under iron-depleted conditions in growth medium, the *frpA* and *frpC* genes are expressed, while they are repressed in the presence of $Fe^{2+}$-ions in the growth medium. This regulation is expected to depend on the ferric uptake regulation mechanism "Fur" since recognition sequence for regulatory Fur-proteins, the Fur-box, has been identified in the promoter sequences upstream ORF1, which is located upstream *frpA* and *frpC* and is co-transcribed with these genes (Thompson *et al*., 1993). Interestingly, the *apxIV* operon, which shows the same genetic structure as the *frpA* and *frpC* operons (Figure 30.1), is not regulated by $Fe^{2+}$ (Schaller *et al*., 1999). ApxIVA is not produced when *A. pleuropneumoniae* is grown in a growth medium under several different conditions and not in the absence or in the presence of many co-factors tested, including $Fe^{2+}$. However, since pigs infected with *A. pleuropneumoniae* show a rapid sero-conversion for ApxIVA, it is concluded that the *apxIVA* gene is specifically induced *in vivo* during the infection by a mechanism currently still unknown (Schaller *et al*., 1999).

## PHYLOGENY AND THE SPREAD OF RTX CYTOLYSIN GENES

The genetic relationship of the different RTX toxins was calculated from the similarity of analysis of the nucleotide sequences of the structural toxin A using the Jukes-Canter algorithm (Jukes and Cantor, 1969) and cluster analysis. A phylogenetic unrooted tree was built by the neighbor-joining method as described by (Chiesa *et al*., 1993) (Figure 30.2). Based on their genetic relationship, RTX toxins can be grouped in three main clusters (Figure 30.2). The said clusters reflect some of the main *in vitro* properties of these toxins, as well as their basic operon structures. Thus, cluster 1 exclusively contains hemolysins/cytolysins that have the typical *pCABD* operon structure mostly found in *Pasteurellaceae* but also in *E. coli* and *M. bovis*. All these A-genes also show a characteristically low GC-content of their nucleotide composition as a further common feature, which is close to that of the species of the family *Pasteurellaceae* (Table 30.1). While cluster 1 can be further subdivided phylogenetically into two subclusters, this further subdivision cannot be attributed to a particular function or gene structure. Both subclusters each represent a relatively homogenous group of structural RTX toxin genes with genetic distances below 50% (Figure 30.2). In contrast, some of the host bacteria harboring these RTX genes are phylogenetically distant from each other. In particular, *E. coli*, which harbors *hlyA*, referred to as the archetype of RTX toxin genes, is phenotypically only distantly related to the species *A. pleuropneumoniae*, a member of the *Pasteurellaceae* harboring *apxA*. However, *hlyA* is phylogenetically most closely related to *apxI* (Figure 30.2) and shows very similar phenotypic characteristics under *in vitro* conditions, too. Moreover, the GC content of *hlyA,* which is 41%, strongly differs from that of the *E. coli* genome (50%), but is close to that of most *Pasteurellaceae* genomes (41%–43%) (Table 30.1). It clearly indicates that *hlyA*, and with it the entire *hlyCABD* operon, was horizontally transferred, most probably from a species of the *Pasteurellaceae* family. This also seems to be true for the *mbxA* gene of *M. bovis*, a member of the family of *Moraxellaceae* (order *Pseudomonadales*). The *mbxA* gene is most closely related to the *aqxA* hemolysin of *A. equuli*, an equine pathogen belonging to the family of *Pasteurellaceae*.

The second cluster of RTX genes contains exclusively RTX protease genes, including the metalloprotease genes *prtB* and *prtC* of *E. chrysanthemi* and *prtA* of *P. luminescens*, as well as the clip and link protease genes *frpC* and *frpA* of *N. meningitidis* and *apxIV* of *A. pleuropneumoniae* (Figure 30.2). While the genetic organization of the metalloproteases includes secretory genes, the operons and the clip and link proteases are devoid of export functions. On the whole, all these protease genes are phylogenetically distant from the hemolysin-cytolysin genes found in cluster 1, which reflects not only the different biological activities of their gene products, but also a generally higher GC content. This group of RTX genes generally also has a GC content corresponding to the genomic GC content of their respective hosts (Table 30.1). Both the GC contents and the phylogenetic relationship among members of protease-RTX genes of this cluster allow speculation that their respective hosts adopted these genes earlier in evolution than the "classical" RTX operons.

The third cluster of RTX genes (Figure 30.2) contains rather heterogeneous members. Although, to some extent, their operon organizations seem to be composed of blocks of the "classic" pCABD operons, the structural toxin genes are distantly related to the latter and are composed of GC contents that are significantly

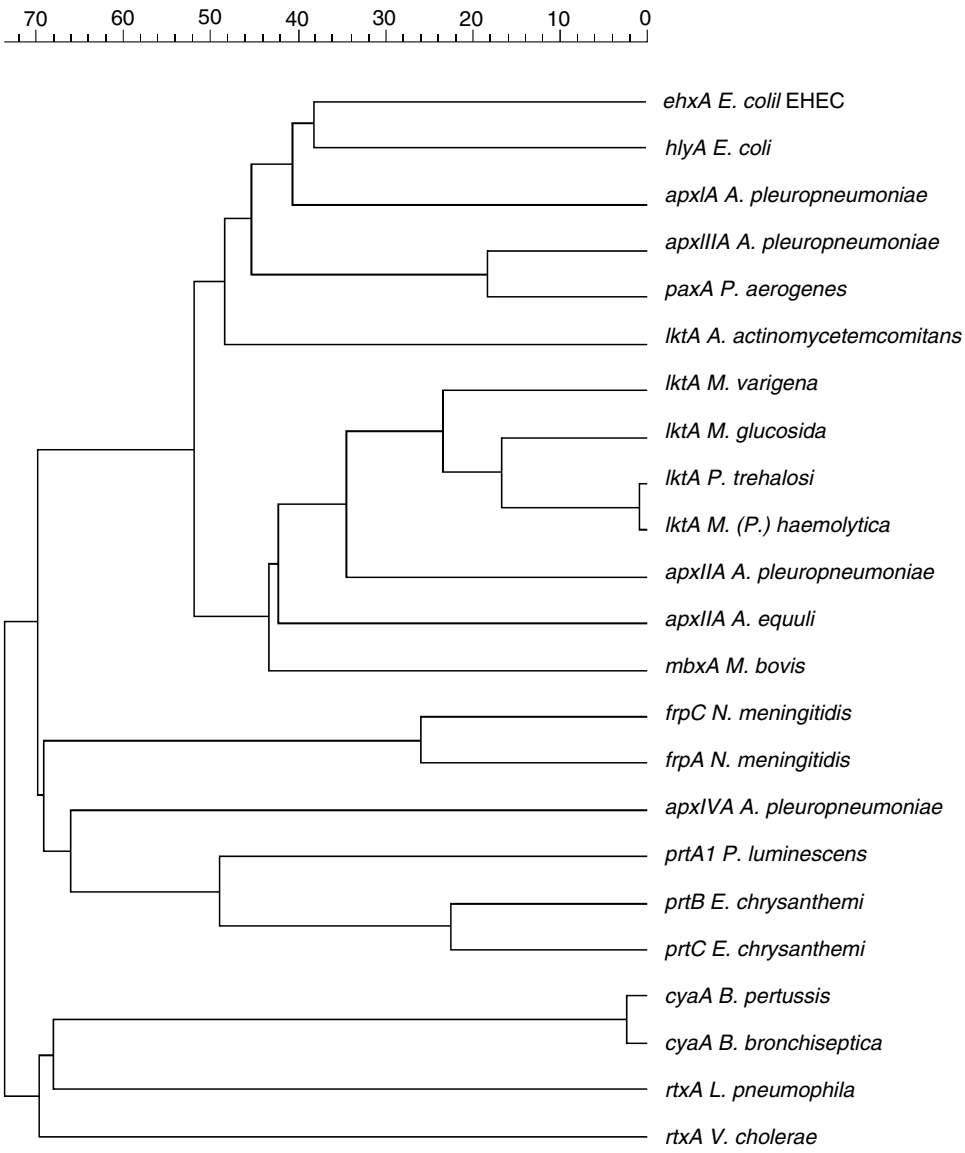

**FIGURE 30.2** Phylogenetic relationship of structural RTX toxin genes of various Gram-negative bacteria. The scale on the top represents the genetic distances in percent nucleotide difference. For the calculation of the distance matrix, only the hemolysin moiety of the *cyaA* genes has been used.

higher and more closely adapted to the genomes of their hosts, which represent members of distant bacterial families (Table 30.1).

## CONCLUSION

Genes encoding RTX toxins are found among a broad diversity of Gram-negative bacterial species. They are most commonly found in species of the *Pasteurellaceae* family from where the typical RTX genes with the pCABD operon organization (Figure 30.1) seem to have developed. This type of RTX genes, which encode for hemolysins and cytolysins, seem to have spread horizontally into other bacterial species such as *Escherichia coli*, where they are found in uropathogenic and enterohemorrhagic *E. coli*, and into *Moraxella bovis*. The two phylogenetically distantly related groups of RTX toxins do not only show different phenotypic and biochemical functions, but are also organized in different operon structures. While they all contain glycin-rich repeated arrays with $Ca^{2+}$-binding capacity in their structural toxin peptides, which group them to the family of RTX toxins, their different genetic, phylogenetic, and functional features indicate that they should be treated as a different group or subgroup of toxins.

CHAPTER

# 31

# The family of two-component cytolysins of *Serratia* and other bacteria

*Volkmar Braun and Ralf Hertle*

## INTRODUCTION

This report is a follow-up of the review in the former *Comprehensive Sourcebook of Bacterial Protein Toxins* (Braun and Hertle, 1999). The previously described major findings will be briefly summarized, and new findings will be discussed in more detail. For a complete list of older references, the reader is referred to the literature cited in the earlier review.

The *Serratia marcescens* hemolysin (cytolysin; ShlA) has several novel features: secretion across the outer membrane by a specific protein that also converts the polypeptide into an active hemolysin and the dependence of the activity on phospholipids, specifically on phosphatidylethanolamine and phosphatidylserine. The ShlA secretion mechanism has become the paradigm of over 100 predicted exoproteins, few of which have been genetically and biochemically characterized. The *S. marcescens* cytolysin is the first example of a protein exotoxin determined by two genes; *shlA* encodes the cytolysin, and *shlB* encodes an outer membrane protein required for ShlA secretion and activation (Braun *et al*., 1987; Poole *et al*., 1988). These two adjacent genes are transcribed in the order *shlB shlA* from an iron-regulated promoter upstream of *shlB*. In *Escherichia coli* transformed with the *shlBA* genes, iron regulation occurs via the Fur protein, which when loaded with $Fe^{2+}$, acts as a transcriptional repressor (Poole and Braun, 1988).

Over 90% of tested clinical isolates of *S. marcescens* and *S. liquefaciens* synthesize the hemolysin. Cytolysins with amino acid sequences similar to ShlA/B have been described in *Proteus mirabilis*, *Haemophilus ducreyi*, *Edwardsiella tarda*, and *Photorhabdus luminescens* (Brillard *et al*., 2002), and encoding genes are found in the genome sequences of *Yersinia pestis*, *Chromobacterium violaceum*, and *Xylella fastidiosa* (Figure 31.1 A, B)

Mature ShlA is composed of 1,578 residues, which can be truncated to an N-terminal fragment of 238 residues that is still secreted, but is non-hemolytic. Progressive deletion of the C-terminus of ShlA gradually reduces hemolytic activity; the smallest active fragment of 104 kDa exhibits only 3% of wild-type activity and still integrates into erythrocyte membranes. An N-terminal nonhemolytic 72-kDa fragment binds to but does not insert into the erythrocyte membrane. ShlA remains active in 6 M urea and is cleaved by trypsin (0.3 M urea) into a major 89-kDa fragment. Upon integration into the erythrocyte membrane, ShlA becomes trypsin-resistant from outside the erythrocyte membrane, but is cleaved into 143- and 14.5-kDa fragments when inside-out erythrocyte vesicles are treated with trypsin. Upon longer exposure, the 143-kDa fragment is further cleaved into 138-, 58-, and 38-kDa fragments. In the presence of Triton X-100, which could partially reflect the hydrophobic environment in erythrocyte membranes, trypsin cleaves ShlA into fragments of 138-, 89-, and 58-kDa. The data suggest that ShlA is an integral membrane protein with no trypsin-sensitive sites exposed at the erythrocyte surface, but with trypsin cleavage sites exposed at the cytosolic side. In the membrane, ShlA assumes a conformation that differs from that in buffer.

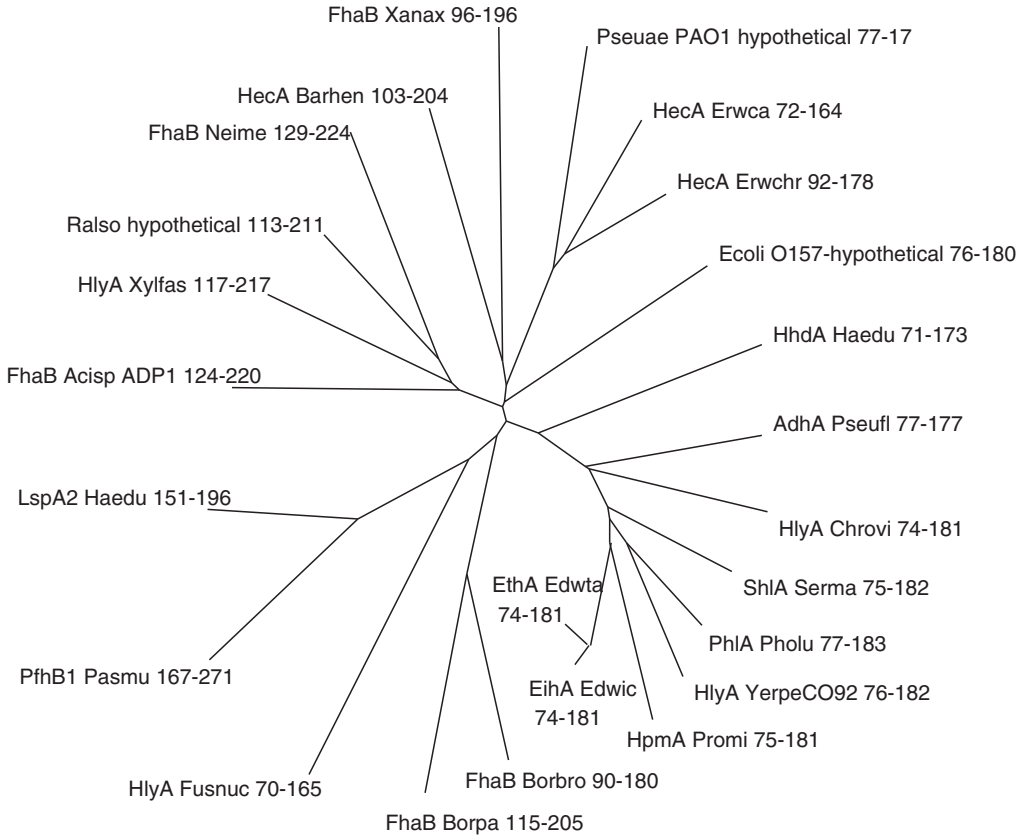

**FIGURE 31.1** A dendrogram of proteins related to the *S. marcescens* hemolysin ShlA. Sequences of the activation and secretion domain were aligned (108 amino acids for ShlA, as shown in Figure 31.2). The first and last amino acid residues of the homologous sequences are indicated after the strain name. *Serratia marcescens* (ShlA Serma) and the related hemolysins of *Edwardsiella tarda* PAO1 (Pseuae PAO1 hypothetical), *Pseudomonas fluorescens* (AdhB Pseufl), *Acinetobacter* sp. ADP1 (FhaC Acisp ADP1l), *Xanthomonas axonopodis* (FhaC Xanax), the large secretory protein from *Haemophilus ducreyi* and *Pasteurella multocida* (LspB Haedu and LspB Pasmu, respectively), and *Escherichia coli* O157:H7 (Ecoli O157-hypothetical) as determined by the CLUSTAL-W program, are shown.

ShlA forms pores of a limited size range in the erythrocyte membrane that cause osmolysis. Added maltoheptaose (molecular weight 1,152) largely prevents osmolysis because it does not diffuse through the ShlA pores and thus counterbalances the internal osmotic pressure of the erythrocytes.

## PHOSPHOLIPIDS ARE REQURED FOR ShlA ACTIVITY

No active ShlA is formed in the absence of ShlB. Inactive ShlA is not secreted into the culture medium, but rather stays in the periplasm. A lysate of cells that synthesize inactive ShlA (ShlA$^*$) and secrete it into the periplasm via the Sec system mixed with a lysate of cells having ShlB in the outer membrane results in hemolytic ShlA. However, highly purified ShlA$^*$ mixed with ShlB fails to yield hemolytic ShlA. The missing component in the mixture is phosphatidylethanolamine, the major phospholipid in the *S. marcescens* outer membrane, which when added to the latter mixture results in active ShlA. Incubation with phospholipase A2, which cleaves the fatty acid at the C2 position of the glycerol residue and which is devoid of protease activity, inactivates active ShlA and prevents activation of ShlA$^*$ by ShlB. These results show that ShlB activates ShlA$^*$, secretion across the outer membrane is not required for activation, and ShlA activity requires phospholipids.

Previously, we have reported that phospholipid is not covalently bound, but is rather tightly bound to ShlA and remains associated with ShlA during SDS-PAGE. Electrophoresis experiments with a higher resolution in the 160 kDa region revealed that the former association of radioactivity with ShlA is a contaminant of the radiolabeled phospholipid preparations (G. Walker, thesis). To determine the region in ShlA to which phospholipid is bound, complementation and binding assays have been used. A deletion derivative

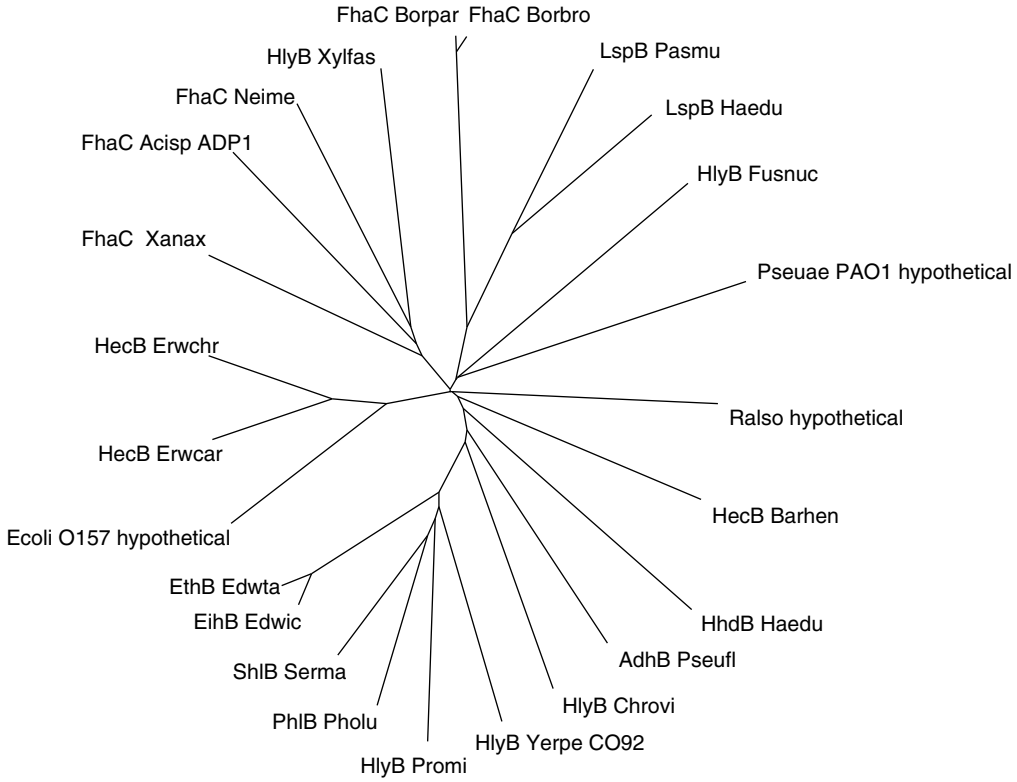

**FIGURE 31.1, Cont'd.**

lacking residues 3–97 of mature ShlA, ShlAΔ3–97, is inactive and not secreted by ShlB into the culture medium. It can be complemented to hemolytic ShlA by N-terminal ShlA fragments, the shortest of which consists of residues 1–238 (ShlA238). This N-terminal fragment is secreted by ShlB and therefore contains the information for specific recognition and secretion by ShlB. It also contains the activation domain. The N-terminal fragments ShlA238, ShlA269, and ShlA667 do not complement phospholipase-A2-treated ShlAΔ3–97, but ShlA1003 and ShlA1144 complement. Treatment of ShlA1003 and ShlA1144 with phospholipase A2 reduces the complementing activity. Phospholipids are associated with ShlA1003 and ShlA1144 and restore the activity of phospholipase-treated ShlAΔ3–97 (G. Walker thesis, 2001). However, radioactive phosphatidylethanolamine binds to ShlA268 (Hertle, unpublished observation), which suggests that phospholipids bind to the N-terminal and the central part of ShlA, or that the ShlA fragment must have a certain length to fold, such that phospholipid binding sites are formed. It has been estimated that three to four phospholipid molecules bind to one ShlA molecule over its entire length. This number of phospholipid molecules is not sufficient to form a micelle around ShlA. Rather, it indicates specific phospholipid binding sites in ShlA.

## ACTIVATION OF ShlA BY A CONFORMATIONAL CHANGE

Hemolytic ShlA incubated with SDS at 20°C forms two bands after SDS-PAGE and one band if first incubated at 95°C. The structural change revealed by the different electrophoretic mobilities is not observed with inactive ShlA, which forms one band at both temperatures. Structural differences between active and inactive ShlA are also revealed by strong differences in trypsin sensitivities. Hemolytic ShlA exhibits a single trypsin cleavage site after incubation at 0°C, yielding two fragments of 60 and 100 kDa, whereas inactive ShlA is completely degraded by trypsin. Electrospray mass spectrometry has determined the same molecular weight for the two proteins, which corresponds exactly with the calculated value. Activation does not change the chemical structure of ShlA, but rather the conformation.

ShlA aggregates and rapidly precipitates, which can be prevented by 6 M urea in which ShlA is physically

stable and active. An N-terminal fragment of 242 residues, ShlA242, is soluble in buffer lacking urea. ShlA242 complements non-hemolytic ShlA and ShlAΔ3–97 to active ShlA when secreted by ShlB and displays no complementation when it is synthesized by cells lacking ShlB. To determine ShlA activation, ShlA242 has been used because it is easier to study experimentally. Four ShlA242 samples have been studied: ShlA242 remaining in the cytoplasm owing to the lack of a signal sequence for secretion; ShlA242 in the periplasm synthesized in the absence of ShlB; ShlA242 in the culture supernatant exported through ShlB; and ShlA242 exported, but not activated by an ShlB mutant that contains a tetrapeptide insertion after residue 136, ShlB136ARSG (Yang *et al*., 2000). Electrospray mass spectroscopy shows that the four derivatives have the same molecular weight, which corresponds to the calculated molecular weight. Upon native polyacrylamide gel electrophoresis (no heating, SDS, mercaptoethanol), the three inactive ShlA242 derivatives display a much slower electrophoretic mobility than active ShlA242. Circular dichroism reveals differences in the secondary structure between active ShlA242 and the three inactive derivatives (Walker *et al*., 2004). These results clearly demonstrate that activation of ShlA242 occurs through changes in conformation. Since ShlA242 secretion and activation reflect ShlA secretion and activation, and ShlA242 complements inactive ShlA and ShlAΔ3–97, the conclusions drawn for ShlA242 apply for ShlA. The secretion and activation domain of ShlA is located in the N-terminal segment of approximately 240 residues. This finding presumably applies also to the other cytolysins of the *S. marcescens* type, and this assumption is supported by the cross-complementation of non-hemolytic HpmA of *P. mirabilis* by ShlA269 and of inactive ShlA by an inactive N-terminal HpmA fragment, and activation of non-hemolytic HpmA by ShlB, despite the lack of cross-reaction of a polyclonal anti-ShlA antiserum with HpmA.

## SECRETION OF ShlA

The elucidation of the mechanism of ShlA secretion by ShlB across the outer membrane was first approached by studying the transmembrane topology of ShlB. All outer membrane proteins with determined crystal structures consist of antiparallel β-strands connected by surface loops of various length and of short periplasmic turns. The β-strands form β-barrels that are partially or completely closed by surface loops, globular domains, or an α-helix that inserts into the β-barrels from the periplasmic side. It is likely that ShlB has the same basic design. The antigenic 11-residue M2 epitope has been inserted at different sites along the ShlB protein, and the reaction with a monoclonal antibody has been determined in cells (Könninger *et al*., 1999). Since the antibody does not enter the cells, only those epitopes exposed to the cell surface react, thereby identifying amino acid residues of surface loops. These data have been compared with data obtained with isolated outer membranes, leading to the determination of additional sites in transmembrane areas or in periplasmic turns. A tentative model of ShlB that predicts 20 transmembrane β-strands has been derived (Könninger *et al*., 1999).

In another study, a tetrapeptide has been inserted at 11 sites of ShlB, which yielded, among others, two mutants that secrete inactive hemolysin (Yang *et al*., 2000). The inactive ShlA derivatives are activated *in vitro* by wild-type ShlB and complemented to active ShlA by ShlA255. The secretion-competent but activation-incompetent mutant with an insertion after residue 136 does not activate or secrete ShlA when the tetrapeptide is elongated to a 15-residue insertion by the M2 antigenic epitope (Könninger *et al*., 1999). Residue 136 is located in the most prominent predicted surface loop, and residue 224 is located in the adjacent transmembrane segment. In the two mutants, secretion is uncoupled from activation. With isolated and purified ShlB, activation is uncoupled from secretion. The two ShlB activities can be separated from each other, even though they might be coupled *in vivo*. The region defined by the two mutations seems to play a vital role in activation and a lesser role in secretion.

Secretion of ShlA by ShlB might basically occur as secretion of proteins by the autotransporter mechanism (type V secretion). Proteins secreted by the type V mechanism consist of two domains—the transporter and the passenger domains. The transporter domain integrates into the outer membrane and allows translocation of the passenger domain. Once at the cell surface, the passenger domain is autoproteolytically cleaved from the transporter domain and released from the cells, whereas the transporter domain remains in the outer membrane. In the case of ShlAB, the covalently linked domains of the autotransporters are separate and encoded by two genes. ShlB is equivalent to the transporter domain and ShlA to the passenger domain.

There are conflicting data on the structure of the transporter domain of autotransporters that have relevance for the export mechanism. The crystal structure of the transporter domain of the NalP exoprotease of *Neisseria meningitidis* reveals a 12-stranded β-barrel filled with an N-terminal α-helix (Oomen *et al*., 2004). This structure suggests that the proteolytic passenger

domain cleaves itself from the α-helix after translocation across the outer membrane through the channel formed by the β-barrel. After translocation of the passenger domain, the α-helix closes the channel, through which poisonous compounds could enter the cells. The diameter of the pore in the β-barrel allows passage of only an unfolded protein, in agreement with studies on the secretion of the IgA protease of *Neisseria gonorrhoeae* (Maurer *et al*., 1997), which is the first described example of an autotransporter. In contrast to the single NalP molecule, electron microscopy of the IgA translocator domain, overproduced in *E. coli*, reveals a multimeric structure (Veiga *et al*., 1999). In addition, a disulfide cross-linked scfv antibody chain linked to the IgA translocator domain is secreted with low efficiency, which suggests translocation of a folded protein through a channel formed by the multimer.

These and other conflicting data discussed in Oomen *et al*. (Oomen *et al*., 2004) have led to the proposal of an alternative translocation model. In this model, the passenger domains of autotransporters are translocated across the outer membrane through a pore formed by the Omp85 protein, rather than through a pore formed by the transporter domain. The transporter domain plays a role in the specific recognition of the cognate passenger domain. Omp85 is important for the assembly of outer membranes of Gram-negative bacteria (Voulhoux *et al*., 2003) and might be involved in the translocation of large hydrophilic surface loops of integral outer membrane proteins.

The question arises as to which of the three autotransporter models, if any, applies to the translocation of ShlA by ShlB. In four experimental approaches, ShlB monomers rather than multimers have been observed. ShlB solubilized with a Tris-EDTA-1% octylglucoside buffer from outer membranes of *E. coli* transformants that synthesized ShlB or ShlB ShlA migrates on SDS-polyacrylamide gels at 25, 37, 50, and 100°C as one band of 60 kDa, which corresponds to the molecular mass of monomeric ShlB (Könninger *et al*., 1999). There is no evidence for multimer formation, as observed with the porins that form trimers in the same experiments at temperatures up to 50°C. Electrophoresis of column-purified ShlB in the presence of octylglucoside on a native gel also reveals only the 60-kDa band. Chemical cross-linking experiments also do not yield multimer ShlB forms. After treatment of spheroplasts with formaldehyde and glutaraldehyde, only ShlB monomers are observed after SDS-PAGE. After treatment with *N*-ethyl-*N*′-(3-dimethylaminopropyl) carbodiimide-*N*-hydroxysucciniimide-3-sulfonic acid, trace amounts of a 115-kDa compound appear, which could represent an ShlB dimer (Könninger, doctoral thesis, 1998). A functional assay also provides no evidence for multimer formation. If ShlB forms a multimer, overexpression of an inactive ShlB mutant protein together with an active wild-type ShlB should reduce ShlB wild-type activity (negative complementation). Co-expression of wild-type ShlB with the secretion-competent but activation-incompetent mutant ShlB136-ARSG or ShlB224PDLA results in the same hemolytic activity as obtained with cells expressing only wild-type ShlB (Yang *et al*., 2000). These results demonstrate an ShlB monomer and exclude functionally relevant amounts of stable ShlB multimers. They suggest a secretion model in which ShlA is translocated through a pore formed by the ShlB β-barrel, or the involvement of a protein that is equivalent to the Omp85 protein. However, a homology search reveals only one protein in *S. marcescens* with 23% identity to Omp85, only between residues 214 and 471 from a total of 797 residues. For comparison, the *E. coli* homologue displays 31% identity over the entire neisserial Opm85 length.

Pore formation of ShlB in artificial lipid bilayer membranes was studied with a highly purified sample solubilized in 1% octylglucoside (Könninger *et al*., 1999). ShlB forms very small pores with a single channel conductance of 10 pS, which only occasionally opens for a short time to a much higher level of 1.25 nS. The results reveal the potential of ShlB to form pores that are mostly closed. This result is not unexpected since cells cannot tolerate a large, permanently open channel in the outer membrane. Rather, one might expect that the pore only opens during ShlA secretion. Two ShlB deletion derivatives—one lacking a portion of the predicted first surface loop, the adjacent transmembrane segment, and part of the second loop; the other lacking most of the second loop—form more stable channels of 1.25 nS. A pore with 1.25 nS conductance could accommodate an unfolded protein. As described above, the high trypsin sensitivity of ShlA prior to its secretion points to an unfolded conformation. Folding at the cell surface could provide the energy for translocation. To elucidate the secretion mechanism of ShlA by ShlB, it will be important to determine the crystal structure of ShlB. Gentle purification procedures have been developed that may form the basis for obtaining crystallizable samples (Hertle *et al*., 1997; Sauter *et al*., 2003).

## THE TWO-PARTNER SECRETION (TPS) PATHWAY

Secretion of the hemolysins of the *Serratia* type and of the large family of adhesins of the FHA type has been collectively termed two-partner secretion (TPS) (Jacob-

Dubuisson *et al*., 2001). In the present review, the sequences are compared and possible secretion mechanisms are discussed.

Attention has been focused on the secretion and activation determinant of ShlA—the region covered by the N-terminal fragments of ShlA that are secreted and activated by ShlB. This domain contains two sites conserved in related proteins (Figure 31.1): AN(69)PNL and LAN(109)PNGIS. Replacement of N69 and N109 by isoleucine results in secretion- and activation-incompetent ShlA derivatives. Both mutant derivatives are highly trypsin-sensitive, which suggests lack of a native conformation. The corresponding mutation of N71 and N111 does not affect ShlA secretion and activation (Schoenherr *et al*., 1993). The inactive derivatives defined two important sites for ShlA secretion and activation. As more cytolysin sequences of the *Serratia* type were elucidated, it became apparent that the ANPN and the LANPNGIS(T) sequences are largely conserved. In fact, a much larger region around the second domain is nearly identical among the cytolysins. A third domain, ILNEVIG in ShlA, is contained in all cytolysins (Figure 31.2).

Studies on the secretion of the filamentous hemagglutinin FHA of *Bordetella pertussis* revealed a secretion mechanism very similar to that of ShlA (summarized in Jacob-Dubuisson *et al*., 2001). FHA contains an N-proximal sequence of approximately 300 residues that contain three sequence motifs similar to the three sequence motifs in the secretion domain of ShlA. FHA with the N-proximal fragment is secreted by the FhaC protein, which displays sequence similarities (18% identity) to the ShlB protein, is contained in the outer membrane, and forms pores with properties similar to those of ShlB in artificial lipid bilayer membranes (Jacob-Dubuisson *et al*., 1999). FhaC changes its structure when it secretes the N-proximal secretion domain (Guedin *et al*., 2000). Transmembrane topology models have been predicted for ShlB and FhaC using computer programs designed for analyzing crystal structures of outer membrane proteins, insertion of antigenic epitopes, and protease cleavage sites along the entire length of proteins (Guedin *et al*., 2000; Könninger *et al*., 1999). The models of the two proteins agree fairly well, except in the position of the N-terminus. A transmembrane segment predicted for ShlB is surface-exposed in FhaC. This results an odd number (19) of β-strands for FhaC, which has not yet been found in crystal structures of outer membrane proteins, instead of the 20 β-strands found in ShlB. There is experimental evidence for the positioning of the N-terminus of FhaC at the cell surface and only weak evidence for the positioning of the N-terminus of ShlB in the periplasm. However, if the basic design of the crystal structure of the translocation domain of the NaP protease applies also for ShlB and FhaC, the N-terminus of each protein would form an helix inserted into the β-barrel from the periplasm. The N-terminus of ShlB would bind the N-terminus of ShlA, move along with ShlA through the pore of the β-barrel, and close it after translocation of ShlA has been completed. The predicted ShlB model, but not the predicted FhaC model, can be reconciled with such a structure. The determination of the crystal structures of ShlB and FhaC will reveal which model is closer to reality.

The crystal structure of the N-terminal secretion domain of FHA (304 residues, designated Fha44) has been determined to 1.7 Å resolution (Clantin *et al*., 2004). It forms a right-handed parallel β-helix of nine complete turns that contains 37 parallel β-sheets (Figure 31.3). It is highly likely that the secretion domain of ShlA assumes a similar structure. The NPNL and ANPNGI motifs, indicated in Figure 31.3, form type I β-turns and are considered to stabilize the structure. Their role may be more than structural in that they contribute to recognition of ShlA (FHA) by ShlB (FhaC). The β-helix supports the theory that ShlA (FHA) is secreted as an extended structure that folds at the bacterial surface. The location of the highly conserved ILAEVT motif (Figure 31.2) is also shown in Figure 31.3.

A BLAST search reveals over 100 cell surface proteins, eight of which are hemolysins and the rest are predicted to be adhesins/hemagglutinins (Figures 31.1, 31.2). Besides the well-characterized FHA hemagglutinin of *B. pertussis*, secretion of the HMW (high-molecular-weight) adhesins of *Hemophilus influenzae* and the Lsp proteins of *Haemophilus ducreyi* have been studied in some detail. Two surface-exposed HMW proteins, HMW1 and HMW2, each require one protein, HMW1B/HMP2B and HMW1C/HMW2C, respectively, for secretion. Conversion of the NPNGI motif to IAIG results in loss of HMW1 secretion (St. Geme and Grass, 1998). In contrast to the secretion of a single protein by one export protein, secretion of the LspA1 and LspA2 proteins is mediated by one LspB protein, which is an orthologue of FhaC (Buscher *et al*., 2004).

## *ShlAB* AND ITS HOMOLOGUES: COMPARATIVE GENOME ANALYSIS

The comparison of the sequences of the ShlAB proteins deduced from sequenced genomes reveals that the N-terminal sequences of the ShlA proteins, which are recognized by ShlB proteins and their orthologs, exhibit a

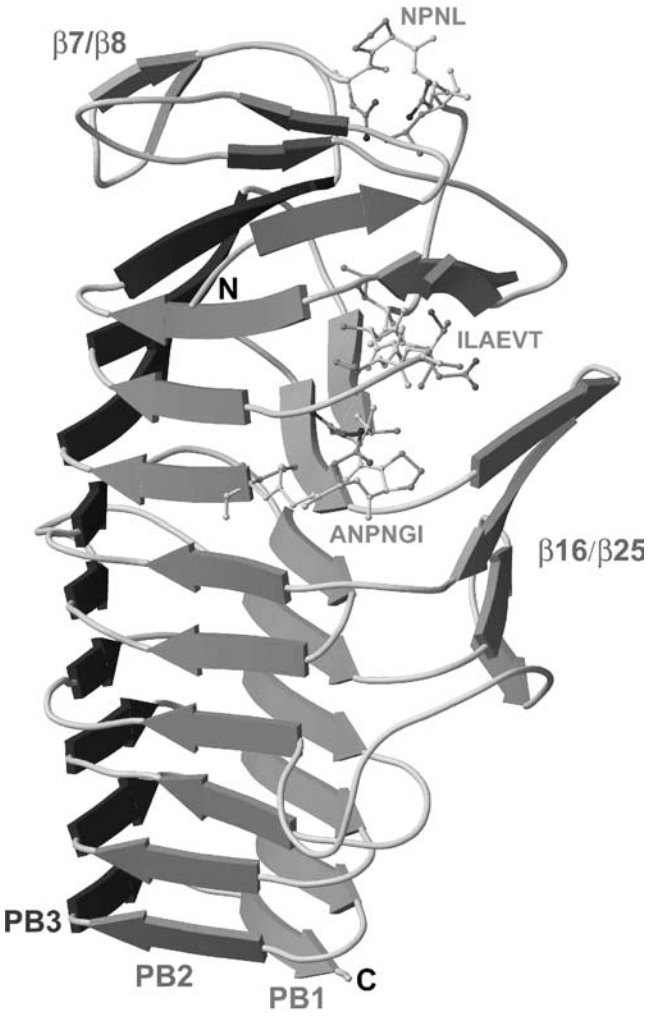

**FIGURE 31.3** Ribbon diagram of the crystal structure of the N-terminal region, residues 1–304 (Fha30), of the *B. pertussis* hemagglutinin. The regions NPNL, ANPNGI, and ILAEVT that are highly similar to regions of ShlA and related hemolysins and hemagglutinins are indicated in Figure 31.2. The structure consists of a right-handed parallel β-helix composed of three parallel β-sheets (PB1, PB2, and PB3), three extrahelical motifs, and an N-terminal capping. Reproduced with permission from Clantin *et al*., 2004.

much higher sequence identity than the entire hemolysins (in Figure 31.1A, only the sequences with high levels of identity are used for analysis). The sequence identity of the *H. ducreyi* ShlA protein is rather low, but it is a hemolysin (Palmer and Munson, 1995). The genomes of *Y. pestis* KIM and CO92 contain a second set of *shlA shlB* genes. There are currently 43 N-terminal sequences with 43–63% sequence identity to the ShlA N-terminus; most of the proteins with this N-terminal sequence are tentatively annotated as adhesins/hemagglutinins. In the ShlB family, there is a clear cut-off point between cytolysins and agglutinins at around 30% identity to ShlB.

In *S. marcescens* and *Y. pestis*, the *shlB-shlA* operons are located between the *lysC* (lysine-sensitive aspartokinase III) and *metH* (5-methyltetrahydrofolate-homocysteine methyltransferase) genes. Although the *lysC* and *metH* loci are close to each other in other organisms, such as *Erwinia carotovora, E. coli* O157 EDL933, *Salmonella typhi, P. luminescens,* and *P. mirabilis*, the distance between the two loci in *P. mirabilis* and *S. marcescens* is farther apart (1772 bp and 19065 bp, respectively), and the genes located between the two loci differ and contain no *shlAB* genes. The hemolysin genes of *P. mirabilis* and *P. luminescens* are located outside the *lysC-metH* locus.

## INTERACTION OF ShlA WITH MEMBRANES

In erythrocytes from various animal sources, ShlA showed no specificity for pore formation. This raised the question of why ShlA does not kill bacterial producer cells. Activation during or after secretion across the outer membrane by ShlB could be a means of protecting the bacterial producer cells. To test this hypothesis, stable protoplast-type L-forms of *P. mirabilis* that do not have an outer membrane were transformed with a plasmid carrying the *shlA shlB* genes (Sieben *et al*., 1998). Inactive ShlA* is secreted by the L-form cells, and ShlB is associated with the cytoplasmic membrane. The protoplasts are not lysed by ShlA, which suggests that the prokaryotic cytoplasmic membrane is resistant to ShlA. Some eukaryotic factors essential for pore formation are lacking in prokaryotic membranes. Specificity does not seem to be conferred by a protein receptor (Hertle, 2002). Rather, the lipid composition of the membrane is important for hemolysis. Negatively charged liposomes are amenable to ShlA-elicited lysis. The negative charge in eukaryotic membranes is mostly carried by phosphatidylserine (PS). Artificial liposomes with a composition reflecting that of erythrocytes—75% phosphatidylcholine (PC), 18% phosphatidylethanolamine (PE), and 7% PS—are lysed by ShlA. Liposomes consisting of 100% PC or 80% PC with 20% PE are completely resistant. *Serratia* and *Proteus* strains have up to 90% PE in the outer membrane and about 75% PE in the inner membrane, but lack PS, which renders these organisms resistant to ShlA treatment. The mechanism of pore formation is not well understood, but one can speculate that the negatively charged PS heads on the inside of eukaryotic membranes could play an essential role in the orientation and stabilization of the ShlA pore. Once bound to the membrane, active ShlA undergoes a conformational change upon membrane integration and

pore formation, whereas inactive ShlA (ShlA*) only binds to the membranes without any detectable conformational change (Hertle, 2002). These data also support the evidence of ShlA and ShlA* having different conformations.

## PORE FORMATION AND CYTOTOXICITY OF ShlA ON EUKARYOTIC CELLS

As *S. marcescens* is an important opportunistic pathogen that causes respiratory and urinary tract infections, bacteremia, endocarditis, keratitis, arthritis, and meningitis (Lyerly and Kreger, 1983; Maki *et al*., 1973), the role played by secreted and cell-bound ShlA is of interest. ShlA is not only a hemolysin, but also a cytolysin that damages tissues and causes release of the inflammatory mediators leucotrienes (LTB4 and LTC4) from leukocytes and the release of histamine from rat mast cells (König *et al*., 1987; Scheffer *et al*., 1988).

ShlA is inactive on keratinocytes, endothelial cells, and monocytes, but highly cytotoxic to epithelial cells, and elicits ATP depletion and potassium efflux in epithelial cells and in fibroblasts (Hertle *et al*., 1999). ATP is strongly depleted, down to 50% within minutes, even with sublytic doses of ShlA. Potassium efflux through the ShlA pores activates the membrane-bound Na/K-ATPase to restore the electrolyte levels. Pores formed by ShlA in the eukaryotic plasma membrane are smaller than the 1–3 nm estimated for ShlA pores in artificial black lipid membranes and in erythrocytes based on their failing to support the influx of propidium iodide ($M_r$ 668) and trypan blue, as measured by flow cytometry with cells depleted to 10% of the initial ATP level. ATP depletion is not affected by osmoprotection with oligosaccharides, which prevents ShlA-mediated hemolysis (Hertle *et al*., 1999). However, ATP depletion is reversible if vacuolation or cell lysis is prevented. Under these conditions, the ATP level is restored, presumably by the repair or closure of the ShlA-produced pores in the plasma membrane since repair requires protein synthesis, as evidenced by failure in the presence of cycloheximide.

The osmotic imbalance, indicated by potassium efflux, ATP depletion, and cell swelling, results in vacuolation. Small vacuoles appear all over the cytoplasm. Upon prolonged incubation, they fuse to form irregular larger vacuoles that fill the entire cytoplasm. Vacuolation is thought to be the result of a mechanism similar to macropinocytosis. Extracellular medium is found inside the spacious vacuoles. In contrast to vacuoles formed by the *Helicobacter pylori* cytotoxin VacA (Cover *et al*., 1993), vacuoles induced by ShlA are not acidified, vacuolation is not inhibited by bafilomycin, and vacuolation cannot be reversed, which indicates that the vacuoles are not derived from lysosomes.

## THE ROLE OF ShlA IN PATHOGENICITY

ShlA contributes to the uropathogenicity of *E. coli* 536/21, as shown with *shlA shlB* transformants (Marre *et al*., 1989). However, the pathogenicity of *Serratia* strains is a multifactorial process and includes the hemolysin, fimbriae, proteases, lipase, nuclease, and undefined determinants that facilitate invasion. These factors act in concert, and the resulting effects are adherence, host cell invasion, cytotoxic effects, and finally cytolysis. Because the hemolytic activity is mainly cell-associated, its effect arises predominantly after adherence of the bacteria to host cell tissues. The contribution of the hemolysin to *S. marcescens* pathogenicity has been shown with a *Caenorhabditis elegans* infection model, in which a hemolysin-negative mutant is less cytotoxic than the wild-type strain (Kurz *et al*., 2003).

Recently, it has been shown that ShlA in low doses induces apoptosis in Jurkat cells (Schallenberg and Hertle, unpublished observation). Hence, ShlA is a major factor in *S. marcescens* pathogenicity.

Invasion of tissue cells by *S. marcescens* depends on ShlA production (Hertle and Schwarz, 2004). Isogenic hemolytic-negative *S. marcescens* strains display a lower invasiveness than ShlA+ cells. The wild-type strain invades epithelial cells at a 0.10% entry level, whereas the hemolytic-negative mutant invades at a 0.0025% entry level. However, the cytotoxicity mediated by ShlA reduces the invasion of wild-type cells since ShlA cytotoxicity lyses the host cells, thereby decreasing the number of intracellular bacteria. In addition, adhesion of *S. marcescens* to the epithelial cells via mannose-sensitive pili (SafA) is essential for invasion (Hertle, Elsilk, and Priemer, unpublished observation). ShlA does not contribute to adhesion.

## CYTOTOXICITY OF ShlA-RELATED HEMOLYSINS/CYTOTOXINS

### HpmA of *Proteus mirabilis*

The *P. mirabilis* cytolysin HpmA acts as a potent cytotoxin against HRPTEC (human renal proximal tubular epithelial cells; Mobley *et al*., 1991), Daudi,

Raji (human-cell lymphoma), U973 (human monocytes), and Vero cells (African green monkey kidney cells) (Swihart and Welch, 1990). Cytotoxicity is determined as the release of lactate dehydrogenase (LDH); the cellular effects have not been studied in detail. As is the case with ShlA, cytolysis of target cells is very rapid and is caused by the pore formation by HpmA.

The ability of *P. mirabilis* to adhere to and invade urothelial cells is closely coupled to swarming (differentiation into hyperflagellated, filamentous swarm cells). Invasion is predominantly determined by flagellin production, and the hemolysin plays a minor role in this process (Allison *et al*., 1992). Invasion by swarm cells occurs within 30 min and is about 15-fold greater (about 0.18% entry after 2 h) than is invasion by vegetative cells (about 0.012% entry), which are internalized more slowly. A hemolysin-negative strain of WPM111 does not significantly alter virulence, but the flagella contribute to the ability of *P. mirabilis* to colonize the urinary tract, leading to acute pyelonephritis in an experimental model of ascending urinary tract infection. Inhibition of eukaryotic protein synthesis by cycloheximide does not reduce bacterial uptake. In addition, internalization of *P. mirabilis* into HRPTEC is decreased by HpmA because of cytolysis (Chippendale *et al*., 1994). The hemolysin-negative mutant strain WPM111 is recovered during the experiment in progressively higher numbers (10- to 100-fold) than the hemolytic parent strain BA6163.

### HhdA of *Haemophilus ducreyi*

*H. ducreyi* causes the sexually transmitted disease chancroid. It adheres to and penetrates epithelial cells (Lagergard *et al*., 1993) and is cytotoxic for HEp-2 and HeLa cells. Ulcer formation depends on iron deficiency (Sturm, 1997). Adherence is manifested after 15 min and reaches a maximum after 2–3 h. Cytotoxicity is ascribed to a cell-associated cytotoxin (Alfa, 1992), which is a hemolysin, HhdA, with sequence similarity to ShlA (Palmer and Munson, 1995). HhdA enhances the invasiveness of the organism and thus contributes to virulence (Wood *et al*., 1999). A screening of 90 *H. ducreyi* isolates has revealed the prevalence of the hemolysin genes *hhdB/hhdA*. The secreted hemolysin is immunogenic in a rabbit and primate infection model (Dutro *et al*., 1999).

Attachment to epithelial cells is mediated by more than one mechanism. Proteinase K treatment, but not trypsinization of *H. ducreyi*, significantly reduces attachment, which suggests the involvement of proteins. It is thought that the first step in the pathogenesis of chancroid is the adherence of bacteria to epithelial cells, followed by the action of cytotoxin and further bacterial proliferation. It has been suggested that this sequence of events results in the production of genital ulcers by *H. ducreyi*.

### EthA of *Edwardsiella tarda*

*E. tarda* can penetrate and replicate in HEp-2 cells (Janda *et al*., 1991). In contrast to other bacteria that replicate in the cytoplasm, such as *Listeria monocytogenes* and *Shigella flexneri*, *E. tarda* does not appear to harness actin or engage in direct cell-to-cell spreading. Invasion depends on the presence of EthA, a hemolysin of the ShlA type (Strauss *et al*., 1997). Hemolysin production enhances HEp-2 cell invasion, and a hemolysin-negative mutant strain (Tn*5* insertion in *ethB*) enters HEp-2 cells two or three orders of magnitude less efficiently than the parental strain.

### PhlA of *Photorhabdus luminescens*

*P. luminescens* is an entomopathogenic bacterium symbiotically associated with nematodes. Recently, it has been shown that hemolytic activity is iron-regulated (Brillard *et al*., 2002) and that this activity is due to secretion of PhlA mediated by PhlB. However, in a comparison of the wild-type strain to a chromosomal *phlA* mutant, no difference in virulence in an insect infection model was observed (Brillard *et al*., 2002) and the *phlBA* promoter was active. The authors hypothesize a possible cytolytic activity of PhlA against insect hemocytes and cells to convert insect cadaver tissue into a source of nutrients.

## CONCLUSION

The *S. marcescens* hemolysin forms the prototype of a number of pore-forming cytotoxins. The cytotoxic activities and related virulence-enhancing activities have been shown for the *S. marcescens* hemolysin and the hemolysins of *P. mirabilis, E. tarda, P. luminescens,* and *H. ducreyi*. The hemolysins identified from the analyses of sequenced bacterial genomes of *Y. pestis, Y. enterocolitica, C. violaceum, X. fastidiosa,* and *Edwardsiella ictaluri* remain to be characterized. Open questions concern the mechanisms of secretion and activation of the hemolysins. The hemolysins seem to be secreted like the adhesins of the *B. pertussis* hemagglutinin type. Data on the secretion of the hemolysins and the hemagglutinins might complement each other and result in an understanding of the novel secretion mechanism.

CHAPTER

# 32

# Alpha-helix and beta-barrel pore-forming toxins (leucocidins, alpha-, gamma-, and delta-cytolysins) of *Staphylococcus aureus*

*Gilles Prévost, Lionel Mourey, Didier A. Colin, Henri Monteil, Mauro Dalla Serra, and Gianfranco Menestrina*

## INTRODUCTION

Among more than 40 peptidic toxins that can be secreted by *Staphylococcus aureus*, pore-forming toxins (PFT) constitute one of the most important groups besides staphylococcal superantigens (Prévost, 2005). This group of toxins is both diverse and multiple among those toxins secreted by this bacterium. This may bring an advantage towards the memory immune response that can be overcome by the simultaneous secretion of several antigenically related compounds bearing similar functions. Staphylococcal pore-forming toxins are divided into two subgroups comprised of those with alpha-helical structures and those rich in beta-strand sequences. Delta-hemolysin is one example of an alpha-helix structured toxin, while beta-sheet–rich PFT can be further divided into two subfamilies of a homo-oligomeric toxin, alpha-hemolysin and hetero-oligomeric bicomponent leucotoxins. Recent years have brought several structures' determinations to light, and further knowledge in their mechanism of action, roles in the pathogenicity by *in vivo* investigations, and molecular studies applied to intoxinated cells have also been the focus of numerous works. Perspectives of applications with beta-rich PFT are currently being explored. This review deals with the most recent findings with regards to these two groups of toxin.

## AN ALPHA-HELIX CYTOLYSIN PROTOTYPE: DELTA-HEMOLYSIN

The staphylococcal delta-hemolysin is 26 amino acid residues long, and forms a single amphiphilic α-helix that is supposed to associate in a lypical barrel-stave octamaric pore (Tappin *et al*., 1988; Dufourcq *et al*., 1999). This octamer has to cross the lipid bilayer to determine a pore by the space created by the monomers. Each monomer bears an amphipathic structure, which allows interaction with phospholipids while displaying a hydrophilic lumen inside the pore. Delta-hemolysin displays a very large blood cell spectrum and other cells, as well as membrane models, may also be lysed very actively. There is no evidence of pore formation into 1-palmitoyl, 1-2 oleoyl-sn-glycero-3-phosphocholine vesicles, whereas permeabilization of the vesicles concurrently occurs to the translocation of that toxin (Pokorny *et al*., 2002). In the latter case, formation of trimers was suggested. Some relatives of this toxin were characterized in other staphylococcal

species such as *Staphylococcus epidermidis*, *S. simulans*, *S. warneri*, and in bee venom. Delta-hemolysin is expressed at late exponential growth, and the corresponding encoded gene is included in that of the accessory gene regulator locus (Peng *et al*., 1988), whose expression depends essentially on the extracellular concentration of signal molecules, such as small peptides. The main question concerns the amounts of delta-toxin that a strain is able to produce while spreading to various cells. This level of expression, depending on that of a regulatory factor, may never be high. However, the lack of *agr* expression may lead to antibiotic resistance, but it is generally linked to a deficit in virulence (Sakoulas *et al*., 2002; Schwan *et al*., 2003), at least in some infections. To date, no investigation that only focused on the invalidation of the delta-hemolysin encoding gene has been reported.

## A BETA-BARREL PORE-FORMING TOXIN PROTOTYPE: ALPHA-HEMOLYSIN

### A mushroom-shaped structure of the pore

α-hemolysin or α-toxin (Smith and Price, 1938) is in fact not so much active upon human erythrocytes (HRBC) as the γ-hemolysin HlgA-HlgB is (Berheimer, 1974; Prévost *et al*., 1995). These two toxins are secreted by almost all *S. aureus* strains. Alpha-toxin harbors different hemolytic activities according to mammalian species and is particularly active on rabbit red blood cells (RRBC). This is a 293-amino-acid-long secreted protein that has an alkaline pH of 8.11, after the removal of the 26 residues' signal peptide (Gray and Kehoe, 1981). As other leukotoxins, it is secreted at the late exponential growth phase. But contrary to bicomponent leukotoxins, the secreted monomers may aggregate in solution or oligomerize as functional complexes in the presence of sodium deoxycholate (Bhakdi, 1981), independently of the temperature (4°–45°C) (Watanabe *et al*., 1987; Belmonte *et al*., 1986; Forti and Menestrina, 1989). This property was nicely exploited to determine the three-dimensional structure of the mushroom-shaped heptamer forming the pore in its lipostable form (Song *et al*., 1996). The heptameric oligomerization of α-toxin was confirmed by MALDI-TOF analysis of oligomers in solution and 2D-crystallization combined with atomic force microscopy (Vécsey-Sémjen, 1997; Gouaux *et al*., 1994; Malghani *et al*., 1999). However, hexamers can also be observed in certain phospholipid composition (Czajkowski *et al*., 1998). This mushroom structure has a height of 100 Å and a similar width at its cap domain that does not completely insert into the membrane (Figure 32.1). The stem is arranged as a β-barrel, which inserts into the membrane for about 50 Å. In fact, three protein domains can be distinguished in a given protomer extracted from the whole structure. The core of the protein (or Cap) gathers a β-sandwich of two to six antiparallel β-sheets that account for 55%

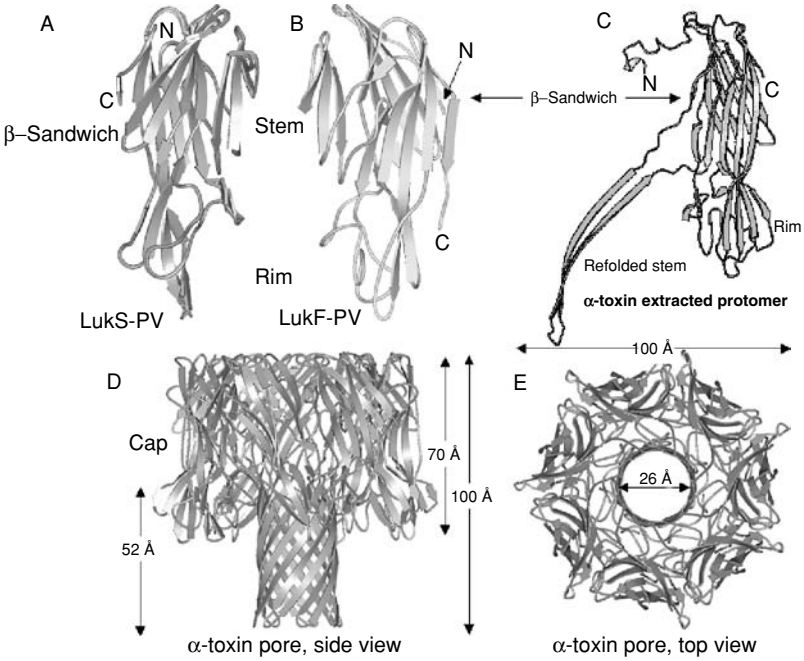

**FIGURE 32.1** Synthetic scheme of structures of LukS-PV (A), LukF-PV (B) with N- and C-terminal extremities mentioned, an α-toxin protomer (extracted from the structure of the oligomer) (C), the side view (D), and the top view (E) of the α-toxin.

of the total peptide sequence, and the rim that forms a four-stranded open-face β-sandwich and accounts for 28% of the peptide sequence. The third domain corresponds to the stem-central region that overlaps residues 109–150 and appears as a 65 Å long β-hairpin in the extracted protomer. The association of seven β-hairpins will form the β-barrel transmembrane pore whose diameter is 26 Å at its entry and which establishes after conformational changes consecutive to membrane interactions (Gouaux *et al*., 1997). The N-terminal extremity of the α-toxin is also extended and interacts with two adjacent monomers at the internal side of the pore mouth.

## Binding of α-toxin to membrane ligands

The interaction of α-toxin with RRBC was reported to be protease sensitive and consists of a high-affinity binding (Bhakdi and Tranum-Jensen, 1991), although it is able to form pores in pure lipid vesicles or may bind to some serum compounds at a lesser affinity (Bhakdi *et al*., 1983; Menestrina, 1986; Forti and Menestrina, 1989; Bhakdi and Tranum-Jensen, 1991). This toxin does not form a pore through the membrane of resistant cells, even if oligomerization may occur (Valeva *et al*., 1997). Moreover, it has a preference for synthetic bilayers constituted of choline-type phospholipids and cholesterol rather than other phospholipids (Freer *et al*., 1968) or sphingoglycolipids (Cheley *et al*., 1997). Recently, Pany *et al*. (2004) reported that residues from Trp179 to Trp187 of α-toxin bear a conserved pattern of binding to caveolin-1 from HyXHyXXXXHy/XXHy, where Hy is an aromatic residue. Purified caveolin-1 was able to dramatically reduce the α-toxin binding onto RRBC and its biological activity. Finally, a partition between high- and low-affinity membrane ligands cannot be excluded for such toxins because one of the intrinsic functions of PFTs is to interact with membranes.

## The α-toxin pore

When using synthetic membranes, the pore size and the conductivity of bulk solutions directly affect the conductance G that can be derived from the height of the current steps induced by the opening of pores: ($G = \sigma \,.\, \pi \,.\, r^2 \,/\, l$; where σ is the solution conductivity, and r and l are the radius and length of the pore, respectively). On the basis of electron microscopy data, the length of the pore was first estimated at 10 nm and the diameter at 1.1 nm (Menestrina, 1986), whereas a diameter of 2.7 nm was found using sugar exclusion methods (Krasilnikov *et al*., 1992; Bezrukov *et al*., 1996). In fact, the α-toxin pore is not a perfect cylinder, but rather a funnel with an entrance diameter of 2.8 nm, which decreases to a minimum diameter of 1.4 nm at the bottom of the stem (Song *et al*., 1996). Water molecules (Paula *et al*., 1999) and other non-electrolytes (Bashford *et al*., 1996) pass through these extrinsic pores, but the whole electrical field induced depends on charges at the entrance of the pores, which modify local concentrations for ions, and on secondary charges inside the course of the lumen, if any (Cescatti *et al*., 1991; Bezrukov *et al*., 1993). In the case of α-toxin, an anionic selectivity is essentially induced by charged residues that globally ensure an anionic filter: Asp45, Asn49, Lys51 (Song *et al*., 1996). In contrast, channels may select ions at their entrance and also inside their lumen (Doyle *et al*., 1998). This is not the case for pores formed by α-toxin. Therefore, the electrostatic filter provided by pores remains rather poor, but they well may be secondarily engineered. Conductance of pores may vary according to pH, applied voltage, or presence of divalent cations (Menestrina, 1986; Kasianowicz and Bezrukov, 1995; Menestrina and Vécsey-Sémjen, 1999). Although pore formation is quite an irreversible phenomenon, it is not sure whether or not the β-barrel could partially disassemble into a non-functional form because a low-conductance state representing 8% of the high-conductance was observed (Korchev *et al*., 1995a and b). Human fibroblasts have been observed to repair lesions caused by α-toxin (Valeva *et al*., 2000). This event was accompanied by a movement of residues oriented towards the lumen of the pore to a more lipophilic environment.

Besides residues involved in the interaction with membranes, some other residues like His35 form the interface between each monomer. Numerous substitutions of His35 have demonstrated its role in the oligomerization of α-toxin (Jursch *et al*., 1994; Menzies *et al*., 1994; Krishnasastry *et al*., 1994; Walker *et al*., 1995). Moreover, the concept of a prepore was demonstrated from the concurrent tests of oligomers' SDS-resistance and the modification of the environment of a single cysteine-substituting residue by using the environment-sensitive fluorophore acrylodan (Valeva *et al*., 1996). This prepore is in fact the result of multiple steps and a cooperative process in which the environment of residues located at the N-terminal extremity changes, as is the case for His35, for residues of the Rim, and especially for residues of the central domain (Valeva *et al*., 1996, 1997a, b, c). A periodicity of residues exposed either to the hydrophilic or to the hydrophobic compartments was found by using diazofluorene as a photoactivated probe (Lala and Raja, 1995). Residue 130 located at the extremity of the β-hairpin was demonstrated to be in a hydrophilic compartment by resonance energy transfer (Ward *et al*., 1994). Unfolding of the N-terminal extremity and of the stem domain are

associated and cooperative (Cheley *et al*., 1997). Interacting residues inside the oligomer were characterized by mutagenesis (Panchal and Bayley, 1995), and steps of the pore formation were tentatively arrested by artificial disulfide bond generation inside monomers (Kawate *et al*., 2003). These intricately conformational changes respond to a mechanism similar to the allosteric transition of an oligomeric enzyme, with the difference being that they are irreversible and cause minimal changes in the rest of the α-toxin structure (Valeva *et al*., 2001). The event mediating these concerted transitions remains to be defined.

## Target cells for α-toxin

Besides erythrocytes, α-toxin is active against a series of signaling cells such as T lymphocytes, platelets (Bhakdi *et al*., 1988), keratinocytes (Jonas *et al*., 1994; Walev *et al*., 1993), and fibroblasts (Walev *et al*. 1994), and other cells, such as PC12 (Fink *et al*., 1989), gastric (Thibodeau *et al*., 1994), chromaffin cells (Ahnert-Hilger *et al*., 1985), and endothelial lung cells (Seeger *et al*., 1990; Bhakdi *et al*., 1996). The activity of α-toxin onto rat aortic endothelial cells was shown to initiate a vasoconstriction through P-selectin, a surface protein also present in human PMNs, thus evoking that the interaction between the two kinds of cells is mediated by selectins (Buerke *et al*., 2002). IL-1 is secreted from α-toxin–treated monocytes, although these cells are not highly sensitive cells to lysis (Bhakdi *et al*., 1989). Alpha-toxin increases the arachidonic acid metabolism consecutive to the cell $Ca^{2+}$-activation, and generates prostacyclin, leukotriene secretions, and also nitric oxide from endothelial cells (Suttorp *et al*., 1985, 1987, 1993). Vascular leakage in perfused rabbit lungs was reported (Seeger *et al*., 1990). In a model of isolated perfused rat heart, α-toxin induced a liberation of thromboxane and prostacyclin that can be blocked by acetylsalicylic acid or indometacin (Sibelius *et al*., 2000). These features are associated with coronary vasoconstriction and loss of myocardial contractility, two symptoms that account for cardiac failures observed in cases of *S. aureus* septic shock. Simvastatin may act as an antagonist of the α-toxin–induced leucocyte-endothelial cell interaction (Pruefer *et al*., 2002). Similar cell inflammatory responses plus IL-8 expression were also confirmed in treated lung alveolar cells where NF-κB signal transduction seems to be involved (Rose *et al*., 2002).

## α-toxin and apoptosis

Some authors have suggested that apoptosis may be induced by α-toxin (Jonas *et al*., 1994), but the broad collection of data on that topic remains unclear. Such research can be aimed toward understanding what the cell effects of sublytic doses of toxin in the infection background are (Moreau *et al*., 1997). Thus, doses of toxin have to be thoroughly considered in these assays, as well as the purity and homogeneity of α-toxin. Granule-mediated cell killing by cytotoxic lymphocytes requires a functional membranolytic perforin and granule-associated serine proteases. Replacing perforin by α-toxin both in Jurkat and Yac-1 cells did not lead to apoptosis, probably meaning that pores were not effective for the entry of granzymes (Browne *et al*., 1999). The broad-spectrum caspase inhibitor, N-benzyloxycarbonyl-Val-Ala-Asp-fluoromethyl ketone, prevented necrosis, plasma membrane destruction, loss of mitochondrial membrane potential, IL-1 beta release (Bhakdi *et al*., 1999) and CD14 shedding induced by α-toxin in monocytic cells. This necrosis was concluded to be mediated by a cell death pathway through passive $K^+$ efflux and activation of caspase-like proteases (Warny *et al*., 1999). However, α-toxin was estimated to induce apoptosis in umbilical vein endothelial cells, since there was less DNA fragmentation induced by an α-toxin-deficient *S. aureus* mutated isolate (Menzies *et al*., 2000). *Staphylococcus aureus*-induced cell death and caspase activation are also mediated by α-toxin, and both events can be abrogated by specific antibodies and are not induced with supernatants of an α-toxin-deficient *S. aureus* strain (Bantel *et al*., 2001). The α-toxin induces caspase-8 activation in normal cells and in CD95-resistant Jurkat T cells lacking CD95, but not in cells stably expressing the anti-apoptotic protein Bcl-2, Fas-activated death domain. α-toxin induces the release of cytochrome C from intact cells and also from isolated mitochondria in a Bcl-2–controlled manner, thus demonstrating that *S. aureus* α-toxin triggers caspase activation via the intrinsic death pathway independently of death receptors. These findings suggested that a specific signaling pathway was used in *S. aureus*-induced cytotoxicity. Another study focused on mononuclear cells (MNC) evidenced that unlike Jurkat T cells, apoptosis was additionally mediated by a caspase-9-independent component (Haslinger *et al*., 2003). Monocytes, but not Jurkat T cells, produced the tumor necrosis factor TNF-alpha upon stimulation. Blocking that release with a TNF-alpha receptor antagonist partially decreased apoptosis. Thus, whereas in Jurkat T cells apoptosis is solely mediated by the mitochondrial pathway, in MNC endogenous TNF-alpha and a death receptor-dependent pathway seemed to be involved, which may contribute to the depletion of immune cells during an *S. aureus* infection. However, recent data obtained in Jurkat T cells suggest that α-toxin-induced cell death remains independent from caspase activation and internucleosomal DNA fragmentation and from their

respective inhibition (Essmann *et al*., 2003). Caspase inhibition had no effect on both the α-toxin-induced lactate dehydrogenase release and the ATP depletion. Electron microscopy demonstrated that in the presence of active caspases, α-toxin–treated cells displayed a necrotic morphology characterized by cell swelling and cytoplasmic vacuolation, and once again the α-toxin-induced cell death was suggested to operate in a caspase-independent, necrotic-like manner.

## STAPHYLOCOCCAL BICOMPONENT LEUKOTOXINS

Staphylococcal bicomponent leukotoxins (Woodin *et al*., 1959; Prévost *et al*., 1995c, 1999) represent a subgroup among PFT that operates via two distinct proteins, a class S (31 kDa) and a class F protein (34 kDa) that are necessary to create bipartite oligomeric pores into monocytes (M), macrophages (MΦ), and polymorphonuclear cells (PMN) membrane, which are common denominator targets (Table 32.1, Figure 32.2). The genes are tandemly arranged and co-transcribed: the gene encoding an S protein being upstream to that encoding an F protein and only separated by a thymine. But any class S protein may give a specific leukotoxin when combined with a class F protein (Szmigielski *et al*. 1998; Prévost, 1999). These temperature sensitive proteins are quite soluble (> 20 mg/mL), depending on pH and ionic strength, and they have basic isoelectric points comprised between 7.4 and 9.9 (Prévost, 1999). The S protein always binds first to membranes, then allowing the secondary interaction of an F protein before the oligomerization and the formation of the pores (Colin *et al*., 1994). Thus, proteins are cited in the same order, S then F, to evoke a leukotoxin. There is only limited sequence identity (< 25%) among S and F proteins and α-toxin, but these are much more homologous, especially into the central domain forming the pore (Figure 32.3). Homologues also include β-toxin from *Clostridium perfringens* (Hunter *et al*., 1993), and CytK and HlyII from *Bacillus cereus* (Baida *et al*., 1999; Lund *et al*., 2000; Menestrina *et al*., 2001), and the transmembrane domain of several other PFTs. There are several loci characterized, but any combinations of a class S protein with a class F protein may give a new leukotoxin. These loci are diversely encountered in clinical isolates and may be linked to different clinical diseases (Prévost *et al*., 2003). Before their mode of action is reviewed, these toxins will be individually considered.

### Panton-Valentine leucocidin (PVL)

PVL is formed by LukS-PV and LukF-PV (Woodin *et al*., 1960). Its secretion has been associated with furuncles (Cribier *et al*., 1992; Couppié *et al*., 1994). PVL-producing strains also may be isolated from respiratory tract infections (Prévost *et al*., 1995b; Couppié *et al*., 1997; Baba Moussa *et al*., 1999a; Lina *et al*., 2001; Gillet *et al*., 2002) with a "probable" greater frequency depending on sanitary conditions. In the past, occurrence of furuncles was

known to potentially evolve into septicemia, and bullous pneumonia of young children was clinically linked with frequent furuncles in patients or in their family. However, albeit rare, these community pneumonia are severe and often affect young adults as primitive or as secondary infections of influenza (van der Flier *et al*., 2003). The result of these infections is the necrosis of tissues and the eventual spreading of the bacteria. The occurrence of PVL-producing strains does not exceed 2–5% among human routine clinical isolates (Prévost *et al*., 1995b). The gene encoding PVL is located inside a bacteriophage (Kaneko *et al*., 1998; Narita *et al*., 2001). But the recent emergence of methicillin-resistant strains (MRSA) producing this toxin may confer an increased morbid risk and necessitates careful therapeutic attitudes (Vandenesch *et al*., 2003; Liassine *et al*., 2004). Such strains may be the result of the spreading of the PVL locus-carrying prophage after

the removal of insertion sequences inside its genome, or of the mutation of the penicillin-binding protein 2a. PVL has a narrow specificity towards M, MΦ, and PMNs of humans and rabbits (Figure 32.2). In fact, it is active upon metamyelocyte and its lineage (Meunier *et al*., 1995). When interdermally injected in the rabbit skin, PVL is responsible for dermonecrotic lesions (Ward and Turner, 1980).

## Gamma-hemolysin

This ancient name that originates with a hemolytic activity operating on sheep, rabbit, horse, and human erythrocytes in fact gathers two distinct toxins, HlgA-HlgB and HlgC-HlgB (Smith and Price, 1938; Bernheimer, 1994; Guyonnet and Plommet, 1968; Cooney *et al*., 1993; Kamio *et al*., 1993; Prévost *et al*., 1995c). The first one has a broad range of target cells, including human T lymphocytes and erythrocytes (Figure 32.2), while HlgC-HlgB does not lyse T lymphocytes and is less active onto human erythrocytes (Prévost *et al*., 2001; Gauduchon *et al*., 2001). Of all known leukotoxins, HlgA-HlgB has the most potent efficacy on synthetic bilayers (PC:Cho, 1:1) (Ferreras *et al*., 1998). That toxin is secreted by almost all isolates, and an *hlg* deficient strain was shown to induce a slower growth, thus lowering inflammation in a rabbit endophtalmitis model (Supersac *et al*., 1996).

## LukE-LukD leukotoxin

This toxin was previously identified in the Newman strain (NTCC 8178) because of a residual leukotoxic activity in the culture supernatant of a *hla::tet, hlg::erm* double mutant, which does not secrete PVL (Gravet *et al*., 1998). It is located between a restriction-modification system *hsdS-hsdM* (Kuroda *et al*., 2001) and the hemine (*hem*) operon (von Eiff *et al*., 1997). It is produced by about one-third of the isolates, and a variant was characterized (Morinaga *et al*., 2003). In fact, more than 70% of isolates carry the corresponding encoding locus, and because of numerous mutations rendering these genes non-functional, this toxin should not be detected by genotyping tests (G. Prévost, personal communication). The production of LukE-LukD may occur both in methicillin-sensitive and -resistant strains. It is active upon human T lymphocytes in addition to PMN. The secreting isolates may be issued with a great probability from staphylococcal bullous impetigo where epidermolysin is also produced (Gravet *et al*., 2001) and from *S. aureus* antibiotic-associated diarrhea where enterotoxin (EntA > EntC > EntD) production also occurs (Gravet *et al*., 1999). These diarrhea affect aged patients (>65 years old) having undergone an antimicrobial therapy, often comprising a second-generation fluoroquinolone. LukE-LukD might enhance inflammation, at least in the tissues concerned by clinical associations. A bad prognosis can be encountered to the latter diarrhea with a significant risk of bacteremia, but an anti-staphylococci dedicated treatment can eradicate the infection, as well as stopping the treatment when possible. When injected in ligated ileal loops of rabbits, enterotoxin A and LukE-LukD generate a huge accumulation of bloody fluid inside the loop within 12 hours, which is associated with the degradation of intestinal microvillosities (Gravet, 2001).

## LukM-LukF-PV like

This leukotoxin has only been reported to be produced by animal strains isolated from bovine, ewe, and goat mastitis (Kaneko *et al*. 1997). It is distinct from PVL antigenically and by its biological activity (Gravet *et al*., 1998; Rainard *et al*., 2003). Its encoding operon is located onto a specific bacteriophage genome (Zou *et al*., 2000).

## LukS-I-LukF-I

The gene encoding LukS-I-LukF-I is expressed in probably all *S. intermedius* isolates (Prévost *et al*., 1995a). The presence of such a toxin into another bacterial species reveals the possible transfer and evolution of the genetic information for these toxins. That leukotoxin is active upon PMN and dendritic cells. *S. intermedius* is considered as a skin pathogen for small carnivores.

## Three-dimensional structures of soluble leukotoxin monomers

The structures of HlgB (Olson *et al*., 1999; PDB: 1LKF), LukF-PV (Pédelacq *et al*., 1999; PDB: 1PVL), and LukS-PV (Guillet *et al*., 2004a and b; PDB: 1T5R) have been successively determined by x-ray crystallography (Figure 23.1). These structures evidence the relation between bicomponent leukotoxins and α-toxin (Song *et al*., 1996; PDB: 7AHL), favoring the hypothesis of a common ancestor, with some differences probably sustaining the specifications of all these toxins. Compared to the α-toxin structure, those of the leukotoxin component revealed the necessary conformational modification of their central domains, folded as three β-strands at the hydrosoluble state into a long protruding, lipid-stabilized β-hairpin. The fold of the pore-forming leukotoxins superfamily shows a high content of β-strands defining a class of structurally related toxins with an ellipsoid shape. The largest domain gathers more than half of the sequences in two

six β-stranded antiparallel β-sheets that, after association of monomers, will form part of the cap domain of the mushroom-shaped heptameric pore (Song *et al*. 1996). The rim domain of these proteins that forms the bottom of the cap is composed of a four-stranded open-face β-sandwich, two helical structures, and two omega-loops whose arrangement varies according to the proteins. The three-dimensional structures of the highly homologous class F proteins, LukF-PV and HlgB (72% sequence identity), are similar, and only connecting loops of the rim and at the COOH-terminus display minor differences due to sequence variability. For a complete superimposition of the core and the rim domains of HlgB (or LukF-PV) to those of α-toxin, a rotation of about 10 degrees is necessary. The rim domains with exposed loops structures interact with the membrane, and some amino acids may be anchored in a lipid environment (Valeva *et al*., 1997a; Vécsey-Sémjen *et al*., 1997). It is evident that the organization of the rim domains in all known three-dimensional structures is not identical (see Figure 32.4).

## Binding properties of the bicomponent leukotoxins

In the circulating blood, it is not excluded that leukotoxins bind to soluble proteins, despite having low affinity (Katsumi *et al*., 1999). α-toxin and HlgB were co-crystallized with PC and LukF-PV with MES buffer, which shares part of its molecular skeleton with PC. In the structures of LukF-PV in HlgB and α-toxin, the conserved amino acids Trp176, Arg198, Tyr179, Glu191, and Arg197 delineate a crevice where Trp176 and Arg197 interact with PC (Figure 32.4). However, Pany *et al*. (2004) recently showed the interaction of caveolin-1 with a peptide motif of α-toxin including aromatic residues HyXXHyXXXXHy, which encompasses the first two amino acids of this binding site, and a dual binding in these proteins remains questionable. Caveolin-1 is normally absent at the trans side of human PMNs.

Phorbol myristyl-acetate positively activates protein kinase C pathway. Gauduchon *et al*. (2001) evidenced that this molecule negatively affects the binding of LukS-PV to humans PMN, whereas its inhibitor staurosporine restores this binding. The number of binding sites is about 197,000 for LukS-PV with an apparent $K_d$ around 0.07 nM, and an apparent $K_d$ for LukF-PV approaching 2 nM. LukS-PV and HlgC may compete at the same binding site, but not with HlgA or LukE. However, HlgA-HlgB is the leukotoxin having the greatest activity on synthetic bilayers (Meunier *et al*., 1997). Thus, these observations suggest that binding of at least some leukotoxins can be influenced by the presence of some receptors at the cell surface.

