Chapter 22

LYSERGIC ACID DIETHYLAMIDE (LSD)

HISTORY

In 1938 at Sandoz Laboratories, Arthur Stoll and Albert Hoffman synthesized LSD from the ergot alkaloid, lysergic acid during their search for an analeptic drug similar to nikethamide.[1] The ergot alkaloid was a hydrolysis product of the fungus, *Claviceps purpurea* (Fr.) Tul., which commonly infects grains. Historically, ergot alkaloids were the active ingredient in the visionary Eleusinian rite of classical times, the epidemic ergotism (St. Anthony's fire) of the Middle Ages, and some New World religious rites (ololiuqui). A group of ergot alkaloids rather than lysergic acid diethylamide (i.e., LSD) probably was the biologic source for these mind-altering effects.[2] Lysergic acid diethylamide is abbreviated *LSD* rather than *LAD* because the German word for acid is *saeure*. LSD had little analeptic or oxytocic activity, and Hoffman abandoned his research on LSD for 5 years. In 1943 after renewing his research on the compound, Hofmann inadvertently discovered its psychotropic properties (intense kaleidoscopic colors, images of extraordinary vividness); he decided to verify the effects of LSD by intentionally ingesting 250 µg LSD.[3] Subsequently, he developed vertigo, agitation, unpleasant visual illusions, and synesthesias. He returned to normal the following day. Subsequent research confirmed that *d*-lysergic acid diethylamide is the only 1 of 4 isomers derived from lysergic acid that has powerful mind-altering properties.

Publication of the experiences of Stoll and Hoffman with LSD initiated the experimental use of LSD on animals, healthy volunteers, and psychotic patients by psychiatrists and other researchers.[4] During the 1950s and 1960s, unpleasant reactions eventually limited the use of LSD in clinical experiments. Later in life, Hoffman admitted that he spent far too much of his research time on LSD.[5] In 1954, Gaddum and Hameed reported that LSD antagonized the effect of serotonin on peripheral tissues in animal bioassays.[6] Of 8 ergot compounds, LSD was the most potent presynaptic serotonin antagonist. Later studies demonstrated that LSD was best described as a mixed $5\text{-HT}_2/5\text{-HT}_1$ receptor partial agonist.

During the 1950s, the self-administration and the administration of LSD to volunteer house staff and psychiatric patients was associated with changes in body ideation, visual illusions, loss of concentration, feelings of irresponsibility, and occasional severe adverse effects (schizophrenia-like behavior, bad trip).[7] In 1957, the Canadian research psychologist, Humphry Osmond introduced the word, psychedelic ("mind-manifesting") as a term to describe hallucinogenic drugs (e.g., LSD, mescaline) that provide clear, euphonious effects uncontaminated by other associations. Illegal use of LSD increased dramatically in the 1960s, and the US Drug Enforcement Administration (DEA) added LSD to the list of schedule I controlled substances in 1966. Medical uses in the 1950s included the treatment of alcoholism, psychoneurosis, sexual abnormalities, autism in children, sociopathy, and analgesia in terminal patients, but controlled clinical trials did not confirm the efficacy of LSD when compared with psychotherapy alone.

IDENTIFYING CHARACTERISTICS

Structure

LSD (CAS RN: 50-37-3) is the semisynthetic diethylamide derivative of the ergot alkaloid, lysergic acid (CAS

RN: 82-58-6), that is structurally similar to nikethamide as displayed in Figure 22.1. LSD does not occur naturally.[8] As lysergic acid has 2 asymmetric carbon atoms (C5, C8), 4 possible stereoisomers exist (*d*- and *l*-lysergic acid and *d*- and *l*-isolysergic acid). Of the 4 isomers, only the *d*-LSD analogs (e.g., *d*-LSD) are active psychedelic drugs. Most LSD derivatives are less potent psychotomimetic agents than LSD. *d*-Lysergic acid amide (CAS RN: 478-94-4, ergine or lysergamide) is a naturally occurring compound that is a structurally similar ergot alkaloid to LSD. This compound has about one tenth the hallucinogenic activity of the semisynthetic *d*-LSD.[9] Only LSD derivatives substituted at the N6 position are nearly as potent as the parent compound.

Physiochemical Properties

LSD is a colorless, tasteless, odorless compound that is water- and alcohol-soluble. The molecular weight of LSD is 323.44 g/mol with a molecular formula of $C_{20}H_{25}N_3O$. *d*-LSD crystallizes from benzene or isopropyl ether in the form of pointed prisms with a melting point of 80–85°C (176–185°F). The tartrate salt of LSD is stable; LSD usually occurs in solution as either the free base or the tartrate salt. Rapid decomposition of LSD occurs following exposure to sunlight. LSD is one of several common drugs of abuse that cause hallucinations (see Table 22.1). Psychedelic is a poorly defined term that commonly refers to drugs (e.g., LSD, mescaline, peyote, dimethyltryptamine, harmaline) that produce thought, mood, and perceptual changes rarely experienced except in dreams, flashbacks, or acute psychoses. Although the perceptual alterations associated with LSD may be similar to hallucinations associated with psychotic disorders, LSD intoxication is not usually associated with the delirium (i.e., alteration in consciousness with cognitive changes) present during a psychotic disorder. In contrast to the psychotic patient, most LSD users retain insight into their altered perceptions, and they understand the drug-induced origin of these altered perceptions of reality.[10]

Terminology

The official US Pharmacopoeia name for LSD is lysergide. Other synonyms include delysid, LSD-25, *N*,*N*-diethyl-*d*-lysergamide, and 9,10-didehydro-*N*,*N*-diethyl-6-methylergoline-8-β-carboxamide. Street names include acid; blotter acid; paper acid; orange or purple wedges; yellow, blue, brown, or green caps; blue, pink, or yellow drops; white lightning; purple haze; California sunshine; sunshine; window panes; beast; microdots; the ghost; or hawk.

Form

LSD is a white, crystalline compound. Previously, a popular form of LSD use involved the use of tiny, round tablets (microdots) that were impregnated with LSD. Now a more popular form of LSD use involves spraying or basting of the drug on colorful sheets of blotting paper that are dried, perforated, and sold as blotter paper, postage stamps, or squares of gelatin (windowpane acid; Figure 22.2). These forms of LSD may be blank or imprinted with characteristic designs (e.g., Bart Simpson, Beavis and Butthead, Felix the Cat, Tasmanian Devil).[11]

FIGURE 22.1. Chemical structure of lysergic acid diethylamide (LSD).

TABLE 22.1. Commonly Abused Drugs Causing Hallucinations.

Class	Common Drugs of Abuse
Indole Alkaloids	Bufotenine, dimethyltryptamine, harmine, ibogaine, LSD, psilocin, psilocybin
Phenylethylamine Compounds	Mescaline, *p*-methoxyamphetamine (PMA), methylenedioxyamphetamine (MDA), 2,5-dimethoxy-4-amphetamine (STP), 3,4-methylenedioxymethamphetamine (MDMA), 2,5-dimethoxy-4-methylamphetamine (DOM)
Cannabinoids*	Marijuana
Piperidines†	Atropine, hyoscine, hyoscyamine, ketamine, phencyclidine, dextromethorphan

*Although hallucinations may occur during cannabis intoxication, the effects of cannabis are substantially different than classic hallucinogens and cannabis is usually discussed separately from hallucinogens.
†Although included in some classifications of hallucinogens, these drugs are more dissociative agents that reduce or block sensory input to the conscious part of the brain.

FIGURE 22.2. Confiscated blotters containing lysergic acid diethylamide (LSD). (Photo courtesy of the US Drug Enforcement Agency).

EXPOSURE

Epidemiology

The popularity of LSD peaked during the mid-1960s; then use declined during the 1970s and 1980s. However, the illicit use of LSD began increasing again during the 1990s, particularly in midwestern and western United States among middle-class Caucasian high school and college students. In general, the highest risk of using psychedelic drugs occurs during the transition from adolescence to adulthood.[12] According to the National Institutes of Drug Abuse (NIDA) 1993 nationwide survey, the percentage of 8th-, 10th-, and 12th-grade students with a history of experimenting with LSD was 3.5%, 6%, and 10%, respectively.[13] Updates of this survey indicate that LSD use among these 3 grades declined sharply from about 2001 to 2005; since that time, annual prevalence rates remained relatively stable ranging from 1.3–2.7% in these 3 grades. LSD is an inexpensive drug that is popular at rave parties along with other psychedelic drugs [e.g., MDMA (Ecstasy; Adam), MDA (Love drug; Eve), methamphetamine (Meth)].[14]

Sources

Lysergic acid and diethylamine are precursors used in the synthesis of *d*-lysergic acid diethylamide. Lysergic acid occurs naturally in grain parasitized by the fungus *Claviceps purpurea*. The seeds from the heavenly blue morning glory (*Ipomoea violacea* L.), ololiuqui or Christmas vine [*Turbina corymbosa* (L.) Raf. or *Rivea corymbosa*] and Hawaiian baby wood rose or elephant creeper (*Argyreia nervosa* (Burm. f.) Bojer] contain *d*-lysergic acid amide (ergine).[15,16] Minor indole alkaloids in these plants include *d*-isolysergic acid amide (iso-ergine), chanoclavine, elymoclavine, lysergol, seto-clavine, and agroclavine. LSD is a semisynthetic drug that is frequently imported into the US illicitly. The Federal Controlled Substances Act classifies LSD as a schedule I drug (high abuse potential, no medical uses in the United States), whereas the LSD precursors lysergic acid and *d*-lysergic acid amide (ergine) are DEA schedule III drugs.

Typically, samples of illicit LSD are relatively pure, and adulteration has been uncommon since the 1970s. Prior to that time, substitutions for LSD included meth-amphetamine, PCP, and caffeine. Of all illicit drugs, LSD is probably the least adulterated with the validity rate for LSD analysis being almost 90% in some studies of street samples.[17] Although there are 4 stereoisomers of LSD as a result of the asymmetric carbon atoms at positions 5 and 8, only the *d*-LSD isomer is an active psychedelic drug.[9] Most illicit samples of LSD are racemic mixtures of all 4 stereoisomers. Diethylamine is a potential contaminant of illicit LSD synthesis. The epimer, *iso*-LSD and the metabolite, *iso-nor*-LSD are inactive. These synthetic compounds are byproducts of the illicit preparation of LSD; consequently, the presence of *iso*-LSD in urine is an indication of LSD use as detected by gas chromatography/mass spectrometry or liquid chromatography/electrospray ionization/tandem mass spectrometry.[18,19]

Methods of Abuse

The preferred route of LSD administration is almost always orally with intravenous (IV), pulmonary, and nasal routes rarely used. Typically, the pattern of LSD use is intermittent rather than intense and sustained, in part reflecting the rapid development of tolerance with chronic use. LSD users are frequently polydrug abusers (e.g., alcohol, amphetamines, marijuana), but the use of sedative-hypnotics and opiates occurs less frequently in LSD users than in other polydrug users. Although the use of LSD may become the focal point of the user's lifestyle, physical withdrawal symptoms do not occur following abrupt cessation of use.

DOSE EFFECT

The administration of LSD produces dose-dependent changes in mentation, perception, emotion, arousal, and self-image. LSD is a potent, perception-altering drug that is approximately 3,000–5,000 times more powerful than mescaline on a weight-for-weight basis. The minimal, clinically perceptible adult oral dose is approximately 25 μg with optimal psychedelic doses ranging from 100–500 μg, depending on tolerance. The usual street dose varies between 50–300 μg and averages about 100–150 μg. Single oral doses of 30 μg/kg produce an intense depersonalization and derealization experience lasting up to 24 hours.[10] Flashbacks and acute anxiety attacks can reoccur in experienced LSD users without the ingestion of additional doses of LSD. Fatal doses of LSD for humans are not well defined on a clinical basis. There is substantial interspecies variability in the susceptibility of animal to LSD with the LD_{50} ranging approximately 500 times between the Asiatic elephant (0.1 mg/kg or 300 mg intramuscular [IM])[20] and mice (46 mg/kg).

TOXICOKINETICS

Absorption

LSD easily crosses the mucosa of the gastrointestinal tract and nose with clinically significant concentrations of the drug appearing in the blood within 15–20 minutes.[21] Following the ingestion of 2 μg LSD/kg, peak plasma concentrations as measured by a spectrofluorometric method occurred in 30–75 minutes with heavy meals reducing and slightly delaying the peak plasma LSD concentration.[22] There are few data on the absorption of LSD by the lungs, but smoking is not a popular form of LSD abuse, probably as a result of the degradation of LSD during heating.

Distribution

After an IV dose of 2 ug LSD/kg to 5 volunteers, the estimated V_d of LSD correlated to extracellular water (i.e., ~0.25 L/kg) as measured by fluorometry.[23] About 90% of LSD in plasma is protein-bound.

Biotransformation

There are limited data on the metabolites of LSD in humans, but *in vitro* studies indicate that *N*-demethylation (*N*-demethyl-LSD), *N*-deethylation (*N*-desethyl-LSD), and hydroxylation (13-OH-LSD, 14-OH-LSD) are the common metabolic pathways in humans. *N*-demethyl-LSD is probably a minor metabolite (i.e., 1–2 %).[24] Potential metabolites of LSD include *N*-demethyl-LSD (*nor*-LSD), 13-OH-LSD, 14-OH-LSD, lysergic acid ethylamide (LAE), *iso*-LAE, 2-oxo-LSD, and 2-oxo-3-hydroxy-LSD.[25,26] Figure 22.3 demonstrates the structure of LSD and major metabolites. *iso*-LSD is a contaminant of illicit LSD synthesis rather than a part of the biotransformation of LSD. Studies in animals suggest that the major metabolic route is hydroxylation of the phenyl ring to form phenols, which are subsequently conjugated as glucuronides and excreted in the bile. De-ethylation and demethylation probably are minor metabolic pathways in rats.[27]

Elimination

The plasma elimination half-life of LSD in humans is about 2–3 hours with substantially shorter half-lives in some experimental animals (mice, monkeys, cats).[28] Intravenous LSD doses of 2 μg/kg to 5 volunteers produced plasma LSD concentrations ranging from about 4–6 ng/mL 1–2 hours after administration to <1 ng/mL 8 hours after administration as measured by fluorometry.[29] The kidney excretes small amounts (i.e., <1% of the absorbed dose) of unchanged LSD in the urine. The urinary elimination half-life of the *N*-demethyl-LSD metabolite is somewhat longer (i.e., 8–10 hours vs. 4–6 hours) compared with unchanged LSD.[24] Renal excretion of hydroxylated metabolites (13-OH-LSD, 14-OH-LSD) occurs after conjugation with glucuronic acid. Preliminary studies indicate that the metabolite, 2-oxo-3-hydroxy-LSD is not conjugated with glucuronide prior to renal excretion.[30] Animals studies suggest that biliary excretion accounts for most of the elimination of LSD from the body.

Tolerance

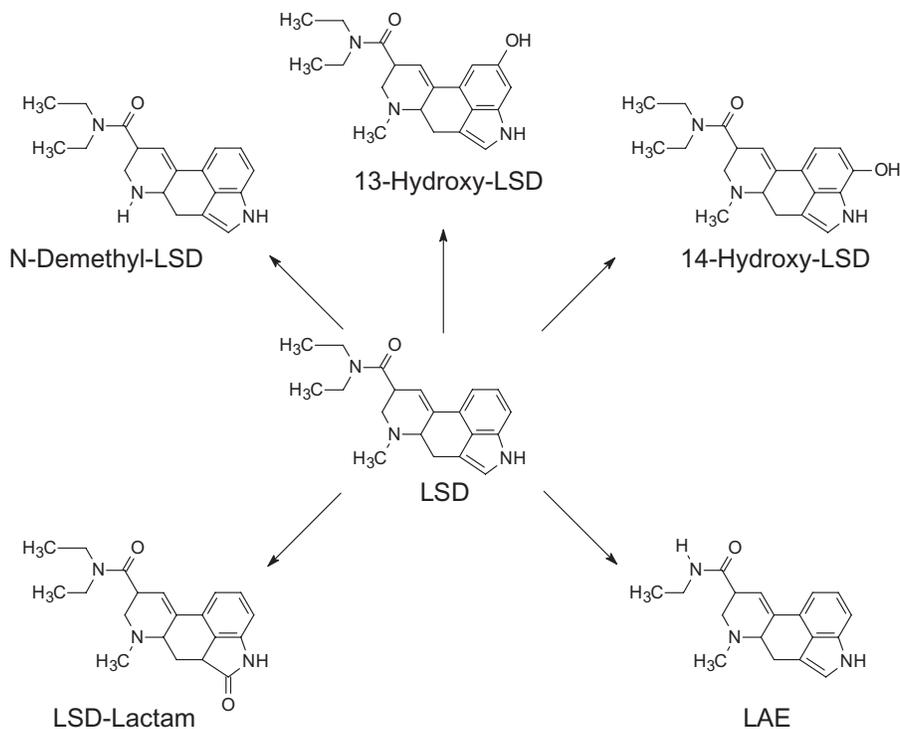
Tolerance to the behavioral effects of LSD occurs rapidly in both humans and animals.[31] Although a


FIGURE 22.3. Lysergic acid diethylamide and major metabolites. LSD = lysergic acid diethylamide; LAE = lysergic acid ethylamide.[132]

300-μg LSD dose produces typical psychotomimetic reactions in adults without recent LSD use, subsequent daily 100-μg doses cause minimal reactions after the second dose.[9] Tolerance typically develops after a few days of daily use, but acute tolerance disappears within 3–4 days of the cessation of LSD use.[32] In animal models, cross-tolerance develops to LSD following the administration of psilocybin and mescaline,[33,34] but not with *d*-amphetamine.[35]

Drug Interactions

In a study of 32 experienced LSD users, structured interviews using a standardized questionnaire indicated a subjective decrease in the response of 88% (28 participants) to LSD following the administration of selective and nonselective serotonin reuptake inhibiting antidepressant drugs (fluoxetine, paroxetine, sertraline, trazodone) for at least 3 weeks.[36] In this study, an additional participant receiving fluoxetine for only 1 week had an increased response to LSD. In contrast to selective serotonin reuptake inhibitors, the chronic administration of tricyclic antidepressants and lithium was associated with an enhanced response of volunteers to LSD, whereas decreases in the subjective response to LSD was reported after the chronic use of monoamine oxidase inhibitors.[37]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Although the exact mechanism of action of LSD has not been identified, animal studies indicate that central serotonin receptors (5HT) mediate the acute discriminative stimulus effects of LSD, particularly the $5HT_{2A}$ receptor.[38,39] LSD is probably best described as a mixed $5HT_2/5HT_1$ receptor partial agonist.[40] This compound binds to $5HT_{1A}$ and to G-protein coupled $5-HT_2$ receptor subtypes in areas of the hippocampus, corpus striatum, cerebral cortex, and, to a much lesser extent, cerebellum.[41] The partial agonist action of LSD on these receptors results from LSD-stimulated phosphoinositide hydrolysis at these receptor sites, particularly at the postsynaptic $5-HT_{2A}$ receptor.[42,43] Although stimulation of the $5-HT_{2A}$ receptor is a necessary prerequisite for the hallucinogenic effects of LSD, the biochemical and signaling pathways responsible for these effects remain undetermined.[44] LSD also interacts as a mixed agonist/antagonist with central dopamine D_1 and D_2 receptors,[45] but the clinical significance of this interaction is unclear. The cause of hallucinogen persisting perception disorder (*flashbacks*) also has not been determined, but the use of benzodiazepines to treat this disorder suggests that the mechanism of toxicity involves receptors (e.g., inhibitory GABA) other than, or in addition to, serotonin receptors.

CLINICAL RESPONSE

Illicit Use

Following the ingestion of 1-2 μg LSD/kg, psychedelic effects typically begin within approximately 30–90 minutes with peak effects in 1.5–2.5 hours, although some sympathomimetic effects (e.g., tachycardia, pilo-erection, tremor, flushing) may occur slightly earlier (i.e., 10–15 minutes).[2] Pupillary dilation is a consistent, very prominent sign associated with LSD use that often measures 8 mm in diameter.[10] Pulse rate, body temperature, and respirations increase slightly during intoxication, but the blood pressure usually remains normal.[46] Peripheral sympathomimetic effects of LSD include uterine contraction, piloerection, and bronchoconstriction (i.e., high LSD doses). Parasympathomimetic effects (e.g., nausea, vomiting, salivation, lacrimation) occur occasionally.

The administration of LSD causes changes in arousal, cognition, and self-image as well as alterations of sensory cues.[10] There is considerable variability in the interindividual and intraindividual response to LSD depending on the set. The main psychologic experience during LSD intoxication involves alterations of perception (sound, color intensity, crossover of sensory modalities) and cognition (decreased attention, unusual associations, less abstract thought), euphoria, subjective slowing of time, distortion of body image, and loss of physical boundaries (i.e., depersonalization). Afterimages become prolonged, with flat surfaces assuming depth and fixed objects undulating. Although visual illusions are common at therapeutic doses, the individual usually retains the ability to discriminate between these altered perceptions and reality. Hyperacusis and amplification of background noise occur occasionally; however, the presence of true auditory hallucinations suggests an underlying psychosis. The blending of sensory inputs (i.e., synesthesias or seeing sounds/hearing colors) is relatively rare.

Alteration of thought processing during LSD intoxication includes the loosening of associations, alteration of body image, feeling of rapid aging, concrete thinking, and depersonalization. The individual usually remains oriented, but the development of paranoia or ideas of persecution can cloud judgment. Weakness and insomnia may develop after resolution of the acute effects of LSD. Psychomimetic effects begin declining about 4 hours after ingestion depending on dose; these symptoms usually disappear within 6–12 hours.

Adverse physiologic reactions following LSD use include nausea, headache, diaphoresis, general weakness, impaired concentration, and exhaustion. Higher incidences of adverse reactions occur in individuals unaware of the administration of LSD;[47] however, adverse reactions may occur despite the frequent use of LSD without complications.[48] The differential diagnosis of a patient with perceptual illusions and mydriatic pupils includes the administration of atropine, scopolamine (Jimson weed), psilocybin mushrooms, phencyclidine (PCP), cocaine, and amphetamine-related psychedelic drugs (MDMA, MDA, DOM). The sympathomimetic effects are generally much more prominent after the use of cocaine or amphetamine than with LSD. In contrast to PCP intoxications, nystagmus is usually absent with pupils typically being dilated during LSD intoxication. The prominent signs of anticholinergic poisoning (atropine, scopolamine) include dry, flushed skin, dry mucous membranes, urinary retention, and reduced bowel sounds (i.e., gastrointestinal hypomotility). These clinical features are typically absent during LSD intoxication.

BEHAVIORAL ABNORMALITIES

Acute anxiety and acute panic attacks are common adverse reactions to LSD intoxication, particularly after the accidental ingestion of LSD by children.[49] The ingestion of 50–150 μg LSD by a 2-year-old child produced tachycardia, tachypnea, diaphoresis, visual illusions, and acute anxiety that resolved within 1 day without residual effects.[50] Similar symptoms (anxiety, hyperreflexia, perceptual distortion) occurred in a middle-aged woman following the accidental ingestion of LSD.[51] A 2-mg LSD ingestion in a 2-year-old child caused mydriasis and ataxia followed by areflexic catatonia, mild hypertension, tachycardia, and tachypnea.[52] Although myalgias and muscle tremor developed later, all symptoms resolved within 48 hours.

Behavioral complications of LSD use typically involve accidental trauma as a result of aggressive behavior during panic attacks, suicide attempts during depressive states,[53] reckless behavior during recurrent flashbacks, and self-inflicted trauma (e.g., solar maculopathy,[54] self-enucleation[55]). Although homicides occur during and after LSD intoxication,[56,57] multiple-drug use, bias, and premorbid personality confound the causal link between LSD use and murder, particularly when goal-directed planning and delayed gratification occur during LSD-induced psychosis.[58] Amnesia does not usually occur during LSD intoxication. Predicting behavior is difficult because of the number of variables (e.g., setting, expectation, underlying personality, emotional stress) that affect behavior in addition to the dose of LSD. Intoxicated LSD users are usually quiet, passive, and withdrawn, but hostility may develop. Sociability

and sexual drives frequently are diminished. Moods are labile, ranging from euphoria to depression.