## Prepore-pore formation and calcium entry

Rapidly after the application of leukotoxins to human PMN and with the presence of physiological concentrations of $Ca^{2+}$, $Ca^{2+}$ enters the cells and gives rise to fluorescent probes (Fink-Barbançon *et al*., 1993; Colin *et al*., 1994). This entry of $Ca^{2+}$ has been shown to be inhibited by ethylene-glycol tetra-acetate, while the entry of ethidium is maintained. Moreover, drugs such as econazole or $La^{3+}$ also selectively inhibit this $Ca^{2+}$ influx (Staali *et al*., 1998). Other modifications of the stem domain, such as mutations or deletions, may result in the uncoupling of the two phenomenons (Baba Moussa *et al*., 1999; Werner *et al*., 2002). Finally, linking the central domain to the β-sandwich domain by two disulfide bridges in a state avoiding its unfolding into the β-hairpin abolishes pore formation and dramatically inhibits the entry of ethidium, but preserves that of $Ca^{2+}$ (Nguyen *et al*., 2002). Thus, the

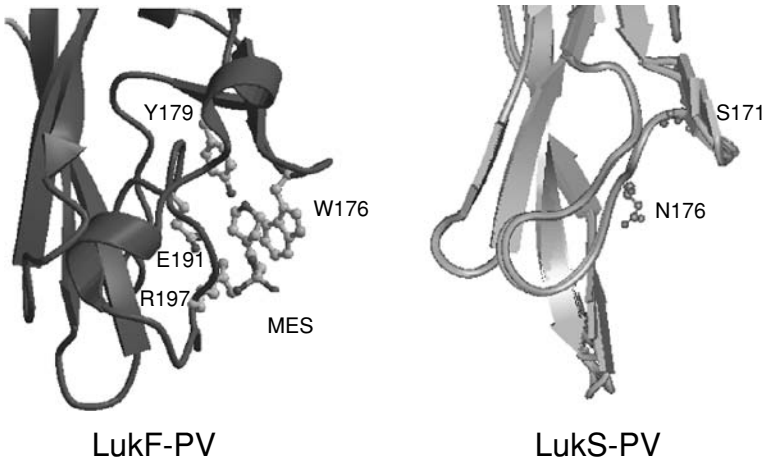

**FIGURE 32.4** Differences in the molecular architures of the rim domains of LukF-PV and LukS-PV. LukF-PV was co-crystallized with MES. HlgB and α-toxin were co-crystallized with phosphatidyl-choline (PC). MES and PC partially have similar molecular skeletons.

entry of $Ca^{2+}$ using other structures than the pores was strongly suggested.

The stoichiometry of the pore has been studied using different techniques, which leads to different results. First, kinetics of component associations strongly suggested an equal number of S and F protomes, and oligomers of an apparent molecular mass of 200 kDa were identified both onto PC-Cho small unilamellar vesicles and on PMN by SDS-PAGE on non-boiled samples (Ferreras *et al*., 1998; Werner *et al*., 2001). It has been shown that oligomers identified are immunologically reactive to both anti-S and anti-F antibodies. Therefore, due to the 4 kDa difference in the molecular mass of the two proteins, the formation of single protein homo-oligomers can be excluded. Moreover, Miles *et al*. (2002) constructed derivatives of HlgC and HlgB with C-terminal peptide tails that conserved the initial biological properties of leukotoxins. Then, non-boiled samples were applied to SDS-PAGE, and different ratios of the wild type toxins and mutants evidenced oligomers of different apparent masses, which were in favor of the formation octamers. Furthermore, the substitution into cysteine of residues located at the mouth of the lumen in each of the two proteins evidenced a four-step current modification when these residues reacted with the (2-sulfonaethyl) methane-thiosulfonate reagent, thus again suggesting octamers. However, Nguyen *et al*. (2003) suggested the formation of hexamers by using electron microscopy.

Moreover, Nguyen *et al*. (2002) showed that the combination of HlgA with an engineered HlgB, where the central domain was constrained to the protein core by a disulfide bridge, abolished pore formation but not the calcium entry, and that some kind of prepore was formed. Another fundamental difference in the structures of leukotoxin components (Pédelacq *et al*., 1999; Guillet *et al*., 2004b) with respect to that of α-toxin resides in the orientation of the N-terminal extremity. Whereas the N terminus is stacked to the upper part of the β-sandwich core in leucotoxins soluble monomers, it is deployed and interacts with two adjacent monomers at the entry of the pore lumen of the assembled α-toxin. Glutathion S-transferase fusion of S or F components at the N-termini keep significant biological activity. The sequence of the LukS-PV N-terminus remains seven residues shorter than that of LukF-PV. Thus, the interaction of the N-termini of bicomponent leukotoxins at the mouth of the lumen with adjacent monomers remains to be demonstrated. Also, the mode of accumulation of each type of monomer remains to be determined:

- Does the pre-location of several class S proteins determine the further interaction of class F proteins?
- Is the binding of one class S protein sufficient to assess further addition of S and F proteins?

## Bicomponent leucotoxins pore

After the assembly of monomers, the three-stranded central domains will unfold and edify the β-barrel transmembrane pore by a yet undefined mechanism. Pore formation is delayed to the activation and involves both class S and class F proteins. The diameter of the pore was suggested to be 19–21 Å by Sugawara *et al*. (1997, 2002) by using electron microscopy, while Baba Moussa *et al*. (1999) found a similar value by evaluating the exclusion of polyethylene glycols from the HlgA-HlgB pore, since molecules larger than 1,000 Da were excluded. Osmotic protection performed either with polyethylene glycols or sugars gave different values; they were homogenous when comparing the different bicomponent leukotoxins (Menestrina *et al*., 2003). Values for leukotoxins are about 10% higher than those for α-toxin. This may be due to a difference in the stoichiometry or to differently distributed charges inside the pore lumen. Leukotoxin pores are more sensitive to monovalent cations, and their opening disrupts the $Na^+/K^+$ gradient from the *trans* and *cis* sides of the membranes. Miles *et al*. (2001) showed that the conductance of the HlgC-HlgB pore was higher than that of α-toxin (190 pS vs 90 pS in 0.1 M NaCl, and 2.5 nS vs 0.775 nS in 1M NaCl), indicating divergences between these pores. Indeed, the selectivity of the α-toxin pore is rather anionic (Figure 32.5). Differences of charges pointing inside the pore lumen and the effect of their combinations have been emphasized by a mutagenesis approach (Comai *et al*., 2002). Whereas positive charges are found at the mouth of the α-toxin pore (Asp45, Asn49, Lys51), they are negative for leukotoxins (Asp43, Asp47, or Asn, Asp49). Indeed, when including positive charges at the mouth of HlgA-HlgB, selectivity became comparable to α-toxin. Other differences are also encountered in the pore lumen where negative charges are found in bicomponent leucotoxins that may not be compensated in the case of the HlgC-HlgB pore. By residue substitution, it has been possible to generate a HlgA-HlgB pore with a conductance selectivity similar to that of HlgC-HlgB.

## Bicomponent leukotoxins and cell response

Staphylococcal leukotoxins have been suggested to induce numerous cell responses that may be related with the $Ca^{2+}$ activation (Wang *et al*., 1990). They are able to induce leukotriene B4 and IL-8 secretion (Hensler *et al*., 1994a) and their expression (König *et al*., 1994). These two molecules are involved in leukocytes' recruitment (Figure 32.5). Histamine, which is respon-

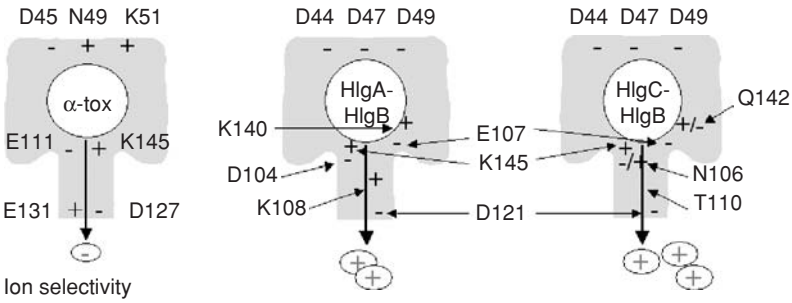

**FIGURE 32.5** Schematic representations of the pores formed by α-toxin, HlgA-HlgB, and HlgC-HlgB the hemolysins with charged residues solely or not that point inside the pore lumen, and the ionic selectivities associated.

sible for vasodilatation, is also produced (König *et al*., 1995). Control of the oxydative burst from human PMNs is also involved in inflammation (Colin *et al*., 2003) (Figure 32.6). Numerous cell pathways leading to IL-6, IL-12 secretion, and enzymes' secretion were shown to be involved (König *et al*., 1995, 1997; Prévost *et al*., 2003), but variations exist according to leukotoxins (König *et al*., 1997). Small GTP-binding proteins (Hensler *et al*., 1994b) were suggested to take part in cell activation, and leukotoxins might also induce apoptosis (Köller *et al*., 1993). Of course, cell lysis may, after activation, enhance mediators' liberation. These features are consistent with leukocyte recruitment, vasodilatation, and cell invasion and tissue necrosis observed in furuncles (Cribier *et al*., 1992) and in *S. aureus* community-acquired pneumonia (Couppié *et al*., 1997). The intradermal injection of PVL resulted in necrotizing lesions in rabbit skin (Cribier *et al*., 1992), but not in mouse skin, which suggests that the murine model may not be suitable.

## STAPHYLOCOCCAL PORE-FORMING TOXINS CHALLENGED IN PATHOGENESIS

Mutated strains with an α-toxin allelic replacement demonstrated the probable importance of this toxin in the course of infections, particularly in peritonitis (O'Reilly *et al*., 1986; Patel *et al*., 1987), mastitis (Bramley *et al*., 1989), arthritis (Nilsson *et al*., 1999),

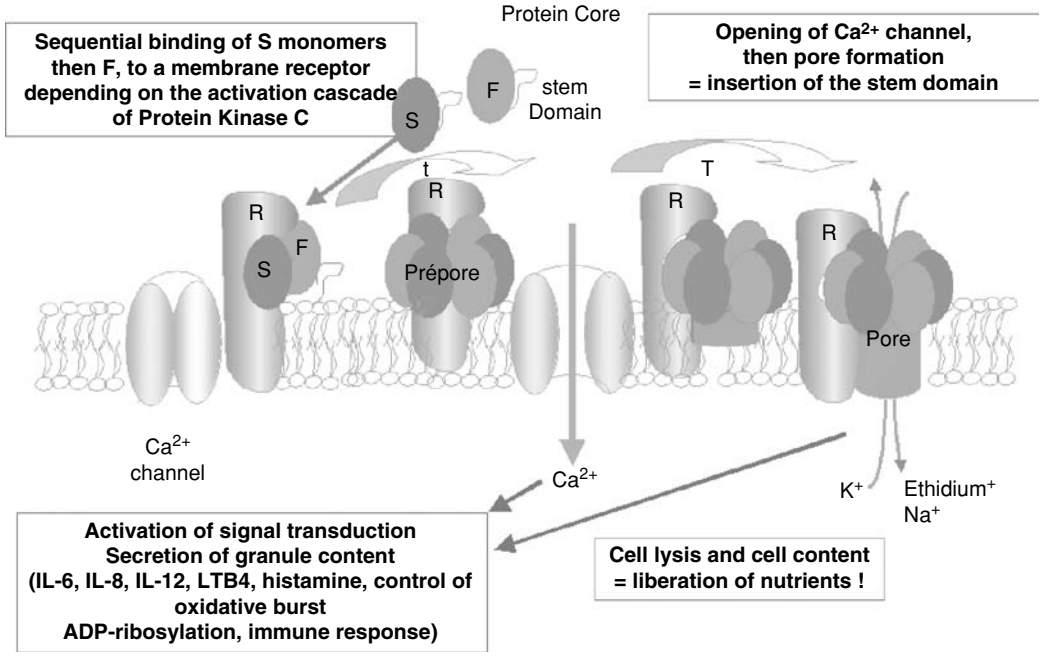

**FIGURE 32.6** Synthetic scheme of the mode of action of the staphylococcal bicomponent leucotoxins

corneal keratitis (O'Callaghan *et al*., 2003), and pneumonia (McElroy, 1999). Alpha-toxin is able to originate corneal disease in rabbits (O'Callaghan *et al*., 1997), and immunization against α-toxin reduced this damage, despite keeping the bacteria alive (Hume *et al*., 2000). Mutated Newman strains (NTCC 8178) for α-toxin or gamma-hemolysin genes produced infections with less dramatic lesions than those observed with the wild-type strain (Dajcs *et al*., 2002a). Finally, a deeper comparison between isogenic strains suggested that α-toxin and to a lesser extent γ–hemolysin may play a major role in the tissue destruction observed in keratitis (Dajcs *et al*., 2002b). These studies were focused on toxins whose genes were conserved in the *S. aureus* genome. Siqueira *et al.* (1997) compared the pro-inflammatory potential of bipartite leucotoxins in the posterior chamber of the rabbit eye. They observed that these toxins induce a considerable inflammatory reaction that may extend toward the anterior chamber and the entire eyeball, depending on the dose. In fact, the different S and F components can be combined to generate more leukotoxins than those which could be represented by the encoding genes. These combinations may generate a disease simulating endophthalmitis. This phenomenon might provide the advantage of escaping the humoral immune defense. When injected in ligated ileal loops of rabbits, enterotoxin A and LukE-LukD generate within 12 hours a huge accumulation of bloody fluid inside the loop associated with the degradation of intestinal microvillosities (Gravet, PhD thesis, 2001). In another approach, Schwan *et al*. (2003) isolated from a signature-tagged mutagenesis library *agr*C and *agr*A (assessory gene regulators C and A) defective mutants that allowed similar survival in a model of murine abscess. Moreover, an α-toxin defective mutant induced the same survival level as for the two *agr* genes' mutants. The *agr* mutated strains were not hemolytic, and most of the exoproteins were repressed. These authors suggested a potential role of α- and δ-toxins contributing to wound progress. However, no statement was developed about γ-hemolysin, which are hemolytic for a wide series of mammals and whose expression remains sensitive to *agr* loss. Often, the toxin genotype of the considered isolates remains unknown, some isolates may directly be issued from clinics, and the role of other virulence factors is difficult to exclude. Besides these observations, few authors checked for the effective expression of α-toxin or other virulence factors in the conditions of an infection where the inoculum was not huge. In a *S. aureus* infective endophthalmitis model, leucotoxins were shown to be expressed very early in the infection context, and the *agr* regulation was not implied at bacterial densities around $10^6$ CFU/mL (Bronner *et al*., 2003), contrary to *in vitro* conditions (Bronner *et al*., 2000). Proteomic investigations, rather than gene expression analysis, provided a better analysis of the effective and concerted production of virulence factors.

## APPLICATIONS AND ENGINEERED PORE-FORMING TOXINS IN PERSPECTIVE

Pore formation and the rupture in the ionic equilibrium of the cells led to the use of α-toxin to study cell response cascades or exocytosis (Anhert-Gilger *et al*., 1985; Bhakdi *et al*., 1993). Integration of the pore in an electrical circuit offers a model to study currents of low frequencies (30–120 Hz) (Misakian *et al*., 2002), according to the bulk pH and ionic strength (Kasianowicz *et al*., 2003). In fact, diverse small molecules (< 2000 Da) pass through the α-toxin pore, and the use of detectable tagged molecules with other analytes that can act as competitors allows quantification of these analytes (Kasianowicz *et al*., 2001).

Nucleic acid molecules (single-stranded DNA or RNA) traverse the α-toxin pore (Kasianowicz *et al*., 1996), and their microsecond time-scale transfer through the pore affects its electrical properties, so that event has been modeled with precision on experimental basis (Akeson *et al*., 1999; Hendrickson *et al*., 2000; Kasianowicz *et al*., 2001, 2002, 2004; Kong *et al*., 2002, 2004). Such studies are consistent with further applications using cell transfection and/or DNA-DNA recombination in isolated cells.

Because the β-stranded pore-forming toxins offer some structural robustness, modified toxins have been engineered and also tested in different fields. A modified α-toxin with an HisX5-tag produced a switch where pore activity can be (i) turned off by micromolar concentrations of divalent zinc ions and (ii) turned back on with the chelating agent EDTA (Walker *et al*., 1994). Such a switch was also shown to be operational to generate a limited number of pores for osmo-protection of cells with trehalose flowing in the pore, and it results in a significant yield of viable cells after thawing or anhydrobiosis (Russo *et al*., 1997; Eroglu *et al*., 2000; Chen *et al*., 2001). Trehalose, a non-toxic disaccharide, was used to enter some cell lines, and intracellular concentrations up to 0.5 M were reached and resulted in an appreciable yield of viable cells after thawing or anyhydrobiosis (Acker *et al*., 2003; Buchanan *et al*., 2004). $His_{5-}$ and $His_{4-}$ actuated switch-

able pores or mixtures of heteropores with the wild-type protein were also investigated for their sensing properties towards a series of divalent cations ($Zn^{2+}$, $Co^{2+}$, $Ni^{2+}$, $Cd^{2+}$, $Cu^{2+}$) (Braha *et al*., 1997, 2000). The α-toxin pore has also been modified with 7 or 14 arginine residues pointing within the lumen, either of which can interact with β-cyclodextrin molecules, which in turn may block the pore (Cheley *et al*., 2002) or reverse the ionic selectivity (Gu *et al*., 2000). Exploration of biosensing has also been investigated toward the detection of organic molecules, such as olfactive or explosive compounds (Gu *et al*., 1999, 2001; Shin *et al*., 2002), and phosphate oxyanions, such as inositol triphosphate IP3 (Cheley *et al*., 2002). Specific tethered adapters can also be installed within the pore lumen so that the recognition of proteins (Movileanu *et al*., 2000; Howorka *et al*., 2004) or nucleic acid (Howorka *et al*., 2001a and b, 2002; Sanchez-Quesada *et al*., 2004) ligand blocks the pore function, giving again a specific electrical signature.

## CONCLUSION

The family of pore-forming toxins secreted by *Staphylococcus aureus* illustrates the incredible diversification of toxic compounds encountered in this bacteria. The different beta-barrel PFTs provide biological activity toward the wide variety of human blood cells, and several encoding genes can be genetically maintained in a single isolate, thus enhancing the leucotoxin combinations. This variety might constitute a benefit to the bacteria to escape the immune memory by the preservation of the biological activity of certain toxins at least. These toxins certainly constitute interesting tools for the bacteria to acquire the bulk of nutrients after cell lysis. The generation of cell ghosts constitute another pitfall for the cytotoxic immune response, physically and by the burst of inflammatory mediators contained in activated but lysed cells. With these qualities, beta-barrel PFTs represent interesting targets that can be targeted for the control infections. On this fundamental aspect, α-toxin and leukotoxins illustrate how complex the transition between a hydrosoluble state and the oligomeric and lipostabilized state is and, despite the fact that they operate similarly, several elements remain to be understood as the molecular targets of toxins, the association process of the constitutive proteins, and rules that define the robustness of oligomers. Nevertheless, their molecular architecture has proven the possibility of modification in order to control their ionic selectivity and their development as biosensors for a wide variety of molecules.

## ACKNOWLEDGMENTS

This review is dedicated to the memory of our regretted friend, and nice researcher, Gianfranco Menestrina (d. 2004).

CHAPTER

# 33

# Aerolysin and related *Aeromonas* toxins

*Laure Gurcel, Ioan Iacovache, and F. Gisou van der Goot*

## INTRODUCTION

As contributors to their virulence, many pathogenic bacteria produce protein toxins. The largest class of these is composed by the pore-forming toxins (PFTs), which make up some 25% of all toxins. Some bacteria produce PFTs directed towards other bacteria, such as colicin producing *E. coli*. Most bacteria, however, produce PFTs directed towards eucaryotic host cells. These latter toxins share a similar mode of action despite their lack of sequence homology. The toxin is produced in a water-soluble form that may or not require proteolytic processing. The toxin then diffuses towards the target cell with which it binds with high affinity via the interaction with a receptor, which can either be a protein, a lipid, or a carbohydrate moiety. Cell surface concentration of the toxin promotes oligomerization into a ring-like structure that subsequently inserts into the membrane and forms a pore. Production of PFTs is common to Gram-positive and Gram-negative bacteria and is a phenomenon also found in parasites.

One member of this large family of PFTs is aerolysin produced by *Aeromonas* species. *Aeromonas* species are Gram-negative bacteria found in fresh water environments throughout the world (Austin *et al*., 1996). Members of the genus are pathogenic to many species, including amphibians, fish, reptiles, and humans and are a major source of economic losses in aquaculture (Altwegg and Geiss, 1989). In humans, *Aeromonas* spp., including *A. hydrophila, A. caviae, A. veronii biovar sobria, A. sobria, A. jandaei*, and *A. veronii biovar veronii,* have been involved in wound infections, sepsis, outbreaks of water- and food-borne gastroenteritis (Kirov, 1997; Janda and Abbott, 1998), and is an emerging pathogen in immuno-compromised hosts. Analysis of poultry, fish, and shrimp has indicated that more than 50% of commercial raw food samples and 20–30% of processed and ready-to-eat food samples contained *Aeromonas* species (Kingombe *et al*., 1999). In addition to commercial food, a recent study showed that fish caught off the Indian coast were frequently (37% of the isolates) contaminated with *A. hydrophila*, which were not only hemolytic but also multiple resistant to antibiotics (Thayumanavan *et al*., 2003).

Among the variety of potential virulence factors produced by *Aeromonas* spp., aerolysin has been considered the most important toxin, as illustrated by the facts that aerolysin is lethal to mice (Chopra *et al*., 2000), that immunization against the toxin leads to protection towards the bacterium, and that aerolysin-deficient strains are significantly less toxic than the parental strain in a mouse model (Chakraborty *et al*., 1987).

There is an ongoing debate regarding the nomenclature of this toxin. Very similar aerolysin-like molecules have been named: small beta, Greek-hemolysin, cytolytic enterotoxin, Act, and aerolysin. However, given their similarities in sequence (Figure 33.1), origin, and function, the common name aerolysin will be used throughout this chapter.

## PRODUCTION, PURIFICATION, AND PRIMARY STRUCTURE

Aerolysin from *A. hydrophila* was first discovered and partially purified by Bernheimer and Avigad (Bernheimer *et al*., 1975) and then purified to homogeneity by Buckley and co-workers (Buckley *et al*., 1981). A number of aerolysin genes were cloned and sequenced for different species, including two from *A. hydrophila* (aerolysin, SwissProt entry P09167) (Howard and Buckley, 1986; Howard *et al*., 1987) and Act Q44063 (Chopra *et al*., 1993), one from *A. punctata* (Wang *et al*., 1996) (P94128), *A. trota* (Khan *et al*., 1998) (O85370), and *A. sobria* (Q8GCZ4)(Fujii *et al*., 1998), showing a very high degree of sequence identity at the protein level (Figure 33.1). Interestingly, aerolysin related toxins were also found in a Gram-positive bacterium, *Clostridium septicum* α-toxin (Gordon *et al*., 1997) (Figure 33.1) and in a plant seed enterolobin, (Sousa *et al*., 1994) (Figure 33.1), indicating that the gene crossed not only the Gram-positive/Gram-negative barrier, but also that barrier between prokaryotes and eucaryotes.

Production of high amounts of aerolysin was made possible by expressing the gene in low protease, producing *A. salmonicida* strains allowing purification, using a two-step chromatography of the precursor protein, proaerolysin, from the bacterial supernatant (Buckley, 1990; Chopra *et al*., 2000). Proaerolysin can also be produced in *E. coli* using vectors that allow expression of the protein in the periplasm of the bacterium—to allow disulfide bond formation (see below)—with a C-terminal histidine tag and purification with nickel columns (Tsitrin *et al*., 2002).

## STRUCTURE OF PROAEROLYSIN

The toxin is synthesized as a pre-proaerolysin, with an N-terminal signal sequence that directs it to translocation across the inner bacterial membrane and a C-terminal precursor peptide. The signal sequence is removed upon translocation and the precursor, proaerolysin, is then secreted to the extracellular medium. Proaerolysin is a 470 amino acid long chain, with a molecular mass of approx. 52,000 Da and no hydrophobic stretches, in contrast to most membrane-spanning proteins. When the sequence was obtained, this observation led to the prediction that aerolysin would not cross the membrane as hydrophobic α-helices, but rather as a β-barrel, as do bacterial outer-membrane porins (Weiss *et al*., 1990).

This prediction was supported by the X-ray structure of proaerolysin (Parker *et al*., 1994) (Figure 33.2), which revealed a protein rich in β-structure with little α-helical structure in agreement with circular dichroism data (42% β and 21% α structure) (van der Goot *et al*., 1992). The protein was found to be an L-shaped molecule, divided into a small N-terminal lobe (domain 1) and a large lobe, composed of three additional domains. Two disulfide bonds (C19–C75 in domain 1 and C159–C164 in domain 2) were predicted by the structure, and confirmed experimentally, that stabilize the toxin and protect the 154–167 loop from proteolysis (Lesieur *et al*., 1999).

Proaerolysin crystallized as a head to tail dimer, not surprisingly since dimers can be found in solution (van der Goot *et al*., 1993a; Barry *et al*., 2001) at toxin concentrations above 0.1 mg/ml (Fivaz *et al*., 1999). Dimerization involves a domain-swapping interaction between domain 1 of one monomer and the large lobe of the adjacent monomer. It is not yet clear why dimerization occurs, but presumably it confers stability to the protein or reduces its sensitivity to proteases. Another possibility is that dimerization is required for the secretion of proaerolysin by the bacterium (see below).

Domain 1, the only domain that is continuous in sequence (residues 1–82) plays an important role in receptor binding (through residues Trp-45, Ile-47, Met-57, and Lys-66; Figure 33.2) (MacKenzie *et al*., 1999) and is involved in dimerization. This domain shows a strong structural homology with a fold found in S2 and S3 subunits of pertussis toxin of *Bordetella pertussis* (Rossjohn *et al*., 1997), and similar folds are found in C-type lectins, suggesting a role in carbohydrate binding (see below). Domain 2 (residues 83–178, 311–398) also plays an important role in receptor binding (through residues Tyr-162, Trp-324, His-332; see below) (MacKenzie *et al*., 1999) and additionally is important in the initiation of oligomerization (Buckley *et al*., 1995). Interestingly, domain 2 contains most of the α-helical structure of the protein. Domain 3 (residues 179–195, 224–274, 299–310, and 399–409) is thought to play an important role in monomer-monomer interactions within the oligomer (Lesieur *et al*., 1999). Increasing evidence also points towards a role of domain 3, and in particular one loop, in channel formation as discussed below. Domain 4 (residues 196–233, 275–298, and 410–470) contains the peptide that is proteolytically removed upon conversion of proaerolysin into mature aerolysin and was thought to be responsible for channel formation (Parker *et al*., 1994), a view that has been recently challenged, as discussed below.

Interestingly, the structure of *Clostridium perfringens* epsilon toxin was recently solved (Cole *et al*., 2004).

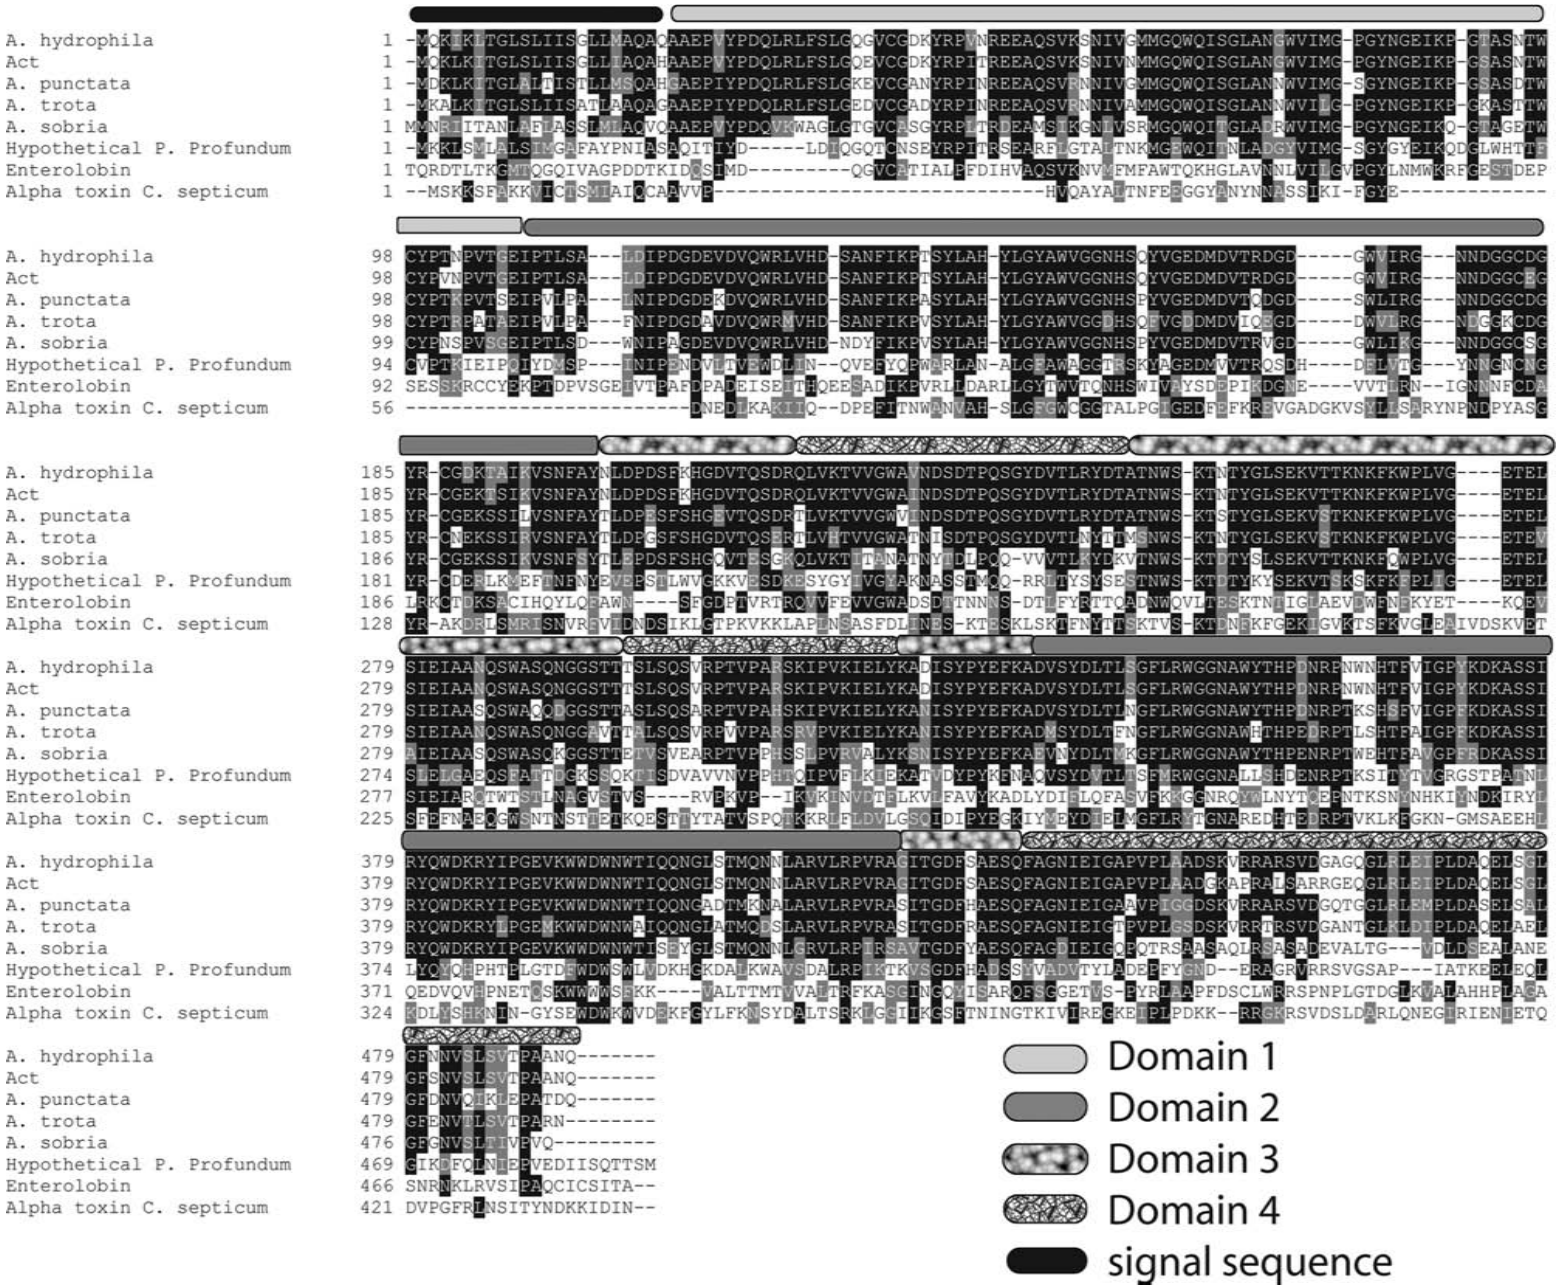

**FIGURE 33.1** Alignment of aerolysins and related toxins. Five different aerolysin-related toxins from four different *Aeromonas* species were aligned to illustrate the extent of sequence identity. A hypothetical protein from *Photobacterium profundum* was also identified when searching for related proteins. As previously shown, aerolysin also shares significant sequence identity with the α-toxin from *Clostridium septicum* and the seed cytolysin enterolobin. The four structural domains of aerolysin, as well as the signal sequence, are indicated in different shades of gray and patterns above the alignment and correspond to the same shades of gray and patterns in Figure 33.2.

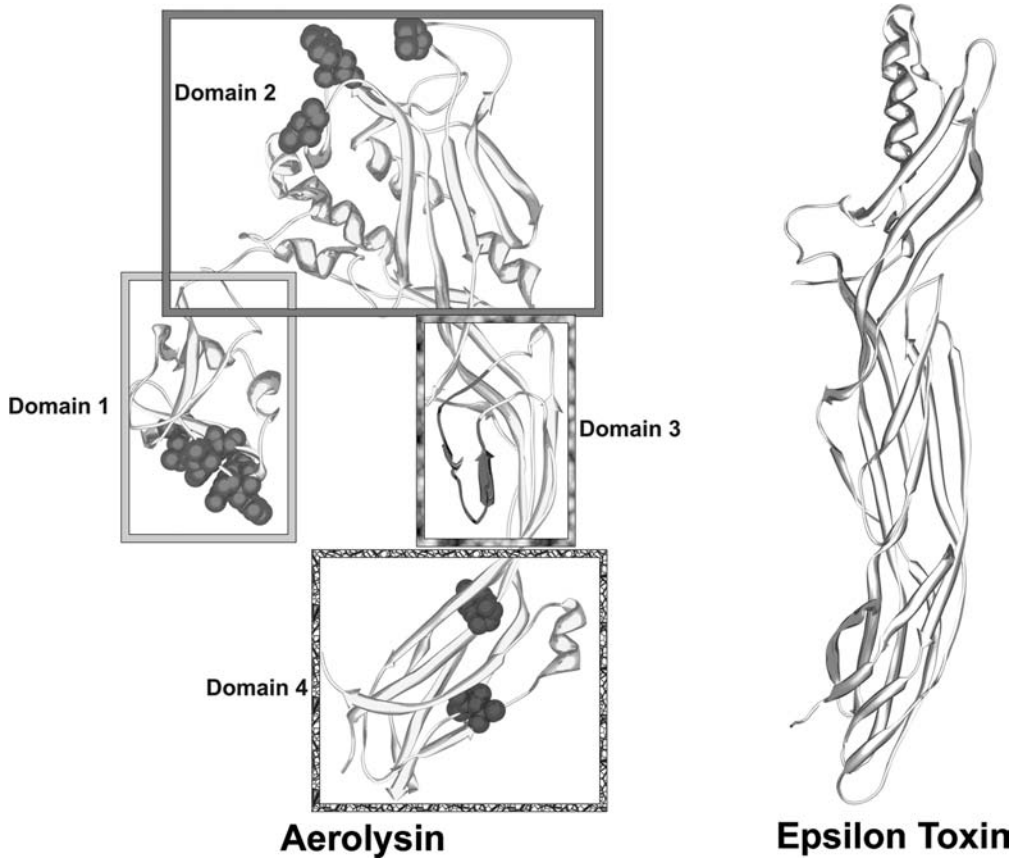

**FIGURE 33.2** Structure of *A. hydrophila* proaerolysin and *C. perfringens* epsilon toxin. Ribbon diagrams are shown to illustrate the structures, and their similarities, of *A. hydrophila* proaerolysin (left) (Parker *et al*., 1994) and *C. perfringens* epsilon toxin (right) (Cole *et al*., 2004). Domains in aerolysin are boxed with shades of gray and patterns corresponding to the alignment in Figure 33.1. Residues that have been implicated in receptor binding are shown in the space filled. In domain 1, these correspond to residues W45, I47, M57, K66 and in domain 2 to residues Y162, W324, H332. They are also shown in the space-filled residue Y221 in domain 3, which when mutated to glycine, inhibits membrane insertion of the toxin, and residues G202 and I445 in domain 4, which when both are mutated to cystein, leads to a disulfide bond between the mature protein and the pro-peptide.

Although this toxin shares only 13.9% identity with aerolysin, it has essentially the same mode of action (proteolytic activation of a precursor, receptor binding, and heptamerization) (Miyata *et al*., 2002), and above all a structure remarkably similar to that of the large aerolysin lobe (Cole *et al*., 2004) (Figure 33.2b), except for the region corresponding to domain 2 of aerolysin. This difference suggests that epsilon toxin might bind to different receptors than aerolysin, a notion that is further supported by the potency of this toxin, which is effective at 100-fold lower concentration and shows a strong cell type specificity.

## SECRETION OF PROAEROLYSIN

Proaerolysin is secreted by *Aeromonas* in a two-step process, which allows it to cross sequentially the inner and then the outer bacterial membrane of the Gram-negative bacterium. Interestingly, complete folding of the protein appears to occur in between the two steps so that the second translocation step occurs in a fully folded state, in contrast to all other known translocation processes, such as crossing the eukaryotic endoplasmic reticulum or mitochondrial membranes.

The N-terminal signal sequence directs the pre-pro-toxin to the *sec* secretion machinery for translocation through the inner bacterial membrane (Howard and Buckley, 1985b; for review see Pugsley, 2004). Within the oxidizing environment of the periplasm, the toxin folds, forms its two disulfide bridges, and can dimerize (Hardie *et al*., 1995), presumably all with the help of periplasmic chaperones and redox folding enzymes. Translocation across the outer bacterial membrane occurs via the so-called type II secretion apparatus, the main branch of the general secretion

pathway (Russel, 1998; Stathopoulos *et al*., 2000). This pathway has been best characterized in *Klebsiella oxytocca* for the secretion of pullulanase (Peabody *et al*., 2003; Pugsley *et al*., 2004) and involves some 14 gene products called the *Pul* proteins in *Klebsiella* and *exe* in *Aeromonas* (Jiang and Howard, 1991, 1992; Howard *et al*., 1993; Jahagirdar and Howard, 1994; Howard *et al*., 1996). The proteins share significant sequence similarity with components of the type IV pilus biogenesis system. Translocation of aerolysin across the outer membrane is poorly understood. It appears that both the electron motive force and ATP are required (Wong and Buckley, 1989; Letellier *et al*., 1997), although there is no known source of ATP available to the outer membrane. The transduction of the metabolic energy to the opening of a secretion port in the outer membrane involves the two inner membrane proteins, ExeA and ExeB (Howard *et al*., 1996). The translocon itself is thought to be composed of the protein ExeD (Ast *et al*., 2002). The *Klebsiella* homologue, PulD, was shown to form homo-oligomeric ring-like pores in reconstituted membranes (Nouwen *et al*., 2000). It is not clear how the gating of such a huge channel would operate and prevent the cell from becoming leaky. The targeting of a protein to this type II secretion system is equally unclear. No specific linear sequence that would target proteins to the type II secretion system has been found, although regions in *Pseudomonas* exotoxin A and in pullulanase have been found to enable secretion of other proteins (Sauvonnet and Pugsley, 1996). The information for secretion through this system might lie in the three-dimensional structure.

## RECEPTOR BINDING

Once in the extracellular milieu, proaerolysin diffuses towards its target cells. Both proaerolysin and mature aerolysin (see below) have the ability to bind specifically to cells. Although the toxin may exist as a dimer, surface binding occurs in the monomeric state (Fivaz *et al*., 1999). Binding to mammalian cells was found to be specific and saturable (Abrami *et al*., 1998b), indicating the existence of a surface receptor. Moreover, no species or cell type specificity was found, suggesting that the receptor was ubiquitous. In the late 1990s, proaerolysin was indeed found to bind to glycosylphosphaditylinositol (GPI) anchored proteins, which are ubiquitous (Cowell *et al*., 1997; Nelson *et al*., 1997; Abrami *et al*., 1998b; Diep *et al*., 1998b). Interestingly, the main binding determinant turned out to be the glycan core of the anchor. This posttranslational modification is present throughout evolution from protozoa to mammals (Kinoshita *et al*., 1997; Ferguson, 1999). GPI-anchored proteins (GPI-AP) have no transmembrane domains, and thus no cytosolic domain. The protein is attached to the cell surface via the GPI anchor, which is composed of a specific phospholipid, phosphatidylinositol (PI), on which are sequentially linked a glucosamine, three mannose residues, and an ethanolamine phosphate, which is linked by an amide bond to the C-terminus of the protein (Figure 33.3a). The inositol ring of the GPI is initially acylated during biosynthesis of the GPI anchor and subsequently deacylated, except in certain cell types such as human erythrocytes (Kinoshita *et al*., 1997; Ferguson, 1999). The conserved GPI glycan core can be additionally modified in a great variety of manners, depending on the species, on any of the different sugars (Kinoshita *et al*., 1997; Ferguson, 1999). Modification of the second mannose by addition of a beta-N-acetylglucosaminyl phosphate diester residue was recently found to be crucial for aerolysin binding (Fukushima *et al*., 2003) (Figure 33.3a). Acquisition of a presynthesized GPI anchor by a newly synthesized protein occurs after the removal, in the endoplasmic reticulum lumen, of a C-terminal GPI-anchoring signal sequence. The lipid-anchored protein is subsequently transported to the plasma membrane.

That GPI-anchored proteins are the receptor of aerolysin is supported by several lines of evidence. Treatment of cells with a phosphatidyl inositol-specific phospholipase C (PI-PLC), which removes the GPI-AP from the surface of the cell, leads to a decrease in sensitivity to aerolysin, except for human erythrocytes, due to acylation of the inositol ring. Also GPI-deficient cells have a three-fold reduced sensitivity to aerolysin (Nelson *et al*., 1997; Gordon, 1999). And finally, screening for aerolysin-resistant Chinese hamster ovary (CHO) mutants led mostly to cells defective in GPI biosynthesis (Abrami *et al*., 2001; Hong *et al*., 2002).

Since the glycan core is the main binding determinant and since it is common to all GPI-anchored proteins, aerolysin is, in principle, able to bind to all GPI-anchored proteins. Indeed, aerolysin was found to bind to a great variety of GPI-anchored proteins that have no sequence homology, such as Thy-1, a major surface glycoprotein of T-lymphocytes and mammalian neurons (Nelson *et al*., 1997); contactin, a brain cell adhesion molecule (Diep *et al*., 1998b); CD14, a monocyte differentiation factor also involved in lipopolysaccharide signaling; semaphorin K1, a brain GPI-anchored protein; carboxypeptidase M (unpublished); and the GPI-anchored form of adhesion molecule N-CAM (Fivaz *et al*., 2002). Two mammalian exceptions, however, have been found: the complement inhibitory protein CD59 (Abrami *et al*., 2002) and

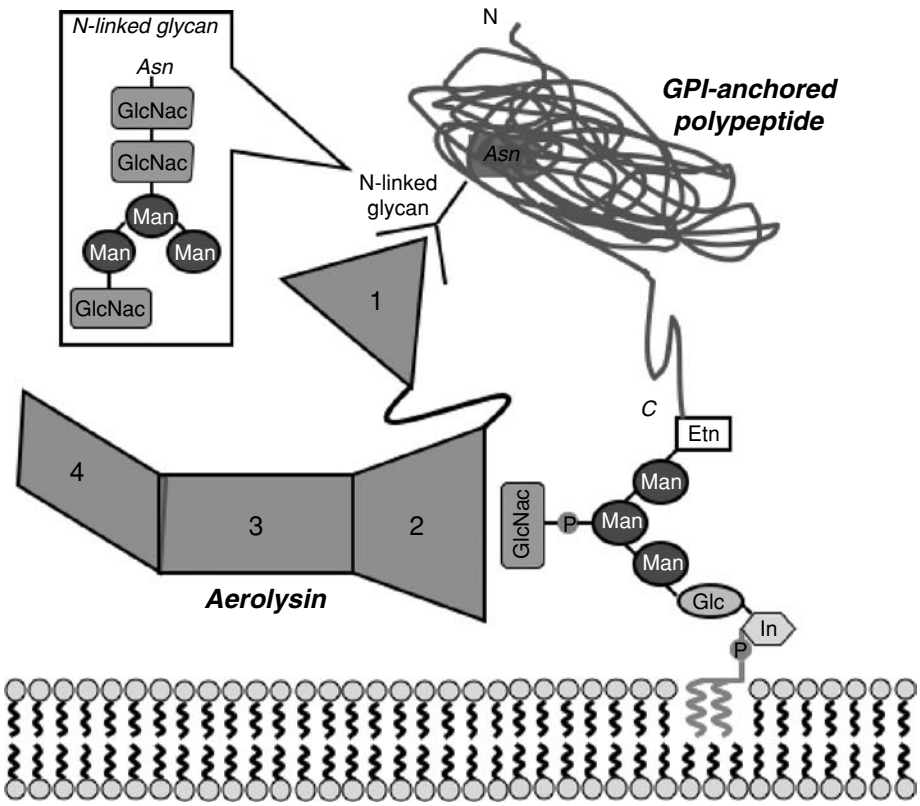

**FIGURE 33.3** Schematic representation of aerolysin bound to its glycosylated GPI-anchored receptors. Aerolysin is shown with its four structural domains. Domain 1 binds to a properly trimmed N-linked sugar, the minimal structure of which is schematized in the inset. Domain 2 binds to the glycan core of the anchor, which is imbedded into the external leaflet of the plasma membrane by a phosphatidylinositol phospholipid. The GPI glycan core shows a GlcNac (N-Acetylglucosamine) modification on the second mannose that is important for receptor binding. Asn: Asparagin, Etn: Ethanol amine, In: inositol, P: phosphate group, Glc: Glucose, Man: Mannose, GlcNac:N-Acetylglucosamine.

the prion protein (unpublished), as well as *Leshmania* gp63 (Abrami *et al*., 2002). This parasite protein was able to bind aerolysin when expressed in mammalian cells (Diep *et al*., 1998b), suggesting that modifications of the glycan core in the parasite hinder aerolysin binding.

Although the identity of the protein attached to the GPI anchor does not influence binding, the presence of the protein was found to be necessary since aerolysin does not bind to protein-free GPIs (Abrami *et al*., 2002). This is because the protein harbors a second binding site for the toxin, as recently found in a screen for low aerolysin binding CHO cells (Hong *et al*., 2002) (Figure 33.3a). Interestingly, as for the first receptor binding site, the toxin does not recognize the polypeptide, but recognizes a second posttranslational modification: the presence of N-linked sugars. ER N-linked glycosylation is not sufficient for aerolysin binding; the N-glycan needs to be properly trimmed. More specifically, α-mannosidase II in the Golgi must remove mannoses from the complex glycan initially added to asparagine residues in the endoplasmic reticulum (Hong *et al*., 2002). Addition of terminal galactose and syalic acid was not required, indicating that the minimum N-glycan structure for aerolysin binding is Gn-M3-Gn2-N (Gn, N-acetylglucosamine; M, mannose; N, asparagine). Since all known GPI-anchored proteins are glycosylated and - often hyperglycosylated, this second binding site does - not reduce the number of potential receptors. Aerolysin shares the requirement of N-linked sugars for binding with *Clostridium botulinum* C2 toxin (Eckhardt *et al*., 2000). This AB type toxin is composed of an enzyme component C2I and a separate binding/translocation component C2II. As aerolysin, C2II undergoes proteolytic activation, heptamerization, and requires asparagine-linked complex glycans for binding to host cells.

To the two binding sites on the aerolysin receptors correspond two binding sites on the toxin, one in domain 1 (Diep *et al*., 1999) and the second in the long lobe of the protein (Diep *et al*., 1998a) (Figures 33.2 and 33.3a). This notion was initially proposed by Buckley and colleagues, based on the observations that a hybrid toxin composed of domain 1 (Figure 32.2) of aerolysin followed by the α toxin of *Clostridium septicum* (Figure 32.1, which is homologous to aerolysin but lacks domain 1), had a higher receptor-binding affinity (approximately 50 times) than α-toxin alone (Diep *et al*., 1999), which also binds GPI-anchored proteins (Gordon *et al*., 1999). More specifically, domain 1 is involved in binding to the

complex N-glycans (Hong *et al*., 2002). Interestingly, recombinant domain 1 appeared to bind only to N-glycans that are present on GPI-anchored proteins, suggesting that it, in fact, recognizes a site to which both the N-glycan and the GPI-glycan core contribute. Mutation of residues Trp-45, Ile-47, Met-57, Tyr-61, and Lys-66 lead to reduced receptor binding as measured by plasmon resonance using immobilized Thy-1 (MacKenzie *et al*., 1999). Binding to the GPI anchor occurs via domain 2, involving in particular Tyr-162, Trp-324, and His-332, which when mutated led to a decrease in Thy-1 binding affinity (MacKenzie *et al*., 1999). The combination of these two binding sites leads to the high-affinity interactions of aerolysin with its receptors. The apparent Kd for binding of proaerolysin to BHK cells was estimated to be around 20nM (Abrami *et al*., 1998b) and similar value was found when measuring binding of proaerolysin to purified Thy-1 using plasmon resonance (66nM) (MacKenzie *et al*., 1999). Strikingly, many of the residues identified as being important for binding to either of the two carbohydrate sites are aromatic residues. Similar observations have been made for other carbohydrate-binding proteins in which aromatic residues have been shown to stack against the pyranose rings of sugars (Quiocho, 1986).

The precise manner in which aerolysin binds to its receptor requires further investigation. Indeed, it is not clear how domain 2, a rather large domain, can interact with a small glycan core, which is sandwiched between the polypeptide of the GPI-anchored protein and the membrane (Figure 33.3). A second puzzle is the binding to N-linked sugars. How can aerolysin bind to almost any GPI-anchored protein despite the fact that these have N-linked sugars at different positions on their tertiary fold? Finally, even more mysterious is how aerolysin reaches its high-affinity binding site on the glycan core of the GPI anchor. Indeed, this part of the receptor is very little exposed at the cell surface, especially in intestinal cells. In order to cross the thick layer of glycocalyx covering epithelial cells, aeolysin may initially bind to surface oligosaccharides with low affinity, possibly through its lectin-like domain 1 or tryptophan-rich regions of the molecule (18 in total), before being progressively shuttled to the membrane vicinity where it would bind to the glycan core of the GPI anchor (MacKenzie *et al*., 1999). This model of relay of low- and high-affinity binding sites remains to be proven, but is supported by the finding that polarized epithelial cells are always more sensitive to aerolysin from their apical side—more abundant in oligosaccharides—than from their basolateral side, irrespective of the localization of their GPI-anchored proteins (Abrami *et al*., 2003).

## FROM THE PRECURSOR TO THE ACTIVE TOXIN

Conversion of proaerolysin to aerolysin requires proteolytic cleavage of a C-terminal peptide (Figure 33.2), a step that can occur prior or subsequent to receptor binding. Cleavage can be achieved by a variety of enzymes either produced by the bacterium (Howard and Buckley, 1985a) or found in the digestive tract, such as trypsin (Howard and Buckley, 1985a), or present at the surface of the cell, such as members of the furin family (Abrami *et al*., 1998a). Three cleavage sites have been identified: Lys-427 by trypsin, Arg-429 by chymotrypsin (van der Goot *et al*., 1992), and Arg-432 by furin (Abrami *et al*., 1998a), suggesting that the loop containing these residues (which was not seen in the crystal structure) is very sensitive to proteases.

Proteolysis at the C-terminus—in domain 4—leads to conformational changes that spread throughout the entire structure all the way to domain 1 (Cabiaux *et al*., 1997). The exact changes have not been identified, but a 10% increase in β-sheet structure at the detriment of random structure was measured by Fourier Transformed Infra Red spectroscopy (FTIR) with no major change in tertiary structure (Cabiaux *et al*., 1997).

## HEPTAMER FORMATION

Once processed into aerolysin and bound to the receptor, the toxin undergoes oligomerization into a ring-like structure composed of seven monomers, as observed both by electron microscopy (Wilmsen *et al*., 1992) and mass spectrometry (Moniatte *et al*., 1996). While oligomerization can occur in solution, it is far more efficient at the surface of cells. This is to a large extent due to the increase in concentration that accompanies the decrease in dimensionality when going from a three- to a two-dimensional space (estimated to be a 3,000- to 10,000-fold increase). An additional concentration factor is provided by the association of the GPI-anchored receptors with special plasma membrane domains, or lipid rafts, thus further promoting oligomerization (Abrami and van der Goot, 1999).

The mechanism by which the heptamer assembles (i.e., does it assemble through gradual association of monomers, or do dimers and trimers form and then associate) has not been characterized. What is known is that oligomerization involves no change in secondary structure, as measured by circular dichroïsm (CD) (van der Goot *et al*., 1993b), but the rearrangement of the tertiary organization as observed both by CD and FTIR (Cabiaux *et al*., 1997). This rearrangement leads to the formation of an extraordinarily stable structure, more

so than heptamers of other toxins, such as staphylococcal α-toxin. The incubation of the aerolysin heptamer in 8M urea for 24 hours not only does not separate the subunits, but does not even affect its tertiary structure as witnessed by circular dichroïsm in the near ultraviolet, which monitors the flexibility of aromatic residues and in particular tryptophans (Lesieur *et al*., 1999). Heptameric assembly is also maintained in guanidium hydrochloride (6M), but this stronger chaotropic agent does lead to loss of tertiary packing. Finally, the heptamer is resistant to boiling in SDS (Lesieur *et al*., 1999).

In order to identify the regions involved in the tight maintenance of the complex, limited proteolysis studies were performed using the enzyme boilysin, an engineered enzyme, which retains its activity at high temperatures and even in the presence of SDS (Van den Burg *et al*., 1998). Boilysin treatment led to truncated but still oligomeric aerolysin complexes, the composition of which was identified by N-terminal sequencing and MALDI-TOF analysis (Lesieur *et al*., 1999). Two fragments, corresponding to amino acids 180–307 and 401–427, were identified, showing that the domains 3 and 4 are crucial for maintaining the heptamers assembled, while domains 1 and 2 are not required (Lesieur *et al*., 1999).

Although domain 2 is not responsible for the extreme stability of the heptamer, it is involved in initiating the oligomerization process. Mutation of His-132 in domain 2 completely abolishes *in vitro* heptamerization (Green and Buckley, 1990) and channel formation in planar lipid bilayers (Wilmsen *et al*., 1991). It was shown that protonation of histidine at position 132 is necessary for oligomerization (Buckley *et al*., 1995). This histidine has a very unusual environment that severely modifies its pKa, allowing histidine protonation at physiological pH. Mutations of His-107 also reduced oligomerization, but to a lesser extent (Green and Buckley, 1990). Mutation of trypthophans at positions 371 and 373, also in domain 2, had the opposite effect since oligomerization was accelerated possibly by a partially destabilizing effect that favors the rearrangements leading to heptamerization (van der Goot *et al*., 1993b).

Many PFTs, including staphylococcal α-toxin and cholesterol-dependent toxins (CDT), first oligomerize into a prepore state and then undergo a second concerted conformational change that leads to channel formation. In the case of aerolysin, there is no evidence for a prepore state, and oligomerization appears to be systematically accompanied by the appearance of hydrophobic patches, as witnessed by measuring binding of fluorescent hydrophobic dyes (van der Goot *et al*., 1993b). A very interesting aerolysin point mutation, Y221G, has been identified that leads to a non-hydrophobic heptamer (Tsitrin *et al*., 2002). This mutant can still bind to GPI-anchored proteins and heptamerize, but these heptamers cannot insert into membranes (Nelson *et al*., 1999; Tsitrin *et al*., 2002). It is not clear whether this mutation allows the trapping of a not previously observed prepore state, whether it leads to aberrant, dead-end heptamers, or whether the mutation, repeated seven times in the heptamer, has converted the hydrophilic complex into a hydrophilic one.

Analysis of the Y221G heptamer by cryoelectron microscopy single particle analysis and 3D reconstruction—rendered possible because of the solubility of the complex—provided a 13 Å model of the aerolysin heptamer, corresponding to a significant improvement over the previous 25 Å resolution model (Wilmsen *et al*., 1992). The aerolysin heptamer has a mushroom-shaped structure (Figure 33.4) in which domains 1 and 2 form the cap, domain 3 the mouth of the channel, and domain 4 the transmembrane part. As described below, experimental evidence suggests that this model is somewhat incorrect, in particular with respect to the positions of domains 3 and 4, despite the rather good fit obtained when docking the crystal structure into the

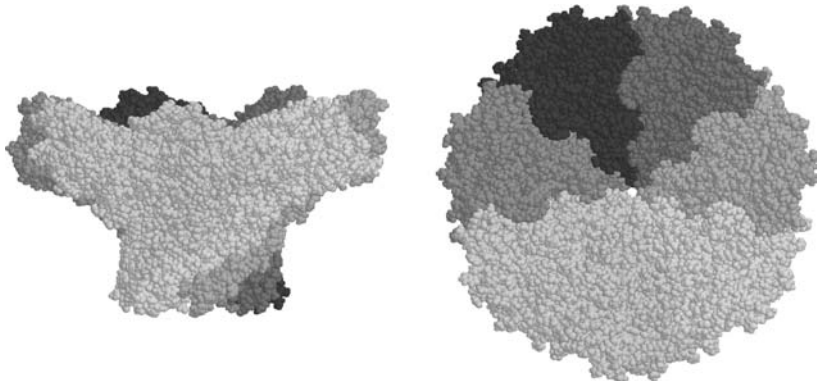

**FIGURE 33.4** Space-filled model of the aerolysin Y221G heptamer. Single particle analysis of soluble Y221G heptamers led to a 3D reconstruction with a 13 Å resolution in which the crystal structure was docked, leading to a high resolution model that is shown here in space-filled, viewed either from the side (left) or from the top (right) (Tsitrin *et al*., 2002).

electron density map (Tsitrin *et al*., 2002). A full understanding of the heptameric structure therefore awaits further studies.

## MEMBRANE INSERTION AND CHANNEL PROPERTIES

Since aerolysin does not appear to transit through a prepore state, heptamerization is directly followed by membrane insertion. As for other β-sheet containing PFTs, channel formation is thought to occur by the formation and spontaneous membrane insertion of a β–barrel. Little is known about this last step, both in terms of the interaction with lipids and the structure of the transmembrane region. It has been suggested that the junction between lipid rafts and the fluid phase region is a site of unfavorable energetic effects, and these unstable boundaries might provide a favorable insertion site (Brown, 1998). Also, the insertion of aerolysin heptamers in artificial liposomes is enhanced by the presence of lipids favoring lamellar-to-inverted hexagonal phase transition (Alonso *et al*., 2000). These authors indeed showed that the rate of dye leakage from unilamellar egg-phosphatidylcholine vesicles is enhanced by the presence of phosphatidylethanolamine, diacylglycerol, or cholesterol. On the other hand, lipids that stabilize the lamellar phase, such as sphingomyelin and saturated phosphatidylcholines, reduced the rate of channel insertion.

It is at present not clear which part of aerolysin actually forms the transmembrane region. The low- and medium-resolution models (Parker *et al*., 1994; Tsitrin *et al*., 2002) of the heptamer propose that domain 4 crosses the membrane. This model is, however, challenged by experiments that indicate that a loop in domain 3 (Figure 33.2) is necessary for channel formation (manuscript in preparation). This loop, corresponding to residues 238 to 260, has previously been implicated in oligomerization since immobilization of this loop, by an engineered disulfide bond that links it to the protein core, inhibited heptamerization (Rossjohn *et al*., 1998). More recently, we have found that restraining the flexibility of the loop, by disulfide bond engineering within the loop, does not prevent heptamerization but blocks channel formation (in preparation). Finally, the corresponding loop in *C. Septicum* α-toxin was also found to interact with the membrane (Melton *et al*., 2004). Formal proof that the loop actually crosses the bilayer is still lacking, however. If, indeed, the loop does form the transmembrane channel, the role and localization of domain 4 will have to be seriously reevaluated and the discrepancy between the function data and the electron microscopy analysis elucidated.

Electrophysiological measurements in planar lipid bilayers showed that aerolysin makes well-defined, slightly anion selective channels with a single-channel conductance of 420pS (Chakraborty *et al*., 1990; Wilmsen *et al*., 1990). The channels remain opened in the range of –70 to +70 mV and undergo voltage-dependent closing outside of this range. From the analysis of 2D crystals of the aerolysin heptamers, the measured inner diameter of the channel was estimated at 17 Å (Parker *et al*., 1994; Tsitrin *et al*., 2002), but somewhat greater diameters were reported from small-molecule release experiments (30 Å) (Howard and Buckley, 1982) and optical single-channel analysis (40 Å) (Tschödrich-Rotter *et al*., 1996). *In vivo* data suggests that the channels formed in living cells are somewhat smaller, as the heptamer seems to discriminate between ethidium monomer and ethidium dimer (Krause *et al*., 1998) and does not allow the passage of entire molecules of trypan blue (960 Da) into cells (Abrami *et al*., 1998b).

## CELLULAR CONSEQUENCES OF AEROLYSIN

Upon channel formation in the plasma membrane of mammalian cells, aerolysin leads to the permeabilization to small ions but not proteins (Abrami *et al*., 1998b). As the pore allows ions to go through, this leads to a dissipation of the $Na^+$ and $K^+$ gradients and the loss of membrane potential (Abrami *et al*., 1998b; Laohachai *et al*., 2003). Importantly, aerolysin channels also allow the entry of extracellular calcium (Krause *et al*., 1998).

In cells that are unable to repair or counteract membrane damage, this breach in plasma membrane permeability leads to osmotic lysis. However, except at late stages of *Aeromonas* infection when a bacteremia is reached, the toxin is unlikely to encounter erythrocytes. In nucleated cells, the consequences of membrane damage by aerolysin are far more complex and are both concentration- and cell-type dependent. We will briefly describe some of the observed effects. The link between these various observations remains unclear, and obtaining the full picture will require intensive further studies. The massive efflux of potassium and the entry of calcium are two events that on their own are likely to cause a multitude of effects.

### Morphological changes

At concentrations of 1 nM and below, intestinal and other epithelial cells undergo cytoplasmic vacuolation. These vacuoles were found to originate from the endo-

plasmic reticulum, leaving the endocytic compartments and Golgi complex morphologically unchanged (Abrami *et al*., 1998a; Abrami *et al*., 1998b). This process was inhibited when extracellular calcium was chelated with EGTA (unpublished), but was not solely dependent on calcium entry since calcium ionophores did not lead to ER vacuolation (Abrami *et al*., 1998b). ER vacuolation was dependent on the dynamic properties of the compartment since vacuolation was inhibited by ATP depletion or depolymerization of the microtubules network (Abrami *et al*., 1998b). Induction of neutral pH cytoplasmic vacuoles was also observed for other pore-forming toxins, such as Staphylococcal α-toxin (Abrami *et al*., 1998b), *Serratia marcescens* hemolysin (Hertle *et al*., 1999), and *Vibrio cholera* hemolysin (Coelho *et al*., 2000; Mitra *et al*., 2000), although in the two latter cases, the ER was not formally identified. ER vacuolation was not observed for Streptolysin O, possibly because it forms larger pores (Walev *et al*., 2001). Note that these PFT-induced vacuoles differ from those induced by the *Helicobacter pylori* vacuolating toxin VacA, which leads to acidic vacuoles that originate from late endocytic compartments (Montecucco and de Bernard, 2003).

In addition to the appearance of cytoplasmic vacuoles, intestinal and epithelial cells often undergo plasma membrane blebbing when exposed to aerolysin (Abrami *et al*., 1998a; Abrami *et al*., 1998b; Galindo *et al*., 2004b).

## Changes in gene expression and production in pro-inflamatory molecules

Chopra and colleagues have extensively analyzed the changes in gene expression upon exposure to aerolysin, both of RAW macrophages and of primary macrophages (Chopra *et al*., 2000; Galindo *et al*., 2003; Galindo *et al*., 2004a). These studies have led to the identification of some 200 up- and 200 down-regulated genes between 0 and 12 h of toxin treatment. Further studies will be required to understand how these genes fall into pathways and what their relevance is. Immediately apparent, however, and perhaps not surprisingly, aerolysin was found to trigger the production of a variety of pro-inflammatory molecules, in particular tumor necrosis factor α (TNFα), interleukin 1β (ILlβ), interleukin 6, and protasglandin E2 (Chopra *et al*., 2000; Ribardo *et al*., 2002; Galindo *et al*., 2003; Galindo *et al*., 2004a). Aerolysin was also found to induce the expression of nitric oxyde synthase (iNOS), possibly via up-regulation of TNF-α and IL-1 in the host cell (Chopra *et al*., 2000). Nitric oxyde (NO) production by iNOS is an essential element of antimicrobial immunity and host-induced tissue damage.

## Induction of apoptosis

That aerolysin triggers apoptosis was first observed on T lymphocytes, as witnessed by DNA laddering, an event that could be overcome by the overexpression of bcl2 (Nelson *et al*., 1999). Since then, aerolysin also has been shown to trigger apoptosis in murine macrophages (Galindo *et al*., 2003) and intestinal cells (Galindo *et al*., 2004b), but not on fibroblast-like cells (Abrami *et al*., 1998b). Note, however, that different assays were used by different laboratories to monitor apoptosis, including DNA condensation and genomic DNA laddering, annexin V binding.

The pathway(s) by which aerolysin triggers apoptosis has not been elucidated. Entry of calcium through the aerolysin channel has been proposed to be the cause (Nelson *et al*., 1999). A recent study suggests that apoptosis could be a secondary effect due to the toxin-induced production of TNFα (Galindo *et al*., 2004b). Galindo *et al*. observed that apoptosis, and the concurrent cleavage of caspase 3, was drastically reduced in aerolysin-treated macrophage lacking the two TNF receptors TNFR-1 and TNFR-2 (Galindo *et al*., 2004b).

## Activation of signaling pathways

The first evidence that aerolysin was able to trigger signaling cascades came from the observation that channel formation led to the activation of Pertussis-sensitive G proteins that subsequently led to the production of inositol (1,4,5)-triphosphate (IP3) and the release of calcium from the ER via IP3-dependent channels (Krause *et al*., 1998). It was apparent from this study that increases in cytoplasmic calcium were not only due to entry of the ion through the toxin channel at the plasma membrane, but also that the toxin triggered release from intracellular stores. Intracellular calcium release was clearly dependent upon pore formation, and not binding or clustering of GPI-anchored proteins, since channel-impaired mutants (such as Y221G or G202C-I445C) had no effect. How aerolysin is able to trigger activation of G proteins remains mysterious, but could involve stretch- or stress-activated receptors. Another possibility is that the aerolysin channels affect the integrity of rafts, which have been implicated in modulating and integrating signaling events at the plasma membrane (Simons and Toomre, 2000). In agreement with the activation of G-proteins, aerolysin was found to stimulate chemotaxis (Jin *et al*., 1992; Krause *et al*., 1998).

In addition to G proteins, aerolysin triggers the activation of multiple signaling cascades. Activation of p38, ERK1/2, and JNK kinases, as well as some of their upstream effectors and downstream targets, has been

observed (Galindo *et al*., 2004b), indicating that aerolysin activates three of the major MAPK signaling routes present in cells involved in cell proliferation, differentiation, apoptosis, and inflammation. The relevance of these findings remains to be fully evaluated.

### Evidence that cells mount a defense against aerolysin

The fact that perforation of the plasma membrane triggers a great variety of effects in the host cell, leading to the up- and down-regulation of genes, is not so surprising, but thorough analysis of the mechanisms involved is now required.

Most astonishing is the recent finding that cells, and organisms, actually mount a defense against pore-forming toxins. The observation was originally made by gene expression analysis of *Caenorhabditis elegans* challenged with an insecticidal, pore-forming toxin (Huffman *et al*., 2004). As for aerolysin-treated macrophages, pore-forming toxins treated with *C. elegans* led to the up- and down-regulation of a variety of genes, among which was the *C. elegans* homologue of p38 MAPK. Aorian and colleagues subsequently showed that worms harboring a mutation in this gene were hypersensitive to the toxin (Huffman *et al*., 2004). These studies were extended to mammalian cells and aerolysin and indicated that cells treated with a p38 MAPK inhibitor died more rapidly than control cells (Huffman *et al*., 2004). This is the first time that a survival pathway is observed as being activated and functional against PFTs. The survival strategy of cells, linked to the innate immune system, is likely to include other pathways, which remain to be found.

## AEROLYSIN AS A TOOL

### Study of GPI-anchored proteins

Mammalian GPI-anchored proteins, which all contain a similar, if not the same, glycan core and are generally highly glycosylated, respond to the two requirements for efficient aerolysin binding. With the exception of two mammalian proteins [CD59 (Abrami *et al*., 2002) and the prion protein], aerolysin does not appear to discriminate between GPI-anchored proteins and is therefore a powerful tool to identify, purify, and study them.

Using aerolysin overlay assays (Cowell *et al*., 1997; Abrami *et al*., 1998b) and two-dimensional electrophoresis, the map of all GPI-APs in a given cell type can be generated (Fivaz *et al*., 2000; Fivaz *et al*., 2002), which combined to the mass spectrometry can lead to their identification (Fivaz *et al*., 2000). Such studies have revealed that cells only express a specific set of GPI-AP, which greatly varies from one cell type to the other. For example, 10 different GPI-linked proteins could be detected on baby hamster kidney cells, whereas rat R6 cells only produced a single GPI-anchored protein, which is Thy-1. Aerolysin overlays are and have also been useful to probe for GPI-anchored proteins on one-dimensional gels of whole cell extracts or subcellular fractions (Drab *et al*., 2001; Herreros *et al*., 2001).

In addition to its use as a pan-GPI–anchored protein probe in biochemical assay, aerolysin and its inactive mutants can be used as probe for both electron (Fivaz *et al*., 2002) and fluorescence microscopy on both fixed and live cells (Abrami *et al*., 2002; Fivaz *et al*., 2002; Sotgia *et al*., 2002; Sharma *et al*., 2004). A useful mutant for detection of GPI-anchored proteins with aerolysin on living cells is the so-called ASSP in which the activation peptide is linked to the mature toxin by an engineered disulfide bond, and therefore remains inactive unless it is reduced, a step that occurs upon arrival in late endocytic compartments (Fivaz *et al*., 2002). This probe binds as a monomer to its receptor and therefore does not lead to clustering. In contrast, the Y221G mutant is a single-point mutation that does not hinder heptamerization but prevents membrane insertion (Tsitrin *et al*., 2002), making it a useful probe to induced controlled clustering of GPI-anchored proteins (Fivaz *et al*., 2002; Sharma *et al*., 2004) in contrast to antibodies.

### Future applications of aerolysin as a probe to study GPI-anchored proteins

One interesting example is the use of aerolysin and its mutants to coat atomic force microscopy cantilevers to study the surface behavior of these lipid-anchored molecules and their surrounding environment (Kasas, van der Goot and Lafont, in preparation).

### Diagnostic

The ability of aerolysin to bind to GPI-anchored proteins has also made it a powerful tool to diagnose a disease that is due to the absence of this class of proteins on hematopoietic cells, namely paroxysmal nocturnal hemoglobinuria (PNH) (Brodsky *et al*., 1999; Brodsky *et al*., 2000). PNH is a clonal stem cell disorder caused by a somatic mutation of the pig-A gene, which is implicated in the biosynthetic pathway of GPI-anchored proteins (Kinoshita *et al*., 1997). PNH blood cells (erythrocytes, lymphocytes, and granulocytes), in contrast to blood cells from healthy patients,

were found to be resistant to aerolysin. So far, the current diagnosis for PNH had been flow cytometric analysis of surface CD59, a GPI-AP implicated in the protection against complement lysis. Aerolysin is, however, a far more sensitive tool to detect PNH populations, in addition to the fact that it is a far simpler and less expensive test (Krauss, 2003; Wang *et al*., 2003).

### Other applications

Aerolysin has also been shown to be useful for purification of parasites, such as trypanosomes and Leishmania, from tissue or blood. These parasites are completely insensitive to the toxin, in contrast to the host blood cells, thereby allowing lysis of the mammalian cells and purification of the parasite (Pearson *et al*., 1982). Considering that these parasites are covered with GPI-anchored proteins, i.e., potential aerolysin receptors, this finding seems surprising. GPI-anchored proteins may be so densely packed at the surface of the parasites (Ferguson, 1999) that aerolysin does not have access to its binding site on the glycan core of the anchor. For Leishmania, another explanation is that *in vitro*, aerolysin is not able to bind to the leishmainia GPI-AP gp-63, suggesting that the structure of the anchor is not compatible with aerolysin binding (Abrami *et al*., 2002).

## CONCLUSION

Tremendous progress has been made over the last decade in the understanding of the mode of action of aerolysin: the structure of proaerolysin has been solved, the receptors have been identified, and two different steps in host cell interaction have been identified. The next period should bring our understanding to a more atomic level: How does oligomerization take place, how does membrane insertion occur, and what is the structure of the final channel? The coming years should also bring a clearer picture as to how a cell reacts to pore formation—how is the breach in the plasma membrane sensed? Are membrane repair mechanisms turned on? Is there a branch of the innate immune system that is able to counteract pore-forming toxins?

## ACKNOWLEDGMENTS

We would like to thank Laurence Abrami for the critical reading of this chapter. This work was supported by the Swiss National Science Foundation.

CHAPTER

# 34

# *Clostridium septicum* pore-forming α-toxin

*Jody Melton and Rodney K. Tweten*

## INTRODUCTION

Descriptions of myonecrosis (gas gangrene) have been recorded in history since the Middle Ages. Bottini was able to clearly demonstrate the bacterial origin behind this disease in 1871; however, he was not able to isolate a causative organism (Bottini, 1871). The first of these organisms was identified in 1877 by Pasteur and Joubert and given the name *Vibrion septique* (Pasteur and Joubert, 1877). Today, this organism, now known as *Clostridium septicum*, is one of six histotoxic clostridia that are able to initiate gas gangrene (clostridial myonecrosis) in humans (MacLennan, 1962). Whereas most histotoxic clostridia primarily cause gangrene after contamination of a wound or injury with spores or vegetative cells, *C. septicum* is a major cause of non-traumatic gas gangrene and necrotizing enterocolitis in individuals who have colonic cancer, neutropenia, diabetes, leukemia, and various other predisposing conditions. Since no external trauma is required to initiate this disease, it is thought that the infection arises from an endogenous source, presumably the colon.

*C. septicum* elaborates various toxins and virulence factors that are likely to contribute to disease. The first of these was discovered and partially purified in 1944 by Bernheimer and given the name alpha toxin (AT) (Bernheimer, 1944). While the lethal and hemolytic activities of *C. septicum* were purified together by Bernheimer, the fact that AT was responsible for both of these activities was not confirmed until AT was purified to homogeneity nearly 50 years later by Ballard (Ballard *et al*., 1992). AT is secreted by *C. septicum* and exhibits the typical structure of a type II secreted protein with a 31-residue amino terminal signal peptide signal. Secreted AT exhibits a mass of 46,550 D, and it is produced as an inactive protoxin. As is described below, activation of AT requires the cleavage of an amino terminal propeptide of 45 amino acids. AT is the sole lethal factor secreted by *C. septicum* with a reported $LD_{50}$ of 10 μg $kg^{-1}$ in mice (Ballard *et al*., 1992). Upon injection with purified AT mice undergo shock and death, the same course seen in human patients with non-traumatic gas gangrene (Ballard *et al*., 1992). Thus, it appears that AT is the major cause of shock-like symptoms that occur during *C. septicum* non-traumatic gas gangrene.

Although many clostridial species produce toxins, AT is, so far, unique among the clostridia. AT was thought to have similarity to toxins from *C. chauvei* and *C. histolyicum*; however, neither of these organisms produce toxins that are cross-reactive with antibodies against AT (Ballard *et al*., 1992). AT is a pore-forming toxin that forms homo-oligomeric complexes on cell membranes consisting of five to seven monomers. This makes it similar in action to several non-clostridial bacterial toxins, including *Staphylococcus aureus* alpha hemolysin (Gouaux *et al*., 1997), the cytotoxin from *Pseudomonas aeruginosa* (Xiong *et al*., 1994), the protective antigen component of anthrax toxin (Benson *et al*., 1998), enterolobin from the Brazilian tree *Enterolobium contortisiliquum* (Fontes *et al*., 1997), and aerolysin from *Aeromonas hydrophila* (Howard and Buckley, 1985). The primary structure of AT (Imagawa *et al*., 1994; Ballard *et al*., 1995) displayed striking sequence similarity to aerolysin (72% similarity, 27% identity) (Ballard *et al*., 1995).

Based on the similarity of its primary structure and its functional characteristic with that of aerolysin, AT now belongs to the small and unusual class of aerolysin-like cytolytic toxins. The aerolysin-like family of cytolytic toxins is novel among all pore-forming toxin families in that it contains members from a Gram-positive bacterium (AT from *C. septicum*), a Gram-negative bacterium (aerolysin from *Aeromonas hydrophila*), and a eukaryotic organism (enterolobin from seeds of the Brazilian tree. *contortisiliquum*). Furthermore, the recent solution of the crystal structure of *C. perfringens* epsilon toxin suggests that it is the newest member of this family of toxins (Cole *et al*., 2004; Chapter 35, this volume). To date, this toxin family is the most phylogenetically diverse family of pore-forming toxins. The members of this family display a high degree of sequence similarity with aerolysin (27% with AT, 36% with enterolobin); however, there is no significant sequence homology between AT and enterolobin or epsilon toxin. The similarities in structure and function between AT and aerolysin have provided an important resource for the study of the structure and mechanism of this family of toxins.

## MECHANISM OF ACTION AND STRUCTURE OF α-TOXIN

AT follows a distinct, ordered path for pore formation and much about the sequential order of the steps involved in this path has been determined. AT is produced as a preprotoxin containing an N-terminal type II signal sequence and a C-terminal propeptide. Protoxin monomers are secreted from the bacterial cells and bind to glycophosphatidylinositol (GPI)-anchored eukaryotic cell surface receptors. Once bound, cleavage of a 5-kDa C-terminal covalently linked propeptide by a furin like cell surface protease produces activated monomers. Activated toxin monomers then oligomerize on the cell surface before inserting into the membrane and forming a pore (Sellman *et al*., 1997). The pore sizes generated by these oligomers in planar lipid membranes have been estimated at 1.5 nm for AT (Ballard *et al*., 1993) and 1.0 nm for aerolysin (van der Goot *et al*., 1993). For aerolysin, it has been shown that the oligomer contains 7 monomers (Wilmsen *et al*., 1992) (Moniatte *et al*., 1996). Due to the similarity in their pore size, it is believed that AT may also form a heptameric oligomer, but this remains to be proven.