MENTAL DISORDERS

Psychiatric complications associated with LSD use include psychosis, persistent or recurrent major affective disorders (i.e., depression), deterioration of underlying psychiatric illness, acute panic or paranoid reactions, disruption of normal function (i.e., burnout), and posthallucinogen perceptual disorder (i.e., flashbacks). Depressive and schizophrenic patients may decompensate, and susceptible schizophrenics may develop prolonged hallucinations.[59] Severe depression and intense loneliness may occur within the 24-hour period after the psychomimetic effects of LSD resolve.[14]

ACUTE PSYCHOSIS.   A drug-induced schizophreniform reaction may develop in patients vulnerable to both substance abuse (e.g., LSD) and psychosis.[60] In a study of 52 patients with LSD-associated psychosis and 29 matched first-break schizophrenics, the LSD patients were fundamentally similar to the schizophrenics in genealogy, phenomenology, and clinical features except the prominence of alcohol abuse in their parents.[61] Whether LSD hastens the onset of chronic undifferentiated schizophrenia remains unclear. In a matched, controlled study of 37 chronic schizophrenics with and without LSD use prior to the onset of schizophrenia, retrospective chart review did not detect a difference in the 2 groups in regard to the age of onset of symptoms or the age of first admission to a psychiatric hospital.[62]

FLASHBACKS AND HALLUCINOGEN PERSISTING PERCEPTION DISORDER (HPPD).   Flashbacks are pseudo-hallucinations that typically involve false perception of movement (i.e., stationary objects in motion), color flashes, intensification of colors, halos around objects, comet-like trailing images, moving and shimmering objects, and reappearance of kaleidoscopic, brightly-colored geometric patterns. These visual alterations, time distortions, and changes in body image recur in experienced LSD users during periods of abstinence. Flashbacks are usually benign, spontaneous, recurrent, transient occurrences that do not cause emotional distress. The impaired color perception may persist in chronic LSD users for 2 years after cessation of LSD use.[63] Both physiologic (e.g., fatigue, driving, sepsis, electrolyte disorders, heavy ethanol consumption) and emotional stress can precipitate flashbacks.[64,65]

More frightening flashbacks involve the sudden appearance of hideous apparitions (e.g., Satan) or the distortion of people's body images. In contrast to relatively benign flashbacks, hallucinogen persisting perception disorder (HPPD) is an uncommon, persistent, distressing, spontaneous, pervasive condition that causes an unpleasant dysphoria months rather than days after the cessation of LSD use.[66] The diagnosis of this disorder requires the onset of this perceptual disorder after LSD use and the exclusion of other similar disorders (visual epilepsy, migraine, dementia, schizophrenia, delirium, hypnopompic hallucinations).[67] This phenomenon involves the experience of one or more perceptual symptoms from prior LSD experiences that causes significant distress and/or impairment of social functioning. HPPD often occurs in patients with no prior history of psychiatric disease. These patients are usually aware of these debilitating illusions, and they frequently seek psychiatric care. The clinical course of HPPD is highly variable ranging from subtle perceptual disturbances to severe, debilitating images with associated anxiety and depression. These clinical features may resolve spontaneously or progress to a chronic relapsing syndrome.[68]

MEDICAL COMPLICATIONS

Several case reports suggest that neurologic complications (e.g., seizures,[69] headache with small-artery occlusive changes, [70] occlusion of internal carotid artery[71]) may develop after recreational doses of LSD. However, a causal link between these complications and the use of LSD remains unproven because of the confounding of multiple-drug abuse and biases associated with case reports.

Overdose

Several case reports indicate that hyperthermia may complicate large ingestions of LSD along with rhabdomyolysis, renal failure, and hypotension.[21,72] All LSD overdose patients in these case reports recovered without medical or psychiatric sequelae after supportive care that included ventilatory support. Neuroleptic malignant syndrome (NMS)-like clinical features developed in a 21-year-old man admitted to the hospital with coma, bilateral extrapyramidal rigidity, and rhabdomyolysis.[73] The serum LSD concentration (69.9 ng/mL) drawn 24 hours after admission confirmed the ingestion of massive amounts of LSD. Deaths associated with medical consequences of LSD intoxication are rare, and these case reports are not well-documented.[74] A 25-year-old man died within 24 hours after ingesting LSD secondary to hyperpyrexia (41.6°C/106.9°F), hypotension, renal failure, rhabdomyolysis, and liver necrosis.[75] Analysis of antemortem blood confirmed a high LSD concentration (14.4 ng/mL). The presence of respiratory depression during massive LSD overdose suggests that death may occur following the use of very large LSD doses.[21]

Abstinence Syndrome

The chronic use of LSD is not associated with symptoms or signs of withdrawal; the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-IV-TR*) does not list a LSD-dependence syndrome.[66] There are few data on the neuropsychologic effects of chronic LSD use, in part because of the frequent use of other drugs of abuse and the difficulty controlling various confounding variables including premorbid cognitive function, personality, and previous drug use.[76] Existing data suggest that any changes are subtle and there are few, if any, long-term neuropsychologic deficits attributable to chronic LSD use.[32] Affective abnormalities following LSD use include exhaustion, profound depression, loss of motivation, and emotional lability.

Reproductive Abnormalities

There is no clear evidence that LSD is teratogenic.[77] Case reports associate the illicit maternal use of LSD during pregnancy with rare congenital abnormalities including anophthalmia (absence of ocular tissue),[78] true limb aplasia (absence of entire limb bud),[79] and multiple cerebral and cerebellar malformations.[80] Uncontrolled studies of women using LSD during pregnancy suggest elevated incidences of spontaneous abortions[81] and major congenital abnormalities[82] compared with national averages. However, the potential presence of a number of confounders (e.g., ingestion of other illicit drugs, infectious diseases, poor maternal nutrition) preclude a definitive correlation between LSD and the occurrence of human birth defects.

At normal recreational doses, there are no unequivocal data to indicate that LSD is a mutagen.[83] *In vitro* human and experimental animal studies are inconsistent, and the data from the 1960s and 1970s indicate that LSD is, at most, a weak mutagen.[84,85] Chromosomal studies in LSD users are also inconsistent. Elevated chromosomal abnormalities occurred in the leukocytes of LSD users, but these changes were not dose-related.[86] Studies of lymphocytes from 50 hospitalized psychiatric patients administered LSD did not demonstrate a statistically significant elevation of chromosomal abnormalities when compared with matched controls.[87,88]

DIAGNOSTIC TESTING

Analytic Methods

SCREENING

Identification of LSD in biologic fluids is a difficult task. The rapid and extensive metabolism of LSD produces very low urine concentrations (i.e., <1 ng/mL) of unchanged parent LSD, limiting the detection of this compound by various screening methods. Fluorometric and thin-layer chromatographic methods of LSD detection are relatively insensitive. Radioimmunoassay is a sensitive method of detection (i.e., limit of detection [LOD], 0.020 ng/mL), but this procedure is time consuming and uses radioactive material. Commercial immunoassays for LSD are rapid, relatively low cost analytic procedures for the detection of LSD, but these assays do not provide the specificity and quantitative capabilities of gas chromatography/mass spectrometry or liquid chromatography/mass spectrometry. Simple, non-isotope immunoassays have been developed on automated analyzers to screen urine samples for LSD including microplate enzyme immunoassay (EIA),[89] EMIT, microparticle-based immunoassay (OnLine®),[90] and cloned enzyme donor immunoassay (CEDIA).[91] These immunoassays cross-react with LSD metabolites depending on the individual assay;[92,93] confirmation techniques are necessary to separate LSD and LSD metabolites.[94,95] The cross-reactivity of EIA with *nor*-LSD was 16–28% depending on the *nor*-LSD concentration.[88] Cross-reactions with ergot alkaloids (e.g., ergonovine, ergotamine, dihydroergocristine, dihydroergotamine) are relatively minor, but some commonly used medications may cause false-positive results with LSD immunoassays as a result of cross-reactivity. Potential medications that may produce false-positive results with LSD immunoassays include amitriptyline, bupropion,[96] fentanyl, haloperidol, metoclopramide, sertraline, and ambroxol.[97,98] Common adulterants (e.g., ascorbic acid, bleach, salt, apple juice, vinegar, liquid soap) do not usually produce false-negative results on immunoassays, but false positive results for LSD may occur.[99] The current US Department of Defense cutoff for positive confirmation of LSD in positive screening assays in urine is 0.020 ng LSD/mL, whereas the cutoff for screening LSD in urine is 0.050 ng/mL. LSD is not often included in urine drug abuse screens.

CONFIRMATORY

Low volatility, instability at high temperatures, and the high adsorptive capacity of LSD for chromatographic columns complicate the analysis of LSD by chromatographic methods. Derivatization of LSD is necessary to prevent sample loss during chromatography as a result of irreversible adhesion of LSD to the column.[100] Analytic methods for the confirmation of LSD in biologic fluids include radioimmunoassay, high performance liquid chromatography coupled with fluorometric detection,[101] high performance liquid chromatography/mass spectrometry, and gas chromatography/mass

spectrometry (GC/MS).[102] These techniques are targeted toward LSD rather than LSD metabolites; therefore, immunoassays, which cross-react with LSD metabolites, may detect LSD use longer than these confirmatory procedures as a result of the inclusion of parent LSD as well as cross-reacting metabolites.[90] Methods that do not require derivatization include liquid chromatography/electrospray ionization/tandem mass spectrometry and immunoaffinity chromatography/high performance liquid chromatography/mass spectrometry.[103] The lower limit of quantitation (LLOQ) for LSD and iso-LSD in whole blood samples was 0.01 ng/mL, as measured by liquid chromatography/tandem mass spectrometry.[104] This method also quantitates the metabolite, 2-oxo-3-hydroxy-LSD in urine samples. Atmospheric pressure matrix-assisted laser desorption/ion trap/mass spectrometry is a relative easy and rapid method that is a good quantitative measure of LSD when interference from high-background ions is eliminated.[105] These analytic procedures are highly sensitive. The LLOQ and LOD for LSD using gas chromatography/tandem mass spectrometry and an internal ion trap detector were 0.080 ng/mL and 0.020 ng/mL, respectively.[106] Established cutoff limits for RIA procedures are usually near 0.50 ng/mL, although actual detection limits may be slightly lower (0.25 ng/mL). Analysis of urine samples for 2-oxo-3-hydroxy-LSD increases the detection window for LSD because this metabolite is usually present in substantially higher urinary concentrations compared with LSD, iso-LSD, and nor-LSD.[107] In this study, the mean ratio of 2-oxo-3-hydroxy-LSD/LSD was approximately 15. LSD possesses a native fluorescent chromophore (fluorophore) and HPLC with fluorescence detection is a sensitive method of detecting LSD. However, this method is not specific because of interference from other fluorescent compounds absorbing at similar wavelengths. The use of ultra performance liquid chromatography/tandem mass spectrometry allows the detection of LSD and LSD metabolites (N-demethyl-LSD, iso-LSD, 2-oxo-3-hydroxy-LSD) in blood with an LOD of 0.005–0.010 ng/mL.[108] The LLOQ in blood or urine for LSD and iso-LSD is 0.020 ng/mL and 0.050 ng/mL, respectively, similar to other LSD metabolites.

STORAGE

LSD is unstable under prolonged exposure to heat, alkaline conditions, and ultraviolet light irradiation. Proper storage of LSD typically involves the use of amber glass or nontransparent polyethylene containers. Frozen samples of LSD are stable for at least 3 months.[109,110] However, LSD is photosensitive, and rapid deterioration of LSD occurs in sunlight. The amount of deterioration under lighted conditions depends on the wavelength, light intensity, and exposure time.[111] The loss of LSD from spiked samples stored at 4°C and -20°C under dark conditions was minimal over 2 weeks, whereas the loss of LSD from samples stored at room temperature under normal fluorescent lights in clear vials was approximately 50% over 2 weeks.[112] Under experimental conditions, loss of LSD from spiked samples stored in polyethylene bottles at room temperature in light and dark conditions was limited to 10%.[109] The LSD metabolite, 2-oxo-3-hydroxy lysergic acid diethylamide is relatively stable up to 2 months under refrigerated and frozen conditions, but some deterioration occurs if the sample is stored at or above room temperature.[113]

Biomarkers

BLOOD

EXPERIMENTAL/ILLICIT USE.   Typically, the LSD concentration in blood following the ingestion of recreational LSD doses is in the low ng/mL range.[114] Peak plasma LSD concentrations following the IV administration of 2 μg/kg are approximately 6–7 ng/mL within about 30 minutes; the LSD concentration decreases to nondetectable concentrations in about 8 hours.[29] In 5 patients presenting to an urban emergency department with bizarre, agitated behavior after ingesting LSD, the serum LSD concentrations 2–10 hours after ingestion ranged from 1.3–1.8 ng/mL as measured by high performance liquid chromatography with fluorescent detection.[115] This method is not specific for LSD because of the interference of other compounds with fluorescent properties. The LSD concentration did not correlate to adverse effects (agitation, flashbacks).

OVERDOSE.   Plasma LSD concentrations ranged from 4–6 ng/mL 1–2 hours after the IV administration of 2 μg/kg, [23] and up to 8.8 ng/mL 2 hours after the ingestion of 160 μg of LSD as measured by a less-specific fluorometric method.[116] A massive LSD overdose occurred following the insufflation of LSD by 8 patients who presented to an emergency department 15 minutes later.[21] On admission to the emergency department, 2 patients were comatose, vomiting, and displaying prominent sympathomimetic signs. Analysis of blood samples demonstrated admission LSD plasma concentrations of 6.6 ng/mL and 11.6 ng/mL. Another patient had vomiting, catatonia, and hyperreflexia with fixed dilated pupils; the admission plasma LSD concentration of the latter patient was 16.0 ng/mL.

POSTMORTEM.   In blood samples from a 25-year-old man, who died 16 hours after hospital admission, the

postmortem LSD concentrations was 4.8 ng/mL as measured by radioimmunoassay.[117] Details of the clinical course were not reported; however, the coroner concluded that the man died from LSD intoxication. The antemortem plasma was 14.8 ng/mL. No other drugs were detected as analyzed by radioimmunoassay, high performance liquid chromatography, and GC/MS.

URINE

Following ingestion, the kidneys excrete small amounts of LSD rapidly in urine; therefore, the concentration of LSD usually decreases below the confirmation cutoff (0.200 ng/mL) within 12–24 hours following the ingestion of a recreational dose (50–100 µg) of the drug.[118] Lowering the detection limit to 0.010 ng/mL with ion trap GC/MS can extend the detection time to approximately 72 hours after ingestion of a 50 µg recreational dose of LSD.[119] Some metabolites of LSD appear in higher concentrations than LSD, and analysis directed toward the detection of these urinary metabolites may extend the detection time to 96 hours. Following the ingestion of 4 µg LSD/kg by volunteers, 2-oxo-3-hydroxy-LSD remained >0.200 ng/mL for 48 hours and above the LOD for 96 hours as measured by gas chromatography/tandem mass spectrometry with solid-phase extraction. Current immunoassays for LSD do not significantly cross-react with 2-oxo-3-hydroxy-LSD.[30] In a series of 49 urine specimens from workplace drug testing programs that were positive for LSD by screening immunoassay, the mean ratio of 2-oxo-3-hydroxy-LSD/LSD was approximately 24 with a range of 0.03–136.[120] Analysis of urine samples by radioimmunoassay demonstrated LSD concentrations ranging from 1.5–55 ng/mL within 24 hours after the ingestion of LSD doses of 200–400 µg.[121]

Abnormalities

Experimental doses of LSD produce laboratory evidence of a nonspecific stress reaction (i.e., leukocytosis, eosinophilia).[10] Rhabdomyolysis may occur, particularly in severely agitated, restrained patients[73] or in unrestrained patients.[122] After LSD administration, the amplitude of the electroencephalogram (EEG) tracings decreases with alpha rhythms disappearing and low-voltage fast or desynchronized discharges predominating, particularly the slower frequencies. The rhythmic after-discharges associated with photo-evoked potentials are suppressed, but the clinical significance of these changes is unclear.[123] There are inadequate clinical data on the chronic effects of LSD use on neuropsychologic testing, in part because of the difficulty controlling for the effects of multiple drug use and the absence of data on premorbid cognitive and personality function. A review of the limited EEG and neuropsychologic testing data on chronic LSD users in the 1960s and 1970s demonstrated few, if any, long-term neuropsychologic deficits attributable to LSD use.[75,124] The cognitive effects of LSD complicate the interpretation of neuropsychologic testing of individuals given LSD acutely.

Driving

There are few data on the effects of LSD on driving skills. Case series of polydrug abusers suggest that prolonged afterimages, visual illusions, and alteration of cognition and judgment may occur while driving under the influence of psychedelic drugs including LSD.[125] However, the prevalence of these effects and the exact role of LSD remain unclear.

TREATMENT

Stabilization

Life-threatening medical reactions to LSD intoxication are extremely rare. All patients should be evaluated for organic disease with vital signs, physical examination, and a thorough history that includes current symptoms, premorbid function, and prior medical and psychiatric conditions. Vital signs should include an accurate rectal temperature that is repeated if the patient deteriorates. The sympathomimetic effects of LSD are usually mild and transient, except in patients with underlying cardiovascular disease or very large overdose. Laboratory investigations in patients with severe LSD intoxication to exclude organic disease include complete blood count, serum electrolytes, hepatic aminotransferases, creatinine and creatine kinase, urinalysis, and urine for drugs of abuse as well as computed tomography of the brain if neurologic disease is suspected. Seizures may occur in patients using LSD, but the causal link between LSD use and seizures is not well delineated. Therefore, these patients should be evaluated for other causes of seizures; benzodiazepines are first-line drugs for the treatment of agitation and persistent seizures.

Gut Decontamination

The usual methods of decontamination (e.g., activated charcoal) are almost always unnecessary because of the rapid absorption of LSD and the relatively small amounts of the ingested drug. Additionally, the use of decontamination measures complicate the treatment of agitated patients.

Elimination Enhancement

As the volume of distribution is large, there are no clinical data to support the use of methods to enhance the elimination of LSD.

Antidotes

There is no specific antidote for LSD intoxication.

Supplemental Care

Occasionally, peripheral vascular ischemia and lower extremity gangrene is associated with LSD use that does not respond to conventional treatment including IV heparin, nicardipine, methylprednisolone, and topical nitroglycerin. A case report documented restoration of normal luminal caliber and prompt reperfusion of LSD-induced extensive lower extremity vasospasm in a previously healthy 19-year-old woman.[126] Acute renal failure secondary to LSD-induced rhabdomyolysis is one of the few indications for hemodialysis after LSD intoxication.

ACUTE PANIC ATTACK

Reassurance that the frightening images are temporary and illusory along with reduction of sensory stimulation are the most important aspects of the management of LSD-related panic attacks.[47] The patient should be placed in a safe, quiet environment, preferably with a familiar person who can provide constant reassurance (i.e., "talkdown"). This person should reorient the patient by interpreting the anxious feelings while attempting to restore a sense of control and well-being to the patient overwhelmed with frightening visions and emotions. Continuous interpretations of sensory misperceptions and pseudo-hallucination are necessary to reduce the anxiety associated with a "bad trip".[11] This "talkdown" period typically lasts 8–12 hours, and during that time the patient may move in the room as long as the patient does not display destructive behavior. Restraints should be avoided if possible, but impulsive and potentially dangerous actions should be controlled as necessary to prevent destructive behavior. Diazepam (5 mg IV every 1–2 hours, adult) or lorazepam (1–2 mg IV every 1–2 hours) are the drugs of choice for sedation, particularly for restrained patients. Haloperidol (2–5 mg IM, adult) may be administered as a second-line drug if the above measures fail to calm the patient and continued agitation represents an substantial medical risk unless the patient has symptoms consistent with neuro-leptic malignant syndrome. There are few published data on the use of droperidol, midazolam, ziprasidone, or newer generation antipsychotic drugs (aripiprazole, olanzapine, quetiapine, risperidone) for the treatment of LSD-induced agitation. Patients sedated for agitation should be observed closely for respiratory depression.

All patients requiring the continued use of restraints should have the first voided urine specimen sent for myoglobin and urinalysis. A positive dipstick test for hematuria in the absence of microscopic evidence of red blood cells suggests myoglobinuria and the need for generous fluid replacement along with sedation as required by the mental status of the patient. If the patient does not respond to reassurance and regain control over the frightening thoughts, 24-hour hospitalization may be necessary. Follow-up to a mental health facility is important to assess the need for further therapy.

ACUTE PSYCHOTIC REACTIONS

Most visual hallucinations are actually illusions rather than true hallucinations, and these patients understand that what they are seeing is drug-induced. Haloperidol has been administered successfully in the setting of LSD-induced psychotic reactions,[127] but there are no clinical data to compare haloperidol with other antipsychotic drugs including the newer antipsychotic drugs.

HALLUCINOGEN PERSISTING PERCEPTION DISORDER (HPPD)

The treatment of benign flashbacks is similar to the treatment of acute panic attacks. Reassurance that the flashbacks diminish with time frequently reduces the anxiety associated the occurrence of flashbacks. Avoidance of stress, antihistamines, fatigue, ethanol, and other drugs of abuse helps reduce the recurrence of flashbacks.[128] The treatment of HPPD often requires drug therapy depending on the severity of the anxiety and social disruption caused by pervasive perceptual disturbances. Treatment modalities include psychotherapy, identification of triggers, benzodiazepines, and other drugs (clonidine, perphenazine, clonazepam).[129] Case series of HPPD patients suggests that high potency benzodiazepines (e.g., clonazepam 2 mg/day for 2 months) are more effective than low potency benzodiazepines (e.g., alprazolam) for the treatment of HPPD.[130] In this case series, the improvement continued after tapering the patients off clonazepam over 1 month. Older medical literature suggests that haloperidol is an option for the treatment of HPPD.[131]

Chapter 23

BARBITURATES (AMOBARBITAL, BUTALBITAL, PENTOBARBITAL, SECOBARBITAL)

In 1864, Adolf von Baeyer first synthesized barbituric acid as a product of the condensation of malonic acid (acid derivative of apples) and urea (component of animal excrement). Barbituric acid does not produce central nervous system (CNS) depression, but the addition of alkyl or aryl groups at C5 confers sedative hypnotic properties to these drugs. Conrad and Guthzeit synthesized the first barbituric acid derivative, diethylbarbituric acid (barbital, veronal, malonal, Gardenal) in 1881.[1] In the prebarbiturate era of the latter half of the 19th century, the common hypnotic drugs included bromides, scopolamine, chloral hydrate, paraldehyde, and morphine; Fischer and von Mering published the first scientific report on the hypnotic properties of barbital in 1903.[2] This compound became the first barbiturate introduced into clinical practice as a hypnotic by the German companies, E. Merck (Darmstadt) and F. Bayer and Company (Elberfeld) in 1904. During the 20th century, modification of the barbituric acid molecule resulted in over 2,500 barbiturate derivatives with about 50 of these compounds introduced into clinical practice.[3] In 1911, Horlein synthesized phenobarbital; the following year, F. Bayer and Company introduced this drug into clinical practice as Luminal®. Following World War I, the US Congress passed the Trading with the Enemy Act of 1917 that allowed the manufacture of patented German products by American subsidiaries of German companies by the modification of the generic name. Diethylbarbituric acid became barbital in the United States, whereas this compound was barbitone in the United Kingdom. Thus, the nomenclature of barbiturates persisted as differences in the 2 endings, -al and -one. Alfred Hauptmann serendipitously discovered the anticonvulsant properties of phenobarbital in 1912,

when he administered this barbiturate to epileptic patients as a sedative for sleep.[4] In the early 1920s, Klaesi introduced the use of barbiturates as a treatment for psychotic patients by the induction of deep, prolonged sleep as means to facilitate communication between the patient the psychotherapist.[5] Between the 1920s and the mid-1950s, barbiturates became the major sedatives and hypnotics in clinical practice.[3] By 1930, the use of phenobarbital superseded the use of bromides as anticonvulsants despite reports of tolerance and withdrawal seizures. In 1923, Schonle and Moment at Eli Lilly Company synthesized amobarbital (Amytal®, Eli Lilly Company, Indianapolis, IN); 6 years later, Schonle synthesized secobarbital (Seconal®). Both of these drugs had similar pharmacologic properties as the earlier synthesized barbiturate, butalbital, Volwiler and Tabern synthesized pentobarbital (Nembutal®, Abbott Laboratories, Abbott Park, IL) and thiopental (Pentothal®) in 1930. The latter barbiturate was a sulfur derivative of pentobarbital that became a popular intravenous (IV) anesthetic.[6]

Although many barbiturates were synthesized during the early 20th century, only a few barbiturates became widely used as sedative hypnotics, anticonvulsants, and anesthetics. Pharmacologic differences in the duration of action allows a practical categorization of the common barbiturates into the following: 1) short- and intermediate-acting: hypnotics; 2) long-acting: anticonvulsants, anxiolytics, treatment of withdrawal symptoms; and 3) ultrashort-acting: induction of anesthesia for minor operation and procedures. Table 23.1 displays identifying data for common barbiturates.

Other uses of barbiturates included treatment of essential tremor (primidone) and headache (i.e., in

TABLE 23.1. Classification of Common Barbiturates.

Class	Barbiturate	Trade Name	Chemical Name	CAS Number
Ultrashort	Thiopental	Pentothal	5-ethyl-5-(1-methylbutyl)-thiobarbituric acid	76-75-5
Short	Pentobarbital	Nembutal	5-ethyl-5-(1-methylbutyl)-barbituric acid	76-74-4
	Secobarbital	Seconal	5-allyl-5-(1-methylbutyl)-barbituric acid	76-73-3
Intermediate	Amobarbital	Amytal	5-ethyl-5-isopentylbarbituric acid	57-43-2
	Butalbital	*	5-allyl-5-isobutylbarbituric acid	77-26-9
Long	Phenobarbital	Luminal	5-ethyl-5-phenylbarbituric acid	50-06-6

*Butalbital is usually marketed as a variety of proprietary preparations with several other drugs (e.g., caffeine, aspirin, acetaminophen, or codeine).

combination with other analgesics). Sodium amobarbital and sodium pentobarbital ("truth serum") were adjuncts during narcoanalysis to allow increased interaction of catatonic and schizophrenic patients with their therapists, particularly during the treatment of these patients during the 1930s and 1940s.[7] Following World War II, the use of amobarbital interviews was a popular method to express repressed feelings, particularly for aiding soldiers with posttraumatic stress from combat experiences.[8] In contrast to hypnosis, amobarbital interviews could be administered to all patients rather than only those individuals susceptible to hypnosis.

Smith, Kline, & French introduced Dexamyl® (amobarbital, dextroamphetamine) as an antidepressant in the 1930s. The abuse of this combination (street name: goofballs) became widely publicized in the 1970s and early 1980s when Dr. George C. Nichopoulos was indited (but not convicted) for prescribing this drug and other narcotics to Elvis Presley and Jerry Lee Lewis. Dexamyl® was withdrawn from the US market in 1981. Short- (pentobarbital, secobarbital) and intermediate-acting (amobarbital, butalbital) barbiturates are more frequently associated with drug abuse than the long-acting (phenobarbital) barbiturates based on admissions to drug treatment centers in the 1970s.[9] Typically, the short- and intermediate-acting barbiturates have half-lives ranging from 10–50 hours.

Peak US production of barbiturates occurred in the late 1940s and 1950s prior to the introduction of benzodiazepines. Dependence on barbiturates ("Veronal habit"). was recognized soon after the introduction of first commercial barbiturate, barbitone (Veronal). Despite the synthesis of over 2,500 derivatives of barbituric acid, no barbiturate eliminated the problems of dependence and fatalities associated with barbiturate overdose. Although barbiturates were not included in the US Dangerous Drugs Act of 1920, the Poisons Rules in 1935 required a prescription for barbiturates. Well-documented reports of barbiturate dependence did not appear until the 1950s.[10] By the 1960s, barbiturate abuse was a well-recognized problem.[10] In 1962, Marilyn Monroe died of a barbiturate overdose. In that same year, President Kennedy convened a special drug-dependence committee to investigate the extent of the barbiturate dependence, estimated at that time to involve 250,000 barbiturate addicts in the United States. The introduction of chlorpromazine in 1952 and chlordiazepoxide in 1960 led to the development of more efficacious and safer alternatives to barbiturates. Currently, barbiturates are alternatives for the treatment of epilepsy, insomnia, preoperative sedation, sedative-hypnotic withdrawal, gastrointestinal (GI) functional disorders, and migraine headaches (i.e., as combination formulations).

AMOBARBITAL

IDENTIFYING CHARACTERISTICS

In general, increased lipophilicity is associated with more rapid onset of action, shorter duration of effect, and greater hypnotic properties. Table 23.2 lists some physiochemical properties of amobarbital. Street names for amobarbital include Amys, Birds, Blues, Blue Angels, Blue Birds, Blue Bullets, Blue Clouds, Blue Devils, Blue Dolls, and Blue Heaven. Figure 23.1 displays the chemical structure of amobarbital.

EXPOSURE

Epidemiology

Epidemiologic data indicate that the prevalence of amobarbital abuse began declining in the 1960s and 1970s as benzodiazepines began replacing barbiturates as preferred sedative hypnotic drugs. The yearly average US emergency department visits for amobarbital misuse/abuse reported by DAWN (Drug Abuse Warning Network) decreased from 1,945 in the late 1970s to 439

TABLE 23.2. Some Physiochemical Properties of Amobarbital.

in the mid-1980s.[11] During these times, drug misuse/abuse related deaths reported by DAWN medical examiner facilities in the United States also decreased from 294 to 65. Both amobarbital and secobarbital were among the prescription drugs with the highest reported drug-related deaths per dispensed prescriptions during the 1970s and 1980s. Currently, the estimated emergency department visits related to barbiturate misuse/abuse are approximately 5% (i.e., about 11,000) of the emergency department visits related to benzodiazepine misuse/abuse, based on DAWN data.[12] These rates have been relatively stable over the last few years.

Sources

Tuinal® (Eli Lilly) was a commonly abused barbiturate for sedative and euphoric effects, particularly during the 1960s and 1970s. This drug combination contained equal amounts of amobarbital and secobarbital in total barbiturate doses of 50 mg, 100 mg, and 200 mg.

Methods of Abuse

Typically, amobarbital abuse results from the ingestion of excessive doses of amobarbital. Occasionally, amobarbital is injected; however, the irritancy of barbiturates frequently causes skin ulcers. Rapid acting barbiturates (amobarbital, pentobarbital, secobarbital) are more common drugs of abuse than the long-acting barbiturates (barbital, phenobarbital).

DOSE EFFECT

The adult therapeutic dose of amobarbital ranges from 50–150 mg with doses up to 500 mg for narcoanalysis and adjunctive therapy during anesthesia. Predicting toxicity based on the estimated amobarbital dose is complicated by several variables including tolerance, time of supportive care in relation to the ingestion, and concomitant administration of other CNS depressants (e.g., ethanol, sedative hypnotic drugs). The ingestion of 2–3 g amobarbital is potentially fatal in nontolerant individuals. The ingestion of 20 g amobarbital by a 52-year-old man was associated with coma, apnea, hypotension, and hypothermia.[13] He survived with intensive supportive care. Barbiturate-dependent patients usually ingest supratherapeutic doses of barbiturates, but the daily dose frequently fluctuates. Daily amobarbital doses exceeding 800 mg are associated with dependence and withdrawal upon cessation of use.[14] A 54-year-old woman gradually increased her consumption of amobarbital over 13 years with some fluctuation. At the time of her admission to a detoxification unit, her daily amobarbital consumption was 1,800 mg with reported maximum daily intake up to 3 g.[15]

TOXICOKINETICS

Kinetics

The GI absorption of amobarbital is almost complete with no significant first-pass metabolism.[16] The rate-limiting factors for amobarbital absorption are drug dissolution and dispersal. Distribution of barbiturates depends on lipid solubility, protein binding, and the extent of ionization. The average protein binding is approximately 55–60%. The liver metabolizes most of the amobarbital dose; amobarbital undergoes almost complete biotransformation to 3′-hydroxyamobarbital via *C*-hydroxylation and to *N*-hydroxyamobarbital via *N*-hydroxylation as demonstrated in Figure 23.2.[17] Oxidation of amobarbital to 3′-hydroxyamobarbital accounts for approximately one-half of the amobarbital dose. Minor urinary metabolites include *N*,*N*'-dimethylamobarbital and 5-(3′-carboxybutyl)-5-ethylbarbituric acid.[18] There is substantial interspecies variation in the metabolism of amobarbital with the virtual absence of diol metabolite in humans and the absence of amobarbital-*N*-glucoside in animals (dog, rodents, guinea pig, hamster).[19]

The average serum elimination half-life of amobarbital is approximately 24 hours with substantial interindividual variation.[20,21] In a study of 7 healthy men and 9 healthy women receiving 3.54 mg amobarbital/kg intravenously, the mean serum elimination half-life was

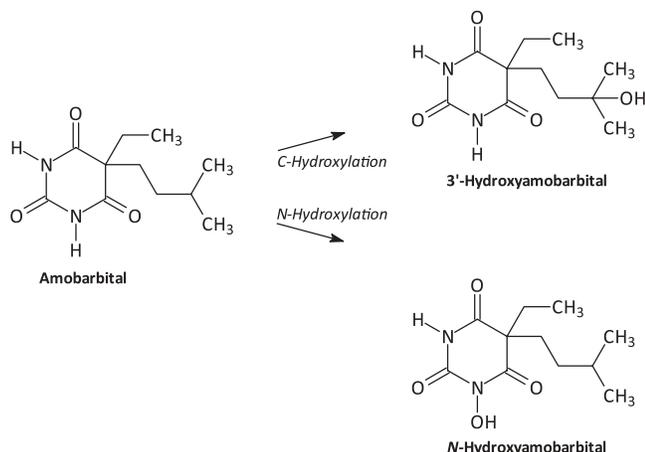
469


FIGURE 23.2. Biotransformation of amobarbital.

approximately 21 hours (mean, 22.7 ± 1.6 hours; women, 20.0 ± 1.0 hour).[22] In 4 mothers at term receiving 200 amobarbital daily during the last month of pregnancy, the plasma amobarbital elimination half-life ranged from 8.4–19.3 hours, whereas the fifth mother had a prolonged elimination half-life (70.2 hours).[23] Similar variation, but more prolonged elimination occurs in the neonates.[24] In a study of 36 healthy individuals receiving a single therapeutic dose of amobarbital, the mean clearance of amobarbital was 36.7 ± 10.0 mL/minute.[16] Over the first 48 hours, 3′-hydroxyamobarbital accounted for about 34% of the administered dose. Limited pharmacologic studies suggest that 3′-hydroxyamobarbital may exhibit some CNS activity.[25] The kidney excretes very small amounts of amobarbital in the urine unchanged, even in overdose; little amobarbital appears in the bile.[26] In a study of 5 volunteers receiving 200 mg sodium amobarbital, the percentage of the amobarbital dose excreted in the urine over 6 days ranged from about 34–49% compared with 1–3% as unchanged amobarbital measured by gas chromatography.[27] The estimated average amobarbital half-life in blood was 25 hours following nonfatal amobarbital poisoning measured by ultraviolet spectrophotometry.[28]

Maternal and Fetal Kinetics

Amobarbital crosses the placenta and the amobarbital concentration in cord and maternal serum are similar.

Tolerance

Tolerance to barbiturates results from both pharmacokinetic and pharmacodynamic effects. In both humans and animals, the chronic administration of amobarbital

and short-acting barbiturates (pentobarbital, secobarbital) induces hepatic microsomal enzymes and increases the elimination rate of barbiturates.[15,29] A pharmacokinetic study compared the dose of Tuinal® necessary to produce toxicity (drowsiness, slurred speech, ataxia, nystagmus) in 9 patients admitted to a detoxification unit for Tuinal® addiction with healthy medical students and volunteer medical staff.[30] The mean toxic dose of the Tuinal® abusers was about 58% higher than the controls. Induction of CYP450 enzymes occurs in a few days and pharmacodynamic tolerance develops over weeks to months, depending on the dose. Cross-tolerance of barbiturates with alcohol and benzodiazepines also occurs.

Drug Interactions

Similar to other barbiturates, amobarbital induces CYP450 isoenzymes. Following the daily ingestion of 200 mg amobarbital for 3 weeks, the average half-life of antipyrine decreased about 35% (CYP1A2).[31] The metabolism of antipyrine involves at least 10 cytochrome P450 isoenzymes including CYP1A2, CYP2A6, CYP3A4, CYP2B6, CYP2C8, CYP2C9, CYP2C18, CYP2C19, CYP2D6, and CYP2E1.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Barbiturates are CNS depressants that suppress neuronal excitability, impulse conduction, and the release of neurotransmitters. These compounds potentiate the inhibitory effects of γ-aminobutyric acid (GABA) in the CNS to cause cognitive and motor impairment characteristic of CNS depression. The GABA_A receptor is a pentameric transmembrane chloride ion channel that binds GABA as well as barbiturates, benzodiazepines, and ethanol. Barbiturates enhance the binding of GABA to the chloride channel receptors, and these drugs promote, rather than displace, the binding of benzodiazepines to these receptors. Only the GABA_A α- and β-subunits rather than the γ-subunit are necessary for the clinical effects of barbiturates.[32] Short- and intermediate-acting barbiturates have similar mechanisms of action, binding to the picrotoxin allosteric site on the GABA receptor-ionophore complex and directly activating the GABA-related chloride channels to enhance presynaptic chloride conductance. These drugs prolong the opening of the chloride channels, whereas benzodiazepines increase the frequency rather than the duration of chloride channel opening. Barbiturates also depress voltage-activated calcium currents and reduce glutamate-induced polarization mediated by the α-amino-3-hydroxy-5-methylisoxazole-4-propionic   acid

(AMPA) receptors.[33] Barbiturates are cardiorespiratory depressants that cause apnea by decreasing the respiratory drive and diaphragmatic movements. Autopsy findings of individuals dying from amobarbital intoxication are nonspecific with features primarily of asphyxia.

CLINICAL RESPONSE

Illicit Use

In general, barbiturates produce clinic effects similar to ethanol intoxication, manifest by dysarthria, ataxia, nystagmus, lightheadedness, impaired cognition, poor judgment, loss of inhibitions, and confusion. Similar to short-acting and other intermediate-acting barbiturates, amobarbital produces CNS and cardiorespiratory depression. Apnea occurs early in the course of severe amobarbital intoxication.

Overdose

Hypotension and hypothermia may complicate large overdoses of amobarbital. Alteration of consciousness ranges from drowsiness to coma with unstable vital signs. Reed et al [34] classified barbiturate coma into 5 stages as defined in Table 23.3. Pupils typically are constricted early in the course of coma; in the later stages of coma, pupil dilate. The clinical features of stage 4 barbiturate coma include nonreactive pupils, loss of brainstem reflexes (corneal, oculovestibular), absent deep tendon reflexes, and evidence of pathologic reflexes (e.g., Babinski sign). This clinical pattern is nonspecific; severe intoxications with other sedative hypnotics (meprobamate, glutethimide, ethchlorvynol, methaqualone) and hypoxic encephalopathy produce similar findings including benzodiazepines. Skin bullae are another nonspecific finding in barbiturate coma. Blanching, erythematous lesion are intra- or subepidermal lesions that appear on pressure points within the first 24 hours of coma and progress to bullae within 2–3 days. Resolution occurs spontaneously in 1–2 weeks in the absence of local complications.

Abstinence Syndrome

Considerable interindividual variation occurs in the clinical features of barbiturate withdrawal including the abstinence syndrome associated with amobarbital. The severity of the withdrawal reaction following cessation of chronic barbiturate use relates directly to the duration and intensity of barbiturate use. Some patients develop only weakness and anxiety, whereas other patients progress to delirium, multiple seizures, hyperthermia, and acute psychosis. Minor symptoms following discontinuation of amobarbital, short-acting, or other intermediate-acting barbiturates begin 8–36 hours after the last dose including anxiety, lightheadedness, tachycardia, diaphoresis, coarse tremor, generalized weakness, insomnia, anorexia, visual hallucinations, and nightmares. Other effects include hyperreflexia, postural hypotension, vomiting, and autonomic hyperactivity. Maximum effects occur within 24–48 hours after the last dose. Serious effects following the abrupt cessation of barbiturate use include hyperpyrexia, delirium, florid hallucinations, and seizures. Convulsions may occur 1–5 days after the last dose; in contrast to withdrawal from ethanol, seizures during barbiturate withdrawal frequently are multiple. Psychosis with visual hallucinations may develop following these seizures, manifest by agitation, insomnia, tremors, confusion, delusions, disorientation, and hallucinations. The delirium typically lasts <5 days and a period of prolonged sleep ensues.[14] Withdrawal symptoms resolve over 2–15 days, depending on the severity of the withdrawal reaction.

Reproductive Abnormalities

There are limited human data on the teratogenicity and fetotoxicity of amobarbital; previous studies on amobarbital and congenital abnormalities are inconsistent. The US Food and Drug Administration (FDA) lists amobarbital in category D (positive evidence of human fetal risk). In a convenience sample of 9 children born to mothers attempting suicide with amobarbital during the first trimester, there were no congenital abnormalities or evidence of fetal growth retardation.[36] A retrospective study of prescription drug use during pregnancy and congenital abnormalities detected a statistically significant increase in major malformation (6.9%) in neonates born to mothers ingesting amobarbital during the first trimester, when compared with controls.[37]

TABLE 23.3. Reed Classification of Barbiturate Coma.[34]

Stage*	Clinical Features
0	Stuporous, responsive to verbal command
1	Responsive to painful stimuli, unresponsive to verbal stimuli
2	Unresponsive to verbal and painful stimuli, reflects intact, vital signs stable
3	Unresponsive, areflexic, stable vital signs
4	Unresponsive, areflexic, unstable vital signs

*Patients in stage 4 coma are not always areflexic and patients in stage 3 coma may be areflexic without changes in the vital signs.[35]

DIAGNOSTIC TESTING

Analytic Methods

Screening for barbiturates in blood involves enzyme-multiplied immunoassay technique (EMIT® tox Serum Barbiturates, Siemens Healthcare Diagnostics, Deerfield, IL) and fluorescence polarization immunoassays (FPIA) including ADx serum barbiturates (Abbott Diagnostics, Abbott Park, IL) and COBAS INTEGRA 700 Barbiturates (Roche Diagnostic Systems, Somerville, NJ). Positive cutoffs for these methods are 3 mg/L, 2 mg/L, and 0.2 mg/L, respectively. The cross-reactivity of these assays vary with the type of barbiturate because the antibodies are raised against secobarbital.[38] Consequently, this assay is highly sensitive to secobarbital, but the cross-reactivity to amobarbital is about 18%.[39] Methods for the quantitation of amobarbital in biologic samples include ultraviolet (UV) spectrophotometry, thin layer chromatography, gas chromatography, high performance liquid chromatography, gas chromatography/mass spectrometry (GC/MS), and liquid chromatography/electrospray/mass spectrometry.[40] The lower limit of quantitation (LLOQ) of amobarbital in serum using the latter method is 0.5 mg/L with an interday coefficient of variation of <7%. The LLOQ for GC/MS with addition of formic acid to the carrier gas is 0.1 mg/L,[41] whereas the use of liquid extraction with methyl-*tert*-butyl ether/chloroform and alkylation to the *N*-ethyl derivative results in a LLOQ near 0.05 mg/L (coefficient of variance, ~5–6%).[42] Both *N*-hydroxyamobarbital and 3′-hydroxyamobarbital are detectable in urine with GC/MS combined with on-column methylation and pyrolysis.[43] Micellar liquid chromatography with UV detection allows the direct inject of plasma samples without preanalytic derivatization.[44] The limit of detection (LOD) for amobarbital in biologic samples ranges from 0.2–0.4 mg/L. Thermal instability of *N*-hydroxyamobarbital limits the detection of this metabolite by gas chromatography. In urine samples, GC/MS allows the detection of amobarbital in the presence of other barbiturates (butalbital, pentobarbital, secobarbital) with limits of detection in the range of 0.01–0.02 mg/L.[45] Micellar liquid chromatography allows the analysis of complex matrices without extraction. Limits of detection for amobarbital using this method with UV detection is approximately 0.07 mg/L.[46] Barbiturates including amobarbital are relatively stable in pH-neutral biologic specimens, even after chemical fixation with formalin. Substantial amounts of amobarbital are detectable in liver tissue and in formalin at least 20 months after death.[47] The postmortem stability of barbiturates in blood and tissues depends on pH with amobarbital being relatively stable in the mildly acidic conditions present in most postmortem blood samples. Amobarbital is relatively stable in unpreserved blood and liver tissue at 4°C (39.2°F) and 25°C (77°F) for 2–3 months at pH 6.4–7.0. Under these storage conditions, amobarbital decreased to 76 ± 5% and 77 ± 9%, respectively, over 2 months of storage.[48]

Biomarkers

After barbiturate poisoning, the liver typically contains the highest barbiturate concentration followed by kidney, spleen, and brain.[47]

Blood

Therapeutic/Recreational Doses.   Twelve hours after the IV administration of 250 mg amobarbital/70 kg to 6 healthy volunteers, the mean amobarbital concentration was 2.49 ± 0.24 mg/L as measured by gas chromatography/flame ionization detection.[25] The mean serum amobarbital concentration 30 minutes after the injection of 3.54 mg amobarbital/kg to 6 healthy volunteers was 5.14 ± 0.11 mg/L.[22] The mean plasma amobarbital concentration in 5 patients a half-hour after receiving 600 mg amobarbital over the preceding 3 hours was 8.7 mg/L, declining to 6.6 mg/L 4 hours later.[49] All of these patients demonstrated signs of drug effect (sedation, unsteady gait, poor balance, and coordination) at the time of initial testing. In a study of newly admitted patients to a psychiatric ward with anxiety, the mean dose of sodium amobarbital administered to 23 patients was 463 mg (range, 286–657 mg). After 7 days of treatment, the mean plasma amobarbital concentration was 4.11 ± 0.30 mg/L (range, 1.68–7.06 mg/L). There was no accumulation of amobarbital over the 7-day study; the response to treatment did not correlate with plasma amobarbital concentrations.

Overdose.   In a case series of 3 amobarbital overdoses requiring intubation and ventilatory support, the maximum serum amobarbital concentrations ranged from 40–67 mg/L as measured by gas chromatography.[50] The duration of coma ranged from 44–59 hours. As measured by UV spectrophotometry, blood amobarbital concentrations of 20–25 mg/L are associated with light coma (reflexes present) and 55–60 mg/L with severe intoxication (comatose with unstable vital signs).[28] A 23-year-old woman presented with coma, absent corneal and gag reflexes, mild hypothermia, and dilated right pupil with increased tone in her left arm.[51] There were no imaging studies reported, and she recovered after 40 hours of coma. The admission blood amobarbital concentration was 63 mg/L (method not reported).

POSTMORTEM   In a series of 55 cases involving amobarbital as the cause of death, the postmortem blood concentrations (site and analytic method not specified [NOS]) ranged from 13–96 mg/L.[52] The report did not include the presence or absence of other drugs other than a comment that amobarbital poisoning was the cause of death. In a convenience series of 17 fatalities, the lowest amobarbital concentration in postmortem blood attributed to the cause of death was 27 mg/L by UV spectrophotometry.[53] The report did not include sample site, clinical details, or the presence of other drugs in postmortem specimens. The mean postmortem amobarbital concentration in blood samples (site NOS) from 6 deaths attributed to amobarbital intoxication was 47 mg/L (range, 29–68 mg/L).[54] In this case series, the mean postmortem liver concentration of amobarbital was 219 mg/kg (range, 106–580 mg/kg). In postmortem blood (site NOS) from 4 amobarbital-related fatalities, the mean amobarbital concentration was 41 mg/L (range, 25.5–78.5 mg/L) compared with a mean of 4.2 mg/L (range, 1.1–8.4 mg/L) for amobarbital concentrations in 11 non-drug related fatalities.[55] The amobarbital-related fatalities were single-drug fatalities with the exception of ethanol, nicotine, and caffeine. The distribution of amobarbital to bone is relatively small compared with blood, liver, and kidney; however, amobarbital does persist in bone for prolonged periods. Remnants of the skeleton from a 33-year-old psychiatric patient were found 1½ years after her disappearance.[56] The concentrations of amobarbital in the skeletal remnants were as follows: rib 9.3 mg/kg; sternum, 25.6 mg/kg; and vertebra, 9.2 mg/kg.

Abnormalities

Rhabdomyolysis with subsequent acute renal dysfunction may complicate prolonged barbiturate-induced coma, manifest by elevated serum creatine kinase, urinary myoglobin, and increasing serum creatinine. Additionally, hypoglycemia may occur during amobarbital intoxication.

TREATMENT

Stabilization

Amobarbital is a CNS depressant that may cause respiratory and cardiovascular depression during severe intoxications. Patients should be evaluated for the presence of hypoxia and respiratory insufficiency; intubation and ventilatory support may be necessary in severe cases. Hypotension initially is treated with IV fluids, but vasopressors (dopamine, norepinephrine) may be necessary in patients unresponsive to saline infusion.