The crystal structure of aerolysin was the first one determined for a pore-forming toxin (Parker *et al*., 1994) and has had a significant impact on elucidating structure-function relationships for this family of toxins. While a crystal structure for AT has not been solved, a molecular model for it has been generated, based on the crystal structure of aerolysin and the high degree of similarity (72%) between domains 2–4 of aerolysin and AT (Melton *et al*., 2004). As seen in Figure 34.1, aerolysin is a bi-lobal protein with a small lobe comprised of the first 83 amino acids, also called domain 1(D1), and a large lobe that consists of two domains (D2–3). AT lacks a region homologous to D1 of aerolysin, but is homologous to domains 2–3 of aerolysin, making it a single-lobed structure consisting of three domains (Figure 34.1). The structure of the large lobe of aerolysin and the model of AT are largely β-sheet in structure.

### Binding and cellular receptors

It has been well established that members of the aerolysin and AT bind GPI-anchored cell surface receptors. Cellular receptors for AT include the human folate receptor (hFR), the neuronal surface molecule contactin, and Thy-1 (CD90) (Gordon *et al*., 1999), as well as members of the SAG family of cell surface proteins of *Toxoplasma gondii* (Wichroski *et al*., 2002). Aerolysin receptors include Thy-1, contactin, the

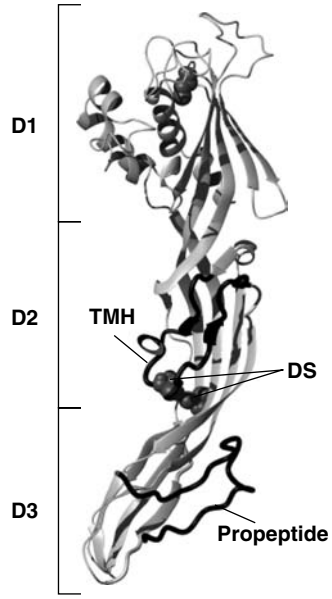

**FIGURE 34.1** Aerolysin-based structural model of α-toxin. Shown is a ribbon representation of α-toxin based on the aerolysin crystal structure (Parker *et al*., 1994). TMH: transmembrane β-hairpin (Melton *et al*., 2004), DS: engineered disulfide described by Melton *et al*. (Melton *et al*., 2004). The AT model was generated using Swiss model (Guex and Peitsch, 1997), and the ribbon structure was drawn using MolMol (Koradi *et al*., 1996).

47–kDa erythrocyte aerolysin receptor, and the variant surface glycoprotein (VSG) of *Trypanosoma brucei* (MacKenzie *et al*., 1999). While aerolysin also binds contactin and Thy-1, it does not bind to hFR (Gordon *et al*., 1999). In a similar manner, AT cannot bind to the other identified aerolysin receptors. Thus, it appears that the two toxins bind to different sets of GPI-anchored proteins. Interestingly, the protein components of the AT- and aerolysin-binding GPI-anchored receptors lack sequence homology; however, all of the receptors identified for each toxin share a common property in that they are linked to the membrane through a GPI anchor. The GPI anchor appears to play a greater role in toxin binding than the protein to which it is attached.

The role of the GPI anchor in toxin binding has been of considerable interest in recent years. It has been established that the core of the GPI anchor itself acts as a binding determinant for aerolysin (Diep *et al*., 1998), and cell lines that are unable to synthesize GPI anchors have been shown to have a reduced or complete loss of sensitivity to aerolysin and AT, respectively (Gordon *et al*., 1999). However, the GPI anchor alone cannot function as a receptor for these toxins since not all GPI-anchored proteins are receptors (Diep *et al*., 1998; Abrami *et al*., 2002). It appears that the carbohydrate structure of the GPI anchor may be important, as the N-glycan core is necessary for aerolysin binding but not AT binding (Hong *et al*., 2002).

Previous work has identified residues in two of the four domains of aerolysin that are involved in receptor binding. Rossjohn *et al*. have shown that D1 of aerolysin contains a motif similar to the carbohydrate-binding domain of pertussis toxin, now named the aerolysin pertussis toxin (APT) domain (Rossjohn *et al*., 1997). As AT lacks a region homologous to D1 of aerolsyin, this observation may explain why the two toxins bind to different sets of GPI-anchored proteins. In fact, when the small lobe of aerolysin is fused to the amino terminus of AT, the hybrid toxin is able to bind receptors previously limited to aerolysin (Diep *et al*., 1999). Additional studies identified specific residues in domains 1 and 2 of aerolysin that participate in receptor binding. Using surface plasmon resonance, MacKenzie *et al*. found five site-specific mutations in D1 and four in D2 that had a significant effect on receptor binding (MacKenzie *et al*., 1999). Together, these data suggest a role for domains 1 and 2 of aerolysin in receptor binding. As AT lacks a region homologous to D1 of aerolysin, the results from aerolysin would suggest that at least a portion of the receptor-binding domain for AT would exist in D1 of AT (homologous to D2 of aerolysin).

## Activation and oligomerization of alpha toxin

Once protoxin is bound to the cell surface, the next step in the mechanism of action of these toxins is activation by a cell surface protease. Purified AT was a 48-kDa protein; however, most toxin preparations contained an additional 44-kDa protein that reacted to an antibody purified with the 48-kDa protein (Ballard *et al*., 1992). It was later determined that the 48-kDa protein represented an inactive protoxin requiring *in vitro* cleavage of a C-terminal propeptide by trypsin. It was subsequently shown that furin, and to a lesser extent proteases with a furin-like specificity, were necessary to activate AT on the surface of eukaryotic cells (Ballard *et al*., 1993; Gordon *et al*., 1997).

Proteolytic cleavage of the AT propeptide was necessary for its oligomerization into a pore-forming complex (Ballard *et al*., 1993). Therefore, the propeptide inhibited the interaction of membrane-bound monomers, and oligomerization only proceeded after AT had been proteolytically activated. Trypsin and furin cleave AT within a putative loop that is rich in basic amino acids. The furin consensus cleavage site is RXKR and is found within the AT motif of KKR-RGKR↓SVD. Cleavage occurs immediately after the furin recognition site of RGKR.

Sellman *et al*. (Sellman and Tweten, 1997) found that the propeptide of AT functions as an intramolecular chaperone by preventing the toxin from incorrect folding and premature aggregation in solution. When AT is activated in solution, the toxin forms solution aggregates that are not active on erythrocytes (Sellman and Tweten, 1997). If AT is activated in solution, it can form an oligomer, but this oligomer is incapable of interacting with and forming a pore on the membrane. They showed that in order for pore formation to occur, AT must follow an ordered pathway of assembly. First, monomers bind to the membrane via their GPI-anchored receptors and then are activated by protease. Only after binding and activation can the monomers oligomerize on the surface into functional pores. Therefore, the propeptide functions as an intramolecular chaperone by preventing improper association of the monomers until they reach the membrane where they are activated by furin.

Interestingly, the propeptide does not immediately dissociate from the toxin following proteolytic cleavage, but rather remains non-covalently associated with the monomer, and appears to be displaced during the oligomerization process (Sellman and Tweten,

1997). Thus, the covalent linkage of the propeptide with AT prevents its displacement until it is proteolytically activated. Furthermore, the addition of excess synthetic propeptide to activated AT monomers abrogates toxin activity by blocking oligomerization of activated monomers (Sellman and Tweten, 1997). Apparently, excess propeptide shifts the equilibrium onto the toxin and inhibits association of the monomers by occupying its position on the toxin, even in the absence of a covalent linkage. In the molecular model of AT the propeptide is located in domain 3 (Figure 34.1). The propeptide appears to protect an interfacial domain in domain 3 that is involved in monomer-monomer interaction.

The formation of a prepore complex has been demonstrated for several pore-forming toxins. The prepore complex is defined as a membrane-bound oligomer that has not formed the pore complex. Presumably the formation of the prepore complex organizes and coordinates the insertion of the membrane-spanning β-barrel of the pore-forming toxin. It has been shown that AT binds and oligomerizes on erythrocytes with nearly identical kinetics at both 4˚C and 37˚C; however, pore formation of the oligomer-containing membranes is completely abrogated at 4˚C (Sellman *et al*., 1997). The block in pore formation at 4˚C can be removed by a temperature shift to 37˚C, leading to the immediate formation of pores (Sellman *et al*., 1997). The fact that oligomers are present at 4˚C without pore formation supports the idea that AT oligomerizes into a prepore complex on the membrane surface prior to insertion.

## The transmembrane domain of AT and membrane insertion

Bacterial pore-forming toxins are unique proteins that exhibit an amphipathic nature in which they can exist in both soluble and membrane-associated states. Pore-forming toxins are often secreted from the bacteria into the surrounding milieu as water-soluble, hydrophilic monomers that bind to target cells, where they eventually protrude into the bilayer to reach their end-stage conformation as pore-forming homo-oligomers (Heuck *et al*., 2001). The fact that these proteins spontaneously insert into target membranes without the aid of complex machinery makes them distinctive from other end-stage, membrane-embedded proteins. Unlike colicins and other membrane-interacting proteins that contain long stretches of hydrophobic amino acids used to span the membrane, bacterial pore-forming toxins lack such hydrophobic regions in their sequence.

The crystal structure of the pore complex of the *Staphylococcus aureus* α-hemolysin by Song *et al*. (Song *et al*., 1996) provided considerable insight into the structure of a β-barrel pore. The pore was comprised of seven amphipathic β-hairpins that formed a 14-stranded β-barrel, a structure similar to that of the Gram-negative porins. The residue side chains comprising an amphipathic β-barrel have alternating hydrophobic/hydrophilic characters. Thus, once formed, one "side" of the barrel is capable of interacting with the hydrophobic membrane, while the other forms for interacting with the hydrophilic lumen of the pore. To date, the transmembrane structure of pore-forming toxins has often been determined to be an amphipathic β-strand. These include α-hemolysin from *Staphylococcus aureus* (Valeva *et al*., 1996), the protective antigen (PA) component of anthrax toxin (Benson *et al*., 1998), and perfringolysin O from *Clostridium perfringens* (Shepard *et al*., 1998; Shatursky *et al*., 1999). The size of the β-barrel formed by the various pore-forming toxins varies considerably; α-hemolysin and anthrax PA typically form heptameric oligomers, whereas the size of the PFO oligomer can vary from about 35–37 monomers (Czajkowsky *et al*., 2004), each of which contribute two transmembrane β-hairpins to the β-barrel structure.

Based on the crystal structure of aerolysin, it was hypothesized that D4 of aerolysin inserts three β-strands into the target membrane upon cleavage and removal of the propeptide (Parker *et al*., 1994). They suggested that removal of the propeptide following activation would expose a patch of hydrophobic residues in D4 of aerolysin capable of interacting with the hydrophobic core of the bilayer (Parker *et al*., 1994). A study on a point mutant of aerolysin that forms a water-soluble heptamer reiterated this idea, in which the authors hypothesized that the upper boundary of the transmembrane domain was distinguished by an aromatic belt in D4, similar to those found in porins (Tsitrin *et al*., 2002). However, no direct interaction of this domain with the membrane had been demonstrated. Other studies on aerolysin demonstrated that movement of a loop region in D3 of its structure (homologous to D2 of AT) is required for pore formation (Rossjohn *et al*., 1998). The authors were able to "lock" the loop region to the backbone of the molecule by mutating two residues (one on the loop region and one on the backbone) to cysteines and producing a disulfide bond. This form of aerolysin is completely inactive until a reducing reagent is added, at which time full activity is regained. In contrast to AT, aerolysin exists as a head-to-tail dimer in solution. As head-to-head oligomers are necessary for pore formation, the head-to-tail dimer must be dissociated prior to oligomerization of the prepore complex on the membrane. By locking this loop into place, the aerolysin

disulfide mutant failed to oligomerize, unless the disulfide was reduced. Thus, movement of the loop region in D3 of aerolysin may be required for head-to-tail dimer dissociation, pore formation, or both.

In contrast to aerolysin, AT does not appear to form a dimer in solution and so does not require dissociation of a dimer complex for membrane oligomerization. This aspect of AT simplified the search for the transmembrane domain of AT, and recently the membrane-spanning domain for AT was identified and determined to form an amphipathic β-barrel (Melton *et al*., 2004). The transmembrane domain of AT is comprised of the loop region in D2 of its molecular model, spanning from residues F200 to S235, and is homologous to the D3 loop of aerolysin discussed previously (Melton *et al*., 2004). This region was a candidate transmembrane domain based on the following observations. First, the primary structure of this region alternates between residues with hydrophobic and hydrophilic side chains, as would be expected for an amphipathic β-strand. Second, the manner in which the loop is extended from the backbone of the molecule in the molecular model appears to give it conformational freedom to move away from the backbone of the molecule and insert into the bilayer. This region was defined as the transmembrane domain by the use of various techniques. First, the construction of various sized deletion mutants that removed approximately 30% (Δ212–222), 60% (Δ208–226), or 90% (Δ204–231) of this region each demonstrated a complete loss of cytolytic activity, while retaining full receptor binding and oligomerization (Melton *et al*., 2004). As mentioned above, previous work on aerolysin in which an engineered disulfide bond was used to fasten the homologous loop region to the backbone of the molecule showed that movement of this region is required for pore formation. The analogous mutations were engineered into AT to determine if movement of the homologous region was required for pore formation. The disulfide-trapped mutant of AT bound to the receptor and oligomerized on membranes similar to wild-type AT; however, it was cytolytically inactive, unless the disulfide bond was reduced (Melton *et al*., 2004). These studies showed that movement of this loop in AT was required for the successful conversion of the prepore to the pore.

A direct interaction of this region with the membrane was demonstrated using the fluorescence-based approaches of Shepard *et al*. (Shepard *et al*., 1998) and Shatursky *et al*. (Shatursky *et al*., 1999), previously used for the identification and characterization of the transmembrane domains of PFO. These techniques take advantage of the environmentally sensitive properties of the sulfhydryl-specific fluorescent dye iodoacetamide-NBD (NBD). When NBD is attached to a residue that enters a hydrophobic environment such as the membrane, its fluorescent intensity will increase. On the other hand, when NBD is attached to a residue that remains in a hydrophilic environment, such as the lumen of the channel, its fluorescent intensity is quenched by water. When the residues of the loop region in D2 of AT (F200-S235) were individually mutated to cysteine and labeled with NBD, the fluorescence intensity changes detected upon insertion into membranes produced an alternating periodicity defining an amphipathic β-strand (Melton *et al*., 2004). The location of residues within the membrane was verified using a membrane-restricted collisional quencher of NBD, DOXYL-stearic acid. This lipid contains a nitroxide on the fatty acyl chain that is buried within the membrane. Nitroxides are efficient collisional quenchers of NBD; therefore, if the NBD resides within the membrane, its fluorescence will be quenched. When DOXYL-stearic acid was incorporated into the membranes, the NBD modified, cysteine-substituted residues that exhibited an increase in fluorescence intensity, when AT was membrane inserted, were quenched by the presence of the collisional quencher. Since this quencher could only quench NBD that was buried in the bilayer, these experiments confirmed that these residues formed a membrane-penetrating amphipathic β-hairpin (Melton *et al*., 2004).

## AT AND PATHOGENESIS

*C. septicum* is an infrequent cause of human infection, responsible for only 1.3% of all human clostridial infections (Kornbluth *et al*., 1989). While it is associated to the greatest extent with non-traumatic gas gangrene, it has also been associated with numerous other disease states, such as cerebritis (Roeltgen *et al*., 1980), meningitis (Dirks *et al*., 2000; Cheng *et al*., 1997), osteomyelitis (Neimkin and Jupiter, 1985; Shetty *et al*., 1998), necrotizing enterocolitis (Bignold and Harvey, 1979; Lev and Sweeney, 1993), necrotizing fasciitis (Schreuder and Chatoo, 1997), pericarditis (Brahan and Kahler, 1990), and as a superinfection of *E. coli* O157:H7-induced hemolytic uremic syndrome (Barnham and Weightman, 1998). No matter the disease course, infection with *C. septicum* is always accompanied by a predisposing condition, most notably malignancy. The association between *C. septicum* infection and malignancy has been detected in 81–85% of all known cases, and is occult in 35–37% of these cases at the time of

presentation (Alpern and Dowell, 1969; Kornbluth *et al*., 1989).

The most common form of malignancy associated with *C. septicum* infection is adenocarcinoma of the colon, found in up to 88% of all cases of *C. septicum* bacteremia and present in 84% of all cases with occult malignancies (Kornbluth *et al*., 1989). The relationship between *C. septicum* bacteremia and intestinal malignancy is so high that the bacteremia is often the first sign of an occult colonic carcinoma (Stevens *et al*., 1990).

The precise relationship between AT and *C. septicum* pathogenesis remains elusive. AT appears to be the sole lethal factor secreted by *C. septicum* (Ballard *et al*., 1992), but due to the difficulty of genetic manipulation of *C. septicum*, a gene knockout of AT is currently unavailable to assess its contribution to experimental myonecrosis. Several experiments using purified AT have produced convincing evidence that it is likely a major contributor to *C. septicum* myonecrosis. First, purified AT injected into mice induces rapid shock and death (Tweten and Brackett, unpublished results). AT-induced shock in these animal models is due to the sudden loss of fluid from the circulatory system, similar to the symptoms seen in the latter course of most human cases of *C. septicum* non-traumatic gas gangrene and necrotizing enterocolitis. In addition, immunization to AT provides protection to mice challenged with *C. septicum*. AT-immunized mice demonstrate a 20% mortality rate versus a 70% mortality rate in non-immunized animals when challenged with live *C. septicum* (Ballard *et al*., 1992). The ability of AT to exclusively mediate systemic effects has also been evidenced in a human case of *C. septicum*–associated meningeal vasculopathy, where complete lysis of vascular smooth muscle was observed in the absence of culturable organism or inflammation (Crowley *et al*., 1997). The immunogenicity of AT is also apparent in survivors of atraumatic gas gangrene, in whom AT has been shown to be the major immunodominant extracellular antigen (Johnson *et al*., 1994).

## CONCLUSION

A significant understanding of the structure-function relationships and cytolytic mechanism of AT, and that of the related aerolysin, has been gained in the last decade. It is likely that future investigations will focus on the contribution of AT to disease. It is apparent that several clostridial species can cause myonecrosis, yet they exhibit a varied array of lethal toxins that are not highly conserved among the histotoxic clostridia. For instance, *Clostridium septicum* produces the pore-forming AT, whereas *C. perfringens* produces an α-toxin that is a phospholipase C enzyme. Although each organism produces a different array of toxins, both cause virtually indistinguishable myonecrosis. Therefore, the central enigma to this disease is how lethal factors with very different mechanisms of actions contribute to its development.

Another interesting arena of investigation will be the study of the newest members of this family of toxins, enterolobin and *C. perfringens* epsilon toxin. Enterolobin is unusual since it is produced by a plant and is phylogenetically distant from the bacterial members of this family. Clearly, enterolobin is likely used in a very different way by the *E. contortisiliquum* tree than its bacterial counterparts. Little is understood about its mechanism or contribution to the life cycle of *E. contortisiliquum*. Whether epsilon toxin or enterolobin follow a similar mechanistic pathway to AT and aerolysin remains to be determined. The evolution of this family of toxins is also of interest, as it remains to be determined if the family members arose via divergent and/or convergent evolution. It is likely that the continued study of this family of toxins will reveal additional surprises and insights into how they function and contribute to the survival of their host species.

CHAPTER

# 35

# *Clostridium perfringens* ε-toxin

*Ajit K. Basak, M. Popoff, R. W. Titball, and Ambrose Cole*

## INTRODUCTION

The genus *Clostridium* is a diverse and heterogeneous group of Gram-positive, anaerobic spore-forming bacteria. They are widely distributed in soil, sewage, and water. In addition, some species are present as part of the normal flora in the gastrointestinal tract of humans and animals. To date, over 100 different species of the *Clostridium* genus have been characterized and classified into different clusters on the basis of their 16s rDNA sequences. *Clostridium perfringens* is one member of this genus and is the causative agent of a wide variety of diseases, including gas gangrene, food poisoning, and necrotic enteritis in humans. The bacterium also causes a range of severe gastrointestinal and enterotoxemic diseases in domesticated livestock. The etiology of diseases caused by *C. perfringens* can be ascribed mainly to the production of various extracellular toxins, which are classified as either major or minor toxins. Based on the production of different major toxins (α-, β-, ε-, and ι-toxin), *C. perfringens* has been classified into five different groups (A, B, C, D, and F) (Table 35.1). In addition to the major toxins, the bacterium is also capable of producing a range of minor toxins such as θ-, λ-, ι-, μ-, κ-, and β2-toxin, as well as enzymes such as neuraminidase and urease (Laetitia *et al*., 1999; Rood, 1998). Not all these toxins have a proven role in virulence, and the recent genome sequence of *C. perfringens* type A has identified the presence of many more putative virulence genes whose functions are not yet known (Shimizu *et al*., 2002).

Recent evidence suggests that some of the toxins produced by this microorganism could be exploited as biological weapons. The activities of the United Nations Special Commission (UNSCOM, available at the Center for Non-proliferation Studies, Monterey Institute of International Studies, (http://www.cns.miis.edu/iiop/cnsdata) clearly identified *C. perfringens* as one of the microorganisms used to develop biological weapons by various aggressor states (Bowmann, 1998; Cordesman, 1998; Starr, 1998). The α-, β-, and ε-toxins and enterotoxin have all been suggested as candidate biological weapons in the past, but the ε-toxin is the most potent of this group with a mouse lethal dose ($LD_{50}$) of only 100ng/kg of body weight (Gill, 1982). This toxin is included in the Centers for Disease Control list of selected agents that might be used as biological weapons (Atlas, 1998).

In spite of research on ε-toxin over the past 50 years, its mode of action is still not clear. However, during the past decade some major advances have been made in understanding the molecular basis of toxicity. The aim of this article is to review these advances and summarize our knowledge of ε-toxin.

## ε-TOXIN

Of the five toxinotypes (A–E), only type B and D strains of *C. perfringens* produce ε-toxin (Brooks *et al*., 1957), and these strains are isolated mainly from the gut of diseased sheep and lambs, though occasionally from goats, cattle, and rarely from humans (Smith and Williams, 1984).

The ε-toxin, which has a predicted molecular weight of 32.5 kDa and 311 amino acids, is secreted as an inactive prototoxin (McDonel, 1986), which is activated to a mature lethal toxin by proteolytic cleavage (Bhown and Habeeb, 1977). Either the host or the bacterium

**TABLE 35.1** Diversity of *Clostridium perfringens* toxinotypes, genotypes, and the pathology associated with animals

| Toxinotype | Major toxin produced | Gene type and location | Associated pathology in domestic animals |
|---|---|---|---|
| A | α-toxin | *plc* / chromosome | Enterotoxemia in bovine and ovine, fowl necrotic enteritis, Myonecrosis, equine colitis, etc. |
| | α-toxin | *plc* / chromosome | Dysentery, chronic enteritis in lambs, entertoxemia in bovine and equine, bovine enteritis, etc. |
| B | β-toxin | *cpb1* / plasmid | |
| | ε-toxin | *etxB* / plasmid | |
| | α-toxin | *plc* / chromosome | Fowl necrotic enteritis, entertoxemia in ovine, bovine, equine, porcine, etc. |
| C | β-toxin | *cpb1, cpb2* / plasmid | |
| | α-toxin | *plc* / chromosome | Enterotoxemia in lambs and calves, bovine enterotoxemia. |
| D | ε-toxin | *etx*D / plasmid | |
| | α-toxin | *plc* / chromosome | Enterotoxemia in bovine and ovine, rabbit enteritis. |
| E | ι-toxin | *iap, ibp* / chromosome | |

provides the proteases, such as trypsin, chymotrypsin (Bhown and Habeeb, 1977; Hunter *et al*., 1992), or λ-protease (Jin *et al*., 1996; Minami *et al*., 1997) for cleavage of the prototoxin (Figure 35.1).

Maximum activation of the toxin occurs when a combination of trypsin and chymotrypsin is used, resulting in the loss of 13 N-terminal basic residues and 29 C-terminal residues, producing a mature toxin that is greater than 1,000-fold more toxic than the prototoxin, with an $LD_{50}$ of 70ng/kg. If activation occurs using pure trypsin, then cleavage at the C-terminus occurs seven residues later. This causes lower toxicity with an $LD_{50}$ of 320ng/kg. As mentioned, the toxin can also be activated by a protease secreted by *C. perfringens*, known as λ-toxin. This cuts the C-terminus at the same point as chymotrypsin, but leaves three extra residues at the N-terminus. The resulting activity is close to maximal with an $LD_{50}$ of 100ng/kg (Minami *et al*., 1997). The cleavage also causes a marked shift of pI from 8.02 for the prototoxin to 5.36 in the mature toxin, as well as a moiety with a pI of 5.74 thought to be partially activated toxin (Worthington and Mulders, 1977).

## GENETIC ARRANGEMENT

The ε-toxin encoding gene (*etx*) is located on a large plasmid (Canard *et al*., 1992) and appears to be associated with *IS1151* (Johnson, 1997), suggesting that it may be mobile. Both toxinotype genes (*etxB* and *etxD*) have been sequenced and only two differences have been found in the open reading frame (Figure 35.2). The first change, at position 762, does not result in an amino acid substitution. The second change, at position 962, results in a substitution from serine, in *etxB*, to tyrosine in *etxD* (Havard *et al*., 1992).

The upstream regions of the *etxB* and *etxD* genes are not identical with different putative −10 and −35 promoter regions (Figure 35.3). This suggests that expression of these genes may be regulated in different ways in type B and type D strains of *C. perfringens*. This possibility is supported by the observation that the strain from which the *etxD* gene was isolated (NCTC 8346) produced 10 times the amount of ε-toxin as the strain from which the *etxB* gene was isolated (NCTC 8533) (Havard *et al*., 1992). The prototoxin is expressed with a

**FIGURE 35.1** The points of cleavage of the ε-prototoxin to form the mature toxin by three proteases: trypsin, chymotrypsin, and λ-toxin.

**FIGURE 35.2** The genetic sequence of ε-Toxin, *etxB*. Underlined is the signal sequence for secretion and those letters in superscript refer to the sequence found in the *etxD* gene. In bold and italics are the regions cleaved for maximal activation (Hunter *et al*., 1992). Essential residues for lethal ativity are indicated by asterisks.

signal sequence of 32 amino acids that directs export of the toxin from the cell. When cloned into *Escherichia coli*, the signal sequence appears to direct export of the toxin across the cell membrane, resulting in accumulation of the toxin in the periplasmic space (Hunter *et al*., 1992).

## SEQUENCE ANALYSIS OF ε-TOXIN

The primary structure of ε-toxin bears no sequence similarity to any protein with a known structure in the current protein data bank (www.rcsb.org/pdb). However, the amino acid sequence of ε-toxin shows some homology to the *Bacillus sphaericus* mosquitocidal toxins Mtx2 and Mtx3, with 26% and 23% sequence identity, respectively. The *B. sphaericus* toxins and ε-toxin may have a similar mode of action, and both are activated by proteolytic cleavage (Liu *et al*., 1996; Thanabalu and Porter, 1996).

Studies on the chemical modification of ε-toxin have identified several essential amino acids, which include tryptophan, as well as some tyrosine and histidine residues (marked with an asterisk in Figure 35.2) that are essential for the activity of ε-toxin and its putative receptor binding to the membrane (Sakurai and Nagahama, 1985; Sakurai and Nagahama, 1987a; Sakurai and Nagahama, 1987b; Payne and Osten, 1997). Substitution of the two histidine residues, His119 or His162 (numbered from the prototoxin start), either with alanine or with serine, does not abolish

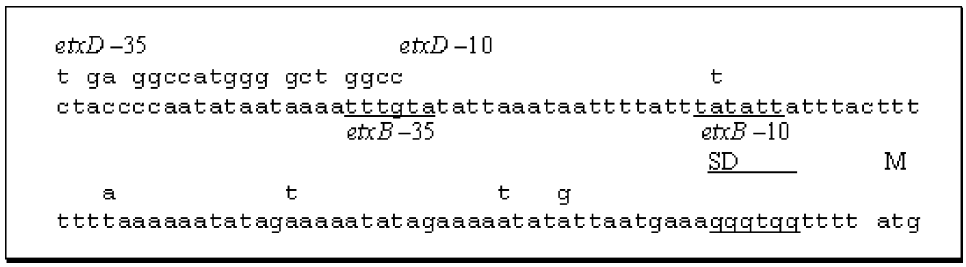

**FIGURE 35.3** The nucleotide sequence of the upstream promoter-binding region of both the *etxB* and *etxD* genes. Above the sequence is the prospective –35 and –10 regions for the *etxD* gene along with the substitutions. Below the sequence is the prospective *etxB* gene –35 and –10 regions. The Shine Dalgarno site (SD) is the same in both genes. The last three nucleotides code for the first methionine (M) of the signal sequence (Havard *et al*., 1992).

lethal activity; however, the change of His162 to alanine results in a significant decrease in lethal activity (Oyston *et al*., 1998).

## PATHOLOGY ASSOCIATED WITH INTOXICATION

Small amounts of toxin in the gut of animals are considered innocuous, but high concentrations lead to disease. For example, the toxin is responsible for a severe enteritis and an often fatal form of enterotoxemia in domestic livestock animals. *C. perfringens* type B is associated especially with dysentery in lambs, while *C. perfringens* type D is associated with enterotoxemia in sheep and lambs, along with a condition known as pulpy kidney or overeating disease (Bullen, 1970). These diseases are usually fatal and are characterized by a short period of time between the first appearance of symptoms and death. The mortality rate can be as high as 100%, and the diseases are of major economic significance, especially in industries based on intensive farming.

Pulpy kidney disease is closely correlated with changes in the microbial balance of the gut and often follows changes to the diet or treatment with antibiotics. Undigested food passed into the ileum creates a rich anaerobic environment in which *C. perfringens* can grow and multiply as high as $10^9$ cells per gram of ileum contents with each cell producing ε-toxin (Payne and Oyston, 1997). Crude vaccines exist for the prevention of disease associated with type B and D strains of *C. perfringens*. These vaccines are based on formaldehyde-treated cell filtrates or bacterial cells. The immunogenicity of these vaccines is variable (Percival *et al*., 1990), and the vaccines may not provide complete protection from disease. In this context, methods for the reliable production of ε-toxoid vaccines remain one of the challenges facing the veterinary vaccine industry.

The symptoms of disease, including neurological dysfunction and interstitial and pulmonary edema, can be reproduced by the administration of purified ε-toxin into goats and lambs (Uzal and Kelly, 1997; Uzal and Kelly, 1998), and generally appear within an hour. Many animals die peracutely, without premonitory signs (Niilo, 1993; Popoff, 1984). Peritoneal and pericardial effusions are common in naturally infected sheep (Jubb *et al*., 1993), and hyperglycemia and glycosuria are pathognomonic (Gardner, 1973; Niilo, 1993). Focal encephalomalacia, with bilaterally symmetrical brain lesions, is a chronic neurological manifestation of enterotoxemia (Buxton *et al*., 1981; Hartley, 1956). Other clinical signs of intoxication with ε-toxin include retraction of the head, opisthotonus (spasm of the body where the head and heels are bent backward and the body is bowed forward), convulsions, agonal struggling, hazard roaming, and head pressing, and they are often seen during the progression of this form of enterotoxemia (Songer, 1996).

A number of studies have shown that large doses of the toxin cause increased intestinal permeability, facilitating entry into the blood. The toxin then crosses the blood-brain barrier and accumulates in the brain as well as in the kidney, causing widespread osmotic alterations by disrupting vascular endothelia. These degenerative changes eventually cause serum proteins and red blood cells to leak out of the vasculature and cause massive edema (Finnie, 1984a) (Figure 35.4).

## NEUROTOXICITY

Pathological changes are apparent mainly within the brain, where necrotic brain lesions can be observed. Low doses of ε-toxin have been shown to damage the hippocampus, as well as the corpus striatum, cerebral cortex, vestibular area, corpus callosum, and corpus medullar cerebelli (Finnie, 1984b). In rats and mice, the

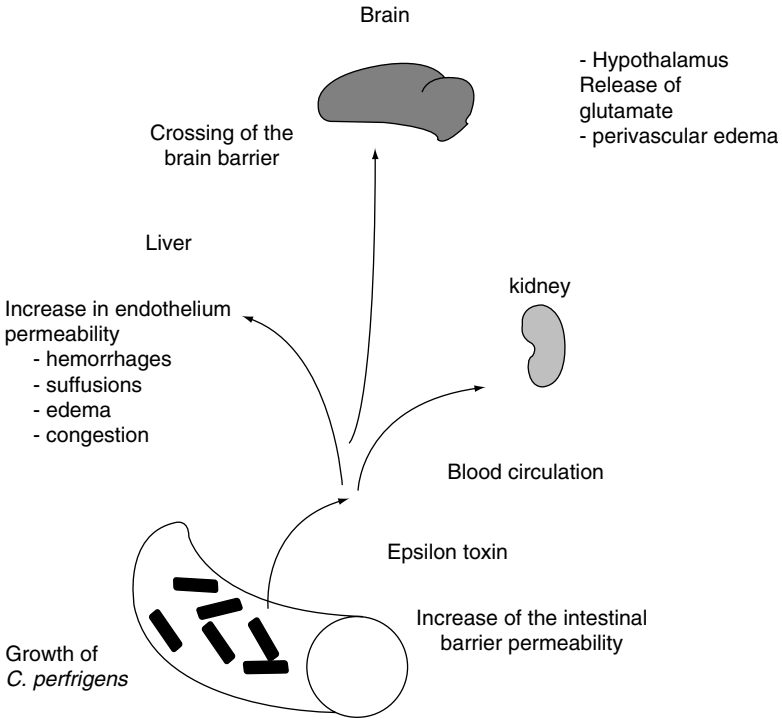

**FIGURE 35.4** Schematic representation of the ε-toxin mode of action.

hippocampal damage is associated with increased release of glutamate within specific regions (Miyamoto *et al*., 1998; Miyamoto *et al*., 2000). This increase in post-synaptic glutamate levels is apparently not the result of membrane damage because prior treatment of animals with glutamate release inhibitors reduces this effect and also gives some protection from intoxication. Cholinergic fibers in the same region are not affected, suggesting interaction with cells that use glutamate as a neurotransmitter. Focal-to-diffuse areas of degeneration and necrosis are common in affected animals (Buxton and Morgan, 1976), and bilateral macroscopic foci of encephalomalacia can occur (Buxton *et al*., 1981; Hartley, 1956; Finnie, 1984a; Finnie, 1984b). Clinical signs indicative of central nervous system (CNS) derangement, including incoordination and convulsions, are directly related to the severity of lesions (Griner *et al*., 1956). Vascular endothelial tight junctions degenerate (Buxton and Morgan, 1976), causing swelling and rupture of perivascular astrocyte processes (Finnie, 1984a). In mice, purified ε-toxin disrupts the permeability of the blood-brain barrier and allows the leakage of radiolabeled polyvinyl-pyrroliodone or human serum albumin into the brain, a discovery that led to the toxin first being labeled as a permease (Worthington and Mulders, 1975).

In sheep, intoxication with ε-toxin results in increased levels of cyclic adenosine 3', 5' mono-phosphate in the blood. This is thought to be a consequence of increased levels of ephedrine and norephidrine, which are, in turn, caused by the widespread edema (Worthington *et al*., 1979). Changes in these catecholamine levels have not been observed in mice (Nagahama and Sakurai, 1993). A significant drop in dopamine levels in brain tissue has been recorded in mice when large doses of toxin are administered. It has also been observed that drugs that inhibit the release of dopamine partially protect the mice from the lethal effects of ε-toxin (Nagahama and Sakurai, 1993).

Prior injection of mice with ε-prototoxin has also been shown to reduce the effects of the active toxin. This along with its clear preference for certain cell types indicates the presence of a specific receptor to which epsilon toxin binds. Activated ε-toxin has been shown to have a high affinity-binding site in the rat brain synaptosomal membrane (Nagahama and Sakurai, 1992) and has been suggested that the receptor is a sialoglycoprotein (Nagahama and Sakurai, 1992; Payne *et al*, 1997). The treatment of synaptosomal fractions of brain tissue with various enzymes has been used to try to ascertain what is important for ε-toxin binding. Pretreatment with a neuraminidase reduces binding, therefore suggesting that a sialoglycoprotein is important for the binding of ε-toxin (Nagahama and Sakurai, 1992).

## TOXICITY TOWARD CULTURED CELLS

A major step forward in the study of the mode of action of ε-toxin was the finding that Madin Darby Canine kidney (MDCK) cells were sensitive to ε-toxin (Knight *et al*., 1990; Payne *et al*., 1994). Subsequently, Lindsay and coworkers examined 17 different human cell lines along with MDCK cells and established that exposure of cells to 2μg/ml of ε-toxin reduced cell viability to 50% ($LC_{50}$) (Lindsay, 1996a). The only susceptible human cell line, Caucasian renal leiomyoblastoma (G-402) cells, was more resistant to intoxication with an $LC_{50}$ of 280 μg/ml.

*In vitro* exposure of MDCK cells with purified *C. perfringens* ε-toxin reveals evidence of cytoskeletal changes and irreversible damage to cells' plasma membrane (Donelli *et al*., 2003). MDCK cells become permeable to propidium iodide within two min of exposure to ε-toxin (Petit *et al*., 2001) and rapidly develop morphologic changes consistent with intoxication (Borrmann *et al*., 2001; Hambrook *et al*., 1995; Lindsay, 1996a; Petit *et al*., 1997; Petit *et al*., 2001). Cells subsequently swell, develop membrane blebs, and lyse (Borrmann *et al*., 2001; Petit *et al*., 1997; Petit *et al*., 2001) (Figure 35.5). However, there is no evidence of internalization of the toxin; the treatment of MDCK cells with sodium azide or agents that block endosome acidification (chloroquine, monensin, and bafilomycin A1) does not reduce toxicity, suggesting that endocytosis or other energy-dependent mechanisms are not required (Lindsay, 1996b; Petit *et al*., 1997).

The binding of ε-toxin to MDCK cells (and rat synaptosomal membranes) is associated with the formation of a stable high molecular weight complex (Nagahama *et al*.; 1998; Petit *et al*.; 1997). The formation of large complexes has also been observed with other pore-forming bacterial toxins, such as *Staphylococcus aureus* α-hemolysin (Song and Gouaux, 1998), *C. septicum* α-toxin (Melton *et al*., 2004), *Pseudomonas aeruginosa* cytotoxin (Ohnishi *et al*., 1994), and *Aeromonas hydrophilia* aerolysin (Wilmsen *et al*., 1992). Membrane fractions of neuronal cells exposed to $^{125}$I-labeled ε-toxin analyzed by SDS-PAGE and autoradiographed show the toxin migrating as two distinct bands. The first is a light band at 34 kDa, which approximately fits the predicted size of the monomer. The second is far heavier at 155 kDa and indicates the presence of some form of multimer. This 155-kDa band represents a highly stable, SDS-resistant complex of ε-toxin present in the membranes, allowing the efflux of $K^+$ (Petit *et al*., 1997).

Fully activated toxin is cleaved both at the N and C termini. Recombinant forms of the toxin, with these regions removed (Δ-C, Δ-N, and Δ-NΔ-C forms of the toxin), show differing abilities to form multimers. Constructs possessing the C-terminal sequence are never observed to form the large complexes, whereas those missing this sequence do (Miyata *et al*., 2001). The presence of two monomers, Δ-C and Δ-NΔ-C, with the ability to form a large complex have made it possible to ascertain the number of molecules present. Heterogeneous mixtures of the two forms produce autoradiographs with six intermediary bands present when using various molar ratios of the two constructs. This indicates that the complex formed is, in fact, a heptamer. This is inconsistent with the recorded size of the complex, as a heptamer of Δ-NΔ-C truncated toxin would have a mass of 198.25 kDa, whereas the recorded bands are between 155–180 kDa. But the heptameric form of the protein is SDS resistant and this may affect travel distance on a gel (Figure 35.6).

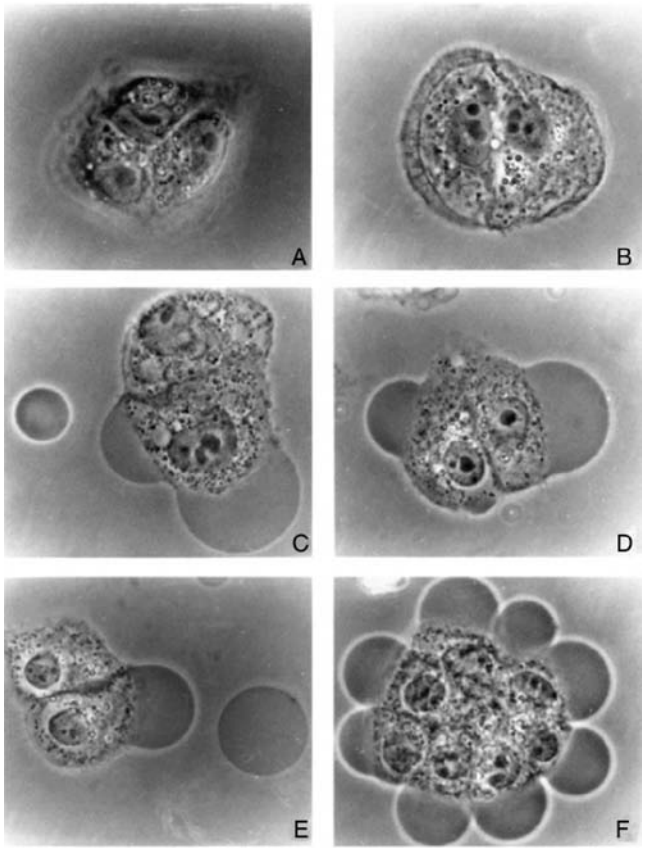

**FIGURE 35.5** Morphological changes of MDCK cells induced by ε-toxin. The cells were exposed to ε-toxin (50–375 ng/ml) for 60 minutes at 37°C in a 5% $CO_2$ incubator and were observed under phase contrast (magnification, X100). (A) Control cells; (B to F) cells exposed to ε-toxin at 50 ng/ml (B), 120 ng/ml (C and D), 210 ng/ml (E), and 375 ng/ml (F). Swelling is observed in panel B, and blebbing is observed in panels C to F. (Reproduced from *J. Bacteriol*, 1997, **179**, No. 20, 6480–6487, with permission from Prof. M. Popoff)

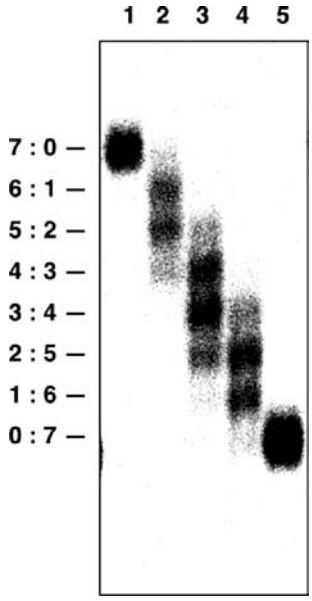

**FIGURE 35.6** Heptameric complex formation through copolymerization of [$^{32}$P]-Δ-C-PD and [$^{32}$P]-Δ-NΔ-C-PD. The proteins were mixed in different proportions: 1:0 (lane 1), 2:1 (lane 2), 1:1 (lane 3), 1:2 (lane 4), and 0:1 (lane 5). Each mixture (12 ng of protein) was incubated with synaptosomal membranes (2.2 μg of protein) in 12 μl of TBS. Samples were heated in SDS-sample buffer and separated on a 5% SDS-PAGE gel and autoradiographed. The predicted molar ratios of [$^{32}$P]-ΔC-PD to [$^{32}$P]-ΔNC-PD are listed on the left. (Reproduced from *J. Biol. Chem*. 2001, **276**, No. 17, 13778–13783, with the permission of Prof. A. Okabe.)

The possible pore-forming ability of ε-toxin has also been investigated via experiments using lipid bilayers. Activated ε-toxin added to bilayer membranes causes an increase in conductance across the membrane in a stepwise fashion after about two minutes. After about 30 minutes, the increase is of about three orders of magnitude (Petit *et al*., 2001). This stepwise increase indicates not only the presence of pores within the membrane after the addition of ε-toxin, but also that these pores are long lived with no association-dissociation equilibrium. Though various lipids have been used in these experiments, the toxin has not been shown to have any lipid preference (Petit *et al*., 2001). The size of these pores has also been investigated and shown to be at least 2 nm in diameter. The method, however, has limitations, as the polyethylene glycols (PEGs) used to size the pores have been shown to be slightly toxic to the MDCK cells.

Many pore-forming toxins have been shown to interact specifically with regions of the membrane known as detergent resistant micro-domains (DRMs). These regions within the membrane have a distinct liquid-ordered phase and preferentially contain distinct classes of proteins. Toxins such as aerolysin (Fivaz *et al*., 2001) and perfringolysin (Waheed *et al*., 2001), as well as their close relatives, all use DRMs as their main point of attack. These toxins share many similarities to ε-toxin with their pore-forming activity and mainly beta-sheet nature. Studies have therefore been carried out to ascertain ε-toxin's interaction with these regions. Both monomeric and heptameric toxin accumulates in this region, and depletion of cholesterol, a major constituent of DRMs, has an inhibitory effect on the toxin (Miyata *et al*., 2002). Additionally, the prototoxin is seen to bind mainly to DRMs. Although the prototoxin is unable to heptamerize, it is able to bind to the same receptor as that used by activated toxin, indicating that heptamerization is not a prerequisite for interactions with susceptible cells, but rather a result of binding. The putative receptor for ε-toxin is therefore thought to be present mainly in the DRMs, and all steps from binding to membrane insertion are thought to occur in these regions. The toxin is capable of forming channels in lipid bilayers easily without the presence of a receptor (Petit *et al*., 2001). This is also the case with other toxins, such as aerolysin, and has led to the proposition that as the receptors to which proteins bind are conserved to DRMs, they act in a manner so as to locally concentrate the toxins allowing heptamerization (Abrami and van Der Goot, 1999). However, ε-toxin is different from many pore-forming toxins in its specificity, because it only binds to very few cell types, unlike aerolysin, which binds to many GPI-linked proteins that are preferentially sequestered to DRMs.

## THE ε-TOXIN STRUCTURE

Recently, the 3D structure of ε-toxin was determined (Cole *et al*., 2004), although using the method of multiple anomalous diffraction as a model with enough similarity was not available in the current protein structure data bank (www.rcsb.org/pdb). The structure of ε-toxin is very elongated (100Å×20Å ×20Å) and is composed of mainly β-sheets (Figure 35.7a). The molecule can be divided into three domains with two strands (57–91 and 172–207) that travel the entire length of the molecule, covering a distance of approximately 130Å with only minor distortion occurring between domains. The first domain contains the largest α-helix (20–42), followed by a loop and then a short $3_{10}$ helix (46–49). Beyond this is the first strand of a three-stranded anti-parallel sheet (55–65, 197–206, and 214–220) upon which the large helix lies. In the region between domains one and two, there is a short $3_{10}$ helix (221–225) followed by a long loop (226–236). The region immediately after the long helix (42–52)

and part of the loop between domains (225–230) all exhibit some disorder as seen in the B-factors. The second domain is a β-sandwich containing a five-stranded sheet (62–82, 184–196, 237–248, 109–119, 150–160) and a two-stranded sheet (124–132, 141–146), both of which are anti-parallel. The final domain is also a β-sandwich motif, with one four-stranded (80–91, 172–185, 250–258, 262–267) and one three-stranded sheet (96–109, 161–170, 281–291). The final strand of the three-stranded sheet is the only parallel strand in the structure and forms a large part of the C-terminus that is removed on activation.

## COMPARISON OF ε-TOXIN AND AEROLYSIN

The overall fold of the ε-toxin structure shows some distinct similarity to aerolysin from the Gram-negative bacterium *Aeromonas hydrophila* (Parker *et al*., 1994). Despite the relatively poor sequence identity (~14%), both the structures show remarkably similar beta sheet arrangements (Figure 35.7a, b). In addition, ε-toxin shares many of the properties of aerolysin. Both toxins form heptameric pores (Moniatte *et al*., 1996) and both are secreted as prototoxins, which are activated by the removal of a C-terminal sequence by proteases.

One clear difference between the structures of ε-toxin and aerolysin is the presence of an additional domain in aerolysin (domain I in Figure 35.7b) (Parker *et al*., 1994). This domain has been postulated to be responsible for initial interaction with cells (MacKenzie *et al*., 1999). This initial binding can occur before activation, because furin, found in the eukaryotic cell membrane, is often the activating factor. However, furin is not preferentially located in detergent-resistant micro-domains (DRMs) where aerolysin

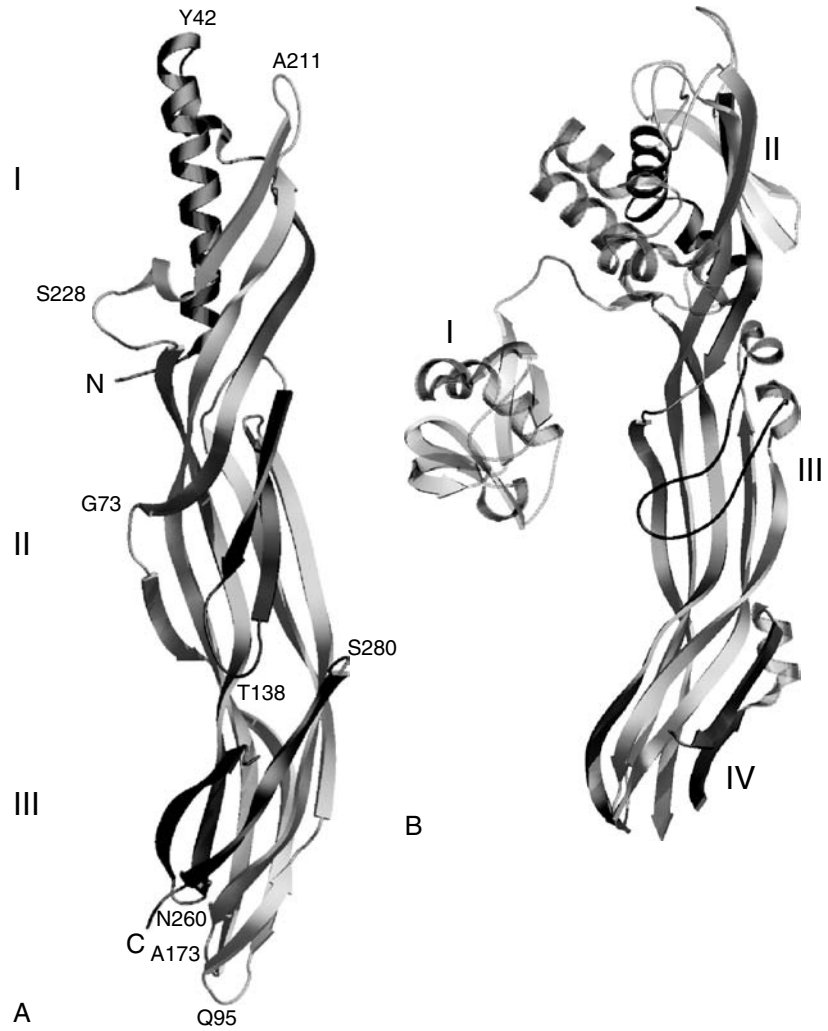

**FIGURE 35.7** Ribbon diagram of *C. perfringens* epsilon toxin **(a)** and *Aeromonas hydrophilia* aerolysin **(b)** colored from black at the N-terminus to medium-gray at the C-terminus. The additional domain in the aerolysin structure is colored in light-gray.

accumulates, therefore, some lateral movement of the toxin on the cell is required for activation.

The first domain of ε-toxin shows some similarity to that of domain 2 of aerolysin (Figure 35.7a, b). In aerolysin this domain binds to the GPI anchors of proteins that are found in DRMs. It is possible that this domain performs a similar function in ε-toxin. If the roles of these domains are indeed similar, then the major reported differences in the target cell specificities of aerolysin and ε-toxin could be a function of the different structures and properties of these domains.

The second domain of ε-toxin exhibits obvious structural similarity to the third domain of aerolysin. On the basis of studies with *C. septicum* α-toxin, a homologous toxin to aerolysin, this domain in aerolysin has been proposed to be involved in membrane insertion (Melton *et al*., 2004). In both the ε-toxin and aerolysin structures, this domain is composed of a five-stranded sheet with a two-stranded sheet with an amphipathic sequence lying against it. An analogous region in *C. septicum* α-toxin to the two-stranded sheet was tested for insertion into a membrane, using sequential cysteine mutation, modified with a fluorescent probe sensitive to changes from an aqueous to a lipid environment. This technique showed that alternately these residues pointed into a lipid and then aqueous environment when bound to a membrane, indicating insertion of the two-stranded sheets in a similar manner to *S. aureus* α-toxin (Figure 35.8a, b).

The final domain of ε-toxin contains the C-terminus of the protein, cleavage of which is important for activation of the toxin. Interestingly, the carboxy termini of ε-toxin and aerolysin are located on opposite sides of the sheets in this domain. In the precursor forms of ε-toxin and aerolysin, the carboxy termini appear to block protein heptamerization. Both termini could therefore cover regions that form vital complementary surfaces required for oligomerization. The difference is that one C-terminus inhibits the interaction of the first with the second subunit of the heptamer, and the other inhibits the first with the seventh, given that the resulting structure would be a ring-shaped pore.

## CONCLUSION

Over the past several years, intense research on various biophysical, biochemical, and chemical properties, as well as the 3D structure of the toxin, has resulted in considerable progress in understanding the mode of

function of the *Clostridium perfringens* ε-toxin. The results of these studies will allow progress in understanding the molecular basis of toxicity and its role in various animal diseases. However, many key questions still remain unanswered, such as the mechanisms of interaction for ε-toxin to the cell membrane and the precise role of the amino acids for those membrane interactions, as well as the mechanism of oligomerization or the formation of the heptameric form. The structure of ε-toxin in its pore form is a major challenge for the future. The knowledge of structural reorganization that might take place upon activation will be an invaluable tool in elucidating the mechanics of its pore formation. This, in turn, will also help to design a candidate vaccine that can block the activity of ε-toxin.

Investigations need to be carried out about the significance of various residues throughout this toxin that have been previously identified to have some role in its biological activity. These residues include the single tryptophan (190), some tyrosine residues that have been shown to be important in binding to a receptor. To study the specific role of these residues in a possible binding site may lead to the discovery of prospective inhibitors.

Apart from the work on ε-toxin, 3D structures of other proteins with some homology, for example, mtx2 and mtx3 of *B. sphaericus*, may shed important information in the search for new methods in the control of malaria-causing mosquitos in the poor and developing world.

CHAPTER

# 36

# Repertoire and general features of the family of cholesterol-dependent cytolysins

*Joseph E. Alouf, Stephen J. Billington, and B. Helen Jost*

## INTRODUCTION

The cholesterol-dependent cytolysins (CDCs) (Shatursky *et al*., 1999; Tweten *et al*., 2001), also called cholesterol-binding cytolysins (Rossjohn *et al*. 1997; Alouf, 1999; Gilbert, 2000), constitute a group of 50- to 60-kDa single-chain, pore-forming bacterial protein toxins previously designated "sulfhydryl" (or "thiol-activated)" cytolysins. This group of structurally, antigenically, and functionally related cytolysins constitutes the largest family of bacterial protein toxins produced by Gram-positive bacteria. Moreover, the CDCs belong to a larger superfamily of structurally unrelated pore-forming toxins known as the beta-barrel pore-forming toxins (Heuck *et al*., 2001).

CDCs are lethal to animals and highly lytic towards eucaryotic cells, including erythrocytes. Their lytic and lethal properties are suppressed by sulfhydryl-group blocking agents and reversibly restored by thiols or other reducing agents. Another fundamental property of CDCs is the irreversible suppression of their biological activities by very low concentrations of cholesterol and other 3β-hydroxysterols. Membrane cholesterol is thought to be the toxin-binding site at the surface of target eukaryotic cells (see Morgan *et al*., 1996; Alouf, 1999, 2000, 2001; Billington *et al*., 2000; Palmer, 2001; Tweten *et al*., 2001).

While the CDCs have been named due to their dependence on cholesterol as part of the target membrane, other individual bacterial cytolysins, unrelated to the CDC family, also possess cholesterol-binding properties: *Burkholderia pseudomallei* (Ashdown and Koehler, 1990), *Vibrio cholerae* (Zitzer *et al*., 2003), and *Vibrio vulnificus* cytolysins (Kim and Kim, 2002; Chapter 44, this volume), the membrane-associated hemolysin of *Mycoplasma pulmonis* (Jarvill-Taylor and Minion, 1995), and the thiol-independent *E. coli* enterohemolysin (Figueiredo *et al*., 2003).

## REPERTOIRE OF THE CHOLESTEROL-DEPENDENT CYTOLYSINS

To date, the CDC family comprises 22 toxins produced by 24 Gram-positive bacterial species from seven genera (Table 36.1). The abbreviations of these toxins and of their structural genes are shown in Table 36.1.

Almost all CDC-producing species (except *Listeria seeligeri)* are pathogenic for humans and/or certain animals. However, *Bacillus thuringiensis, Brevibacillus* (formerly *Bacillus*) *laterosporus,* and *Paenibacillus* (formerly *Bacillus*) *alvei* are only pathogenic for certain insects, and very rarely in humans for the latter. Furthermore, among the CDC-producing species, only *Listeria monocytogenes* and *Listeria ivanovii* are intracellular pathogens that grow and release their toxins [(listeriolysin O (LLO) and ivanolysin O (ILO)] and various enzymes inside host phagocytic cells (Dramsi and Cossart, 2002). All CDCs are secreted into the extracel-

lular medium, except pneumolysin (PLY), which remains intracytoplasmic due to the lack of a signal peptide. This cytolysin is released outside *Streptococcus pneumoniae* cells upon bacterial autolysis (Johnson, 1977).

Streptolysin O (SLO), the most widely studied member of the CDCs, is considered as the eponymous archetype/prototype of this vast family of toxins (Bernheimer, 1976; Thelestam and Möllby, 1980; Pinkney *et al*., 1989; Bhakdi *et al*., 1996).

## HISTORICAL BACKGROUND AND IDENTIFICATION OF CHOLESTEROL-DEPENDENT CYTOLYSINS

CDCs have been progressively discovered over the past 106 years. Historically, they have been identified on the basis of their lytic effects on human and/or animal erythrocytes incubated with the supernatent fluids of bacterial cultures or by the formation of hemolytic zones around bacterial colonies on blood agar plates. Further investigations have showed that the toxins were also able to lyse and disrupt other eukaryotic cells (see "Cytolytic and Membrane-damaging Effects").

### The 1898–1960 period

In 1898, no less a person than Paul Ehrlich (1898) reported the presence of a hemolytic factor, tetanolysin (TLY), in *Clostridium tetani* culture fluids. This toxin was the first CDC discovered. Then Marmorek (1902) described the hemolytic effects of streptococcal cultures, which were probably due to a mixture of both streptolysin S (SLS) and the cholesterol-binding streptolysin O (SLO) produced by most *Streptococcus pyogenes* strains. These two cytolysins were differentiated later by Todd (1932, 1938) and Weld (1935). Pneumolysin (PLY) was revealed as early as 1901 by Tizzoni and Panichi (see Guillaumie, 1950), followed by Libman (1905) and Cole (1914). Since then, a number of investigations have been carried out on crude PLY preparations by Neill (see below), Cohen *et al*. (1940), and Halbert *et al*. (1946). The relationship of PLY to SLO and the inhibition of its hemolytic activity by cholesterol has been clearly established.

Perfringolysin O (PFO), previously known as θ-toxin, may have been detected first by Herter (1906–1907), but it is difficult to tell whether the author worked with this cytolysin or with *C. perfringens* α-toxin. PFO activities were clearly described later by Wuth (1923).

After these pioneering works, important achievements in the study of these toxins took place in the 1925–1945 period, particularly the systematic studies in the United States by Neill and his coworkers on PLY, PFO, TLY, and SLO (Neill, 1926 a, b, c; Neill and Mallory, 1926; Neill and Fleming, 1927). These authors developed the concept of the "oxygen-labile" nature of these toxins, which was extended to the other toxins of the group as they were discovered. This concept persisted in the literature until the end of the 1990s. These and other authors (Todd, 1934; Smythe and Harris, 1940; Herbert and Todd, 1941; Todd, 1941) observed that the hemolytic activities of crude or partially purified toxin preparations progressively disappeared on standing in air and less rapidly in the absence of oxygen. These activities were immediately restored by reducing agents, such as hydrosulfites or thiols, which are the most effective (Bernheimer and Avigad, 1970). The loss of activity was attributed (without direct chemical proof) to the oxidation of toxin molecules by $O_2$. However, this hypothesis was not supported by the finding that highly purified preparations of SLO, alveolysin (ALV), and PFO did not lose their lytic properties by flushing toxin solutions for several hours with air or $O_2$ (Alouf, 1980; Sato, 1986). The loss of activities in preparations observed by earlier investigators is probably due to a kinetically slow $O_2$-favored blockade of certain regions of toxin molecules (particularly the SH-group of the cysteinyl residue) by undefined molecules from culture media or bacterial metabolism. This, along with the discovery of members of this family that were truely not oxygen labile, led to the abandonment of the "old" term of oxygen-labile for the CDCs (Alouf, 1999; Billington *et al*., 2000).

Botulinolysin (BLY) produced by *Clostridium botulinum* was probably detected by Wheeler and Humphreys (1924) on the basis of the development of hemolytic zones around bacterial colonies on blood agar plates. This cytolysin was investigated in detail in the 1980s, as described in another section. Histicolysin O (ε-toxin) produced by *Clostridium histolyticum* was discovered by Mita (1934) and investigated by Howard (1953), who showed its "oxygen-labile" character, the inhibition of its hemolytic activity by cholesterol, as well as its antigenic relationship to SLO.

Septicolysin O (δ-toxin) produced by *Clostridium septicum* was detected by Eisenberg (1907) and later characterized by Moussa (1958). Sordellilysin produced by *Clostridium sordellii* was detected by Guillaumie and Kreger (1950). Oedematolysin (novyilysin) and bifermentolysin produced by *Clostridium oedematiens* and *Clostridium bifermentans* (*C. sordellii*), respectively, were discovered by Oakley *et al*. (1947) and Guillaumie (1950) and investigated later by Rutter and Collie (1969).

### The 1960–2003 period

The biochemical identification and purification of the *L. monocytogenes* CDC, listeriolysin O (LLO), was reported by Njoku-Obi *et al*. (1963) and Jenkins *et al*. (1964). However, earlier studies mentioned the production of a soluble hemolysin by this microorganism (Burn, 1934; Harvey and Faber, 1941). In 1970, Kingdon and Sword (1970) showed the inhibition of the hemolytic properties of the toxin by cholesterol. Thereafter, Geoffroy *et al*. (1987) purified LLO to apparent homogeneity and provided the unambiguous evidence that LLO is an SLO-related toxin belonging to the CDC family. The closely related ivanolysin O (ILO) and seeligeriolysin O (LSO) produced by *L. ivanovii* and *L. seeligeri*, respectively, were purified and characterized a few years later (Vazquez-Boland *et al*., 1989; Leimeister-Wächter and Chakraborty, 1989; Geoffroy *et al*., 1989).

In 1967, Bernheimer and Grushoff (1967a) reported the discovery of cereolysin O (CLO) produced by *Bacillus cereus*, which was shown to belong to the CDC family. Thuringiolysin O (TLO) was identified later (Pendelton *et al*., 1973) in the culture fluids of *Bacillus thuringiensis*, a species practically identical to *B. cereus*. Bernheimer and Grushoff (1967b) investigated several sporogenic bacilli and reported the detection of SLO-like "thiol-activated" cytolysins produced by *Bacillus* (now *Brevibacillus*) *laterosporus* and *Bacillus* (now *Paenibacillus*) *alvei*. Alveolysin (ALV), released by the latter, was purified and widely investigated in the early 1980s (Alouf *et al*., 1977; Geoffroy and Alouf, 1982, 1983), as described later in this chapter. New members of the CDC family were discovered and purified in the 1990s: suilysin (SLY) produced by *Streptococcus suis* (Jacobs *et al*., 1994), intermedilysin (ILY) produced by *Streptococcus intermedius* (Nagamune *et al*., 1996, 2000), pyolysin (PLO) produced by *Arcanobacterium pyogenes* (Funk *et. al*., 1996; Billington *et al*., 1997), and recently, anthrolysin O (ALO) produced by *Bacillus anthracis* (Shannon *et al*., 2003). The latter is very similar (98% identity) to CLO. New members of the CDC family may be discovered in the future.

## GENOMIC AND STRUCTURAL ASPECTS OF THE CHOLESTEROL-DEPENDENT CYTOLYSINS

The 16 structural genes of CDCs so far sequenced (Table 36.2) are all chromosomal. Interestingly, a number of these genes are located on genomic islands, suggesting that they were acquired by horizontal

transfer. The gene encoding LLO is located on the pathogenicity island LIPI-1 (Vazquez-Boland *et al*., 2001), while SLY and PLO genes are located on genomic islands, which may have been inherited through homologous recombination (Rudnick *et al*., 2003; Takamatsu *et al*., 2002). The amino acid sequence of the toxins deduced from the nucleotide sequences of the corresponding structural genes defines the 14 following toxins: SLO from *S. pyogenes*, *S. dysgalactiae* subsp. *equisimilis*, and *S. canis*, respectively, PLY, PFO, ALV, LLO, ILO, LSO, CLO, TLO, TLY, ILY, SLY, PLO, and ALO.

This family of toxins shows significant levels of amino acid similarity (about 40 to 70%), particularly in the carboxy-terminal portion of the proteins (Tweten *et al*., 2001; Shannon *et al*., 2003). Phylogenetically, CDCs tend to group based on closely related species, with PLO being the most divergent member of the family (Billington *et al*. 1997; Figure 36.1). However, SLO molecules are more closely related to the bacillus and clostridial CDCs than to pneumolysin or the other streptococcal CDCs (Figure 36.1). The molecular masses of the mature forms of the above-mentioned toxins range from about 60 to 51 kDa (Table 36.3). The longest amino acid sequence is that of SLO (60.2 kDa), while the smallest is that of ALV (51.8 kDa).

The largest region of sequence identity or homology in the proteins is an 11 amino acid region located near the C-terminus of the molecule, known as the undecapeptide or the Trp-rich region. This sequence is identical among 11 of the 14 sequenced CDCs (SLO, PLY, PFO, ALV, LLO, ILO, TLY, TLO, SLY, CLO, ALO) and is composed of the following sequence, ECTGLAWEWWR, containing the single cysteine residue of the toxin molecules and, conspicuously, three tryptophan residues (positions 7, 9, 10) (Figure 36.2).

The remaining three CDCs (PLO, ILY, and LSO) exhibited various substitutions in this "consensus" region, some of which are conservative and others which are not (Tweten, 2001). Very interestingly, PLO and ILY contained an alanine residue in position 2 instead of the cysteine residue, which for a long time

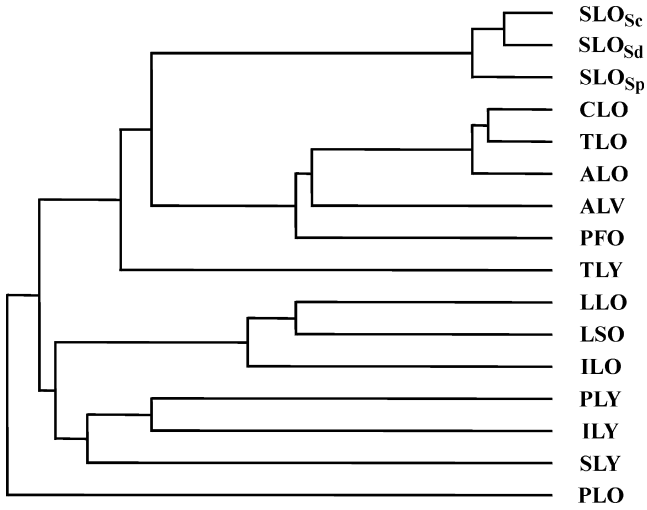

**FIGURE 36.1** Phylogenetic analysis of protein sequences showing the relationship between the cholesterol-dependent cytolysins. Cytolysins are indicated by their three-letter abbreviations, and SLO$_{Sp}$, SLO$_{Sd}$, and SLO$_{Sc}$ represent SLO molecules from *S. pyogenes*, *S. dysgalactiae* subsp. *Equisimilis*, and *S. canis*, respectively.

was thought strictly necessary for the biological activity of the CDC family. These two toxins were quite resistant to inactivation by sulfhydryl group blocking reagents and were fully biologically active (Billington *et al*., 1997; Nagamune *et al*., 1997). Moreover, PLO and ILY also have significant differences in the last four to five residues of the undecapeptide. In the latter, the glutamic acid residue (position 8) is replaced by glycine acid and the tryptophan residue (position 9) by proline. Therefore, ILY only contains two tryptophans in this region, while all of the other CDCs contain three tryptophans. PLO shows a conservative change of glutamic acid to aspartic acid (position 8), but this toxin also contains an insertion of a proline between positions 8 and 9, and lacks the terminal arginine residue (position 11) of the motif. In LSO, a single residue change in the undecapeptide occurs in which the alanine residue (position 5) is replaced by a phenylalanine. Interestingly, this toxin contains a second cysteine residue located outside the undecapeptide region nearer to the C-terminus.

## Structure-function relationship

The solving of the crystal structure of PFO monomer by Rossjohn *et al*. (1997) opened the door for a more systematic analysis of the roles of individual parts of the CDC molecule in biological activities. The 3D structure of PFO indicated an elongated protein of four domains, and while CDC primary amino acid sequences vary, the backbone of the 3D structure is fairly conserved. Hence, the four domain structure is probably representative of CDCs in general. Several models of pore formation have been proposed, with early models suggesting that insertion of a preformed pore would be energetically unfavorable, given the size of CDC pores (Palmer *et al*., 1998), but recent evidence favors the formation of a pre-pore complex prior to membrane insertion (Shepard *et al*., 2000). CDC structure-function relationships will be discussed in more detail in the following chapters. Here we will summarize the contribution of the four domains of the toxin to CDC biological function.

Based primarily on site-directed mutagenesis (Palmer *et al*., 1998; Abdel Ghani *et al*., 1999) and neutralization of epitopes with monoclonal antibodies (Darji *et al*., 1996), which abrogate oligomerization but not membrane binding, domain 1 has been implicated in subunit-subunit oligomerization. However, disulphide trapping and fluorescence experiments suggest that monomer-monomer interactions occur between β-strands on either side of domain 3 (Ramachandran *et al*., 2004), although residues involved in these interactions lie at the domain 1-domain 3 junctions.

Little information is available regarding the precise role of domain 2 in pore formation. However, this domain may act as a linkage domain, allowing significant movement of other domains relative to one another during membrane assembly.

The discovery that portions of domain 3 of the PFO molecule, which exist in the monomer as α-helices, are inserted into the host membrane (Shepard *et al*., 1998; Shatursky *et al*., 1999) revolutionized models of CDC pore formation in eukaryotic membranes. The results of Shatursky *et al*. (1999) confirmed the conversion of six domain 3 α-helices to two transmembrane β-hairpins (TMHs), which fully span the host membrane in the final pore, indicating significant structural alterations between the monomer CDC form and that of the membrane-inserted oligomer. Interestingly, two of the core β-strands that extend from the TMHs appear to be involved in oligomerization of the toxin on host membranes, with one of the interacting strands shielded in the monomer, presumably to prevent aberrant oligomerization in solution (Ramachandran *et al*., 2004).

Domain 4 was originally thought to be the portion of the molecule that inserted into the host membrane (Rossjohn *et al*., 1997). However, recent evidence suggests that domain 4 does not penetrate deeply into

the host membrane (Ramachandran *et al*., 2002), and that the TMHs of domain 3 actually form the faces of the inserted pore (Shatursky *et al*., 1999). Evidence from monoclonal antibody inhibition (de los Toyos *et al*., 1996) and toxin truncation studies (Tweten *et al*., 1991) indicates that domain 4 is involved in membrane cholesterol binding, but the fluorescence-based studies of Ramachandran *et al*. (2002) indicate that only the loops at the very tip of domain 4 move into the membrane. These authors suggest that domain 4 acts as a pivot for the reorientation of other portions of the molecule during membrane insertion. Domain 4 contains the characteristic CDC undecapeptide, which forms an extended loop at one end of the PFO 3D structure, and is included in the portion of domain 4 that accesses the membrane. The cysteine residue in this sequence is clearly responsible for the oxygen-labile nature of the majority of CDCs. Mutagenesis of the cysteine to alanine in PLY results in a toxin molecule that is fully active and unaffected by reducing agents (Saunders *et al*., 1989); CDCs that naturally lack this cysteine residue, PLO and ILY, are not oxygen labile (Billington *et al*., 1997; Nagamune *et al*., 1997); and introduction of the cysteine residue into PLO renders it thiol-active (Billington *et al*., 2002). A plethora of mutagenesis data indicates that the conserved CDC undecapeptide region is critical for the activities of most CDCs. In particular, mutagenesis of the three tryptophan residues results in significant effects on the cytolytic function of a number of CDCs (Boulnois *et al*., 1991; Michel *et al*., 1990; Sekino-Suzuki *et al*., 1996; Korchev *et al*., 1998; Billington *et al*., 2002). In addition, several studies have indicated that the tryptophan residues in this region move from a polar to a non-polar environment as the toxin moves into the host membrane (Nakamura *et al*., 1995; Heuck *et al*., 2000). The knowledge that domain 4 does not penetrate deeply into the host membrane (Ramachandran *et al*., 2002) and that the tryptophans of the undecapeptide sequence are close to the interface between the target membrane and the surrounding environment has led to the interpretation that the undecapeptide region may be involved in the sampling or initial tethering of the toxin to the host membrane.

## PURIFICATION AND BIOCHEMICAL CHARACTERIZATION OF THE TOXINS

Among the toxins listed in Table 36.1, only 16 (underlined) have been purified to apparent homogeneity, either as native or recombinant molecules, allowing subsequent characterization of their properties. The other toxins of the group have been practically disregarded so far since their discovery (see Guillaumie, 1950; Oakley *et al*., 1947; Moussa, 1958; Bernheimer and Grushoff, 1967b; Rutter and Collee, 1969; Hatheway, 1990) and will not be considered here. The purification procedures, characterization, physicochemical, molecular, and biological properties of SLO, PLY, PFO, CLO, ILY, and the listeriolysins are described in separate chapters of this volume. We will briefly describe here the following cytolysins: ALV, TLO, TLY, BLY, SLY, PLO, and ALO.

### Alveolysin (ALV)

This toxin is produced by *P. alvei,* as first reported by Bernheimer and Grushoff (1967b). No further characterization was performed until the systematic study of this toxin by Alouf and his coworkers. *P. alvei* is a soil organism that is often found in honeybee larvae suffering from European foulbrood. It is not considered pathogenic in vertebrates, although rare cases of human opportunistic infection have been reported (Reboli *et al*., 1989; Coudron *et al*., 1991). ALV was first purified by Alouf *et al*. (1977) by ammonium sulphate precipitation, gel filtration, isoelectric focusing, and ion-exchange chromatography. Toxin production was enhanced by about 10-fold ($2 \times 10^4$ HU/ml) in *P. alvei* shaken cultures in the presence of activated charcoal. ALV was then easily purified (specific activty $10^6$ HU/mg of protein) by thiol-disulphide interchange chromatography (Geoffroy and Alouf, 1983). The primary structure of the toxin was deduced from the nucleotide sequence of the gene (Geoffroy *et al*., 1990). The mature form comprised 469 amino acid residues (51766 Da) and contained a unique Cys residue in the consensus undecapeptide. The membrane-damaging activities of ALV were investigated on cultured human diploid lung fibroblasts (Thelestam *et al*., 1981). Toxin interaction with thiol group reagents, particularly tosyl lysine chloromethyl ketone (TLCK), prevented binding to erythrocytes and thereby hemolysis (Geoffroy and Alouf, 1982). The toxin was also used to permeabilize Raji cells and purified human peripheral blood lymphocytes. This procedure allowed investigation of the phosphoinositide pathway in these cells (Berthou *et al*., 1992).

### Thuringiolysin O (TLO)

This toxin produced by *B. thuringiensis* was first characterized by Pendleton *et al*. (1973), who obtained a partially purified preparation by precipitation of culture supernatants by ammonium sulphate followed

by isoelectric focusing. TLO was shown to focus into two distinct peaks of hemolytic activity at pI 6.0 and pI 6.5. The toxin was purified (specific activity $10^5$ HU/mg of protein) by ultrafiltration of the culture filtrates of strain H1–30 serotype 1, followed by chromatography on thiopropyl-Sepharose 6B columns (Rakotobé and Alouf, 1984). The toxin shared all the properties of the other "classical" antigenically related CDCs. The structural gene for TLO has been identified from the genome sequence of *B. thuringiensis*, and the deduced amino acid sequence is practically identical to CLO, with both toxins showing 98% amino acid identity with ALO (Shannon *et al*., 2003).

## Tetanolysin (TLY)

This toxin was first identified in 1898 in the culture filtrates of *Clostridium tetani* by Ehrlich (1898) (see also Neill, 1926c), who clearly differentiated it from the "true killing toxin" of *C. tetani* (tetanus neurotoxin) as established later by Hardegree (1965). Little information is available on TLY production by *C. tetani* strains. Lucain and Piffaretti (1977) reported a comparative study of TLY produced by nine different Tulloch serotypes of *C. tetani* as regards molecular weights, pIs, and electrophoretic mobilities. All TLY preparations were similar in these respects. The molecular weights measured by gel filtration were 47,000 ± 3,000 Da, and the pI values determined by isoelectric focusing in sucrose gradient were 6.54 for a major form, and 6.15 and 5.84 for minor forms, respectively. TLY purification from culture filtrates of Massachusetts C2 strain and Harvard A-47 strain was reported by Alving *et al*. (1979) and Mitsui *et al*. (1980), respectively. The procedure used by the former group involved ammonium sulphate precipitation, gel filtration, and chromatography. This procedure was modified by Rottem *et al*. (1990), who purified this toxin by sequential chromatography using Mono-Q and Sephadex G-100 columns. In both procedures, the purified toxin had a molecular weight of 45,000 Da and a specific activity of $10^6$ HU/mg. Two forms with pIs of 6.1 and 6.4 were found (Blumenthal and Habig, 1984). Recent deduction of the TLY amino acid sequence from the genome sequence of *C. tetani* confirms its similarity to other members of the CDC family.