Hemodynamic monitoring (echocardiography, Swan-Ganz catheter) may be necessary in patients with stage 4 coma and hemodynamic instability. Hypoglycemia occurs in a substantial portion of comatose patients with barbiturate intoxication; all patients should be evaluated with point of care testing and glucose and thiamine administered as indicated. Severe hypothermia may occur in deeply comatose patients during severe amobarbital intoxication; these patients may require prolonged cardiopulmonary resuscitation as a result of persistent ventricular fibrillation unresponsive to defibrillation. In rare cases, thoracotomy, internal cardiac massage, and direct rewarming of the mediastinum is necessary to increase the body temperature sufficiently to allow successful defibrillation.[57] Other than hypothermia-associated dysrhythmias, barbiturate poisoning is usually not complicated by rhythm disorders.

Gut Decontamination

In general, if the patient presents within 1–2 hours of ingestion, the administration of a single dose of activated charcoal (1 g/kg body weight) is a therapeutic option; however, there are inadequate data on the clinical outcome of this intervention. *In vitro* studies suggest that the adsorption of amobarbital to activated charcoal is limited (<51 mg/g activated charcoal at pH 1.3 and 37°C) and lower than other barbiturates (secobarbital, 124 mg/g; pentobarbital, 103 mg/g).[58] The actual adsorption of amobarbital during overdose is probably lower as a result of the presence of mucous, bile acids, food, and altered GI motility.

Elimination Enhancement

There are limited data on the use of artificial means to enhance the elimination of amobarbital; however, existing data suggest that the elimination of amobarbital with these methods is very limited. Charcoal hemoperfusion for 3.5 hours at 200 mL/minute removed 4% of the estimated dose of amobarbital from the blood of a comatose, hypotensive 54-year-old man with amobarbital intoxication.[59] Dialysis for 31.5 hours in a 52-year-old man with severe amobarbital intoxication removed only about 3% of the estimated amobarbital dose; he remained intubated for 24 hours after hemodialysis ended.[13] Forced diuresis is contraindicated in barbiturate overdose because of the lack of efficacy and the potential for fluid overload and pulmonary edema. Multiple-dose activated charcoal (MDAC) enhances the elimination of phenobarbital, but there are inadequate data on the efficacy of MDAC for the treatment of life-threatening amobarbital poisoning.[60]

Antidotes

There are no antidotes for barbiturate intoxication.

Supplemental Care

Barbiturate withdrawal requires pharmacotherapy and hospital admission. Oral loading with phenobarbital is a technique developed in the 1970s for the treatment of barbiturate withdrawal. The dose is 120 mg phenobarbital/hour until at least 3 of the following effects occur: nystagmus, dysarthria, ataxia, drowsiness, or emotional lability. Table 23.4 provides a rating scale for the evaluation of these 5 signs. Hourly phenobarbital loading terminates when the score is ≥8. These signs are evaluated each time before the next loading dose along with frequent vital signs and level of consciousness. In a study of 21 barbiturate addicts (daily consumption, 0.5–4 g), the mean phenobarbital loading dose was 23.4 ±7.1 mg/kg with a median postloading phenobarbital concentration of 35.9 mg/L (range, 13.2–71.6 mg/L).[61] Most of these patients were polydrug users (e.g., alcohol, diazepam, methaqualone, amphetamines). Discharge or rehabilitation usually can occur 48 hours after phenobarbital loading begins. Patients becoming intoxicated at ≤7 mg/kg (i.e., about 500 mg) phenobarbital are prob-ably not physically dependent and do not require full phenobarbital loading.[62] High-dose oral diazepam (10–20 mg/h until reduction in withdrawal symptoms or appearance of toxic effects) is an alternative to oral phenobarbital loading, similar to the treatment of ethanol withdrawal; however, there are inadequate clinical data to compare the efficacy of phenobarbital loading and benzodiazepine use in barbiturate withdrawal.

BUTALBITAL

IDENTIFYING CHARACTERISTICS

Butalbital (5-allyl-5-isobutylbarbituric acid, CAS RN: 77-26-9) is a white odorless powder that is slightly soluble in cold water and soluble in boiling water. This compound is also soluble in alcohol and alkaline solutions of hydroxides and carbonates. Figure 23.3 displays the chemical structure of butalbital. Table 23.5 lists some physiochemical properties of butalbital.

TABLE 23.4. Rating Scale for Oral Phenobarbital Loading.[69]

Category	Sign	Score
Nystagmus	Absent	0
	Present on lateral gaze only	1
	Easily elicited and sustained	2
	Coarse, sustained	3
Dysarthria	Absent	0
	Minor slurring over some words	1
	Moderate slurring	2
	Severe slurring, unintelligible	3
Ataxia	Absent	0
	Mildly unsteady on tandem gait	1
	Moderately unsteady on regular gait	2
	Needs support on regular gait	3
Drowsiness	Alert	0
	Awake but drowsy	1
	Asleep but roused easily	2
	Asleep and difficult to arose	3
Emotional lability	Normal, same as before loading	0
	Some mood change	1
	Obvious mood change	2
	Uninhibited, mood swings	3

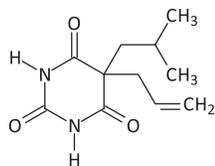
Note. Score each of the 5 categories before loading and before each hourly dose. Discontinue phenobarbital loading when the score is ≥8. Vital signs are repeated frequently until the patient is alert.


FIGURE 23.3. Chemical structure of butalbital.

TABLE 23.5. Some Physiochemical Properties of Butalbital.

Physical Property	Value
Molecular Weight	224.3 g/mol

Water Solubility	1700 mg/L (25°C/77°F)

EXPOSURE

Fiorinal® (Novartis, Basel, Switzerland) is a capsule containing 330 mg acetylsalicylic acid (ASA), 40 mg caffeine, and 50 mg butalbital. Other Fiorinal® preparations may substitute acetaminophen for ASA or may add codeine. Many Fiorinal® abusers use the preparation containing codeine and also abuse other drugs (benzodiazepines, opioids, sedative hypnotics). The FDA approved butalbital-containing medications for the treatment of tension headache, but not for migraine headaches; however, patients with migraine headaches frequently receive prescriptions for these medications.[63] A meta-analysis of placebo-controlled trials of patients with episodic tension-type headaches indicated that butalbital compounded with aspirin, acetaminophen, and/or caffeine is efficacious;[64] however, there are inadequate data to determine the effectiveness of this combination for migraine headache.[65] Abuse of butalbital typically involves the chronic ingestion of butalbital-containing medication; however, abuse of suppositories occurs as a result of the rapid absorption of these preparations and the higher concentrations of butalbital (150 mg vs. 50 mg) in suppositories.[66]

DOSE EFFECT

In a case series of 29 Fiorinal® abusers admitted to a detoxification unit, the mean daily intake of butalbital was 700 mg (i.e., 14 capsules) with a range of 300–1,500 mg.[67] The mean loading phenobarbital dose for this cohort was 1,120 mg, which indicated moderate dependence. Disorientation, agitation, insomnia, tremu-

lousness, and auditory hallucinations occurred in a 59-year-old man after cessation of butalbital use.[68] He had ingested up to 1,500 mg butalbital daily in the preceding 2 years. In another series of 18 butalbital abusers admitted to a detoxification unit, the mean daily consumption of butalbital tablets was 13.4 (range, 8–20).[69] The sedative dose of butalbital in nontolerant individuals is 50–100 mg; the hypnotic dose is 100–200 mg. Predicting toxicity based on the estimated butabarbital dose is complicated by several variables including tolerance, time of supportive care in relation to the ingestion, and concomitant administration of other CNS depressants (e.g., ethanol, sedative hypnotic drugs).

TOXICOKINETICS

Absorption of butalbital is rapid with peak butalbital concentrations in the blood occurring within 1 hour of ingestion. The volume of distribution is approximately 0.8 L/kg; protein binding of butalbital in the blood is relatively small (i.e., 26%). Butalbital undergoes almost complete metabolism by the liver, primarily by C5 oxidation. The major metabolites are 5-isobutyl-5-(2,3-dihydroxypropyl)barbituric acid and 5-allyl-5-(3-hydroxy-2-methyl-1-propyl)barbituric acid. There are limited and somewhat inconsistent pharmacokinetic data on the serum elimination half-life of butalbital. This drug is an intermediate-acting barbiturate with a biologic half-life in the range 30–40 hours based on renal excretion, similar to pentobarbital and secobarbital. In a study of 5 healthy volunteers receiving 100 mg butalbital in combination with aspirin and caffeine, the mean plasma elimination half-life of butalbital was 61 hours (range, 35–87.5 hours).[70]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Butalbital is a CNS depressant that suppresses neuronal excitability, impulse conduction, and the release of neurotransmitters, similar to other barbiturates including amobarbital. The mechanism of action and toxicity is similar to amobarbital (see Amobarbital Histopathology and Pathophysiology).

CLINICAL RESPONSE

As with other barbiturates, the clinical features of butalbital are similar to ethanol intoxication and include cognitive impairment, dysarthria, ataxia, unsteady gait, slurred speech, sedation, poor attention, emotional lability, and inappropriate judgment. Clinical effects associated with chronic butalbital abuse include nausea, restlessness, irritability, asthenia, impaired memory

and concentration, depression, and neurotic behavior. Chronic daily headaches (i.e., rebound headaches) are a complication of the misuse of butalbital-containing analgesics. The clinical features of withdrawal from chronic butalbital abuse is similar to other barbiturate abstinence syndromes with agitation, tachycardia, and diaphoresis within ~48 hours after the last dose.[71] Other clinical effects include insomnia, anorexia, hyper-reflexia, tremor, hypertension, and seizures. In contrast to ethanol withdrawal, seizures often are multiple and occur later (i.e., >48 hours) during the abstinence syndrome. Depending on the duration and magnitude of butalbital use, the clinical course may progress to visual hallucinations, delirium, and acute psychosis. Neonatal abstinence syndrome may occur in children born to mothers abusing butalbital.[72] Clinical features of this syndrome include jitteriness, irritability, rhinitis, muscle jerks, nystagmus, dysconjugate gaze, and poor feeding.

DIAGNOSTIC TESTING

Analytic Methods

Methods for quantitation of butalbital in biologic fluids include UV spectrophotometry, gas chromatography with flame ionization or electron capture detection, micellar electrokinetic capillary chromatography,[73] solid phase extraction with high performance liquid chromatography and UV detection at 220 nm,[74] and gas chromatography/mass spectrometry (GC/MS). The limits of quantitation for butalbital in blood and urine using GC/MS are similar to amobarbital (0.050 mg/L and 0.020 mg/L, respectively) with a coefficient of variance near 8–9%,[42] whereas the LLOQ for high performance liquid chromatography and UV detection is 3.75 mg/L.[74]

Barbiturates including butalbital are relatively stable in pH-neutral biologic specimens, even after chemical fixation with formalin; however, barbiturates diffuse out of tissue into surrounding formalin solutions during storage. The recovery rate of butalbital from liver tissue fixed in formalin and stored for 6 months was about 22% of the initial value at autopsy.[75] Substantial amounts of butalbital diffused from the tissue to the formalin during storage. The surrounding formalin contained approximately 66% of the original butalbital concentration in the liver at autopsy for a total recovery of about 88%. The postmortem stability of barbiturates in blood and tissues depends on pH with butalbital being relatively stable in the weakly acidic conditions usually present in postmortem blood samples.

Biomarkers

The whole blood/plasma ratio of butalbital is near unity. In a study of 5 healthy volunteers receiving 100 mg butalbital in combination with 80 mg caffeine and 660 mg ASA, the mean whole blood/plasma ratio was 0.987 (range, 0.763–1.148).[70] The mean peak butalbital concentration of 2.14 mg/L occurred at 2 hours with the butalbital concentration declining to 1.39 mg/L at 30 hours after ingestion. In postmortem blood (site NOS) from 3 butalbital-related fatalities, the mean butalbital concentration was 13.8 mg/L (range, 1.9–31 mg/L) compared with a mean of 7.1 mg/L (range, 1.6–22 mg/L) for butalbital concentrations in 8 nondrug-related fatalities.[55] The butalbital-related fatalities were single-drug fatalities with the exception of ethanol, nicotine, and caffeine.

Large doses of butalbital may cross react with some urine immunoassays reportedly specific for phenobarbital (e.g., EMIT® 2000 Phenobarbital Assay, Syva Co., San Jose, CA).[76]

TREATMENT

The treatment of butalbital is supportive. This drug is a CNS depressant that may cause respiratory and cardiovascular depression during severe intoxication. The treatment of acute butalbital intoxication is similar to other barbiturates (See Amobarbital Treatment). Common clinical practice of patients chronically using butalbital containing analgesics is to taper the dose by 1 tablet every 2–3 days, when daily use is <10 tablets daily. Supervised withdrawal is usually necessary when the daily consumption exceeds 10 tablets or outpatient withdrawal is unsuccessful as a result of medical or psychiatric conditions. For the use of phenobarbital loading for prevention of barbiturate withdrawal, the conversion ratio of 30 mg phenobarbital to 100 mg butalbital converts to 300 mg phenobarbital for patients ingesting 20 50-mg butalbital tablets daily.

PENTOBARBITAL

IDENTIFYING CHARACTERISTICS

Pentobarbital [5-ethyl-5-(1-methylbutyl)-barbituric acid, CAS RN: 76-74-4] is a racemate; the stereocenter is in the 2-position. Table 23.6 lists some physiochemical properties for pentobarbital. Figure 23.4 displays the chemical structure of pentobarbital. Street names for

TABLE 23.6. Some Physiochemical Properties of Pentobarbital.

pentobarbital include Nebbie, Nembie, Yellow Bullet, Yellow Doll, Yellow Football, and Yellow Jacket. Propylene glycol is a constituent of IV preparations of both pentobarbital and phenobarbital.

EXPOSURE

Epidemiology

Similar to amobarbital and secobarbital, epidemiologic data indicate that the prevalence of pentobarbital abuse began declining in the 1960s and 1970s as benzodiazepines began replacing barbiturates as preferred sedative hypnotic drugs. The yearly average US emergency department visits for pentobarbital misuse/abuse reported by the DAWN network decreased from 678 in the late 1970s to 195 in the mid-1980s.[11] During these times, drug misuse/abuse related deaths reported by DAWN medical examiner facilities in the United States also decreased from 214 to 52.

Sources

Pentobarbital (Nembutal) is available as an injectable solution of 50 mg/mL for sedation and the induction of barbiturate coma. This preparation contains 40% propylene glycol and the pH is adjusted to 9.5. This drug is also available as a veterinary drug for euthanasia; additionally, pentobarbital is a drug of choice for assisted suicide.

Methods of Abuse

The abuse liability of pentobarbital is greater than most other prescription hypnotic drugs based on reinforcement, actual abuse, memory impairment, toxicity, and animal studies.[77] Heroin addicts use IV barbiturates as a substitute for heroin when heroin is unavailable; occasionally, both drugs are abused together.[78]

DOSE EFFECT

The adult IV hypnotic dose of pentobarbital is initially 100 mg, followed by repeat doses up to 200–500 mg total dose with close observation and monitoring of vital signs. The IV dose in children is 1–3 mg/kg to a maximum of 100 mg until asleep. The loading dose for barbiturate coma is 5–10 mg/kg given slowly over 1–2 hours with close monitoring of blood pressure and oxygen saturation. The initial maintenance infusion is 1 mg/kg/hour with an increase to 2–3 mg/kg/hour as required for the desired clinical endpoint. The pentobarbital dose that produces intoxication depends on tolerance. Ingestion of 400 mg pentobarbital daily may cause inebriation initially, but signs of intoxication disappear with daily dosing over 2–3 weeks based on studies of healthy volunteers with histories of narcotic violations.[79] In these studies, cessation of 400 mg pentobarbital daily for 90–360 days is not usually associated with abstinence symptoms, whereas all 18 men in a study at an addiction center ingesting 900–2,200 mg pentobarbital daily for over 30 days developed symptoms of withdrawal. Delirium developed in 12 of these men; 14 men had withdrawal seizures. Thirty milligrams of phenobarbital is equivalent to 100 mg pentobarbital.

Predicting toxicity based on the estimated pentobarbital dose is complicated by several variables including tolerance, time of supportive care in relation to the ingestion, and concomitant administration of other CNS depressants (e.g., ethanol, sedative hypnotic drugs). The ingestion of 2–3 g pentobarbital is potentially fatal. A 24-year-old woman was unresponsive to verbal or physical stimulation with stable vital signs (stage 3 coma) after the ingestion of an estimated dose of 3,500 mg pentobarbital, whereas a 20-year-old woman was apneic after an estimated ingestion of 5,000 mg pentobarbital.[80] Both women survived with supportive care. Their medication history was not reported, but no other drugs were detected in their blood.

TOXICOKINETICS

The GI absorption of pentobarbital is relatively rapid, similar to secobarbital. The volume of distribution (V_d)

of pentobarbital is relatively small (0.8–1 L/kg) with protein binding of approximately 65%. Pharmacokinetic studies indicate that protein binding varies between the two enantiomers. In a study of 7 healthy volunteers receiving 100 mg racemic pentobarbital, the mean protein binding of the *R*- and *S*-enantiomers were 63.4% and 73.5%, respectively.[81] The V_d of the *R*-enantiomer was approximately 13% larger than the *S*-enantiomer with a mean volume of distribution (V_d) of 1.24 ± 0.55 L/kg and 1.11 ± 0.52 L/kg, respectively. The liver metabolized almost all of the pentobarbital dose, primarily to 3′-hydroxypentobarbital and *N*-hydroxypentobarbital.

The kidney excretes very little (<1%) of the pentobarbital dose as parent drug.[82] The terminal plasma half-life of pentobarbital following therapeutic doses is about 20–30 hours.[83] The estimated average pentobarbital half-life in blood was 20 hours following nonfatal pentobarbital poisoning, as measured by UV spectrophotometry.[28] Some differences exist in the clearance of enantiomers of pentobarbital. In a study of 7 volunteers receiving 100 mg racemic pentobarbital, the median clearance of the (*R*)-enantiomer was about 25% higher than the (*S*)-enantiomer (43 mL/min and 33 mL/min, respectively).[81]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Pentobarbital interacts with the GABA receptor-ionophore complex, binding the γ-aminobutyric acid type A (GABA$_A$) receptor. Electrophysiologic studies suggest that pentobarbital and other barbiturates exert at least some of their CNS effects by increasing the mean channel open time of the chloride ion channel in the GABA receptor-ionophore complex.[84,85] Aliphatic-substituted barbiturates (e.g., pentobarbital, secobarbital) significantly enhance GABA receptor-coupled responses in comparison to the lack of responses with phenyl-substituted barbiturates (e.g., phenobarbital).[86] At low micromolar concentrations, pentobarbital potentiates GABA$_A$-evoked responses, whereas high micromolar concentrations open the GABA$_A$ receptor downstream of the middle of the M2 domain.[87] At millimolar concentrations, pentobarbital reduces the response of the GABA$_A$ receptor. Pentobarbital is a CNS and cardiovascular depressant similar to other short-acting and intermediate-acting barbiturates.

CLINICAL RESPONSE

Similar to other short-acting and intermediate-acting barbiturates, pentobarbital produces coma, apnea, and hypotension following the ingestion of high doses. During the 1960s and 1970s, pentobarbital and secobarbital accounted for a large percentage of serious drug intoxications.[88] Clinically significant hypothermia may complicate severe pentobarbital intoxication, particularly following prolonged exposure during pentobarbital-induced coma. These patients may survive without clinically significant sequelae despite prolonged ventricular fibrillation and cardiopulmonary resuscitation during the period of severe hypothermia.[89] Prolonged use of pentobarbital and phenobarbital infusions for barbiturate coma may cause propylene glycol toxicity, manifest by lactic acidosis, refractory hypotension, hyperosmolality, hemolysis, and renal failure.[90] The abstinence syndrome associated with pentobarbital is similar to other short-acting (i.e., secobarbital) and intermediate-acting (e.g., amobarbital, butalbital) barbiturates.

DIAGNOSTIC TESTING

Analytic Methods

Methods for the quantitation of pentobarbital in biologic samples include gas chromatography with flame ionization detection,[91] liquid chromatography/electrospray/mass spectrometry,[40] and GC/MS.[45,92] The LOD for pentobarbital in serum using the latter 2 methods is 0.50 mg/L. The LLOQ for pentobarbital in blood and urine using GC/MS is similar to amobarbital (0.050 mg/L and 0.020 mg/L, respectively) with a coefficient of variance near 7–9%.[42] Pentobarbital is detectable in hair following solid phase microextraction and gas chromatography/chemical ionization/tandem mass spectrometry; LOD and LLOQ with this method are 0.07 ng/mg and 0.1 ng/mg, respectively.[93] Pentobarbital is relatively stable in unpreserved blood and liver tissue at 4°C (39.2°F) and 25°C (77°F) for 2–3 months at pH 6.4–7.0. Under these storage conditions, pentobarbital did not deteriorate over 2 months of storage.[48] Increasing degradation of proteins to amines results in a more alkaline environment in the decaying body compared with the first 24 hours after death. *In vitro* studies indicate that pentobarbital is relatively stable in formaldehyde solutions (37%) present in embalming preparations. Over 1 month, degradation of pentobarbital in 37% formaldehyde solution at pH 7 and 9.5 was <13% and 30%, respectively. Substantial amounts of pentobarbital are detectable in liver tissue and in formalin at least 20 months after death.[47] Storage of plasma containing pentobarbital at –20°C (–4°F) resulted in minimal degradation (2.5%) of the pentobarbital as measured by gas chromatography with flame ionization detection.[94]

Biomarkers

The mean plasma pentobarbital concentration in 5 patients a half-hour after receiving 600 mg pentobarbital over the preceding 3 hours was 3.0 mg/L, declining to 2.0 mg/L approximately 8 hours later.[49] All of these patients demonstrated signs of intoxication (sedation, unsteady gait, poor balance, and coordination) during the study. McCarron et al. evaluated 1,140 cases of short-acting barbiturate intoxication and correlated an intoxication score with serum barbiturate concentrations as measured by UV spectrophotometry.[95] Ultraviolet spectrophotometry does not distinguish between the parent barbiturate and metabolites; therefore, this method is not as specific as GC/MS. Table 23.7 outlines the results of their work. This table provides a broad guideline for the interpretation of serum pentobarbital and secobarbital concentrations, depending on tolerance and the concomitant ingestion of other CNS depressants. A 24-year-old woman was comatose with stable vital signs (Reed State 3 coma) after ingesting pentobarbital.[80] Her serum pentobarbital concentration was 13.6 mg/L 4 hours after ingestion with no other drugs detected as measured by high performance liquid chromatography and GC/MS. In the same series, a mildly hypotensive, comatose 31-year-old woman had a serum pentobarbital concentration of 29.82 mg/L 12 hours after pentobarbital ingestion. She also had no other drugs detected in her serum. In 2 comatose patients with pentobarbital intoxication, the maximum serum pentobarbital concentrations were 26 mg/L and 27 mg/L as measured by gas chromatography.[50] The duration of coma was 43 hours and 27 hours, respectively; neither patient required intubation and ventilatory support. As measured by UV spectrophotometry, blood pentobarbital concentrations of 15–25 mg/L are associated with light coma (reflexes present) and >35 mg/L with severe intoxication (comatose with unstable vital signs).[28]

In a convenience series of 15 cases of death associated with pentobarbital intoxication, the lowest pentobarbital concentration in postmortem blood was 12 mg/L by UV spectrophotometry.[53] The report did not include sample site, clinical details, or the presence of other drugs in postmortem specimens. In a series of 43 cases involving pentobarbital as the cause of death, the postmortem blood (site, analytic method NOS) ranged from 12–88 mg/L.[52] The peripheral postmortem pentobarbital concentrations in 2 men found dead after deliberately ingesting veterinary pentobarbital sodium were 8.6 mg/L and 27 mg/L.[96] Stomach samples from these two cases contained high concentrations of pentobarbital (4.3 g and 1.27 g, respectively). The report did not include the presence or absence of drugs other than pentobarbital. Propylene glycol is a diluent for iv pentobarbital preparations that is usually present in postmortem blood of individuals dying of pentobarbital intoxication from IV preparations.[97]

TREATMENT

The treatment of pentobarbital intoxication is supportive, similar to the treatment of amobarbital poisoning. The main life-threatening complication are CNS and cardiopulmonary depression. Dysrhythmias are uncommon during pentobarbital intoxication, and the presence of QTc prolongation suggests the presence of other drugs (e.g., tricyclic antidepressants).[80] In general,

TABLE 23.7. Correlation of Serum Pentobarbital and Secobarbital Concentrations with Clinical Effects in Nonbarbiturate Dependent Individuals.[95]

Clinical Stage	Clinical Features	Serum Concentration (mg/L)*
Alert	No signs of CNS depression	<6
Drowsy	CNS depression between alert and stuporous	8 ± 2
Stuporous	Markedly sedated, responsive to verbal or tactile stimuli	14 ± 3
Coma 1	Responsive to painful stimuli, unresponsive to verbal or tactile stimuli, stable vital signs	18 ± 2
Coma 2	Unresponsive to verbal or painful stimuli, stable vital signs	22 ± 2
Coma 3	Unresponsive to all stimuli or abnormal response to painful stimuli, abnormal spontaneous respirations (slow, shallow, or rapid) and/or low blood pressure with adequate perfusion	26 ± 2
Coma 4	Unresponsive to all stimuli or abnormal response to painful stimuli, apnea or inadequate respirations and/or inadequate blood pressure	34 ± 6

Abbreviation: CNS = Central nervous system.