## Botulinolysin (BLY)

This cytolysin produced by *C. botulinum* constitutes with eight other clostridial membrane-damaging toxins the largest subgroup of the CDC family (Table 36.1). A comparative study of toxin production in culture supernatants of six, three, and five strains from *C. botulinum* type C, D, and E, respectively, showed important variation in toxin production (140 to 3,400 HU/ml) (Haque *et al*., 1992). The high toxin-producing strain C-340 was used by these investigators for toxin purification. Culture supernatants were fractionated by ammonium sulphate precipitation, ion exchange, and gel filtration procedures and SP Toyopearl 650 M exchange column chromatography. The molecular weight of purified BLY was about 58 kDa. The 50% lethal dose in mice was 310 ng/ml and the 50% cytotoxic dose for Vero cells was 120 ng/ml.

Surprisingly, BLY was reported to contain four cysteine residues by amino acid analysis, in contrast to the single cysteine residues found in most other CDC molecules. BLY lysed the erythrocytes of many animal species, with higher lytic potency for rabbit, human, and guinea pig cells. The pharmacological activity of BLY on rat aortic ring and coronary vasoconstriction has been widely investigated (Sugimoto *et al*., 1995; 1997). Toxin damage on rabbit erythrocytes was studied by Sekiya *et al*. (1998) by electron microscopy, as described in another section.

## Suilysin (SLY)

SLY is produced by *S. suis*, a major cause of contagious porcine diseases, such as arthritis, septicemia, meningitis, pericarditis, endocarditis, polyserositis, and pneumonia. SLY was first purified by Jacobs *et al*. (1994) from culture supernatant by gel filtration and ammonium sulphate precipitation (specific activity 0.7 x $10^6$ HU/mg). Hemolytic activity was susceptible to oxidation and alkylation, inhibited by cholesterol, and increased by β-mercaptoethanol. SLY is hemolytic for erythrocytes from a number of animal species.

Molecular characterization of the *sly* gene confirmed that SLY is indeed a member of the CDC family, possessing the characteristic CDC undecapeptide (Segers *et al*., 1998) with a calculated molecular weight of 54,850 Da prior to signal sequence cleavage. Unlike other CDC-producing bacteria, not all *S. suis* strains possess the *sly* gene, and as such, not all strains produce SLY. The *sly* gene is more commonly present in virulent isolates and, interestingly, is present in a significant number of the predominant serotype 2 strains in Europe and Asia, but only in low numbers of North American serotype 2 isolates.

SLY is lytic for epithelial cells (Norton *et al*., 1999; Lalonde *et al*., 2000), which may facilitate access of *S. suis* to the bloodstream and brain microvascular endothelial cells (Charland *et al*., 2000; Vanier *et al*., 2004), which could lead to increased permeability of the blood-brain barrier, as well as phagocytic cells (Segura and Gottschalk, 2002).

However, consistent with the data that not all virulent *S. suis* strains contain *sly*, defined *sly* mutants, while avirulent in mice, are able to cause clinical signs in various pig models (Allen *et al*., 2001; Lun *et al*., 2003). Purified SLY protected mice against experimental *S. suis* infection, but afforded only partial protection in pigs (Jacobs *et al*., 1994; Jacobs *et al*., 1996).

## Pyolysin (PLO)

This CDC is produced by the commensal and opportunistic pathogen of livestock and wildlife, *A. pyogenes* (Ding and Lammler, 1996; Funk *et al*., 1996; Billington *et al*., 1997). First identified as a hemolytic toxin by Lovell (1937), it was not until its molecular characterization by Billington *et al*. (1997) that this toxin was recognized as a member of the CDC family, primarily because this was the first identified member of the family that was not subject to oxygen inactivation. PLO is an important virulence factor in *A. pyogenes* infections, as a *plo* knockout mutant is attenuated for virulence in a mouse model (Jost *et al*., 1999) and acts as an effective vaccine against experimental *A. pyogenes* infections (Billington *et al*., 1997; Jost *et al*., 1999; Jost *et al*., 2003). This toxin is lytic for erythrocytes, macrophages, and polymorphonuclear leucocytes from a variety of species (Ding and Lammler, 1996; Jost *et al*., 1999), as well as being dermonecrotic and lethal to laboratory animals by injection (Lovell, 1939; Lovell, 1944; Jost *et al*., 1999). Purification of recombinant PLO indicated a specific activity of $1.25 \times 10^5$HU/mg. While clearly a member of the CDC family of toxins, PLO shows some important differences. Phylogenetically, it is the most diverse member of the family (Figure 36.1; Billington *et al*., 1997) and exhibits 31 to 41% similarity with other CDCs. In addition, PLO, along with ILY, have C-terminal undecapeptide sequences, which diverge significantly from the consensus for this family (Figure 36.2; Billington *et al*., 1997; Nagamune, 1997). PLO lacks the conserved cysteine residue at position 2 of the undecapeptide, substituted with alanine, which is responsible for the thiol-activated nature of CDCs (Figure 36.2; Billington *et al*., 1997). This finding is consistent with the insensitivity of PLO activity to reducing agents. Mutagenesis of the alanine residue to cysteine conferred thiol activation on PLO, confirming the importance of the cysteine residue in this function (Billington *et al*., 2002). In addition, the PLO undecapeptide contains a conservative glutamic acid to aspartic acid substitution at position 7, the insertion of a proline residue between positions 7 and 8, and, finally, lacks the terminal arginine residue of the consensus motif. The divergent undecapeptide sequence of PLO appears to be required for its cytolytic activity, as mutations that bring the undecapeptide sequence closer to consensus, including a substitution with the consensus undecapeptide sequence, resulted in PLO molecules with low hemolytic activities (Billington *et al*., 2002).

## Anthrolysin O (ALO)

Databases of microbial genomes have allowed the identification of CDC homologues within the genome sequences of a number of bacterial species. One such homologue is ALO, the CDC of *B. anthracis*, which is closely related to CDCs produced by other *Bacillus* species, including TLY and CLO (Shannon *et al*., 2003). ALO is hemolytic against sheep and human red blood cells, although *B. anthracis* is not hemolytic on sheep blood agar plates. ALO is particularly active against human erythrocytes, with as few as 24 molecules of recombinant ALO per erythrocyte resulting in cell lysis. This toxin shares the properties of other CDCs, in that its activity is increased by reducing agents and inhibited by cholesterol.

# STEROL-BINDING PROPERTIES

The most characteristic biochemical property of CDCs is the specific and irreversible inhibition of their lytic, lethal cardiotoxic, and other biological properties by very low (nanomolar) amounts of cholesterol and certain structurally related sterols (Alouf, 1977, 1980; Cowell and Bernheimer, 1978; Smyth and Duncan, 1978). The inactivation of the other toxins by cholesterol and other sterols was subsequently demonstrated (Geoffroy and Alouf, 1983; Geoffroy *et al*., 1987; Ohno-Iwashita *et al*., 1988; Vazquez-Boland *et al*., 1989; and other authors as mentioned in this and other chapters).

## Structural requirements

The structural and stereospecific features necessary for inhibition of toxin were investigated in detail on quantitative bases for PLY, SLO, and PFO (see Watson and Kerr, 1974; Prigent and Alouf, 1976; and the abovementioned references). All inhibitory sterols possessed (i) an OH group in the β configuration on carbon-3 of ring A of the cyclopentanoperhydrophenanthrene nucleus, such as is found in cholesterol and kindred sterols; (ii) a lateral aliphatic side chain of suitable size (isooctyl chain in the case of cholesterol) attached to carbon-17 on the D ring; (iii) the presence of a methyl group at C-20; and (iv) an intact B ring. Neither the saturation state of the B ring nor the positions of the

double bonds or the stereochemical relationships of rings A and B were critical factors. The presence of an α-OH group on C-3 (epicholesterol), esterification of the β-OH group, or its substitution with a keto group or with a 3β-SH group (thiocholesterol) rendered the sterol inactive (Alouf and Geoffroy, 1979), presumably because such substitutions or orientations preclude correct presentation of the reactive 3β-OH group to the toxins.

## Characteristics of toxin-sterol interaction

Early experiments in liquid phase suggested the formation of complexes between toxin and sterol molecules (Smyth and Duncan, 1978; Cowell and Bernheimer, 1978). The first direct demonstration of the occurrence of these complexes, and thereafter, their separation, were provided by Alouf and his coworkers. The complexes were visualized by allowing SLO or ALV to diffuse from wells in sterol-containing agar gels (Prigent and Alouf, 1976; Alouf and Geoffroy, 1979; Geoffroy and Alouf, 1983). The complexes formed appeared as white, opaque halos (around toxin wells), constituted by insoluble (hydrophobic) precipitates of irreversibly bound toxin-sterol material stainable by protein dyes. Only inhibitory sterols showed such a pattern.

The separation of toxin-sterol complexes formed in liquid phase was reported by Johnson *et al*. (1980), who mixed pure PLY, SLO, or ALV preparations with [$^3$H]cholesterol solutions at concentrations in which this sterol was present in a soluble micellar form. Advantage was taken of the fact that when solutions of cholesterol in phosphate buffer are added to Sephadex or Sephacryl columns, the free cholesterol molecules stick to the gel and only toxin-sterol complexes elute with buffer. The separated complexes were hemolytically inactive and of high molecular weight. The amounts of bound sterol increased linearly with toxin concentration. The reaction was rapid and temperature independent, similar to the binding step of toxin interaction with target cells. The specificity of cholesterol binding was assessed by adding unlabeled inhibitory or non-inhibitory sterols to toxin before adding [$^3$H]cholesterol. Epicholesterol caused only a small decrease of binding, whereas 7-dehydrocholesterol inhibited radiolabeled binding to an extent equal to that observed with unlabeled cholesterol. Hemolytically inactive SLO obtained by treatment with oxidized dithiothreitol or by reaction with parahydroxymercuribenzoate showed no decrease in cholesterol-binding activity, whereas the ability of the toxins to bind to erythrocytes was modified by such treatment. This result is in agreement with the further finding that the SH group of cysteine is not involved in toxin interaction with its binding "receptor" (cholesterol). The blockade of the SH group very likely produced a steric hindrance to toxin fixation to the cholesterol embedded in the erythrocyte membrane. Such a hindrance does not take place when the toxin interacts with free cholesterol. The isolation of toxin-sterol complexes in liquid phase was also reported by Geoffroy and Alouf (1983), who separated and identified [$^3$H]cholesterol-ALV complexes by sucrose gradient ultracentrifugation. The complexes formed were relatively heterogeneous in size. Heat-denaturated toxin did not bind cholesterol, indicating that the native structure is essential for binding. ILO-cholesterol complexes were also separated by centrifugation at 25,000*g* (Vazquez-Boland *et al*., 1989).

## Stoichiometry

The limited solubility of cholesterol and other sterols in aqueous phase, the non-uniform nature of their dispersions in water, and their tendency to stick to solid surfaces, among other reasons, has made it difficult to obtain information on the stoichiometry and thermodynamics of toxin-sterol interaction. Cholesterol has a maximum solubility in aqueous solutions of 1.8 μg/ml (4.7 μM) and undergoes a reversible self-association at the critical micellar concentration (CMC) of approximately 27–44 nM at 25°C (see Geoffroy and Alouf, 1983). Such cholesterol aggregates are heterogeneous in size and rod-shaped, each containing about 260–360 cholesterol molecules (Smyth and Duncan, 1978). Ideally, the study of toxin-cholesterol interactions should be performed at concentrations below the CMC to ensure proper stoichiometry with cholesterol molecules dispersed as monomers rather than aggregates. Aggregate status appears to have been the case in the studies on SLO (Prigent and Alouf, 1976; Badin and Denne, 1978), CLO (Cowell and Bernheimer, 1978), and PFO (Hase *et al*., 1976), as cholesterol concentrations found to inhibit 1 HU ranged from 12 to 25 nmol, corresponding to a molar cholesterol-toxin ratio of about 500–1,000. The number of cholesterol molecules reportedly required to neutralize a single molecule of a given CDC ranged from 170 to 1 x $10^6$ (Smyth and Duncan, 1978). By using a dilution technique involving sterol solutions in absolute ethanol, Geoffroy and Alouf (1983) avoided dealing with micellar solutions and were able to determine for the first time a linear inhibition "titration" curve of ALV by cholesterol. The stoichiometry was found practically equimolar (about 1.6 molecules of cholesterol "neutralized" by 1 molecule of ALV).

## CYTOLYTIC AND MEMBRANE-DAMAGING EFFECTS

The most striking biological property of the toxins reviewed here is their potent lytic activity toward all mammalian and other eukaryotic cells so far tested. Lysis results from the disorganization or disruption of the cytoplasmic membrane of target cells. The intracellular organelles are also disrupted. The membrane-damaging effects are also reflected by alterations in the permeability and integrity of cholesterol-containing artificial lipid model membranes (liposomes, black films, monolayers) (Alouf *et al*., 1984; Korchev *et al*., 1998; Menestrina *et al*., 1990).

### Cell lysis markers

The lytic process triggered by the toxins reviewed here and other cytolysins is classically investigated and monitored by the measurement of the *in vitro* release of intracellular components (from cell cytoplasm or from the disrupted organelles) into the incubation medium by the toxin-damaged cells (Alouf, 1977; Smyth and Duncan, 1978; Alouf and Palmer, 1999). The release of radiolabeled, colored, or fluorescent markers entrapped in resealed erythrocyte vesicles (Buckingham and Duncan, 1983) or in liposomes (Duncan, 1984; Menestrina *et al*., 1990) has been also used in the studies of toxin-induced damage of these vesicles.

The spectrophotometric determination of hemoglobin (Hb) is the most usual method employed in the monitoring of erythrocyte lysis (hemolysis) and its kinetics (Alouf and Geoffroy, 1988). The release of $K^+$ or $^{86}Rb$ from toxin-treated erythrocytes was also used as a marker of cell lysis by TLY (Blumenthal and Habig, 1984) or by SLO (Smyth and Duncan, 1978). A highly sensitive approach is the measurement by a bioluminescence method of the release of ATP from erythrocytes and other cells devised by Fehrenbach *et al*. (1980) and used for the study of the kinetics of erythrocyte lysis by SLO (Niedermeyer, 1985). A comparative study of Hb and ATP release showed that the latter was a much more sensitive indicator of SLO-induced lysis ($10^{-11}$–$10^{-12}$ M ATP) than Hb.

Platelet lysis by SLO and ALV was followed by the assay of released serotonin, lactate dehydrogenase, and other enzymes (Launay and Alouf, 1979; Launay *et al*., 1984). Membrane damage of human lung fibroblasts by SLO, PFO, and ALV was assessed by the leakage of three different-sized cytoplasmic markers (Thelestam and Möllby, 1980; Thelestam *et al*., 1981). The cells were first preloaded with [$^{14}$C]amino isobutyric acid ($M_r$ 103) or treated with radiolabeled uridine to obtain either a labeled nucleotide ($M_r$ < 1,000) or RNA ($M_r$ < 200,000) before toxin challenge. The release of these markers was monitored for the study of the time course of the lytic process and for the estimation of the size of the functional "pores" (whatever their physical reality) elicited in the damaged membrane (Thelestam and Möllby, 1983). In this respect, references to "pores," "channels," or "lesions" are meant to indicate functional entities with the potential to allow passage of molecules up to a certain size (Buckingham and Duncan, 1983).

Preloaded [$^3$H]choline or [$^{35}$S]methionine Lettre murine tumor cells were used as precursors for labeled intracellular markers for the study of the mechanism of lysis of these cells by PFO and other toxins (Menestrina *et al*., 1990).

### Membrane cholesterol as the toxin target

Several lines of experimental evidence suggest that cholesterol molecules embedded in the lipid bilayer of the cytoplasmic membrane of eukaryotic cells constitute the binding site of the toxins:

i. The toxins are inactivated by cholesterol and can no longer bind target cells (Alouf, 1980; Ohno-Iwashita *et al*., 1986).
ii. The toxins have no lytic effects on prokaryotic cells (bacterial protoplasts and spheroplasts), which lack cholesterol in their cytoplasmic membranes. However, parasitic mycoplasma cells that contain cholesterol are bound and damaged by the toxins. Saprophytic mycoplasma cells, on the other hand, in which carotenol replaces cholesterol in their membranes, are not damaged by these toxins (Smyth and Duncan, 1978; Rottem *et al*., 1976, 1990). Incubation of these cells with a cholesterol-Tween mixture reestablished their ability to bind CLO. Furthermore, the treatment of human erythrocyte membranes and *Acholeplasma laidlawii* cells containing cholesterol with cholesterol oxidase abolished their ability to bind CLO and to inhibit hemolysis (Cowell and Bernheimer, 1978).
iii. The lytic activity of the toxins is abrogated by incubation with erythrocyte membranes; in membrane extracts, only those lipid fractions that contain cholesterol inactivate the toxins (Hase *et al*., 1976; Smyth and Duncan, 1978). Similarly, *A. laidlawii* cells grown in the presence of cholesterol inhibited the hemolytic activity of CLO, but not *A. laidlawii* cells grown in the absence of cholesterol.
iv. The pretreatment of erythrocyte membranes with agents that are known to bind cholesterol such as polyene antibiotics and saponins prevented the

inhibition of the hemolytic activity of CLO and SLO (Shany *et al*., 1974). In addition, the treatment of nucleated mammalian cells (L cells and HeLa cells) with inhibitors of cholesterol synthesis, such as 20α-hydroxysterol or 25-hydroxysterol, significantly reduced SLO binding and abolished cell susceptibi-lity to the lytic effect of the toxin; the incubation of refractory cells with serum or cholesterol restored their sensitivity to SLO (Duncan and Buckingham, 1980).

v. The partial evulsion of cholesterol (about 30%) from human erythrocytes decreased PFO binding and cell susceptibility to lysis (Mitsui *et al*., 1982), whereas experimentally cholesterol-enriched erythrocytes exhibited increased sensitivity to lysis by SLO (Linder and Bernheimer, 1984).

vi. Only cholesterol-containing phospholipid (but not pure phospholipid) vesicles or films are bound and disrupted by the toxins (Alouf *et al*., 1984).

Despite the plethora of evidence that CDCs interact directly with cholesterol in the host membrane, the exact nature of this interaction is still in debate. While most CDCs bind to all cholesterol-containing membranes, albeit with different affinities, ILY appears to be particularly specific for human-derived cells (Nagamune *et al*., 1996), suggesting that cholesterol is unlikely to be involved in membrane recognition by this toxin. Recent findings by Giggings *et al*. (2003) indicated that depletion of cholesterol from erythrocyte membranes stalled each of PFO, SLO, and ILY at the prepore complex. In addition, these authors showed that depletion of membrane cholesterol, while decreasing PFO binding approximately 10-fold, did not affect the binding of SLO or ILY to host membranes. Therefore, in contrast to implications that cholesterol is the major host cell receptor for CDCs, these results suggest that cholesterol plays its primary role in facilitating the structural changes in CDCs that lead to membrane insertion.

## ELECTRON MICROSCOPY STUDIES OF TOXIN INTERACTION WITH BIOLOGICAL AND ARTIFICIAL TARGET MEMBRANES

As described in detail in the next four chapters, toxin molecules bind as monomers to the membrane surface with subsequent oligomerization (about 50 monomers). This process is reflected by arc- and ring-shaped structures surrounding large pores generated by this process. As early as 1966 such ring- and arc-shaped structures were observed by electron microscopy on the suface of erythrocytes treated with SLO (Dourmashkin and Rosse, 1966). This observation led to extensive studies over the following 35 years on these and other eukaryotic cells challenged with SLO (Duncan and Schlegel, 1975; Bhakdi *et al*., 1985; Niedermeyer, 1985; Sekiya *et al*., 1993, 1996; Palmer *et al*., 1998), PFO (Smythe *et al*., 1975; Mitsui *et al*., 1979), CLO (Cowell *et al*., 1978), TLY (Alving *et al*., 1979), LLO (Jacobs *et al*., 1998), BLY (Sekiya *et al*., 1998), and PLY (Morgan *et al*., 1994; Korchev *et al*., 1998). Interestingly, the formation of similar arc- and ring-shaped structures at the surface of target cells was observed in the case of the eukaryotic sea anemone *Metridium senile*, which produces a cholesterol-binding cytolysin sharing several biological properties of bacterial CDCs (Bernheimer *et al*., 1979). Furthermore, artificial cholesterol-containing lipid vesicles (liposomes) treated with some of these CDCs also showed similar arc- and ring-shaped structures (Morgan *et al*., 1995; Korchev *et al*., 1998).

## CONCLUSION

Important progress has been made in the past five years with regard to the mechanisms of toxin insertion and oligomerization in target cells in relation to membrane cholesterol (Shatursky *et al*., 1999; Gilbert *et al*., 1999, 2000; Palmer, 2001; Tweten *et al*., 2001; Giddings *et al*., 2003) and the genetics and structural characteristics of these toxins (see following chapters). However, the role of certain CDCs in disease, particularly in inflammatory processes and probably in sepsis, remains poorly understood. Moreover, the involvement of CDCs in host-signaling pathways still requires further investigation. Finally, the potential use of certain CDCs as potent permeabilization probes in cell biology or as vaccines or novel therapeutical agents remains an important and promising issue.

CHAPTER

# 37

# Comparative three-dimensional structure of cholesterol-dependent cytolysins

*Galina Polekhina, Susanne C. Feil, Julian Tang, Jamie Rossjohn, Kara Sue Giddings, Rodney K. Tweten, and Michael W. Parker*

## INTRODUCTION

The cholesterol-dependent cytolysins (CDCs) are one of the most widely distributed toxins known. The toxin gene or its product has been identified in numerous species from seven different genera of Gram-positive bacteria, including the *Clostridium*, *Bacillus*, *Streptococcus*, *Listeria*, *Brevibacillus, Paenibacillus,* and most recently the *Arcanobacterium* (Tweten *et al*., 2001). The fact that this gene is so widely distributed among these various pathogenic bacteria suggests that it plays an important role in the pathogenic mechanism of these organisms. For example, listeriolysin O is an essential virulence factor that is responsible for the release of the intracellular pathogen *Listeria monocytogenes* from the phagocytic vacuole (Jones and Portnoy, 1994).

The CDCs exhibit many unique features, including an absolute dependence of their cytolytic activity on the presence of cholesterol in the membrane and also the formation of very large oligomeric pores, more than 150 Å in diameter, on the membranes of cells. These toxins have been shown to be cytolytic to many eukaryotic cell types, although the bulk of the literature has focused on the hemolytic activity of these toxins. The crystal structures of two CDCs have been solved, and experimental approaches combining molecular biology techniques and various biophysical analyses have helped uncover fundamental features by which these toxins assemble and insert into the membrane. Several excellent reviews have been published on these toxins (Alouf and Geoffroy, 1991; Alouf, 2000; Gilbert *et al*., 2000; Palmer, 2001; Heuck *et al*., 2001; Tweten *et al*., 2001; Gilbert, 2002), so this review will focus on recent advances in structural studies of CDC toxins. Biological aspects of the toxins discussed in this chapter are covered in other chapters of Section III, particularly in Chapter 38 "Perfringolysin O and intermedilysin: mechanisms of pore formation by the cholesterol-dependent cytolysins."

## CDC PRIMARY STRUCTURES

There are more than 20 members of the CDC family so far identified, and there exists a high degree of sequence similarity (40–80%) among them, suggesting they all have similar activities and 3D structures. The primary structures of streptolysin O (SLO), pneumolysin (PLY), and perfringolysin O (PLO) were revealed in the late 1980s by DNA sequence analyses of their genes (Kehoe *et al*., 1987; Tweten *et al*., 1988; Walker *et al*., 1987). These studies showed that all three toxins exhibited a significant level of identity in their primary structures (Figure 37.1), and that each contained a single cysteine residue in a highly conserved region near the C-terminal end of each protein. It was this cysteine, upon modification with thiol-specific reagents, that was responsible for the loss in cytolytic activity of these toxins (Iwamoto *et al*.,

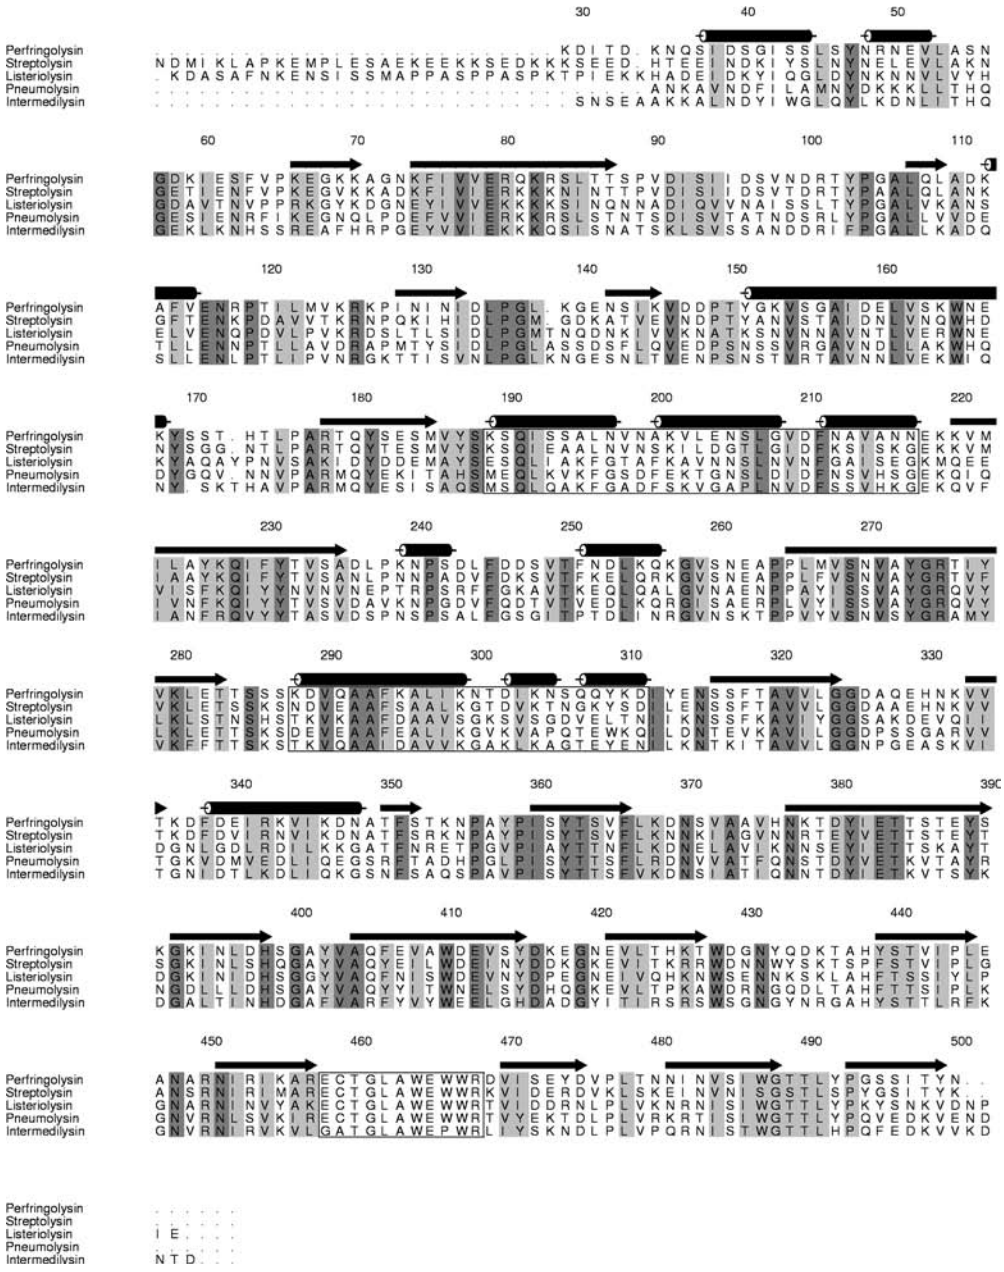

**FIGURE 37.1** Sequence alignment of various cholesterol-dependent cytolysins. Numbering refers to the PFO sequence; strictly conserved regions are shaded in dark gray, and highly conserved regions are shaded in light gray. The secondary structure of PFO, as seen in the crystal structure, is shown above the alignments (helices as cylinders and strands as arrows). The TMH1, TMH2, and undecapeptide regions are shown boxed, in that order, from the N-terminus.

1987). However, this single cysteine residue was shown not to be required for the *in vitro* cytolytic activity of SLO and PLY (Saunders *et al*., 1989; Pinkney *et al*., 1989), and more recently for PFO (Shepard *et al*., 1998). Substitution of the cysteine with alanine by *in vitro* mutagenesis yielded a toxin molecule that was similar in activity to that of the cysteine-containing wild-type. However, substitution of the cysteine with serine or glycine caused a significant decrease in the cytolytic activity of SLO and PLY (Saunders *et al*., 1989; Pinkney *et al*., 1989). Therefore, even though the sulfhydryl group is not required for the *in vitro* cytolytic activity of these toxins, the cysteine residue apparently occupied a site within the toxin structure that is critical to the function of the CDC. Why the cysteine has been retained at this position in these toxins, when alanine would function equally well and is not susceptible to oxidation, is not clear. Of the 11 sequenced CDCs, only pyolysin (PLO) from *Arcanobacterium pyogenes* and intermedilysin (ILY) from *Streptococcus intermedius* (Figure 37.1) have an alanine substituted for the cysteine. Although it is clear that the sulfhydryl is not required for cytolytic activity, it is not known if it has some as yet undefined role *in vivo*.

A cysteine-containing, highly conserved undecapeptide sequence, ECTGLAWEWWR, is present in eight of the 11 sequenced CDCs (Figure 37.1). The remaining three toxins exhibit various substitutions in this region, some of which are conservative and others of which are not. In addition to containing the cysteine residue, this region also contains a conspicuously large number of tryptophan residues: 10 of the 11 sequenced toxins contain three tryptophans in the undecapeptide. The undecapeptide sequence of seeligeriolysin from *Listeria seeligleri* has a single residue change in this sequence in which a phenylalanine is substituted for an alanine. However, the more recently discovered and sequenced CDCs, PLO (Billington *et al*., 1997) and ILY (Nagamune *et al*., 1996; Nagamune *et al*., 2000), exhibit significant differences in this region (Figure 37.1). Both have an alanine substituted for the cysteine residue, thus making them resistant to inactivation due to oxidation of the sulfhydryl. These two toxins also have significant differences in the last 4–5 residues of the undecapeptide. PLO has a conservative change of Glu to Asp (Asp498 of PLO), but also contains an insertion of a proline between Asp498 and Trp500. ILY also exhibits the same aspartate to glutamate and cysteine to alanine changes as PLO, but instead of inserting a proline, a proline has been substituted at position 494, a position where tryptophan would normally be found (Figure 37.1). Therefore, ILY only contains two tryptophans in this region, whereas all of the other toxins have three tryptophans. The role of the highly conserved undecapeptide in the cytolytic mechanism has not yet been completely clarified.

There are many additional differences in the primary structures of these toxins, none of which has been linked to a unique function of a particular CDC. However, one difference is worth noting and is unique to the structure of SLO, which is produced by *Streptococcus pyogenes*. When the SLO amino acid sequence is aligned with the primary structures of the other CDCs, an additional 70–75 amino acids are present at its amino terminus. The additional residues in SLO are located between the predicted signal peptide and the region of SLO that aligns with the approximate amino termini of the secreted forms of the other toxins. This additional sequence does not align with any of the other CDCs and does not exhibit any significant sequence similarity with any other protein. It has been shown that SLO can be nicked with the cysteine proteinase of *S. pyogenes* between residues Lys 77 and Leu 78 (Gerlach *et al*., 1993). This cleavage removes 46 amino acids from the secreted SLO and yields a 55.5 kDa protein. Both the uncleaved and cleaved forms are hemolytically active. Although this cleavage removes a significant portion of the extra sequence, there still remains an extra 26 residues on the small form of SLO, which does not exhibit any sequence similarity with the other CDCs. If the amino terminal region has a function specific for SLO, it has yet to be demonstrated.

## PFO—AN ARCHETYPICAL CDC

*Clostridium perfringens* is a normal inhibitant of the gastrointestinal tract of humans and animals, as well as being commonly found in soil. It causes human gas gangrene and food poisoning, as well as several enterotoxemic diseases in animals. The pathogenesis of gas gangrene (or clostridial myonecrosis) primarily involves the invasion of traumatic wounds or deoxygenated tissues by the Gram-positive bacterium. *C. perfringens* releases numerous virulence factors, including two lethal toxins, alpha-toxin and PFO, which are thought to be the major virulence factors of the bacterium. PFO, or theta-toxin, induces tissue destruction and anti-inflammatory responses and acts synergistically with alpha-toxin in gangrenous lesions (Rood, 1998). PFO is produced by all strains of *C. perfringens*. Its gene encodes a polypeptide that consists of a 27 amino acid signal peptide followed by 500 amino acids of the mature protein.

## CRYSTAL STRUCTURE OF PFO

The crystal structure of PFO was determined in 1997 (Rossjohn *et al*., 1997). The structure was originally determined to a resolution of 2.7 Å, but has since been extended to a resolution of 2.2 Å (Rossjohn, J., Polekhina, G., Feil, S.C. McKinstry, W.J., Tweten, R.K. and Parker, M.W., unpublished results). The PFO molecule is a very elongated molecule with its long axis measuring approximately 115 Å (Figure 37.2). A notable feature of the secondary structure is that it is very rich in beta-sheet. Although the molecule did not closely resemble any other molecule for which a crystal structure was known, its shape and secondary structure content were reminiscent of a number of other toxins including aerolysin (Parker *et al*., 1994), *Staphyloccus* α-hemolysin (Song *et al*., 1996), the protective antigen of anthrax toxin (Petosa *et al*., 1997), and LukF (Olson *et al*., 1999; Pédelacq *et al*., 1999).

The crystal structure demonstrated that PFO is built from four domains: the N-terminal domain or domain 1 (residues 37–53, 90–178, 229–274, 350–373), domain 2 (residues 54–89, 374–390), domain 3 (residues 179–228, 275–349), and the C-terminal domain or domain 4

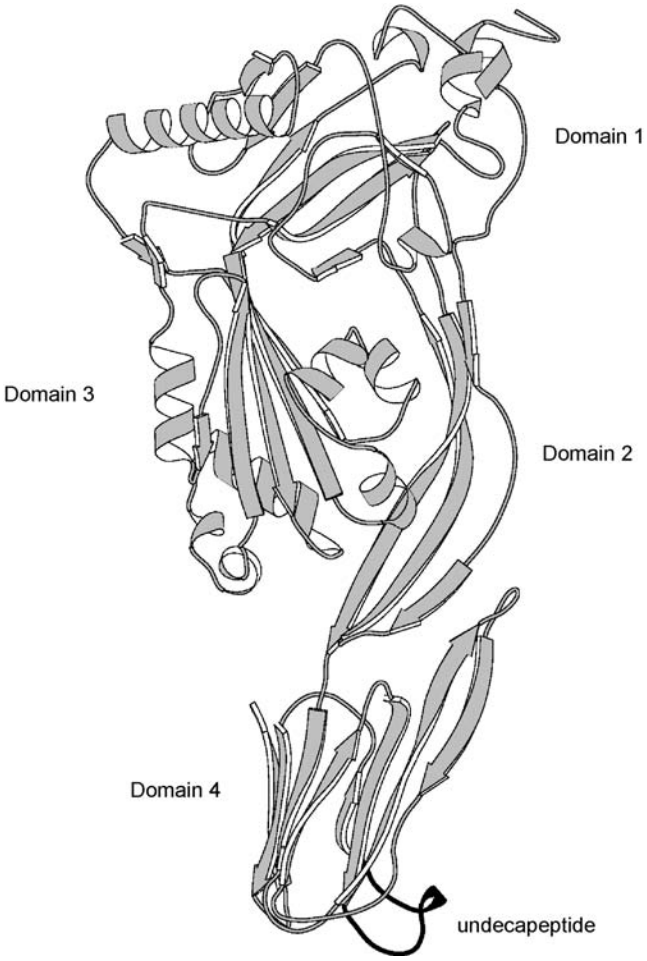

**FIGURE 37.2** Crystal structure of PFO. A ribbon representation indicating the location of domains and the undecapeptide motif (in dark shade). The figure was drawn using MOLSCRIPT (Kraulis, 1991).

(residues 391–500) (Figure 37.2). Domain 1, located at one end of the molecule, adopts an alpha-beta topology with a long helix packing against a core of anti-parallel beta-sheet. Domain 2 consists of a single layer of anti-parallel beta-sheet connecting one end of the molecule to the other. Domain 3 also adopts alpha-beta topology with a core anti-parallel beta-sheet surrounded by helical layers on both sides. Domain 4 adopts a beta-sandwich topology, a common fold found in a variety of proteins.

Two of the domains, domains 3 and 4, exhibited unusual features. The core beta-sheet that runs through domains 1 and 3 has a highly pronounced curvature at the domain interface. The packing of domain 3 onto the rest of the protein is far from complementary and involves predominantly polar contacts. (Normally, domain interfaces have very complementary surfaces and regions of hydrophobic contacts). These two features of domain 3 suggested the possibility that it could readily flex away from domain 2 so as to relieve the energetically unfavorable stress at the domain 1–3 interface.

Domain 4 was of particular interest because it houses the undecapeptide sequence, which had previously been implicated in cholesterol and membrane binding. This sequence was found to form an extended loop with a single turn of helix at the tip of the molecule. The loop curls back into one of the beta-sheets so that the tip of the loop defined by Trp 464 is nestled into the hydrophobic core of a number of long surface side chains. This immediately suggested that this site might be the cholesterol-binding site with the tryptophan side chain mimicking how a cholesterol molecule would bind if the loop was displaced. The undecapeptide motif itself consists of mostly hydrophobic residues, so its displacement would generate a hydrophobic "dagger" that would be capable of inserting into a membrane. Domain 4 is connected to the rest of the protein through a single linking peptide, suggesting that it too could be quite mobile in solution.

## STRUCTURE/FUNCTION STUDIES OF PFO

A major advance in understanding the mechanism of CDC membrane insertion came with the discovery that domain 3 harbored regions that formed the transmembrane (TM) β-barrel. The studies of Shepard *et al*. and Shatursky *et al*. revealed that a series of small helices on either side of a central β-sheet could unfurl into β-hairpins, TMH1 and TMH2, that were capable of spanning membrane bilayers (Figure 37.3). Such conformational changes were unprecedented among toxins and hence represented a new paradigm for how pore-forming proteins generated a membrane-spanning domain.

PFO must interact with membranes as a prerequisite for the insertion of the domain 3 TM hairpins that form the wall of the transmembrane β-barrel (Heuck *et al*., 2000). The conserved undecapeptide and three other short hydrophobic loops, all located at the tip of domain 4 of PFO, penetrate the surface of the membrane and anchor the molecule for the subsequent conformational changes during pore formation (Heuck *et al*., 2000; Nakamura *et al*., 1995; Ramachandran *et al*., 2002). Domains 3 and 4 are conformationally coupled, although they are not in direct physical contact. Mutations in domain 3 can affect the rate at which domain 4 interacts with the membrane, even though the domain 4 undecapeptide interacts with the membrane prior to the insertion of the domain 3 TMHs

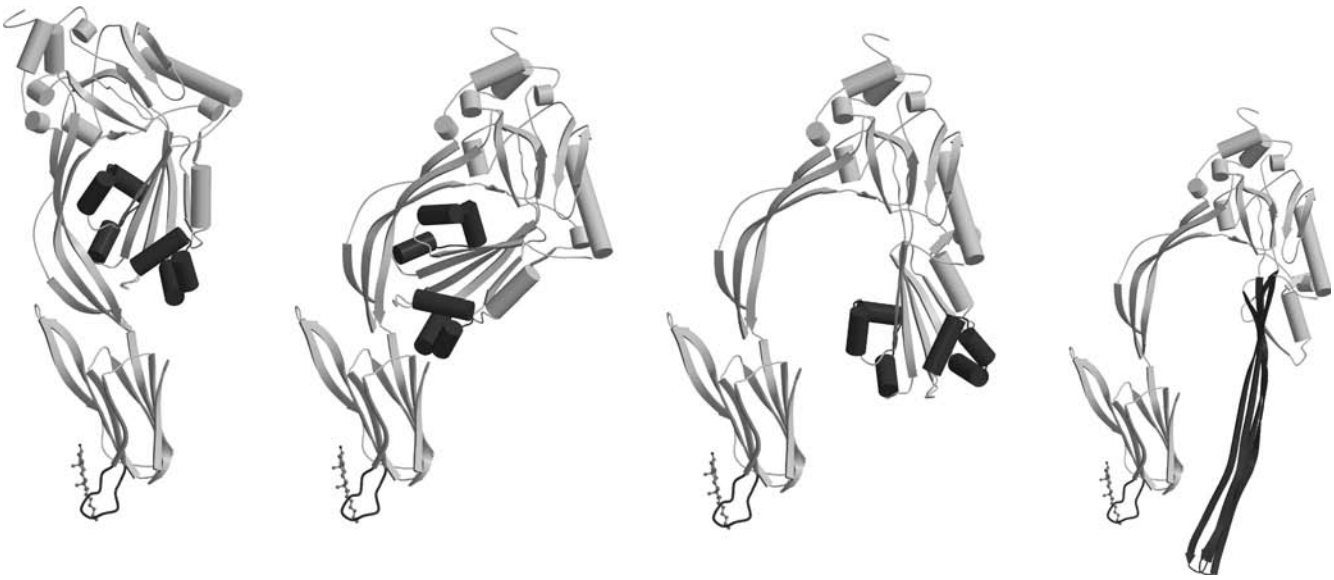

**FIGURE 37.3** A schematic model of stages of CDC insertion into membranes. From left to right: Ribbon representation of the PFO monomer as seen in the crystal structure. This is the structure thought to exist in solution. The TMH1 and TMH2 are highlighted in dark shade, and the undecapeptide loop is shown sprung out with a molecule of cholesterol binding to it. Next, domain 3 starts to rotate away from the body of the molecule, and the TMH regions are released simultaneously to form extended beta hairpins. It is likely that domain 4 curls into the body of the molecule, allowing the TMH regions to fully puncture the membrane so as to form a beta-barrel with the other monomers of the oligomer. Only one monomer is shown for clarity. This figure was produced using MOLSCRIPT (Kraulis, 1991).

(Palmer *et al*., 1998; Abdel Ghani *et al*., 1999; Heuck *et al*., 2000; Hotze *et al*., 2001; Ramachandran *et al*., 2002). The cytolytic activity of PFO is highly sensitive to changes in the undecapeptide motif, especially mutations of the conserved tryptophans or chemical modification of the thiol of the conserved cysteine, which inhibit membrane binding (Nakamura *et al*., 1995; Sekino-Suzuki *et al*., 1996, Alouf, 2000; Iwamoto *et al*., 1987). However, some undecapeptide mutations or modifications appear to affect the global structure of PFO, thus suggesting that its conformation is important to the proper function of the toxin.

A detailed model of the initial stages of membrane insertion by CDCs is now starting to emerge (Figure 37.3). In the first step, the toxin binds to cell surfaces via domain 4. The undecapeptide loop flips out from this domain to form a membrane-penetrating hydrophobic dagger that anchors the protein to the membrane. Many studies suggest that cholesterol acts as a receptor in this step, triggering the conformational change, although recent data suggests the role of cholesterol in this step is toxin dependent (Giddings *et al*., 2003). The partial insertion of domain 4 would bring domain 3 closer to the membrane surface and also would make the toxin oligomerization-competent (Abdel Ghani *et al*., 1999). A recent study suggests membrane binding is associated with conformational changes in domain 3 (Abdel Ghani *et al*., 1999). A prepore complex assembles on the membrane surface by lateral diffusion of membrane-bound monomers (Shepard *et al*., 2000; Hotze *et al*., 2001; Hotze *et al*., 2002). Electron microscopy studies of the CDC, pneumolysin, show that the prepore complex is bound to the membrane via the base of domain 4 where the undecapeptide loop resides (Gilbert *et al*., 1999). The TMH regions in domain 3 are kept unfurled at this stage to prevent premature membrane insertion of isolated monomers (Shepard *et al*., 2000; Heuck *et al*., 2000; Hotze *et al*., 2001). The formation of the oligomer triggers a further conformational change in domain 4, causing a rotation of domain 4 away from the long axis of the molecule and a concerted rotation of domain 3 as described previously. The rotation of domain 3 away from the molecule in the oligomer has been directly observed by electron microscopy (Gilbert *et al*., 1999). These rotations are of the order of 35° to 45° for domain 4 and would be sufficient to break all contacts between domains 2 and 3 and allow the concerted unfurling of the TMH regions to form β-hairpins (Hotze *et al*., 2001). Electron microscopy studies of pneumolysin oligomers support our suggestion that domain 3 swings out from the body of the molecule to adopt a disordered conformation and that the rotation of domain 3 is coupled to domain 4 rotations (Gilbert *et al*., 1999). It has been argued that a concerted insertion of the β-hairpins from all monomers of the oligomer then occurs based

on energetic considerations (Heuck *et al*., 2001), and this hypothesis is supported by recent experimental data (Hotze *et al*., 2002). Our modeling of the oligomer suggests that domain 4 must curl into the body of the molecule so that the extended β-hairpins can penetrate the bilayer. Very recently, a vertical collapse of about 40 Å was observed by atomic force microscopy between the prepore and pore states of PFO. The data is consistent with domain 2 collapsing into a more globular domain, rather than the elongated domain seen in the crystal structure of the water-soluble oligomer (Czajkowsky *et al*., 2004).

## NEW CRYSTAL STRUCTURE OF PFO

The structure of PFO has recently been solved in another crystal form at 3 Å resolution (Rossjohn, J., Polekhina, G., Feil, S.C., McKinstry, W.J., Tweten, R.K. and Parker, M.W., unpublished results). These crystals were grown using butanol as the precipitant, and they contain two molecules per asymmetric unit. The two molecules pack in a head-to-tail arrangement and are essentially identical to each other, with a root-mean-square (r.m.s) deviation of 0.6 Å over all Calpha atoms. They also superpose well with the previously published structure, with an overall r.m.s deviation of 1.0 Å over all Calpha atoms. The conformation of the undecapeptide motif is also very similar, as is the conformation of the TMH1 and TMH2 helical springs, demonstrating that the observed conformations of these critical regions are not artefacts of the cystallization process.

The overall temperature factor, a measure of the order of the molecule, was mapped onto the structures for both the crystal forms. The β-sandwich of domain 4 and the 5-stranded sheet of domain 3 represent the most ordered part of the molecule in the published crystal form. The top and neck of the molecule appears largely mobile, with the outer region of domain 2 being very mobile. The new crystal form shows an overall increased mobility over the entire backbone, despite showing no large-scale structural differences with respect to the wild-type structure. Domain 4 and the β-sheet of domain 3 represent the most ordered regions of the molecule as well.

## MOLECULAR BASIS OF THIOL ACTIVATION

CDCs were initially termed the thiol-activated cytolysins because thiol-reagents such as N-ethyl maleimide and mercury salts (Alouf and Geoffroy, 1991) inhibited cytolytic activity, whereas thiol-reducing reagents reversed these effects. This led to the concept of the "essential thiol." However, it was subsequently shown that the cysteine is not essential *in vivo* (see above). Each CDC contains just one cysteine throughout the sequence, with the exception of ivanolysin, which contains two cysteines. This solitary cysteine is located in the undecapeptide motif, and thus the effects of the thiol-reagents must be directed to the cysteine within the motif. The structural basis of inactivation by these thiol reagents is unknown.

During the course of the structure determination of PFO (Rossjohn *et al*., 1997), two mercury derivatives, mercury acetate (HgOAc) and *p*-chloromercuri-benzene sulfonate (PCMBS), were used. The PCMBS and HgOAc data sets extend to 2.7 Å and 2.9 Å, respectively. To address the structural basis of toxin inactivation, the two mercury-modified forms of PFO have been refined (Rossjohn, J., Polekhina, G., Feil, S.C. McKinstry, W.J., Tweten, R.K. and Parker, M.W., unpublished results). The electron density for both models, in particular the region around the undecapeptide motif, is well defined. The structures of PCMBS-PFO and HgOAc-PFO superpose well with respect to the 2.2 Å resolution wild-type structure. Somewhat surprisingly, the region around the undecapeptide in both metal complexes is virtually identical to the wild-type (Figure 37.4). The chemical modification of Cys 459 can be seen not to disrupt appreciably the conformation of the undecapeptide motif, implying that these thiol reagents must inactivate PFO via another mechanism. One possibility is that cysteine modification affects the flexibility of the undecapeptide loop, which has been hypothesized to flip out from the body of the molecule on binding cholesterol to form a membrane-penetrating hydrophobic dagger (Rossjohn *et al*., 1997; Ramachandran *et al*., 2002; and see below).

## INTERMEDILYSIN—AN ATYPICAL CDC

*S. intermedius* secretes the CDC ILY (Macey *et al*., 2001), and ILY appears to be a major virulence factor of *S. intermedius*, as it is expressed up to 10-fold more in abscesses (Nagamune *et al*., 2000). ILY exhibits three features that distinguish it from most other CDCs. First, it has a variant undecapeptide sequence (GATGLAWEPWR) (Figure 37.1). The normally conserved cysteine of the CDC undecapeptide is replaced by an alanine residue, resulting in an oxidation-resistant toxin (Nagamune *et al*., 1996), and a proline

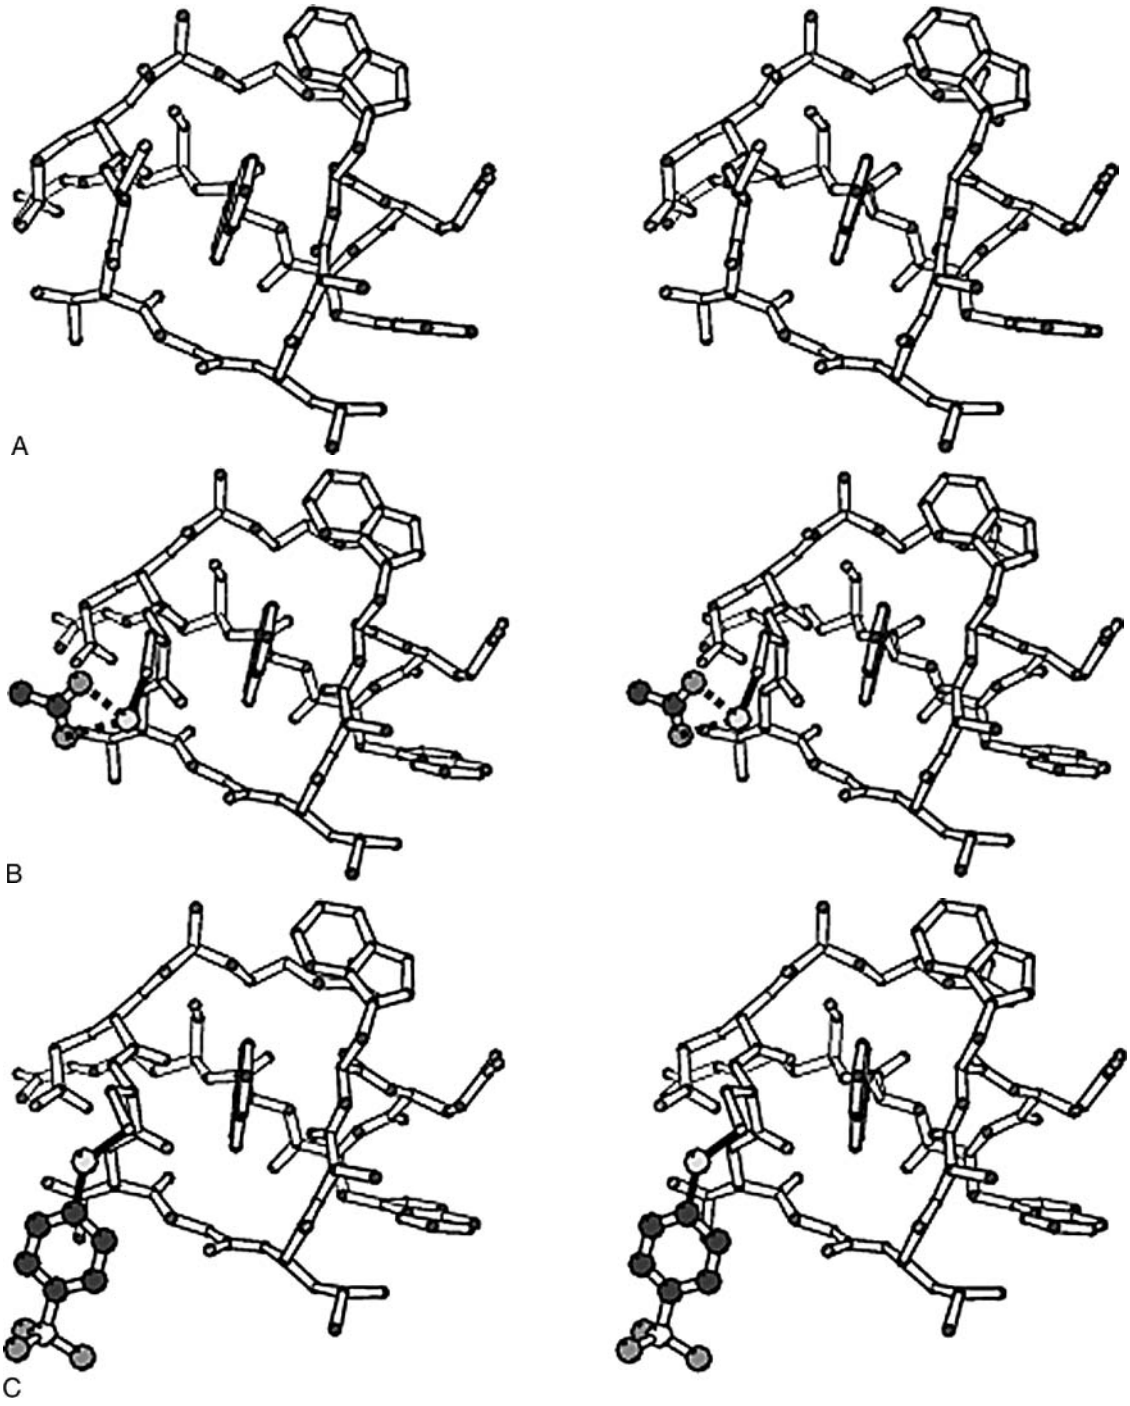

**FIGURE 37.4** Stereoview of the mercury complex structures in the vicinity of the undecapeptide loop in domain 4. residue is substituted for the second conserved tryptophan. Second, ILY is specific for human cells (Nagamune *et al.*, 1996; Macey *et al.*, 2001). Nagamune and coworkers (1996) showed that animal erythrocytes from nine species are not susceptible to ILY and non-human primate erythrocytes are a hundred-fold less susceptible to ILY than human erythrocytes. Third, free cholesterol is only weakly inhibitory. Although the presence of membrane cholesterol is still essential to the activity of ILY, it does not appear

to function as a receptor as it does for PFO (Giddings *et al*., 2003). Giddings and coworkers (2003) showed that depletion of approximately 90% of the membrane cholesterol did not affect ILY binding or that of the related CDC, SLO, to human erythrocytes, but it did completely abrogate the hemolytic activity of both toxins. It was determined by fluorescence spectroscopy that cholesterol depletion prevented the prepore to pore conversion of ILY and SLO. Therefore, cholesterol was necessary for ILY membrane insertion, but not its membrane binding.

The unique aspects of the ILY mechanism, its variant undecapeptide and human cell specificity, prompted us to investigate whether the two aspects were linked. We have pursued a detailed structural investigation of ILY with the aim of understanding how these distinguishing features impact on its interaction with cells.

## CRYSTAL STRUCTURE OF ILY

The crystal structure of ILY has been determined to a resolution of 2.6 Å (Polekhina *et al*., 2004; Polekhina *et al*., 2005). Overall, ILY adopts a similar structure to PFO (see next section), so only a brief overview of the structure will be presented here. It is an elongated boomerang-shaped molecule of dimensions 50 Å × 58 Å × 114 Å (Figure 37.5). The molecule is rich in β-sheet with 40% sheet made up of 23 β-strands contributing to four sheets. One strand (residues 399 to 425) spans about two-thirds of the molecule and measures 100 Å in length. There are 15 helices, varying in length between 4 and 21 residues.

The molecule is comprised of four discontinuous domains. Domain 1 (residues 56 to 79, 116 to 205, 256 to 301, 377 to 400) has an α/β structure with a core of six-stranded β-sheet. Domain 2 (residues 80 to 115, 401 to 417) consists of a three-stranded β-sheet. Domain 3 (residues 206 to 255, 302 to 376) is comprised of an α/β/α three-layer structure. The interface of domains 2 and 3, covering a surface area of 592 Å$^2$, is constructed from the packing of two helices against the β-sheet of domain 2 and consists of four potential hydrogen-bonding interactions and 17 van der Waals interactions. Domain 2 is covalently connected to domain 4 through a single connection. Domain 4 (residues 418 to 528) is folded into a compact β-sandwich consisting of four- and five-stranded sheets. The interface between domains 2 and 4, covering 242 Å$^2$, consists of one salt link (between Arg 92 and Glu 448), three hydrogen-bonding interactions, and 10 van der Waals interactions. In addition, there are numerous

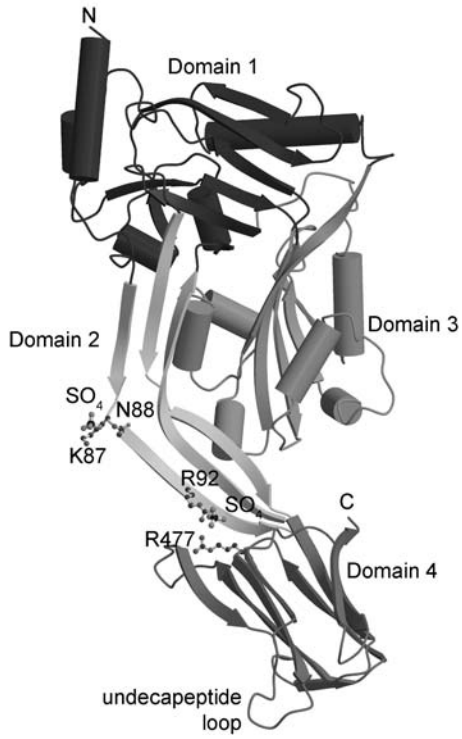

**FIGURE 37.5** Crystal structure of ILY. A ribbon representation indicating the location of domains and the undecapeptide loop. The figure was drawn using MOLSCRIPT.

sulfate ion-mediated contacts between the two domains (see below).

ILY crystallized with two molecules in the asymmetric unit. The two molecules superimpose with a r.m.s. deviation of 2.2 Å on Calpha positions. This large deviation is due to a relative 10° rotation of domain 4 with respect to the rest of the molecule, so that the tips of domain 4 are nearly 16 Å apart when domain 1 of each molecule is superimposed. Superposition of domains 1 to 3 yields a r.m.s. deviation of 0.7 Å and superposition of domain 4 yields a deviation of 0.6 Å. Hence, aside from the rotation of domain 4, the two molecules are very similar.

Sulfate ions were a vital ingredient for crystallization of ILY (Polekhina *et al*., 2004). Four sulfate ions were identified in the asymmetric unit and were found to bind to the same two sites on each of the two protein molecules. This suggests the sulfate binding sites may be more than just an artifact of the crystallization process. One sulfate ion is bound to Arg 92 and Arg 477 and hence bridges domains 2 and 4 (Figure 37.5). Another sulfate is bound in an unusual manner as it is coordinated by two consecutive residues Lys 87 and Asn 88 (through both side chain and main chain atoms), both from domain 2, as well as Arg 477 from

the opposing molecule (Figure 37.5). It is conceivable that the sulfate-binding sites might represent binding pockets for the putative human protein receptor.

## STRUCTURAL COMPARISON OF ILY AND PFO

The most similar structure to ILY in the Protein Data Bank (http://www.rscb.org/pdb) is PFO (Rossjohn *et al*., 1997), the only other CDC for which a three-dimensional atomic structure has been determined. The two proteins have an overall pairwise sequence identity of 40% (197 out of a total of 532 residues) that is distributed relatively evenly over the entire sequence of each molecule. Both proteins share the same number of domains, and each domain shares the same overall topology. The most striking difference between the two molecules is the highly bent shape of ILY compared to PFO, with domain 4 rotated between 20˚ and 30˚ away from the main axis of the ILY molecule (Figure 37.6). (The rotation is either 20˚ or 30˚, depending on which ILY molecule in the asymmetric unit is used in the superposition.)

Domain 4 is the most similar domain between the two molecules with an r.m.s. deviation on 91 equivalenced Calpha atoms of 0.8 Å. The most significant difference in this domain is the conformation of the undecapeptide loop that adopts an extended conformation in ILY, but is curled up against the β-sheet in PFO (Figure 37.6). The extended conformation does not appear to be an artifact of the crystallization, as the loop of one of the two ILY molecules in the asymmetric unit is not involved in crystal contacts, and the loops of both molecules superimpose almost exactly. There is also a movement of a hairpin loop by almost 10 Å at the other end of this domain due to differences in domain 2 (Figure 37.6). Another notable difference is the distribution of electrostatic charge on the surface of domain 4 of each toxin. ILY is predominantly positively charged, whereas PFO is negatively charged with differences particularly pronounced in the region of the undecapeptide motif and at the C-terminus.

A comparison of the domain 4 primary structures of ILY and PFO does not provide any obvious candidate regions of domain 4 that may be involved in cellular specificity of ILY (Figure 37.1). About 60% of the residues are not conserved between the two domains, and these differences are distributed comparatively evenly throughout domain 4. A surface analysis over the domain 4 region of the crystal structures is also not illuminating. There are no compelling patches of unique or unusual sequence on the surface of this domain that would suggest a receptor-binding region.

**FIGURE 37.6** Superposition of ILY and PFO. Calpha traces of ILY (light gray) and PFO (black), based on a domain 1 superposition.

Domain 1 is the next closest with 1.2 Å r.m.s. deviation on 145 equivalenced Calpha atoms (Figure 37.6). The most significant differences in this domain are the positions of the two helices seen in PFO with the longer helix (residues 178 to 195) shifted by about 3.5 Å and the shorter one (residues 278 to 284) by 2.8 Å. There is also an additional short helix (residues 122 to 127) in ILY not seen in PFO. The N-terminal helix (residues 56 to 70) in ILY is longer and more ordered than in PFO and is also shifted by about 3 Å compared to PFO.

Domain 3 with an r.m.s. deviation of 3.1 Å (over 130 equivalenced Calpha atoms) does not superimpose well because, although the core β-sheet is similar (r.m.s. deviation of 1.5 Å over 38 equivalenced atoms), the helices packing on either side of the sheet adopt different positions relative to the sheet (Figure 37.6).

In particular, the helices on the surface of the ILY molecule (TMH2) are not as closely nestled to the sheet as they are in PFO (with shifts of up to 7 Å), and they exhibit high temperature factors. The helices at the interface between domains 3 and 2 (TMH1) also shift by up to 3 Å compared to PFO. If the two molecules are superimposed using domain 1 only, domain 3 is shifted by about 2 Å in ILY compared to PFO (Figure 37.6). Domain 2 does not superimpose well due to a twist in the β-sheet in the middle of the domain, causing a r.m.s. deviation of 2.9 Å over 51 equivalenced Calpha atoms (Figure 37.6). This deviation is responsible for the pronounced kink in the shape of the molecule compared to PFO.

The solution of the ILY structure demonstrates that the basic features of the CDC 3D structure appear to be conserved among the CDCs. A phylogenetic tree generated by the alignment of the known CDC primary structures (15 in all), using the nearest-neighbor method of Saitou and Nei (1987), shows that PFO and ILY are two of the most distantly related CDCs (data not shown), yet they exhibit similar 3D structures. Therefore, it is likely that all CDCs will exhibit 3D structures similar to that of PFO and ILY.

## CHOLESTEROL-BINDING SITES

Previous work has implicated cholesterol as the receptor for the CDC family, where it is thought to act by concentrating the toxin in cholesterol-rich domains of the target cell membrane to promote oligomerization (Alouf and Geoffroy, 1991). We have previously hypothesized that cholesterol could bind to PFO by displacing the undecapeptide loop and binding to one face of the β-sheet in domain 4 (Rossjohn *et al*., 1997). A striking feature of the ILY structure is the extended conformation of the undecapeptide loop (Figure 37.6), a conformation predicted for PFO when it binds cholesterol. We have computationally docked a cholesterol molecule into the ILY structure and found no preferred clustering of cholesterol molecules into the putative binding site (Polekhina *et al.*, 2005). The conformation of the undecapeptide loop in ILY provided a basis for modeling the equivalent loop, in its sprung-out form, in PFO. We then docked cholesterol into the modified PFO structure and found that the majority of docks yielded a close clustering of cholesterol molecules with the same orientation and position in the putative binding pocket. The cholesterol molecule was found to stack against the aromatic side chains of Trp 466 and 467 and the 3β-hydroxy moiety, forming a hydrogen bond to Glu 407 of PFO. A comparison of the key residues involved in interacting with cholesterol in PFO with the equivalent residues in ILY showed that some are not conserved. Glu 407 (PFO) is replaced by Tyr 434 in ILY, and this residue does not appear capable of providing a hydrogen bond to the 3β-hydroxyl of cholesterol. Trp466 (PFO) is substituted by Pro493 in ILY; the latter residue is likely responsible for the extended conformation of the undecapeptide observed in ILY and also disrupts the aromatic stacking interaction between cholesterol and the tryptophans suggested in the PFO model.

In summary, PFO possesses a plausible binding site in domain 4 for a cholesterol molecule if it is assumed that the undecapeptide adopts an extended conformation, as observed in the crystal structure of ILY. Surprisingly, ILY is not predicted to possess such a site. We hypothesize that ILY does not need a cholesterol-binding site because its undecapeptide is already "sprung out." These suggestions are in keeping with earlier work that has shown that free cholesterol is only weakly inhibitory for ILY cytolytic activity in contrast to PFO (Nagamune *et al*., 1996). Nevertheless, cholesterol does play a role in the insertion process of ILY (Giddings *et al*., 2003), indicating that cholesterol may play multiple roles in CDC activity.

## CONCLUSION

The crystal structure of PFO has proved a valuable basis for numerous structure-function studies that have revealed many details of the membrane insertion process (Shepard *et al*., 1998; Shatursky *et al*., 1999; Heuck *et al*., 2000; Shepard *et al*., 2000; Hotze *et al*., 2001; Hotze *et al*., 2002; Ramachandran *et al*., 2002; Heuck *et al*., 2003; Czajkowsky *et al*., 2004; Ramachandran *et al*., 2004). The structure of ILY, an atypical CDC, demonstrates that the overall protein fold first seen in PFO is almost certainly maintained in all members of the family. Key differences include different orientations of domain 4 with respect to the rest of the protein and different conformations of the undecapeptide loop, presumably in response to sequence differences in the region. Further structural studies are required to illuminate the role of cholesterol in CDC activity and the molecular detail of the CDC oligomer.

## ACKNOWLEDGMENTS

# 38

# Perfringolysin O and intermedilysin: mechanisms of pore formation by the cholesterol-dependent cytolysins

*Kara S. Giddings, Arthur E. Johnson, and Rodney K. Tweten*

## INTRODUCTION

Perfringolysin O (PFO) is a prototypic member of the large pore-forming toxin (PFT) family, the cholesterol-dependent cytolysins (CDCs). Members of the CDC family exhibit a high level of identity at the primary structure level, and therefore are predicted to share many similar features that define the CDC pore-forming mechanism. Of those features, two hallmark characteristics of this family include the formation of large, homo-oligomeric structures on the surface of the membrane (about 300 Å in diameter) and the absolute dependence of their cytolytic activity on the presence of membrane cholesterol (Heuck *et al*., 2001). The CDCs are produced as soluble monomers by various Gram-positive bacterial pathogens, but ultimately form a membrane-embedded, pore-forming oligomer. It is the transition from the soluble monomer to membrane pore and the associated structural changes in the monomer structure that have been one of the most intensively studied aspects of the CDCs in recent years. As will be discussed in this review, the study of the PFO mechanism has been key to understanding these structural transitions.

The ability of free cholesterol to abrogate toxin cytolytic activity has often been used to classify these toxins as CDCs. The inhibitory effect of adding free cholesterol to the CDCs was proposed to result from the occupation of a cholesterol-binding site on the toxin, thereby preventing it from binding to cholesterol-containing membranes (Alouf, 1999). Although this effect is well-known, the role of cholesterol in the mechanism of the CDCs has been difficult to elucidate. Recent studies on the novel CDC intermedilysin (ILY) suggest that the role of cholesterol in the CDC mechanism is more complex than originally proposed. ILY is unique among the CDCs in that it exhibits a restricted specificity for human erythrocytes (Nagamune *et al*., 1996). The ability of ILY to specifically target human cells suggested that it did not use cholesterol as its cellular receptor. Hence, ILY has proven to be a valuable tool for investigations into the role of cholesterol in the CDC mechanism, and its study has revealed some novel features that are incorporated into the CDC structure.

The material covered in this review will focus on aspects of the CDC cytolytic mechanism that have been elucidated in the last six years. These studies have led to the identification of several unique features that provide a more complete understanding of the fundamental changes in CDC structure that led to the assembly of the pore complex from the soluble CDC monomers. Furthermore, the discovery that the cytolytic activity of ILY was restricted to human cells has provided an important tool for the study of membrane recognition by the CDCs and the complex role of cholesterol in the CDC cytolytic mechanism.

## GENERAL FEATURES OF CDC STRUCTURE AND FUNCTIONAL MECHANISM

Specific details of CDC structure and function are provided in the following sections, but a brief overview will be provided here in order to orient the reader. The structure of the soluble monomer of PFO is shown in Figure 38.1 (see Chapter 37). PFO is largely comprised of β-sheet, and its structure can be divided into four domains. Domain 4 (D4) contains a highly conserved, tryptophan-rich undecapeptide. This peptide is highly conserved among the CDCs, but its role in pore formation remains elusive. It is clear that part of the undecapeptide inserts into the membrane (Nakamura *et al*., 1995; Heuck *et al*., 2003), though not to a significant depth (Heuck *et al*., 2003). In addition, three other short hydrophobic loops at the tip of D4 have been shown to insert into the membrane and help anchor PFO to the membrane (Ramachandran *et al*., 2002). It is also thought that the undecapeptide may interact directly with cholesterol, but a direct interaction between cholesterol and the undecapeptide has not been rigorously demonstrated.

After binding to the membrane, monomers diffuse laterally to initiate formation of the oligomer. Major structural rearrangements occur in D3 of PFO during this process. First, a loop comprised of a short β-strand and an α-helix must rotate away from one edge of the D3 core β-sheet to allow oligomerization of the monomers (Ramachandran *et al*., 2004). The monomers oligomerize into what has been termed a "prepore" complex (Shepard *et al*., 2000; Hotze *et al*., 2001). This complex resembles the pore complex, but it has not yet inserted its transmembrane β-barrel into the bilayer to form the pore. The transmembrane pore is formed when two α-helical bundles in D3 are converted to two extended amphipathic β-hairpins (Shepard *et al*., 1998; Shatursky *et al*., 1999) that insert into the membrane in a concerted fashion in the oligomer to form the pore (Hotze *et al*., 2002).

## CHOLESTEROL INVOLVEMENT IN THE CDC CYTOLYTIC MECHANISM

A fundamental issue in elucidating the mechanism of action for the CDC toxins is the role of membrane cholesterol. Numerous studies have previously implicated cholesterol as the membrane receptor for PFO and streptolysin O (SLO) and have equated the cholesterol-dependent inhibition of CDC activity to a blockage of CDC binding to receptor. It has been thought that occupation of the cholesterol-binding site on PFO (and other CDCs) prevents binding to membrane cholesterol. Ohno-Iwashita and co-workers have demonstrated that PFO can bind cholesterol directly and that PFO membrane binding is sensitive to the loss of membrane cholesterol (Ohno-Iwashita *et al*., 1986; Ohno-Iwashita *et al*., 1988; Iwamoto *et al*., 1990; Ohno-Iwashita *et al*., 1990; Ohno-Iwashita *et al*., 1991). However, the role of cholesterol in pore formation by the CDCs appears to be more complex than originally conceived.

Some evidence suggests that cholesterol may not control membrane recognition for all CDCs. One of the first observations to directly challenge the role of cholesterol as the CDC cellular receptor was a study by Jacobs *et al*. (Jacobs *et al*., 1998). They found that preincubation of LLO with exogenous cholesterol inhibited the cytolytic activity of the toxin, but did not appear to inhibit its binding to target membranes. They suggested instead that cholesterol affected a downstream event in pore formation by LLO, specifically oligomerization. The importance of cholesterol to CDC pore formation has also been examined for pneumolysin, a CDC produced by *Streptococcus pneumoniae*. Boulnois *et al*. (Boulnois *et al*., 1991) also suggested that cholesterol affected an event in the mechanism that occurred downstream of membrane binding. More recently, Billington *et al*. (Billington *et al*., 2002) showed that specific mutants of the CDC pyolysin (PLO), secreted by *Arcanobacterium pyogenes*, exhibited decreased cholesterol binding and cytolytic activity, but retained their ability to bind erythrocytes similarly to native toxin. But the most intriguing observation to cast doubt on the cholesterol-as-receptor dogma was made by Nagamune *et al*. (Nagamune *et al*., 1996). They found that the CDC intermedilysin (ILY) from *Streptococcus intermedius* formed pores only in human cells, an observation that was seemingly inconsistent with cholesterol serving as the CDC receptor.

Based on these previous studies, Giddings *et al*. (Giddings *et al*., 2003) examined the effect of membrane cholesterol depletion on the function of three different CDCs: PFO, ILY, and streptolysin O (SLO). They showed that the binding of SLO and ILY to the membranes was unaffected by the loss of approximately 90% of membrane cholesterol, while the cytolytic activity of both toxins on the same cholesterol-depleted erythrocytes was reduced greater than 99.9%. Under the same conditions, PFO binding was reduced approximately 10-fold in the absence of about 90% membrane cholesterol, yet PFO hemolytic activity was reduced by more than 11,000-fold (Giddings *et al*., 2003). Thus, the dependence of pore formation on cholesterol was

much greater than the dependence of protein binding to the membrane on cholesterol. It appears that the essential role of cholesterol in pore formation may be due primarily to its involvement in membrane insertion of the prepore complex and not membrane binding. In every case, the full activity of these toxins on the cholesterol-depleted membranes was restored by adding back cholesterol. Therefore, the loss of activity was due solely to the depletion of cholesterol from the membrane.

Giddings *et al*. (Giddings *et al*., 2003) determined that the loss of membrane cholesterol effectively stalled CDCs in a prepore complex. Therefore, the depletion of membrane cholesterol prevented the insertion of the transmembrane β-barrel. How cholesterol regulates the insertion of the CDC β-barrel remains unclear. It is possible that the effect of cholesterol on the bulk bilayer lipids (i.e., the formation of cholesterol-rich lipid rafts) provides conditions that facilitate the insertion of the β-barrel. An alternative but not mutually exclusive explanation is that a specific region of the CDC structure (presumably D4, see below) must interact with cholesterol to subsequently facilitate the conversion of the prepore to pore.

The work of Giddings *et al*. also explained how the cytolytic mechanism of the human cell–specific ILY could remain sensitive to cholesterol, but did not use it as a receptor. Therefore, their studies provided the impetus to explore the possibility that ILY used a nonsterol receptor to specifically recognize human cells. The ILY receptor is discussed below in detail.

## THE ROLE OF DOMAIN 4 IN CDC PORE FORMATION

### The interaction of domain 4 with the membrane

One of the most studied domains of PFO is D4. It is this domain that appears to interact with cholesterol, it contains the highly conserved undecapeptide sequence, and it is the first domain of the CDCs to interact with the membrane. Therefore, understanding its structure and function is key to understanding the subsequent structural changes that occur in the CDC molecule during pore formation.

In early studies, a proteolytically derived carboxy-terminal fragment of PFO (residues 305–500) containing all of D4 was shown to bind membrane independently of the intact PFO molecule (Iwamoto *et al*., 1990; Tweten *et al*., 1991). Based on crystal structure of PFO (Rossjohn *et al*., 1997) and location of D4 in the PFO molecule, it was postulated that D4 was not only responsible for the initial contact with the membrane, but that D4 penetrated the bilayer to generate the aqueous-lipid interface following pore formation (Rossjohn *et al*., 1997). Since that time, studies have unequivocally demonstrated that D3 of PFO harbors the peptide sequences that interact directly with the non-polar core of the bilayer during pore formation to create the β-barrel pore (Shepard *et al*., 1998; Shatursky *et al*., 1999) (see below).

Although D4 does not directly participate in the formation of the transmembrane β-barrel, it has been shown that the conserved undecapeptide and three other short hydrophobic loops at the tip of D4 insert into and anchor the monomer to the membrane (Heuck *et al*., 2000; Ramachandran *et al*., 2002). Collisional quenching studies showed that these loops did not penetrate deeply into the membrane and therefore were not involved in creating the pore, but instead were necessary to anchor the monomer to the bilayer and to orient it approximately perpendicularly to the membrane (Ramachandran *et al*., 2002). Furthermore, it appears that the surface of D4 that projects above the membrane is not in intimate contact with adjacent monomers in the CDC oligomeric pore complex and is, in fact, surrounded by the aqueous milieu (Ramachandran *et al*., 2002).

### Conformational coupling of domains 4 and 3

It is clear that the interaction of D4 with the membrane elicits subsequent structural changes that enable the membrane-bound monomers to oligomerize and form the pore structure. Heuck *et al*. first revealed that D3 and D4 are conformationally coupled in PFO, even though they are not in direct physical contact (Heuck *et al*., 2000). The interaction of PFO monomers with the membrane can be monitored by changes in the intrinsic fluorescence of the tryptophans within the undecapeptide region as they insert into the membrane (Nakamura *et al*., 1995). Kinetic analyses of the fluorescence changes associated with these tryptophans and with probes in D3 revealed that the interaction of D4 with the membrane preceded the insertion of the D3 transmembrane β-hairpins into the bilayer. Therefore, D4 interacts with the membrane surface before the transmembrane β-hairpins (Heuck *et al*., 2000). Interestingly, they also found that mutations in D3 that slowed the rate of insertion of the transmembrane β-hairpins also slowed the rate of association of D4 with the membrane. Since D4 interacted with the membrane before D3, the only explanation for this observation was that the two domains were conformationally coupled.

Although it is not unusual for two domains to be conformationally coupled, in this instance, the coupling

occurs even though the two domains are not in direct physical contact. Therefore, the coupling must require the involvement of D2, which is in contact with both domains 3 and 4, and possibly D1, which is in contact with D3 and D2. The results of these studies suggest that the undecapeptide and adjacent loops at the tip of D4 insert into the membrane, thereby anchoring the monomer firmly to the membrane. These changes in the D4 structure must trigger other changes in the structure of PFO outside of D4 that facilitate oligomerization into the prepore structure and modulate the insertion of the D3 transmembrane β-hairpins. Although the precise nature of the D3-D4 structural communication is not known, many aspects of the structural changes in the rest of the molecule that result in oligomerization and formation of the transmembrane β-barrel have been elucidated.

### Identification of a non-sterol membrane receptor for ILY

As described previously, it has been assumed for decades that cholesterol acts as the receptor for the CDCs. However, the recent studies of Giddings *et al*. (Giddings *et al*., 2003) have demonstrated that the major impact of cholesterol depletion from erythrocyte membranes on the CDC mechanism was on prepore to pore conversion, and not membrane binding. Hence, this finding showed that ILY activity remained sensitive to the presence of membrane cholesterol, but that cholesterol did not necessarily serve as a receptor for ILY. Nagamune *et al*. (Nagamune *et al*., 1996) showed that the activity of ILY was decreased on trypsin-treated human erythrocytes. Subsequently, Giddings *et al*. (Giddings *et al*., 2004) showed that under similar conditions of trypsinization, the binding of ILY was also decreased, further suggesting a non-sterol, proteinaceous receptor for this toxin. A detailed investigation by Giddings *et al*. (Giddings *et al*., 2003) into the interaction of ILY with human and non-human cells revealed that ILY utilizes human CD59 (huCD59) protein as its cellular receptor on the membrane surface.

CD59 is a glycosyl-phosphatidylinositol (GPI)-anchored membrane protein that normally functions to inhibit the formation of the complement membrane attack complex (MAC) on host cells (Rollins and Sims, 1990) by binding to components of the MAC complex and thereby preventing the formation of the MAC pore (Chang *et al*., 1994; Lockert *et al*., 1995). CD59 specifically binds to complement proteins C8α and C9 of the MAC complex via a peptide region that includes residues 42–58 of the CD59 molecule (Zhao *et al*., 1998; Zhang *et al*., 1999). This peptide region exhibits the greatest level of heterogeneity between human, non-human primate, and animal CD59 molecules, and appears to be responsible for the species-selective inhibition of the complement MAC by CD59. The variability of this region between CD59 molecules of the various species also made it an ideal candidate to explain how ILY bound to huCD59, but not CD59 molecules from non-human species. Giddings *et al*. (Giddings *et al*., 2004) showed that the human cell specificity of ILY resulted from its recognition of this region of huCD59.

Giddings *et al*. (Giddings *et al*., 2004) also determined that D4 of ILY was sufficient for recognition and binding to huCD59. Using an ILY D4 glutathione-S-transferase (GST) fusion protein, they show that D4 alone could recognize and bind huCD59 similarly to native ILY. Furthermore, it appeared that the aberrant ILY undecapeptide was not involved in the cellular specificity of ILY (Nagamune *et al*., 2004).

These discoveries have altered how we view CDC membrane recognition and binding. It is now reasonable to propose that the first stage of the cytolytic mechanism of ILY, and perhaps other CDCs, involves the recognition of a cellular receptor other than membrane cholesterol. It also needs to be emphasized that although ILY does not use cholesterol as a receptor, it is clear from the above studies that its pore-forming mechanism is still highly dependent on the presence of membrane cholesterol. Therefore, the definition of these toxins as "cholesterol-dependent cytolysins" is the most appropriate nomenclature because it does not imply that these toxins must bind or use cholesterol as a receptor, but that their mechanism is still dependent on the presence of membrane cholesterol.

## FORMATION OF THE PREPORE

Several pore-forming toxins have been shown to first oligomerize on the cell surface into a prepore complex (Walker *et al*., 1995; Fang *et al*., 1997; Miller *et al*., 1999; Nguyen *et al*., 2002). The formation of a prepore complex by the CDCs is now well-established (Heuck *et al*., 2000; Shepard *et al*., 2000; Hotze *et al*., 2001; Hotze *et al*., 2002; Giddings *et al*., 2003; Heuck *et al*., 2003; Czajkowsky *et al*., 2004; Ramachandran *et al*., 2004). Generation of a prepore intermediate for PFO was first established by the observation that oligomer formation could proceed in the absence of pore formation at low temperatures (Shepard *et al*., 2000). Hotze *et al*. (Hotze *et al*., 2001) subsequently showed that a disulfide bond between D2 and the α-helical bundle that eventually

forms transmembrane β-hairpin 1 (TMH1) to D2 (Figure 38.1) effectively blocked pore formation, but not oligomerization of PFO. Reduction of this disulfide bond resulted in a rapid insertion of the transmembrane β-hairpins and formation of the pore complex. The size of the insertion-competent prepore complex is also large, and only large complexes form pores (Shepard *et al*., 2000; Hotze *et al*., 2002; Heuck *et al*., 2003) (see the next section for a complete discussion of the pore size). Hence, the CDCs form a large prepore complex prior to the insertion of the transmembrane β-barrel.

One of the features of all water-soluble, pore-forming toxin monomers secreted by bacteria is the necessity to undergo a structural change upon binding to the membrane in order to initiate oligomerization on the surface. Ramachandran *et al*. (Ramachandran *et al*., 2004) recently identified the structural rearrangement within the PFO monomer structure that is necessary to promote membrane oligomerization. They showed that a loop in D3 (Figure 38.1) blocks the association of monomers by preventing the hydrogen bonding of one β-strand at the edge of the core β-sheet of one D3 (β4) with a β-strand (β1) at the other edge of the D3 core β-sheet of a second monomer. This loop is comprised of a short β-strand (β5) and an α-helix. β5 forms hydrogen bonds with β4 of the D3 β-sheet and effectively blocks the interaction of β4 with β1 of a second monomer. However, when D4 binds to the membrane surface, a conformation change occurs more than 70Å above the surface that moves β5 away from β4 and thereby exposes β4 so that it can associate with β1 of another PFO molecule and initiate (or extend) oligomerization. Since monomers in solution (up to 20 mg/ml) do not associate or aggregate with each other, the short β5 loop acts as a dominant-negative regulator of oligomerization. Only after D4 binding to the membrane elicits a nearly coincident long-range allosteric conformational change far above the membrane can PFO monomers associate. These experiments (Ramachandran *et al*., 2004) also demonstrated that the edge-on interactions of the β1 and β4 strands of the D3 core β-sheet form a major interfacial region between the monomers in the membrane oligomer.

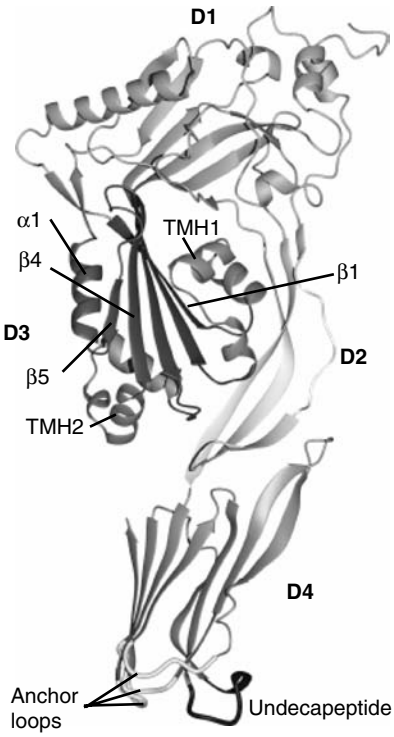

**FIGURE 38.1** The crystal structure of PFO. A ribbon representation of the crystal structure of the soluble monomer of PFO (Rossjohn, 1997) is shown. Shown are short hydrophobic loops of domain 4 (anchor loops) that have been determined to insert into the membrane surface (Ramachandran *et al*., 2002). The undecapeptide is labeled and shown in black. The two α-helical bundles (3 α-helices each) that ultimately form the twin transmembrane β-hairpins are labeled as TMH1 and TMH2 (**T**rans**M**embrane β-**H**airpin 1 and 2) (Shepard *et al*., 1998; Shatursky *et al*., 1999). The loop comprised of β-strand 5 (β5) and a short α-helix (α1) within domain 3 has been shown to block oligomerization of soluble PFO (Ramachandran *et al*., 2004). D1–D4: domains 1–4. The ribbon structure was created using the program MolMol (Koradi *et al*., 1996).

## PREPORE TO PORE CONVERSION

During prepore to pore transition each PFO monomer inserts two TMHs (TMH1 and TMH2, Figure 38.1) per monomer to create the large β-barrel pore (Shepard *et al*., 1998; Shatursky *et al*., 1999). Each β-hairpin is derived from an α-helical bundle in D3 that contains three short α-helices (Figure 38.1). This α-helical to β-strand transition in secondary structure is unique to the CDCs. Upon pore formation, these two α-helical bundles unravel to form the two extended β-hairpins that ultimately cross the membrane. This transition represents a major change in the monomeric structure of PFO as it makes the transition from membrane-bound monomer to a membrane-embedded oligomer. Although the structure of the soluble monomer and the membrane spanning β-hairpins of PFO were determined nearly six years ago, many of the molecular details of this transition have been revealed in only the past few years.

Hotze *et al*. (Hotze *et al*., 2002) first demonstrated that monomer-monomer interactions drive prepore to pore transition. They identified a mutation in PFO,

tyrosine 181 to alanine ($PFO^{Y181A}$) that trapped PFO in a prepore conformation. Yet, sufficient native PFO could force the TMHs of $PFO^{Y181A}$ to insert into the membrane in hybrid oligomers containing both wild-type and mutant PFO. In oligomers comprised of only $PFO^{Y181A}$, or a mixture of $PFO^{Y181A}$ and native PFO in which the concentration of native PFO was insufficient to overcome the barrier to insertion posed by the Y181A mutation, prepore to pore conversion did not occur. Thus, the conformational changes that occur in native monomers within the hybrid oligomer induce $PFO^{Y181A}$ to undergo the conformational change necessary for TMH insertion and pore formation. These data demonstrate that the monomers within the prepore complex act cooperatively to drive insertion of the transmembrane β-barrel into the bilayer.

Interestingly, the Y181A mutation led to the discovery of another important aspect of the prepore to pore conversion. Ramachandran *et al*. (Ramachandran *et al*., 2004) showed that the PFO β-barrel was successfully into the membrane only if tyrosine 181 formed a π-stacking interaction with phenylalanine 318 in β1 of the adjacent monomer. If either residue was substituted with a non-aromatic residue or its location altered by two residues (to position the amino acid side chain on the same side of the β-strand), the oligomer was trapped in the prepore state. A double mutant, in which the positions of Y181 and F318 were shifted to 179 and 320, respectively, maintained the relative alignment of the single aromatic residues in β1 and β4, and hence, the π-stacking interaction. This mutant was cytolytically active, further showing that the interaction of these two aromatic residues is important in aligning the adjacent TMHs and ensuring that all of the TMHs in the oligomer are in proper register prior to insertion. Having such a mechanism to prevent the misalignment of the TMHs is particularly important in a pore-forming complex that contains 35–50 monomers that must coordinately insert up to 100 TMHs into the membrane to form the β-barrel pore.

A central enigma in the mechanism of pore formation has been how the elongated TMHs were able to cross the bilayer from their location above the membrane surface. A previous study by cryoelectron microscopy of the membrane structure of another CDC, pneumolysin (PLY), concluded that the TMHs were approximately 40 Å too far from the membrane surface to successfully span the bilayer (Gilbert *et al*., 1999). However, it was clear from the studies of Shepard *et al*. (Shepard *et al*., 1998) and Shatursky *et al*. (Shatursky *et al*., 1999) that the TMHs of PFO were able to both traverse the bilayer and generate a β-barrel pore. However, Ramachandran *et al*. (Ramachandran *et al*., 2002) then showed that D4 was oriented perpendicular to the membrane. Since this arrangement of D4 more or less would position D3 far above the membrane unless the PFO conformation was altered from that of the soluble monomer, it was clear that additional conformational changes had to accompany pore formation.

Experimental demonstration of the major structural changes that occur during pore formation was reported by Czajkowsky *et al*. (Czajkowsky *et al*., 2004), who used atomic force microscopy (AFM) to examine PFO in the prepore and pore states. They showed that the height of the pore complex is 40 Å less than the height of the prepore complex. Hence, the prepore complex undergoes a 40 Å vertical collapse that brings the TMHs of D3 to the surface of the membrane and allows the TMHs to insert into and span the bilayer. They also showed that the lateral dimensions and topography of the prepore and pore oligomers were nearly identical, suggesting that there was no significant rotational "tipping over" of the monomers that would account for this collapse. Instead, the substantial reduction in the vertical height of the prepore complex is presumably achieved by a collapse of the D2 structure that allows D3 to move to the membrane surface. D2 is primarily comprised of two long β-strands whose structure is intimately associated with that of the D3 α-helical bundles that ultimately form TMH1. The stability of the D2 conformation is therefore very likely to be dependent on its interaction with the D3 α-helical bundles. If the D3 α-helices move away from D2 and undergo their transition to form TMH1 during the prepore to pore transition, the structural integrity of D2 would be compromised. This scenario is consistent with the absence of any significant difference in the topography of the prepore and pore structures in the plane of the membrane and would not require any change in the perpendicular orientation of D4 with the membrane.

The final stage of the pore-forming process is the production of a large membrane pore that is comprised of more than 35 monomers with a diameter of 250–300 Å. One still unknown question about pore formation is whether incomplete oligomeric rings can insert into the membrane and form a pore. Over the past 20 years, both circular oligomeric rings and incomplete rings (arcs) of CDCs have been observed on membranes using electron microscopy (Mitsui *et al*., 1979; Bhakdi *et al*., 1985). Although the size of the minimal pore-forming CDC complex remains ambiguous, it is clear that the prepore complex must reach an appreciable size before it inserts and forms a large pore (Heuck *et al*., 2000; Shepard *et al*., 2000; Hotze *et al*., 2001; Heuck *et al*., 2003). Liposome marker release assays per-

formed at limiting concentrations of PFO and SLO, in which an average of one pore per liposome was formed, showed that the rate of release was virtually identical for markers with substantially different hydrodynamic radii (≈ 10–140 Å) (Heuck *et al*., 2003). Since small molecules encapsulated in liposomes are released with the same kinetics as very large molecules, the holes formed by PFO and SLO do not appear to grow as a function of time. Instead, any hole formed is large enough to release both large and small molecules. Hence, PFO and SLO, and probably all CDCs, do not form small pores in membranes, and any small prepore complexes (i.e., small arcs) are apparently incapable of inserting into the membrane. It has been proposed that CDC molecules can insert individually into the bilayer rather than cooperatively as a complete circular prepore complex, thereby creating an intermediate state in which one side of the proposed hole is formed by exposed lipid, while the other side is formed by a CDC β-sheet in an arc (Palmer *et al*., 1998). While no direct evidence of arc insertion has yet been reported and the preponderance of evidence to date supports a concerted insertion mechanism, it remains unclear whether large, incomplete rings can make a transition from the prepore to pore, or if only complete rings are insertion competent.

## ROLE IN PATHOGENESIS

One of the most remarkable aspects of the CDCs is the size of the pore formed by these toxins in both mammalian cell membranes and also cholesterol-containing liposomes. It has always been somewhat puzzling as to why such a large pore is required if the primary use of these toxins is simple cell lysis. A much smaller pore, comprised of far fewer protein monomers, such as the *Staphylococcus aureus* α-hemolysin, would seem sufficient and would require much less energy to produce. The damaging effects of these toxins in terms of pore formation are easily recognized *in vitro*; however, the *in vivo* role of the CDC pore has been difficult to ascertain. The lysis of cells, particularly erythrocytes, has been a convenient model system for measuring the pore-forming activity of the CDCs. Yet, there has been no direct evidence to date that hemolysis or general cell lysis is a major role of the CDCs in bacterial pathogenesis.

The fact that the CDC pore is large enough to facilitate the passage of very large proteins suggests that the CDC pore can be used by bacterial pathogens in much more sophisticated ways. Madden *et al*. (Madden *et al*., 2001) showed that the SLO pore is used as a protein translocation channel by *Streptococcus pyogenes*. The SLO pore is utilized by *S. pyogenes* to permeabilize the membrane of keratinocytes and translocate a bacterial NAD-glycohydrolase enzyme (Spn) into the eukaryotic cytosol. In essence, the SLO pore acts as a Gram-positive bacterial analog of the Gram-negative bacterial type III secretion system. SLO differs structurally from other CDCs in that it contains about 80 additional amino acids at its amino terminus that are required for this translocation mechanism (Meehl and Caparon, 2004). Therefore, while the basic pore-forming mechanism is maintained, the SLO structure has evolved such that it can function as a protein translocation channel. This study is the first direct demonstration of a functional purpose for a CDC pore by a bacterial pathogen, and it also shows that the CDC structure is sufficiently adaptable that it can be employed to perform different tasks by changes in its structure.

Despite the progress made in understanding the individual steps that define the cytolytic mechanism of PFO, the importance of PFO to the development and progression of *C. perfringens* gas gangrene is less well understood. Both genetic and immunological studies have definitively established that α-toxin and PFO exhibit a synergistic effect in the development of gangrene. However, α-toxin is the primary virulence factor in this disease (Awad *et al*., 1995; Ellemor *et al*., 1999). Surprisingly, even though PFO is highly cytolytic, it does not appear to contribute significantly to the tissue necrosis (Awad *et al*., 1995). Apparently, PFO contributes to the leukostasis that results in the characteristic absence of polymorphonuclear leukocytes (PMNL) from the necrotic tissue in gas gangrene disease (Ellemor *et al*., 1999). More recently, it has been suggested that PFO could play a role in preventing macrophage-mediated clearing of *C. perfringens* (O'Brien and Melville, 2004). PFO appeared to be the primary agent responsible for killing macrophages, and the escape of *C. perfringens* from the macrophage phagosome was the consequence of PFO activity.

*S. intermedius* typically causes liver and brain abscesses, but the role of ILY in disease is not well understood. Due to the human cell specificity of ILY, it is unlikely that an animal model for *S. intermedius* disease will be developed in the near future. Indirectly, it has been shown that treatment of PMNL with ILY enhances the surface expression of the leukocyte integrin CD11b (Macey *et al*., 2001), which is also known as complement receptor 3. Defects in CD11b affect phagocytic cell adhesion and migration to the site of infection. Therefore, the excess of dysfunctional PMNL cells that is typically found in the abscesses of *S. intermedius* (Wanahita *et al*., 2002) might be the result of one or more effects of ILY. Also, ILY production in isolates

from deep-seated infections is 6–10 times higher than in isolates from the normal flora (Nagamune 2000). The ILY receptor human CD59 is up-regulated on the surface of activated PMNL (Gordon *et al*., 1994), and so during abscess formation, *S. intermedius* produces an excess of ILY that can then target a receptor-rich population of PMNL. Whether ILY directly lyses these cells or modifies their function in some way that is advantageous to the bacteria cell remains unknown.

## CONCLUSION

A number of major advances in understanding the CDC mechanism have been made in recent years by the study of the PFO and ILY. These studies have revealed many new paradigms for the CDC pore-forming mechanism and at the same time have changed our perspectives on long-held dogma. These and other studies have also shown that while the basic pore-forming mechanism is likely the same for the CDCs, their structures exhibit a plasticity that enables them to adapt and facilitate the pathogenic mechanism of the bacterial pathogen. In the future, the continued study of the CDC mechanism will reveal additional insights into the fundamental process of pore formation. It is also likely that more attention will now be focused on the structural plasticity of the CDCs that allows them to be customized for a specific purpose by the bacterial pathogen and how these pathogens use the toxins during disease development.

CHAPTER

# 39

# Pneumolysin: structure, function, and role in disease

*Tim J. Mitchell*

## INTRODUCTION

Pneumolysin (PLY) is a hemolytic protein toxin produced by *Streptococcus pneumoniae* (the pneumococcus). The pneumococcus causes several important diseases of man including pneumonia, bacteraemia, meningitis, and otitis media. Infections with *S. pneumoniae* continue to have significant medical impact throughout the world (Ortqvist, 2001). The organism produces several potential virulence factors, including a polysaccharide capsule, a range of enzymes (hyaluronidase, neuraminidases, and superoxide dismutase), surface proteins (PspA and PsaA), and at least two hemolysins (Paton *et al*., 1993a; Canvin *et al*., 1997). There have also been three screens of the pneumococcal genome for virulence factors using signature-tagged mutagenesis (Polissi *et al*., 1998; Lau *et al*., 2001; Hava and Camilli, 2002), which identified hundreds of genes involved in its ability to survive in the murine host. Several virulence factors have been investigated with regard to their role in the pathogenesis of pneumococcal infection, and some can be considered as possible antigens for use in protective vaccination. There is obviously an interaction between virulence factors, and it has been demonstrated that there is an additive attenuation of the pneumococcus by the mutation of genes for PLY and other virulence factors (Berry and Paton, 2000). Many studies show that one of the key virulence factors produced by the pneumococcus is the pore-forming toxin PLY. This chapter will concentrate on PLY and will consider its mode of action, role in the disease process, and possible role in pneumococcal vaccines.

## HISTORICAL

Pneumococci were first reported to produce a hemolysin in 1905 (Libman, 1905). Since this report, numerous studies have been carried out using crude preparations of the toxin (Cohen *et al*., 1942; Cohen *et al*., 1940; Cole, 1914; Halbert *et al*., 1946; Neill, 1926; Neill, 1927), which demonstrated that the protein was toxic, susceptible to oxidation (a process that could be reversed by treatment with thiol-reducing agents), antigenic, and irreversibly inactivated by cholesterol. The sensitivity of the toxin to oxidation and reactivation with thiol-reducing agents led to the toxin being named "a thiol-activated toxin," a name that is now considered to be inappropriate. I will refer to this family as the "cholesterol-dependent cytolysins," or CDC. This family of proteins are produced by five genera of Gram-positive bacteria (Table 39.1). Recent advances in molecular biology and protein purification have now allowed large amounts of highly purified PLY to be produced and evaluated in a range of biological systems both *in vitro* and *in vivo*.

## STRUCTURE AND FUNCTION STUDIES OF PLY

### Mechanism of lytic action—the dogma

PLY is a lytic toxin able to lyse all cells that have cholesterol in their membranes. The mechanism of action of the members of this group of toxins are believed to be similar and has been reviewed (Morgan *et al*., 1996;

**TABLE 39.1** Cholesterol-dependent cytolysins and their primary amino acid sequence identity with PLY

| Organism | Toxin | % Identity with PLY amino acid sequence |
|---|---|---|
| **Streptococcus pneumoniae** | Pneumolysin | - |
| *Arcanbacterium pyogenes* | Pyolysin | 40 |
| *Bacillus alvei* | Alveolysin | 41 |
| *Bacillus anthracis* | Anthrolysin | 41 |
| *Bacillus cereus* | Cereolysin | 41 |
| *Clostridium perfringens* | Perfringolysin O | 45 |
| *Clostridium tetani* | Tetanolysin | 44 |
| *Listeria ivanovii* | Ivanolysin | 43 |
| *Listeria monocytogenes* | Listeriolysin O | 43 |
| *Listeria seelegeri* | Seeligerolysin | 43 |
| *Streptococcus intermedius* | Intermedilysin | 53 |
| *Streptococcus pyogenes* | Streptolysin O | 41 |
| *Streptococcus suis* | Suilysin | 50 |

Smyth and Duncan, 1978). Two of the major steps in the lytic process are membrane binding and oligomerization of the toxin to form pores. These two steps show differences in their temperature dependency. The binding of the toxin to cells is temperature independent, while oligomerization only occurs at higher temperatures. The lytic activity of the toxin can be inhibited by pre-incubation with cholesterol. This has led to the suggestion that membrane cholesterol is the receptor for this toxin. Once bound to the cell membrane, the toxin undergoes oligomerization to give high molecular weight pore-like structures composed of up to 50 monomeric units (Morgan *et al*., 1994). The exact mechanism of pore formation is still debated. Some studies suggest that these toxins can insert into the membrane and form pores by lateral diffusion (Palmer *et al*., 1998), while others suggest that the formation of a "pre-pore" is necessary prior to insertion into the membrane (Czajkowsky *et al*., 2004). Whatever the mechanism of insertion, these pores are believed to mediate the lysis of the cells by osmotic mechanisms. Inhibition of the lytic process by cholesterol is assumed to represent occupancy of the cholesterol binding site by free cholesterol preventing binding of the toxin to target cell membranes. However, studies with the related protein listeriolysin O suggest that inhibition of toxin action by cholesterol may not be due to a blockage of binding but to interference with the oligomerization process (Jacobs *et al*., 1998). More recently, similar experiments with PLY have shown that inhibition of the toxin with cholesterol does not prevent interaction with cells as measured by the PLY-induced production of gamma interferon (Baba *et al*., 2002). Also, it has been shown that for several members of this toxin family, depletion of membrane cholesterol traps the toxin in the prepore complex, suggesting that cholesterol is required for membrane insertion rather than binding (Giddings *et al*., 2003). The recent identification of CD59 as a protein receptor for intermidilysin (Giddings *et al*., 2004) also adds to the case that cholesterol may not serve as the primary receptor for all these toxins. Whether the contribution of cholesterol to the activity of PLY is solely as a receptor still remains to be determined.

## Analysis and modification of the primary amino acid sequence of PLY

PLY consists of a single 53kDa polypeptide chain and is produced by virtually all clinical isolates of the pneumococcus (Kanclerski and Mollby, 1987; Paton *et al*., 1983). PLY is the only member of this family of proteins that is not secreted from the cell but remains within the bacterial cytoplasm (Johnson, 1977). It has been shown, however, that some strains of the pneumococcus may be capable of active secretion of the toxin. Strain WU2 was shown to able to release PLY in the absence of autolytic activity (Balachandran *et al*., 2001).

The genes encoding PLY from serotype 1 and serotype 2 pneumococci have been cloned, sequenced, and expressed in *Escherichia coli* (Mitchell *et al*., 1989; Paton *et al*., 1986; Walker *et al*., 1987). Genes for PLY have also been cloned from several other serotypes, including from the genome sequence of a type 4 pneumococcus (Tettelin *et al*., 2001). Comparison of the derived amino acid sequences of these proteins shows a very high level of conservation with only a single amino acid change in the type 1 or type 4 sequence when compared to the type 2 sequence. Alignment of the amino acid sequence of PLY with the other members of the family shows there is a high degree of

similarity between the proteins (Table 39.1). Analysis of the primary amino acid sequence of PLY shows no major areas of hydrophobicity that could be involved in membrane insertion. The hydrophobic nature of PLY (Johnson *et al*., 1982) must therefore reflect the generation of hydrophobic areas during the folding of the primary sequence. In agreement with the cytoplasmic location of the toxin, the predicted amino acid sequence does not contain a signal sequence for secretion.

As PLY is thiol-activated, it was thought for many years that the activation process involved the reduction of an intramolecular disulphide bond (Smyth and Duncan, 1978). However, the primary amino acid sequence shows that PLY contains only a single cysteine residue. This residue lies at the C-terminal end of the molecule (amino acid position 428) in a region of 11 amino acids that is conserved among many of the family of toxins (Morgan *et al*., 1996). This conserved sequence (ECTGLAWEWWR) plays an important role in the activity of the toxin, as judged by studies using site-directed mutagenesis. Interestingly, the cysteine residue is not essential for activity and can be replaced with alanine with no effect on the lytic activity of the toxin *in vitro* (Saunders *et al*., 1989). However, the nature of the residue at this position is important, as substitution with glycine or serine results in a reduction in the activity of the toxin. Substitutions in other residues within the motif also affect the activity of the toxin, with changes in the tryptophan at position 433 having a dramatic effect. Attempts to define the nature of the defect in the mutants with reduced activity have been unsuccessful and have only determined that the effect is not due to a gross defect in the ability of the toxins to bind to cells or oligomerize (Saunders *et al*., 1989). It seems that the cysteine motif may play an important part in mediating a conformational change in the toxin when it interacts with membranes and allows the insertion of the toxin into the lipid bilayer.

Naturally occurring mutations in the amino acid sequence of PLY can also be informative. PLY derived from some serotype 8 pneumococci contains several alterations in amino acid sequence compared to the protein from other serotypes (Lock *et al*., 1996). The type 8 protein has substitutions at positions 172, 224, and 265 and has a two amino acid deletion (residues 270–271). Interestingly, these changes make the protein run with an apparent molecular weight on SDS-PAGE, which is greater than that from other more typical strains of the pneumococcus (Lock *et al*., 1996). Construction of chimeric molecules between the type 8 and the type 2 proteins demonstrated that it is the substitution at position 172 (threonine to isoleucine) that is responsible for the decreased activity of this version of the protein (Lock *et al*., 1996).

The mechanism by which PLY binds to cells is still unclear. The evidence that cholesterol is the receptor for the toxin is based on studies of the inhibition of toxin activity by prior incubation of the toxin with cholesterol in solution. The finding that the related toxin listeriolysin O is inactivated by cholesterol but is still able to bind to cells suggests that binding of these toxins to cells may involve a receptor other than cholesterol (Jacobs *et al*., 1998). Interaction with cholesterol may play a role in the assembly of the functional oligomer (Giddings *et al*., 2003). The region of the PLY molecule involved in cell binding has been inferred from studies using truncated versions of the protein (Owen *et al*., 1994). Removal of the five C-terminal amino acids of the toxin was sufficient to prevent cell lysis by the protein. A substitution of the proline residue at position 462 with serine causes a 90% reduction in the ability of the toxin to bind to red blood cells.

Studies with monoclonal antibodies have also been used to investigate the functional regions of PLY (de los Toyos *et al*., 1996). A panel of monoclonal antibodies was raised against PLY, all of which recognized linear epitopes of the protein. Three of these antibodies (termed PLY-4, PLY-5, and PLY-7) were capable of inhibiting the hemolytic activity of the toxin. One of the neutralizing antibodies (PLY-4) did not prevent binding of the toxin to cells, but did prevent the subsequent oligomerization of the toxin to form pores (as determined by electron microscopy), while the other two (PLY-5 and PLY-7) prevented cell binding by the toxin. Proteolytic treatment of PLY with proteinase K generates two fragments of 37kDa and 15kDa (Morgan *et al*., 1997). Purification and characterization of these fragments showed that the 15kDa fragment represented an N-terminal portion of the protein (K1), while the 37kDa fragment contained the remaining C-terminal part of the protein. The site of cleavage as determined by amino acid sequencing was between amino acids 142 and 143 (Morgan *et al*., 1997). Isolated K2 was still able to bind to liposomes and to form oligomer-like structures. Antibodies PLY-5 and PLY-7 both recognized the K2 portion of the protein, whereas PLY-4 recognized neither fragment. PLY-4 therefore recognizes at or near to the proteolytic cleavage site and prevents oligomerization. More recent studies have suggested that PLY-4 recognizes a conformational epitope, which includes the arginine residue at position 232 (Suarez-Alvarez *et al*., 2003). Further analysis of the binding site for PLY-5 using peptide mapping demonstrated that it recognizes the conserved undecapeptide region and prevents binding of the toxin to cells (Jacobs *et al*., 1999). PLY-7 recognizes residues 401–407 (Suarez-

Alvarez *et al*., 2003). The findings with monoclonal antibodies support the findings using truncated PLY that the C-terminus of the molecule is involved in cell binding. These findings are further supported by the observation that the purified C-terminal domain of PLY (amino acid residues 360–471) can still bind to cells (Baba *et al*., 2001).

The mechanism of pore formation by PLY is also still unclear. A recent paper by Czajkowsky *et al.* (2004) described the pre-pore to pore transition process. Site-directed mutations can be made in the conserved cysteine-containing region that have a dramatic effect on the lytic activity of the toxin, but no effect on the ability of the toxin to generate oligomers as observed by electron microscopy. In attempts to define the differences in the nature of the pore formed by wild-type PLY and a lytic-deficient mutant in which the tryptophan at position 433 has been replaced with phenylalanine (F433), the proteins have been studied in their effects on cells and on planar lipid bilayers (Korchev *et al*., 1998). The mutation at position 433 has no effect on the ability of the toxin to bind to cells or to form oligomeric structures as observed by electron microscopy. The mutation does affect the ability of the toxin to induce leakage of markers from Lettre cells and to induce conductance channels in planar lipid bilayers. PLY-induced leakage from Lettre cells is sensitive to inhibition by bivalent cations. The sensitivity to inhibition by bivalent cations was much reduced in the mutant form of the toxin. When inserted into planar lipid bilayers, PLY induces a range of conductance channels exhibiting small (less than 30pS), medium (30pS–1nS), and large (greater than 1nS) conductance steps. Small and medium channels are preferentially closed by bivalent cations. Wild-type toxin forms mainly small channels, whereas the mutant formed mostly large channels, which are insensitive to closure by divalent cations. Osmotic protection studies show that cells treated with wild-type toxin can be protected from lysis by polysaccharides with a molecular mass of more than 15kDa, whereas cells treated with the mutant form of the toxin were not protected with by polysaccharides with molecular mass over 40kDa. This also suggests that the functional pores are larger in the membranes treated with the F433 mutant. The cysteine motif therefore probably plays a role in the functionality of the pores generated by PLY. As no differences in the structure of the pores were observed by electron microscopy, the structural appearance of the pores does not reflect the functional state of the channels.

Purified PLY is also able to activate the classical complement pathway (Paton *et al*., 1984), and this effect has been linked to the ability of the toxin to bind to the Fc portion of human immunoglobulin (Mitchell *et al*., 1991). Analysis of the amino acid sequence of PLY showed it did not contain any homology to known IgG binding proteins, but did show some limited homology to the human acute phase protein C-reactive protein (CRP) (Mitchell *et al*., 1991). CRP is also able to activate the classical complement pathway, although this effect is mediated by a direct binding of complement component C1q (Volanakis and Kaplan, 1974). Mutagenesis of the homologous region in PLY revealed that residues 384 and 385 are involved in antibody binding and complement activation by the toxin (Mitchell *et al*., 1991). Subsequent analysis of a structural model of PLY based on the x-ray crystal structure of perfringolysin (Figure 39.1) (Rossjohn *et al*., 1998) showed there is no structural homology between the region of PLY and CRP. There is, however, a structural similarity between domain 4 of PLY and the Fc portion of antibody. As complement activation via the classical pathway is dependent on C1q binding to multimers of Fc, it is possible to suggest several mechanisms by which activation could occur. Aggregates of PLY could act to bind C1q in a similar manner to native Fc. Alternatively, the toxin may form mixed aggregates with immunoglobulins and activate complement. Certainly, the ability of the toxin to activate complement seems to be linked to its ability to interact with antibody (Mitchell *et al*., 1991). However, if PLY itself has structural similarities to immunoglobulin, it is possible that the original experiments measuring antibody binding are flawed. The molecular mechanism of complement activation by PLY requires further study.

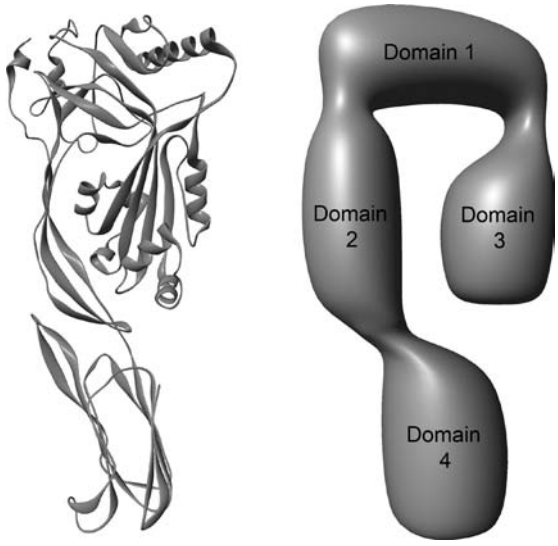

**FIGURE 39.1** Structural model of pneumolysin based on the crystal structure of perfringolysin (generated as described by Rossjohn *et al*. (Rossjohn *et al*., 1998)). Schematic illustrates the four domains of the protein. Figure generated by Graeme Cowan, University of Glasgow.

The studies described above allowed the generation of mutant versions of the PLY gene and proteins that have been instrumental in defining the roles of the various activities of the toxin during infection.

## BIOLOGICAL EFFECTS OF PLY

The biological effects of PLY are summarized in Table 39.2. PLY has been studied in a range of systems in attempts to define those properties that are important in the pathogenesis of infection. These systems include the study of the interaction of the purified protein with isolated cells, with organ cultures, and with whole animals. It is clear from the studies discussed below that the response of different cells and tissue to PLY can vary significantly. For example, the sensitivity of human monocytes and epithelial cells to PLY are different, and this difference may be affected by the activation status of the cells (Hirst *et al*., 2002).

The use of molecular genetic approaches has also allowed the role of the toxin to be addressed within the context of the whole organism via the construction of isogenic mutants that either do not express the protein or express a version that has an activity altered by modification of the toxin gene. These approaches have allowed detailed models to be built up of the role played by PLY in a range of experimental infections.

### Inflammatory properties of PLY

The effects of PLY on mouse macrophages appear to involve an interaction with Toll-like receptor 4 (TLR4) (Malley *et al*., 2003). Malley and co-workers (Malley *et al*., 2003) showed that the stimulation of macrophages to produce TNFα and IL-6 is dependent on the cytoplasmic TLR-adaptor molecule myeloid differentiation factor 88 (MyD88), and macrophages from mice with the targeted deletion of MyD88 did not respond to PLY. Purified PLY has a synergistic interaction with pneumococcal cell walls, which mediate inflammatory action via TLR2 (Yoshimura *et al*., 1999). Furthermore, when compared with wild-type macrophages, macrophages from mice carrying a spontaneous mutation in TLR4 were less responsive to both PLY alone and PLY in conjunction with pneumococcal cell wall. Interstingly, TLR4 mutant mice were more susceptible to lethal infection after intranasal colonization with pneumococci than were control mice. These findings show that interaction of PLY with the innate immune system via TLR-4 protects colonized animals from disease and suggests that inappropriate interaction with TLR4 could be responsible for some of the pathology seen in pneumococcal diseases such as pneumonia and meningitis.

Very low, sub-lytic concentrations of PLY can have dramatic biological effects on cells. The toxin has been shown to affect the production of pro-inflammatory mediators such as TNF-α, IL-1β, and IL-6

**TABLE 39.2** Selected biological activities of pneumolysin

(Houldsworth *et al*., 1994) and stimulate nitric oxide (NO) production from macrophages, as well as increased transcription of the genes for COX-2 (Braun *et al*., 1999). COX-2 is the induced, rate-limiting enzyme involved in prostaglandin synthesis. The pathway by which PLY activates mouse macrophages is dependent on IFN-γ, as macrophages with a genetically inactivated IFN-γ signaling pathway are unable to produce NO in response to the toxin (Braun *et al*., 1999). PLY may have the ability to act as a general activator of macrophages, possibly through activation of NF-κB (Braun *et al*., 1999).

PLY can activate phospholipase A in pulmonary epithelial cells (Rubins *et al*., 1994). The activated phospholipase has a broad substrate specificity for cellular membrane phospholipids. Activation of phospholipase during an infection could contribute directly to lung damage by the release of free fatty acids and lysophophosphatides. Release of arachidonic acid by the activated phospholipase could promote chemotaxis and respiratory burst of neutrophils (Badwey *et al*., 1984; Curnutte *et al*., 1984). Arachidonic acid could also be metabolized through the eicosanoid pathway, leading to the production of leukotrienes and platelet activating precursor (Holtzman, 1991). Products of the eicosanoid pathway are also major chemotaxins for neutrophils (Cabellos *et al*., 1992).

The toxin interacts with neutrophils to cause increased production of superoxide, increased production of elastase, increased expression of $\beta_2$ integrins, and increased production of protaglandin $E_2$ and leukotriene $B_4$ (Cockeran *et al*., 2001a; Cockeran *et al*., 2001b). The toxin is therefore extremely pro-inflammatory. Cell recruitment may also be affected by PLY, as it has been shown to stimulate the production of IL-8 from human neutrophils (Cockeran *et al*., 2002). Thus, PLY has the potential to cause increased recruitment of inflammatory cells and increased production of pro-inflammatory mediators from these cells. The toxin has also been shown to potentiate the oxidative inactivation of alpha-1 proteinase inhibitor by activated neutrophils (Cockeran *et al*., 2004), which could lead to increased proteolytic activity in the lung and promote pneumococcal invasion. Activation of inflammatory pathways explains the ability of the toxin to induce pneumonitis similar to that induced by the whole organism (Feldman *et al*., 1991a). It seems somewhat of a paradox that the organism contributes to its own demise by producing this toxin and inducing inflammation. However, it may be that the inflammation induced is not effective in actually clearing the organism, as the toxin has also been shown to reduce killing of pneumococci by neutrophils *in vitro* (Paton and Ferrante, 1983). It might also be that inappropriate recruitment and activation of inflammatory cells by PLY contributes to pathology. However, recent studies using intratracheal administration of PLY to mice showed that the pneumotoxic effects observed were due to a direct effect of the toxin and not to resident or recruited phagocytic cells (Maus *et al*., 2004).

Recently, it has been suggested that pneumococci can induce the migration of CD4 T-cells *in vitro*. The migration induced by pneumococci grown *in vivo* was found to be greater than that by *in vitro* grown organisms. PLY is involved in the induction of the migration of CD4 T-cells, as PLN-A was unable to induce the effect (Kadioglu *et al*., 2004).

The effect of PLY on host gene expression has been examined using microarrays to compare the effect of wild-type pneumococci with PLY organisms on THP-1 mononulear cells (Rogers *et al*., 2003). Genes found to be up-regulated in response to WT but not PLY organisms include mannose-binding lectin 1, lysozyme, α-1 catenin, cadherin 17, caspases 4 and 6, macrophage inflammatory protein 1β (MIP-1β), interleukin 8 monocyte chemotactic protein 3 (MCP-3), IL-2 receptor β (IL-2Rβ), IL-15 receptor α (IL-15Rα), interferon receptor 2, and prosaglandin E synthase. Down-regulated genes include those for complement receptor 2/CD21, platelet-activating factor acetylhydrolase, and oxidized low-density lipoprotein receptor 1 (OLR1). These genes include representatives of functional genes involved in the anti-pathogen response, cell adhesion, cell cycle control, apoptosis, cell/cell signaling, lipid metabolism, protein degradation and folding, protein translocation, and signal transduction. PLY therefore has a dramatic effect on mononuclear cell function, some of which overlaps with known effects of the toxin (stimulation of IL-8 production, for example). The significance of most of these changes to the disease process remains to be determined.

## The role of PLY in apoptosis

*S.pneumoniae* has been reported to induce apoptosis in a number of cell types, including neutrophils, macrophages, and neuronal cells (Zysk *et al*., 2000; Dockrell *et al*., 2001; Braun *et al*., 2002; Stringaris *et al*., 2002). The contribution of PLY to the apoptotic process has been investigated. Zysk *et al*. (Zysk *et al*., 2000) report that PLY is responsible for mainly necrosis in human neutrophils and that apoptosis is induced by heat-killed bacteria. Dockrell *et al*. (Dockrell *et al*., 2001) used a PLY-negative mutant of the pneumococcus to show that apoptosis of macrophages infected with pneumococci was reduced in the absence of PLY. It has also been shown that macrophage apoptosis is mediated by nitric oxide and that this process is

induced by PLY to a greater extent by internalization of toxin-expressing bacteria than by exogenous toxin (Marriott *et al*., 2004). Apoptosis induced by PLY may be cell specific, as apotosis induced by the pneumococcus in lung epithelial cells is independent of the toxin (Schmeck *et al*., 2004).

As *S. pneumoniae* is a major cause of meningitis, a crucial interaction is between the organism and the blood-brain barrier (BBB). Using endothelial cells of cerebral origin as a model of the BBB, it has been shown that the majority of the damage inflicted on these cells is caused by PLY (Zysk *et al*., 2001). The damage induced by the toxin was dependent on protein synthesis, tyrosine phosphorylation, and caspase activity (Zysk *et al*., 2001).

The most detailed studies of the role of PLY in apoptosis have been done using neuronal tissues. Braun *et al*. (Braun *et al*., 2002) report that PLY can induce an apoptosis-inducing factor-dependent (AIF-dependent) form of apoptosis. Using a combination of bacterial mutants, it was shown that both PLY and hydrogen peroxide are responsible for the apoptosis of human microglial cells induced by *S. pneumoniae*. Ultrastructural analysis of human microglial cells showed that blocking the activity of PLY and hydrogen peroxide reduced the mitochondrial damage caused by the pneumococcus. The effects of the whole pneumococcus on microglial cells could be reproduced by addition of purified PLY, and the effect was dependent on the pore-forming activity of the toxin. PLY induces the increase of intracellular calcium levels and triggers the release of AIF from mitochondria in primary rat neurones. Pretreatment of microglial cells with the intra- and extra-cellular calcium chelator BAPTA-AM [1,2-bis (o-aminophenoxy) ethane N,N,N′,N′-tetraacetic acid tetra(acetomethoxyl)ester] blocked the release of AIF induced by PLY, suggesting that this event is mediated by increases in intracellular calcium levels. Finally, it was shown that PLY contributes to the neuronal damage in a rabbit model of pneumococcal meningitis.

An effect of PLY on calcium levels has also been demonstrated in neuroblastoma cells, where purified PLY was shown to induce apoptosis in a calcium-dependent manner (Stringaris *et al*., 2002). The changes in calcium levels were due to pore formation by the toxin, rather than opening of voltage-gated $Ca^{2+}$ channels. This study also showed that mitogen-activated protein kinase (MAPK) p38 was important in PLY-induced cell death.

## Interaction of PLY with animal tissue

Purified PLY has been evaluated for its effects on a range of tissues. When introduced into a ligated lobe of rat lung, the toxin induces histological features that are very similar to those observed in pneumonia (Feldman *et al*., 1991b). Intranasal inoculation of PLY into mice was associated with a dose-dependent influx of neutrophils, increased levels of interleukin-6, macrophage inflammatory protein-2, and KC into brochoalveolar lavage fluid (Rijneveld *et al*., 2002). When altered forms of the toxin are used, which have decreased lytic or complement-activating activity, the histological changes observed are much less than those induced by the wild-type toxin. This is an *in vivo* indication that the ability of PLY to lyse cells and to activate the complement pathway contributes to the pathogenesis of the inflammatory disease observed in the lung.

The effects of PLY on human respiratory mucosa have been investigated in an organ culture model. The toxin causes a slowing of the cilial beat of human nasal epithelium and at higher concentrations disrupts the integrity of the tissue (Feldman *et al*., 1990). This effect may be important in compromising the physical barrier of the mucocilary escalator during the development of an infection. PLY increases the alveolar permeability of perfused rat lungs and is toxic to type II rat alveolar epithelial cells (Rubins *et al*., 1993). The alveolar capillary barrier is essential in alveolar water and solute transport and may also provide a physical barrier to infection. Perturbation of this barrier by the toxin may play an important role in the development of pneumococcal pneumonia.

As well as causing pneumonia, the pneumococcus can also cause meningitis. A common complication of pneumococcal meningitis is hearing loss (Fortnum, 1992). The role of PLY in hearing loss has been investigated by direct perfusion of the toxin through the guinea pig cochlea. When the toxin was perfused through the scala tympani, widespread histological and electrophysiological damage was induced (Comis *et al*., 1993). Electrophysiological changes included reduced amplitude of both the compound action potential and the cochlear microphonic potential. These studies have recently been extended to show that the toxin has a preferential toxicity towards the inner hair cells of the cochlea (Skinner *et al*., 2004). Histological damage observed by scanning electron microscopy (Comis *et al*., 1993) includes damage to both inner and outer hair cells and supporting cells. Inner hair cells and outer hair cells of row three were most susceptible to the toxin. Damage to hair cells includes disruption and splaying of stereocilia, loss of stereocilia, and complete dissolution of hair bundles. The effects seen were dependent on the toxin concentration used, and at lower concentrations, the effects were reversible. The toxic effects of PLY on the guinea pig cochlea may be mediated, at least in part, by NO

(Amee *et al*., 1995). Pretreatment of the cochlea with $N^G$-methyl-L-arginine, a known inhibitor of NO synthesis, blocked the effect of the toxin. Also, pretreatment of the cochlea with MK-801, a N-methyl-D-aspartate (NMDA) receptor antagonist, also confers protection against PLY. This latter finding is consistent with the idea that excessive stimulation of NMDA receptors within the cochlea is responsible for the production of NO. The role of PLY in hearing loss has also been confirmed in an infection model of meningitis, and this will be discussed below. PLY may also perturb the membrane of the round window during pneumococcal otitis media and allow access of the toxin from the middle ear to the cochlea (Engel *et al*., 1995).

PLY has dramatic effects on the ciliated ependymal cells from the brains of rats. Brain cilia were more sensitive to the toxin than respiratory cilia and as little as 100ng/ml of toxin caused cilial stasis within 15 min (Mohammed *et al*., 1999). This concentration of toxin had no effect on respiratory cilia (Feldman *et al*., 1990). Ciliated cells line the ventricular surface of the brain and cerebral aqueducts and form a barrier between the CSF, which is infected during meningitis, and the brain tissue (Alfzelius, 1979). These cilia may protect the neuronal tissue from damage during infection by allowing continual movement of CSF and preventing migration of bacteria during meningitis. Perturbation of brain cilia by PLY could therefore compromise this defense mechanism. Use of both wild-type and PLY-deficient pneumococci in this system also caused ciliary slowing. However, treatment of wild-type but not PLY-deficient bacteria with penicillin increased the amount of ciliary slowing induced. The effect of antibiotic was blocked by anti-PLY antibodies. These studies show that antibiotic-induced lysis of pneumococci could have a detrimental effect in the brain and that antibodies to PLY may have therapeutic potential (Hirst *et al*., 2004).

The role of PLY in ocular infections has also been investigated. When the purified toxin is instilled into the eye of a rabbit, inflammatory response is generated (Johnson and Allen, 1975). The toxin induced similar pathology to that caused by natural infections with *S. pneumoniae*. If rabbits were made neutropenic prior to challenge with the toxin, the pathology induced was reduced, indicating that leukocytes may be a source of tissue-damaging enzymes such as collagenase (Harrison *et al*., 1993). The role of PLY in ocular infections has been confirmed in a rat model of endopthalmitis (Ng *et al*., 1997). In this study, purified PLY was injected intravitreally and induced many of the clinical and histopathologic features of pneumococcal endopthalmitis. The toxin therefore plays an important role in the inflammation and tissue damage that occurs in pneumococcal endopthalmitis. The role of PLY in ocular infection has also been investigated using infection models with genetically modified pneumococci. These studies will be considered below.

Purified PLY has been shown to affect a variety of cells and tissues. Major effects include compromise of host defence mechanisms and production of a potent inflammatory response. However, extrapolation from studies with a purified virulence factor to the role played by this virulence factor in the pathogenesis of an infection is not always valid. The generation of defined isogenic mutants of the pneumococcus that either do not produce the toxin or synthesize versions of the protein with altered biological activity allows the role played by the toxin in the pathogenesis of disease to be investigated in animal models of the diseases caused by *S. pneumoniae*.

## THE ROLE OF PLY IN PATHOGENESIS

### PLY-negative mutant

Although the existence of a toxin produced by the pneumococcus has been known for more than 90 years, it was not until the studies in James Paton's laboratory in the 1980s and early 1990s that it was shown that the toxin played an important role in the virulence of *S. pneumoniae*. The Paton group showed that immunization with a partially inactivated form of PLY could partially protect mice from challenge with virulent pneumococci (Paton *et al*., 1983). These studies formed the basis of a continuing evaluation of PLY toxoids as vaccine candidates (see below). The cloning and sequencing of the gene for PLY (Paton *et al*., 1986; Walker *et al*., 1987) allowed the construction of isogenic PLY-negative mutants of serotype 2 and serotype 3 pneumococci (Berry *et al*., 1989; Berry *et al*., 1992). In the case of serotype 2 pneumococci, the virulence of the organism was reduced by 100-fold when given intranasally to mice (Berry *et al*., 1989). When injected intravenously into mice, the PLY-negative mutant survived less well (Berry *et al*., 1989). The serotype 2 PLY-negative mutant was designated PLN-A, and this mutant has been key in studies of the role of PLY in the pathogenesis of disease in laboratories around the world.

The role of PLY in colonization of the nasopharynx appears to be strain- (or serotype-) dependent. PLY-sufficient pneumococci were able to colonize successfully and infect the nasophrynx, whereas PLY-deficient PLN-A was less able to colonize and tended to be cleared (Kadioglu *et al*., 2002). Differences in the contribution of PLY to colonization were observed when the

capsular serotype of the organism was changed (Kadioglu *et al*., 2002). This may explain other reports in the literature that suggest PLY plays no role in colonization (Rubins *et al*., 1998).

PLN-A has been used to define the role played by PLY in a mouse model of bronchopneumonia (Canvin *et al*., 1995). PLN-A induced much less inflammation when instilled into the mouse lung. Comparative histology of the inflammation induced by wild-type and pneumolysin-negative pneumococci is shown in Figure 39.2. This was an intriguing finding, as it had long been stated that the inflammation induced by pneumococci was a result of the release of inflammatory cell wall components (Tuomanen *et al*., 1987). Studies with PLN-A suggest that most of the inflammation is induced by the toxin. During pneumonia induced by the pneumococcus, there is a sequential influx of inflammatory cells into the lung (Kadioglu *et al*., 2000). In the absence of PLY, the inflammatory influx is delayed and less intense. The presence of PLY increases the rate of influx of neutrophils (Kadioglu *et al*., 2000). The toxin-negative mutant also showed a reduced ability to replicate in the lung. Invasion from the lung into the bloodstream was also delayed in the infection with PLN-A. In a recent study, the distribution of pneumococci in infected mice was monitored in real time using bioluminescent imaging (Orihuela *et al*., 2004). This study showed the contribution of various pneumococcal virulence factors to pathogenesis in whole animals to be tissue specific and that PLY is important after colonization in the growth of the pneumococcus in the lung and subsequent translocation to the bloodstream. Once in the bloodstream, PLY was required for high titer replication (Orihuela *et al*., 2004).

PLN-A has also been compared to wild-type pneumococci in a bacteremia model (Benton *et al*., 1995). These workers showed that PLY protected the pneumococcus from infection-induced host resistance. The wild-type parent organism exhibited exponential growth after intravenous injection until numbers reached as high as $10^{10}$ colony-forming units (CFU) per ml of blood when the animals died. When PLN-A was used, the initial growth rate was the same as wild-type until numbers of approximately $10^7$ CFU/ml were reached, when the increase in CFU/ml ceased, and the numbers of organisms in the blood remained constant for several days. If PLN-A was co-injected with wild-type organisms, it demonstrated wild-type growth characteristics. This observation suggests that PLY exerts its effect at a distance. In mice infected with PLN-A, there was evidence of an inflammatory response, including a rise in plasma levels of IL-6, a cessation of the net growth of PLN-A, and a control of the net growth of wild-type pneumococci, if given as a subsequent challenge. These data suggest that PLY allows the pneumococcus to cause acute sepsis rather than a chronic bacteremia. This effect seems to be limited to early times in the infection and once chronic bacteremia is established, PLY can no longer act as a virulence factor. Mice actively infected with wild-type pneumococcus produced more IL-6 per CFU in plasma than mice infected with comparable levels of PLN-A, suggesting that the increased resistance in PLN-A–infected mice is not mediated by IL-6 (Benton *et al*., 1995). Gamma interferon was only detected in mice

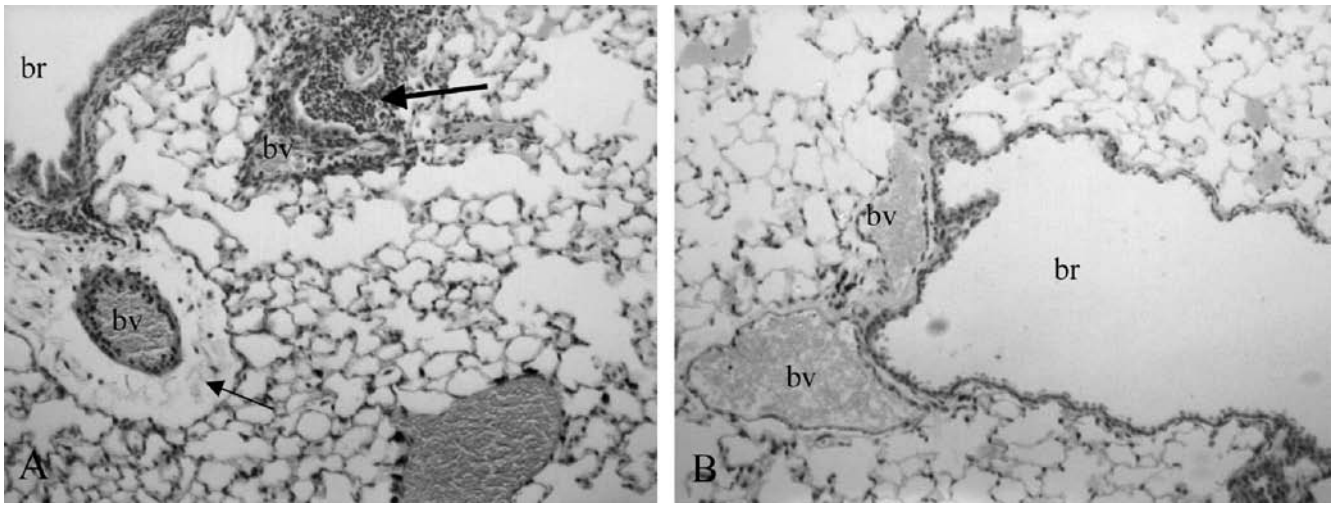

**FIGURE 39.2** Histology of lung 24 hours post-infection with (A) wild-type pneumococci and (B) pneumolysin-negative pneumococci. br: bronchioles, bv: blood vessels, large arrow: cell influx, small arrow: oedema. Figure generated by Alison Kerr, University of Glasgow.

infected with wild organisms that were near death from sepsis, suggesting this cytokine does not mediate the resistance. As PLY has been shown to mediate the production of tumor necrosis factor alpha (TNF-α) (Houldsworth *et al*., 1994), a study was undertaken to investigate the role of pro-inflammatory cytokines in the resistance to pneumococcal infection (Benton *et al*., 1998). These studies showed that the host resistance developed early during infection with PLN-A is dependent on TNF-α, but is independent of interleukin-1β or IL-6. The ability to cause acute sepsis in this model is therefore related to the ability to produce PLY. An inability to produce PLY is associated with chronic bacteremia and development of resistance to wild-type bacteria. This resistance is mediated by the production of TNF-α. The importance of the ability of PLY to stimulate TNF-α production is unclear in this model.

When evaluating the role played by PLY in infection, it is clear that the role played by the toxin differs according to the type of infection model used. In the pneumonia model described above, in which infection is established via the intra-nasal route of inoculation, the infection is typical of a bronchopneumonia. It is also possible to use a model of lobar pneumonia, in which the infection is established by intratracheal inoculation of mice (Rubins *et al*., 1995). When evaluated in this lobar pneumonia model, PLN-A was ten times less virulent than its wild-type parent. This model has been used to evaluate the possible role of PLY in pulmonary infection. Infection of animals with wild-type pneumococci caused an increase in leakage of serum albumin into the air spaces, indicating that the permeability of the alveolar capillary barrier had been compromised. PLY-negative pneumococci showed a decreased ability to grow in the air spaces of the lung and had much less effect on the permeability of the air/blood interface. Once in the lung tissue, the mutant organisms showed a decreased ability to grow within the lung tissue and to cause bacteremia. The virulence properties of PLN-A could be reverted to wild-type by the co-administration of a bolus of PLY. A mechanism by which PLY might affect the permeability of the alveolar capillary junction has been suggested in studies using human respiratory mucosa grown in organ culture (Rayner *et al*., 1995). The interaction of wild-type and PLN-A pneumococci with human respiratory mucosa in an organ culture with an air interface were studied for up to 48h. Beating of the cilia on the epithelium and adherence to and invasion of the epithelium by bacteria were monitored by scanning electron microscopy. Both wild-type and PLN-A caused a decrease in cilial beat frequency, although the onset of the inhibition was delayed in the case of PLN-A. This suggests that PLY is involved in causing cilial slowing, but is not the only factor involved. Histological damage was induced by both wild-type and PLN-A, but again the effect was delayed and less severe when the organisms did not produce PLY. Only the wild-type organism caused separation of tight junctions between epithelial cells, and at 48h post-infection wild-type pneumococci were adherent to the separated edges of otherwise healthy unciliated cells. This separation of tight junctions and adherence to exposed areas may account for the changes in permeability and tissue invasion in the lobar pneumonia model described above.

The interaction of a toxin with the host during pathogenesis of a bacterial infection is also influenced by the genetic status of that host. The interaction of PLY with mice genetically deficient in complement has been investigated (Rubins *et al*., 1995). Lobar pneumonia in complement-deficient mice showed several different features to that seen in complement-sufficient animals. Lack of a complete complement system was associated with increased numbers of bacteria in the lungs and an earlier and greater level of bacteremia. The clearance of PLN-A and especially wild-type pneumococci from lungs was reduced in complement-deficient animals. The total bacterial load increased in the complement-deficient lungs of PLN-A infected mice, whereas complement-sufficient mice were able to clear this organism. The effect of the removal of PLY expression can therefore be partially reversed by the use of complement-deficient mice, illustrating that the interaction of PLY with the complement system is important in these model systems.

The role of PLY in ocular infections with the pneumococcus has been investigated. When a deletion mutant lacking PLY was constructed and used in a rabbit model of ocular infection, it showed greatly reduced virulence (Johnson *et al*., 1990). A non-hemolytic strain of the pneumococcus produced by chemical mutagenesis (probably involving the generation of a point mutation in the PLY gene) was found to show the same virulence characteristics as the parent strain. This suggested that an activity of PLY other than its lytic function was important in the role of the toxin during pathogenesis of ocular infection. This was confirmed in studies using mutants of the toxin devoid of different activities (see below).

From the above, it is clear that PLY makes a contribution to the virulence of the pneumococcus in models of pulmonary, systemic, and ocular infections. Its role in some other diseases is less clear. Use of toxin-positive and toxin-negative isogenic pneumococci in the chinchilla model of otitis media showed that the amount of inflammation induced was similar (Sato *et al*., 1996). It should be pointed out that these studies were done

with a serotype 3 organism, whereas the studies described above with PLN-A are serotype 2. It may be that the contribution of PLY to virulence differs between serotypes. It is becoming increasingly clear that the contribution of various virulence factors to pathogenesis of pneumococcal diseases can differ between strains of the organism (Blue and Mitchell, 2003; McCluskey *et al*., 2004). In a study of the role of PLY in pathogenesis of pneumococcal meningitis, it was found that, although direct intracisternal injection of PLY into rabbits caused a rapid inflammatory response, there was no evidence of a contribution of the toxin to the inflammation caused by the whole organism as determined by infection with wild-type and PLN-A pneumococci (Friedland *et al*., 1995). Therefore, although PLY can stimulate the inflammatory cascade in the central nervous system, it is not necessary for the pathogenesis of meningeal inflammation. Wellmer *et al.* showed that a PLY-negative version of the pneumococcus was less virulent in a mouse model of meningitis (Wellmer *et al*., 2002). It has also been shown that the toxin plays no role in post-antibiotic enhancement of meningeal inflammation (Friedland *et al*., 1995). These findings with regard to inflammation were largely confirmed in the study of Winter and colleagues (Winter *et al*., 1997), who used a guinea pig model of pneumococcal meningitis. Use of wild-type and PLN-A pneumococci in this model showed there was no difference in the amount of inflammation induced. There was, however, less protein influx into the CSF of animals infected with PLN-A. This may be related to the decreased effect PLN-A is known to have on other cell barriers (discussed above for the alveolar/capillary barrier). Although no difference in inflammation was detected, PLN-A induced substantially less ultrastructural damage to the cochlea of infected animals, and there was less associated hearing loss. When meningitis was induced with PLN-A, there was almost no ultrastructural cochlear damage and significantly less hearing loss at all frequencies tested. The ultrastructural damage observed following infection with wild-type pneumococci was very similar to that induced by micro-perfusion of the cochlea with purified PLY (Comis *et al*., 1993). The ultrastructural changes induced by cochlear perfusion with PLY are those that were absent after meningitis due to PLN-A. Thus, in this experimental model, PLY appears not to contribute to inflammation, but the majority of cochlear damage and hearing loss is due to PLY. This also challenges the dogma that damage to the cochlea is due to bystander damage due to the inflammatory response. When considering the use of animal models of human disease, it is always useful to try to put things into a human context. The concentration of PLY in human CSF of human meningitis patients was found to be between 0.85 and 180ng/ml (Spreer *et al*., 2003). This is within the concentration range used in model systems to induce cytotoxity, inflammatory cytokine production, and alteration in cilial beat in both respiratory and ependymal mucosa (Spreer *et al*., 2003). Interestingly, this study also showed that the concentration of PLY in the CSF of rabbits with meningitis could be dramatically reduced by treatment with non-bacteriolytic antibiotics rather than ceftriaxone (Spreer *et al*., 2003).

The above describes some extensive studies on the role of PLY using simple isogenic knockout mutants. With the availability of molecular techniques, it has also proved possible to evaluate the contribution of individual activities or amino acids of the toxin to the virulence of the pneumococcus. These studies are described below.

## Administration of altered versions of purified PLY

As considered above, PLY is a multifunctional protein, and these various activities can be allocated to various parts of the protein. This process has been facilitated by the generation of a homology model of the three-dimensional structure of the toxin (Rossjohn *et al*., 1998). Structure function data for the protein can be used to define the roles played by the various activities of the toxin *in vivo*. Most studies have concerned the relative contribution of complement-activating activity and lytic activity to the pathogenesis of infection.

The first evidence that both complement activation and lytic activity contributed separately to the *in vivo* activity of the toxin was provided by Feldman and colleagues (Feldman *et al*., 1991b), who showed by direct instillation of purified PLY into ligated lobes of the rat lung that the molecule induced an inflammatory response similar to that seen in pneumonia. Use of mutant forms of PLY that lacked either lytic or complement activating activity demonstrated that both these activities contributed to the inflammatory process.

Studies by Rubins and colleagues (Rubins *et al*., 1995) using the rat lobar pneumonia model showed that full virulence could be restored to a PLY-negative mutant of the pneumococcus (PLN-A) by co-administration of a bolus of the wild-type toxin. Co-instillation of mutant forms of the toxin showed that the lytic activity of the toxin was important for allowing growth of bacteria in the lung and invasion into the lung tissue during the early times post-infection (up to 12h). Complement activation by the toxin only appeared to be important at later times.

### Isogenic mutants expressing altered versions of PLY

In order to understand how the various activities of PLY are involved in the virulence of the whole organism, a series of isogenic mutants of a type 2 pneumococcus were constructed that express versions of the toxin that carry various amino acid substitutions that affect the activity of the toxin (Berry *et al*., 1995). This panel of mutants has been used in several models of pneumococcal infection. The contribution of the various activities of the toxin to virulence varies according to the model used.

## ASSAY OF ISOGENIC STRAINS *IN VITRO*

Strains of pneumococci producing PLY, which differed in their ability to activate the complement pathway or cause cell lysis, have been used in assays of complement-mediated killing by human phagocytes to show that complement activation by the toxin is involved in modulating this process (Rubins *et al*., 1996b). Interaction with the complement system may well be important because it is involved in opsonophagocytosis and clearance of pneumococci from the lung (Winkelstein, 1981). Although the pneumococcal cell wall can activate the alternative complement pathway, the pneumococcal polysaccharide capsule is believed to prevent the access of phagocytes to these cell wall–bound opsonins (Winkelstein, 1981). It has been proposed that deposition of opsonins on the surface of the capsule is essential for effective opsonophagocytosis (Brown *et al*., 1983). The experiments with isogenic pneumococci suggest that PLY may be able to protect pneumococci from the classical complement pathway by consuming the components of the classical complement factors in solution. Evasion of the complement system in this way would allow increased bacterial survival, especially when the concentrations of complement factors are already low, such as in the lung.

## ASSAY OF ISOGENIC STRAINS *IN VIVO*: SYSTEMIC INFECTION

The virulence of the strains expressing toxins with altered activity have been compared in a model of intraperitoneal inoculation into mice (Berry *et al*., 1995). There was no significant difference in either median survival time or overall survival rate between mice challenged with wild-type or those with a deficiency in complement activation (strain H+/C–). Strains with reduced hemolytic activity (H2–/C+ and H3–/C+), which reduces the activity of the toxin produced to 0.02% and 0.0001%, respectively, had greater median survival times and overall survival rate than mice challenged with wild-type organisms. In the intraperitoneal model, the contribution of PLY to virulence is largely related to its cytotoxic properties rather than its ability to activate complement. It is interesting to note that very small amounts of hemolytic activity may be required for virulence, as strain H1–/C+ in which the lytic activity of the toxin is only 0.1% of wild-type had intermediate virulence.

The same isogenic strains have also been used in an intravenous challenge model (Benton *et al*., 1997). In this study, strains with decreased complement activation (H+/C–) or decreased lytic activity (H1–/C+, H3–/C+) had virulence characteristics similar to wild-type organisms. Only when mutations in the two activities were combined (H3–/C–) was there any effect on virulence. Moreover, the effect of these combined point mutations on virulence was small compared to that seen with the insertion duplication mutant PLN-A (PLY negative mutant). The PLN-A mutation increased survival time by 6 days, whereas the H3–/C– mutation only increased survival by 0.5 days. This suggests PLY has another activity other than lytic or complement activity that can contribute to virulence in this model. The existence of this third activity (in addition to complement activation and cytolysis) has been demonstrated by Berry *et al.* (Berry *et al*., 1999).

Use of a cirrhotic rat model of bacteremia revealed an important role for complement activation by PLY (Alcantara *et al*., 1999). In these studies, PLY-negative pneumococci and pneumococci expressing PLY without complement-activating activity were cleared from the bloodstream equally well and mortality observed was similar. However, PLY's complement-activating activity was proposed to enhance pneumococcal virulence in the hypocomplementemic, cirrhotic host (Alcantara *et al*., 1999). Under limiting concentrations of complement in the cirrhotic rat, the expression of PLY by pneumococci has a significant negative effect on serum complement levels and reduces serum opsonic activity (Alcantara *et al*., 2001).

## PNEUMONIA MODELS

In bronchopneumonia following intranasal inoculation of pneumococci, both lytic activity and complement activity are important, as reductions in these activities in the isogenic mutants reduced virulence (Alexander *et al*., 1998a). However, it was the ability to

activate complement that most affected the behavior of pneumococci in the lungs and associated bacteremia in the first 24h following infection. These findings were similar to those using a lobar pneumonia model (Rubins *et al*., 1996b), where it was confirmed using strains H3−/C+, H+/C−, and H3−/C− that either absence of lytic activity or complement-activating activity from PLY rendered mutants less virulent. This has been investigated further, and the cytolytic and complement-activating activities of the toxin have been shown to have different effects on cell recruitment (Jounblat *et al*., 2003). Complement activation by the toxin seemed to be involved in inducing T cell influx into the tissue, whereas cytolytic activity was responsible for neutrophil recruitment (Jounblat *et al*., 2003). In contrast to the bronchopneumonia model, these two mutations were not additive in their effect. The lack of additive effect in this system was proposed to show that the lytic activity of the toxin is involved in several steps during pathogenesis, whereas complement activity has a more limited role in reducing bacterial clearance in the lung. The lytic activity of the toxin correlated with acute lung injury and bacterial growth for up to six hours after inoculation. The complement-activating activity of the toxin correlated with bacterial growth and bacteremia at 24h post inoculation. Complement activation by PLY in lobar pneumonia has a singular role in pulmonary infection by promoting survival of pneumococci in the lung tissues and facilitating invasion in the blood (Rubins *et al*., 1996b).

## Summary of the role of PLY in pathogenesis

It is clear that PLY has different roles in different forms of pneumococcal disease. Thus, the toxin has no role in inflammation in meningitis (Friedland *et al*., 1995; Winter *et al*., 1997), but has a distinct role in meningitis-associated deafness (Winter *et al*., 1997) and bacteremia (Benton *et al*., 1995), as well as pneumonia. It also appears that where PLY has a role, the contributions of the hemolytic and complement-activating abilities differ. In bronchopneumonia, the hemolytic activity and complement activation by PLY each contribute to the virulence of pneumococci, and these activities have a distinct role in the disease (Alexander *et al*., 1998b). This is also true in lobar pneumonia (Rubins *et al*., 1996a) but with no additive effect on virulence when both activities were decreased, while in bronchopneumonia the survival time increased if both activities were reduced. After intraperitoneal infection, it was only changes that affected the lytic activity of the toxin that changed virulence (Berry *et al*., 1995), and the amount of hemolytic activity required for virulence was low. In the lung, hemolytic and complement-activating activities have distinct effects on the behavior of pneumococci, and the time at which each activity contributes is different. In bronchopneumonia, complement activation is important throughout the first 24h post-infection. Reduction in hemolytic activity only had an effect after 6h. In contrast, in lobar pneumonia, hemolytic activity was important in the first 6h, with complement activation only playing a role afterwards. It is probably significant that the inoculum entering the lungs is much smaller after intranasal inoculation (to establish bronchopneumonia), and the complement-activating ability of the toxin may be important in protecting this relatively small inoculum. When a large inoculum is used to establish lobar pneumonia, it is the ability to damage the alveolar capillary barrier to release nutrients that becomes important.

During bronchopneumonia, the level of bacteremia is closely related to the level of growth of bacteria in the lung. Mutations affecting growth in the lung (removal of complement-activating ability) therefore caused a corresponding decrease in the amount of bacteremia. Reduction of hemolytic activity had little effect on growth in the lung, and therefore a small effect on numbers of pneumococci in the blood. Studies using intravenous instillation of pneumococci into the blood suggest all mutants should grow at the same rate once into the blood (Benton *et al*., 1995; Berry *et al*., 1995; Benton *et al*., 1997). It therefore appears that continual seeding of bacteria from the lungs contributes to the level of bacteria in the blood rather than being due to a growth of an inoculum in the blood. An alternative explanation is that the wild-type and H−/C+ strain may be affected by passage through the lungs, i.e., entry to the blood via the lungs is different from entry to the blood via a syringe. Wild-type organisms injected into the blood reach levels of up to $10^{10}$ CFU/ml (Benton *et al*., 1995), whereas those entering the blood from the lung reach maximal levels of $10^8$ (Alexander *et al*., 1998a). This difference may be host mediated. Entry via the lungs may induce a host response, which controls subsequent bacteremia, whereas direct injection bypasses the induction of this response and allows greater growth of pneumococci. PLY may contribute to the down-regulation of this response when the organisms gain access to the lungs.

Pneumococci carrying three-point mutation in the PLY gene were not as avirulent as those making no toxin. This indicates that some further unidentified activity of PLY plays a role in infection (Benton *et al*., 1997). This could be related to the ability of strain H3−/C− to bind to the Fc portion of antibody (Mitchell, 1991; Alexander *et al*., 1998a), or could be related to the anticellular activity of sublytic concentrations of the toxin. It will be important to determine the nature of

the "unidentified" activity if PLY genetic toxoids are to be considered as vaccine candidates.

## REGULATION OF PLY EXPRESSION

Currently not much is known about how expression of the pneumolysin gene is regulated. However, with the advent of microarray technology, as well as techniques for the isolation of bacterial RNA from infected animals, this will soon change. Following intraperitoneal infection of BALC/c mice, the expression of PLY increased by threefold at 12h post infection and ten-fold at 24h post infection (Ogunniyi *et al*., 2002). The molecular mechanisms of this regulation are unclear, but the ClpP protease has been shown to play a role in posttranslational regulation of PLY *in vitro* (Kwon *et al*., 2004). Microarray analysis of a LuxS null mutant of strain D39 showed that LuxS plays a role in regulating the expression of PLY, although not in a cell density–dependent manner (Joyce *et al.,* 2004). These studies represent the first attempts to define the mechanisms of control of expression of this important virulence factor.

## USE OF PLY AS A VACCINE

The currently used pneumococcal vaccine for use in humans is based on a mixture of 23 capsular polysaccharides selected from the 90 known types. This vaccine has two major shortcomings. The first is that it is serotype specific, and the second is that protection against the types included may be very poor in high-risk groups who have a poorer antibody response to polysaccharide vaccines than healthy adults (Broome, 1981; Forrester *et al*., 1987). New conjugate vaccines have been developed containing the seven most common pediatric serotype polysaccharides conjugated to CRM197, and trials in Finland and the USA have demonstrated that these vaccines are efficacious in the prevention of invasive disease (Black *et al*., 2000; Eskola *et al*., 2001). However, these vaccines still protect only against seven serotypes, and they may drive selection of types not included in the vaccine. It has been proposed that a cross-serotype protective protein could overcome these problems. Protective pneumococcal antigens would also be attractive candidates for use as carriers for polysaccharides in conjugate vaccines. Conjugation of polysaccharides to proteins increases their immunogenicity and also converts them to antigens capable of generating immunological memory (Snippe *et al*., 1983). Studies with pneumococcal polysaccharides conjugated to a range of proteins have demonstrated enhanced immunogenicity of the polysaccharide (Andrew *et al*., 1994). The new generation of conjugate vaccines may be too expensive to be used in all parts of the world. A protein-based vaccine would therefore have attractions.

PLY is a good candidate as a vaccine antigen, as it is produced by virtually all clinical isolates of the pneumococcus (Kanclerski and Mollby, 1987), and its primary structure varies little (Mitchell *et al*., 1990). Mice can be protected from challenge with virulent pneumococci by passive immunization with either mouse monoclonal antibodies to PLY (Garcia-Suarez *et al*., 2004) or by purified human antibody to pneumolysin (Musher *et al*., 2001). Active vaccination with wild-type PLY is protective in mice (Paton *et al*., 1983), and combinations of PLY with other antigens, such as PspA, can increase protection further (Ogunniyi *et al*., 2000; Ogunniyi *et al*., 2001). Evidence for the production of PLY during invasive pneumococcal in humans is based on serological analysis. Bacteremic pneumococcal pneumonia is associated with a rise in anti-PLY titers in 50–85% of adults, especially in those with more severe pneumonia (Kalin *et al*., 1987; Kanclerski *et al*., 1988; Jalonen *et al*., 1989). Although native PLY is too toxic to be proposed for inclusion in a vaccine, genetically altered PLY with reduced toxicity could be used (Boulnois, 1992). The structure-function data and information on pathogenesis can be used for the rational design of candidate vaccine molecules. Immunization of mice with such a genetically engineered toxoid has been shown to confer protection against at least nine serotypes of the pneumococcus (Alexander *et al*., 1994). In this study, the amount of protection conferred was found to vary with the serotype of pneumococcus used and the route of challenge. No protection was afforded against the serotype 3 strain GBO5 when given intranasally. The absence of protection is not related solely to serotype, as some protection was afforded against another serotype 3 strain. The lack of protection against some pneumococcal isolates conferred by the PLY toxoid suggests that additional pneumococcal immunogens may be required in conjunction with the PLY toxoid. PLY could be used as a component of a multivalent protein vaccine, as an addition to a conventional conjugate vaccine, or as a carrier for pneumococcal polysaccharide. A conjugate of PLY toxoid and 19F polysaccharide has been produced and generates a protective immune response in infant mice (Lee *et al*., 1994a). Ply and toxoids of Ply have been used as carriers for polysaccharide in conjugates in several studies. The responses of animals to these vaccines are superior to those generated using other protein carriers in terms of antibody responses, neutralization of PLY, and protection of the animals for subsequent bacterial

challenge (Lee *et al*., 1994b; Kuo *et al*., 1995; Michon *et al*., 1998; Lee *et al*., 2001), indicating this is a potential route to improve vaccine efficacy. Alternatively, further protection may be achieved by alternative delivery routes of the PLY toxoid.