*Tolerance reduces the response to the listed serum concentration, whereas concomitant ingestion of CNS depressants (e.g., ethanol, other sedative hypnotic drugs) increases the response at a given concentration.

the rate of removal of short- and intermediate-acting barbiturates is slow and the total recovery of pentobarbital in the dialysate is small compared with the absorbed dose. Estimated clearance of pentobarbital during hemodialysis and hemoperfusion is about 20–40 mg/min and 50–120 mL/min compared with a calculated clearance of 7.6 mL/min during 48 hours of continuous venovenous hemodiafiltration for a fatal pentobarbital intoxication.[98] The removal of pentobarbital in this fatal case was about 15% of the estimated pentobarbital dose. During hemodialysis of a 21-year-old woman with severe pentobarbital and secobarbital overdose, the calculated clearance of pentobarbital and secobarbital was 26.6 mL/min with estimated removal of 1.3–3.6 mg/min.[99] She underwent prolonged dialysis (68 hours) with some deterioration in her clinical condition following the temporary cessation of dialysis. There are no antidotes for pentobarbital poisoning.

SECOBARBITAL

IDENTIFYING CHARACTERISTICS

Secobarbital (5-allyl-5-(1-methylbutyl)-barbituric acid, CAS RN: 76-73-3) is a highly lipophilic compound hypnotic drug that is marketed as seconal (secobarbital sodium, CAS RN: 309-43-3). Table 23.8 lists some physiochemical properties of secobarbital (quinalbarbitone). Street names for secobarbital include Blues & Reds, M & Ms, Pinks, Reds & Ripple (R & R), Red Birds, Red Bullets, Reds, Seccy, and Seggy. Figure 23.5 displays the chemical structure of secobarbital.

EXPOSURE

Similar to amobarbital and pentobarbital, epidemiologic data indicate that the prevalence of secobarbital abuse began declining in the 1960s and 1970s as benzodiazepines began replacing barbiturates as preferred sedative hypnotic drugs. The yearly average US emergency department visits for secobarbital misuse/abuse reported by the Drug Abuse Warning Network (DAWN) decreased from 3,626 in the late 1970s to 927 in the mid-1980s.[11] During these times, drug misuse/abuse related deaths reported by DAWN medical examiner facilities in the United States also decreased from 463 to 123. Both secobarbital and amobarbital were among the prescription drugs with the highest reported drug-related deaths per dispensed prescriptions during the 1970s and 1980s. Secobarbital is a schedule II drug in the United States, marketed as 100 mg capsules. Abuse of secobarbital usually involves the ingestion of secobarbital tablets, although occasionally secobarbital causes the death of IV drug abusers.[100]

DOSE EFFECT

In a study at an addiction research center, the daily ingestion of 400 mg secobarbital for 1 year did produce symptoms of withdrawal, whereas minor withdrawal symptoms developed after the daily ingestion of 600 mg pentobarbital for 4 weeks including weakness, tremor, nausea, vomiting, anxiety, and insomnia.[101] More serious withdrawal symptoms occurred after the daily ingestion of 800 mg secobarbital for over 1 month. Thirty milligrams of phenobarbital is equivalent to 100 mg secobarbital. Secobarbital and pentobarbital produce addiction and the abstinence syndrome at equivalent doses.[79]

Predicting toxicity based on the estimated secobarbital dose is complicated by several variables including tolerance, time of supportive care in relation to the ingestion, and concomitant administration of other CNS depressants (e.g., ethanol, sedative hypnotic drugs). The ingestion of 2–3 g secobarbital is potentially fatal in nontolerant individuals. The ingestion 1,750 mg secobarbital by a 47-year-old woman was associated with hypotension, respiratory failure, and death 3 days after ingestion.[88] The report did not include a medication history. Studies of chronically intoxicated healthy adults indicate that some individuals remain ambulatory despite daily secobarbital or pentobarbital doses of 2.2 g.

TABLE 23.8. Some Physiochemical Properties of Secobarbital.

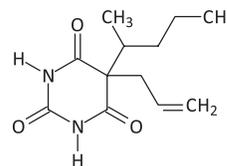

FIGURE 23.5. Chemical structure of secobarbital.

TOXICOKINETICS

Kinetics

The GI absorption of secobarbital is relatively rapid. Following ingestion of 3.3 mg secobarbital/kg by 6 healthy men, the peak whole blood secobarbital concentration occurred between 2–4 hours after ingestion; the mean whole blood secobarbital concentration at 3 hours was 2.01 mg/L.[102] The mean volume of distribution in 7 medical students and staff volunteers was 1.66 L/kg.[103] Volunteer studies suggest that the major urinary metabolite of secobarbital include 5-(2′,3′-dihydroxypropyl)-5-(1′-methylbutyl)-barbituric acid, 5-allyl-5-(3′-hydroxy-1′-methylbutyl)-barbituric acid, and 5-allyl-5-(1′-methyl-3′-carboxypropyl)-barbituric acid.[104] The elimination half-life for secobarbital is relatively long. In a study of medical students and staff volunteers, the mean biologic half-life was 19.3 hours.[103] The calculated biologic half-life in a study of 6 healthy men was 28.9 hours.[102]

Drug Interactions

The drug interactions of secobarbital are similar to other short- and intermediate-acting drugs including the synergistic action of other CNS depressants on the clinical effects of secobarbital. In healthy volunteers receiving 2 mg secobarbital/kg and 0.2 mg morphine/kg intravenously, both drugs alone caused ventilatory depression compared with baseline; the combination caused greater and more prolonged reduction in arterial oxygenation than either drug alone.[105] At 5 minutes after IV administration, the mean arterial oxygen saturations were as follows: morphine alone, 86.6 ± 7.27 mm Hg ($P < .05$); secobarbital alone, 90.1 ± 6.21 mm Hg (P not significant); and morphine/secobarbital together, 80.7 ± 10.64 mm Hg ($P < .01$). Rodent studies indicate that chronic ethanol consumption of ethanol does not produce cross-reactivity with highly lipid soluble barbiturates (e.g., secobarbital) based on responses to hypothermia, tilt-lane, and rotarod.[106] *In vitro* studies indicate that secobarbital is a selective inactivator of CYP2B1.[107]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Similar to other short and intermediate acting barbiturates, secobarbital interacts with the GABA receptor-ionophore complex, binding the γ-aminobutyric acid type A (GABA$_A$) receptor and increasing the mean channel open time of the chloride ion channel in the GABA receptor-ionophore complex. Secobarbital is a cardiorespiratory and CNS depressant. Postmortem findings are nonspecific with signs of asphyxia.

CLINICAL RESPONSE

All short- and intermediate-acting barbiturates produce clinical effects similar to ethanol intoxication, manifest by dysarthria, ataxia, nystagmus, lightheadedness, impaired cognition, poor judgment, loss of inhibitions, and confusion. Complications of serious secobarbital intoxication include apnea, hypotension, and hypothermia. The abstinence syndrome associated with secobarbital is similar to other short-acting (e.g., pentobarbital) and intermediate-acting (e.g., amobarbital, butalbital) barbiturates.

DIAGNOSTIC TESTING

Analytic Methods

Methods for the quantitation of secobarbital include gas chromatography with flame ionization detection,[91] high performance liquid chromatography,[108] gas chromatography/mass spectrometry (GC/MS),[45] and GC/MS in selective ion monitoring mode with barbital as the internal standard.[109] The LOD for secobarbital in serum using the latter method is 0.5 mg/L. The LLOQ for secobarbital in blood and urine using GC/MS is similar to amobarbital (0.050 mg/L and 0.020 mg/L, respectively) with a coefficient of variance near 5–7%.[42] Analysis of the overall precision of GC/MS with solid phase extraction demonstrates a coefficient of variation in the range of 2%.[110] Micellar liquid chromatography allows the analysis of complex matrices for secobarbital without extraction. The LOD for secobarbital using this method with UV detection is approximately 0.064 mg/L.[46] Secobarbital is relatively stable in unpreserved blood and liver tissue at 4°C (39.2°F) and 25°C (77°F) for 2–3 months at pH 6.4–7.0. Under these storage conditions, secobarbital concentrations in samples stored at 4°C and 25°C decreased $91 \pm 12\%$ and $97 \pm 16\%$, respectively over 2 months of storage.[48] Substantial amounts of secobarbital are detectable in liver tissue and in formalin at least 20 months after death.[47] Typically, immunoassays (e.g., enzyme multiplied immunoassay technique, fluorescence polarization immunoassay) are very sensitive to secobarbital because the antibodies for these tests usually are raised against secobarbital.[38]

Biomarkers

The typical therapeutic serum concentration of secobarbital is 1–2 mg/L with toxic symptoms appearing in most

patients with secobarbital concentrations exceeding 8 mg/L. The mean plasma secobarbital concentration in 5 patients a half-hour after receiving 600 mg secobarbital over the preceding 3 hours was 4.3 mg/L, declining to 3.4 mg/L approximately 8 hours later.[49] All of these participants demonstrated signs of intoxication (sedation, unsteady gait, poor balance, and coordination) during the study. As measured by UV spectrophotometry, blood secobarbital concentrations of 12–17 mg/L are associated with light coma (reflexes present) and 35 mg/L with severe intoxication (comatose with unstable vital signs).[28] Serum concentrations of secobarbital and pentobarbital produce similar clinical effects as outlined in Table 23.7.

The highest secobarbital concentrations following fatal overdose occur in the blood, liver, and brain.[111] In a series of 108 cases involving secobarbital as the cause of death, the postmortem blood (site, analytic method NOS) ranged from 11–60 mg/L.[52] The report did not include the presence or absence of other drugs other than a comment that secobarbital poisoning was the cause of death. In postmortem blood (site NOS) from 16 secobarbital-related fatalities, the mean secobarbital concentration was 17.6 mg/L (range, 6.2–37 mg/L) compared with a mean of 5.5 mg/L (range, 1.3–21 mg/L) for secobarbital concentrations in 12 nondrug-related fatalities.[55] The secobarbital-related fatalities were single-drug fatalities with the exception of ethanol, nicotine, and caffeine. Animal studies suggest that substantial postmortem redistribution of secobarbital occurs after death.[112]

TREATMENT

Secobarbital is a CNS depressant that causes respiratory and cardiovascular depression during severe intoxication. The treatment of secobarbital intoxication is similar to other barbiturates (e.g., amobarbital). Similar to other barbiturates, hourly phenobarbital loading is an option for the treatment of secobarbital withdrawal. In a case series of 7 patients undergoing detoxification for secobarbital abuse, the mean phenobarbital loading dose was 31.7 ± 15.0 mg/kg with a mean total phenobarbital dose of 1,560 ± 830 mg.[113]

Chapter 24

ETHCHLORVYNOL

HISTORY

Similar to other older sedative-hypnotic drugs (e.g., methaqualone, meprobamate, glutethimide), ethchlorvynol was introduced as a safer, nonaddictive substitute for barbiturates during the 1950s. However, the abuse potential and toxicity of these sedatives were well recognized during the 1960s and 1970s. During the late 1970s, Drug Abuse Warning Network (DAWN) data indicated that ethchlorvynol use was associated with over 300 deaths yearly.

IDENTIFYING CHARACTERISTICS

Ethchlorvynol is a tertiary alcohol (1-chloro-3-ethylpent-1-en-4-yn-3-ol, CAS RN: 113-18-8) as displayed in Figure 24.1. The aspirate from the gastric lavage of patients with ethchlorvynol overdoses frequently is pink. Table 24.1 lists some physiochemical properties of ethchlorvynol.

EXPOSURE

Ethchlorvynol (Placidyl, Abbott Laboratories, Abbott Park, IL) is a sedative-hypnotic drug for the short-term treatment of insomnia. This seldom used drug has been replaced by other, more effective drugs. Product formulations include gelatin capsules in strengths ranging from 100–750 mg. Based on data from the American Association of Poison Control Centers, ethchlorvynol exposure is relatively rare in the United States with no fatalities and few exposures reported in 2009.[1] Although ethchlorvynol abuse typically involves the excessive ingestion of prescription drugs, occasionally drug abusers inject the liquid capsular contents of ethchlorvynol capsules.[2]

DOSE EFFECT

The typical adult dose of ethchlorvynol is 500–750 mg. Mild to moderate ethchlorvynol intoxication begins with ingestions in the 4–10 g range. The response to ethchlorvynol is variable depending on a number of factors including tolerance and the concomitant ingestion of other central nervous system (CNS) depressants. The ingestion of 30–50 g ethchlorvynol was associated with prolonged coma, respiratory insufficiency, and hypotension.[3] Case reports associated survival after intensive supportive care and prolonged coma following the estimated ingestion of 80–125 g ethchlorvynol.[4]

TOXICOKINETICS

Absorption

Following the ingestion of therapeutic doses of ethchlorvynol, gastrointestinal (GI) absorption is rapid with peak serum ethchlorvynol concentrations occurring about 1–1.5 hours after ingestion. In a small study of healthy volunteers, the peak serum ethchlorvynol concentration occurred about 1 hour after the ingestion of 500 mg and 750 mg.[5] The ingestion of fatty foods delays ethchlorvynol absorption.

Distribution

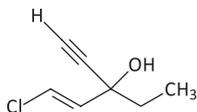
The initial distribution half-life of ethchlorvynol after therapeutic doses is about 1–3 hours with a relatively


FIGURE 24.1. Chemical structure of ethchlorvynol.

TABLE 24.1. Some Physiochemical Properties of Ethchlorvynol.

Physical Property	Value
Melting Point	<25°C (<77°F)
Boiling Point	174°C (345.2°F)
log P (Octanol-Water)	1.650
Vapor Pressure	0.1 mm Hg (29°C/84.2°F)

large volume of distribution (i.e., 4 L/kg). This highly lipophilic drug distributes widely into fatty tissues. The sedative effects disappear in 3–5 hours as ethchlorvynol distributes into peripheral tissues. A rebound increase in serum ethchlorvynol concentrations can develop 7–10 hours after ingestion as a result of the redistribution of ethchlorvynol from peripheral stores. Ethchlorvynol is approximately 50–60% protein bound.

Biotransformation

The liver probably is the primary site of ethchlorvynol metabolism; however, the exact pathway of ethchlorvynol metabolism remains poorly defined. A potential metabolite includes 1-chloro-3-ethynylpent-1-en-3,4-diol from the hydroxylation of C4.[6]

Elimination

The kidney excretes small amounts (i.e., <0.1%) of a therapeutic ethchlorvynol dose unchanged in the urine.[5] The initial serum elimination half-life of ethchlorvynol after a therapeutic dose is relatively rapid (i.e., about 6–8 hours), but a slow β-elimination phase results from a biphasic elimination pattern and the delayed release of ethchlorvynol from tissue stores as demonstrated in Figure 24.2. During acute ethchlorvynol intoxication, the serum elimination half-life may increase substantially (20–100 hours).[7,8] The serum elimination half-life of ethchlorvynol in an obese, hypothyroid man chronically using ethchlorvynol was 78 hours with a total body clearance of 9.92 mL/min.[9] Renal clearance of ethchlorvynol is relatively small.

Maternal and Fetal Kinetics

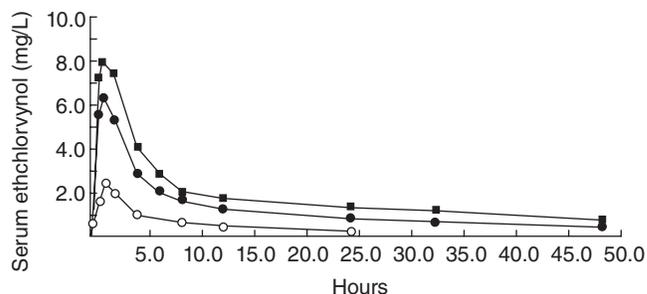
Ethchlorvynol rapidly crosses the placenta, producing equilibration of maternal and fetal ethchlorvynol con-


FIGURE 24.2. Mean serum ethchlorvynol concentrations in mg/L following therapeutic doses: single 200 mg (○), single 500 mg (●), single 750 mg (■).[5] The analytic method was gas chromatography with electron capture detection. (Reprinted from LM Cummins, YC Martin, EE Scherfling, Serum and urine levels of ethchlorvynol in man, Journal of Pharmaceutical Sciences, 1971, Fig. 2, p. 262, permission by John Wiley & Sons.)

centrations based on animal studies. In a study involving 5 pregnant mongrel dogs, the oral administration of 300 mg ethchlorvynol/kg produced rapid equilibration of ethchlorvynol concentrations in maternal and fetal blood ranging from 3.5–6.5 mg/L with amniotic and chorionic fluid concentrations about 20–25% of the maternal blood concentration.[10]

Tolerance

Tolerance develops following the chronic, excessive use of ethchlorvynol. A review of cases of chronic ethchlorvynol abuse reported daily ethchlorvynol consumption ranging from 1–4 g.[11]

Drug Interactions

Ethchlorvynol does not induce hepatic microsomal enzymes and hepatic dysfunction does not alter ethchlorvynol metabolism. Porphyria is a contraindication for ethchlorvynol use because ethchlorvynol increases γ-aminolevulinic acid production. Ethanol increases the sedative effect of ethchlorvynol similar to other CNS depressants.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Ethchlorvynol is a CNS depressant similar to barbiturates and ethanol, but the mechanism of action is not well defined. Experimental studies suggest that ethchlorvynol rather than diluents is responsible for the

pulmonary edema associated with ethchlorvynol intoxication.[12] Postmortem findings during examination of individuals found dead following ethchlorvynol overdose are nonspecific with pulmonary and visceral congestion along with cerebral edema. Massive pulmonary edema may be present at autopsy.[13]

CLINICAL RESPONSE

Illicit Use

The clinical features of chronic ethchlorvynol abuse are similar to chronic ethanol abuse. Symptoms associated with chronic abuse of ethchlorvynol include ataxia, dysarthria, diplopia, blurred vision, generalized weakness, tremor, toxic amblyopia, and central scotomata.[11] Clinical effects begin within 15–30 minutes.

Overdose

The clinical features of mild ethchlorvynol overdose are similar to sedative-hypnotic drug overdose with symptoms ranging from slurred speech, ataxia, and nystagmus to lethargy. In addition, a relative bradycardia and excessive salivation often occurs following ethchlorvynol overdose.[3] Symptoms of intoxication also include a mint-like taste, dry cough, and pungent odor on the breath. Severe ethchlorvynol intoxication produces a prolonged deep coma, hypothermia, respiratory depression, bullae, and hypotension. Serious complications of ethchlorvynol intoxication include aspiration pneumonia, respiratory arrest, and pulmonary edema. Although pulmonary edema occurs more commonly after the injection of ethchlorvynol capsules, occasional case reports associated large ethchlorvynol overdose with the development of noncardiogenic pulmonary edema 24–48 hours after ingestion.[2,14] Prolonged coma during ethchlorvynol intoxication may cause an ischemia-induced peripheral neuropathy. The presence of a pink gastric aspirate with prolonged coma, hypotension, and a relative bradycardia suggests ethchlorvynol poisoning.

Abstinence Syndrome

Heavy, chronic use of ethchlorvynol may cause an abstinence syndrome following abrupt cessation similar to other sedative-hypnotic drugs and delirium tremens. Clinical features of withdrawal include agitation, confusion, disorientation, delirium, tremor, hypertension, tachycardia, hallucinations, and seizures that begin from 3–15 days after cessation of use.[15,16] Symptoms usually resolve in 3–8 days, but occasionally symptoms may persist longer.[11] Case reports associate the development

of withdrawal symptoms during the first several days of a neonate born to a mother using high doses of ethchlorvynol during pregnancy.[17] Symptoms included mild hypotonia, poor suck and Moro reflexes, and poor grasp followed by jitteriness and irritability. The pregnancy was complicated by toxemia.

Reproductive Abnormalities

There are few data on the effects of maternal ethchlorvynol use and reproductive abnormalities, but animal data do not suggest that ethchlorvynol is a significant teratogen. A study of female rats exposed to ethchlorvynol doses of 20 mg/kg and 80 mg/kg did not demonstrate significant differences in the gross anatomy or histology of various organs of the offspring, when compared with the offspring of control rats without ethchlorvynol exposure.[18]

DIAGNOSTIC TESTING

Analytic Methods

Methods for the detection of ethchlorvynol include spectrophotometry,[19,20] high performance liquid chromatography,[21] and gas chromatography.[22] Detection limits for these analytic procedures are in the range of 1 mg/L.[23] Some loss of ethchlorvynol can occur during storage. A case report documents the loss of approximately 22% of the initial postmortem blood ethchlorvynol concentration of 66 mg/L following storage for 90 days at 0°C (32°F).[24]

Abnormalities

The chest x-ray in patients with pulmonary edema following ethchlorvynol poisoning typically demonstrates diffuse bilateral alveolar densities without cardiomegaly.

Biomarkers

BLOOD

OVERDOSE. Interpretation of serum ethchlorvynol concentrations requires consideration of a variety of factors including tolerance, concomitant ingestion of other CNS depressants, coexisting disease, and individual variability. Typically, therapeutic concentrations of ethchlorvynol range from about 2–8 mg/L with toxicity developing when the serum ethchlorvynol concentration exceeds 20 mg/L. In pharmacokinetic studies of healthy volunteers, the mean peak serum ethchlorvynol concentration following ingestion of 500 mg and 750 mg

ethchlorvynol was approximately 6.5 mg/L and 8 mg/L, respectively.[5]

Serious toxicity potentially develops when serum ethchlorvynol concentrations exceed 50 mg/L. Serum ethchlorvynol concentrations do not necessarily correlate to the clinical presentation because of the factors listed above. A 33-year-old, hypothyroid, obese man with a history of drug abuse and chronic ethchlorvynol use (i.e., prescribed dose, 1 g daily for 2 years) was oriented, lethargic, and responsive to verbal command.[9] His initial serum ethchlorvynol concentration was 70 mg/L. Survival occurred in patients treated with intensive supportive care despite the presence of peak serum ethchlorvynol concentrations exceeding 200 mg/L.[25]

POSTMORTEM.   In a series of 4 postmortem cases involving only ethchlorvynol, the ethchlorvynol concentration in postmortem blood samples ranged from 29–94 mg/L with a mean of 55 mg/L as measured by UV spectrophotometry.[7] Case reports indicate that high postmortem concentrations of ethchlorvynol occur in the liver and bile compared with the blood and urine.[26,27] The ethchlorvynol concentration in a postmortem blood sample from a chronic ethchlorvynol abuser found dead was 66 mg/L as measured by gas chromatography with a hydrogen flame detector.[24]

Driving

There are few data on the effect of ethchlorvynol and driving skills; however, the CNS depressant properties indicate that abuse of ethchlorvynol would impair driving skills.

TREATMENT

Stabilization

As for all sedative-hypnotic overdoses, stabilization requires careful evaluation of the level of consciousness and the adequacy of respirations. Seizures may occur during withdrawal from ethchlorvynol along with restlessness, agitation, and delirium. All patients with altered levels of consciousness should be evaluated rapidly for serum glucose concentrations and hypoxemia.

Gut Decontamination

The administration of activated charcoal is appropriate for patients with ethchlorvynol overdose presenting <1 hour after ingestion. However, most patients present to a health care facility >1 hour after ethchlorvynol ingestion, and gut decontamination measures are not necessary as a result of the lack of clinical data to support the use of aggressive decontamination measures in these patients. Theoretically, the administration of activated charcoal more than 1–2 hours after ingestion may decrease ethchlorvynol absorption in comatose patients with decreased gastrointestinal motility, but there are inadequate data to indicate that the administration of activated charcoal at this time improves clinical outcome. Gastric lavage in comatose patients is a therapeutic option, particularly with delayed gastric emptying. However, there are few data on the efficacy of gastric lavage in ethchlorvynol overdose. Syrup of ipecac is not recommended because of the lack of efficacy and the potential for aspiration.