The experiments described above have considered only systemic immunity raised to the PLY toxoid. Since colonization of the nasopharyngeal mucosa by pneumococci is a prerequisite for the development of pneumococcal disease, it may be that mucosal immunity will give better protection from disease. Polysaccharides induce little secretory IgA at the mucosal surface and do not affect carriage rate of pneumococci (Douglas *et al*., 1986). The conjugate vaccines induce anti-capsular IgG and IgA antibodies in nasopharyngeal secretions (Nurkka *et al*., 2001), and immunization in infancy reduces carriage rates of the serotypes included in the vaccine. However, vaccination is accompanied by compensatory rises in the rates of nasopharyngeal colonization with serotypes not covered by the vaccine, and these may be associated with increased disease (at least for otitis media) caused by serotypes not included in the vaccine (Eskola, 2000). It may also be possible to generate a secretory IgA response to other pneumococcal antigens by mucosal immunization and thus influence colonization by virulent pneumococci. One mechanism for mucosal immunization is the use of live delivery vehicles. PLY has been expressed in such a delivery vehicle (Paton *et al*., 1993b). An attenuated *Salmonella* strain expressing PLY toxoid was able to elicit both IgG and IgA antibodies to the toxoid when given by the oral route (Paton *et al*., 1993b). New developments in DNA vaccine technology may also provide alternative routes and methods of vaccination with PLY.

## CONCLUSION

Many years' work have been done on PLY, such that much is now known about its activity. Detailed structure function analysis has revealed where within the molecule some of the biological properties of the toxin lie. A good homology model of the toxin now exists, although we still await a determination of the three-dimensional crystal structure of this toxin. The mechanism of pore formation by PLY is partially understood, but there are still many aspects to this intriguing process that remain to be clarified.

Availability of structure-function data and molecular biology technology in combination with traditional methods of studying pathogenesis has allowed a detailed analysis of the role of this toxin and its various activities in the pathogenesis of pneumococcal infection to be dissected. The role of the toxin is complex and varies according to which disease is examined. These studies highlight the difficulties in defining the role played by bacterial toxins in the disease process. Studies *in vitro* can only go some way to understanding the role of a toxin. Ultimate understanding can only be achieved by the study of *in vivo* systems.

## ACKNOWLEDGMENTS

I would like to thank all members of the Mitchell laboratory, both past and present, for their continued efforts to unravel the complexities of pneumolysin structure/function and biology. I would also like to thank the many collaborators around the world for continued productive interactions. Thanks to Alison Kerr and Graeme Cowan for their help with this chapter and the figures. Work in the Mitchell laboratory is supported by the Wellcome Trust, BBSRC, Royal Society, and the European Union.

CHAPTER

# 40

# Listeriolysin

*José A. Vázquez-Boland, Radek Stachowiak, Lizeth Lacharme, and Mariela Scortti*

## INTRODUCTION

The cholesterol-dependent cytolysin (CDC) produced by the food-borne, facultative intracellular pathogen *Listeria monocytogenes* is known as listeriolysin O (LLO). Its coding gene, *hly*, was the first virulence determinant to be identified and sequenced in *Listeria*. Subsequent characterization of the *hly* locus led to the discovery of *Listeria* pathogenicity island 1 (LIPI-1), a 9-kb chromosomal gene cassette encoding key functions necessary for the intracellular parasitic lifestyle of these bacteria. The elucidation between 1986 and 1989 of the crucial role that LLO plays in escape from the phagocytic vacuole made this toxin the first microbial product for which a function critical for the survival and replication of a parasite within host cells was identified. There is growing evidence that LLO is a multifaceted virulence factor with many other, sometimes subtle roles in the host-pathogen interaction. LLO displays all the common features of CDCs, but also unique properties making it a particularly interesting member of this toxin family. This chapter reviews the advances made in our understanding of the CDC with the best characterized role in pathogenesis. It also illustrates how this fundamental knowledge can be exploited to harness a nasty microbial product for the development of novel vaccines and therapeutic tools.

## CHARACTERIZATION

### Early studies

The production of a soluble hemolysin by *L. monocytogenes* was first reported by Harvey and Faber in 1941. During the 1960s and 1970s, various groups attempted the purification and characterization of this activity (Girard *et al*., 1963; Jenkins and Watson, 1971; Njoku-Obi *et al*., 1963; Siddique *et al*. 1974; Watson and Lavizzo, 1973). Jenkins *et al*., (1964) showed for the first time that the listerial hemolysin is functionally and antigenically related to streptolysin O (SLO), and Kingdon and Sword (1970) demonstrated two of its key characteristics: inhibition by cholesterol and pH optimum below 7. These authors also suggested that the *L. monocytogenes* hemolysin might be involved in the disruption of phagosomal membranes. Finally, Geoffroy *et al*. (1987) purified the toxin to homogeneity, demonstrated that it was a member of the CDC family, named it LLO, and determined that it was active at a narrow pH range, between 4.5 and 6.5 with optimum at 5.5. The 58-kDa CDC from *Listeria ivanovii*, ivanolysin O (ILO), was later purified and characterized (Vázquez-Boland *et al*., 1989a), and it was shown that the weakly hemolytic but non-pathogenic species *Listeria seeligeri* also produced an LLO-related CDC, albeit in small amounts (Geoffroy *et al*., 1989, Leimeister-Wächter *et al*., 1989).

### Molecular genetic studies

The *hly* gene encoding LLO was first identified and sequenced by Mengaud *et al*. (1988). Analysis of its deduced sequence and that of the cloned genes for ILO and the *L. seeligeri* hemolysin, seeligerilysin O (LSO) (Haas *et al*., 1992), revealed that the listerial hemolysins, although similar, are not identical (Figure 40.1). Their degree of similarity, 76–82% and 77–78% identity at the amino acid and nucleotide levels,

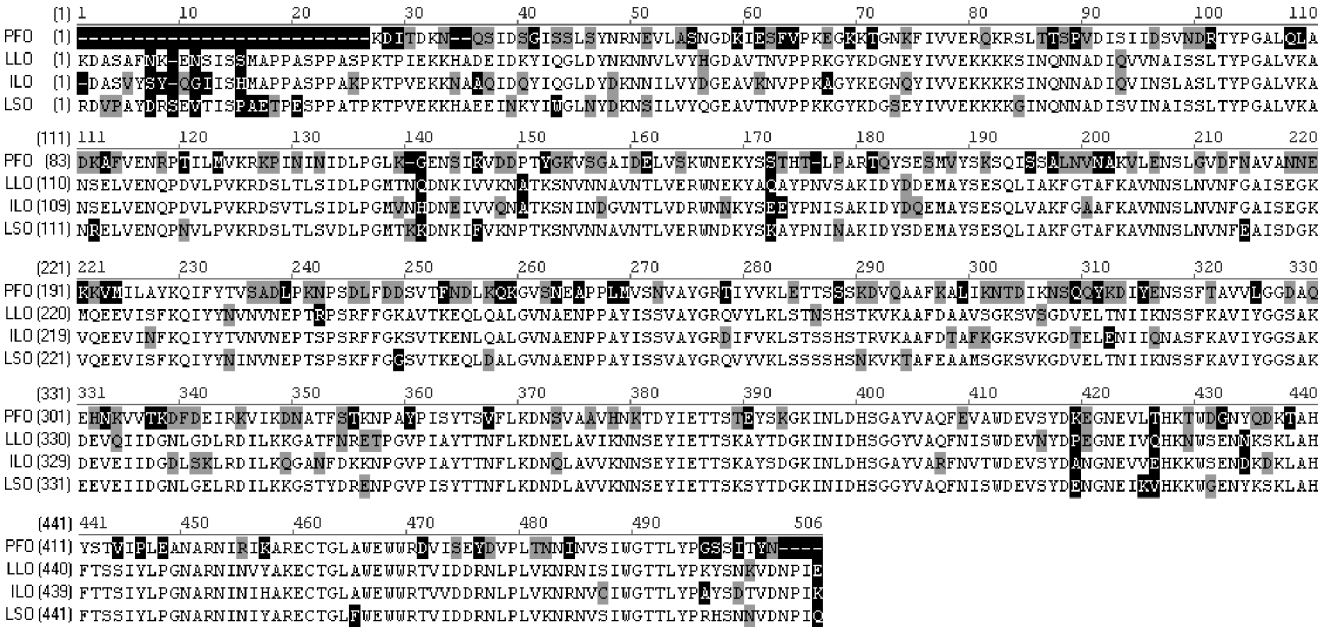

**FIGURE 40.1** Comparison of the amino acid sequeces of listerial CDCs (LLO, ILO, LSO) and PFO from *C. perfringens*. Differences in sequence are highlighted (light shade, conservative changes; dark shade, non-conservative changes). Multiple alignment of the mature proteins constructed with AlignX tool from VectorNTI Suite 9.0.0 package.

respectively, is comparable to that found between other orthologues shared by the three listerial species, consistent with the view that the central virulence gene cluster LIPI-1 bearing the hemolysin determinant (Figure 40.2) evolved vertically during speciation of the common *Listeria* ancestor (Vázquez-Boland *et al*., 2001a; Schmid *et al*., 2005).

## STRUCTURE-FUNCTION

### CDC structure and mechanism of pore formation

A crystal structure is available for the soluble monomer of perfringolysin O (PFO) (Rossjohn *et al*., 1997). Given the extensive overall similarity of CDCs in terms of amino-acid sequence and functional properties, it is reasonable to assume that the domain structure of PFO can be extrapolated to any member of this toxin family. Figure 40.3 depicts the theoretical three-dimensional structure of LLO modeled on the basis of the crystallographic data for PFO. LLO is predicted to consist of four discontinuous, predominantly β-sheet-folded domains spatially organized into two distinct protein regions: an N-terminal region formed by domains 1 to 3 and a C-terminal region formed by domain 4. Domains 1, 2, and 4 are aligned vertically, whereas domain 3 is located parallel to domain 2, forming an elongated mushroom-like molecule. The C-terminal domain 4 folds into a compact β-sandwich structure that is linked to the N-terminal region via residue Gly417 (Gly392 in PFO).

Membrane disruption by CDCs involves the transition from monomeric, water-soluble toxin molecules to non-covalently bound oligomeric, insoluble ring-shaped toxin structures formed by up to 50 monomers, which insert into the membrane, forming large pores about 20 to 30 nm in diameter (Bhakdi *et al*., 1985; Alouf and Geoffroy, 1991; Morgan *et al*., 1994; Sekiya *et al*., 1993) (Figure 40.4). A clear picture of the cytolytic mechanism of CDCs has begun to emerge from the integration of PFO structural data, site-specific mutagenesis analyses, and the information provided by biophysical and fluorescent probe–based studies performed with SLO, pneumolysin (PLY), and particularly PFO (Rossjohn *et al*., 1997; Nakamura *et al*., 1998; Palmer *et al*., 1998a, 1998b; Shepard *et al*., 1998, 2000; Gilbert *et al*., 1999; Shatursky *et al*., 1999; Heuck *et al*., 2000, 2003; Ramachandran *et al*., 2002, 2004) (see relevant chapters in this book for more information). These studies suggest that domain 4 mediates membrane binding and domains 1–3 are involved in toxin oligomerization and membrane disruption. This is consistent with experimental data obtained with LLO showing that neutralizing antibodies against the native toxin that map to domain 4 inhibit binding to cellular membranes (De los Toyos *et al*., 1996), whereas neutral-

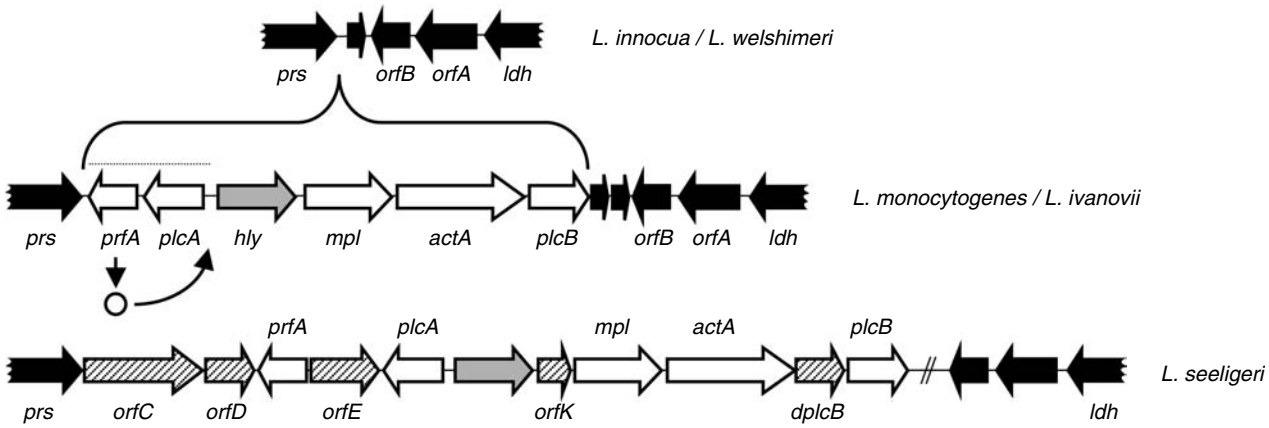

**FIGURE 40.2** Genetic structure of LIPI-1 (central virulence gene cluster) and its insertion region in *Listeria* spp. Genes belonging to LIPI-1 are represented by empty arrows except *hly*, which is in grey. The LIPI-1 insertion region is delimited by the housekeeping loci *prs* (phosphoribosylpyrophosphate synthase) and *Idh* (lactate dehydrogenase). LIPI-1 is absent from the chromosomes of the non-pathogenic species, *L. innocua* and *L. welshimeri*, likely via deletion of the island. In the non-pathogenic species, *L. seeligeri*, LIPI-2 contains numerous insertions (hatched arrows). One of these insertions disrupts the *plcA-prfA* operon, inactivating a positive autoregulatory loop required for the synthesis of the central virulence regulator PrfA, PrfA activates the transcription of LIPI-1 genes and of other virulence determinants located elsewhere on the listerial chromosome. Modified from Vázquez-Boland *et al.* (2001a).

izing epitopes that do not inhibit binding to membranes map to domain 1 (Darji *et al*., 1996).

In the consensus model, initial membrane contact via domain 4 (Heuck *et al*., 2000; Ramacha¡ndran *et al*., 2002) would facilitate the interaction of toxin molecules with cholesterol. This would trigger a conformational change in the monomer, increasing its capacity to self-aggregate and, via the refolding of three α-helices of domain 3 into two membrane-spanning β-hairpins, its hydrophobicity and membrane affinity (Shatursky *et al*., 1999). By lateral diffusion, the vertically arranged membrane-bound monomers would collide with other monomers to form an oligomeric prepore (Shepard *et al*., 2000; Hotze *et al*., 2002; Heuck *et al*., 2003) via edge-to-edge association of domain 3 β-strands (Ramachandran *et al*., 2004). In a second step, the prepore would insert into the membrane by vertical collapse of the toxin structure, which would make the β-hairpins extend across the bilayer, forming a transmembrane β-barrel pore (Czajkowsky *et al*., 2004). The notion that membrane binding and disruption are dissociable events in CDC function is supported by experiments with LLO showing that monoclonal antibodies that neutralize cytolytic activity do not affect toxin binding to target membranes (Nato *et al*., 1991; Darji *et al*., 1996). This is possible if these antibodies block downstream events of toxin fuction, such as oligomerization or pore formation.

## Domain 4

Most targeted mutagenesis studies have focused on domain 4, as this region contains the conserved C-terminal Trp-rich motif, ECTGLAWEWWR, a hallmark of this toxin family. As in other CDCs (Pinkney *et al*., 1989; Saunders *et al*., 1989; Sekino-Suzuki *et al*., 1996; Baba *et al*., 2001), mutational analyses in LLO have shown that this domain, in particular the conserved motif and the C-terminus, is critical for activity (Mengaud *et al*., 1988; Kohda *et al*., 2002). In LLO, single amino-acid substitutions in the undecapeptide resulted in *L. monocytogenes* strains with various degrees of attenuation proportional to the loss of cytolytic activity (Michel *et al*., 1990). LSO from the non-pathogenic *L. seeligeri* carries a naturally occurring Ala-to-Phe substitution in the undecapeptide (Haas *et al*., 1992) (Figure 40.1), which has been shown to be responsible for the weak cytolytic activity for sheep erythrocytes exhibited by this toxin (Ito *et al*., 2001).

### *Role of the single Cys residue*

The undecapeptide motif contains the Cys residue that mediates the characteristic reversible inhibition by oxidation—and reactivation by thiol-reducing agents—that gave this toxin family its former name, "oxygen-labile" or "thiol-activated" hemolysins. The activating effect of thiol-reducing agents was initially thought to be due to the breakage of an intramolecular bond, but sequencing of the LLO gene and of other CDC genes revealed that in most cases only one Cys residue is present in the toxin molecule. This residue was also thought to be essential for activity and to be involved in cholesterol binding (see below) (Smyth and Duncan, 1978; Alouf and Geoffroy, 1991; Alouf, 1999). However, although replacement of the Cys residue by Ala in LLO rendered the toxin insensitive to

**FIGURE 40.3** Theoretical three-dimensional structure of the soluble LLO monomer based on the crystal structure of PFO. Domains are indicated by numbers (the arrow points to the Trp-rich undecapeptide). Ribbon model generated using PyMOL 0.97 (DeLano, 2004).

inactivation by oxidation or thiol-alkylating agents, it had no significant effect on cytolytic activity (Michel *et al*., 1990). Similar results were obtained with other toxins of the family (Pinkney *et al*., 1989; Saunders *et al*., 1989).

The non-essential role of the Cys residue raises questions as to why it is subject to such pressure for conservation. In LLO and other CDCs, its replacement by bulkier residues abolishes most of the activity, suggesting that the mechanism underlying the Cys-mediated reversible inhibition of cytolytic activity involves steric hindrance (Pinkney *et al*., 1989; Saunders *et al*., 1989; Michel *et al*., 1990). Such an effect may result

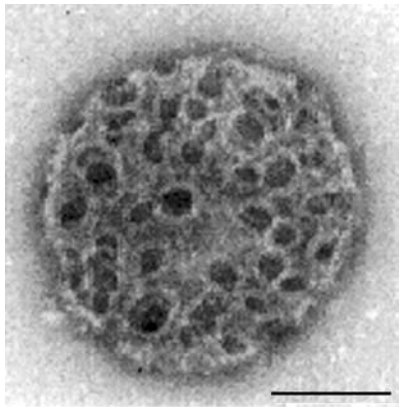

**FIGURE 40.4** Ring-shaped pores formed by LLO on a sheep erythrocyte ghost. Bar indicates 100 nm. Reproduced from Jacobs *et al.* (1998), with permission.

from the formation of toxin dimers or heterodimers with other proteins via disulfide bridges. Indeed, ILO copurifies with a major 27-kDa protein of the *L. ivanovii* culture supernatant, and this heterodimer is resolved by treatment with thiol-reducing agents (Vázquez-Boland *et al*., 1989a). This 27-kDa protein is another listerial virulence factor, the small/excreted internalin i-InlE (Engelbrecht *et al*., 1998), the mature form of which contains a single Cys. This suggests that the Cys residue present in the undecapeptide of most CDCs may play a role in the targeting of other virulence-associated proteins to the eukaryotic cell membrane. It may also have a regulatory role *in vivo*, for example, by enhancing toxin activity in low-pH (reducing) environments, such as the acidified vacuolar compartment.

### *Cholesterol binding*

Based on the capacity of cholesterol to inhibit the cytolytic activity of CDCs irreversibly and the fact that these toxins are active only against cholesterol-containing membranes, it is generally accepted that this membrane lipid acts as the toxin receptor (Smyth and Duncan, 1978; Alouf and Geoffroy, 1991). Indeed, many studies have shown that the extent of CDC interaction with the membrane is directly dependent on the amount of cholesterol present on that membrane (Jacobs *et al*., 2001; Heuck *et al*., 2000; Waheed *et al*., 2001), and a cholesterol-binding region has been unambiguously traced to domain 4 in PFO (Shimada *et al*., 1999, 2002). Consistent with this, C-terminal truncations in LLO, whether involving the undecapeptide or not, abolished binding to immobilized cholesterol (Kohda *et al*., 2002). Experiments with recombinant PLY polypeptides also showed that domain 4 alone binds free cholesterol, whereas a truncated protein

comprising only domains 1–3 does not (Baba *et al*., 2001). In some of these studies, the abolition of cholesterol-binding activity was associated with a loss of membrane-binding activity (Shimada *et al*., 1999; Baba *et al*., 2001), in line with the view that cholesterol recognition is essential for initial interaction with the membrane.

However, experiments in which preincubation of LLO with cholesterol did not impede the binding of the toxin-cholesterol complexes to the cell membrane (Jacobs *et al*., 1998) challenged the above notion. A similar dissociation of cholesterol- and membrane-binding activities was observed in experiments using PFO mutants with single Phe substitutions in the three Trp residues of the undecapeptide. These mutations impaired membrane binding, but did not affect cholesterol binding (Sekino-Suzuki *et al*., 1996). The observation that CDCs in solution form highly stable amphiphilic complexes with free cholesterol led to the development of a simple one-step purification method by selective precipitation with cholesterol (Vázquez-Boland *et al*., 1989a). Using this technique, an inactive, truncated LLO lacking the 49 C-terminal residues (i.e., approx. half of domain 4, including the entire conserved undecapeptide) (Mengaud *et al*., 1988) was shown to form cholesterol-toxin complexes (Vázquez-Boland *et al*., 1989b). Thus, domains involved in cholesterol binding appear to be present outside the undecapeptide and C-terminus of the toxin, either in the remaining part of domain 4 (a possibility not supported by recent evidence obtained with fluorescent probes showing that, except for its tip—the Trp-rich loop—all parts of domain 4 in membrane-bound PFO are accessible to the solvent; Heuck *et al*., 2000) or in the N-terminal region. The latter option is consistent with the observation that although the cholesterol-complexed LLO binds to target membranes, there is no oligomerization (Jacobs *et al*., 1998), suggesting that preincubation with cholesterol blocks sites involved in pore formation (which reside in the N-terminal region; see above). Moreover, the above-mentioned PFO mutants that showed reduced membrane-binding and cytolytic capacities while retaining cholesterol-binding activity were still able to form ring-shaped structures on membranes (Sekino-Suzuki *et al*., 1996). These observations suggest that, rather than acting as the toxin receptor, cholesterol might play a critical role in subsequent stages of membrane-toxin interaction, i.e., during oligomerization and/or membrane insertion.

The view that cholesterol's primary role is to facilitate membrane insertion has received strong support from recent studies showing that cholesterol-depleted membranes stalled PFO, SLO, and intermedilysin (ILY, from *Streptococcus intermedius*) at the prepore stage. All three toxins regained lytic activity if cholesterol was restored to the membrane, suggesting that this lipid is critically involved in the prepore to transmembrane pore transition (Giddings *et al*., 2003).

### *Role of the conserved undecapeptide*

The conserved ECTGLAWEWWR undecapeptide forms a hydrophobic loop at the base of domain 4 (Figure 40.3). This structure penetrates the lipid bilayer and is thought to be responsible for the initial attachment of the CDC monomers to the target membrane during prepore formation (Heuck *et al*., 2000; Ramachandran *et al*., 2002). However, its exact role in toxin function remains unclear, as the contradictory data obtained with LLO illustrate. Thus, membrane binding was not affected in LLO mutants with impaired cytolytic activity due to amino-acid replacements in the undecapeptide, including Trp to Ala substitutions, which almost totally abolished toxin function (Michel *et al*., 1990). Similarly, monoclonal antibodies produced against a synthetic LLO undecapeptide and that recognized the immobilized toxin did not inhibit membrane binding or cytolysis (Nato *et al*., 1991). In contrast, a neutralizing monoclonal antibody raised against native toxin and that specifically bound to the undecapeptide caused LLO membrane-binding inhibition and no longer recognized its target epitope in a pre-formed toxin/ membrane complex (Jacobs *et al*., 1999). The latter experiments are consistent with results obtained with the above-mentioned weakly hemolytic PFO mutants containing Phe-to-Trp substitutions in the undecapeptide, as these displayed significantly impaired erythrocyte membrane-binding activities (Sekino-Suzuki *et al*., 1996). Circular dichroism analyses of membrane-associated mutant PFO toxins suggested that both Trp438 and Trp439 were involved in a conformational change occurring during pore formation (Nakamura *et al*., 1998). Thus, the impaired interaction with the membrane seen with the PFO mutants or LLO bound to the undecapeptide-specific antibody may indicate a role for the conserved motif in the adoption of the correct folding required for membrane insertion and pore formation, rather than a role in the initial stages of toxin-membrane interaction. Such an interpretation is consistent with the observed inhibition of PLY self-interaction by derivatization of the single Cys residue with the thiol-active agent dithio (bis)nitrobenzoic acid (Gilbert *et al*., 1998).

Recently, PFO and ILY mutants displaying a significant loss of hemolytic activity, but retaining wild-type levels of membrane-binding activity, have been shown to oligomerize on the membrane but to be unable to form a pore complex, consistent with a role for the undecapeptide in the prepore-to-pore conversion.

This study also showed that target cell recognition by ILY depends on domain 4, but does not involve the undecapeptide (Polekhina *et al*., 2005) (see below).

### Domains 1–3

A recent study with independently expressed N-terminal (domains 1–3) and C-terminal (domain 4) LLO polypeptides has shown that the two protein fragments were able to bind to erythrocyte membranes and intact mammalian cells, the former even with greater affinity (Dubail *et al*., 2001). Intriguingly, functional complementation was reported to occur after coproduction of both LLO subfragments in *L. monocytogenes*, suggesting that they can reassemble to form a pore complex (Dubail *et al*., 2001). Also intriguing was that a Δ*hly L. monocytogenes* strain, *trans*-complemented with a plasmid encoding a truncated toxin variant lacking the first three residues of the native protein, displayed similar levels of hemolytic activity to wild-type *L. monocytogenes in vitro*, but apparently disrupted the phagocytic vacuole less efficiently and was two orders of magnitude less virulent in the mouse model (Lety *et al*., 2003). It is unclear whether this was actually due to the lack of these three first residues in LLO, which would imply that they play a specific role in the interaction with the phagosomal membrane, or to problems of *in vivo* instability of the plasmid construct encoding the truncated LLO toxin.

## ROLE IN INTRACELLULAR PARASITISM

### Cell biology of *Listeria* infection

*Listeria* belong to a subgroup of intracellular bacterial pathogens that replicate in the cytosol and not in a membrane-bound vacuole. Soon after phagocytosis, whether by macrophages or by any other susceptible cell type actively invaded by these bacteria (epithelial cells, hepatocytes, endothelial cells, etc.), listeriae are seen free in the cytosol. Intracytosolic bacteria polymerize host cell actin at one of their poles by means of the surface protein ActA, a mechanism that propels them across the cytosol at a speed of 0.3 μm/s. The movement is random, and some bacteria eventually reach the cell periphery and protrude from the cell surface at the tip of pseudopod-like evaginations, which penetrate into neighboring cells. This triggers a phagocytosis process, resulting in the formation of a "secondary" phagosome that is surrounded by a double membrane, from which *Listeria* escape again to begin a new replication cycle (Figure 40.5). Thanks to this direct cell-to-cell spread mechanism, *Listeria* rarely leave the intracellular host compartment, facilitating avoidance of the humoral effectors of the immune system and phagocytosis by migrant neutrophils. By rapidly spreading to neighboring cells, they escape the cellular immune response typically directed against infected cells displaying cytosol-released bacterial epitopes in association with MHC class I molecules (San Mateo *et al*., 2002). This strategy contrasts with that used by many other intracellular pathogens (e.g., *Salmonella* or *Mycobacterium*), which avoid the cellular immune response by hiding inside a vacuole, an enclosed environment that prevents/delays the presentation of antigens via the cytosolic MHC class I pathway (for recent reviews see Vázquez-Boland *et al*., 2001b; Portnoy *et al*., 2002; Dussurget *et al*., 2004). Efficient disruption of the phagocytic vacuole membranes is therefore a key process in *Listeria* pathogenesis.

### Role of LLO in phagosome disruption

The pathogenic *Listeria* spp, *L. monocytogenes* and *L. ivanovii*, are hemolytic, whereas the non-pathogenic spp, *L. innocua*, *L. welshimeri*, and *L. grayi*, are non-hemolytic. The only exception to this rule is *L. seeligeri*, which is hemolytic but non-pathogenic. However, as mentioned above, the hemolysin from this species, LSO, is weakly active and is produced in minute amounts (see below). The strong correlation between hemolytic activity and pathogenicity in the genus *Listeria* led various groups to generate, in the mid-late 1980s, isogenic hemolysin mutants by transposon mutagenesis. Analysis of the insertion region in one of these mutants led to the identifica-

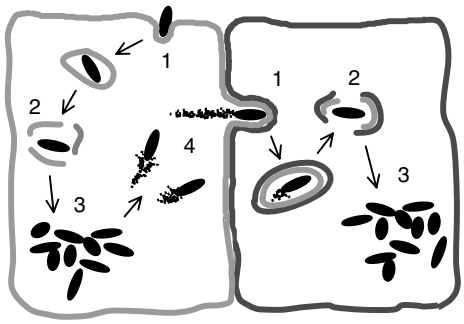

**FIGURE 40.5** Schematic representation of the intracellular infection cycle of pathogenic *Listeria*. PrfA-dependent virulence factors acting at each of the steps of the cycle: (1) cell invasion: surface proteins InlA, InlB and ActA; (2) escape from the phagosome: LLO assisted by the phospholipases, PlcA and PlcB (plus the SmcL sphingomyelinase in *L. ivanoii*); (3) rapid intracellular replication: hexose phosphate transporter, Hpt; (4) actin-based motility and cell-to-cell spread: the actin-polymerising protein, ActA.

tion and characterization of the *hly* gene (Mengaud *et al*., 1987, 1988). The non-hemolytic mutants were much less virulent in mice (increase greater than 4 logs in $LD_{50}$), their spontaneous revertants recovered full pathogenicity, and their *trans*-complementation with the *hly* gene restored virulence to wild-type levels (Gaillard *et al*., 1986; Kathariou *et al*., 1987; Portnoy *et al*., 1988; Cossart *et al*., 1989). Cell culture–based infection assays with these mutants showed that LLO is required for the intracellular survival and proliferation of *L. monocytogenes* in macrophages and non-professional phagocytes (Gaillard *et al*., 1987; Kuhn *et al*., 1988; Portnoy *et al*., 1988). Electron microscopy of infected cells revealed that *hly* mutants remained entrapped within phagosomes, indicating that LLO mediates disruption of the phagosome membrane (Gaillard *et al*., 1987). This was elegantly confirmed by experiments in which the *hly* gene was expressed in *Bacillus subtilis*; this conferred on the non-pathogenic bacterium the ability to escape from the phagocytic vacuole and to replicate within host cells (Bielecki *et al*., 1990). LLO not only mediates lysis of the primary phagosomes formed after the uptake of extracellular bacteria, but it is also required for the efficient escape of *L. monocytogenes* from the double-membrane secondary vacuole that forms upon cell-to-cell spread (Gedde *et al*., 2000; Dancz *et al*., 2002). Although LLO plays a critical role in phagosome disruption, three other membrane-damaging listerial proteins, the phospholipases C PlcA and PlcB, and the sphingomyelinase SmcL in *L. ivanovii*, cooperate in this process (see Vázquez-Boland *et al*., 2001b). The membrane lesions caused by LLO (Figure 40.4) probably facilitate the access of these enzymes to their substrates in the phagosomal membrane, leading to its total dissolution.

The CDC from *L. ivanovii*, ILO, plays a similar role in intracellular infection. Thus, like *L. monocytogenes* $LLO^-$ mutants, *L. ivanovii* $ILO^-$ mutants are strongly impaired in intracellular growth (Figure 40.6), and expression of the ILO gene in a Δ*hly* mutant of *L. monocytogenes* complements the absence of LLO (Frehel *et al*., 2003). Even LSO from the non-pathogenic species *L. seeligeri*, albeit weakly active, appears to be able to promote phagosome disruption. The weakly hemolytic phenotype of this species is in part due to defective expression of the virulence gene (*hly*)-activator protein PrfA as a result of the insertion of a divergently transcribed ORF between the two genes of the *plcA-prfA* operon (Figure 40.2). Complementation of *L. seeligeri* with a functional copy of this operon activated the expression of LSO and conferred to the bacterium the ability to escape from the phagosome and to replicate in the cytosol (Karunasagar *et al*., 1997).

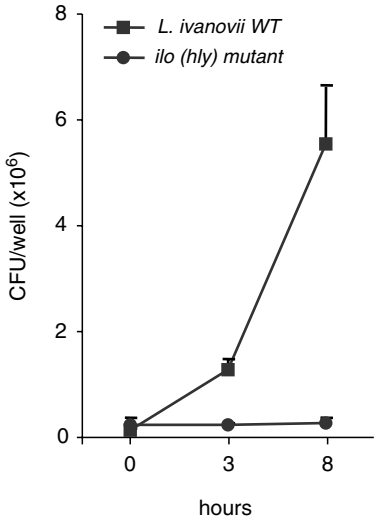

**FIGURE 40.6** Intracellular growth of wild-type *L. ivanovii* and an isogenic $ILO^-$ mutant in bovine MDBK cells. As with *L. monocytogenes*, inactivation of the *hly* gene results in total loss of intracellular proliferation capacity in *L. ivanovii*.

## Adaptation of LLO to the intracellular niche

Experiments in which the genes encoding SLO and PFO were expressed in *B. subtilis* showed that, despite their very close structural and functional similarities, not any CDC can supplant LLO's role in intracellular parasitism. SLO did not facilitate intracellular growth, whereas PFO did; however, in contrast to what is observed with LLO, PFO-mediated growth was associated with host cell damage (Portnoy *et al*., 1992). Expression of the *pfo* gene also failed to restore virulence for mice in a *L. monocytogenes hly* mutant. The resulting strain was hemolytic and showed some ability to escape from phagosomes, but PFO damaged the host cells, thereby preventing normal intracellular growth (Jones and Portnoy, 1994). These results indicated that LLO, produced by an intracellular pathogen requiring an intact intracellular niche to replicate and to spread in host tissues, has evolved mechanisms for preventing cytoxicity not found in PFO, originating from an extracellular pathogen associated with infections characterized by massive tissue destruction. PFO mutations resulting in a lack of cytotoxicity were identified by selecting for *pfo*-expressing *L. monocytogenes* mutants capable of normal intracellular growth. One type of mutation shifted the pH optimum of PFO (normally active in both acidic and neutral conditions) to a value similar to that for LLO, whereas the other decreased the cytosolic half-life of the toxin, providing

insight into the mechanisms by which LLO-mediated cytotoxicity is controlled (Jones *et al*., 1996).

Indeed, weak activity at pH 7.4 (similar to that of the eukaryotic cell cytosol) and a pH optimum of 5.5 (similar to that within phagosomes) is a clever strategy to restrict the membrane-damaging activity of LLO to the acidified vacuole, and thereby to prevent potential deleterious effects of toxin leakage into the cytosol. Evidence for such phagosome-specific compartmentalized activity of LLO has been provided by experiments using the membrane-impermeant fluorophore, 8-hydroxypyrene-1,3,6-trisulfonic acid, in murine macrophages. Rapid acidification of *L. monocytogenes*-containing phagosomes was observed, followed by an increase in pH and the release of the dye from the vacuole. Loss of the fluorophore was prevented by lysosomotropic agents, such as ammonium chloride and bafilomycin A1 (Beauregard *et al*., 1997). These data are consistent with activation of LLO in the acidified phagosome sequentially leading to membrane permeabilization, pH equilibration, and the automatic deactivation of LLO. A single amino acid in domain 4, Leu461 (position 438 in the mature protein as shown in Figure 40.1), was identified as being responsible for the low optimum pH of LLO. Among CDCs, only listerial hemolysins have a Leu residue at this position. The replacement of Leu461 by Thr, as in PFO, caused a 10-fold increase in LLO activity at neutral pH, and *L. monocytogenes* carrying the mutant LLO toxin were cytotoxic (Glomski *et al*., 2002).

The short half-life of LLO in the cytosol is due to the presence in the N-terminus of a PEST-like sequence, normally involved in the targeting of eukaryotic proteins for cytosolic degradation. Deletion of this sequence from LLO increased cytotoxicity and lowered the virulence of the strain; conversely, introduction of the PEST sequence into PFO reduced cytotoxicity, and the mutant PFO toxin supported intracellular growth when produced in *L. monocytogenes* (Decatur and Portnoy, 2000).

The relevance of these distinctive features of LLO to pathogenesis is illustrated by a recent study in mice using *L. monocytogenes* strains with mutations that fail to compartmentalize toxin activity. The more cytotoxic the strain in cell culture, the less virulent it was for mice. The depletion of neutrophils, primarily involved in the killing of extracellular *Listeria*, and treatment with gentamicin, active only against extracellular bacteria, increased the relative virulence of the cytotoxic strain, reflecting that the control of LLO cytolytic activity is a key element in the avoidance of extracellular host defenses by *L. monocytogenes* (Glomski *et al*., 2003).

## OTHER ROLES IN INFECTION

### Immune response

LLO is critically involved in the immune response to *L. monocytogenes* in several ways: (i) The LLO-mediated release of bacteria into the cytosol and subsequent intracellular growth are essential for MHC class I-restricted listerial antigen presentation and the induction of specific protective cytotoxic CD8+ T cells (Berche *et al*., 1987; Brunt *et al*., 1990; Barry *et al*., 1992; Hiltbold *et al*., 1996). It has recently been reported that cytosolic listeriae activate type I IFN expression and many IFN-β-induced genes, whereas phagosome escape-deficient (*hly*) mutants do not (Stockinger *et al*., 2002; McCaffrey *et al*., 2004). Non-pathogenic bacteria engineered to enter the host cytosol via heterologous *hly* expression also triggered this response (O'Riordan *et al*., 2002). Thus, via its membrane-disrupting activity, LLO may play a crucial role not only in the development of the acquired immune response, but possibly also in the activation of key innate immunity mechanisms. (ii) LLO is itself a major protective antigen recognized by *Listeria*-specific $CD8^+$ cytotoxic T cells (CTLs) during infection (Berche *et al*., 1987a; Safley *et al*., 1991; Bouwer *et al*., 1992; Hess *et al*., 1996; Sirard *et al*., 1997). LLO is processed very efficiently into peptides that are presented by MHC class I molecules (Villanueva *et al*., 1995), and one such peptide, nonamer LLO 91–99, is an immunodominant epitope that induces specific $CD8^+$ CTLs, which protect *in vivo* against *L. monocytogenes* infection and confer significant anti-*Listeria* immunity on naive mice upon passive transfer (Pamer *et al*., 1991; Harty *et al*., 1992). (iii) Pore formation by exogenous LLO has been shown to mediate the delivery of soluble antigens to the TAP-dependent cytosolic MHC class I antigen-presentation pathway (Darji *et al*., 1995, 1997), providing an additional mechanism for the generation of $CD8^+$ CTLs against antigens secreted/released by extracellular *L. monocytogenes*. (iv) LLO elicits a potent humoral response and anti-LLO antibodies are detectable after infection with *L. monocytogenes* (see below). Administration of a murine anti-LLO neutralizing monoclonal antibody increased resistance to *Listeria* infection in mice (Edelson *et al*., 1999), thus challenging the old paradigm of cell-mediated immunity, according to which antibodies are not involved in protection against intracellular parasites (Kaufmann, 1993). It is therefore possible that the humoral arm of the immune system contributes to protective immunity against *L. monocytogenes* and that LLO also plays a key role in this protection. Finally, (v) through its modulin activity,

LLO may influence orchestration of the immune response to *Listeria* (see next section).

## Modulation of host responses

LLO has been shown to induce a number of host-cell responses in a variety of cell types, indicating that this toxin is a versatile virulence factor, not only having a direct physical action on phagosome membranes, but also signaling effects on host cells that can influence the fate of *Listeria* infection. One of the mechanisms possibly involved is related to the ability of exogenous LLO to permeabilize cell membranes. Exogenous LLO at sublytic concentrations has been shown to produce $Ca^{2+}$-permeable pores, causing the influx of extracellular $Ca^{2+}$ions into the cell (Repp *et al*., 2002). This may enable cell surface-attached *L. monocytogenes* bacteria to modulate/enhance their entry into host cells, the key first step in listerial intracellular parasitism (Dramsi and Cossart, 2003). LLO-mediated permeabilization of the cell membrane is also required for the induction by the listerial phosphatidylinositol-specific phospholipase C (PlcA) of phosphoinositide hydrolysis and diacylglycerol (DAG) accumulation in human endothelial cells (Sibelius *et al*., 1996a), and for lipid mediator generation and activation in neutrophils (Sibelius *et al*., 1999). Infection experiments with isogenic *hly* and *plcA L. monocytogenes* mutants have also suggested that LLO is required for the induction of PlcA-mediated DAG generation and PKC translocation early in macrophage infection (Wadsworth and Goldfine, 2002). CDC-mediated translocation of effector proteins has recently been demonstrated with the related streptococcal toxin SLO, and it has been suggested that this mechanism may play in Gram-positive bacteria a role similar to that of the type III secretion systems in Gram-negative bacteria (Madden *et al*., 2001; Walev *et al*., 2001).

LLO may also act as a modulin via a mechanism independent of its membrane-permeabilizing activity. Thus, exposure to non-cytolytic LLO-cholesterol complexes has been shown to induce cytokine gene expression (Nishibori *et al*., 1996) and IL-1 release (Yoshikawa *et al*., 1993) in murine macrophages, the release of IL-12, IL-18, and IFN-γ in murine spleen cells (Kohda *et al*., 2002; Nomura *et al*., 2002; Ito *et al*., 2003), and the induction of lipid second messengers in human endothelial cells (Sibelius *et al*., 1996b). Non-cytolytic LLO-cholesterol complexes retain the capacity to bind to cell membranes (see above), and such responses are unlikely to be generated unless the toxin interacts with cell surface receptors, suggesting that CDCs are able to recognize membrane components other than cholesterol. Indeed, it has recently been shown that the human cell-specific CDC ILY from *S. intermedius* uses CD59 as its cellular receptor (Giddings *et al*., 2004). These observations raise the interesting possibility that LLO released extracellularly and rendered non-cytolytic by complexation with free cholesterol present in body fluids may be targeted to host cell surfaces and mediate signaling events upon binding to specific membrane receptors.

Infection experiments in cell culture models using wild-type and *hly*-mutant *L. monocytogenes* bacteria suggest that intracellularly delivered LLO may also induce signaling events leading to a variety of cell responses. These include activation of the Raf-Mek-MAP kinase pathway in epithelial cells (Tang *et al*., 1994, 1996; Weiglein *et al*., 1997), the induction of mucus exocytosis in intestinal cells (Coconnier *et al*., 1998), cytokine gene expression in macrophages (Kuhn and Goebel, 1994; Nishibori *et al*., 1996), degranulation and leukotriene formation in neutrophils (Sibelius *et al*., 1999), and Fas ligand expression on T lymphocytes (Zenewicz *et al*., 2004). In endothelial cells—a major target cell in the neuropathogenesis and placental invasion by *L. monocytogenes*—LLO provokes lipid mediator generation (phosphoinositides, DAG and ceramide) (Sibelius *et al*., 1996a), the up-regulation of adhesion molecules (Drevets, 1998; Kayal *et al*., 1999; Krüll *et al*., 1997), nitric oxide (NO) synthesis, and the release of proinflammatory cytokines such as IL-6, IL-8, monocyte chemotactic protein-1, and granulocyte-macrophage colony-stimulating factor (Kayal *et al*., 1999; Rose *et al*., 2001). This is associated with the induction of the NF-κB signaling pathway via activation of the IκB kinase β subunit of the IKK complex, an effect that has been shown to be mediated by LLO in experiments involving heterologous expression of the *hly* gene in the non-pathogenic species *L. innocua* (Kayal *et al*., 1999, 2002).

Further evidence that LLO is important in modulating the immune response comes from experiments using purified LLO (Carrero *et al*., 2004a), which showed that the toxin was responsible for lymphocyte apoptosis as typically seen in mouse splenic cells both *ex vivo*, especially in type I IFN-activated lymphocytes (Carrero *et al*., 2004b), and *in vivo* (Merrick *et al*., 1997), upon infection with *L. monocytogenes*. The massive regression of the spleen white pulp appears to be pathognomonic of *Listeria* infection in mice (Marco *et al*., 1991; Conlan, 1996) and may well be caused by LLO-mediated apoptotic lymphocyte depletion. Thus, LLO appears to play dual immunomodulatory roles with similar outcomes in host-parasite interaction, inducing the mobilization of innate host defenses (thereby favoring the spread of infection by making available more host cells for bacterial replication) and at the same time attenuating the T cell-mediated responses it inevitably triggers through its role as

immunodominant, cytosolic-released antigen. This immunosuppressive effect is consistent with other observations linking LLO to the down-regulation of major histocompatibility complex I (antigen I-Ab) and II (antigen H-2K$^d$) gene expression, as observed in infected murine macrophages (Schüller *et al*., 1998), and the interference with antigen presentation through the induction of apoptosis in dendritic cells (Guzmán *et al*., 1996) and type I IFN-sensitized macrophages (Stockinger *et al*., 2002).

A note of caution must be introduced, however, as although in most cases the above signaling effects can be reproduced by exposure to exogenous purified LLO, it remains unclear whether such effects are directly exerted by the toxin, are due to other bacterial components (which may also be present as contaminants in the toxin preparations), or are just indirect, nonspecific consequences of membrane destabilization or bacterial intrusion into the cytosol.

Finally, a recent study has revealed a facet of LLO that may be highly relevant to pathogenesis: lipid raft clustering. Gekara and Weiss (2004) have shown that the treatment of J774 murine macrophages with LLO led to raft aggregation and clustering of CD14 and CD24 receptors, suggesting that this may be a key mechanism by which the listerial toxin (and potentially any other CDC) modulates host cell responses.

## APPLICATIONS OF LLO RESEARCH

With its optimum activity at pH 5.6, its reduced activity at neutral pH, and its short cytosolic half-life, LLO is an ideal molecule for selective perforation of the phagosomal membrane without collateral damage to the host cell. This unique property of LLO has been exploited to develop strategies to introduce therapeutic macromolecules into the cytosol. Needless to say, since the discovery of its key role as the immunodominant CD8$^+$ antigen in the protective immune response against *L. monocytogenes* in the mouse model, LLO has been extensively used as a research tool in basic immunological studies (Harty and Bevan, 1992; Unanue, 1997; Shen *et al*., 1998) and in investigations on the efficacy of experimental vaccines (Cornell *et al*., 1999; Rüssmann *et al*., 2001, 2003; Yoshida *et al*., 2001; Barry *et al*., 2003).

### Bacteria-based antigen and DNA delivery vehicles

A number of bacteria have been engineered to induce a robust CD8$^+$-based cytotoxic immune response, necessary for the clearance of intracellular pathogens and tumors, via heterologous expression of the listerial *hly* gene alone or in combination with recombinant antigens. Examples include *Escherichia coli* (Hu *et al*., 2004; Radford *et al*., 2003), *Mycobacterium bovis* BCG (Hess *et al*., 1998), or avirulent mutants of *Salmonella enterica* serovar Typhimurium (Hess *et al*., 2000) and *Bacillus anthracis* (Sirard *et al*., 1997), all of which have provided ample proof of the principle that LLO can indeed mediate the efficient presentation of antigens via the cytosolic MHC class I-restricted pathway (Dietrich *et al*., 2001).

The considerable amount of knowledge gathered on the pathogenesis of *Listeria* infection and its molecular determinants make *L. monocytogenes* bacteria themselves an ideal platform for the rational development of recombinant oral vaccines based on LLO-mediated induction of cellular immunity (Iknomidis *et al*., 1995; Guzman *et al*., 1997; Weiskirch and Paterson, 1997; Dietrich *et al*., 2003). A *Listeria*-based antigen carrier system has the clear advantage that its gene regulation machinery has naturally evolved to ensure the correct spatio-temporal synthesis of LLO (Kreft and Vázquez-Boland, 2001). Being a Gram-positive bacterium, *L. monocytogenes* is also devoid of lipopolysaccharide-associated toxicity. Moreover, in addition to CD8$^+$ CTLs, *L. monocytogenes* also elicits a vigorous Th1-

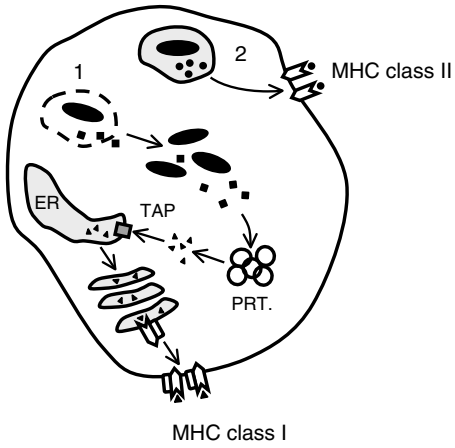

**FIGURE 40.7** Bacteria-based intracellular vaccine delivery and antigen processing and presentation pathways involved. (1) LLO-expressing bacteria lyse the phagosome and their antigens (squares) leak into the cytosol, where they are processed by the proteasome (PRT) into peptides (triangles); these peptides are translocated into the endoplasmic reticulum (ER) by the transporter associated with antigen processing and presentation (TAP) and loaded onto major histocompatibility complex (MHC) class I molecules, leading to induction of a CD8$^+$-mediated response. (2) In contrast, bacteria that remain entrapped within phagosomes present their antigens (circles) primarily via the endosomal, MHC class II pathway, leading to induction of a CD4$^+$-mediated immune response.

biaised $CD4^+$ T-cell response (Guzman *et al*., 1998), possibly because a portion of the bacteria remain entrapped within phagosomes and, consequently, their antigens are processed through the endosomal/phagolysosomal pathway (Figure 40.7). Combined deletions in known virulence genes, such as the *actA-plcB* operon required for cell-to-cell spread, and in metabolic genes leading to auxotrophy—e.g., genes of the D-alanine biosynthetic pathway involved in the synthesis of the cell wall—can be used to create hyperattenuated, environmentally safe *Listeria* vaccine carriers (Thompson *et al*., 1998; Angelakopoulos *et al*., 2002). Robust cell-mediated immunity has been achieved using recombinant *L. monocytogenes* as a vehicle for expression of genes encoding a variety of proteins, including viral (Ikonomidis *et al*., 1994, 1997; Frankel *et al*., 1995; Shen *et al*., 1995) and tumor (Pan *et al*., 1995; Jensen *et al*., 1997; Paglia *et al*., 1997) antigens. Promising results have been obtained in mice with *Listeria*-based anti-HIV (Mata *et al*., 1999, 2001; Lieberman and Frankel, 2003; Peters *et al*., 2003) and anti-cancer (Pan *et al*., 1995; Gunn *et al*., 2001) vaccines. Protection and even the regression of established tumors have been achieved with the latter, demonstrating the therapeutic potential of this bacterial carrier and the LLO-mediated antigen delivery system for curing neoplastic diseases.

*L. monocytogenes* can also be used as a vector for transferring DNA into eukaryotic cells. A plasmid inserted with model antigen genes under the control of a eukaryotic promoter and a *Listeria* phage endolysin gene under the control of the strictly PrfA-dependent *actA* gene promoter (which is selectively activated in the cytosol) were introduced into an *L. monocytogenes* strain attenuated by a deletion in the *actA-plcB* operon. Bacteria underwent lysis upon entry into the cytosol and generated an MHC class I–restricted immune response against the plasmid-encoded model antigens (Dietrich *et al*., 1998). These experiments demonstrated that *Listeria* also provides a system of potential value for the development of DNA vaccines and gene therapy tools (Spreng *et al*., 2000). DNA transfer to host cells has been achieved using LLO-expressing *E. coli* strains rendered invasive by introduction of the *Yersinia pseudotuberculosis inv* gene (Grillot-Courvalin *et al*., 1998).

## Other tools for the cytosolic delivery of macromolecules

Alternative strategies exploiting the capacity of LLO to deliver macromolecules to the cytosolic pathway include the co-administration of the toxin (Darji *et al*., 1995) or its co-encapsulation into pH-sensitive liposomes (Lee *et al*., 1996; Mandal *et al*., 2003). Efficient MHC class I antigen presentation and $CD8^+$ responses have been achieved with these methods (Darji *et al*., 1997; Tanabe *et al*., 1999; Mandal and Lee, 2003), indicating that they are effective in rerouting the passenger or cargo proteins from the endosomal to the cytosolic antigen presentation pathways. LLO-liposomes (called "listeriosomes") can be used for bypassing the endosomal/lysosomal-mediated degradation and/or excretion pathway, thus ensuring that encapsulated chemotherapeutic drugs reach their intracellular targets, as recently shown with the plant-derived, antitumoral toxin gelonin (Provoda *et al*., 2003). Antisense oligonucleotides have also been successfully delivered into the cytosol using listeriosomes (Mathew *et al*., 2003).

## *In vivo* expression technology (IVET) systems

Based on the fact that *hly* mutants are non-hemolytic on blood agar plates and are significantly impaired in virulence, LLO has been used as both a reporter and a selection system to identify *in vivo*-expressed genes in *L. monocytogenes*. The system is based on the screening of *L. monocytogenes* chromosomal libraries generated by inserting random DNA fragments upstream of a promoterless *hly* gene cloned into a shuttle vector. These libraries are expressed in an Δ*hly* mutant, and selection is carried out in mice. Clones with increased survival are isolated, and those carrying constitutive or *in vivo*-induced promoters are differentiated via their respective $LLO^+$ and $LLO^-$ phenotypes. Among the *in vivo*-expressed genes identified was *plcA* (Gahan and Hill, 2000; Dubail *et al*., 2000), a known virulence determinant involved in intracellular survival, providing evidence of the workability of the LLO-based *in vivo* selection system.

## Diagnostic tools

LLO elicits a potent humoral response during infection (Grenningloh *et al*., 1998), and several studies have shown that the detection of LLO-specific antibodies can be used in the serodiagnosis of listeriosis and in serological surveys of *Listeria* infection both in humans (Berche *et al*., 1990; Gholizadeh *et al*., 1996, 1997) and animals (Miettinen and Husus, 1991; Low and Donachie, 1991; Low *et al*., 1992; L'hopital *et al*., 1993). The *hly* gene has been also used as target for the specific detection and quantification of *L. monocytogenes* by molecular (PCR-based) methods (Nogva *et al*., 2000; Rodríguez-Lázaro *et al*., 2004).

## ACKNOWLEDGMENTS

Although we have endeavored to cite all major contributions to current knowledge on LLO, due to space limitations or involuntary omission, some may not have been appropriately cited, for which we apologize to the authors. Our research on *Listeria* is funded by grants from The Wellcome Trust, the Spanish Ministry for Education and Science, and the European Union.

CHAPTER

# 41

# *Enterococcus faecalis* cytolysin toxin

*Karen Carniol and Michael S. Gilmore*

The cytolysin toxin, produced by the Gram-positive bacterium *Enterococcus faecalis*, is unique among bacterial toxins in its ability to lyse both bacterial cells and eukaryotic cells. It was first identified as a hemolysin, but further studies classified it as a divergent member of the lantibiotic family of bacteriocins. This chapter describes what is known about the range of target cells, the molecular determinants of cytolysin activity, the mobility of the cytolysin-encoding locus, regulation of the expression of cytolysin activity, and the role of cytolysin in enterococcal virulence.

## BACKGROUND ON ENTEROCOCCI

Enterococci exist largely as commensal organisms in the gastrointestinal tracts of a wide variety of animals. They thrive in this environment, achieving an average density of roughly $10^6$ colony-forming units per gram of feces (Noble, 1978). Enterococci can also be pathogens colonizing blood, vascular tissue, and retinal tissue (Gilmore *et al*., 2002). Two species of Enterococcus—*faecalis* and *faecium*—are found frequently as the causative agents of nosocomial infections and have emerged as the leading cause of surgical site infections, the second-leading cause of bloodstream infections, the third-leading cause of nosocomial urinary tract infections, and are frequent isolates from subacute endocarditis (Richards *et al*., 2000). Enterococcal infections are of particular concern since strains that are resistant to virtually all available antibiotic therapies have emerged over the last two decades (Huycke *et al*., 1998).

Antibiotic resistance traits are most widespread in strains of *E. faecium*, yet *E. faecalis* strains comprise 70–80% of all nosocomial enterococcal infections (Jett *et al*., 1994; Jones *et al*., 2004). The pathogenicity of *E. faecalis* strains may well be attributable to a larger repertoire of non-antibiotic resistance virulence factors, including the cytolysin toxin (Elsner *et al*., 2000).

## PRE–MOLECULAR–ERA STUDIES OF CYTOLYSIN

E.W. Todd's 1934 study of the hemolytic activity of group-D streptococcal strains (subsequently called *Streptococcus zymogenes*, now called *Entercoccus faecalis*) is generally recognized as the first characterization of what is now known to be the Enterococcus cytolysin. Todd observed hemolysis on blood agar, but was not able to recover the hemolytic activity from liquid culture supernatants, a paradox that inspired the designation "pseudohemolysin." The reasons for this apparent paradox are now better understood and are described below. Subsequent development of a horseflesh infusion medium that could support recovery of active toxin from culture filtrates enabled Todd to characterize the toxin as acid and heat labile, oxygen stable, and non-immunogenic in rabbits (Todd, 1934). Studies by Kobayashi (1940), Roelofsen *et al*. (1964), and Basinger and Jackson (1968) defined a spectrum of susceptibility to cytolysin among erythrocytes from different species. Human, horse, dog, rabbit, and mouse erythrocytes are the most susceptible to lysis, sheep erythrocytes are largely resistant, and goose erythrocytes are completely resistant.

In 1949 Sherwood *et al*. noted that a majority of hemolytic enterococcal strains also produced a bacteriocin active against other streptococcal strains.

Succeeding studies (Stark, 1960; Brock *et al*., 1963; Jett and Gilmore, 1990) demonstrated that several Gram-positive bacteria are susceptible to this bacteriocin activity, including *Staphylococcus, Streptococcus, Clostridium, Leuconostoc, Lactobacillus, Mirococcus, Corynebacterium*, and some *Bacillus* species. *Bacillus subtilis* is only partially susceptible and *Bacillus polymyxa* is completely resistant, as are Gram-negative species, such as *Escherichia coli* and *Proteus vulgaris*. The properties of cells susceptible to cytolysin versus those that are refractory, and the basis for intermediate degrees of sensitivity, are not clear.

Brock *et al*. (1963) noted the complete correspondence between hemolytic activity and the bacteriocin activity elaborated by *S. zymogenes* (hemolytic *E. faecalis*) and speculated that the activities were due to the same molecular entity. Brock and Davie (1963) furnished proof for this speculation by demonstrating that UV irradiation of this strain caused simultaneous loss of hemolytic and bacteriocin activity, and that a reversion event restoring one activity was always concomitant with restoration of the other activity. The term *cytolysin* was adopted to reflect the dual hemolytic/bacteriocin activity of this particular toxin (Gilmore, 1991).

Granato and Jackson (1969) demonstrated that cytolytic activity required more than one factor. Nonhemolytic mutants (obtained by NTG mutagenesis) were assayed for the ability to complement each other extracellularly in pairwise cross-streaks on blood agar. The mutants fell into two complementation groups with distinctive properties—one group appeared defective in a lytic component, the other defective in an activating component. Refined genetic techniques and nucleotide sequence analysis of the cytolysin locus would subsequently elucidate the molecular basis for this astute observation.

## THE CYTOLYSIN LOCUS

The cytolysin locus was initially observed to be encoded on conjugative plasmids in *E. faecalis* strains from infections, as first demonstrated by plasmid curing and broth mating experiments (Dunny and Clewell, 1975; Jacob *et al*., 1975; Ike and Clewell, 1992). At least eight different conjugative plasmids, falling into at least three incompatibility groups, have been observed to encode the cytolysin determinants (Ike and Clewell, 1992). These plasmids may be transferred between strains via a pheromone-responsive conjugation pathway (Clewell *et al*., 1982; Huycke *et al*., 1992; Clewell, 1993; Dunny and Leonard, 1997). Transposon mutagenesis mapped the cytolysin locus on one of these plasmids, pAD1, to an 8-kb region that was sufficient to impart cytolysin activity to *E. coli* (Ike *et al*., 1990). Sequencing of this locus revealed that it contained a six-gene operon (Segarra *et al*., 1991; Coburn *et al*., 1999).

More recently, the cytolysin operon has been observed to be encoded on the chromosome (Ike and Clewell, 1992; Shankar *et al*., 2002). An isolate from a mid-1980s hospital ward outbreak, and a second representing the first vancomycin resistant isolate in the United States, were both found to harbor a chromosomal copy of the cytolysin operon (Shankar *et al*., 2002). In these strains, the cytolysin operon was linked to other virulence genes within a stereotypical pathogenicity island (Shankar *et al*., 2002). While this pathogenicity island appears to be stably integrated into the chromosome, the cytolysin operon itself is subject to deletion at a frequent rate. A precise excision of a 17,036 basepair fragment of DNA that includes the 3' half of the cytolysin operon and six more ORFs, including the virulence gene *esp*, occurs at a frequency of 1 in $10^3$ during overnight *in vitro* cultivation (Shankar *et al*., 2002). This frequency is consistent with that of phase variation in other bacterial species (Fierer and Guiney, 2001). Thus, the cytolysin operon is a variable feature of the *E. faecalis* genome and may be lost or gained, thereby modulating virulence.

## THE MOLECULAR COMPONENTS OF CYTOLYSIN

The cytolytic phenotype requires the activity of at least five different proteins, all of which are encoded in the cytolysin operon (Segarra *et al*., 1991; Gilmore *et al*., 1994). The sixth gene in the cytolysin operon encodes an immunity factor that protects the toxin-producing cell from the toxin (Coburn *et al*., 1999).

The first and second genes of the operon, $cylL_L$ and $cylL_S$, encode the structural components of the toxin: two different peptide subunits of slightly different sizes. $CylL_L$, the larger subunit, and $CylL_S$, the smaller subunit, are initially synthesized as precursor peptides of 68 and 63 residues, respectively (Segarra *et al*., 1991). Each peptide must undergo a battery of posttranslational modifications, including residue dehydration, intra-peptide thioether bond formation, secretion, and two separate steps of proteolytic processing, before becoming active (Booth *et al*., 1996). Postmodification, $CylL_L$ is 38 amino acids and 3.44 KDa (this active form is designated $CylL_L$"), and $CylL_S$ is 21 amino acids and 2.03 KDa (designated $CylL_S$ ") (Segarra *et al*., 1991; Booth *et al*., 1996).

Amino acid analysis of the secreted forms of the peptides demonstrated that two of the three serines in $CylL_L$", the one serine in $CylL_S$", four of the five threonines in $CylL_L$", and all three threonines in $CylL_S$" were dehydrated (Booth *et al*., 1996). Thioether bond formation between a dehydrated serine or threonine and a local cysteine side chain results in the formation of a lanthionine or a β-methyllanthionine residue. Two such residues were detected in $CylL_L$", one in $CylL_S$" (Booth *et al*., 1996). The threonines encoded by codon 31 of $cylL_L$ and codon 42 of $cylL_S$ turned out to be the N terminal residue of each peptide, following complete processing to the mature peptides, and both were predicted to convert to 2-oxo-butyrines, following dehydration based on comparison to related toxins (Kellner *et al*., 1989; Sahl *et al*., 1995) and the observation of a hard block to Edman degradation at these residues (Booth *et al*., 1996). Other yet uncharacterized posttranslational modifications may also take place since the noted ones do not fully account for the discrepancy in predicted molecular weight based on DNA sequence and the mass spectroscopy measurements (Booth *et al*., 1996).

The properties of the structural subunits, which are small, cysteine-rich with dehydrated serines and threonines, lanthionine derivatization, hydrophilic N-termini, and hydrophobic carboxy-termini, classify them as members of the family of lantibiotic bacteriocins synthesized by a number of Gram-positive bacteria. The overall structure of the operon also resembles that of other lantibiotic-encoding loci. Thus, the *E. faecalis* cytolysin has been classified as a Type-A, lactocin S-subtype, pore-forming lantibiotic (Sahl *et al*., 1995). For several years, the *E. faecalis* cytolysin was the only known two-component lantibiotic, but others have since been identified, such as lactacin 3,147 from *Lactococcus lactis* (Ryan *et al*., 1996; Ryan *et al*., 1999) and staphylococcin C55 from *Staphylococcus aureus* (Navaratna *et al*., 1998; Navaratna *et al*., 1999).

The posttranslationally modified forms of $CylL_L$ and $CylL_S$ are designated $CylL_L^*$ and $CylL_S^*$, respectively. The modifications appear to be catalyzed directly or indirectly by a protein called CylM, encoded by the third gene in the cytolysin operon, *cylM*. CylM shares sequence similarity with a class of proteins involved in lantibiotic biosynthesis (Gilmore *et al*., 1994; Sahl *et al*., 1995) and mutations in *cylM* abolish cytolytic activity (Gilmore *et al*., 1994). Studies that probe the role and mechanism of the CylM protein more directly have not been done.

Export of $CylL_L^*$ and $CylL_S^*$ depends on the fourth gene in the operon, *cylB*, that encodes an ABC transporter protein of the HlyB family (Gilmore *et al*., 1990). Mutations that disrupt the production or folding of the CylB protein prevent externalization of both toxin subunit precursors, while mutations predicted to truncate CylB just before the C-terminal ATP-binding domain block only the secretion of $CylL_L^*$, not of $CylL_S^*$ (Gilmore *et al*., 1990; Gilmore *et al*., 1994). These results suggest that secretion of $CylL_L^*$ is an energy-dependent process, while secretion of $CylL_S^*$ depends on a concentration gradient. The CylB protein is predicted to contain an N-terminal cysteine protease domain, which is conserved among other dedicated transporters of peptide bacteriocins. In the case of LagD, the ABC transporter that exports the peptide precursors of the *Lactococcus lactis* bacteriocin lactacin 3,147, this protease domain was shown to cleave the leader sequence from the toxin precursor peptides (Havarstein *et al*., 1995). Given the sequence similarity between LagD and CylB, and also within the leader sequences of the *L. lactis* bacteriocin peptides and those of $CylL_L$ and $CylL_S$, it is presumed that CylB serves a homologous function to LagD, specifically the proteolytic cleavage of $CylL_L^*$ and $CylL_S^*$ concomitant with export. This first proteolytic processing step trims 24 residues from $CylL_L^*$ and 36 residues from $CylL_S^*$ (Booth *et al*., 1996). The cleavages take place within a stretch of 26 amino acids that are highly conserved (25 residues are identical) between the two peptides, although this stretch is situated closer to the N terminus of $CylL_L$ and is more centrally located in $CylL_S$. Precursor peptides that have undergone posttranslational modification, cleavage of the leader peptide, and secretion are designated $CylL_L'$ and $CylL_S'$.

$CylL_L'$ and $CylL_S'$ must each undergo an additional processing step before they are functional as a toxin. This extracellular activator, detected in the blood agar complementation analysis of Granato and Jackson (1969), is the CylA protein, a subtilisin-like serine protease encoded by the fifth gene in the operon, *cylA* (Segarra *et al*., 1991; Booth *et al*., 1996). CylA is synthesized as a pre-proenzyme whose secretion does not depend on *cylB*; rather, it is likely secreted via the general cellular secretion machinery (Segarra *et al*., 1991). Functional studies with purified CylA indicate that it removes the six N-terminal amino acids from both $CylL_L'$ and $CylL_S'$, cleaving within what remains of the stretch of amino acids conserved between the two subunits. The products of the CylA cleavages are the active lytic subunits, $CylL_L$" (38 amino acids) and $CylL_S$" (21 amino acids) (Booth *et al*., 1996). These interact in an unknown way to create a pore in the target cell membrane. The peptide sequence and processing sites of $CylL_L$ and $CylL_S$ are depicted in Figure 41.1.

The immunity factor encoded by the most 3' gene in the operon is called CylI. Sequence analysis of the 327-codon *cylI* ORF predicts a putative signal peptide,

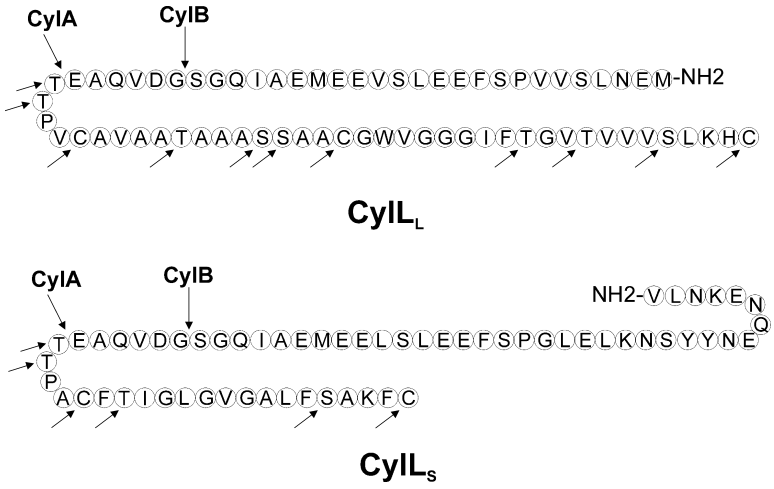

**FIGURE 41.1** The primary amino acid sequence of the cytolysin subunits $CylL_L$ and $CylL_S$. $CylL_L$ and $CylL_S$ are synthesized as 68 and 63 amino acid precursors. CylB cleaves leader sequences from each peptide as they are secreted. Following export, CylA proteolytically removes an additional six amino acids from the N-terminus of each subunit. The recognition sites for CylB and CylA cleavage are indicated by the labeled arrows, and the additional arrows indicate amino acids for which there is evidence of modification, or which are hypothesized to be modified.

putative transmembrane domains, and a putative zinc-metalloprotease motif, but functional studies to verify these predictions and to determine the mechanism of immunity have not been completed.

## REGULATION OF CYTOLYSIN EXPRESSION

The promoter for the *cyl* operon has been identified by primer extension analysis and is characterized by canonical −10 and −35 boxes. Reverse transcription PCR analysis indicates that all six genes are polycistronic and no internal promoters have been detected within the operon (W. Haas and M.S.G., unpublished observations). *cylA* (along with *cylI*) had been thought to be transcribed independently of the *cyl* operon (Segarra *et al*., 1991; Coburn *et al*., 1999), but an appropriately placed promoter has eluded identification. Results leading to that supposition may have been artefacts of read-through transcription from other vector elements. Interestingly, quantification of messages by real-time PCR shows that the $cylL_L$ and $cylL_S$ transcripts are five- to sixfold more abundant than the *cylM*, *cylB*, *cylA*, and *cylI* transcripts. An internal terminator element located between the $cylL_S$ and *cylM* genes seems to limit the quantity of full-length transcripts, perhaps serving as a mechanism for generating an efficient ratio of structural elements to catalytic elements for toxin production (W. Haas and M.S.G., unpublished observations).

Investigations into the regulation of expression of the cytolysin operon *in trans* have recently revealed three interesting and unexpected regulatory features of the system. (i) The cytolysin promoter is largely repressed by the dual action of two novel proteins, CylR1 and CylR2. (ii) The mature, active form of the small toxin subunit $CylL_S$" induces expression of the cytolysin operon once it exceeds a threshold concentration. (iii) The mature, active form of the large toxin subunit $CylL_L$" inhibits the autoinducing activity of $CylL_S$" in the absence of target cells.

### Repression by CylR1 and CylR2

Immediately upstream of the *cyl* operon lies a two-gene operon in the opposite orientation that is divergently transcribed from a promoter that overlaps with the *cyl* operon promoter (Haas *et al*., 2002). Using a *lacZ* fusion, experiments monitoring activity of the cytolysin operon promoter $P_{lys}$ demonstrated that transcription was significantly reduced when *cylR1* and *cylR2* were concomitantly expressed in the same cell (Haas *et al*., 2002). The promoter-proximal of these regulatory genes was named *cylR1,* and the promoter-distal gene named *cylR2*. Mutations in either *cylR1* or *cylR2* or both resulted in full derepression of the cytolysin promoter (Haas *et al*., 2002).

The 66 amino acid CylR2 protein has been purified, and both its x-ray crystal structure (at 1.9A resolution) and its NMR solution structure solved (Rumpel *et al*., 2004; Razeto *et al*., 2004). The structures show that CylR2 dimerizes and possesses a helix-turn-helix DNA-binding domain. Gel-shift analysis indicates that CylR2 binds specifically to a 22-basepair inverted repeat sequence that lies just upstream of the −35 box of the $P_{lys}$ promoter (Rumpel *et al*., 2004). In the presence of the inverted repeat DNA fragment, CylR2 residues undergo NMR chemical shift perturbations that corroborate the gel-shift results and implicate residues Q29, N40, and Q44 as particularly important for DNA binding. Accordingly, a $CylR2^{N40A}$ mutant fails to

repress a $P_{lys}$-*lacZ* fusion, furnishing strong evidence that CylR2 directly represses transcription from the $P_{lys}$ promoter (Rumpel *et al*., 2004).

CylR1 has not yet been purified. Sequence analysis indicates that it is 94 residues long with three predicted alpha-helical transmembrane domains (Haas *et al*., 2002). There are no close homologues in the GenBank database, and the mechanism by which it co-represses the $P_{lys}$ promoter along with CylR2 is yet unknown. As discussed below, CylR1 is presumed to play a role in transmitting the signal for induction of transcription of the *cyl* operon to the promoter-binding protein CylR2.

## Induction by $CylL_S$"

Repression of $P_{lys}$ by CylR1 and CylR2 is not absolute; a low basal level of transcription is still detected in the presence of both intact genes (Haas *et al*., 2002). This allows for the possibility that one or more *cyl* operon products could serve as a transcriptional autoinducer in a quorum-sensing capacity. That is, a threshold concentration of a gene product, achieved via basal-level transcription only when cell density is high, triggers increased transcription from its own promoter. Quorum-sensing autoinduction is employed by a number of pathogenic bacteria to ensure that virulence genes are only highly expressed when there are enough cells present to mount a successful infection (Miller and Bassler, 2001) (see Chapter 4). There is strong evidence that this is the case with induction of *cyl* operon expression. The mature, active form of the small toxin subunit $CylL_S$", encoded by the first gene in the operon, induced transcription from the $P_{lys}$ promoter when added to a culture of a $P_{lys}$-*lacZ* reporter strain at a sufficiently high concentration (Haas *et al*., 2002). Additionally, a $P_{lys}$-*lacZ* reporter strain that also harbored the native cytolysin operon did not express *lacZ* until the cell density in planktonic culture exceeded $10^7$ cells $mL^{-1}$. Only $CylL_S$" and not $CylL_S$' or any form of $CylL_L$ was found to have this autoinducing activity (Haas *et al*., 2002).

The mechanism by which $CylL_S$" effects derepression of $P_{lys}$ is unknown. A simple model is one in which $CylL_S$" interacts with the putative membrane-bound CylR1 protein at the cell surface, causing a signal transduction event that disrupts the repressive binding of CylR2 on the $P_{lys}$ promoter (Haas *et al*., 2002). However, this model is likely to prove too simple, as the DNA binding site of CylR2 is predicted to also block transcription from the divergent promoter ($P_R$) of the *cylR1R2* operon (Rumpel *et al*., 2004), and yet $CylL_S$" does not induce transcription of *cylR1* or *cylR2* concomitantly with transcription of the *cyl* operon (Haas *et al*., 2002).

## Target cell sensing by $CylL_L$"

As described above, a long unanswered puzzle about *E. faecalis* cytolytic activity had been E.W. Todd's observation that it could not be recovered from filtrates of cultures of the same strains that exhibited hemolytic activity on blood agar (Todd, 1934). However, if erythrocytes were included in the liquid cultures, *cyl*-dependent hemolytic activity was observed (Coburn *et al*., 2004). Together, these results suggested that there might be a mechanism to prevent cytolysin expression in the absence of target cells and to trigger it in their presence.

A first hint that $CylL_L$" might be a target cell sensor came from experiments examining $CylL_S$"-inducing activity. $CylL_S$"-dependent induction of *cyl* operon transcription was significantly greater in strains harboring a mutation in $cylL_L$ that truncated $CylL_L$' than in a wild-type strain (Haas *et al*., 2002; Coburn *et al*., 2004). The ability of $CylL_L$" to inhibit the inducing activity of $L_S$" was confirmed by experiments with purified $CylL_L$" and $CylL_S$" demonstrating that (i) $CylL_L$" blocks $CylL_S$"-mediated induction of a $P_{lys}$-*lacZ* reporter strain when the two components are present in equimolar concentration, and (ii) when mixed in solution $CylL_L$" and $CylL_S$" form inert, stable, SDS-resistant multimers ranging in apparent size from 132 kDa to over 216 kDa (Coburn *et al*., 2004).

A model proposing that $CylL_L$" prevents $CylL_S$"-mediated induction in the absence of target cells, but not in their presence, emerged from experiments demonstrating that pre-incubating $CylL_L$" with erythrocytes attenuates its ability to inhibit $CylL_S$"-mediated induction of the *cyl* operon (Coburn *et al*., 2004). The ability of $CylL_L$" to influence the activity of $CylL_S$" based on the presence of target cells depends on the ability of $CylL_L$" to absorb or bind to a target cell membrane differently than $CylL_S$". Evidence that this is indeed the case is derived from surface plasmon resonance experiments demonstrating that $CylL_L$" binds to lipid bilayers with more than a sixfold greater affinity than $CylL_S$". Furthermore, the kinetics of hemolysis are greatly increased if $CylL_L$" is preincubated with erythrocytes prior to addition of $CylL_S$", but are delayed if the subunits are added in the opposite order (Coburn *et al*., 2004).

Taken together, the experimental results support a model in which the structural subunits of the cytolysin toxin are also centrally involved in regulating toxin expression, such that the cell does not waste energy synthesizing and processing toxin unless two important criteria are met: Bacterial cell density is high and target cells are present. This model is illustrated in Figure 41.2.