Elimination Enhancement

The renal clearance of ethchlorvynol during resin hemoperfusion for ethchlorvynol intoxication is high (140–170 mL/min),[28] but there are few data on the effect of resin hemoperfusion on the clinical outcome of ethchlorvynol intoxication. Substantial rebound of ethchlorvynol from peripheral stores may significantly increase the serum ethchlorvynol concentrations within 6–8 hours after treatment. Factors to consider for the use of resin hemoperfusion include failure to respond to supportive measures, life-threatening complications associated with prolonged coma, and serum ethchlorvynol concentrations that exceed 150 mg/L. Although hemodialysis reduces the plasma ethchlorvynol half-life, the effect of hemodialysis on the clinical outcome of ethchlorvynol intoxication is unclear, in part because of relatively high protein binding and the large redistribution from tissue to blood. Three hours of hemodialysis removed 3 g (i.e., about 3–5% of the total dose) of an estimated 80–125 g ingestion of ethchlorvynol.[29] The estimated clearance of ethchlorvynol during hemodialysis for 2 patients with ethchlorvynol poisoning was 46 mL/min and 82 mL/min.[3] Forced diuresis is contraindicated because of the limited excretion of ethchlorvynol and the tendency of ethchlorvynol intoxication to cause pulmonary edema.

Antidotes

There is no antidote.

Supplemental Care

Baseline laboratory tests during ethchlorvynol intoxication include complete blood count and serum electrolytes, glucose, and creatinine as well as chest x-ray and pulse oximetry. Hemodynamic monitoring may be necessary for patients with hypotension unresponsive to

fluid therapy. Prolonged coma is characteristic of serious ethchlorvynol intoxication and potential complications include pulmonary edema, respiratory arrest, and pneumonia.

Chapter 25

GLUTETHIMIDE

HISTORY

In 1954, glutethimide (Doriden®) was introduced into the US market as a safe substitute for barbiturates. Within 1 year, the first report of glutethimide poisoning appeared in the medical literature.[1] Subsequent experience with glutethimide indicated that the severity of the abuse potential and withdrawal symptoms were similar to those of barbiturates; chronic abuse of glutethimide resulted in tolerance, dependence, and an abstinence syndrome. During the 1980s, the combination of codeine and glutethimide ("packs" or "loads") gained popularity as an aphrodisiac and an oral substitute for heroin. In 1991, glutethimide was given a US Drug Enforcement Administration schedule II classification in response to an upsurge in the prevalence of diversion, abuse, and glutethimide-associated fatalities. Today, there is limited medical use of glutethimide in the United States.

IDENTIFYING CHARACTERISTICS

Glutethimide (CAS RN: 77-21-4, $C_{13}H_{15}NO_2$) is structurally related to phenobarbital and thalidomide as displayed in Figure 25.1. The IUPAC name for glutethimide is 2-ethyl-2-phenylglutarimide (3-ethyl-3-phenyl-2,6-piperidinedione). The poor water solubility and high pKa (9.2) of glutethimide limits the gastrointestinal (GI) absorption of glutethimide, particularly during an overdose. Table 25.1 lists some physiochemical properties of glutethimide. The molecular weight of this highly lipophilic drug is 217 g/mol.

Slang terms for the combination of glutethimide and codeine include Loads and Pancakes and Syrup (codeine cough syrup). Other street names for glutethimide are D's, CB, CD, Eight's, Four Doors, Glue, Hits, and Sets.

EXPOSURE

Exposure to glutethimide is very limited in the United States. The American Association of Poison Control Centers' National Poison Data System Annual Report did not list any exposures to glutethimide in 2009.[2] Glutethimide is a sedative-hypnotic drug used for the treatment of anxiety and insomnia. Other potential uses include essential tremor.[3] The 250- and 500-mg dosages are white tablets. Glutethimide is available as a generic drug or under the trade name Doriden® (USV Pharmaceutical, Mumbai, India). A synonym for glutethimide in France and Belgium is Doridene®.

The combination of glutethimide and codeine reportedly produces euphoria similar to intravenous (IV) heroin. Typical oral doses involved with the abuse of glutethimide are 1 g glutethimide and 240 mg codeine.[4] Desired effects from the use of this combination is the relatively long-lasting effects (i.e., up to 8 hours), the avoidance of the complications of IV drug use, and relatively low cost of the ingredients. However, the combination is highly addictive, and the rapid development of tolerance leads to escalating doses and fatalities.[5]

DOSE EFFECT

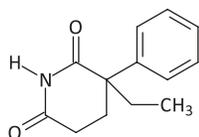
The usual adult hypnotic dose of glutethimide is 250–500 mg with a range up to 1,500 mg. Mild to moderate toxicity may develop when the glutethimide dose exceeds 3–7 g. The ingestion of glutethimide doses


FIGURE 25.1. Chemical structure of glutethimide.

TABLE 25.1. Some Physiochemical Properties of Glutethimide.

Physical Property	Value
Melting Point	84°C (183.2°F)
pKa Dissociation Constant	9.2
log P (Octanol-Water)	1.9
Water Solubility	999 mg/L (30°C/86°F)
Vapor Pressure	1.49E–09 mm Hg (25°C/77°F)

>10–20 g or 150–300 mg/kg are potentially lethal as a result of CNS depression.[6] A variety of factors determine the lethality of a specific dose, and survival after the ingestion of 42.5 g occurred with intensive treatment.[7]

TOXICOKINETICS

Absorption

The poor water solubility of glutethimide results in erratic and delayed GI absorption. Following the ingestion of 500 mg glutethimide by healthy volunteers, the peak plasma glutethimide concentrations ranged from about 3–7 mg/L at 1–6 hours after ingestion.[8]

Distribution

Glutethimide is highly lipophilic, resulting in relatively high glutethimide concentrations in brain and adipose tissue after ingestion. The apparent volume of distribution is about 2.7 L/kg following therapeutic doses of glutethimide. The initial distribution phase into tissues is relatively rapid with a distribution half-life of about 4 hours, whereas the terminal elimination half-life is longer (i.e., about 12 hours). Glutethimide is approximately 50% protein bound in blood.

Biotransformation

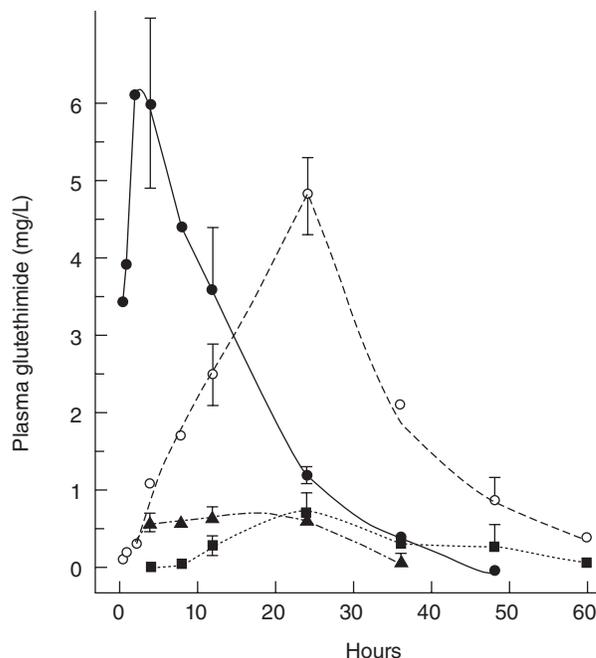
Glutethimide (2-ethyl-2-phenylglutarimide) undergoes extensive metabolism in the liver to both conjugated and unconjugated metabolites that the kidney excretes


FIGURE 25.2. Mean plasma concentrations (mg/L) of glutethimide and glutethimide metabolites for 3 subjects ingesting 13.5 mg/kg body weight glutethimide. Glutethimide (•), 4-hydroxyglutethimide (○), conjugated 4-hydroxygluthethimide (▪), iso-(1-hydroxyethyl)glutethimide (▲). (Reprinted from KA Kennedy, LJ Fischer, Quantitative and stereochemical aspects of glutethimide metabolism in humans, Drug Metabolism and Disposition, Vol. 7, p. 321, copyright 1979.)

in the urine including 4-hydroxy-2-ethyl-2-phenyl-glutarimide (4-hydroxyglutethimide, major metabolite), 2-(1-hydroxyethyl)-2-phenylglutarimide, and 2-ethyl-2-(4-hydroxyphenyl)glutarimide.[9] Minor urinary metabolites include 2-(2-hydroxyethyl)-2-phenylglutarimide, 2-(2-hydroxyethyl)glutarimide, and dihydroxyl metabolites [e.g., 4-hydroxy-2-(1-hydroxyethyl)-2-phenylglutarimide, 2-ethyl-2-(3,4-dihydroxyphenyl)glutarimide].[10] Racemic glutethimide undergoes stereoselective metabolism. Hydrolysis of the glutarimide ring of the *d*-enantiomer forms 4-hydroxyglutethimide, whereas hydrolysis of the *l*-enantiomer results in the release of acetaldehyde from α-phenyl glutarimide. Peak concentrations of the metabolite, 4-hydroxyglutethimide occurred about 24 hours after ingestion of 13.5 mg racemic glutethimide/kg by 3 volunteers.[11] Although some glutethimide metabolites (e.g., 4-hydroxyglutethimide, phenyl-γ-butyrolactone) demonstrate pharmacologic activity in animals,[12] these metabolites are not definitely associated with human toxicity.[13,14] Peak plasma concentration of 4-hydroxyglutethimide occur substantially after the resolution of the sedative effects of glutethimide as demonstrated in Figure 25.2.

Elimination

The kidney excretes minimal unchanged glutethimide in urine with the vast majority (i.e., 98%) of the glutethimide dose appearing in the urine as conjugated metabolites.[11] The major glutethimide metabolites in the urine are the glucuronic acid conjugates of hydroxy metabolites (e.g., 4-hydroxyglutethimide, [1-hydroxyethyl]-glutethimide). The estimated unaided renal clearance of glutethimide is about 0.5–11 mL/min. In therapeutic doses, the elimination half-life of glutethimide is approximately 8–12 hours. The elimination half-life can increase substantially during serious glutethimide poisonings. In a patient with coma, respiratory failure, and hypotension, the plasma elimination half-life of glutethimide was about 13 hours with a peak plasma glutethimide concentration of 41 mg/L.[13] In a case series of 38 glutethimide poisonings, the mean serum elimination half-life was approximately 40 ± 5 hours; however, each calculation was based on only 2 measurements and there was no confirmation that the glutethimide samples were drawn during the postabsorption phase.[15] Additionally, the presence of hypotension in some of these patients may have prolonged the serum half-life. A majority of the glutethimide metabolites undergo enterohepatic recirculation and slow urinary excretion.

Maternal and Fetal Kinetics

Glutethimide easily crosses the placenta to develop similar glutethimide concentrations in maternal and fetal blood. Relatively small amounts of the unchanged glutethimide occur in breast milk,[8] and breastfeeding following the occasional use of a single dose of glutethimide probably is safe for the infant.[16]

Drug Interactions

Glutethimide induces hepatic microsomal enzyme formation. Rodent studies indicate that the administration of glutethimide with codeine potentiates and prolongs the analgesic effect of codeine by increasing the plasma morphine concentration and reducing the plasma concentration of the inactive metabolite, morphine-3-glucuronide.[17] Similar to other sedative-hypnotics, the congestion of ethanol and glutethimide synergistically depresses the CNS. In a volunteer study, the concomitant administration of ethanol and glutethimide increased the blood ethanol concentration while reducing the plasma glutethimide concentration when compared with the administration of ethanol and glutethimide separately.[18]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Glutethimide is a CNS depressant similar to phenobarbital, but glutethimide does not possess anticonvulsant properties. Glutethimide has prominent anticholinergic properties, manifest during glutethimide intoxication by mydriasis, paralytic ileus, and urinary retention. Cardiovascular depression and shock are relatively more common during severe glutethimide intoxication than during similar stages of coma after poisoning by other older sedative-hypnotic drugs. Postmortem examination of patients dying from glutethimide intoxication usually demonstrates nonspecific findings including visceral congestion, cerebral edema, and pulmonary edema.[6]

CLINICAL RESPONSE

Overdose

The clinical features of glutethimide intoxication are similar to other sedative-hypnotic drugs (ethchlorvynol, meprobamate, methaqualone) except the frequent occurrence of fluctuating levels of coma and prominent anticholinergic signs. Serious complications of glutethimide overdose include coma, papilledema, cerebral edema, pulmonary edema, seizures, hypotension, and respiratory arrest.[19,20] Although respiratory depression is less severe following glutethimide ingestion compared with equivalent doses of barbiturates, hypotension occurs at an earlier stage of coma than a similar stage of barbiturate intoxication.[6] Anticholinergic symptoms are often prominent with mydriasis being the most common sign. Thick, tenacious secretions, ileus, urinary retention, and warm, dry skin may occur. Temperature abnormalities include hypothermia followed by elevated body temperatures. Hepatic dysfunction, visceral hemorrhage, and renal dysfunction are uncommon manifestations of glutethimide intoxication. Factors associated with poor outcome during glutethimide intoxication include age >60 years,[21] high-grade coma, large glutethimide ingestion (>10 g), plasma glutethimide level exceeding 30 mg/L, and concomitant ingestion of other CNS depressants.

Abstinence Syndrome

Abrupt withdrawal of glutethimide following chronic use of high doses may produce an abstinence syndrome similar to other sedative-hypnotic drugs (e.g., meprobamate, methaqualone, ethchlorvynol). Clinical features of withdrawal from glutethimide include nausea, vomiting, anxiety, sleep disturbances, and seizures.

Reproductive Abnormalities

Limited data on glutethimide in pregnancy does not suggest that this drug is fetotoxic or teratogenic in therapeutic doses. In a study of 33 glutethimide overdoses in pregnant women, 16 delivered live infants.[22] Three of these infants had congenital abnormalities (fetal alcohol syndrome, pectus carinatum, atrial septal defect type II). Compared with 16 matched siblings, there was no significant difference in congenital abnormalities, cognition, or behavior. The birth weight of the exposed infants was higher than controls as a result of a relatively longer gestation period.

DIAGNOSTIC TESTING

Analytic Methods

Methods for the quantitation of glutethimide in biologic samples include gas chromatography with flame ionization detection (limit of detection [LOD], 0.2 mg/L)[23,24] and gas chromatography/mass spectrometry (GC/MS).[10] Analysis of biologic samples with gas chromatography/flame ionization detection detects both glutethimide and the active metabolite, 4-hydroxy-2-ethyl-2-phenylglutarimide with a LOD of approximately 0.2 mg/L and 0.5 mg/L, respectively.[25] Separation of glutethimide enantiomers by high performance liquid chromatography (HPLC) on cellulose tris(4-methylbenzoate) as the chiral stationary phase followed by detection with HPLC allows the determination of the stereoselectivity of the metabolites formed by glutethimide enantiomers.[26]

Biomarkers

Blood

Overdose.   Serum glutethimide concentrations do not always correlate to clinical effect because of the presence of other drugs, tolerance, underlying medical disease, individual variability, and the metabolism of glutethimide to a possibly active metabolite. Variations in the depth of coma do not correlate well to serum glutethimide or to serum 4-hydroxyglutethimide concentrations. Therapeutic serum glutethimide concentrations range from about 2–6 mg/L, whereas toxic serum glutethimide concentrations range from 10–80 mg/L. Case reports associate serum glutethimide concentrations near 25 mg/L with altered consciousness and responsiveness only to painful stimuli.[27] Coma may persist despite low serum glutethimide concentrations; case reports suggest that the level of consciousness cor-

relates better to serum glutethimide and 4-hydroxy-2-ethyl-2-phenylglutarimide concentrations rather than serum glutethimide alone.[28] However, there are inadequate data to determine the exact contribution of any active glutethimide metabolite to the clinical features of glutethimide intoxication. Fatalities can occur when the serum glutethimide concentration exceeds 30–100 mg/L. A case report associated coma, hypotension, and apnea with a peak plasma glutethimide concentration of 41 mg/L as measured by GC/MS.[13]

Postmortem.   In a case series of 3 fatalities involving only glutethimide, the postmortem blood glutethimide concentration ranged from 29–60 mg/L as measured by a spectrophotometric method that included the 4-hydroxyglutethimide metabolite.[27] Reviews of fatalities following the combined use of glutethimide and codeine indicate that these two drugs potentiate respiratory depression. Consequently, death occurs at lower concentrations of these 2 drugs than the postmortem concentrations detected following overdose fatalities resulting from these drugs alone. In a case series of 16 deaths resulting from the use of glutethimide and codeine, the postmortem blood glutethimide concentration ranged from 0.7–61 mg/L (mean, 12.7 mg/L), whereas the postmortem blood codeine concentrations ranged from 0.07–2 mg/L (mean, 0.6 mg/L).[29] In another case series of 5 fatal poisonings involving only glutethimide and codeine, the postmortem blood glutethimide and codeine concentrations ranged from 7.2–22.1 mg/L (mean, 14.5 mg/L) and 0.29–1.99 mg/L (mean, 1 mg/L), respectively.[30] Although the distribution of glutethimide is relatively low in bone compared with bile, blood, and the liver, bone samples (sternum, ribs) are alternative biologic samples for the qualitative detection of glutethimide in previously interred corpses.[31]

Abnormalities

Although the frequency and reactivity of an electroencephalogram (EEG) correlate positively with the degree of brainstem depression during glutethimide overdose,[12] complete clinical recovery is possible despite the absence of EEG activity when anoxic brain damage is not present.[32]

Driving

A double-blind study of healthy volunteers ingesting an evening dose of 250 mg glutethimide did not detect decrements in psychomotor performance (i.e., choice reaction time, coordination test, divided attention task) when tested the following morning.[33]

TREATMENT

Stabilization

Similar to other sedative-hypnotic overdoses, stabilization requires careful evaluation of the level of consciousness and oxygenation. Seizures may occur during withdrawal from glutethimide along with restlessness, agitation, and delirium. All patients with altered levels of consciousness should be evaluated rapidly for hypoglycemia and hypoxia. Fluctuating levels of consciousness may result in initial improvement followed by serious deterioration of vital signs.

Gut Decontamination

The administration of activated charcoal is appropriate for patients with glutethimide overdose presenting <1–2 hours after ingestion. However, patients who present to a health care facility >1–2 hours after glutethimide ingestion frequently require no gut contamination measures as a result of the lack of clinical data to support the use of aggressive decontamination measures. Theoretically, the administration of activated charcoal more than 1–2 hours after ingestion can decrease glutethimide absorption in comatose patients with decreased GI motility, but there are inadequate data to indicate that the administration of activated charcoal at this time improves clinical outcome. Gastric lavage in comatose patients is a therapeutic option, particularly when delayed gastric emptying and the formation of drug concretions are suspected. However, there are few data on the efficacy of gastric lavage in glutethimide overdose. Syrup of ipecac is not recommended because of the potential for aspiration and the lack of efficacy. Fluctuating vital signs or level of consciousness suggests the presence of continued glutethimide absorption from drug concretions and, therefore, the need for endoscopy.

Elimination Enhancement

There are limited data on the effect of hemoperfusion and hemodialysis on the clinical outcome of severe glutethimide intoxication. Although both resin hemoperfusion and hemodialysis increase glutethimide clearance about 300 mL/min and 30–110 mL/min, respectively, the large tissue stores of glutethimide limit the total amount of drug removed. Reported *in vitro* dialysance of glutethimide at renal flow rates of 200 mL/min was 80 mL/min.[6] Consequently, the exact role of hemodialysis and hemoperfusion remains unclear; most patients require only supportive care. If used, hemodialysis or hemoperfusion should be limited to potentially severe intoxications. Forced diuresis is contraindicated because of the propensity to produce pulmonary edema.

Antidotes

There is no antidote.

Supplemental Care

Baseline laboratory tests include a complete blood count, serum electrolytes, serum glucose, and measures of renal and hepatic function. Chest x-rays and monitoring of oxygen saturation are necessary during moderate and severe glutethimide intoxication to detect pneumonia and pulmonary edema.

Chapter 26

MEPROBAMATE

HISTORY

The development of meprobamate began with the synthesis of mephenesin as a disinfectant for Gram-negative bacteria in the mid-1940s. Discovery of the muscle relaxant properties of mephenesin in animals led to the introduction of this drug as an alternative to tubocurarine during light anesthesia; however, the low potency, short duration of action, and the limited effect on supratentorial structures resulted in attempts to modify the structure of mephenesin. In 1951, Ludwig and Piech reported that meprobamate was an effective alternative to mephenesin as a muscle relaxant.[1] Shortly thereafter, the selective action of meprobamate on anxiety was discovered and this drug soon became a popular sedative.[2] This drug was the first anxiolytic agent and along with chlorpromazine initiated the age of psychopharmacology. In the late 1950s, meprobamate was administered to neurotic patients as a less toxic replacement for the sedative effects of barbiturates, chloral hydrate, bromides, ethanol, opium, and paraldehyde. The first report of meprobamate poisoning appeared in 1956.[3] Although initially marketed as a safe sedative-hypnotic with low abuse potential, later reports of serious overdose and addiction indicated that the adverse effects of meprobamate were similar to other sedative-hypnotics.[4] In a French case series of 141 meprobamate intoxications published in 1968, the mortality rate was 5%, resulting primarily from cardiogenic shock.[5]

IDENTIFYING CHARACTERISTICS

Meprobamate (CAS RN: 57-53-4, $C_9H_{18}N_2O_4$) is a carbamic acid ester of a glycol (2-methyl-2n-propyl-1,3-propanediol dicarbamate) as displayed in Figure 26.1.

Table 26.1 lists some physiochemical properties of meprobamate.

EXPOSURE

Exposure to meprobamate is limited in the United States; however, the exposures reported to American Association of Poison Control Centers for meprobamate are higher than the combined exposures to the other 3 older sedative-hypnotic drugs (ethchlorvynol, glutethimide, methaqualone).[6] The American Association of Poison Control Centers' National Poison Data System Annual Report listed 42 exposures and no fatalities associated with the use of meprobamate in 2009. Meprobamate occurs in a variety of preparations in doses of 200 mg and 400 mg including distribution in the United States under the trade names Equanil® (Wyeth, Madison, NJ) and Miltown® (Wallace Laboratories, El Segundo, CA). Meprobamate remains available in France, primarily as an adjunctive treatment for alcohol withdrawal despite the lack of clinical data to support this indication.

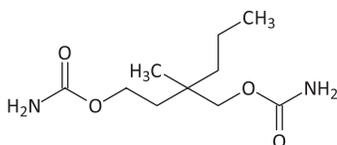
Behavioral studies suggest that the abuse potential of meprobamate is similar to benzodiazepines, but less than barbiturates. In a behavioral study of 9 men with histories of drug abuse housed on a residential research ward, meprobamate had similar abuse potential as lorazepam when compared in a within-subject, double-blind study.[7] Meprobamate produced subjective ratings of drug liking and monetary street value similar to lorazepam, but there was no placebo-control in this study. A study of 14 recreational drug users with histories of prior sedative-hypnotic drug use compared the behavioral and pharmacologic effects of triazolam (0.5 mg), meprobamate (2,400 mg), and butabarbital


FIGURE 26.1. Chemical structure of meprobamate.

TABLE 26.1. Some Physiochemical Properties of Meprobamate.

Physical Property	Value
Conversion Units	1 mg/L = 0.22 μmol/L
	1 μmol/L = 4.55 mg/L
Melting Point	105°C (221°F)
log P (Octanol-Water)	0.7
Water Solubility	4700 mg/L (25°C/77°F)
Vapor Pressure	3.05E-03 mm Hg (25°C/77°F)

(400 mg) in a double-blind, crossover, placebo-controlled study. Meprobamate was indistinguishable from placebo on the euphoria and abuse potential scales. Based on behavioral economics analysis, the ranking of abuse potential was butabarbital > triazolam ≥ meprobamate.