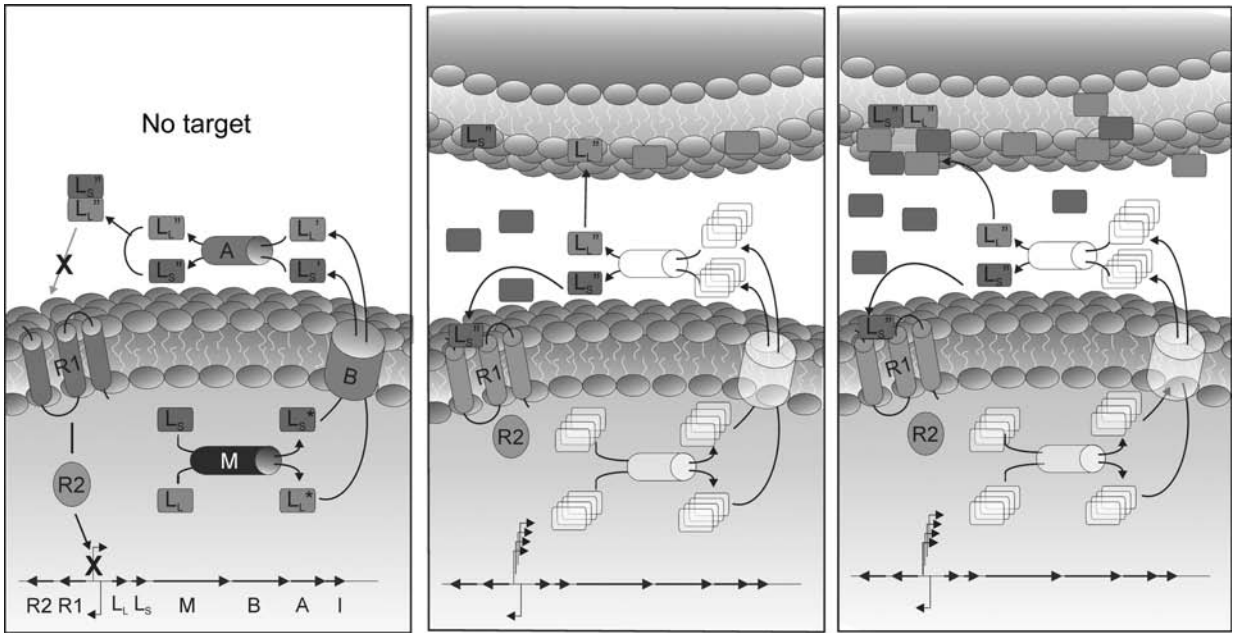

**FIGURE 41.2** Model for the expression of the *Enterococcus faecalis* cytolysin that involves quorum sensing of the inducer $CylL_S$ ", and the detection of target cells by $CylL_L$ ". In the absence of a target cell (left panel), $CylL_L$ " and $CylL_S$", as well as the gene products necessary for post-translational modification (CylM), secretion (CylB), extracellular activation (CylA), and producer immunity (CylI), are expressed at basal levels. The mature cytolysin subunits interact to form an inactive complex that is incapable of affecting target cell lysis and lacks the ability to induce high-level expression of the cytolysin operon. In the presence of a target cell (middle panel), $CylL_L$" binds preferentially to the target cell to the apparent exclusion of $CylL_S$", which allows free $CylL_S$ " to accumulate to a level necessary to trigger high-level cytolysin expression, hypothetically by altering the behavior of the CylR1 and CylR2 transcriptional repressors. Accumulation of $CylL_S$" and $CylL_L$" leads to target cell lysis (right panel) presumably by the formation of a pore.

## MOLECULAR MECHANISM OF CYTOLYSIN ACTIVITY

Little is known about the mechanistic details of cytolysin toxin subunit interactions with each other and with target cell membranes. It is not clear what properties of the cytolysin toxin uniquely endow it with the ability to target both Gram-positive bacteria and some, but not all, mammalian erythrocytes. A relatively higher phosphotidylcholine content in the membranes of erythrocytes most susceptible to cytolysin suggested a role for this lipid in targeting (Roelofsen *et al*., 1964). Support for this hypothesis was furnished by the observation that phosphatidlycholine inhibited the cytolysin-mediated lysis of horse erythrocytes (Miyazaki *et al*., 1993). However, demonstration of a direct interaction or mechanistic basis for this observation is still lacking.

Bacterial cell membranes also competitively inhibit cytolysin activity, and they do so more effectively (by three orders of magnitude) than eukaryotic cell membranes (Basinger and Jackson, 1968). These data suggest that cytolysin may recognize a more specific receptor molecule on bacterial cell membranes than on eukaryotic membranes. The lantibiotic nisin produced by *Lactococcus lactis* uses the bacterial cell wall precursor lipid II as a docking molecule to initiate contact with the cytoplasmic membrane (Brotz *et al*., 1998; Wiedemann *et al*., 2004). It is possible that *E. faecalis* cytolysin employs a similar docking molecule. The variable spectrum of susceptibility of bacterial cells to cytolysin may be due to variable levels of a docking molecule and/or variable levels of an inhibitory factor present within the cell wall or membrane. Both lecithin and ribitol teichoic acid esterified to D-alanine have been found to inhibit cytolytic activity (Brock and Davie, 1963; Davie and Brock, 1965). The resistance of Gram-negative bacteria to cytolysin is probably attributable to the outer membrane, since L-forms of certain species were susceptible (Kalmanson *et al*., 1970).

Thus, the properties of cell membranes that render them cytolysin-senstive are still vaguely defined. Evidence that the cytolysin toxin actually forms a pore in the target cell membrane is derived from parallels drawn with other lantibiotics and hemolysins, and from the observation that cytolysin effects the release of carboxyfluorescein from liposomes (C.P. Bogie and M.S.G., unpublished observations).

Recently a structure-function study of the small toxin subunit was carried out in which every residue of the mature $CylL_S$" protein was individually changed to alanine. Each of the resulting 18 mutants was tested for its molecular weight, hemolytic activity, bacteriocin activity, and *cyl* operon-inducing activity. The majority of the residues appeared to be important for effective hemolytic activity. However, several of the mutations that blocked hemolytic activity did not impair bacteriocin activity. These results suggest that the mechanism of hemolytic activity is in part distinct from that of bacteriocin activity. The residues important for autoinducing activity also appear to be distinct from those required for either hemolytic or bacteriocin activity, as several of the residues that blocked hemolytic activity did not impair inducing activity, and one of the changes, G51A, that blocked inducing activity did not impair bacteriocin activity (P. Coburn and M.S.G., unpublished observations). Whether the distinctive mechanistic requirements for each of the residues is related to specific contacts with other proteins, contacts with lipids, or the overall physical properties of the peptide has yet to be determined.

Interestingly, several of the mutations found to block hemolytic activity actually enhanced bacteriocin and/or induction activity (P. Coburn and M.S.G., unpublished observations). Apparently, maximal bacteriocin/induction capabilities were not selected for evolutionarily. The mutant analysis suggests that these may have been compromised to enable hemolytic activity or some other toxin behavior that may have provided a competitive advantage in obtaining nutrients, thwarting predators, or colonizing hosts. A second, and not mutually exclusive possibility, is that suboptimal bacteriocin/induction activities were selected to prevent self-killing. The ability of *cylI* to protect *E. faecalis* against the most potent bacteriocin mutant has not yet been tested. One of the mutations, P45A, enhances all three assayed activities—hemolysis, bacterial killing, and induction (P. Coburn and M.S.G., unpublished observations). Proline may have been selected at this position to facilitate self-protection (a testable hypothesis), to facilitate lysis of another cell type that has not yet been assayed, to stabilize the molecule against proteases in the environment, or to carry out another activity of $CylL_S$" that has not yet been discovered.

For a number of the mutants, MALDI-TOF analysis failed to detect a peptide from the culture supernatant that was within the predicted molecular weight range of the mutant peptide (P. Coburn and M.S.G., unpublished observations). The failure to detect predicted peptide products for T43A, T44A, C47A, T49A, G55A, S59A, and K61A may prove to be biologically informative. There is evidence that T43, T44, T49, and S59 are all posttranslationally modified. At least one is probably involved in the formation of a lanthionine or β-methyllanthionine residue (Booth *et al*., 1996), and C47 may also be involved in the formation of that residue. Studies of other lantibiotics have shown that the formation of the thioether bridges of lanthionine derivatives confers stability and protease resistance to the peptides (de Vuyst and Vandamme, 1994; Bierbaum *et al*., 1996). Nothing is known specifically about what roles G51 or K61 might play, but K61 represents the only charged residue in the entire mature peptide. Instability, secretion defects, and processing defects are possible explanations for why these mutant peptides were not detected in the culture supernatants by MALDI-TOF. Ongoing studies will address these questions, and a similar analysis of $CylL_L$ mutants may be carried out.

## CYTOLYSIN AS A COLONIZATION AND VIRULENCE FACTOR

The similarities between the cytolysin toxin and the operon encoding it to the toxins and operons of the members of the lantibiotic class of bacteriocins suggest that the earliest incarnation of the cytolysin operon conferred a competitive advantage to *E. faecalis* over other Gram-positive strains vying for control of the same niche. This hypothesis is supported by an *in vitro* experiment in which a cytolytic strain outcompeted a bacteriocin-sensitive strain in mixed liquid culture even when the sensitive strain started out in 100-fold excess (Brock and Davie, 1963). A selective advantage for the ability to fend off protozoan or nematode predators, obtain more nutrients, and/or colonize more niches within host animals may have driven the evolution from a lantibiotic to a cytolysin also capable of lysing eukaryotic cells. However, the fact that the cytolysin determinants are not present in all strains and can in fact become excised at a high frequency (Shankar *et al*., 2002) suggests that toxin activity may not confer a selective advantage to cells in all niches or circumstances.

Does cytolysin toxin contribute to the virulence of *E. faecalis* strains in animal hosts? While many infections are established with non-cytolytic strains, analysis of clinical isolates in several studies supports the hypothesis that cytolysin enhances the severity of infection and may also enhance the propensity to infect. A study examining clinical isolates from a Japanese hospital in the 1980s determined that approximately 60% were cytolytic, compared to 17% of isolates from the stools of

healthy students at a nearby medical school (Ike *et al*., 1987). *E. faecalis* isolates from endopthalmitis patients in the United States were also found to be enriched for the cytolytic phenotype—46.5% versus the 0–17% typically found in stools of healthy volunteers (Booth *et al*., 1998). A number of studies also indicate enrichment (25–28%) for the cytolytic phenotype among isolates from urinary tract infections (Rantz and Kirby, 1943; Facklam, 1972; Libertin *et al*., 1992). On the other hand, isolates from endocarditis patients show a much lower incidence of a cytolytic phenotype (11–16%) (Facklam, 1972; Coque *et al*., 1995; Huycke *et al*., 1995).

A study of bacteremia patients in a Wisconsin hospital and their *E. faecalis* blood isolates determined that patients infected with cytolytic, gentamicin-resistant strains were at a fivefold increased risk of death within three weeks of their bacteremia compared to patients with non-cytolytic, gentamicin-susceptible strains (Huycke *et al*., 1991). The contribution of antibiotic resistance was discounted from this statistic, since all strains remained susceptible to one or more antibiotics, and the disease outcome was not associated with treatment modality. On the other hand, a separate study of bacteremia patients involved in a multicenter study (Vergis *et al*., 2001) determined that only 11% of isolates were cytolytic, and while 9% of patients infected with cytolytic strains died, there was no significant association between 14-day mortality and the cytolytic phenotype, either alone or in combination with *gelE* or *esp*, two other *E. faecalis* virulence genes (Vergis *et al*., 2002).

Cytolysin is one among multiple factors of the bacterium and host that determine *E. faecalis* pathogenicity. Since epidemiological analyses are limited to correlations and are riddled with a wide range of uncontrolled variables, studies in which animal models are infected with isogenic cytolytic and non-cytolytic strains are informative for quantifying the effect of virulence traits on an infected host. The results of such studies uniformly support a key role for cytolysin in *E. faecalis* virulence. In two separate studies, intraperitoneal infections of mice with a cytolytic strain of *E. faecalis* caused a significantly greater rate of lethality than infections with a non-cytolytic strain, with approximately an order of magnitude difference in the $LD_{50}$ (Ike *et al*., 1984; Dupont *et al*., 1998). In one of the studies, a strain with increased copies of the cytolysin operon lowered the $LD_{50}$ even further (Ike *et al*., 1984). A rabbit endocarditis model also indicated an important role for cytolysin as a determinant of lethality. In this study, isogenic *E. faecalis* strains harboring the cytolysin operon, or the gene for aggregation substance (a surface protein involved in conjugation and surface attachment), or both, were injected intravenously after catheterization. Infection with strains expressing only cytolysin did not result in lethality, but cytolysin synergized with aggregation substance to cause lethality in 55% of infected animals versus only 15% of animals infected with a strain expressing just aggregation substance (Chow *et al*., 1993).

Enhanced virulence due to cytolysin was also clear from the development of a rabbit endopthalmitis model system (Jett *et al*., 1992). This system takes advantage of the immune privilege of the eye that enables establishment of an infection with 10–100 bacterial cells. In some ways, this mode of infection is physiologically more similar to nosocomially acquired infections in unhealthy human hosts than is the injection of large numbers of cultured bacteria into healthy animals. Moreover, the progression of a single eye infection can be monitored over multiple time points using the standard tools of ophthalmology. Infection of rabbit eyes with 100 cytolytic *E. faecalis* cells caused the destruction of retinal tissue and architecture and a 99% reduction in retinal neuro-responsiveness. Conversely, infection of rabbit eyes with 100 non-cytolytic *E. faecalis* cells left the retinal tissues largely intact and reduced retinal function by 74.2% (Jett *et al*., 1992).

A non-mammalian host, the nematode *Caenorhabiditis elegans* that ingests *E. faecalis*, is also sensitive to cytolysin. Worms fed a cytolytic strain are killed faster than worms fed a non-cytolytic strain (Garsin *et al*., 2001). While these results suggest that targets of cytolysin might be ubiquitous, cytolysin did not seem to aggravate symptoms in a rat peritonitis model in which the symptoms caused by any *E. faecalis* strain were mild to begin with (Dupont *et al*., 1998). The basis for the resistance of rats to *E. faecalis* and cytolysin are unknown and highlight the importance of carefully interpreting results from animal models.

There are a number of ways in which the presence of the cytolysin toxin might aid establishment of infection and enhance disease severity. It can lyse erythrocytes, and there is evidence that it can damage neural tissue (Jett *et al*., 1992; Stevens *et al*., 1992; Jett *et al*., 1995) and intestinal epithelial tissue (P. Coburn and M.S.G., unpublished observations). These injuries may provide more nutrients for the bacteria, undermine the health of the host, and/or enable the bacteria to penetrate deeper into uncolonized tissue. Cytolysin has also been shown to be active against macrophages and polymorphonuclear leukocytes (Miyazaki *et al*., 1993), suggesting that it could weaken the host immune response. Interestingly though, a cytolytic strain did not maintain viability within mouse peritoneal macrophages any longer than did an isogenic non-cytolytic strain (Gentry-Weeks *et al*., 1999). It is also

possible that the bacteriocin activity of the cytolysin could destablilize the commensal gut flora, clearing the way for colonization by cytolytic *E. faecalis*. However, there is no evidence for this, and in fact the competitive advantage of a cytolytic strain over a non-cytolytic strain observed *in vitro* was not recapitulated *in vivo* in an experiment in which mice pretreated with antibiotics were fed a one-to-one mixture of the two strains. The ratio of the two strains recovered from stool samples one and seven days later hovered at one-to-one (Huycke *et al*., 1995). It is unknown to what extent this experiment reflects the events within a human GI tract, especially considering that the cytolytic strain was isolated from a human patient, and there is evidence that strains of *E. faecalis* are specifically adapted to their host species (Willems *et al*., 2000).

## CONCLUSION

In summary, the cytolysin toxin of *E. faecalis* is a two-subunit hemolysin and bacteriocin capable of lysing a broad range of target cells. The maturation process of the two structural toxin subunits is similar to the maturation process of other lantibiotic bacteriocins, but the regulatory activity of each of these subunits in calibrating toxin expression to reflect cell density and the presence of target cells is novel. Further studies of the components of the cytolysin locus and the target cell-toxin interactions are certain to yield more interesting mechanisms and may inform the development of a therapeutic agent to neutralize this virulence factor.

## ACKNOWLEDGMENTS

We thank Phillip S. Coburn and Christopher M. Pillar for helpful advice during the preparation of this manuscript. Portions of the research described in this manuscript were supported by NIH grants EY08289 and AI41108, and by an unrestricted award from Research to Prevent Blindness.

# Streptolysin S: one of the most potent and elusive of all bacterial toxins

*Joyce C. S. de Azavedo, Kowthar Y. Salim, and Darrin J. Bast*

## INTRODUCTION

Streptolysin S (SLS) is responsible for the hallmark β-hemolytic phenotype seen around colonies of Group A *Streptococcus* (GAS), also known as *Streptococcus pyogenes*, when cultured on blood agar. By contrast, streptolysin O (SLO), another cytolysin produced by GAS, is oxygen-labile and thus only observed under anaerobic culture conditions. Although SLS was discovered in the 1930s (Todd, 1938; Weld, 1934), it has proven difficult to characterize due to the difficulty of obtaining purified preparations since additional factors are required for synthesis and a carrier molecule is needed to provide stability in solution. Consequently, it was not until 1986 that Loridan and Alouf first purified carrier-free SLS and were able to determine its molecular weight (Loridan and Alouf, 1986). However, attempts at N-terminal sequencing of the peptide proved to be unsuccessful, and the amino acid structure remains a mystery despite more recent genetic information as to the structural gene for SLS. An operon associated with SLS production has been identified (Betschel *et al*., 1998; Nizet *et al*., 2000). However, the functions of individual genes in the operon have not been elucidated, and furthermore the sequence of the proposed structural gene does not entirely agree with the published composition.

Although the cytolytic capacity of SLS has been well documented, its contribution to the pathogenesis of GAS disease was not clear until the use of SLS-deficient mutants demonstrated a role in lesion formation and tissue necrosis (Betschel *et al*., 1998). Recent work also provides evidence that the SLS RNA transcript might act as a regulator for other GAS determinants (Li *et al*., 1999; Mangold *et al*., 2004), in which case its role could prove to be complex. Its importance among pathogenic streptococci is underlined by the fact that it is also produced by Lancefield groups C and G streptococci (GGS and GCS) and has been recently reported in the zoonotic pathogen *Streptococcus iniae* (Flanagan *et al*., 1998; Fuller *et al*., 2002; Humar *et al*., 2002). Several detailed reviews have been published on the biological and physicochemical properties of SLS, as well as on the genetics of its production and its role in disease (Ginsburg, 1970; Alouf, 1980; Ginsburg, 1999; Nizet, 2002). In this review, we summarize early work and focus on the more recent findings, such as its genetic organization, regulation, and possible role(s) in the pathophysiology of streptococcal infections.

## GENERAL PROPERTIES AND PRODUCTION OF SLS

The zone of β-hemolysis surrounding SLS-producing streptococcal colonies on blood agar media is reflective of its cytolytic action. It is one of the most potent bacterial cytotoxins known, and it has been shown to exhibit highly toxic membrane-damaging effects on a variety of mammalian cell types, including red blood cells,

lymphocytes, polymorphonuclear leukocytes, platelets, tissue culture cells, and tumor cells (Ginsburg, 1970). It also disrupts subcellular membrane-bound organelles such as lysosomes, nuclei, and mitochondria (see Alouf, 1980).

SLS is synthesized *de novo* and while the majority of the toxin is cell bound, likely linked to the cell wall by lipoteichoic acid, cytoplasmic and extracellular forms have also been described (Calandra and Cole, 1981; Theodore and Calandra, 1981). The formation of SLS by GAS in culture was shown to occur during the stationary phase of growth in the presence of maltose (Ginsburg *et al*., 1963; Taketo and Taketo, 1964). However, the stability of the toxin in solution required the addition of "carrier" molecules or "inducers" such as albumin, α-lipoprotein, or yeast RNA (RNase-free core) (Alouf, 1980; Ginsburg, 1970). Interestingly, not only were the carriers chemically unrelated, but nonionic detergents such as Tween and Triton-X could also suffice (Ginsburg, 1970). Taken together, these data show that maltose is a requirement for the intracellular synthesis of SLS, but that a carrier is needed for its extracellular release. In addition to a carrier, it was shown that a bovine serum albumin derivative consisting of three peptide chains composed primarily of aspartic acid, glutamic acid, and leucine linked by two disulfide bridges was also necessary for release of cell-bound SLS (Akao *et al*., 1992). More recent studies using synthetic peptides have shown that it is the disulfide bridges that are essential, regardless of the number and types of amino acids that constitute the peptides (Akao *et al*., 1999).

Aniline dyes, such as Trypan Blue and Congo Red, abolish the action of SLS but not that of SLO or other hemolytic toxins (Alouf, 1980; Ginsburg, 1970). However, the mechanism of this phenomenon is not known. SLS activity is also inactivated by chymotrypsin, papain, ficin, and cathepsin but not by trypsin, pepsin, lysozyme, hyaluronidase, lipase, or muramidase (Ginsburg, 1970).

## BIOCHEMISTRY OF SLS

The first evidence that SLS was protein in nature was demonstrated by Koyama and Egami in 1963, who showed that a partially purified SLS-oligonucleotide mixture contained 12 different amino acids in varying molar ratios (Koyama and Egami, 1963). Using improved purification methods, Lai *et al.* in 1978 reported a 15-kDa protein containing 32 amino acids, of which 7.1 kDa was the associated carrier (Lai *et al*., 1978). It was estimated that the hemolytic moiety might be a 2.8-kDa peptide composed of approximately 28–30 amino acids.

It was not until 1986 that further modifications in purification methods eventually led to the identification of a 1.8-kDa peptide (pI 9.2), which was then thought to be SLS in its purest form (Loridan and Alouf, 1986; Alouf and Loridan, 1988). The SLS peptide was found to lack cysteine, histidine, proline, and tryptophan. Unfortunately, attempts to deduce amino acid sequence by Edman degradation failed, suggesting that the amino terminal may be blocked, or that the peptide moiety was cyclic (Alouf and Loridan, 1986). Interestingly, this finding at the protein level supports those at the genetic level and will be explained in more detail later in this review. Prior to the studies by Loridan and Alouf (1986, 1988), the isolation of carrier-free SLS in its native form had not been possible, given the strong interaction between the SLS peptide and the carrier.

## MECHANISM OF ACTION

Difficulties in obtaining homogeneous preparations of SLS, as well as the inability to raise antibodies against purified SLS, have limited studies on its mode of action. Although it is evident that SLS, like SLO, affects cell membranes to cause lysis, its precise mechanism of action is unclear, and it is unlikely that both streptolysins have the same mechanism of action. Cholesterol, which forms a major component of mammalian cell membranes, does not inhibit SLS activity, whereas several phospholipids, such as phosphatidyl choline and phosphatidyl ethanolamine, as well as sphingomyelin and lecithin, do (Elias *et al*., 1966). On the other hand, SLO binds to cholesterol giving rise to large transmembrane pores leading to lysis (Palmer *et al*., 1998). By comparison, there is evidence that SLS creates small pores in the membrane, stemming from the fact that sub-lytic concentrations of SLS cause a release only of low molecular weight molecules from human fibroblast cells in tissue culture (Thelestam and Mollby, 1979). Investigation of membrane damage caused by SLS using erythrocyte ghosts revealed pores not more than 45 Å in diameter even at high SLS concentrations, whereas those caused by SLO exceeded 128 Å in diameter (Buckingham and Duncan, 1983). Kinetic experiments further demonstrated that SLO lesions were formed within 1–2 minutes, whereas release of marker molecules from streptolysin S-treated vesicles began only after a 5–15 minute lag period (Buckingham and Duncan, 1983).

Recent studies by Carr *et al*., using a fixed concentration of SLS and varying numbers of target erythrocytes and vice versa, gave dose-dependent response curves consistent with a one-hit mechanism of hemolysis. This

mechanism is similar to complement-mediated lysis, where one molecule of SLS is sufficient to lyse one cell in a time- and temperature-dependent fashion (Carr *et al*., 2001). Further, SLS was shown to become an integral membrane protein and form pores with a predicted size between 0.14 and 0.36 nm, thereby leading to irreversible osmotic lysis of the cell (Carr *et al*., 2001).

## GENETIC BASIS OF SLS PRODUCTION

Prior to studies in our laboratory, and those in collaboration with Nizet *et al*. from the University of California, San Diego and Beall *et al*. from the Centers for Disease Control, nothing was known about the gene(s) encoding the hemolytic moiety of SLS in GAS. We initially demonstrated that a Tn*916* insertional inactivation of a promoter motif just upstream of a novel open reading frame (ORF), encoding a 53-amino acid peptide, abrogated β-hemolysis *in vitro* and reduced the virulence of an M1 GAS strain in a mouse model of tissue neurosis (Betschel *et al*., 1998; Borgia *et al*., 1997). This gene, named *sagA* for streptolysin-associate gene, was pivotal to the elucidation of the genetic control of SLS expression. Concomitantly, Beall *et al*. discovered loss of SLS activity via Tn*917* insertional inactivation of an ORF immediately downstream of *sagA* in an M49 strain. Shortly thereafter, a combined effort between all three groups led to the discovery of eight additional ORFs downstream of *sagA*, forming what is now known as the *sag* operon (Nizet *et al*., 2000). Targeted integrations in each of the nine genes (*sagA* to *sagI*) abrogated hemolytic activity, whereas integrations upstream or downstream of the operon did not, suggesting that each gene is required for SLS production. Unequivocal evidence was provided when the cloning of the entire nine-gene operon from the M49 strain into a non-hemolytic (SLS-deficient) strain of *Lactococcus lactis* conferred a stable hemolytic phenotype.

Upon closer examination of the locus at the amino acid level, it was apparent that the *sag* operon (Figure 42.1) was strikingly similar to bacteriocin operons from other Gram-positive as well as Gram-negative bacteria. Bacteriocins are small bacterial antimicrobial peptides that target specific bacteria other than the producing strain causing lysis. Synthesized first as a larger prepropeptide, which is comprised of a 23–26 amino acid N-terminal leader sequence and a 22–60 amino acid C-terminal propeptide, these antimicrobials are modified at specific residues (serine, threonine, glycine, and cysteine) and subsequently cleaved from their leader sequences before going on to produce a functional bacteriocin (Klaenhammer, 1993). *SagA*, thought to be the structural gene of SLS, encodes a 53-amino acid peptide (Figure 42.2) that is similar in size and amino acid composition to the prepropeptide of Microcin B17 from *Escherichia coli* (Yorgey *et al*., 1993). Also similar to many bacteriocins is the Gly-Gly proteolytic cleavage motif, which separates a putative 23 amino acid leader peptide from a 30 amino acid propeptide rich in the modifiable residues of Ser, Thr, Gly, and Cys (Figure 42.2). The *sag* locus (Figure 42.1) also contains candidate genes required for propeptide chemical modification (*sagB*), self-protection or immunity (*sagE*), an ABC transporter for export and maturation proteolysis of the leader peptide (*sagG* to *sagI*), and an internal terminator motif. The latter allows for differential transcription of structural gene and accessory gene mRNAs so as to allow for an abundance of structural gene (*sagA*) transcripts (Nizet *et al*., 2000).

Transcripts of the *sagA* gene are maximally produced at six hours following mid-exponential phase (Betschel *et al*., 1998) in keeping with maximal SLS production in the stationary phase of growth determined in early biochemical studies on SLS. Also, the predicted size of the SagA propeptide matches the size of mature SLS calculated from earlier biochemical analyses (Koyama and Egami, 1963; Lai *et al*., 1978; Loridan and Alouf, 1986).

**FIGURE 42.1** Schematic representation of sag operon from GAS with deduced amino acid identities among *sag* operons from Group G *Streptococcus* (GGS), and from *S. iniae* (SI). Also shown are the predicted sizes and putative functions of all 8 accessory gene products (SagB to SagI). Percent identities in parentheses reflect amino acid comparisons with GAS.

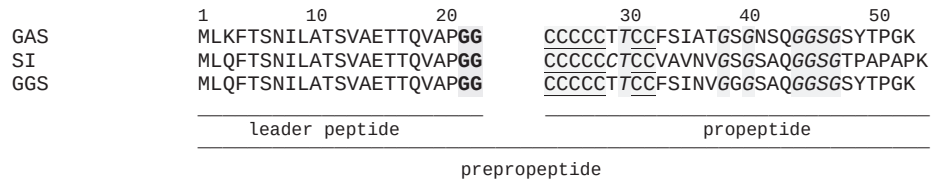

**FIGURE 42.2** Predicted amino acid homologies of SLS (SagA) from Groups A (GAS) and G (GGS), and from *S. iniae* (SI). Highlighted is the putative Gly-Gly (bold) cleavage site, as well as conserved residues hypothesized to undergo post-translational modification [Cys (underlined), Thr, Ser, and Gly (italic)].

Moreover, the previous unsuccessful attempts at sequencing the SLS peptide by Edman degradation may reflect cyclical thioether bridge structures or N-terminal blockage by a 2-oxobutyryl group as seen in other such molecules (Meyer *et al*., 1994). Since cysteine was not detected in purified SLS (Loridan and Alouf, 1986; Alouf and Loridan, 1988), the presence of seven cysteines, five adjacent to each other, is interesting and supports post-translational modification of these residues.

Processing of SagA and its export through the cell membrane are not yet understood. However, HtrA (DegP), a serine protease involved in the folding and maturation of secreted proteins, was shown to affect SLS production (Lyon and Caparon, 2004). An *htr*A insertional mutant showed high levels of SLS activity with expression occurring earlier in the growth phase than with the wild-type. The authors proposed that HtrA either may function to degrade components of the SLS biogenesis machinery or may even affect the tethering of SLS to the cell surface. Interestingly, the increased SLS activity in the mutant did not correlate with an increase in disease severity in a murine subcutaneous infection model; perhaps Htr also affects other virulence determinants that were not examined in this study.

## REGULATION

As described for many GAS determinants, the regulation of *sagA* and SLS activity is complex and has been shown to be influenced by a number of regulators. Furthermore, these regulators form an intricate network influenced by global regulators, making it difficult to determine which one directly regulates SLS expression. Results from studies examining *sagA* transcription do not always agree with those where SLS activity is used as a measure of transcript up-regulation. To complicate matters even further, the *sagA* transcript itself possesses the ability to transcriptionally and post-transcriptionally regulate the expression of other genes involved in the virulence of GAS. The regulation of SLS in GAS as determined by transcriptional analysis and by SLS activity is summarized in Figure 42.3.

### Regulation of SLS expression

Transcriptional regulators that have been shown to influence the expression of *sagA* include Mga, CovRS/CsrRS, the RofA-like family of regulators (RALPs), Rgg, and FasABC. Some of these regulators act directly on *sagA*, while others modulate regulatory networks affecting *sagA* expression. Mga, a global regulator that positively regulates a number of virulence genes involved in adhesion and invasion such as M protein, streptococcal inhibitor of complement, C5A-peptidase, and IgG-binding protein, negatively regulates SLS activity (Kreikemeyer *et al*., 2003) (Figure 42.3a and 42.3b). Thus, an Mga-deficient mutant was shown to exhibit increased cytoxicity to human lymphocytes due to increased SLS production relative to the wild-type (Kihlberg *et al*., 1999). Other negative regulators of *sagA* expression are RofA (Beckert *et al*., 2001) and Nra (Kreikemeyer *et al*., 2002), which belong to the RofA-like family of regulators (RALP) (Krekeimeyer, 2003). An Nra mutant was shown to escape from phagocytic vacuoles faster, due to increased expression of SLS and pyrogenic exotoxins A and B (SpeA and SpeB), suggesting that this regulator might be important in maintaining intracellular persistence of GAS *in vivo* (Molinari *et al*., 2001). Interestingly, Nra and RofA also negatively regulate Mga, but are themselves under positive regulation by Mga (Podbielski *et al*., 1999; Kreikemeyer *et al*., 2002). Consequently, it is difficult to determine which of these regulators might have a direct effect on *sagA* transcription, and mutations in any of them ultimately have an effect on SLS expression (Figures 42.3a and 42.3b).

The two-component signal transduction system CovRS (control of virulence regulator), also known as CsrRS (capsule synthesis regulator), also negatively regulates *sag*A (Figures 42.3a and 42.3b), as well as a number of other virulence determinants, including the *has* operon encoding hyaluronic acid capsule and

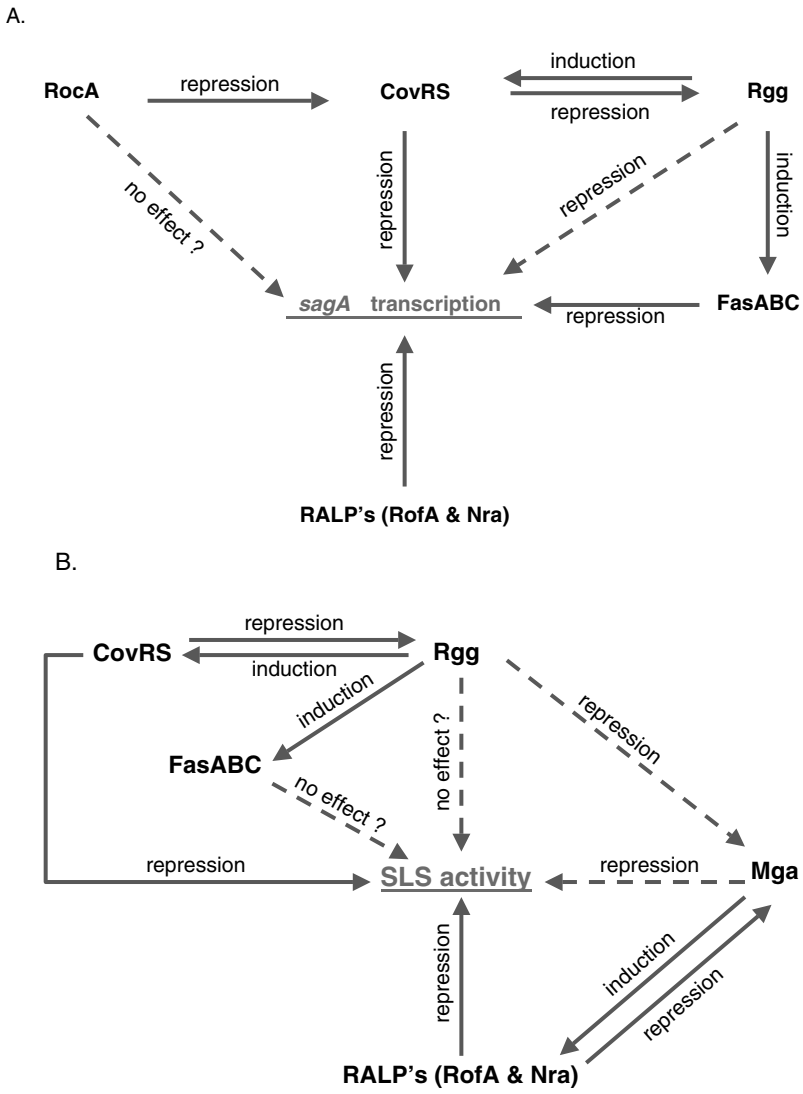

**FIGURE 42.3** Regulatory elements affecting *sagA* transcription (A) and SLS activity (B). Solid arrows indicate direct regulation. Dashed arrows indicate either no effect or inconclusive evidence as to direct or indirect regulation.

the global regulator Rgg/RopB (Federle *et al*., 1999; Graham *et al*., 2002; Heath *et al*., 1999; Levin and Wessels, 1998). CovRS was shown to directly bind the promoter region of the *sag* operon, indicating a direct influence on *sagA* transcription (Miller *et al*., 2001). DNA microarray studies demonstrated *sagA* expression to be increased almost eightfold in a CovRS-deficient mutant relative to the wild-type during the late exponential phase of growth (Graham *et al*., 2002). The transcription of the CovRS genes are themselves influenced by at least two regulators: RocA (regulator of CovR) acting as a negative regulator (Biswas and Scott, 2003) and Rgg (RopB) as a positive regulator (Chaussee *et al*., 2002) (Figure 42.3a and 42.3b). Interestingly, since RocA is a negative regulator of CovRS, which is in turn a negative regulator of *sagA*, one would expect increased expression of SLS in a RocA-deficient mutant, as was observed for hyaluronic acid synthesis (Biswas and Scott, 2003). However, this up-regulation was not observed for *sagA* and warrants further investigation. In addition to regulating CovRS, Rgg/RopB acts as a global transcriptional regulator of a number of genes associated with both metabolism and virulence, as well as the transcriptional regulators Mga and FasABC (Chaussee *et al*., 2001; Chaussee *et al*., 2002). An Rgg-deficient mutant was found to show up-regulation of *sagA* transcript expression (Chaussee *et al*., 2002). Although studies so far do not rule out the possibility that Rgg/RopB could be acting directly on the *sag* operon, the lack of conserved regions in the various promoters under Rgg/RopB control suggests it acts through modulation of other regulatory networks (Krekeimeyer, 2003).

Possible regulation of SagA at the post-transcriptional level comes from studies of the *fasABC* operon, which regulates *sagA* (Figure 42.3a), as well as genes encoding

fibronectin and fibrinogen-binding proteins, and streptokinase in a growth-phase dependent manner (Kreikemeyer *et al*., 2001; Kreikemeyer *et al*., 2003). In a *fasABC* knockout, the transcriptional profile of the aforementioned genes, except *sagA*, directly correlated with the functional activity of each gene product (Kreikemeyer *et al*., 2001). Although an increase in *sagA* mRNA was also observed, this did not correlate with a concomitant increase in SLS, suggesting that in addition to regulating *sagA* transcription, the *fas* operon might also have an effect on SagA transport and processing, which, as described previously, are likely complex.

### The *sagA* transcript as a regulator

Shortly after the identification of *sagA*, Li *et al*. demonstrated that a Tn*917* insertion in the promoter region of the *sagA* gene in an M49 serotype strain resulted in reduced expression of SLS as well as M protein, SpeB, and streptokinase (Li *et al*., 1999). Because of this pleiotropic effect, they designated it *pel* for pleiotropic effect locus. However, the regulatory effect of *sagA/pel* might be serotype dependent since Tn *916* insertions in the *sagA/pel* genes of an M1 and an M18 strain showed loss of SLS activity, but no effect on the production of cell-associated and extracellular proteins, capsule production, DNase, and caseinase activity (Betschel *et al*., 1998). In another study using an M6 serotype strain, the level of *emm* transcript encoding M protein remained unaltered in the *sagA/pel* insertion-deletion mutant, but the M protein was produced in a truncated form lacking its C-terminal domain and was not anchored to the cell surface (Biswas *et al*., 2001). The authors speculated that *sagA* or one of the other genes in the *sag* operon might directly or indirectly decrease the expression of a protease(s) that could truncate M protein. Interestingly, when the M49 *sagA/pel* Tn*917* mutant was passaged in mice, SpeB and streptokinase activity remained down-regulated, but both β-hemolysis and M protein expression were restored despite maintenance of Tn*917* in the *sagA/pel* promoter (Eberhard *et al*., 2001). The authors suggested that additional levels of regulation of SLS expression were selected for by biological pressures *in vivo*.

Further evidence to support *sagA* as a regulatory element comes from a recent study of an M1 serotype strain (Mangold *et al*., 2004). A *sagA*-deficient mutant of this strain not only showed loss of the β-hemolytic phenotype, but also reduced transcription of at least nine genes, including those for M-protein, streptokinase, streptococcal inhibitor of complement, pyrogenic exotoxin C, and NAD-glycohydrolase. Most interesting was the fact that although *speB* transcripts were produced normally, SpeB production was delayed and did not appear until late stationary phase in the mutant, compared with the appearance of activity in late logarithmic phase in the wild-type. Western blot analysis showed that although the mutant secreted the inactive zymogen of SpeB, processing to the active form was delayed. The authors concluded that the *sagA* transcript influenced processing and maturation of SpeB. Thus, in addition to acting as a transcriptional regulator, *sagA* was also acting as a regulator at the post-transcriptional level.

## ROLE OF SLS IN DISEASE PATHOGENESIS

The majority of clinical isolates of GAS, regardless of serotype, produce SLS. Naturally occurring strains of SLS-negative GAS are rare and although such clinical isolates occur, they often are not recognized because non-hemolytic mutants from throat swabs are dismissed as viridans streptococci in the clinical laboratory (Nida and Cleary, 1983). Consequently, it has not been possible to attribute a specific role to SLS based on SLS production by strains associated with a particular disease manifestation. Numerous studies in the past, using purified SLS preparations, attempted to examine the role of SLS in pathogenesis. However, the difficulty of obtaining purified SLS preparations made such studies problematic. Furthermore, the SLS peptide is non-immunogenic, and antibodies against purified SLS have neither been experimentally generated nor detected in sera from patients with GAS infections.

Although the cytotoxic effect of SLS *in vitro* has been demonstrated on a wide variety of cells, what consequence this might have *in vivo* is debatable. Pathological effects of SLS *in vivo* have been described. Mice and rabbits injected intravenously with SLS showed degenerative changes in kidney tubules and glomerulitis, respectively, whereas intramuscular injections showed muscle degeneration and sub-acute inflammation (Ginsburg, 1970). Intravenous injection of large doses of SLS in rabbits caused massive intravascular hemolysis followed by death (Ginsburg, 1970). By contrast, SLS specifically injected into the knee joints of rabbits produced acute arthritis followed by a chronic form on repeated injection (Weissmann *et al*., 1965). However, the purity of SLS may have been questionable in these studies, and these observations could have resulted from contaminants (Ginsburg, 1970).

It has only been through more recent work using SLS-deficient mutants that insight has been gained on the possible role of SLS in pathogenesis. It was not until

1998 that studies in our laboratory provided evidence implicating SLS as a virulence factor associated with skin infection. We showed that an SLS-deficient mutant with a *Tn916* insertion in the *sagA* locus of an M1 strain caused significantly fewer and smaller necrotic lesions and had no adverse effect on mouse weight gain when injected subcutaneously at $10^6$ CFU, compared with the wild-type, which caused weight loss and a necrotic lesion within 72 hours (Betschel *et al*., 1998). Histological examination of the lesion revealed intense neutrophil infiltration, as well as tissue necrosis with the wild-type but not with SLS-deficient mutants. Further work using targeted knockouts in each of the genes of the *sag* locus confirmed that these effects were due to SLS (Nizet *et al*., 2000).

More recently, using double mutants of an M1 strain that were SLS-deficient (Δ*sag*A) and capsule positive (Δ*cov*RS), SLS was shown to correlate with lesion size and together with capsule to be responsible for subcutaneous spread of infection and mortality in the murine model (Engleberg *et al*., 2004). Another study using SLO- and SLS (Δ*sagB*)-deficient mutants of an M5 strain also demonstrated that SLS contributes to lesion size in mice (Fontaine *et al*., 2003). Interestingly, a double-mutant deficient in both SLS as well as SLO produced lesions in fewer mice at $10^6$ CFU than either the SLS- or SLO-deficient mutants alone, indicating that SLO also contributes to necrosis. In this study, $LD_{50}$ was shown to be decreased by 1 log with an SLS-deficient mutant compared with the parent when injected subcutaneously, but no difference was observed with intraperitoneal injection (Fontaine *et al*., 2003), indicating that SLS affects mortality depending on the route of infection. Moreover, mortality may be a function of M type, since in a study utilizing an M3 strain neither SLS- nor SLO-deficient mutants had an effect on mouse survival when injected subcutaneously, and SLS was found to have a slightly lesser contribution to mortality than SLO when mutants were injected intraperitoneally in a murine sepsis model (Sierig *et al*., 2003).

Purified SLS has also been shown to inhibit phagocytosis *in vitro* (Ofek *et al*., 1972). Recently, Dale *et al*. generated antibodies in rabbits, using a synthetic peptide based on amino acid residues 10–30 of the SagA propeptide, which neutralized the activity of SLS *in vitro* and which significantly enhanced phagocytosis when combined with type-specific M protein antibodies (Dale *et al*., 2002). However, *in vitro* studies using M3 SLS- and SLO-deficient mutants showed that SLO but not SLS was associated with impaired polymorphonuclear leukocyte killing and only in an acapsular background (Sierig *et al*., 2003). Thus, the inhibition of phagocytosis seen with purified SLS (Ofek *et al*., 1972), which is obviously of advantage in combating the host immune response, does not appear to occur in the presence of other GAS virulence determinants *in vitro*. However, the intense neutrophil recruitment, which occurs at the site of GAS infection in the murine subcutaneous model without concomitant bacterial clearance, and which is not seen with SLS-deficient mutants, suggests that SLS *in vivo* may affect neutrophil function (Betschel *et al*., 1998). Further studies are needed to determine the synergistic effects occurring with SLS and other GAS virulence determinants *in vivo*.

## SLS PRODUCTION IN OTHER PATHOGENIC STREPTOCOCCI

Following the identification of the *sag* operon in GAS, *sag* operon homologues have been identified in other streptococci. A *sag* operon encoding SLS was identified in GGS strains isolated from patients with necrotizing soft tissue infections (Humar *et al*., 2002). Similar to GAS, a GGS mutant with an inactivation of the *sagA* gene was incapable of forming necrotic lesions in mice as demonstrated by the parent strain (Humar *et al*., 2002). A GCS strain was also demonstrated to produce SLS (Flanagan *et al*., 1998) and to possess *sagA* (Steiner and Malke, 2002). In the latter study, homologues of *cov*RS and the *fas* operon were identified in GCS, and as found in GAS, act as positive and negative regulators of SLS, respectively (Steiner and Malke, 2002). Similarly, the hemolytic phenotype of *S. iniae*, a fish pathogen that also causes soft tissue infections in humans (Weinstein *et al*., 1997), was shown to be due to SLS production, and *sag*-deficient mutants showed SLS to be responsible for necrotic lesion formation in a murine model of subcutaneous infection (Fuller *et al*., 2002). Amino acid sequence comparisons of *sag* homologues reveal striking similarities with *sag*A from GAS, in particular those regions common to bacteriocins, as well as with other *sag* genes (Figure 42.1 and 42.2).

## CONCLUSION

Great strides in the understanding of SLS expression and its contribution to disease have been made in the last decade. Evidence for the dual role of *sagA*, both as the structural gene for SLS as well as a regulator, has emerged. However, many questions remain to be answered. The amino acid structure of the SLS peptide has not been elucidated, nor have the theoretical predictions regarding its processing been verified. Whether the *sagA* transcript alone acts as a regulator or

whether SLS may also function as a quorum-sensing molecule deserves further investigation. The sometimes conflicting results, both in terms of the regulatory capacity of the *sagA* transcript and the role in pathogenesis of *sag* knockout mutants of different M types, suggest that the role of the *sag* operon might differ in different backgrounds. The importance of strain background is not to be underestimated in experiments employing knockout mutants to assess virulence, since genome sequences of GAS strains of differing serotypes show considerable differences. Not only are the regulatory pathways in GAS complex with possible differences in different M types, but regulation of expression of virulence determinants in different biological niches likely varies. For example, we have observed that a capsule negative M1 strain remains acapsular in a mouse skin lesion, but expresses capsule when in the bloodstream (S. Betschel, unpublished data). Although the studies done so far using murine models of subcutaneous infection confirm the contribution of SLS to lesion formation, not all serotypes may show the same outcome. The use of a variety of infection models, as well as mutants of different backgrounds, should help to establish the precise role of SLS in disease. Given the progress made in the research on GAS virulence determinants in recent years, it is our hope that the next decade will shed further light on SLS, which still remains a fascinating and elusive peptide almost 70 years after its discovery.

CHAPTER

# 43

# The group B streptococcal β-hemolysin/cytolysin

*George Y. Liu and Victor Nizet*

## INTRODUCTION

Group B *Streptococcus* (GBS) is the leading cause of invasive bacterial infections in human newborns and is increasingly recognized as a pathogen in adult populations, including the elderly, pregnant women, and diabetics (Berner, 2004; Blancas *et al*., 2004). The GBS β-hemolysin/cytolysin (βH/C) is a surface-associated toxin that plays an important role in virulence of the organism. The βH/C is also responsible for the characteristic zone of clearing around GBS colonies grown on blood agar plates, a useful diagnostic phenotype in the clinical microbiology laboratory.

The GBS βH/C was recognized as early as the 1930s (Todd, 1934), but was largely neglected from an experimental standpoint. Nearly a half-century later, the emergence of GBS invasive disease in newborns triggered renewed interest in the toxin as a potential virulence factor of the pathogen. Studies in the early 1980s provided insight on the basic biochemical properties of the βH/C and its mechanism of erythrocyte lysis. However, further in-depth analysis was hindered by the toxin's lability and apparent non-immunogenicity, factors that to this day pose great challenges to final purification. In the 1990s, the advent of molecular genetic tools for GBS analysis allowed generations of isogenic mutant strains with altered βH/C phenotypes. With this technological breakthrough, the role of βH/C in GBS disease has been explored extensively in tissue culture and small animal models of infection. These studies have shown a toxin with a broad array of cytolytic, proinvasive, proapoptotic, and proinflammatory properties that contribute in a significant fashion to the virulence of GBS (Nizet, 2002; Liu *et al*., 2004). Current knowledge thus suggests the βH/C may represent an attractive therapeutic target in management of neonatal GBS disease.

## BIOCHEMISTRY AND GENETICS

### Basic properties of βH/C

The first report of the GBS βH/C provided by Todd (1934) described an extracellular molecule that is oxygen stable, acid and heat labile, and non-immunogenic. Analogies were drawn to streptolysin S (SLS) of group A *Streptococcus* (GAS), because the two β-hemolysins share many properties at first glance, including their inherent lability, broad-spectrum cytolytic activity, and lack of immunogenicity (Ginsburg, 1970). However, genetic evidence to be discussed below has ultimately revealed these toxins to be unrelated molecules (Nizet, 2002).

Biophysical properties of the GBS βH/C have placed technical hurdles in the path of its purification. The molecule is acid and heat labile, with significant loss of activity at 50°C after 15 minutes (Dal and Monteil, 1983). Normally associated with the bacterial cell surface, GBS βH/C activity is facilitated through direct contact between the bacterium and the target eukaryotic cell (Platt, 1995). Simple culture supernatants of GBS do not possess measurable βH/C activity. However, the presence of certain high-molecular weight "carrier" molecules in solution can stabilize extracellular toxin activity (Ginsburg, 1970).

As experimental proof, placement of an 0.22 micron filter between the GBS and the target erythrocyte blocks hemolysis unless a carrier molecule is added to the medium (Platt, 1995). Examples of carrier molecules that have shown an ability to stabilize βH/C activity include serum proteins such as albumin, Tween 80 and related detergents, starch polymers, and lipotechoic acid (Marchlewicz and Duncan, 1980; Ferrieri, 1982; Tsaihong and Wennerstrom, 1983). In attempted protocols for βH/C purification, separation of the candidate toxin from its carrier molecule has invariably been associated with loss of hemolytic activity.

In an early report on partial purification of the GBS βH/C activity (Marchlewicz and Duncan, 1980), researchers harvested GBS in late log growth phase, resuspended the bacteria in phosphate buffered saline supplemented with 1% glucose plus the stabilizers Tween 80 and starch, and then concentrated the supernatant by methanol or ammonium chloride precipitation. When the extract was applied to a Sephacryl S-300 column, two distinct peaks were noted, one of which harbored most of the hemolytic activity. However, electrophoretic separation of this peak revealed the presence of numerous protein bands. In a subsequent published protocol, βH/C was extracted from a GBS pellet by sonication in a buffer containing bovine serum albumin (BSA) and further purified by gel filtration (Dal and Monteil, 1983). Eluent from the column also produced two peaks, the first of which on electrophoresis resolved into four protein bands. The top three bands were nonhemolytic and consisted of BSA polymer, dimer, and monomer. The front running band was hemolytic, but harbored traces of BSA. The authors attempted further purification by agarose gel electrophoresis or affinity chromatography on protein-absorbing Blue Sepharose CL6B, but these techniques failed to separate hemolytic activity from the BSA carrier.

The above observation of a hemolytic front running band smaller than the size of BSA monomer (about 67 kDa) appears to place an upper limit on the size of the mature toxin (Dal and Monteil, 1983). Moreover, during efforts to purify the βH/C following extraction of GBS with detergent or lipoteichoic acid (LTA), it was observed that βH/C can be bound to these macromolecules without significantly affecting their respective elution profiles macromolecule on column chromatography, suggesting that the βH/C is likely to be a relatively small molecule (Tsaihong and Wennerstrom, 1983).

GBS βH/C expression occurs primarily between the early exponential and early stationary phases of growth (Platt, 1995). In a GBS chemostat system where βH/C is constantly extracted with Tween 40 in the growth medium, optimal release was measured during the late exponential phase. βH/C production also increases significantly under experimental conditions of enhanced GBS growth rate (Ross *et al*., 1999). Production of the toxin is greatly enhanced if a low concentration of glucose (about 2 mg/ml) or other fermentable carbohydrates is present in the medium, but unexpectedly, glucose in the range of 10 mg/ml almost entirely abolished βH/C production, pointing to regulatory linkages of βH/C production to cellular metabolism (Tapsall, 1986). Consistent with this hypothesis, treatment with various metabolic inhibitors including sodium fluoride, iodoacetate, or 2-deoxy-glucose greatly reduced the production of assayable βH/C.

## Mechanism of βH/C pore formation

It is notable that GBS βH/C is cytolytic for a very broad range of eukaryotic cells, including erythrocytes, fibroblasts (Tapsall and Phillips, 1991), lung epithelial and endothelial cells (Nizet *et al*., 1996; Gibson *et al*., 1999), brain endothelial cells (Nizet *et al*., 1997b), and macrophages and neutrophils (Liu *et al*., 2004). By implication, the βH/C must interact with and damage molecular targets common to the cell membranes of all these cells. Though these host molecules have not been fully defined, it is notable that βH/C activity can be markedly inhibited by phospholipids, such as dipalmitolyl phosphatidylcholine (DPPC) and dipalmitoyl phosphatidylethanolamine (DPPE) (Tapsall and Phillips, 1991). This finding suggests that the GBS βH/C may possess an affinity for similar phospholipids in the eukaryotic cell membrane bilayer and that this affinity could guide the toxin to its site of action. In contrast with streptolysin O (SLO) of GAS and related cytolytic toxins, cholesterol does not inhibit GBS βH/C activity.

Membrane pore formation is thought to represent a principal mechanism by which the GBS βH/C exerts its toxic activity, and this phenomenon has been most closely examined in studies of erythrocyte lysis. Marchlewicz and Duncan showed that upon incubation of GBS βH/C extract with a 1% suspension of erythrocytes at 37˚C, sufficient toxin associated with the target cells to produce 80% lysis within three minutes (Marchlewicz and Duncan, 1981). βH/C binding to erythrocytes appeared irreversible, unlike the interactions observed with SLS of GAS (Duncan and Mason, 1976). Also in marked contrast to SLS action, GBS βH/C exhibits a relatively short prelytic lag period, instead resembling lysis by GAS SLO or *Clostridium perfringens* theta-toxin (Bernheimer, 1947). Kinetic analysis revealed that rubidium ion and hemoglobin are released at the same rate from erythrocytes treated

with GBS βH/C, implying that the toxin creates membrane pores of relatively large size (Marchlewicz and Duncan, 1981).

Binding to erythrocytes by the βH/C, the length of the prelytic lag period, and the rate of hemolysis were found to be temperature dependent (Marchlewicz and Duncan, 1981). Since no toxin binding was noted at 0°C, it was proposed that a temperature-dependent fluidity of the membrane is necessary for GBS βH/C adsorption to the erythrocytes. As the incubation temperature increased, the length of the prelytic period decreased and the rate of lysis increased. Using an assay in which a fixed concentration of βH/C is incubated with an increasing concentrations of erythrocytes, the authors determined that more than one βH/C molecule is likely required to lyse a single cell (Marchlewicz and Duncan, 1981). When the logarithm of the fraction of unlysed RBC was plotted against βH/C concentration, a multi-hit survival curve was obtained (Atwood and Norman, 1949). Prediction based on this graph suggests that five molecules of βH/C are required to lyse a single sheep erythrocyte, reflecting a potency identical to that predicted for SLO of GAS (Inoue *et al*., 1976).

## Genetic basis of βH/C production

The first major advance toward understanding the genetics underlying GBS βH/C activity was achieved by Spellerberg and coworkers through negative selection (Spellerberg *et al*., 1999). Using a novel pGh9:ISS1 transposition vector, the group generated a mutant library from which they identifed several nonhemolytic GBS mutants. The transposon insertion sites all clustered within a seven kilobase genetic locus of the GBS chromosome that was named *cyl*, in reference to the cytolytic activity exhibited by the βH/C (Figure 43.1). This study and subsequent reports of the GBS *cyl* gene cluster identified 12 separate open reading frames (ORFs) organized in an operon structure (Spellerberg *et al*., 1999; Spellerberg *et al*., 2000; Pritzlaff *et al*., 2001). The deduced amino acid sequences of five of the genes (*cylD*, *cylG*, *acpC*, *cylZ, cylI*) demonstrate significant homologies to enzymes of prokaryotic fatty acid biosynthesis. Furthermore, the clustered arrangement of these genes in proximity to an acyl carrier protein (*acpC*) gene is reminiscent of the *fab* gene clusters of *Escherichiae coli, Vibrio harveyi*, and *Bacillus subtilis* (Rawlings and Cronan, 1992; Morbidoni *et al*., 1996; Shen and Byers, 1996). The predicted products of *cylA/B* share significant homologies to prokaryotic and eukaryotic ATP binding cassette transporters, which are known to be required for the hemolysin export in *E. coli* (Felmlee *et al*., 1985), *Bordetella pertussis* (Glaser *et al*., 1988), and *E. faecalis* (Gilmore *et al*., 1990, Chapter 41, this volume).

The association of the *cyl* locus with GBS βH/C production was corroborated through independent positive screening of a plasmid library of GBS chromosomal DNA in *E. coli* with the aim of identifying hemolytic transformants (Pritzlaff *et al*., 2001). One such hemolytic clone was isolated and the purified plasmid found to contain the GBS *cyl*E and downstream *cyl*F ORFs, as well as parts of the adjacent ORFs *cyl*B and *cyl*I. Confirmed targeted plasmid integrational disruption of *cyl*B, *cyl*F, and *cyl*I in three different GBS strains failed to consistently abrogate βH/C production. In contrast, targeted disruption of *cyl*E invariably produced a non-hemolytic phenotype, suggesting that of these genes, only *cyl*E was essential for βH/C expression (Pritzlaff *et al*., 2001). In each of the three strains in-frame allelic replacement of *cyl*E with an antibiotic cassette yields a NH (non-hemolytic) mutant

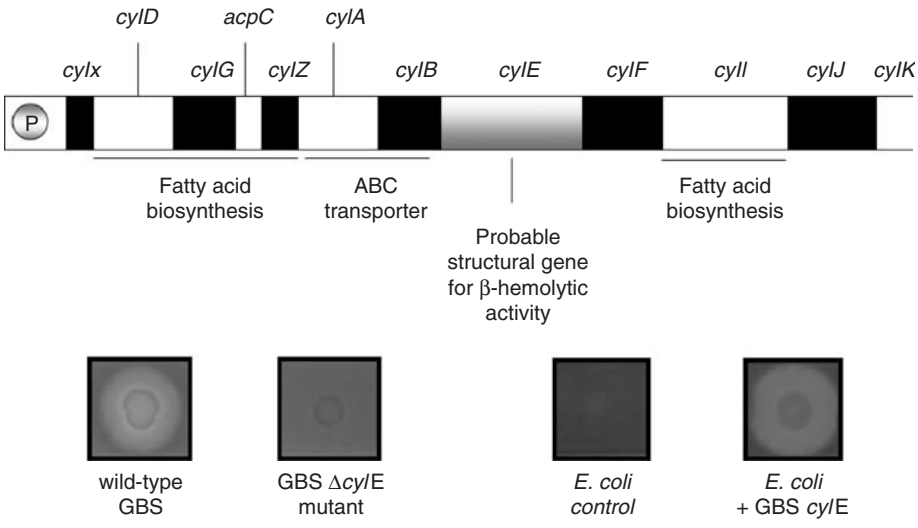

**FIGURE 43.1** Map of the GBS *cyl* operon encoding β-hemolysin/cytolysin activity. Allelic replacement of the *cyl*E ORF yields a nonhemolytic mutant, while heterologous expression of *cyl*E in *E. coli* is sufficient to confer a β-hemolytic phenotype (Spellerberg *et al*. 1999; Pritzlaff *et al*. 2002).

(Figure 43.1) in which βH/C activity can be restored by reintroduction of *cyl*E on a plasmid vector. When expressed in *E. coli* as a recombinant fusion protein, *cyl*E alone is sufficient to confer a robust β-hemolytic phenotype after 48 hours incubation (Pritzlaff *et al*., 2001) (Figure 43.1). The combination of the mutagenesis, complementation, and heterologous expression studies strongly suggests that *cyl*E encodes the structural determinant of the GBS βH/C, but does not exclude the possibility that additional GBS genes are involved in its processing, activation, or export to the cell surface. The predicted product of the *cyl*E ORF is a 78 kilodalton protein without significant homology to any other proteins in the GenBank databases. It remains to be determined whether the full-length protein or a derivative represents the mature toxin, and the lack of sequence homologies precludes further inference on the precise mechanism of βH/C action at this time.

Interestingly, GBS exhibiting a hyperhemolytic (HH) phenotype can be generated by chemical or transposon mutagenesis (Weiser and Rubens, 1987; Nizet *et al*., 1996). These observations suggest the existence of regulatory pathways that may contribute to the observed variations in βH/C expression with growth phase or glucose concentration, for example. Recently, one clear negative regulator of GBS *cyl* operon expression was identified, a homologue of the *cov*S-*cov*R two-component global transcriptional regulator that is so well studied in GAS (Lamy *et al*., 2004). A GBS *cov*S/R knockout mutant showed markedly increased βH/C activity, and *cov*R was shown to bind directly to the promoter motif at the head of the *cyl* operon (Lamy *et al*., 2004).

## Association of βH/C with pigment

An interesting feature of βH/C observed during biochemical and genetic studies is the close association of the βH/C to an orange pigment, also expressed on the surface of GBS. This pigment exhibits a triple peak absorbance at 455, 485, and 520 nm highly characteristic of β-carotene and related pigments (Merritt and Jacobs, 1978; Tapsall, 1986). The GBS carotenoid is quite labile and degrades readily to a single 425 nm peak when heated or subjected to freeze thawing. A close association with the βH/C was apparent because the pigment co-precipitated and co-purified with hemolytic activity (Tapsall, 1986). In fact, the inability to separate the two phenotypes led early investigators to conclude that the pigment could represent the natural carrier for the βH/C or even that the two molecules could be one and the same. However, published reports have since shown that the GBS βH/C and pigment are likely to be different molecules. For example, βH/C activity can be inactivated by subtilin, a serine protease. Other studies have shown that propagation of GBS under different pH and glucose concentrations results in differential yields of βH/C protein and pigment (Tapsall, 1987).

The close linkage between the GBS βH/C and carotenoid pigment holds true at the genetic level, since a screen of a transposon library for non-pigmented mutants once again mapped all insertions to the *cyl* locus (Spellerberg *et al*., 2000). Targeted mutagenesis of *cyl*E performed to knock out the βH/C phenotype also invariably knocked out expression of the orange pigment, and pigmentation returned when *cyl*E was used to complement the mutant *in trans* (Pritzlaff *et al*., 2001). Among clinical isolates, there is a direct correlation between the degree of pigmentation of the GBS colony and the strength of the surrounding zone of β-hemolysis (Merritt and Jacobs, 1978; Tapsall, 1986, 1987). And whether they were generated by chemical, transposon, or targeted mutagenesis, all NH GBS derivatives lack pigmentation and all HH derivatives display enhanced pigmentation (Nizet *et al*., 1996; Spellerberg *et al*., 1999; Spellerberg *et al*., 2000; Pritzlaff *et al*., 2001).

One should not conclude that one gene (*cyl*E) encodes both the βH/C and pigment, since all known carotenoid pigments are assembled in a series of enzymatic steps. Neither of the published complete GBS genome sequences (Glaser *et al*., 2002; Tettelin *et al*., 2002) contain homologues of the enzymes typical of bacterial carotenogenesis (e.g., phytoene synthases, phytoene or carotene dehydrogenases, or lycopene cyclases); thus, the GBS pigment would appear to be the product of a unique biosynthetic pathway. The GBS pigment was recently found to play a role in pathogenesis by virtue of antioxidant properties consistent with the known oxygen radical scavenging potential of carotenoids. The pigment conferred protection to GBS against the antimicrobial effects of hydrogen peroxide, singlet oxygen, superoxide, and hypochlorite, all of which play a role in the oxidative burst-killing mechanism of host phagocytic cells (Liu *et al*., 2004). As a consequence, wild-type (WT) GBS has enhanced intracellular survival compared to non-pigmented, NH Δ*cyl*E mutants in neutrophil and macrophage killing assays, a difference that persists even when DPPC is added to block βH/C activity (Liu *et al*., 2004).

# BIOLOGICAL EFFECTS

## Cytolytic injury to eukaryotic cells

GBS βh/c has been demonstrated to lyse several different cell types, including sheep erythrocytes, murine

fibroblasts (Tapsall and Phillips, 1991), and human lung epithelial cells (Nizet *et al*., 1996; Doran *et al*., 2002), lung endothelial cells (Gibson *et al*., 1999), brain endothelial cells (Nizet *et al*., 1997b), and macrophages (Ring *et al*., 2000; Liu *et al*., 2004). Electron microscopic examination of GBS βh/c-hemolysin-induced injury to lung epithelial cells is consistent with the action of a pore-forming toxin (Figure 43.2). Discrete membrane disruptions, cellular swelling, loss of intracytoplasmic density, changes in subcellular organelles and chromatin are seen that appear to reflect entry of water into the cell and hypo-osmotic damage (Nizet *et al*., 1996). The GBS βh/c contributes to a loss of integrity in the tight junctions of polar lung endothelial cell monolayers, allowing passive flux of macromolecules across tight junctions (Gibson *et al*., 1999). There exist no reports to date of any eukaryotic cell types resistant to the cytotoxic effects of the GBS βh/c.

## Triggering of cellular apopotosis

The clumping of nuclear chromatin observed in epithelial cells injured by GBS βh/c is reminiscent of the pattern observed with apoptosis or programmed cell death. Live GBS has been shown to induce apoptosis in macrophages (Fettucciari *et al*., 2000; Ulett *et al*., 2003; Liu *et al*., 2004), splenocytes (Liu *et al*., 2004), and hepatocytes (Ring *et al*., 2002a), and several investigators have explored a potential linkage of the βH/C to this form of induced cell death.

Fettucciari and co-workers described a hemolytic GBS strain that upon incubation with murine peritoneal macrophages, induced apoptosis of the host cells within 24 hr (Fettucciari *et al*., 2000). Membrane permeability changes were noted as early as 2 hr in 70% of cells by propidium iodide exclusion studies, and progression to apoptosis was demonstrated by electron microscopy, DNA fragmentation assay, and *in situ* TUNEL (terminal deoxynucleotide transferase-mediated dUTP nick end labeling) staining. Under conditions that either inhibited βH/C production (high glucose concentrations) or inhibited βH/C activity (addition of DPPC), apoptosis was abrogated. These observations led the authors to suggest that the βH/C was responsible for macrophage apoptosis. Subsequently, Ulett *et al*. compared the ability of WT or Δ*cyl*E mutant GBS to induce apoptosis in J774 macrophages (Ulett *et al*., 2003). Under their experimental conditions, the viability of macrophages exposed to each strain was similar, but significantly less than that of macrophages exposed to GBS that had been grown in high-glucose media. The authors proposed that macrophage apoptosis induced by GBS was independent of βH/C, and instead reflected the action of a GBS factor coregulated along with βH/C by glucose.

Our recent study attempted to shed light on these discrepancies by assessing macrophage apoptosis induced by GBS strains expressing different levels of βH/C and their corresponding NH Δ*cyl*E allelic exchange mutants (Liu *et al*., 2004). Apoptosis of murine peritoneal macrophage apoptosis was noted only with a strong hemolytic WT strain, but not with a weak hemolytic strain or either of the Δ*cyl*E mutants. The level of apoptosis was more prominent at higher bacterial inocula and could be inhibited with DPPC. Incubation of macrophages with an increasing dose of crude βH/C extract led to a dose-dependent increase

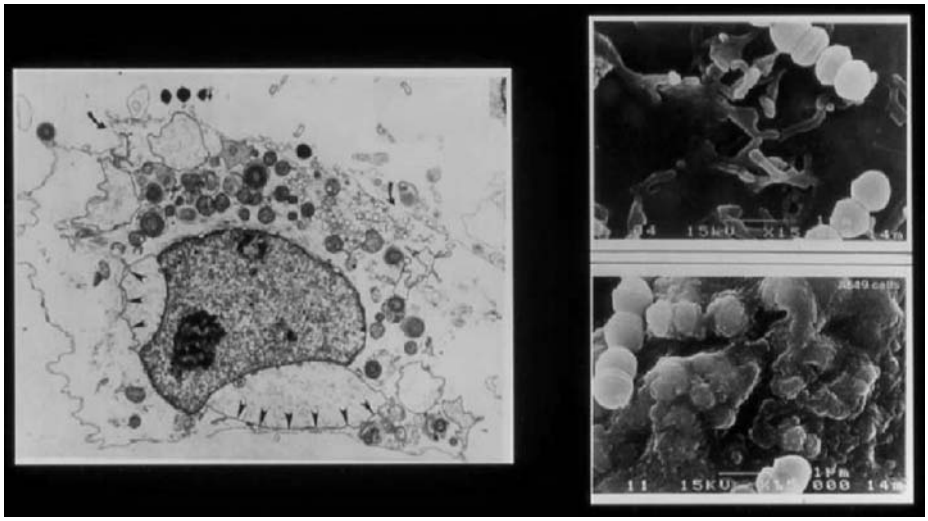

**FIGURE 43.2** GBS β-hemolysin/cytolysin mediated injury to cultured human lung epithelial cells. At left, transmission electron microscopy shows membrane pore formation, swelling of cell contents, and clumping of nuclear chromatin. At right, the normal villous architecture of the lung epithelial surface (top) seen with a weakly hemolytic GBS isolate is abolished to swelling and bleb formation upon exposure to a strongly hemolytic isolate (below) (Nizet *et al*., 1996).

in the number of TUNEL positive-staining macrophages. In mice challenged intravenously with GBS, apoptosis was abundantly evident among splenocytes in those animals infected with a strongly hemolytic WT GBS strain but not in mice challenged with its isogenic Δ*cyl*E mutant (Liu *et al*., 2004). In a study of septic liver injury in rabbits challenged intravenously with WT and βh/c mutant GBS, positive TUNEL staining and activation of caspase-3 in hepatocytes were also correlated to toxin production (Ring *et al*., 2002a). The balance of experimental data suggest that GBS induces apoptosis by βH/C-dependent and βH/C-independent mechanisms, with the toxin playing a greater role at higher bacterial concentrations and in the case of strongly hemolytic strains.

The mechanism of GBS βH/C-induced apoptosis may reflect subcytolytic perturbance of membrane integrity and influx of calcium ion, as the degree of apoptosis is predictably modulated through addition of excess cation to the media or chelation with EGTA (Fettucciari *et al*., 2000). More detailed analyses by Fettucciari and colleagues pointed to the involvement of c-Jun $NH_2$ terminal kinase (JNK), p38, and extracellular signal-regulated kinase (ERK), three members of mitogen-activated protein kinases (MAPKs) family, in GBS-induced macrophage apoptosis (Fettucciari *et al*., 2003). The authors demonstrated that during induction of apoptosis, WT hemolytic GBS stimulates a strong and persistent activation of JNK and p38 with concomitant inhibition of ERK. In contrast, use of a NH GBS strain induces only a transient activation of JNK, p38, and ERK MAPKs with no resultant apoptosis.

## Cell activation and proinflammatory signaling

Membrane pore formation and resulting ion fluxes likely result in activation of signaling cascades within host cells. Pore formation may also facilitate introduction of other effector molecules that directly activate certain host signaling pathways, as has been documented both in enterobactereciae (Cornelis and Van Gijsegem, 2000) and with streptolysin O of GAS (Madden *et al*., 2001). A pore-forming toxin of *Streptococcus pneumoniae*, pneumolysin, interacts with Toll-like receptor 4 (TLR-4) to stimulate innate inflammatory responses (Malley *et al*., 2003). Although it is unknown whether any or all of these potential mechanisms apply, the GBS βH/C has been shown to activate certain inflammatory response genes in target cells.

In human lung epithelial cells, the GBS βH/C stimulates gene transcription and release of interleukin-8 (IL-8), a potent neutrophil chemokine (Doran *et al*., 2002). The βH/C also promotes GBS intracellular invasion of lung epithelium, and both IL-8 release and invasion can be inhibited by the addition of DPPC (Doran *et al*., 2002). In human brain microvascular endothelial cells, oligonucleotide microarray analysis was employed to assess the transcriptional response of the blood-brain barrier to GBS and to specific GBS virulence factors (Doran *et al*., 2003). It was observed that GBS infection of the brain endothelium induced a highly specific and coordinate set of genes that act to orchestrate neutrophil recruitment and activation. These included the chemokines IL-8, Groα and Groβ, the neutrophil stimulating growth factor GM-CSF, the antiapoptotic factor Mcl-1, and the endothelial neutrophil receptor and activating molecular ICAM-1. Strikingly, infection of the endothelial cells with a Δβh/c mutant resulted in a marked reduction in expression of these genes involved in the neutrophil inflammatory response. Cell-free bacterial supernatants containing the βh/c toxin induced IL-8 release, identifying the toxin as the principal provocative factor for blood-brain barrier inflammatory activation. Migration of human neutrophils across polar brain endothelial cell monolayers was stimulated by the βh/c through a process involving IL-8 and ICAM-1 (Doran *et al*., 2003).

In murine macrophages, βH/C induces the expression of nitric oxide synthase (iNOS) and the release of NO, a potent vasodilator proximal mediator of the sepsis cascade (Ring *et al*., 2000). Stimulation of NO release by βH/C appears to depend on protein tyrosine kinases and NF-κB, suggesting the involvement of intracellular pathways similar to those that mediate lipopolysaccharide-induced iNOS activation (Ring *et al*., 2000). The induction of NO by GBS βH/C likely requires a coactivating factor be present on the cell surface, as a cell-free βH/C extract does not trigger NO production. In non-activated macrophages, synergistic activation by GBS cell wall components and βH/C is necessary to induce a NO response, which indicates that both factors cooperate to substitute for the priming signal typically provided by IFNγ (Ring *et al*., 2002b).

In summary, the GBS βH/C is a potent toxin with proven cytolytic activity against a wide variety of cell types encountered during the various steps of human disease pathogenesis. At subcytolytic doses, the GBS βH/C exerts a variety of proinvasive, proinflammatory, and proapoptotic effects on target cells. Therefore, it is logical to hypothesize that such effects would have deleterious consequences on the infected host. The contribution of the βH/C toxin to GBS pathogenesis has been investigated in several *in vivo* models of invasive disease and is reviewed in the next section.

## βH/C IN THE PATHOGENESIS OF GBS NEONATAL INFECTION

Pneumonia, sepsis, and meningitis are the three most common clinical manifestations of invasive GBS infection in human newborns. In the more frequent instance of early-onset infection, the infant directly aspirates an inoculum of GBS from contaminated amniotic or vaginal fluids *in utero* or during passage through the birth canal. These infants present with respiratory signs indicative of an initial pulmonary focus of infection, and the GBS quickly spreads to the bloodstream to produce acute septicemia. Late-onset GBS infections can develop in infants up to several months of age, and are suspected to reflect mucosal colonization with the bacterium and subsequent invasion into the bloodstream. These infections often have a subacute presentation with a high rate of dissemination to end organs, such as the central nervous system to produce meningitis, or to skeletal foci to produce osteomyelitis or septic arthritis (Nizet and Rubens, 2000; Doran and Nizet, 2004). Because clear βH/C activity is apparent in the vast majority of GBS isolated from clinical sources, several efforts have been directed at identifying the role of this toxin in disease pathogenesis. The availability of isogenic transposon or allelic exchange mutants with altered βH/C phenotype has allowed direct assessment of the toxin in several small animal models of GBS infection.

### Pneumonia

The first *in vivo* demonstration of a βH/C effect on lung pathology was accomplished using chemically derived NH and HH GBS mutants (Wennerstrom *et al*., 1985). These researchers used intranasal inoculation to challenge mice with GBS, and found that increased βH/C activity was associated with greater degrees of cellular injury, as measured by lactate dehydrogenase release into the bronchalveolar fluid, and a decreased $LD_{50}$ and earlier time to death for a given inoculum. Similar results were observed upon transthoracic challenge of neonatal rats with WT GBS and isogenic HH and NH transposon mutants. $LD_{50}$ at 48 hr for the NH mutant was 1,000-fold greater than $LD_{50}$ for either the WT strain or HH mutant, and the HH mutant lead to death of the infected animal more rapidly than the WT strain (Nizet *et al*., 1997a).

Most recently, pathophysiology associated with βH/C was investigated in a neonatal rabbit model of pneumonia induced by direct intracheal injection of GBS bacteria (Hensler *et al*., 2005). Animals infected with wild-type (WT) GBS developed focal pneumonia and by 18 h had 100-fold more bacteria in lung tissues than rabbits infected with the Δβh/c mutant. Mortality, development of bacteremia, and mean bacterial blood counts were all significantly higher in the animals challenged with WT GBS compared to the Δβh/c mutant. Lung compliance during mechanical ventilation was impaired upon infection with WT GBS but not with the Δβh/c strain. This work provided *in vivo* evidence for a critical role of the βh/c toxin in GBS neonatal pneumonia and the breakdown of the pulmonary barrier to systemic infection.

When a heavy inoculum of GBS is aspirated by the newborn, βH/C is likely to contribute to pneumonia by direct lysis of lung epithelial and pulmonary endothelial cells and perhaps alveolar macrophages, contributing to barrier breakdown and systemic dissemination (Nizet *et al*., 1996; Liu *et al*., 2004; Hensler *et al*., 2005). Supporting this hypothesis are the *in vitro* studies demonstrating a direct correlation of GBS βH/C activity to lung cellular injury as measured by LDH release, trypan blue nuclear staining, albumin flux, and ultrastructural examination (Nizet *et al*., 1996; Gibson *et al*., 1999). The stimulation of IL-8 release by the βh/c may contribute to neutrophilic inflammation seen in neonatal pneumonia, whereas the toxin's promotion of GBS cellular invasion may facilitate bloodstream entry (Doran *et al*., 2002). The very same phospholipid DPPC that inhibits βH/C-induced cytotoxicity (Nizet *et al*., 1996), apoptosis (Fettucciari *et al*., 2000; Liu *et al*., 2004), and proinflammatory effects (Doran *et al*., 2002) is also the major constituent of human pulmonary surfactant (70% by weight). Deficiency in pulmonary surfactant may explain the markedly increased risk of premature, low-birth weight infants who suffer severe GBS pneumonia and sepsis (Tapsall and Phillips, 1991; Doran and Nizet, 2004).

### Septicemia

Sepsis occurs when GBS successfully breach the primary barrier of the body to produce clinical symptoms of hemodynamic instability and organ dysfunction. The first evidence that the GBS βH/C could contribute to the pathogenesis of septicemia was provided by Griffiths and Rhee, who found that systemic administration of a GBS βH/C extract to rabbits produced a significant acute hypotensive reaction and a limited number of deaths due to shock (Griffiths and Rhee, 1992). In parallel experiments, injection of GAS streptolysin S extract had no such effect on hemodynamics. In comparison of WT GBS and βH/C mutants in

murine intravenous challenge models of septicemia, the toxin is found to contribute markedly to an overall mortality and rapidity of death (Puliti *et al*., 2000; Liu *et al*., 2004). These changes are likely to reflect a combination of the antiphagocytic and proinflammatory properties of the toxin. The ability of GAS βh/c to lyse host neutrophils and macrophages and/or trigger their apoptosis leads to enhanced survival of the organism on encounter with the phagocytic cells (Liu *et al*., 2004). Systemic release of the proinflammatory cytokine IL-6 is greatly increased in response to a hemolytic GBS strain compared to its isogenic NH mutant (Puliti *et al*., 2000).

The most detailed analysis of GBS βH/C in the pathogenesis of septicemia was accomplished using WT GBS and isogenic mutants in the adult rabbit model (Ring *et al*., 2002a). Mortality was highest in rabbits challenged with an HH mutant (67%), compared to animals infected with the weakly hemolytic parent strain (27%) or the NH mutant (0%). Corresponding changes in bacterial counts in the blood and mean arterial pressure confirmed the association of βH/C expression with resistance to phagocytic clearance and induction of sepsis symptomatology. Histopathologically, disseminated septic microabscesses surrounded by necrotic foci were found exclusively in the livers of animals infected with the HH mutant, and they also exhibited a 20-fold increase in serum transaminase levels and evidence of hepatocyte necrosis and apoptosis. Together, the work provided clear evidence that GBS βH/C plays a crucial role in the pathophysiology of GBS sepsis by inducing liver failure and high mortality (Ring *et al*., 2002a).

## Meningitis

A feared but not infrequent manifestation of invasive GBS disease is meningitis. Meningitis is a significant cause of mortality in GBS disease and 25–40% of infants may suffer permanent neurological sequelae, such as hearing loss, cognitive delay, seizures, or cerebral palsy. In animal models, the risk of meningitis can be correlated to the magnitude and duration of GBS bacteremia (Ferrieri *et al*., 1980), and the known effects of βH/C in blocking phagocytic clearance (Liu *et al*., 2004) would be predicted to increase the chance of meningitis on this account alone. GBS also have the ability to invade and transcytose human brain endothelial cells (Nizet *et al*., 1997b), the single-cell layer that comprises the majority of the blood-brain barrier. The ability of the βH/C to stimulate GBS intracellular invasion (Doran *et al*., 2002) could be seen as a second potential factor promoting the development of meningitis. Finally, GBS has been shown to activate inflammatory gene expression in human brain endothelial cells and to promote the consequent recruitment, activation, and transcytosis of neutrophils (Doran *et al*., 2003). Inflammatory damage to the blood-brain barrier induced by the βH/C therefore represents a third mechanism by which the toxin could promote the development of meningitis.

Consistent with the above mechanisms identified by *in vitro* experiments, mice challenged *in vivo* with an isogenic ΔβH/C mutant experience less blood-brain barrier penetration and suffer fewer cases of meningitis than mice challenged with the WT GBS parent strain (Doran *et al*., 2003). Bacterial counts in brain tissue were significantly higher in the animals challenged with WT GBS, and histopathologic studies confirmed meningeal thickening, thrombosis of meningeal vessels, leukocytic infiltration, and areas of bacterial microabscess formation in the brain parenchyma, changes generally absent in mice challenged with the ΔβH/C mutant. Additional studies performed by intrathecal challenge of rats with GBS WT and ΔβH/C mutant strains have shown a direct correlation of toxin expression to apoptosis of hippocampal neurons (J. Weber and V. Nizet, unpublished), a point of clinical concern given the limited plasticity of neuronal cells for regeneration.

## Potential therapeutics

Because the βH/C contributes directly to disease pathogenesis through direct cellular injury, resistance to immune clearance, and activation of local and systemic inflammatory responses, the toxin constitutes an attractive target for adjunctive therapy of infants with GBS infection. Neutralizing antibody to the βH/C does not arise in the course of natural infection (Todd, 1934), and no specific antisera were detected upon repeated injection of partially purified βH/C preparations in rabbits for three months (Dal and Monteil, 1983). Progress in development of antibodies may benefit from more detailed knowledge of protein structure, as a synthetic peptide approach has recently been successful in generating inhibitory antibodies against the naturally non-immunogenic SLS toxin of GAS (Carr *et al*., 2001; Dale *et al*., 2002).

An alternative therapeutic modality to GBS infection may involve the use of phospholipid inhibitors to inactivate the βH/C. DPPC has been shown in many *in vitro* studies to be highly effective in blocking lysis of erythrocytes, fibroblasts, epithelial cells, and macrophages (Tapsall and Phillips, 1991; Nizet *et al*., 1996; Liu and Nizet, 2004). Likewise, cytokine secretion, apoptosis, and cellular invasion promoted by the GBS βH/C can also be prevented using this inhibitor

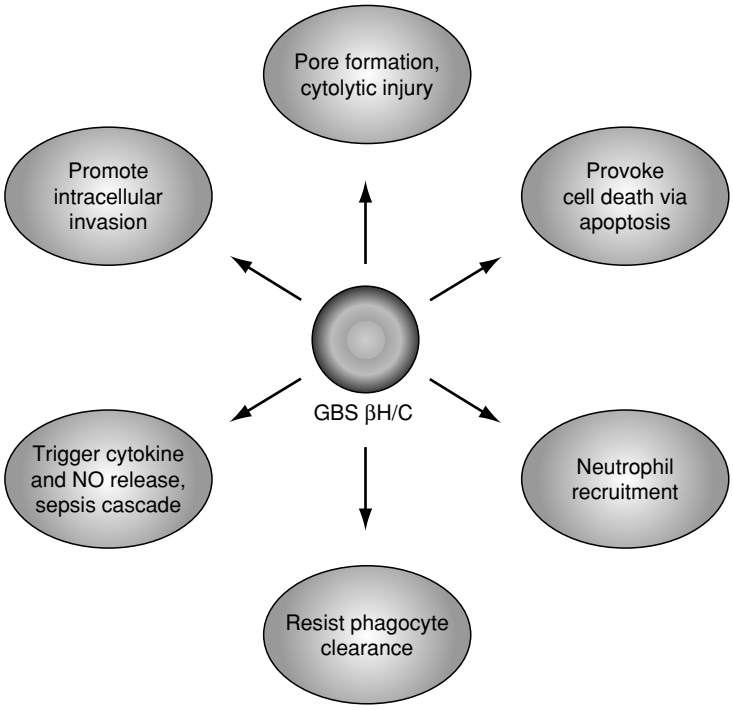

**FIGURE 43.3** Schematic representation of biological activities attributed to the GBS β-hemolysin/cytolysin, a multifunctional toxin and virulence factor in the pathogenesis of invasive infection.

(Fettucciari *et al*., 2000; Doran *et al*., 2002; Liu *et al*., 2004). DPPC is a major component of surfactant, which is used therapeutically to restore lung compliance in premature neonates. Indeed, experiments in a ventilated premature rabbit model of GBS pneumonia and retrospective analysis of clinical data from human neonates with early onset GBS suggest beneficial effects of surfactant therapy against GBS-induced lung injury (Herting *et al*., 1997; Herting *et al*., 2000). Recent data identifying a key role of the βH/C in newborn pneumonia and lung injury (Hensler *et al*., 2005) may provide a key molecular mechanism explaining the therapeutic efficacy of surfactant replacement in terms of DPPC inhibition of the toxin.

## CONCLUSION

Fueled by technological innovations in streptococcal genetics, the past decade has witnessed a resurgence of research into the biology and function of the GBS βH/C. The role of the βH/C as a virulence factor in disease pathogenesis has been confirmed in many animal models of GBS infection, and several unique properties of the toxin have been characterized. It is apparent that the βH/C is a multifunctional molecule, capable of exerting cytolytic, proapoptotic, proinvasive, proinflammatory, or antiphagocytic effects on a variety of target cells (Figure 43.3). At the biochemical level, select signaling pathways triggered by the βH/C are beginning to be unraveled. Yet the basic structural properties of the toxin remain poorly characterized because of difficulties presented in purification of this labile and apparently non-immunogenic toxin. Determination of the structure of the mature protein toxin represents the overriding challenge for the future of GBS βH/C research.

CHAPTER

# 44

# Hemolysins of *vibrio cholerae* and other *vibrio* species

*Sumio Shinoda and Shin-ichi Miyoshi*

## INTRODUCTION

Bacteria of the genus *Vibrio* are normal habitants of the aquatic environment, but the 11 species listed in Table 44.1 are believed to be human pathogens (Janda, 1988; Chakraborty, 1977). These species can be classified into two groups according to the types of diseases they cause: One group causes gastrointestinal infections and the other extraintestinal infections (Table 44.1). The pathogenic species produce various pathogenic factors including enterotoxin, hemolysin, cytotoxin, protease, siderophore, adhesive factor, and hemagglutinin, with hemolysin being the one most widely distributed in the pathogenic vibrios (Table 44.2). Although the most important pathogenic factor of *Vibrio cholerae* O1/O139 is cholera enterotoxin (CT), a hemolysin (El Tor hemolysin) produced by biovar *eltor* is also reported to cause diarrhea. A thermostable direct hemolysin (TDH) produced by *Vibrio parahaemolyticus* is also believed to be a major pathogenic component of the species. This article offers a review of recent information on hemolysins of pathogenic vibrios with special reference to the above two representatives.

## *VIBRO CHOLERAE* HEMOLYSINS

Of the currently recognized pathogenic vibrios, the species *V. cholerae* is the most extensively studied because it is the causative agent of the often lethal disease cholera. The total genome sequence of 1,072,314 bp of *V. cholerae* strain N16961 was published by Heidelberg *et al*. (2000). Cholera is characterized by copious uncontrolled purging of rice water stools leading to severe electrolyte depletion, dehydration, acidosis, shock, and, if left untreated, death. Characteristic signs and symptoms of severely dehydrated patients include an increase in pulse rate and a decrease in pulse volume, hypotension, an increase in respiratory rate accompanied by deep respiration, sunken eyes and cheeks, dry mucous membrane, decreased skin turgor, abdominal pain, a decrease in urine output, and thirst (Harvey *et al*., 1966).

*V. cholerae* is serologically classified by the major surface O antigen. Until the emergence of the O139 serogroup, only the O1 serogroup had been thought to be the etiologic agent of cholera. All strains that were identified as *V. cholerae* on the basis of biochemical tests but were negative for agglutination with O1 antiserum were referred to as non-O1 *V. cholerae*. The emergence of *V. cholerae* O139 Bengal as the second etiologic agent of cholera in October 1992 in the southern Indian coastal city of Madras (Ramamurthy *et al*., 1993; Albert *et al*., 1993) necessitated the redefinition of non-O1 *V. cholerae* to non-O1/non-O139 *V. cholerae*. The majority of non-O1/non-O139 strains do not produce cholera enterotoxin (CT) and are not associated with epidemic diarrhea, although non-O1/non-O139 strains are occasionally isolated from cases of diarrhea and a variety of extraintestinal infections, including wounds, ear, sputum, urine, and cerebrospinal fluid (Morris, 1990).

CT is the major toxin causing the severe watery diarrhea produced by *V. cholerae* O1 and O139 strains. Zonula occludens toxin (Zot) (Fasano, 1991) and accessory cholera toxin (Ace) (Trucksis *et al*., 1993) have also

**TABLE 44.1** Pathogenic species of the genus *Vibrio*

| Gastrointestinal diseases | Extraintestinal disease |
|---|---|
| *V. cholerae* O1 | *V. vulnificus* |
| *V. cholerae* O139 | *V. damsela* |
| *V. cholerae* non-O1/non-O139 | *V. alginolyticus* |
| *V. mimicus* | *V. cincinnatiensis* |
| *V. parahaemolyticus* | *V. metschnikovii* |
| *V. fluvialis* | |
| *V. furnissii* | |
| *V. hollisae* | |
| *V. metschnikovii* | |

been demonstrated to be enterotoxic factors of these two serogroups. *V. cholerae* non-O1/non-O139 strains have been reported to produce a 17 amino acid, heat-stable enterotoxin (NAG-ST) (Takeda *et al*., 1991), and the production of hemolysins has also been reported.

El Tor strains of *V. cholerae* O1 produce a hemolysin (El Tor hemolysin) that has a lytic effect on Vero and other mammalian cells in culture (Honda and Finkelstein, 1979). Some strains of *V. cholerae* non-O1/non-O139 produce a hemolysin (NAG hemolysin) that is indistinguishable biologically, physicochemically, and antigenically from El Tor hemolysin (Yamamoto *et al*., 1986). Hemolysins were purified from culture filtrates of the vibrios and their properties were investigated. Both hemolysins were indistinguishable in their molecular sizes (about 65 kDa), amino acid compositions, and immunological characteristics. As El Tor hemolysin and NAG hemolysin are thought to be the same hemolysin, they are abbreviated to VCC (*V. cholerae* cytolysin) in this chapter. VCC can cause bloody fluid accumulation in ligated rabbit ileal loops, in contrast to the watery fluid produced by CT (Ichinose *et al*., 1987); thus, VCC may play a role in the pathogenesis of gastroenteritis caused by *V. cholerae* strains.

**TABLE 44.2** Hemolysins produced by vibrios

| | Name or abbreviation | Remarks |
|---|---|---|
| 1. Hemolysins related to El Tor hemolysin | | |
| *V. cholerae* O1 biotype eltor | El Tor hemolysin (VCC) | 65kDa (64,864Da)[a], Two-step processing for mature protein, Colloid osmotic hemolysis, RIL[b] positive |
| *V. cholerae* non-O1/non-O139 | NAG hemolysin | Indistinguishable from El Tor hemolysin (biologically, physicochemically, immunologically) |
| *V. mimicus* | VMH | 63kDa (65,972Da), Two-step processing for mature protein, Colloid osmotic hemolysis, RIL positive, 76% homology with El Tor hemolysin gene |
| *V. fluvialis* | | 63kDa, Related to VCC immunologically and genetically |
| *V. furnissii* | | Indistinguishable from *V. fluvialis* hemolysin |
| *V. anguillarum* | | 84,260Da (Calculated from amino acid sequence deduced from open reading frame including signal peptide), 57% homology with El Tor hemolysin gene |
| 2. Hemolysin related to Vp-TDH | | |
| *V. parahaemolyticus* | | |
| KP positive strains | Vp-TDH | Dimer of 21kDa (18,496Da) subunit, Thermostable (heating at 100°C), Colloid osmotic hemolysis, RIL positive, Cardiotoxicity |
| KP negative but pathogenic strains | Vp-TRH | Closely related to Vp-TDH but thermolabile, Virulence factor in diarrheal cases due to KP-strains |
| *V. hollisae* | Vh-rTDH | Thermolabile |
| *V. cholerae* non-O1/non-O139 | NAG-rTDH | Thermostable |
| *V. mimicus* | Vm-rTDH | Thermostable |
| 3. Other hemolysins | | |
| *V. vulnificus* | VVH (vulnificolysin) | 50kDa (50,851Da), Colloid osmotic cell lysis, Inducing apoptosis, Temperature-independent binding to cholesterol (suspected binding site) |
| *V. damsela* | Damselysin | 69kDa, Phospholipase D |
| *V. metschnikovii* | | 50kDa, Colloid osmotic cell lysis |
| *V. parahaemolyticus* | LDH (TLH) | 43kDa (41,453Da) and 45kDa (42,794Da), Lecithin-dependent indirect hemolysis (Phospholipase A2/lisophospholipase) |
| | δ-VPH | Produced by transformed *E. coli* cell, but not found in *V. parahaemolyticus* culture |

[a] Molecular weight deduced from SDS PAGE and amino acid sequence in parenthesis
[b] Rabbit ileal loop test (a test for enterotoxic activity)

Cell vacuolation by VCC is thought to contribute to virulence of *V. cholerae*. Coelho *et al*. (2000) showed correlation between vacuolation of Vero cells and VCC production in *V. cholerae* O1 Amazonia variant, and Mitra *et al*. (2000) showed that vacuolation of HeLa cells caused by various serogroups of *V. cholerae* was the action of VCC. Figueroa-Arredondo *et al*. (2001) demonstrated that one-third of diarrhea-associated non-epidemic *V. cholerae* strains from Mexico caused vacuolation of cultured Vero cells. They cloned the gene for vacuolating activity and found it to correspond to *hlyA* encoding VCC. The effect on local intestinal inflammatory or other defense responses by perturbing intracellular trafficking or ion exchange is suggested.

Yamamoto *et al*. (1990a) cloned and sequenced the genes of VCC composed of *hlyA* and *hlyB*, in which *hlyA* is a structural gene of the hemolysin molecule (Figure 44.1) and *hlyB* is thought to play a role of chaperone. They demonstrated that the VCC is synthesized as an 82-kDa precursor form (prepro-HlyA) consisting of a signal peptide (25 amino acid residues) at the N-terminus, a pro-region (132 residues), and a mature region (584 residues) at the C-terminus. The mature form of VCC is produced by a two-step processing; during passage through the inner membrane, the signal peptide is cleaved off, followed immediately by extracellular secretion in which the pro-region is lost. This two-step processing is necessary to activate VCC (Yamamoto *et al*., 1990a; Hall and Drasar, 1990; Nagamune *et al*., 1996). Nagamune *et al*. (1997) suggested that the pro-region of the hemolysin functions as an intramolecular chaperone, which plays a role in

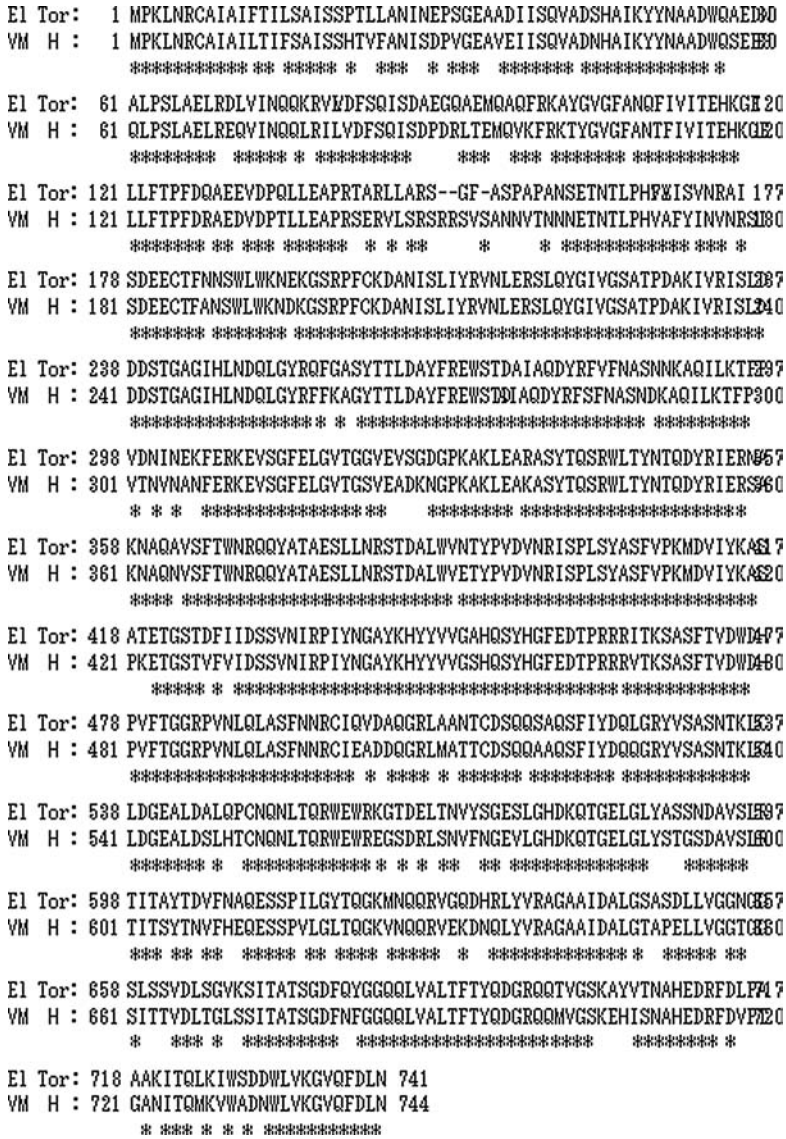

**FIGURE 44.1** DNA sequences of *hlyA*, gene encoding El Tor hemolysin (Yamamoto *et al*., 1990a) and VMH (Kim *et al*., 1997), whose GenBank Accession numbers are CAA36035 and AAB58399, respectively.

the correct folding of mature VCC (65 kDa). Valve *et al*. (2004) showed that 79 kDa pro-VCC also had binding ability to eukaryotic cells and was activated to mature form by the cellular metalloproteinase. A 50 kDa VCC is also found in culture filtrate of *V. cholerae*. Ikigai *et al*. (1999) showed that the 50 kDa VCC is in the C-terminus region of 65 kDa VCC and retains the essential part for oligomerization.

VCC is thought to act as a pore-forming toxin through its oligomer formation (Figure 44.2). The estimated size of the pore is 1.2 – 1.6 nm (Ikigai *et al*., 1996), and it is composed of pentameric oligomers (Zitzet *et al*., 1999). Cholesterol in the target cell membrane was reported to play an important role in the assembly of the toxin oligomers needed for pore formation by triggering oligomerization (Ikigai *et al*., 1996). Formation of channels in planar lipid phosphatidylcholine-cholesterol-bilayer membranes was also demonstrated (Ikigai *et al*., 1997). Saha and Banerjee (1997) showed carbohydrate-mediated regulation of interaction of VCC with erythrocyte and phospholipid vesicles. Menzl *et al*. (1997) showed some preferential movement of anions over cations through the pores at neutral pH by measuring zero-current membrane potentials, and has suggested that the VCC channel is moderately anion-selective. Although VCC is thought to be a unique pore-forming toxin differing from a paradigm such as staphylococcal α-hemolysin, amino acid sequence analysis and 3D structure modeling indicated similarity of the core sequence of VCC and α-hemolysin (Olson and Gouaux, 2003). Zhang *et al*. (1999) suggested that glycophorin, a snaloglycoprotein of erythrocyte membrane, is a receptor for VCC using a monoclonal antibody, which not only blocks the binding of VCC to human erythrocytes but also inhibits the VCC action.

The *tdh* gene encoding TDH of *V. cholerae* non-O1 (NAG-TDH) has 98.6% homology with *tdh*, which is thought to be the actual gene producing TDH of *Vibrio parahemolyticus* (Vp-TDH), so the property of NAG-TDH is quite similar to Vp-TDH (Baba *et al*., 1991).

A hemolysin having phospholipase C activity was purified from *V. cholerae* O139 strain and characterized (Pal *et al*., 1997). Fallarino *et al*. (2002) showed the existence of a new thermostable hemolysin of *V. cholerae*, Vc-δTH, which resembles the δ-VPH of *V. parahemolyticus* reported by Taniguchi *et al*. (1990).

## *VIBRIO PARAHEMOLYTICUS* HEMOLYSINS

*V. parahemolyticus* inhabits coastal and estuary waters and is recognized to cause gastroenteritis following consumption of seafood. This vibrio was discovered by Fujino *et al*. (1953) when an outbreak of food poisoning occurred in the southern suburbs of Osaka, Japan in October 1950.

The outstanding features of *V. parahemolyticus* infection are severe abdominal pain, diarrhea, nausea, vomiting, and mild fever, with headache, diarrhea (frequently bloody stools), and abdominal pain being the main symptoms (Miwatani and Takeda, 1976). The mean incubation period is 6 to 12 hours and diarrhea or soft stools persist for 4 to 7 days. The mortality rate is very low, although the first outbreak reported by Fujino *et al*. (1953) resulted in high mortality (20 victims out of 272 patients).

Although *V. parahemolyticus* is a natural inhabitant of seawater as shown above, only some of the isolates are pathogenic to humans. Miyamoto *et al*. (1969) reported that the hemolytic characteristic of this vibrio on a special agar medium (Wagatsuma's medium) correlated well with human pathogenicity. The hemolytic property on this medium was referred to as the Kanagawa phenomenon (KP) because its discoverers belonged to the Kanagawa Prefectural Public Health Laboratory. Sakazaki *et al*. (1968) examined the KP of the isolates

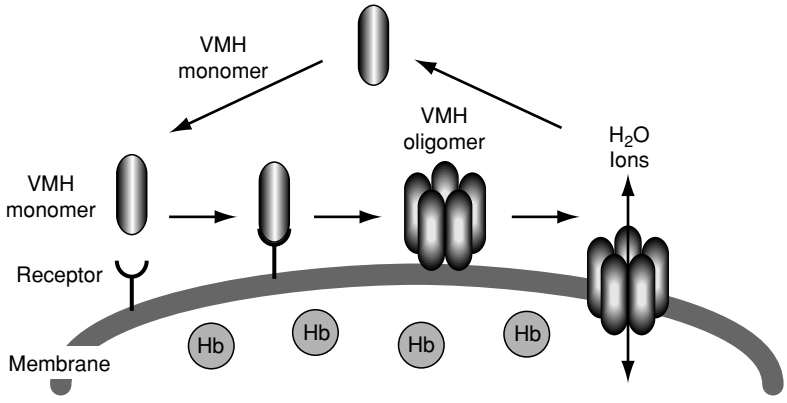

**FIGURE 44.2** Scheme for hemolysis induced by VMH (*Vibrio mimicus* hemolysin)

from human patients and from ocean fish and seawater and found a good correlation of KP and pathogenicity.

*V. parahemolyticus* is the major causative agent of food poisoning in Japan, and it is thought that the Japanese custom of eating raw fish, such as "sashimi" or "sushi," is the main reason for this high frequency. However, fish that are going to be eaten are handled very carefully in Japan, and are well-cleaned and kept at a low temperature. Therefore, it is suspected that a secondary source of contamination might be the utensils used to prepare the seafood.

The hemolysin causing KP is designated as TDH (thermostable direct hemolysin) because of its stability at 100°C. As similar hemolysins are found in vibrios other than *V. parahemolyticus*, the hemolysin of this species is often designated as Vp-TDH. Vp-TDH is a protein toxin having an approximate molecular size of 42 kDa composed of two identical 21 kDa subunits. The subunit consists of 165 amino acid residues with one disulfide bond near the carboxyl terminus (Tsunasawa *et al*., 1987). This result is in good agreement with that obtained from the nucleotide sequence of the gene encoding TDH (*tdh*).

Vp-TDH lyses red blood cells from various animal sources, one exception being the horse (Honda and Iida, 1993). The toxin is also cytotoxic to various cultured cells, such as HeLa cells, FL cells, and fetal mouse heart cells (Honda and Iida, 1993). In a rabbit ileal loop test, challenge of purified Vp-TDH at 100–250 μg/loop induced fluid accumulation (Honda and Iida, 1993; Miyamoto *et al*., 1980), which suggests that Vp-TDH is enterotoxic. The amount inducing fluid accumulation is higher than that of enterotoxins from other diarrheagenic bacteria; for example, 0.2 μg of CT is enough to induce this fluid accumulation. The contribution of Vp-TDH as the diarrheagenic factor has therefore been doubted. Other enterotoxic factors of *V. parahemolyticus*, such as one causing morphological change of Chinese hamster ovary (CHO) cells or cholera enterotoxin-like toxin immunologically cross-reactive in GM1-ganglioside ELISA, have also been suggested, but concrete evidence of the contribution of these factors has not been demonstrated. Extensive study of the rabbit ileal loop test with either Vp-TDH-producing or non-producing *V. parahemolyticus* strains suggested that only the former can induce fluid accumulation. To obtain evidence for the role of Vp-TDH in the enteropathogenicity of *V. parahemolyticus*, Nishibuchi *et al*. (1992) compared a KP-positive strain and its isogenic TDH-negative mutant in which both the *tdh1* and *tdh2* genes were specifically inactivated by successive allelic exchange procedures. Whole culture preparations of the parent strain gave positive fluid accumulation results in the rabbit ileal loop test, while the TDH-negative mutant induced no fluid accumulation in the model. Additional evidence for the enterotoxic activity of Vp-TDH was obtained with rabbit ileal tissue mounted in Ussing chambers, a sensitive technique for studying intestinal ion transport. Culture filtrates of the TDH-positive strain induced an increase in the short circuit current, whereas no such increase was observed with the isogenic TDH-negative strain (Nishibuchi *et al*. 1992). Returning the cloned *tdh* gene to the isogenic mutant complemented the mutation and restored the ability to increase the short circuit current. Thus, Vp-TDH is believed to be an important virulence factor in *V. parahemolyticus* gastroenteritis. Park *et al*. (2004), however, suggested the possibility of the existence of another factor for enterotoxicity. They constructed mutants of a pandemic strain of the vibrio lacking *tdhA* and/or *tdhS*, synonyms *tdh2* and *tdh1*, respectively, and showed that the mutant lacking both genes still showed partial enterotoxicity. They speculated that the reason for the contradiction with the results of Nishibuchi *et al*. (1992) might be the difference in strains. For example, a prepandemic strain was used in the former test, but a pandemic strain in the latter. The recent pandemic strain may have acquired a novel enterotoxic factor(s) in addition to TDH and TRH.

The mode of action of Vp-TDH has not yet been completely elucidated, though the hemolysis is thought to proceed in a colloid osmotic manner, which is shown in the section on VVH. Vp-TDH is believed to damage the erythrocyte membrane by acting as a pore-forming toxin (Honda *et al*., 1992). The functional pore size made by the hemolysin has been estimated to be 2 nm. One of the essential mechanisms in the damage that Vp-TDH inflicts during the hemolytic process is apparently the phosphorylation of the 25-kDa protein on the erythrocyte membrane. Yoh *et al*. (1996) found that TDH induced the phosphorylation of two proteins, 22.5 and 25 kDa, on membranes of human erythrocytes that are sensitive to TDH, but only the 22.5 kDa protein was phosphorylated on the membranes of horse erythrocytes that are insensitive. Furthermore, a mutant hemolysin, which retained binding ability but had lost hemolytic activity, also phosphorylated only the 22.5 kDa protein on human erythrocyte membranes. Zhang and Honda (1999) reported the disappearance of glyceraldehyde 3-phosphate dehydrogenase from the erythrocyte membrane by treatment with Vp-TDH and suggested a role of the enzyme in the hemolytic action.

Vp-TDH seems to cause hemolysis and to lyse cultured cells in a calcium-independent manner (Tang *et al*., 1994; Tang *et al*., 1995). A calcium-dependent chloride secretion by Vp-TDH, however, is observed in Caco-2 and IEC-6 cells, although calcium-independent

cell death was observed at a high concentration of the toxin (Raimondi *et al*., 2000). Vp-TDH increases the intracellular calcium level and modulates the cytoskeletal organization of IEC-6 cells (Fabbri *et al*., 1999).

A number of reports have described the structural-functional relationship of Vp-TDH (Tang *et al*., 1994; Honda *et al*., 1989; Toda *et al*., 1991; Baba *et al*., 1992; Iida *et al*., 1995). Tang *et al*. (1994) reported the isolation of an interesting mutant toxin of Vp-TDH in which the hemolytic activity had diminished almost completely, but retained the ability to bind to erythrocytes. The mutant toxin, R7, possessed an amino acid substitution at Gly 62 to Ser 62, suggesting that the site is functionally important for Vp-TDH. R7 has been used as a probe to identify the receptor for Vp-TDH (Tang *et al*., 1997a). Tang *et al*. (1997b) analyzed the functional domains of TDH and demonstrated that the N-terminal region may be involved in the binding process while the region near the C-terminal may be involved in the postbinding process. Lang *et al*. (2004) showed that Vp-TDH induces the cation permeability and the breakdown of phosphatidylserine asymmetry of the membrane, a typical feature of erythrocyte apoptosis. Apoptosis by Vp-TDH was also demonstrated by Naim *et al*. (2001).

Vp-TDH shows various biological activities, including lethal toxicity, cytolytic activity (Sakurai *et al*., 1976), and cardiotoxicity (Honda *et al*., 1976a), in addition to the enterotoxicity. Honda *et al*. (1976b) purified the lethal toxin from culture filtrate of *V. parahemolyticus* and found that it was identical to Vp-TDH. Intravenous injection of 5 μg of purified Vp-TDH killed mice within 1 minute and even 1 μg of the toxin killed mice within 20 minutes (Honda *et al*. 1976b). Honda *et al*. (1976b) showed that the lethal activity was due to its cardiotoxic activity. An electrocardiogram of rats injected with TDH showed a wider and higher P wave, suggesting changes in the conduction of an intra-atrial impulse, and an increase in voltage of QRS, suggesting changes in intra-ventricular impulses of electrical activation. Thereafter, the PQ intervals became longer, suggesting inhibition of atrio-ventricular conduction. The cardiotoxicity of Vp-TDH was also demonstrated using cultured mouse heart cells (Honda *et al*., 1976a).

KP-negative strains are occasionally suspected to be the causative agent of food poisoning. Some of those strains produce a TDH-related hemolysin called TRH, which is not detected by Wagatsuma's agar test (Honda *et al*., 1988; Honda *et al*., 1989; Honda *et al*., 1990). TRH shows enterotoxicity and has common antigenicity with TDH, but is thermolabile. Kelly and Stroh (1988) reported that clinical isolates obtained from patients with locally acquired gastroenteritis in Canada all hydrolyzed urea, but none of the isolates was KP-positive, suggesting that the urease-positive strains are the predominant biotype of *V. parahemolyticus* associated with gastroenteritis in the Pacific Northwest. However, Oosawa *et al*. (1996) reported evidence suggesting that urea hydrolysis is not a reliable marker for identifying *tdh*-carrying *V. parahemolyticus* strains in Japan, but may be a marker for *trh*-carrying strains. Okuda *et al*. (1997) analyzed the *tdh* gene and *trh* genes in urease-positive ($Ure^+$) strains of *V. parahemolyticus* isolated on the west coast of the United States and indicated a very strong correlation between the $Ure^+$ phenotype and the *trh*, gene reported for strains isolated in Asia (Suthienkul *et al*., 1995). Iida *et al*. (1997) showed genetic linkage of the *ure* and *trh* genes. Analysis with pulsed field gel electrophoresis of *NotI*-digested DNA fragment and accurate polymerase chain reaction showed localization of *tdh, trh* and *ure* within 40 kb and close proximity of *trh* and *ure* at less than 8.5 kb (Iida *et al*., 1998). The urease gene cluster, however, is not involved in the regulation of *tdh* and *trh* expression (Park *et al*., 2000; Nakaguchi *et al*., 2003).

A TDH gene (*tdh*) having 567 bp was cloned and the DNA sequence was determined (Kaper *et al*., 1984; Taniguchi *et al*., 1985). Nine *tdh* genes have been demonstrated and *tdh2* is thought actually to express in the KP positive strain (Nishibuchi and Kaper, 1990; Nishibuchi and Kaper, 1995). The *tdh* genes are usually, but not exclusively, located in the chromosome. All of the cloned *tdh* genes encode predicted protein products composed of 189 amino acid residues (including signal peptides), which have hemolytic and other biological activities. The nucleotide sequences of the various *tdh* genes are well conserved (greater than 97% identity), and the protein products are immunologically indistinguishable. Similarity of *tdh2* with *trh1* is 68.6%. Similar genes to *tdh* are also found in *V. cholerae* non-O1, *Vibrio mimicus*, and *Vibrio hollisae* (Nishibuchi and Kaper, 1990). These vibrios produce hemolysin similar to Vp-TDH; the hemolysins from the former two are thermostable, but the hemolysin from the latter is thermolabile (Table 44.2). *V. parahemolyticus* possesses two circled chromosomes (Tagomori *et al*., 2002). The complete genome sequence of an epidemic strain of *V. parahemolyticus* RIMD2210633 was published and revealed the presence of a pathogenicity island having *tdh* genes on chromosome 2 (Makino *et al*., 2003).

In addition to TDH and TRH, production of two hemolysins, LDH (lecithin dependent hemolysin) and δ-VPH, by *V. parahemolyticus* was reported. Taniguchi *et al*. (1985) obtained a transformant producing LDH, which was designated as a thermolabile hemolysin (TLH) in their paper. Because of the universal existence

of *tlh* encoding LDH/TLH, the gene is expected to be a tool for the identification of *V. parahemolyticus* (Bej *et al*., 1990). Although LDH of *V. parahemolyticus* had been reported to be a phospholipase A2, Shinoda *et al*. (1991) demonstrated that it should be classified as a phospholipase B or an atypical phospholipase to be designated as phospholipase A2/lysophospholipase. Taniguchi *et al*. (1990) cloned a gene encoding another hemolysin, δ–VPH. The production of δ–VPH was observed in *Escherichia coli* transformed by the cloned gene, but not in *V. parahemolyticus* culture, although all strains of the vibrio possessed its gene. Contribution of these two hemolysins to the pathogenicity has not been demonstrated.

## *VIBRIO VULNIFICUS* HEMOLYSINS

The first isolation of *V. vulnificus* was from a leg ulcer, although it was reported as a *V. parahemolyticus* infection (Roland, 1970). Although the bacterium showed similar characteristics to *V. parahemolyticus*, including having a slightly halophilic property and being negative in sucrose fermentation, it was different in that it had positive lactose fermentation (Hollis *et al*., 1976). The bacterium was therefore called lactose-positive vibrio (Hollis *et al*., 1976), and was subsequently termed *V. vulnificus* (Farmer, 1979). The bacterium causes two types of illness, primary septicemia and wound infection (Blake *et al*., 1980). The former is remarkable for its high fatality rate. *V. vulnificus* is now recognized as being among the most rapidly fatal of human pathogens. In the majority of cases, primary septicemia is associated with the consumption of raw seafood, especially shellfish such as oysters, contaminated with the vibrio. In the United States, 95% of all seafood-related deaths are due to *V. vulnificus*, most commonly from the consumption of raw oysters (Klontz *et al*., 1988; Oliver, 1995). Primary septicemia due to *V. vulnificus* is an opportunistic infection, although most patients with septicemia have underlying disease(s) of liver dysfunction, alcoholic cirrhosis, or hemochromatosis, which leads to an increased plasma iron level and decreased host defense system. Infections in patients having malignant tumors or Acquired Immunodeficiency Syndrome have also been reported. In two-thirds of patients, edematous and/or hemorrhagic secondary skin lesions appear on the extremities and the trunk. Symptoms of the digestive tract, such as diarrhea or vomiting, are very rare. Wound infection is characterized by the development of edema, erythema, or necrosis around a new wound exposed to seawater. This type of infection can occur in healthy persons, as well as in compromised hosts, and may occasionally progress to septicemia.

Tison *et al*. (1982) documented that *V. vulnificus* strains isolated from diseased eels differed phenotypically from typical human isolates. They classified these strains as *V. vulnificus* biotype 2. This biotype is primarily an eel pathogen, and it rarely causes human infections.

*V. vulnificus* produces various exocellular toxic factors, such as hemolysin or protease (Miyoshi *et al*., 1993; Miyoshi and Shinoda, 1997). This vibrio protease is a metalloprotease and degrades a number of biologically important proteins, including elastin, fibrinogen, and plasma proteinase inhibitors of complement components (Miyoshi *et al*., 1995). The protease is also known to enhance vascular permeability through activation of the Factor XII-plasma kallikrein-kinin cascade (Miyoshi *et al*., 1993) and/or exocytotic histamine release from mast cells (Miyoshi *et al*., 2003a), and to form a hemorrhagic lesion through digestion of the vascular basement membrane, which finally provokes severe dermonecrotis (Miyoshi *et al*., 1998). Thus, the protease is the most probable candidate for tissue damage and bacterial invasion during an infection. *V. vulnificus* protease is further thought to supply iron, an essential element for bacterial growth, through cooperation with hemolysin; the hemolysin releases hemoglobin from erythrocytes and the protease liberates iron (protoheme) from the hemoglobin (Nishina *et al*., 1992).

Gray and Kreger (1985) purified a heat-labile hemolysin from a clinical isolate of *V. vulnificus* by ammonium sulfate precipitation, gel filtration with Sephadex G-75, hydrophobic interaction chromatography with Phenyl-Sepharose CL-4B, and isoelectric focusing. This hemolysin, which is currently called VVH (*V. vulnificus* hemolysin) or vulnificolysin, has an isoelectric point of 7.1 and is a hydrophobic 56 kDa single chain polypeptide. Oh *et al*. (1993) found that, in the case of a biotype 2 strain, CHAPS [(3-cholamidopropyl) dimethylammonio-1-panesulfinate] treatment of the preparation obtained by ammonium sulfate precipitation was more efficient for purification of the hemolysin.

The DNA fragment encoding the hemolysin gene was cloned and sequenced (Yamamoto *et al*., 1990b); the sequence contained two open reading frames, *vvhA* and *vvhB*. The *vvhA* is a structural gene for the hemolysin, and encodes a 50,851 Da polypeptide preceded by a 20-amino acid signal peptide. The *vvhB* gene encodes an 18,082 Da polypeptide, but the function of this polypeptide has not been determined. The fragment of the *vvhA* gene has been used as a DNA probe for identification of the vibrio, because this fragment showed 100% specificity and sensitivity for

*V. vulnificus* strains isolated from both clinical and environmental sources. Furthermore, Brauns *et al*. (1991) succeeded in detecting viable but nonculturable *V. vulnificus* cells using the polymerase chain reaction based on amplification of the *vvhA* gene.

Purified VVH is active against erythrocytes from many animal species and against various cultured cells, such as CHO, HeLa, or pulmonary artery endothelial cells. Mouse, sheep, pig, monkey, burro, cat, and pigeon erythrocytes are more sensitive to the hemolysin, while those from rabbit, human, and chicken are less sensitive (Yamanaka *et al*., 1989). In addition, the sublytic doses of the hemolysin can trigger the apoptotic signaling pathway in human ECV304 cells, a vascular endothelial cell strain (Kwon *et al*., 2001).

The hemolytic process has been studied using sheep or mouse erythrocytes as target cells (Shinoda *et al*., 1985; Yamanaka *et al*., 1987b; Kim *et al*., 1993). Hemolysis induced by VVH is temperature-dependent and is optimal between 30 and 37°C. At 4°C, although no erythrocytes are disrupted, the hemolysin can bind to them irreversibly. Therefore, hemolysis by VVH is believed to be a two-step process consisting of a temperature-independent, toxin-binding step followed by a temperature-dependent cell disruption step. Shinoda *et al*. (1985) reported that a small amount of cholesterol abolished the hemolytic ability of VVH, whereas other lipid components in the erythrocyte membrane had no effect on the activity. Yamanaka *et al*. (1987a) found that VVH was active against cholesterol-phosphatidylcholine liposome, but liposome containing a negligible amount of cholesterol was far less sensitive to the action of the hemolysin. No inhibitory effect of cholesterol was recognized when it was added after the hemolysin had bound to the erythrocytes or liposomes. These findings strongly suggest that cholesterol is the binding site for VVH.

At 37°C, VVH treatment of erythrocytes induced rapid $K^+$ efflux that was followed by the release of hemoglobin (Yamanaka *et al*., 1987b). This phenomenon indicates that the temperature-dependent cell disruption step can be further divided into two stages: a small-pore-forming stage causing $K^+$ efflux, and a membrane-bursting stage eliciting the release of hemoglobin (i.e., hemolysis). Namely, intracellular $K^+$ initially pass through the small transmembrane pore formed by VVH, then extracellular low-molecular-weight substances and water enter the erythrocyte via the pore, resulting in the physical explosion of erythrocyte membranes owing to the increased intracellular osmotic pressure. The initial pore-forming stage is temperature-dependent, while the latter one is temperature-independent. Hemoglobin release, but not $K^+$ efflux, from VVH-treated erythrocytes was inhibited completely by the addition of 30 mM (equivalent to intracellular hemoglobin) dextran 4 (molecular diameter of 3.5 nm) and partially by inulin (2.8 nm), although raffinose (1.2 nm) had no effect, denoting that the diameter of the transmembrane pore formed by VVH may be around 3 nm (Yamanaka *et al*., 1987b). The hemolytic reaction by VVH was also inhibited by the addition of a divalent cation such as $Ca^{2+}$, $Mg^{2+}$, or $Mn^{2+}$ (Shinoda *et al*., 1985). However, neither the toxin-binding nor the small pore-forming process interfered with the cation (Yamanaka *et al*., 1987b). Park *et al*. (1994) found that, as well as dextran 4 and other oligosaccharides, calcium functioned as an osmotic protectant preventing the final membrane-bursting stage.

Gray and Kreger (1985) and Shinoda *et al*. (1985) reported that more than one VVH molecule might be required to lyse a single erythrocyte. This suggestion was subsequently supported by experiments using liposome (Yamanaka *et al*., 1987a). When VVH was allowed to act on the cholesterol-phosphatidylcholine liposome entrapping $K^+$, the leakage of $K^+$ accompanied by the formation of the hemolysin oligomer with a molecular weight of about 200 kDa was observed, suggesting that some VVH molecules assembled and formed a single pore on a target cell membrane. The oligomerization of the hemolysin molecules also goes on the erythrocyte membrane (Kim *et al*., 1993) and cholesterol particles (Miyoshi *et al*., 2004). The hemolytic reaction induced by a hemolysin from enteropathogenic *Vibrio* species continues for a long period. Thus, all erythrocytes in the assay tube are disrupted by prolonged incubation (Miyoshi *et al*., 1997b). By contrast, the hemolysis by VVH terminates within a few hours, and the rate of the hemolysis depends upon the amount of the hemolysin.

During cultivation of the vibrio, the hemolytic activity in the culture supernatant reaches a maximum at logarithmic growth phase; however, at early stationary phase, the activity decreases drastically, inversely proportional to the secretion of the protease. Shao and Hor (2000) found that the extracellular hemolytic activity of a protease-deficient mutant, which was constructed by *in vivo* allelic exchange, was about twice that of the parental strain and was retained into the stationary growth phase, indicating proteolytic inactivation of VVH. Indeed, purified *V. vulnificus* protease could convert the hemolysin to the nicked protein through cleavage into 40 kDa and 10 kDa fragments joined together with disulfide bond(s) (Miyoshi *et al*., 2004). In the case of hemolysin from a biotype 2 strain, which is gradually inactivated by autoaggregation because of a highly hydrophobic property, it was modified to a

more hydrophilic and stable form through nicking by the protease (Miyoshi *et al*., 1997a).

Purified VVH has been described as possessing the vascular permeability-enhancing activity. This permeability-enhancing reaction is abolished by the simultaneous administration of an antihistaminic agent. Yamanaka *et al*. (1990) and Kim *et al*. (1998) reported that the hemolysin elicited the histamine liberation from isolated mast cells, and that this liberation was accompanied by the leakage of lactate dehydrogenase, indicating the lysis of mast cells. Thus, VVH inoculated into the dorsal skin may act directly on and disrupt mast cells, resulting in the leakage of histamine and enhancement of the vascular permeability. Gray and Kreger (1987) stated that VVH injected subcutaneously into mice caused severe structural alteration of the skin, which was very similar to the skin lesion shown in *V. vulnificus* infection. In addition, the enzyme-linked immunosorbent assay using the polyclonal or monoclonal antibody demonstrated *in vivo* VVH production by the bacterium (Gray and Kreger, 1989).

Gray and Kreger (1985) have reported that purified VVH administered by the intravenous route was lethal for mice (the 50% lethal dose was about 3.0 μg/kg). This hemolysin has also been documented to cause severe hypotension and vasodilatation through induction of expression of the nitric oxide synthase gene (Kang *et al*., 2002) or activation of guanylate cyclase (Kook *et al*., 1996). These findings suggest that VVH might contribute to the development of systemic *V. vulnificus* infection. However, Morris *et al*. (1987) demonstrated that the virulent potential of individual strains in mice did not correlate with *in vitro* ability to elaborate VVH. Furthermore, Massad *et al*. (1988) and Wright and Morris (1991) reported that hemolysin-negative mutants were as virulent as wild-type strains in mouse models. Thus, VVH may be less important in the development of systemic *V. vulnificus* infection, although it is clear that it plays some role in the pathogenesis.

Testa *et al*. (1984) found that *V. vulnificus* produced phospholipase(s). The partially purified preparation could hydrolyze both acyl ester bonds of all classes of phospholipids except sphingomyelin, demonstrating that the phospholipase preparation possesses both phospholipase A2 and lisophospholipase activities. Therefore, as LDH from *V. parahemolyticus* (Shinoda *et al*., 1991), *V. vulnificus* phospholipase may elicit hemolysis in the presence of lecithin. A novel hemolysin gene *vllY* has been cloned and sequenced by Chang *et al*. (1997). The product of this gene has a molecular weight of 40 kDa and an isoelectric point of 7.1, and its deduced amino acid sequence is similar to legiolysin, a hemolytic toxin from *Legionella pneumophila*.

## *VIBRIO MIMICUS* HEMOLYSINS

*V. mimicus*, a species closely related to *V. cholerae* (Davis *et al*., 1981), is a causative agent of human gastroenteritis. Pathogenic strains of *V. mimicus* show various clinical symptoms, from watery to dysentery-like diarrhea (Hoge *et al*., 1989), suggesting that this pathogen produces many kinds of virulent factors. Enterotoxins similar to CT (Chowdhury *et al*., 1987; Spira and Fedorka-Cray, 1984) and heat-stable enterotoxin (Gyobu *et al*., 1988) have been found in some clinical strains to be causative factors of watery diarrhea. However, most virulent strains lack the ability to produce any of these enterotoxins; in such cases, enterotoxic hemolysins are thought to be candidates for the enteropathogenic factors. Honda *et al*. (1987) found production of two types of hemolysin by *V. mimicus*: One was heat-labile and immunologically similar to VCC (El Tor hemolysin), while another was heat-stable and closely related to Vp-TDH.

The heat-stable hemolysin called Vm-rTDH was purified and characterized by Yoshida *et al*. (1991), and Terai *et al*. (1991) determined the nucleotide sequence of the structural gene of the hemolysin (*tdh*). Shinoda *et al*. (2004) documented that about 30% of the clinical isolates had the *tdh* gene, while this gene was not present in any of the environmental isolates.

Shinoda *et al*. (1993) studied the hemolytic mechanism of the heat-labile hemolysin designated *V. mimicus* hemolysin (VMH). The VMH was indicated to be a member of the pore-forming hemolysins and thought to form a transmembrane pore with a diameter of about 3 nm. The pore formed by the hemolysin was permeable by water and monovalent ions, such as $Na^+$ and $K^+$, but impermeable by hemoglobin. This suggests that VMH causes hemolysis in a colloid osmotic manner. Miyoshi *et al*. (1997b) purified VMH, of which molecular weight is 63 kDa, by ammonium sulfate precipitation followed by column chromatography on Phenyl Sepharose HP and Superose 6 HR. The hemolytic reaction induced by VMH continued up to disruption of all erythrocytes in the assay system. Moreover, VMH bound preliminarily to erythrocyte ghosts showed sufficient ability to attack intact erythrocytes. These results suggest reversible binding of the hemolysin molecule to the membrane. The final cell disruption stage was effectively inhibited by various divalent cations, and some, such as $Zn^{2+}$ and $Cu^{2+}$, blocked the pore-forming stage at higher concentration. Although VMH could disrupt various mammalian erythrocytes including bovine, rabbit, sheep, human, and mouse, those from horse were most sensitive to the hemolysin. Horse erythrocyte was found to

have the most toxin-binding sites and to be hemolyzed by the least membrane-bound toxin molecules, suggesting that toxin-binding to and pore formation on horse erythrocyte takes place most effectively.

Purified VMH induced fluid accumulation into a ligated rabbit ileal loop in a dose-dependent manner, and the antibody against the hemolysin obviously reduced enteropathogenicity of living *V. mimicus* cells (Miyoshi *et al*., 1997b). These findings clearly demonstrate that VMH relates to virulence of this human pathogen. The C-terminal region of VMH was suggested to be essential for induction of the fluid accumulation. Namely, the 50 kDa derivative obtained through proteolytic removal of the C-terminal 13 kDa polypeptide caused negligible fluid accumulation (Miyoshi *et al*., 2003b).

The structural gene of VMH (*vmhA*) was cloned and the nucleotide sequence was determined (Rahman *et al*., 1997; Kim *et al*., 1997). A 2,232 bp open reading frame encodes a polypeptide of 744 amino acid residues, and has a calculated molecular weight of 83,903 Da. The sequence of the gene was closely related to the VCC gene shown above, with 76% homology (Figure 44.1). The 13 amino acid residues of the amino terminus of 63 kDa mature VMH were identical from S-152 to T-164, as predicted from the nucleotide sequence. So, it seems that the mature VMH is processed upon deleting the first 151 amino acids, and the molecular weight is 65,972 Da. Analysis of the deduced amino acid sequence showed the existence of a potential signal sequence of 24 amino acids at the amino terminal, suggesting that, like VCC, two-step processing also exists in VMH maturation. Since all *V. mimicus* strains tested were revealed to have the *vmhA* gene (Shinoda *et al*., 2004), this toxin gene may be a suitable target for genetic identification of *V. mimicus*.

The phospholipase A gene (*phl*) was identified by Kang *et al*. (1998), and Lee *et al*. (2002) isolated its gene product (PhlA) from a transformant. The recombinant PhlA isolated showed phospholipase A activity, but not lisophospholipase, sphingomyelinase, or phospholipase C activity, and also elicited cytolysis of several fish erythrocytes and cultured cells.

## OTHER *VIBRIO* HEMOLYSINS

In addition to the above, some vibrio species have been reported to be pathogenic to human or fish. *Vibrio fluvialis, Vibrio furnissii*, and *Vibrio hollisae* cause gastroenteritis to human, whereas *Vibrio damsella* is a pathogen of extraintestinal infection. Extraintestinal infections by *Vibrio alginolyticus* and *Vibrio metscnikovii* have also been reported occasionally (Blake *et al*., 1980). These vibrios pathogenic to humans inhabit a brackish or seawater environment; *Vibrio anguillarum* is found in fresh or brackish water and is a fish pathogen.

These vibrios also produce hemolysins. *Vibrio fluvialis* is believed to be a bacterium that is pathogenic to humans, in that it is implicated in food poisoning. The infection is usually associated with the consumption of seafood. Kothary *et al*. (2003) purified a heat-labile hemolysin by hydrophobic interaction chromatography with Phenyl-Sepharose CL-4B and gel filtration with Sephacryl S-200. The purified hemolysin has a molecular weight of 63 kDa and an isoelectric point of 4.6, and shows the hemolytic activity against various kinds of erythrocytes and the enterotoxic activity in the suckling mice model. This hemolysin is immunologically and genetically related to VCC. *V. furnissii* is a new species distinguished from *V. fluvialis* by its property of gas production, and is thought to cause diarrhea in humans, although this has not been well established due to the small number of clinical cases. It has been reported to produce a hemolysin that is immunologically indistinguishable from that of *V. fluvialis* (Yamada *et al*., 1988).

*V. hollisae* sometimes causes gastroenteritis with symptoms including diarrhea, abdominal pain, and fever; in rare cases, it causes bacteremia. A hemolysin (Vh-rTDH) is thought to be the diarrheagenic factor. Vh-rTDH resembles Vp-TDH, is 86% homologous in amino acid sequences, but is heat-labile (Yoh *et al*., 1989).

A hemolysin gene of *V. anguillarum* was cloned (Hirono *et al*., 1996). The open reading frame of the gene was 2,253 bp and corresponded to a protein of 751 amino acid residues. The deduced amino acid sequence showed a significant degree of homology with that of VCC and VVH, and the overall amino acid identities were 57.3% and 25.5%, respectively. However, contribution to pathogenicity of this hemolysin has not been documented. *Vibrio tubiashi*, a pathogen of bivalve mollusks, produces a heat-labile hemolysin similar to VVH (Kothary *et al*., 2001). Like VVH, the hemolysin purified was found to be sensitive to cholesterol and to cause hemolysis by a multihit process that is dependent on temperature.

Although *V. metschnikovii* was recognized more than 100 years ago, there have been few reports of isolation of this organism as a human pathogen. It has occasionally been implicated in bacteremia, cholecystitis, diarrhea, and urinary tract infections. A hemolysin produced by this bacterium has been purified and characterized as a pore-forming toxin (Miyake *et al*., 1988; Miyake *et al*., 1989).

*V. damsela* has been reported to cause wound infection. It may cause localized or wide-ranging cellulitis and sometimes more severe complications, such as

disseminated intravascular coagulation. A hemolysin (damselysin) was purified and its phospholipase D activity was reported (Kreger *et al*., 1987). The gene encoding damselysin was cloned and sequenced, but no homology was observed with the sequence of other vibrio hemolysins (Cutter and Kreger, 1990).

## CONCLUSION

Hemolysins produced by pathogenic vibrio are classified into three groups, namely the VCC group, TDH group, and others. This review focused on four hemolysins: VCC (*V. cholerae*), Vp-TDH (*V. parahemolyticus*), VVH (*V. vulnificus*), and VMH (*V. mimicus*), which have been extensively studied. All four are pore-forming toxins, but their precise mechanism of action remains to be investigated. VCC, Vp-TDH, and VMH have activity that causes diarrhea, the major symptom of infection of these vibrios, although VCC is no more than a supplemental factor of CT and VMH is only one of the many enterotoxic factors. Vp-TDH is thought to be the major pathogenic factor of *V. parahemolyticus*, which is one of the most important food poisoning bacterium in Japan and other eastern and southeast Asian countries; the mechanism causing diarrhea, however, has not been identified. Furthermore, it is unclear whether a similar mechanism with the pore-forming action on the erythrocytes contributes to cause diarrhea. Molecular biological studies of the toxins, such as nucleotide and amino sequence, functional domain, or mode of secretion from cell and processing, have been well developed in the past one or two decades. Total genome analysis of *V. cholerae, V. parahemolyticus*, and *V. vulnificus* has been completed in the past half-decade. This genetic information will stimulate the progress of studies by elucidating the pathogenic mechanism for prevention of the disease.

CHAPTER

# 45

# *Clostridium perfringens* enterotoxin

*Bruce A. McClane*

## INTRODUCTION

### Enterotoxin-producing *Clostridium perfringens*

The Gram-positive, anaerobic, spore former *C. perfringens* causes an impressive array of enteric and histotoxic diseases in humans and domestic animals. The pathogenic versatility of this bacterium is largely attributable to its prodigious toxin-producing abilities, with at least 14 different *C. perfringens* toxins now reported in the literature.

However, individual *C. perfringens* isolates produce only subsets of this toxin arsenal, forming the basis for a commonly used toxinotype classification scheme (McClane, 2001) that assigns *C. perfringens* isolates to one of five types (A–E) based upon their ability to produce alpha, beta, epsilon, and iota toxins (Table 45.1). About 1–5% of *C. perfringens* isolates, mostly belonging to type A (McClane, 2001), express another biomedically important toxin named *C. perfringens* enterotoxin (CPE). The 35 kDa CPE polypeptide has a unique primary sequence, except for some limited homology (of unknown significance) with the Antp70/C1 protein made by certain strains of *C. botulinum* (Melville *et al*., 1997).

Several interesting features of CPE action, genetics, and expression represent the major focus of this chapter.

### The biomedical importance of enterotoxin-producing *C. perfringens*

Traditionally, CPE-positive type A isolates have been associated with *C. perfringens* type A food poisoning, which ranks among the most common of all foodborne human GI diseases (McClane, 2001). For example, the Centers for Disease Control and Prevention estimate that more than 250,000 cases of this food poisoning occur annually in the U.S.A. (Mead *et al*., 1999).

*C. perfringens* type A food poisoning results from ingestion of foods (usually meat or poultry products) contaminated with high levels of vegetative cells of a CPE-positive type A isolate (McClane, 2001). Those ingested bacteria later sporulate in the intestines, allowing CPE production (further discussion later). Symptoms of *C. perfringens* type A food poisoning typically include diarrhea and abdominal cramps (McClane, 2001), which typically persist for 24 h prior to full recovery; however, this can be a fatal illness in the elderly or debilitated.

Several lines of evidence (McClane, 2001) implicate CPE as the major virulence factor responsible for the symptoms of *C. perfringens* type A food poisoning. For example, CPE is detectable (often at levels known to be enterotoxic in animal models) in the feces of virtually all people suffering from this food poisoning. Additionally, human volunteer feeding studies showed that ingestion of purified CPE is sufficient to reproduce the diarrhea and cramping symptoms of natural *C. perfringens* type A food poisoning. Finally, CPE expression appears to be required for the enteric virulence of most (or all) food poisoning isolates since specific inactivation of the enterotoxin gene (*cpe*) in SM101, a transformable derivative of food poisoning isolate NCTC 8798, produced an isogenic mutant lacking the ability to cause GI effects (e.g., fluid accumulation, histopathologic damage) in rabbit ileal loops (Sarker *et al*., 1999).

In the mid-1980s, enterotoxin-producing type A isolates also became linked to non-foodborne human GI

**TABLE 45.1** *Clostridium perfringens* toxinotypes

| | Toxins Produced | | | |
|---|---|---|---|---|
| **Type** | **Alpha** | **Beta** | **Epsilon** | **Iota** |
| A | + | – | – | – |
| B | + | + | + | – |
| C | + | + | – | – |
| D | + | – | + | – |
| E | + | – | – | + |

diseases (Carman, 1997), including antibiotic-associated diarrhea (AAD) and sporadic diarrhea (SD). CPE appears to play an important role in the pathogenesis of many or all AAD/SD cases since specific inactivation of the *cpe* gene in SD isolate F4969 eliminates that isolate's ability to cause enteric pathology in rabbit ileal loops (Sarker *et al*., 1999).

Compared to *C. perfringens* type A food poisoning, the GI symptoms of CPE-associated AAD/SD tend to be more severe and of longer duration (Carman, 1997). Recent studies (Fisher *et al*., 2005) suggest these clinical differences may be attributable, at least in part, to most CPE-positive AAD/SD isolates producing an additional enterically active toxin, i.e., the recently discovered beta2 toxin (Gibert *et al*., 1997). Specifically, Fisher *et al*. found that more than 75% of the CPE-positive AAD/SD isolates they tested could produce beta2 toxin, while only than 15% of the CPE-positive *C. perfringens* food poisoning isolates they examined were able to produce beta2 toxin. Given those results, it is notable that F4969, the CPE-positive SD isolate used for constructing isogenic *cpe* knockout mutants (as described above), was recently determined (Fisher *et al*., 2005) to be an atypical CPE-positive SD diarrhea isolate that is beta2 toxin–negative (see CPE Genetics for further discussion).

CPE-positive isolates have also been linked to certain veterinary GI diseases (Songer, 1996). For example, enterotoxin-producing type A isolates are implicated in canine enteritis (Marks *et al*., 2002). Some type C and D (and perhaps B) veterinary disease isolates also produce CPE, but the contribution (if any) of CPE to the pathogenesis of type C and D veterinary infections has not yet been evaluated.

## THE GENETICS AND EXPRESSION OF CPE

### CPE genetics

#### *The* cpe *gene*

The enterotoxin gene (*cpe*) includes an open reading frame (ORF) encoding a 35 kDa protein of 319 amino acids (Czeczulin *et al*., 1993). The *cpe* ORF appears to be remarkably conserved among type A isolates, i.e., sequencing analyses detected not a single nucleotide difference among the *cpe* ORFs present in eight different type A isolates, whether obtained from food poisoning or AAD/SD sources (Collie *et al*., 1998). Recent observations (Sayeed, Fisher, and McClane, unpublished) indicate that the *cpe* ORF nucleotide sequence present in most (if not all) *cpe*-positive type C and D isolates is identical to the classical *cpe* ORF present in type A human GI disease isolates. Interestingly, most (if not all) type E isolates carry *cpe* ORF sequences that are silent, in part due to the presence of nonsense and frame-shift mutations (Billington *et al*., 1998; and see *cpe* Genotype section, below).

The DNA region immediately upstream of the *cpe* ORF is also reasonably conserved among type A isolates (Melville *et al*., 1994; Zhao and Melville, 1998), except for the presence in some type A isolates of a 45 nucleotide insert about 265 bp upstream of the *cpe* start codon. The presence or absence of that small insert has no apparent effect on CPE expression levels (Collie *et al*., 1998). As shown in Figure 45.1, primer extension and deletion analyses (Zhao and Melville, 1998) demonstrated the presence of at least three promoters directly upstream of the *cpe* ORF (see Regulation of CPE Expression for further discussion).

A putative stem loop structure, followed by an oligo dT tract, is located about 36 bp downstream of the *cpe* ORF in most, if not all, type A isolates (Czeczulin *et al*., 1993). This stem loop–containing region possesses characteristics of a rho-independent transcriptional terminator and may also contribute to *cpe* mRNA stability (see Regulation of CPE Expression for further discussion).

#### *Association of the* cpe *gene with mobile genetic elements*

In type A isolates, the *cpe* gene can be present on either the chromosome or a large plasmid (Cornillot *et al*., 1995; Collie and McClane, 1998); no single type A isolate has yet been found to carry both a chromosomal and plasmid-borne *cpe* gene. The location of the *cpe* gene in type C and D isolates has not yet been determined, but the silent *cpe* sequences present in most/all type E isolates are located on the same plasmid that also carries functional iota toxin genes (Billington *et al*., 1998).

As shown in Fig. 45.2, both the chromosomal and plasmid-borne *cpe* genes of type A isolates are closely associated with insertion sequences (Miyamoto *et al*., 2002; Wen *et al*., 2003; Miyamoto *et al*., 2004). When chromosomal, the *cpe* gene may be present on an about 6.3 kb transposon named Tn*5565* (Brynestad *et al*., 1997; Brynestad and Granum, 1999). This putative

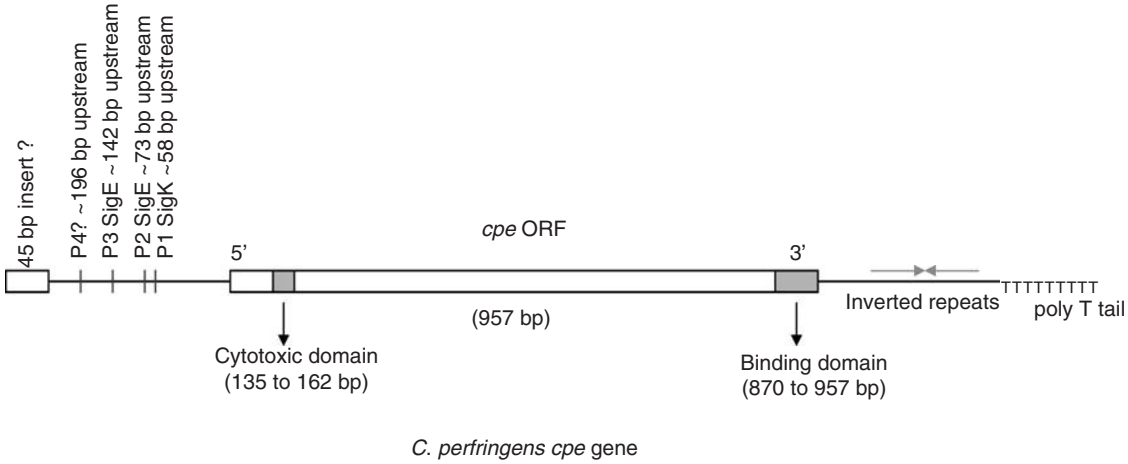

**FIGURE 45.1** Arrangement of the *cpe* gene. Note the presence of at least three promoters (P1, P2, and P3) immediately upstream of the *cpe* ORF as confirmed by primer extension analyses, Rnase T2 protection assays, and deletion mutagenesis (Melville *et al*., 1994; Zhao and Melville, 1998); a fourth potential promoter (P4) identified by primer extension analysis could not be confirmed by other techniques (Melville *et al*., 1994; Zhao and Melville, 1998). A 45 nucleotide insert present upstream of the *cpe* promoters in some type A isolates (Melville *et al*., 1994) has no effect on CPE expression (Collie *et al*., 1998). The 957 nucleotide *cpe* ORF encodes a unique protein of 35 kDa that lacks a signal peptide. Regions of the *cpe* ORF encoding cytotoxic or receptor-binding activity are also indicated in the figure. Finally, a region containing inverted repeats followed by an oligo-T tract is located immediately downstream of the *cpe* termination codon; those sequences may be involved in transcriptional termination and/or message stability (Czeczulin *et al*., 1993).

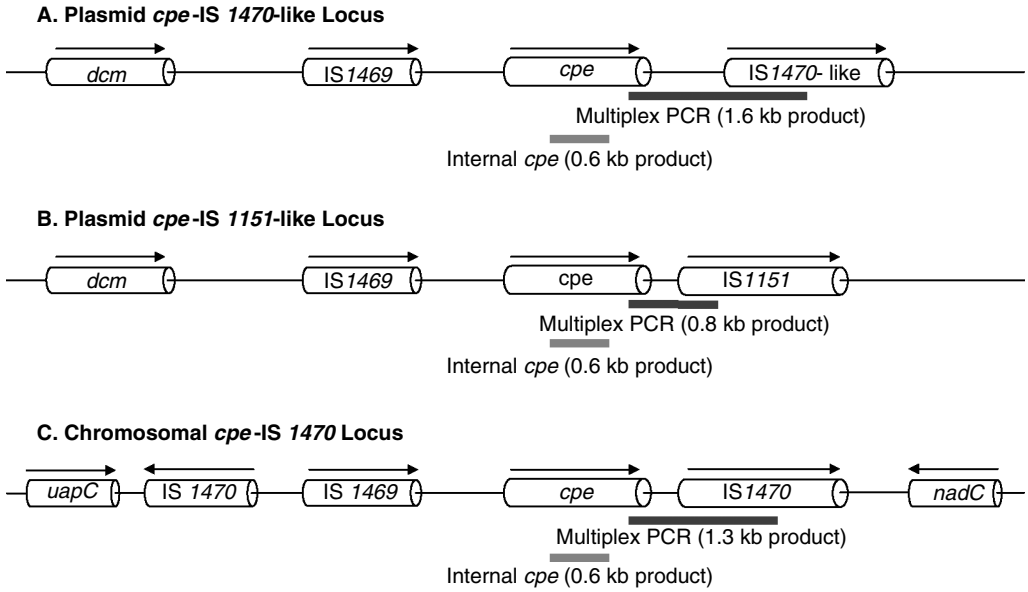

**FIGURE 45.2** Organization of the plasmid *cpe* locus of non-foodborne human GI disease isolates F4969 (A) or F5603 (B) versus the chromosomal *cpe* locus of food poisoning isolate NCTC8239 (C). This figure is based upon results from (Miyamoto *et al*., 2002; Wen *et al*., 2003; Miyamoto *et al*., 2004); those findings were used to develop a multiplex PCR *cpe* genotyping assay (Miyamoto *et al*., 2004) capable of distinguishing between chromosomal *cpe* isolates (C), plasmid *cpe* isolates with IS*1470*-like sequences in their plasmid *cpe* locus (A), and plasmid *cpe* isolates with IS*1151* sequences in their plasmid *cpe* locus (B).

transposon, which carries IS*1469* sequences directly upstream of the *cpe* gene, is flanked on both ends by IS*1470* sequences. Some evidence (Brynestad and Granum, 1999) suggests that Tn*5565* can excise from the chromosome and then form a circular intermediate, which could facilitate *cpe* gene movement. However, actual movement/insertion of Tn*5565* from one DNA location to another has not yet been demonstrated.

As shown in Figure 45.2, IS*1469* sequences are similarly present upstream of the plasmid-borne *cpe* gene in type A isolates (Miyamoto *et al*., 2002; Wen *et al*., 2003; Miyamoto *et al*., 2004). However, neither upstream nor downstream intact IS*1470* sequences flank the plasmid *cpe* gene of type A isolates. Instead, about 70% of type A isolates carrying a *cpe* plasmid have defective IS*1470*-like sequences downstream of their *cpe* gene; the remaining 30% of type A isolates carrying a *cpe* plasmid have IS*1151* sequences downstream of their *cpe* gene (Miyamoto *et al*., 2002; Wen *et al*., 2003; Miyamoto *et al*., 2004). Recent studies (Fisher *et al*., 2005) found that the ~75 kb plasmid with the *cpe*-IS*1151* locus typically also carries a *cpb2* gene encoding beta2 toxin. In contrast, the ~75 kb plasmid with the *cpe*-IS*1470*-like locus lacks a *cpb2* gene; diversity clearly exists among the *cpe* plasmids of type A isolates.

As already mentioned, type E isolates usually carry a plasmid with silent *cpe* sequences located near their functional iota toxin genes (Billington *et al*., 1998). IS*1151* sequences are also present in this region of the type E virulence plasmid (Billington *et al*., 1998). Together, those observations suggest the typical type E virulence plasmid may have resulted from insertion of a genetic element containing iota toxin–like genes, which can be found in several pathogenic clostridial species, near the promoter of a plasmid *cpe* gene in a type A isolate. This insertion event inactivated that plasmid *cpe* gene, permitting the accumulation of additional mutations in the ribosome-binding site and ORF of the (now silent) *cpe* sequences in this newly created type E isolate.

The *cpe* mutations present in most/all type E isolates are very similar (Billington *et al*., 1998), suggesting that the progenitor type E virulence plasmid has spread to other *C. perfringens* type A isolates. That observation provided an early suggestion that plasmids carrying *cpe* sequences might be transferable between *C. perfringens* isolates, which has been directly confirmed in a recent study (Brynestad *et al*., 2001) demonstrating that the *cpe* plasmid from type A isolate F4969 can conjugatively transfer among type A isolates.

### *Relationships between* cpe *genotypes and GI disease*

It is now well established that type A isolates causing *C. perfringens* type A food poisoning typically carry a chromosomal *cpe* gene, while type A isolates causing CPE-associated AAD/SD usually have a plasmid-borne *cpe* gene (Cornillot *et al*., 1995; Collie and McClane, 1998; Sparks *et al*., 2001; Miyamoto *et al*., 2002; Wen *et al*., 2003; Miyamoto *et al*., 2004). Possible explanations are now emerging for these strong associations between *cpe* genotypes (i.e., whether an isolate carries a plasmid-borne or chromosomal *cpe* gene) and specific CPE-associated human GI diseases.

Two observations offer at least partial explanations for the common involvement of chromosomal *cpe* isolates in *C. perfringens* type A food poisoning. First, type A isolates carrying a chromosomal *cpe* gene are much more heat-resistant than type A isolates carrying a plasmid *cpe* gene (Sarker *et al*., 2000), a trait that likely favors their survival in the incompletely cooked or inadequately held foods that cause food poisoning outbreaks. Second, recent studies (Wen and McClane, 2004) have established that meat and poultry, which are the most common food vehicles for *C. perfringens* type A food poisoning, are much more likely to be contaminated with type A isolates carrying a chromosomal *cpe* gene rather than a plasmid *cpe* gene.

The strong linkage between type A isolates carrying a *cpe* plasmid and CPE-associated AAD/SD also appears to be multifactorial. For example, while *C. perfringens* type A food poisoning results from ingestion of greater than $10^6$–$10^7$ *C. perfringens* vegetative cells/ml, some evidence suggests that CPE-associated AAD/SD often results from ingestion of a low *C. perfringens* dose (Carman, 1997). Under low infecting doses, establishment of CPE-associated AAD/SD might be assisted by the presence of the *cpe* gene on a conjugative plasmid (as already shown for SD isolate F4969 (Brynestad *et al*., 2001)), which would allow ingested *cpe*-positive *C. perfringens* cells to transfer their *cpe* plasmid to the *cpe*-negative *C. perfringens* commonly found in the normal human GI flora. This putative *in vivo cpe* plasmid transfer would convert the recipient normal flora *C. perfringens* isolates to enteric virulence, thus amplifying the original infective dose and thereby increasing the probability of colonization and disease.

Putative *in vivo* transfer of the *cpe* plasmid potentially offers a second contribution to AAD/SD, i.e., this process will result in the presence of the *cpe* gene in normal flora *C. perfringens* isolates. As normal flora *C. perfringens* are presumably under selective pressure for persistence in the human GI tract, conjugative acquisition of the *cpe* plasmid by colonization-proficient normal GI flora *C. perfringens* might help explain clinical observations (Carman, 1997), indicating that the GI symptoms of CPE-associated AAD/SD typically persist longer than the GI symptoms of *C. perfringens* type A food poisoning.

Finally, it has already been mentioned that recent studies (Fisher *et al*., 2005) found greater than 75% of all type A isolates carrying a plasmid-borne *cpe* gene also express beta2 toxin while fewer than 15% of chromosomal *cpe* isolates express beta2 toxin (Fisher *et al*., 2005). Since purified beta2 toxin can kill the human enterocyte-like CaCo-2 cell line (Fisher *et al*., 2005), the ability

of most type A isolates carrying a plasmid *cpe* gene to produce two potentially enterically active toxins, i.e., CPE and beta2, could help explain why the GI symptoms of CPE-associated AAD/SD are typically more severe than those of *C. perfringens* type A food poisoning.

## CPE expression

### *Features of CPE expression*

Since the pioneering work of Duncan's group back in the 1970s (Melville *et al*., 1997), a strong linkage between CPE expression and sporulation has been apparent. Duncan's early studies showed that a stage 0 sporulation mutant of *C. perfringens* food poisoning isolate NCTC8798 lost the ability to produce CPE. Western blot studies (Czeczulin *et al*., 1993) further confirmed a relationship between sporulation and CPE production by demonstrating more than 1500-fold higher CPE production by sporulating vs. vegetative cells of food poisoning isolate NCTC 8239. Other Western blot studies (Collie *et al*., 1998) later demonstrated that CPE expression from both the chromosomal and plasmid-borne *cpe* genes is strongly sporulation-associated. Two recent studies (Huang *et al*., 2004; Varga *et al*., 2004) using genetic approaches added further support to a relationship between CPE expression and sporulation by showing that isogenic SpoOA and CcpA mutants prepared in the SM101 CPE-positive food poisoning derivative are completely or partially (respectively) blocked for both sporulation and CPE production.

Another pathogenesis-relevant feature of CPE expression is the extremely large amount of this toxin produced by many type A isolates. CPE often accounts for greater than 15% of the total protein present inside sporulating cells of those *C. perfringens* isolates (Czeczulin *et al*., 1993; Collie *et al*., 1998).

### *Regulation of CPE expression*

The sporulation-associated nature of CPE expression involves strong regulation at the transcriptional level. Northern blot and RNA slot blot studies (Melville *et al*., 1994; Czeczulin *et al*., 1996) detected significant levels of *cpe* mRNA in sporulating, but not vegetative cultures, of *C. perfringens* food poisoning isolates. Those Northern blot analyses (Czeczulin *et al*., 1996) also revealed that *cpe* mRNA is ~1.2 kb in size, which is consistent with transcription of the *cpe* gene as a monocistronic message. Monocistronic transcription of the *cpe* gene is compatible with the (previously mentioned) identification of (i) several promoters located ~200 bp upstream of the *cpe* initiation codon and (ii) a putative transcriptional terminator loop/oligo dT tract that is present 36 bp downstream of the *cpe* termination codon (Czeczulin *et al*., 1993; Zhao and Melville, 1998).

The strong association between sporulation and CPE expression likely involves DNA sequences present immediately upstream of each of the three *cpe* promoters (Zhao and Melville, 1998). Those upstream sequences share homology with *Bacillus cereus* sequences associated with SigE-dependent or SigK-dependent promoters, which is significant since SigE and SigK are sporulation-associated alternative sigma factors that become active in mother cells during the sporulation of *B. cereus* (Zhao and Melville, 1998). Presumably, these two alternative sigma factors function similarly during the sporulation of *C. perfringens* to activate transcription of some sporulation-associated genes (including *cpe?*).

The high levels of CPE produced by many enterotoxigenic *C. perfringens* isolates (see previous section) appear attributable, at least in part, to the multiple promoters located upstream of the *cpe* gene. This hypothesis receives direct support from recent studies (Chen *et al*., 2004), demonstrating that *cpe* promoters can also drive strong, sporulation-associated production of foreign proteins (e.g., HIV proteins) in recombinant *C. perfringens* (Note: *cpe* promoter-driven foreign antigen expression represents a key component of recent studies (Chen *et al*., 2004) aimed at developing attenuated *C. perfringens* constructs as possible vaccine delivery vectors).