DOSE EFFECT

The usual adult therapeutic dose is 600–1,600 mg daily in 3–4 divided doses up to a daily maximum of 2,400 mg. Meprobamate doses in the range of 6–10 g produce ataxia and transient hypotension, whereas the ingestion of 10–20 g causes significant hypotension and respiratory insufficiency.[8] The ingestion of 30–40 g meprobamate produced profound coma, hypotension, and respiratory failure.[9]

TOXICOKINETICS

Absorption

Although the ingestion of large doses of meprobamate may delay GI absorption, peak meprobamate concentrations following the administration of therapeutic doses typically occur about 2–4 hours after ingestion.[10] Low water solubility, stability in acid solutions, and reduced gut motility contribute to the formation of drug masses and the subsequent delay in absorption and serious toxicity. Approximately 25 g meprobamate

remained in the stomach of a woman during the post-mortem examination; she died of respiratory arrest after initially regaining consciousness following a large meprobamate overdose.[11] Forty hours after the ingestion of an estimated meprobamate dose of 36 g, gastrotomy removed approximately 25 g meprobamate from the stomach of a 56-year-old woman.[12]

Distribution

The volume of distribution of meprobamate is relatively small (0.75 L/kg) with limited plasma protein binding (i.e., 10–20%). Arterial-venous differences in the plasma meprobamate concentration may develop during meprobamate overdose. In a study of 35 meprobamate intoxications, the mean plasma meprobamate concentration in femoral arterial blood samples was about 10% higher ($P < .01$) than in plasma venous samples.[13] Case reports of the meprobamate concentrations in various postmortem tissues suggest that meprobamate distributes preferentially into muscle, heart, and bile with relatively low concentrations in the brain.[14]

Biotransformation

Meprobamate undergoes biotransformation in the liver by *N*-glucuronidation of the parent drug and by oxidation of the propyl side-chain to hydroxymeprobamate. The latter metabolite is probably inactive. Meprobamate is a metabolite and prodrug of the muscle relaxant, carisoprodol.

Elimination

The kidney excretes about 10% of a therapeutic dose of meprobamate unchanged in the urine. The unaided renal clearance of meprobamate is about 5–30 mL/min. The serum elimination half-life of meprobamate is approximately 8–12 hours following the administration of therapeutic doses of meprobamate to healthy volunteers,[15] but a case report suggests that the elimination half-life may increase during an overdose.[16] However, the propensity of meprobamate to form concretions during an overdose complicates the interpretation of such increases in serum half-life during meprobamate intoxication.

Maternal and Fetal Kinetics

Meprobamate crosses the placenta and produces similar maternal and fetal meprobamate concentrations following the maternal use of meprobamate. Meprobamate is excreted in breast milk.

Tolerance

Animal studies suggest that chronic use of meprobamate causes tolerance to the behavioral effects of meprobamate, similar to other sedative hypnotic drugs.[17]

Drug Interactions

Sedative-hypnotics, antipsychotics, opioids, and ethanol synergistically increase the central nervous system depressant effects of meprobamate. Chronic induction of hepatic CYP450 isoenzymes (e.g., ethanolism) reduces the serum half-life of meprobamate by increasing meprobamate elimination,[18] whereas acute administration of ethanol decreases the meprobamate metabolism.[19] In a study of 4 alcohol abusers and 4 nonabusers, the administration of ethanol for 1 month under metabolic ward conditions (i.e., up to 46% of the caloric intake) reduced the mean serum half-life of meprobamate for these 2 groups from 16.7 ± 2.5 hours to 8.1 ± 1.5 hours and 13.7 ± 1.0 hour to 8.2 ± 0.3 hour, respectively.[20] The administration of meprobamate to patients with acute porphyria is contraindicated because meprobamate increases the concentration of *S*-aminolevulinic acid.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Meprobamate is a CNS depressant that inhibits spinal reflexes and produces limited muscle relaxation. Following the ingestion of high dose of meprobamate, depressed cardiac contractility and slightly reduces systemic vascular resistance may cause hypotension, typically before respiratory depression.[21] An echocardiographic study of hypotensive patients during meprobamate intoxication demonstrated hypokinesis of the heart manifest by a low cardiac index and increased diastolic filling pressures (dilated inferior vena cava).[22] The mechanism of cardiac toxicity during meprobamate poisoning remains unclear. Postmortem findings following fatal meprobamate intoxication are nonspecific (i.e., pulmonary edema, visceral congestion).[11]

CLINICAL RESPONSE

Adverse effects associated with the medical use of meprobamate include drowsiness, headache, weakness, paresthesias, blurred vision, and GI upset.

Overdose

Meprobamate produces a clinical picture of CNS depression that is similar to those of other sedative-hypnotic drugs including phenobarbital. Symptoms range from nystagmus, dysarthria, ataxia, and confusion to deep coma, hypotension, apnea, and pulmonary edema. Serious complications of meprobamate overdose include profound hypotension, shock, hypothermia, and respiratory failure. Because of depressed myocardial contractility during meprobamate intoxication, cardiogenic pulmonary edema may develop, particularly following the administration of substantial amounts of IV fluids.[23] In a review 57 meprobamate overdoses from the files of a clinical laboratory, the most common physical signs associated with meprobamate intoxication were dysarthria (21%) and hypotension (18%) followed by tachycardia, ataxia, miosis and mydriasis, nystagmus, respiratory depression, hallucination, seizures, dysconjugate gaze, and hypothermia.[16] Fluctuating levels of consciousness may result from the delayed release of meprobamate from concretions in the stomach; sudden deterioration may occur after initial improvement because of the release of meprobamate from these concretions. Hypotension usually correlates to the depth of coma, but occasionally hypotension develops during the lighter stages of coma. Convulsions are more common in the recovery phase of meprobamate overdose compared with other sedative-hypnotic drug overdoses.

Abstinence Syndrome

Case reports suggest that the chronic use of high meprobamate doses causes withdrawal symptoms following the abrupt cessation of use. The clinical features of meprobamate withdrawal are similar to barbiturate withdrawal, particularly when the daily dose of meprobamate ranges from 3–6 g. Signs of withdrawal of patients ingesting high doses of meprobamate include insomnia, nausea, vomiting, tremors, anxiety, muscle twitching, headache, ataxia, delirium, and seizures.[24] The abstinence syndrome is much less common in patients ingesting daily meprobamate doses below 1.6 g; however, a 50-year-old man chronically using meprobamate (i.e., estimated 1,200 mg meprobamate daily for 3 years) developed hypertension, sweating, agitation, incoherent behavior, and hallucinations in the hospital 4 days after cessation of use.[25] Although fatalities can occur during meprobamate withdrawal, the contribution of meprobamate withdrawal to these deaths is not well-defined.[26]

Reproductive Abnormalities

There are few data on the effect of meprobamate on human reproduction, and there is no definite evidence that meprobamate use during pregnancy is teratogenic.

An epidemiologic study of 1,870 children of mothers using meprobamate during pregnancy did not detect an increased incidence of fetal demise or abnormalities in these children up to the age of 4 years.[27] In a case series of 42 infants born to mothers ingesting an overdose of meprobamate during pregnancy, 7 infants had congenital abnormalities compared with 4 congenital abnormalities in matched siblings (OR = 1.7; 95% CI: 0.5–4.9).[28] Of the 14 mothers ingesting an overdose of meprobamate during the first trimester, 2 infants had minor congenital abnormalities (undescended testes, congenital hip dysplasia).

DIAGNOSTIC TESTING

Analytic Methods

Analytic methods for the determination of meprobamate concentrations in biologic fluids include thin layer chromatography,[29] liquid chromatography/tandem mass spectrometry with [^{13}C-^{2}H$_3$]-meprobamate as the internal standard,[30] gas chromatography with liquid-liquid[31] or liquid-solid extraction,[32] and gas chromatography with electron impact mass spectrometry.[33] The limit of detection (LOD) for meprobamate using gas chromatography with flame ionization detection or liquid chromatography/tandem mass spectrometry is approximately 1 mg/L.[30,34] For gas chromatography/mass spectrometry with carisoprodol as the internal standard, the LOD and lower limit of quantitation (LLOQ) for meprobamate are 0.58 mg/L and 1.93 mg/L, respectively.[35] Meprobamate is unstable at high temperatures and displays no useful UV spectrum.

Biomarkers

A study of healthy volunteers receiving single therapeutic doses of meprobamate (400 mg, 800 mg, 1,200 mg) indicated that meprobamate is detectable in hair samples beginning about 4–5 days after ingestion with peak concentrations occurring about 7–9 days after exposure.[36] Meprobamate was not detectable in most hair samples 2 weeks after exposure. There are inadequate data to determine the dose and time of ingestion based on meprobamate concentrations in hair samples. Bile is an alternative postmortem sampling site with meprobamate concentrations exceeding 53 mg/L consistent with potentially fatal overdoses.[37]

BLOOD

OVERDOSE. Serum meprobamate concentrations do not always correlate to clinical effects because of the presence of other drugs, tolerance, underlying medical disease, and individual variability. Therapeutic serum concentrations of meprobamate range from approximately 10–20 mg/L with toxic effects occurring in nontolerant individuals when the serum meprobamate concentration approaches 30–50 mg/L. Serum meprobamate concentrations in the range of 80–120 mg/L are associated with significant alteration of consciousness, whereas serum meprobamate concentrations in the range of 150–200 mg/L produce deep coma and hemodynamic instability. Although the level of consciousness does not always correlate to the serum meprobamate concentration,[16] most patients regain consciousness when the meprobamate concentration decreases below 50 mg/L. A 2-year-old child was unconscious, responding only to painful stimuli after ingesting meprobamate tablets that produced a peak plasma meprobamate concentration of 170 mg/L.[38] The patient regained consciousness when the plasma meprobamate concentration was 144 mg/L. The serum meprobamate concentration helps guide management, but these concentrations must be interpreted along with clinical features because of a variety of factors affecting response including tolerance. For example, a serum meprobamate concentration of 67 mg/L was associated with lethargy and responsiveness to verbal stimuli in a nontolerant individual, whereas a tolerant individual was alert when his serum meprobamate concentration was 82 mg/L as measured by a spectrophotometric method that did not include meprobamate metabolites.[39]

POSTMORTEM. Analysis of postmortem blood samples for cases involving meprobamate often demonstrates the presence of other drugs, particularly ethanol. In a series of 19 cases demonstrating meprobamate in postmortem blood samples, the mean whole blood meprobamate concentrations was 182 mg/L with a range of 41–397 mg/L.[40] Only 2 cases involved *only* meprobamate (68 mg/L, 168 mg/L) as measured by gas chromatography/mass spectrometry with solid phase extraction. In a case series of 12 fatalities involving only meprobamate intoxication, the meprobamate concentrations in postmortem blood samples ranged from 142–342 mg/L (mean, 226 mg/L) as measured by colorimetry.[41] In blood samples from 10 fatalities involving both meprobamate and ethanol, the blood meprobamate concentration ranged from 43–155 mg/L with a mean of 117 mg/L.

Abnormalities

The development of cardiac dysrhythmias and bradycardia are rare during meprobamate intoxication.

Driving

There are limited data on the effect of meprobamate on driving skills. Based on the pharmacologic similarity of meprobamate and barbiturates, the ingestion of substantial doses of meprobamate would be expected to impair coordination and slow reaction times. In a study of drivers arrested for driving under the influence with only carisoprodol/meprobamate present in blood samples, inappropriate driving behaviors included weaving, driving slowly, swerving, erratic lane changes, and impacts with both stationary and moving objects.[42] Meprobamate is a metabolite of the muscle relaxant, carisoprodol.

TREATMENT

Stabilization

Similar to other sedative-hypnotic overdoses, stabilization requires careful evaluation of the level of consciousness, oxygenation (pulse oximetry, arterial blood gases), and hemodynamic stability (rhythm, blood pressure). Hypotension may occur with minimal alteration of consciousness, but fluid overload must be avoided because of the depressant effects of meprobamate on myocardial contractility. Vasopressors are a therapeutic option for patients unresponsive to initial fluid replacement (i.e., 2 L of normal saline); however, hemodynamic monitoring (e.g., Swan-Ganz catheter, echocardiography) may be necessary to guide the management of fluids and vasopressors, particularly in the presence of hypotension and hypokinesis of the heart (reduced left ventricular ejection fraction, cardiac index). Case reports of severe meprobamate intoxication monitored by Swan-Ganz catheter indicate that severe meprobamate intoxication produces myocardial depression and vasodilation rather than noncardiac pulmonary edema.[43]

Gut Decontamination

The administration of activated charcoal is appropriate for patients with meprobamate overdose presenting <1–2 hours after ingestion. However, most patients present to a health care facility >1–2 hours after meprobamate ingestion, and these patients frequently require no gut contamination measures as a result of the lack of clinical data to support the use of aggressive decontamination measures. Theoretically, the administration of activated charcoal more than 1–2 hours after ingestion can decrease meprobamate absorption in comatose patients with decreased GI motility, but there are inadequate data to indicate that the administration

of activated charcoal at this time improves clinical outcome. Gastric lavage in comatose patients is a therapeutic option, particularly when delayed gastric emptying and the formation of drug concretions are suspected. However, there are few data on the efficacy of gastric lavage in meprobamate overdose. Syrup of ipecac is not recommended because of the potential for aspiration and the lack of efficacy. Fluctuating vital signs or level of consciousness suggests the presence of co-ingestants or continued meprobamate absorption from drug concretions and therefore, the need for endoscopy.[44]

Elimination Enhancement

There are few clinical data to compare the clinical outcome of various methods of enhancing the elimination of meprobamate during overdose. Case reports indicate that the use of hemoperfusion substantially increases the clearance of meprobamate from the blood. In a series of 4 cases of severe meprobamate intoxication treated with hemoperfusion, the renal clearance of meprobamate ranged from about 150–220 mL/min with the clearance slightly higher for resin cartridges compared with charcoal cartridges.[45,46,47] Hemodialysis also increases the clearance of meprobamate, but the clearance rates are several times less than the clearance rates during hemoperfusion. In a patient with hypotension, coma, and respiratory failure after a meprobamate overdose (serum meprobamate concentration, 500 mg/L), the clearance rate for meprobamate during hemodialysis was about 62 ± 10 mL/min.[9] Continuous arteriovenous hemoperfusion (CAVHP) with coated activated charcoal is an alternative to hemoperfusion and hemodialysis that does not require a pump. The technique of CAVHP is similar to arteriovenous hemofiltration with the exception that a carbon cartridge replaces the hemofilter. Case reports indicate that despite low mean arterial blood pressure (i.e., about 50 mm Hg), CAVHP can achieve meprobamate clearance rates of about 50 mL/min.[48] Following hemodynamic stabilization, the clearance rates of CAVHP are similar (i.e., 170–210 mL/min) to the clearance achieved by charcoal or resin hemoperfusion. Unaided renal clearance of meprobamate is approximately 5–30 mL/min. Factors involved with the decision to use methods to enhance meprobamate elimination include lack of response to supportive care and massive meprobamate ingestion (30–40 g) or serum meprobamate concentrations of 100–200 mg/L with hemodynamic instability.

A case report suggests that the use of serial activated charcoal (50 g every 6 hours for 5 doses) reduces the serum half-life of meprobamate during mild to moderate meprobamate intoxication, but there are inadequate

kinetic and clinical data to verify the efficacy of serial activated charcoal during meprobamate intoxication.[49] The relatively small volume of distribution suggests that rebound increases in blood meprobamate concentrations following the use of measures to enhance elimination are unlikely, and the presence of such increases suggests the presence of continuing meprobamate absorption (i.e., bezoar). Forced diuresis is contraindicated during meprobamate intoxication because of the propensity of meprobamate toxicity to cause pulmonary edema. Peritoneal dialysis is much less effective than hemodialysis.

Antidotes

There is no antidote.

Supplemental Care

Baseline laboratory tests for severe meprobamate ingestion include a complete blood count, serum electrolytes, glucose, creatinine, chest x-ray, and arterial blood gases. Frequent vital signs are necessary during the initial stages of meprobamate intoxication because of the occurrence of hypotension during the early stages of coma. Fluctuating vital signs or coma may indicate a drug mass and gastroscopy should be considered. Pulmonary complications of meprobamate intoxication include pulmonary edema and aspiration pneumonia. Chronic meprobamate users may develop an abstinence syndrome 1–4 days after the cessation of meprobamate use.

Chapter 27

METHAQUALONE and RELATED COMPOUNDS

METHAQUALONE

HISTORY

Methaqualone originally was developed during the investigation of antimalarial drugs in India during the early 1950s.[1] The first experimental studies of the hypnotic properties of methaqualone began in 1956,[2] and the first controlled clinical trials comparing methaqualone with barbiturate hypnotic drugs were published in 1961.[3] In 1959, methaqualone was introduced in Japan as a nonprescription drug; the following year, this drug was introduced in the British market as an alternative to barbiturate sedative hypnotic drugs.[4] Methaqualone abuse and an associated abstinence syndrome (delirium, seizures) was first reported in Japan soon after the introduction of this drug.[5] In 1965, Rohrer introduced methaqualone into the United States market as a Drug Enforcement Administration (DEA) schedule V drug (i.e., unlimited prescription refills) under the brand name Quaalude™. Methaqualone was marketed as a safe hypnotic drug with low abuse potential, rapid onset of sleep induction, and few adverse effects. However, methaqualone quickly gained popularity as a "street aphrodisiac." By the early 1970s, methaqualone was recognized as major drug of abuse, particularly on college campuses in combination with ethanol ("luding out").[6] The United Nations listed methaqualone under the UN Convention on Psychotropic Substances, leading to the banning of methaqualone in most member countries. Methaqualone use in the United Kingdom was restricted by the British Drug Prevention of Misuse Act in 1971. The DEA reclassified this drug as a schedule I drug in 1975. Subsequently, the legal production of methaqualone ceased in the United States. The oral abuse of methaqualone decreased in Western countries since the late 1980s; however, illicit production of methaqualone continues, particularly in South Africa where smoking methaqualone is a popular form of drug abuse.[7]

IDENTIFYING CHARACTERISTICS

Methaqualone is a structurally unique sedative-hypnotic drug (Fig. 27.1), being a 2,3-bisubstituted quinazalone [CAS RN: 72-44-6, 2-methyl-3-o-tolyl-4-(3H)-quinazolinone]. This drug is a slightly water soluble, highly lipophilic, weak acid with a pKa of 2.4. Table 27.1 lists some physiochemical properties of methaqualone. Street names for methaqualone include Wallbanger, Quads, Ludes, Sopers, Mandies, Dr. Jekyll and Mr. Hyde Drug, Love Drug, and Soapers. Trade names for methaqualone include Quaaludes, Sopor, Mequin, and Mandrax (methaqualone and diphenhydramine). A case report associated a severe necrotizing cystitis manifest by dysuria, frequency, and suprapubic pain with contamination of illicit methaqualone by o-toluidine during the clandestine production of methaqualone.[8]

EXPOSURE

Although legal production of methaqualone ceased in the United States, the American Association of Poison Control Centers' National Poison Data System Annual Report listed 4 exposures and no fatalities associated with the use of methaqualone in 2009.[9]

Water Solubility	4.730 mg/L (25°C/77°F)
Vapor Pressure	1.16E-07 mm Hg (25°C/77°F)

Sources

Methaqualone is a sedative-hypnotic drug that has been banned in most countries as a result of the abuse potential of this drug. However, illicit production of methaqualone continues in the Middle East, south and central Asia, southern Africa, and particularly in South Africa. Clandestine laboratories synthesize methaqualone and methyl derivatives of methaqualone.[10] Methods of illicit methaqualone synthesis involve 1) preparation of *N*-acetyl anthranilic acid from anthranilic acid and acetic anhydride followed by condensation with *o*-toluidine to form methaqualone with phosphorus trichloride as a dehydrating agent, and 2) refluxing anthranilic acid, *o*-toluidine, and acetic acid (or acetic anhydride) with polyphosphoric acid as a dehydrating agent. The presence of 2-methyl-3-(*o*-carboxyphenyl)-4-quinazolinone indicates the former synthetic process, whereas the presence of *o*-methyl acetanilide indicates the use of the latter synthetic process. Other less common synthetic processes include the cyclization of *o*-acylamino (*N*-substituted) benzamide compounds.[11] Despite the synthesis of numerous quinazolinone derivatives of methaqualone for CNS depressant and anticonvulsant properties, no currently used anticonvulsant contains the 4(3H)-quinazolinone ring system.[12] Previous pharmaceutic formulations of methaqualone included methaqualone base (150-mg and 300-mg tablets), methaqualone hydrochloride (200-mg and 400-mg capsules), and combination tablets (e.g., Mandrax, 250 mg methaqualone, 25 mg diphenhydramine).

Methods to identify routes of illicit methaqualone synthesis include analysis of precursors and by-products by gas chromatography/mass spectrometry and infrared/nuclear magnetic resonance.[13,14] Both the licit and illicit manufacturing of methaqualone produce similar isomers; therefore, analysis of methaqualone enantiomers does not help determine the origin of an illicit methaqualone sample.

Methods of Abuse

The ingestion of 300–450 mg methaqualone with wine (luding out) previously was a popular college pastime. Common methods of methaqualone abuse in South Africa involve smoking a mixture of crushed methaqualone tablets and cannabis called *witpyp* or white pipe, usually in a male-dominated, communal setting.[15,16] Desired effects of methaqualone abuse include euphoria, diminished proprioception, a sense of well-being, ataxia, paresthesias, reduced inhibitions, and increased libido. The popularity of methaqualone as an illicit drug results, in part, from the perception that methaqualone enhances intimate and interpersonal relations through reduction of inhibitions. In a questionnaire of recruited methaqualone users, the percentage of respondents reporting increased libido, enhanced body sensations, paraesthesias, and desire for sexual intercourse was substantially higher than the percentage of respondents expecting these effects prior to drug use.[17] Almost all of these respondents used marijuana concurrently with methaqualone and about one-half ingested alcohol with the methaqualone. Approximately 52% of these respondents were students. Comparative trials indicate that methaqualone produces more euphoria and less sedation compared with benzodiazepines (e.g., lorazepam, alprazolam, diazepam).[18]

DOSE EFFECT

In volunteer studies, the ingestion of 200 mg methaqualone is associated with euphoria and sedation.[19] Typical "street" doses of methaqualone associated with euphoria, paraesthesias, and relaxation range from about 150–500 mg. Chronic methaqualone abusers may use up to 2 g methaqualone daily. Methaqualone doses ranging from 500–1,000 mg cause dizziness, gastrointestinal distress (GI), ataxia, anxiety, and fatigue, whereas methaqualone doses between 1,000–2,000 mg produce increased hyperreflexia and myoclonus. Ingestion of >2 g methaqualone causes serious central nervous system (CNS) toxicity. A 23-year-old man was somnolent and poorly responsive to painful stimuli 2 days after

ingesting an estimated 4–5 g methaqualone during a suicide attempt.[20] Within 2 days, he became comatose with respiratory failure secondary to noncardiogenic pulmonary edema. He recovered completely after 6 days of intubation and ventilatory support. Estimation of the fatal dose of methaqualone is complicated by various factors including tolerance, concomitant drug ingestion, baseline health of the patient, and reporting bias. Although case reports associate death with the ingestion of 8–20 g methaqualone, survival can occur with intensive supportive care following the ingestion of methaqualone doses in the range of 20–25 g.

TOXICOKINETICS

Absorption

The GI tract rapidly adsorbs therapeutic doses of methaqualone with peak methaqualone concentrations occurring about 1–2 hours after ingestion.[21,22] In a study of 7 healthy volunteers administered 300 mg methaqualone, the average peak plasma methaqualone concentration was about 3 mg/L 2 hours after ingestion as measured by gas chromatography with flame ionization detection.[23] Ingestion of 450 mg methaqualone/hour for 4 doses produced a peak serum methaqualone concentration of 9 mg/L 3 hours after administration of the last dose.[24] Based on neuropsychologic testing of healthy volunteers, the maximum effect of methaqualone occurs before peak methaqualone concentrations and the duration of action is <4 hours despite persistent plasma methaqualone concentrations.[25] Ethanol does not significantly delay methaqualone absorption in human volunteers.

Distribution

Methaqualone is highly lipophilic with a large volume of distribution (2.4–6.4 L/kg). The initial distribution phase into peripheral tissues is relatively rapid with an initial distribution half-life of 2–4 hours. Methaqualone is highly protein bound (75–90%).[26]

Biotransformation

Methaqualone undergoes metabolism in the liver to *N*-oxide and hydroxylated metabolites.[27] There is substantial interindividual variability in *C*-oxidation by P450 cytochrome isoenzymes and the formation of hydroxylated metabolites of methaqualone that are subsequently excreted in the urine as glucuronide conjugates.[28,29] Volunteer studies indicate that extensive biotransformation by CYP450 isoenzymes produce at least 5 major hydroxylated metabolites (2′-hydroxy-methaqualone, 3′-hydroxymethaqualone, 4′-hydroxy-methaqualone, 6′-hydroxymethaqualone, and 2-hydroxymethaqualone) as demonstrated in Figure 27.2. Although the specific isoenzymes involved with the biotransformation of methaqualone have not been identified, CYP2D6 and CYP2C19 isoenzymes are probably not involved in this metabolic process.[30] The hydroxylated metabolites are inactive. Dihydroxy, dihydrodiols, and hydroxymethoxy derivatives of methaqualone probably are minor metabolites.

Elimination

The kidney excretes <1–3% of an absorbed dose of methaqualone unchanged in the urine. Most of the methaqualone metabolites appear in the urine as glucuronide conjugates.[31] The terminal elimination following single therapeutic doses of methaqualone is relatively long (i.e., 20–40 hours).[32] In a study of 7 healthy men (mean age, 36 years), the elimination of methaqualone from the plasma was biphasic with an initial and terminal mean plasma elimination half-life of 0.9 hours and 16 hours, respectively.[33]

Maternal and Fetal Kinetics

In rodents, methaqualone crosses the placenta; 1.5 hours after maternal ingestion, the methaqualone concentration in fetal brain and liver is lower than corresponding maternal tissue.[34] The renal clearances of some drugs increase during the third trimester of pregnancy as a result of increased renal blood flow and glomerular filtration rates. In a convenience sample of 10 pregnant women in the third trimester of pregnancy, the mean half-life of methaqualone was 4.36 ± 0.84 hours compared with 6.18 ± 0.92 hours in 13 nonpregnant women.[35]

Tolerance

Animal studies indicate that tolerance develops in rodents after daily administration of methaqualone. The daily intraperitoneal administration of 30 mg methaqualone to female rats produced tolerance to the effects of methaqualone on the Rotorod test as well as cross-tolerance to the effects of phenobarbital.[36] Tolerance to methaqualone also occurs in observational studies of polydrug users, but the degree of tolerance is not well-defined in these studies.[37]

Drug Interactions

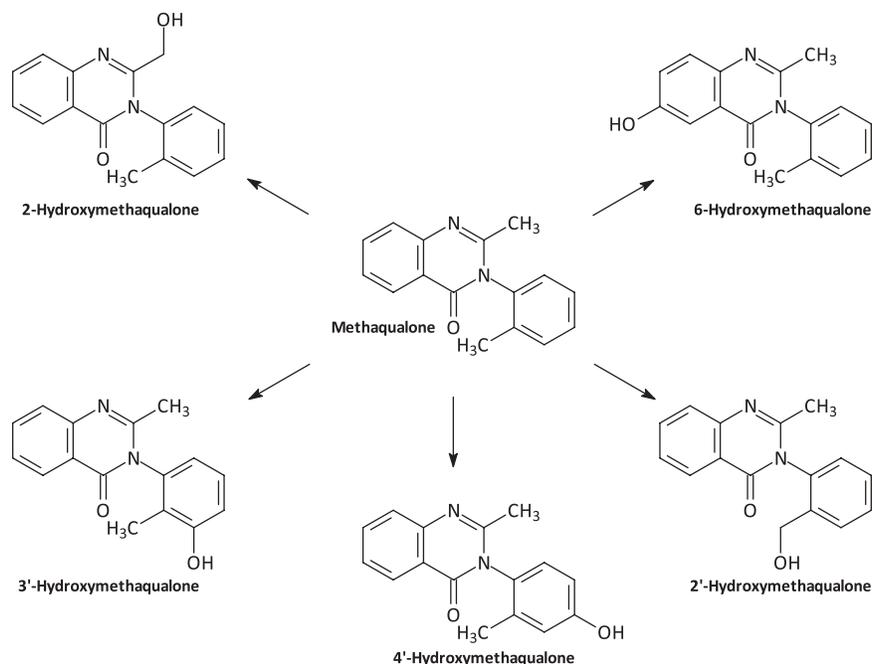
In vitro studies indicate that administration of diphenhydramine with methaqualone produces a dose-related inhibition of methaqualone metabolism.[38] The combina-


FIGURE 27.2. Major hydroxylated metabolites of methaqualone.[59]

tion of methaqualone and diphenhydramine is a frequently abused drug combination. Ethanol consumption slightly increases blood methaqualone concentrations during elimination and methaqualone produces relatively greater impairment of cognitive and psychomotor tasks when combined with ethanol.[39]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Methaqualone is a sedative-hypnotic drug with euphoriant properties.[4] In contrast to hyporeflexia and muscular depression associated with other sedative-hypnotic drugs, high doses of methaqualone produce selective depression of polysynaptic spinal reflexes with subsequent hypertonia and muscle hyperactivity. Hypotension usually results from myocardial depression. Although hypotension and respiratory insufficiency occurs during serious methaqualone intoxication, the occurrence of hypotension and respiratory insufficiency is relatively less common during methaqualone intoxication compared with most other older sedative-hypnotic overdoses. Pulmonary edema is usually noncardiogenic, resulting from increased capillary permeability. *In vitro* studies of animal and human platelets indicate that methaqualone significantly inhibits the primary phase of adenosine diphosphate (ADP)-induced aggregation as well as platelet adhesiveness.[40] The ingestion of toxic

methaqualone doses also increases the propensity for spontaneous hemorrhage by prolongation of the prothrombin and partial thromboplastin times and reduction in factors V and VII.

CLINICAL RESPONSE

Dermatologic effects associated with the medicinal use of methaqualone include fixed drug eruption, diaphoresis, erythema multiforme, bromhidrosis, and urticaria.[41]

Illicit Use

Ingestion of "street" doses of methaqualone (i.e., 150–500 mg) classically produces euphoria with marked paresthesias followed by a period of deep relaxation. Sleep usually follows the initial period of euphoria. The ingestion of higher doses of methaqualone causes GI distress (nausea, vomiting, diarrhea), dry mouth, lightheadedness, anxiety, restlessness, loss of coordination, blurred vision, fatigue, myoclonus, and painful hyperacusis.

Overdose

Methaqualone is a CNS depressant, which produces toxic effects ranging from GI distress, drowsiness, ataxia, slurred speech, and paresthesias to agitation, convulsions, and coma. Mild methaqualone intoxication

507

produces clinical features similar to barbiturate intoxication including blurred vision, loss of coordination, nystagmus, dilated pupils, salivation, and mild CNS depression. More serious complications of methaqualone overdose include delirium, coma, respiratory depression, increased risk of aspiration with salivation and spontaneous vomiting, seizures, and prominent pyramidal signs (myoclonus, hyperreflexia, hypertonicity). In contrast to most of the older sedative-hypnotic drugs, increased muscle tone frequently occurs during severe methaqualone intoxication,[42] and muscular hyperactivity may be severe enough to require paralytic agents and respiratory support.[43] Although tachycardia is a common feature of methaqualone intoxication, cardiovascular collapse is uncommon except following very large ingestions of methaqualone. Hypotension occurs less commonly in comatose patients compared with other older sedative-hypnotics drugs.[44] The ingestion of large doses (i.e., 4–5 g) of methaqualone can produce respiratory failure and noncardiogenic pulmonary edema several days after ingestion.[20] Spontaneous bleeding (e.g., subconjunctival hemorrhage, retinal hemorrhage, GI hemorrhage) may develop during severe methaqualone intoxication as a result of thrombocytopenia and hypoprothrombinemia.[44,45] Skin lesions developing during serious methaqualone poisoning include bullae, purpura, and petechiae.

Abstinence Syndrome

The methaqualone withdrawal syndrome resembles the clinical features of ethanol and barbiturate withdrawal. Case reports indicate that the daily ingestion of 1.5–2 g methaqualone for several months produces withdrawal symptoms within 1–5 days after cessation of methaqualone use. The most common features of methaqualone withdrawal include headache, tremulousness, anorexia, nausea, vomiting, abdominal pain, and insomnia.[46] Other clinical effects of the abstinence syndrome range from restlessness, confusion, and hyperreflexia to visual hallucination, seizures, and delirium.[47] Brief muscle twitches, sudden diffuse muscle jerks, and tonic-clonic seizures developed in a 20-year-old woman 5 days after stopping the daily ingestion of 300 mg methaqualone.[48]

Reproductive Abnormalities

There are few data on reproductive abnormalities in pregnant women ingesting methaqualone. In rodent studies, fetal abnormalities occur at methaqualone doses (e.g., >25 mg/kg/d) that cause maternal toxicity.[49]

DIAGNOSTIC TESTING

Analytic Methods

Methods for the determination of methaqualone concentrations include immunoassays, ultraviolet (UV) spectrophotometry, gas chromatography with flame ionization, nitrogen phosphorus or electron capture detection, and gas chromatography/mass spectrometry (GC/MS).[50] The limit of detection (LOD) for gas chromatography with nitrogen phosphorus detection is near 0.020 mg/L,[51] whereas the lower limit of quantitation (LLOQ) for GC/MS ranges from about 0.050–0.100 mg/L.[52] Under some gas chromatographic conditions, thermal conversion of the methaqualone-N-oxide metabolite, which represents about 5–9% of methaqualone metabolites, increases the apparent concentration of methaqualone.[53] Gas chromatography/mass spectrometry effectively separates the structurally similar methaqualone compounds (nitromethaqualone, mecloqualone) from methaqualone.[54] Ultraviolet spectrophotometry does not separate unchanged methaqualone from metabolites; therefore, this method measures total methaqualone (methaqualone plus metabolites).[55]

Biomarkers

BLOOD

Interpretation of the serum methaqualone concentrations requires careful evaluation of the clinical setting and the physical evidence of intoxication. Blood methaqualone concentrations do not correlate well to the clinical response because of the presence of tolerance, concomitant ingestion of other respiratory depressant drugs, and the time since drug ingestion.[56] Deep coma and respiratory failure may occur in patients following large ingestions of methaqualone despite the presence of relatively low serum methaqualone concentrations and high concentrations of metabolites.[20] The therapeutic range of methaqualone is 1–5 mg/L. In a study of 7 healthy men receiving 300 mg methaqualone hydrochloride, the mean peak plasma methaqualone concentration was 2.12 ± 0.44 mg/L 3 hours after ingestion.[33] Toxicity is associated with methaqualone concentrations exceeding 10–30 mg/L. In a retrospective review of 60 cases of methaqualone intoxication, serum methaqualone concentrations associated with CNS depression exceeded 9 mg/L.[57] Serious intoxication can occur when the serum methaqualone concentrations exceeds 25–30 mg/L, particularly at serum methaqualone concentration >80 mg/L. There are few data on the methaqualone concentrations in postmortem blood samples

from individuals dying of methaqualone toxicity. Analysis of postmortem blood samples from a 62-year-old man found dead after a massive, intentional ingestion of toquilone compositum (methaqualone and diphenhydramine) demonstrated a methaqualone concentration of 800 mg/L.[58]

URINE

The Roche Abuscreen ONLINE™ (Roche Diagnostics, Indianapolis, IN) and the Syva EMIT II™ (Syva Co., San Jose, CA) are sensitive methods for the detection of methaqualone in the urine.[59] Because of the minimal excretion of unchanged methaqualone in the urine, the sensitivity of these immunoassays depends on the high cross-reactivity of the reagents for the conjugated metabolites of methaqualone.

Abnormalities

Laboratory abnormalities associated with methaqualone intoxication include thrombocytopenia, prolonged prothrombin time/international normalized ratio, and transient elevation of serum hepatic aminotransferases. Nonspecific ST-T wave changes and sinus tachycardia are the most common electrocardiographic changes seen during methaqualone intoxication; serious cardiac abnormalities are rare.[42]

Driving

There are limited data on the effects of methaqualone on driving skills. Analyses of blood samples submitted by law enforcement officers for suspected driving under the influence in Switzerland indicate that the use of methaqualone by impaired drivers is relatively uncommon (i.e., <5%).[60] Ingestion of methaqualone can produce sedation, loss of motor coordination, and slowing of motor responses. A double-blind study of healthy volunteers ingesting an evening dose of 250 mg methaqualone and 25 mg diphenhydramine did not detect decrements in psychomotor performance (i.e., choice reaction time, coordination test, divided attention task) when tested the following morning.[61] In a series of 536 drivers arrested for driving under the influence and testing positive only for methaqualone, the median blood methaqualone concentration was about 4 mg/L with a range of 1–9 mg/L as measured by analytic methods that excluded methaqualone metabolites.[62] Blood methaqualone concentrations above 2 mg/L were frequently associated with obvious intoxication (i.e., staggering, drowsiness, and slurred speech). Methaqualone was detected in 3 of 440 (<1%) blood samples drawn from Swiss drivers arrested for suspected driving while impaired (50 of the 440 blood samples contained no detectable drugs).[63] The methaqualone concentrations ranged from 0.15–2.36 mg/L.

TREATMENT

Stabilization

As for all sedative-hypnotic overdoses, stabilization requires careful evaluation of the level of consciousness and the adequacy of respirations. Patients with methaqualone intoxication frequently have a sinus tachycardia, but hypotension is relatively rare. Seizures may occur during withdrawal from methaqualone along with restlessness, agitation, and delirium. All patients with altered levels of consciousness should be evaluated rapidly for serum glucose concentrations and hypoxia (e.g., pulse oximetry).

Gut Decontamination

The administration of activated charcoal is appropriate for patients with methaqualone overdose presenting <1–2 hours after ingestion. However, most patients present to a health care facility >1–2 hours after methaqualone ingestion, and these patients frequently require no gut contamination measures as a result of the lack of clinical data to support the use of aggressive decontamination measures. Theoretically, the administration of activated charcoal more than 1–2 hours after ingestion can decrease methaqualone absorption in comatose patients with decreased GI motility, but there are inadequate data to indicate that the administration of activate charcoal at this time improves clinical outcome. Syrup of ipecac is not recommended because of the potential for aspiration and the lack of demonstrated efficacy.

Elimination Enhancement

Case reports indicate that hemodialysis reduces plasma methaqualone concentrations, but there are few data on the effect of hemodialysis on clinical outcome during methaqualone intoxication. Hemodialysis produces mean methaqualone clearance of approximately 29 mL/min during severe methaqualone intoxication, whereas the mean clearance during peritoneal dialysis was substantially lower (i.e., about 7 mL/min).[64] The clearance of methaqualone is superior following hemoperfusion (e.g., 179 mL/min) compared with hemodialysis (e.g.,

29 mL/min), but clinical response is limited perhaps because of the large volume of distribution, high protein binding, and large tissue stores of methaqualone during methaqualone intoxication. Blood methaqualone levels >40 mg/L suggest the need for hemoperfusion. Forced diuresis is contraindicated because of the propensity of methaqualone to cause pulmonary edema.

Antidotes

There is no antidote.

Supplemental Care

Most methaqualone overdoses require only supportive care. Baseline laboratory tests for severe methaqualone poisoning include a complete blood count, platelets, prothrombin time, electrolytes, glucose, creatinine, liver function tests, pulse oximetry, and an electrocardiogram. Patients with moderate to severe methaqualone overdoses require observation for the development of aspiration pneumonia and pulmonary edema. Because of the association of thrombocytopenia and reduced prothrombin times following methaqualone overdoses, these patients also should be observed for the development of spontaneous hemorrhage (e.g., GI, retinal). The treatment for persistent hemorrhage during methaqualone intoxication includes platelet packs, vitamin K, and fresh-frozen plasma as indicated by diagnostic testing. Muscular hyperactivity may require muscle relaxants (e.g., diazepam, lorazepam), but these patients should be carefully observed for the development of respiratory depression. Withdrawal symptoms may develop 1–5 days after cessation of methaqualone use. There are inadequate clinical data on specific therapeutic options for the treatment of methaqualone addiction; typically, benzodiazepines (e.g., diazepam) are first-line drugs used for the treatment of methaqualone dependence.[65]

MECLOQUALONE

Mecloqualone (CAS RN: 340-57-8, 2-methyl-3-ortho-chlorophenyl-4(3H)-quinazolinone) is a chlorinated homologue of methaqualone; mecloqualone is also a drug of abuse. The DEA lists both methaqualone and mecloqualone (Nubarene) as schedule I drugs. Clandestine laboratories synthesize mecloqualone and methyl derivatives of methaqualone as well as methaqualone.[66] Mecloqualone undergoes extensive bio-transformation, primarily by hydroxylation.[67] The major metabolite of mecloqualone in the urine is 3-(2-chloro-4-hydroxyphenyl)-2-methyl-4[3H]-quinazolinone. Minor metabolites include 3-(o-chlorophenyl)-2-(hydroxymethyl)-4[3H]-quinazolinone and 3-(o-chlorophenyl)-6-hydroxy-2-methyl-4[3H]-quinazolinone. Approximately one-half of the dose of mecloqualone is eliminated within 2 days and 80% within 5–6 days, primarily in the urine as conjugates.[68] The kidney excretes very small amounts (i.e., <2–3%) of unchanged mecloqualone in the urine. The molecular weight and lack of a strong anionic group suggest that mecloqualone has very limited enterohepatic recirculation. Analytic methods for the separation and detection of quinazolinone compounds include thin layer chromatography, gas liquid chromatography, nuclear magnetic resonance, and gas chromatography/mass spectrometry.[54,67] Ultraviolet spectra identify the quinazolinone nucleus, but UV spectroscopy is incapable of distinguishing between methaqualone, methaqualone metabolites, nitromethaqualone, or mecloqualone.

NITRO-METHAQUALONE

Nitromethaqualone [CAS RN: 340-52-3, 2-methyl-3-(2'-methoxy-4'-nitrophenyl)-4(3H)-quinazolinone] is a non-barbiturate hypnotic drug (Parnox®) introduced in Europe in 1967.[69] In a study of 2 healthy volunteers, peak plasma nitromethaqualone concentrations were 65 ng/mL at 2 hours and 135 ng/mL at 1.5 hours after the ingestion of 25 mg of this drug as measured by gas chromatography with electron capture detection.[70] Based on volunteer studies the most important unconjugated metabolite of nitromethaqualone biotransformation is 2-methyl-3-(2'-methoxy-4'aminophenyl)-4(3H)-quinazolinone as a result of the reduction of the nitro group to the corresponding amino derivative.[69] Excretion of this metabolite occurs partially in the acetylated form. o-Demethylation followed by reduction of the nitro group is a minor metabolic pathway in humans. Cleavage of the quinazolinone nucleus results in formation of 2-methoxy-4-nitroaniline. Volunteer studies indicate that biotransformation is the primary route of elimination with minimal excretion of unchanged nitromethaqualone in the urine.[69] This study suggests that extensive enterohepatic circulation results in the protracted excretion of nitromethaqualone metabolites. Analytic methods for quantitation of nitromethaqualone include gas chromatography with electron capture detection.[70]

Chapter 28

BUPRENORPHINE

HISTORY

Buprenorphine was first developed as an analgesic with low addiction potential based on animal studies and marketed under the trade name Temgesic® (Schering-Plough, Kenilworth, NJ). This drug was available as a pre-anesthetic medication and as an analgesic for moderate to severe pain in dosages of 0.2 mg. Since 1987, buprenorphine has been marketed in France as an analgesic. During the early 1980s in England and Australia, reports documented the intravenous (IV) abuse of analgesic preparations of buprenorphine,[1] while reports from Scotland documented the IV abuse of illegally diverted buprenorphine as a heroin substitute during the late 1980s, frequently in combination with benzodiazepines.[2] In 1996, a high-dose sublingual formulation under the trade name Subutex® (Reckitt-Benckiser, Slough, United Kingdom) became available in France for the treatment of opioid addiction. A buprenorphine transdermal delivery system was released in Europe during 2001 for the treatment of chronic pain at release rates of 35 µg/h, 52.5 µg/h, and 70 µg/h over 72 hours corresponding to daily buprenorphine doses of 0.8 mg, 1.2 mg, and 1.6 mg, respectively. The US Food & Drug Administration (FDA) approved the use of sublingual buprenorphine for the treatment of opioid addiction in 2002. Although buprenorphine is a relatively safe drug, case series soon associated fatalities with the illicit use of buprenorphine and benzodiazepines including the use of this combination in drug-facilitated sex crimes.[3,4] Abuse of buprenorphine preparations for the treatment of opioid dependence continues both in patients undergoing buprenorphine maintenance treatment and in untreated opioid addicts.[5]

IDENTIFYING CHARACTERISTICS

Buprenorphine is a highly lipid soluble, semisynthetic opioid (Fig. 28.1) that is derived from thebaine. The source of this latter alkaloid is the opium poppy, *Papaver somniferum* L. Buprenorphine is structurally related to morphine. In rodent antinociceptive assays (writhing, tail pressure), parenteral buprenorphine is about 25–40 times more potent than morphine, whereas oral buprenorphine is approximately 7–10 times more potent than morphine.[6] Buprenorphine is a partial agonist at µ-opioid receptors and a weak antagonist at κ-opioid receptors. The slow dissociation of buprenorphine from µ-opioid receptors results in a prolonged duration of action. Table 28.1 lists some physiochemical properties of buprenorphine.

EXPOSURE

Epidemiology

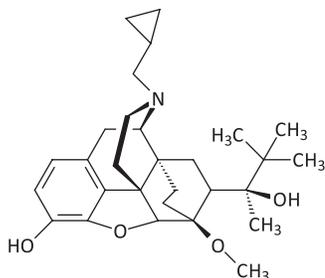
Both the intentional and accidental ingestion of buprenorphine has increased as the clinical use and availability of this drug has increased. In a review of all pediatric admissions (<18 years of age) to a Maine medical center from 1999 to 2009, the number of children admitted for buprenorphine toxicity tripled the last 5 years of the study compared with the first 5 years.[7] The admissions included 6 adolescents (3 suicidal ingestions, 3 recreational ingestions). Overall, the prevalence of abuse of sublingual buprenorphine is relatively low compared with methadone and heroin.[8] Although experimental use of buprenorphine occurs among polydrug users, the use of buprenorphine as a primary drug


FIGURE 28.1. Chemical structure of buprenorphine.

Property	Value
CAS Number	52485-79-7
Molecular Formula	$C_{29}H_{41}NO_4$
pKa	8.31
log P (Octanol-Water)	4.98
Water Solubility	0.636 mg/L (25°C/77°F)

of abuse is relatively uncommon depending on the population studied. In a study of >1,000 prescription opioid abusers, buprenorphine was the preferred drug of abuse in <3% of this convenience sample.[9] A cross-sectional survey of 343 French IV drug users attending community pharmacies, vending machines, and needle exchange programs to obtain equipment indicated that ~34% of the polydrug users occasionally injected buprenorphine, whereas ~24% injected only buprenorphine within the last 6 months.[10] A cross-sectional study of 404 individuals in a French buprenorphine maintenance therapy program indicated that about one-half of these opioid addicts had injected buprenorphine during their lifetime and about two-thirds of this group used illicit IV buprenorphine since joining the buprenorphine maintenance program.[11] In a field-recruited Australian cohort of 316 currently injecting drug users, 33 (10%) of the users reported the regular injection of buprenorphine, whereas 101 (32%) of this cohort reported the injection of buprenorphine within the preceding 3 months.[12] A survey of 350 needle exchangers reported the use of buprenorphine by 89% of injecting heroin abusers and 24% of injecting amphetamine abusers.[13] The reported use of buprenorphine by heroin addicts was primarily related to self-detoxification of the treatment of withdrawal, whereas the use of buprenorphine for euphoria was more common in IV amphetamine users.

Sources

Buprenorphine is synthesized from the opiate alkaloid, thebaine, during a 7-step process. In the United States,

buprenorphine is available in the following two sublingual preparations: (1) Subutex®—oval, white tablet in 2 mg (embossed B2) and 8 mg (embossed B8) dosages, and (2) Suboxone®— hexagonal orange tablet in 2 mg buprenorphine/0.5 mg naloxone (embossed N2) and 8 mg buprenorphine/2 mg naloxone (embossed N8) dosages. Because the bioavailability of oral naloxone is poor, the ingestion of the combination of buprenorphine and naloxone produces pharmacologic effects primarily related to buprenorphine. However, the injection of dissolved tablets of the buprenorphine/naloxone can cause opioid withdrawal symptoms.[14] Most abuse of buprenorphine results from the illicit diversion of pharmaceutic preparations of buprenorphine. Consequently, the abuse of buprenorphine typically involves relative pure preparations without significant contaminants or additives. Of the 33 individuals regularly using buprenorphine in an Australian study of currently injecting drug users, about two-thirds obtained their buprenorphine through prescription, and the remainder of this subgroup obtained this drug illicitly (i.e., friends, street purchase).[12] Another Australian study suggests that the prevalence of the diversion of buprenorphine sublingual preparations is higher than the diversion of liquid preparations of methadone.[15]

Methods of Abuse

Consistent with the μ-opioid receptor agonist properties of buprenorphine, this drug has abuse potential although this potential is relatively low compared with full μ-opioid agonists (e.g., heroin, methadone). Typically, the abuse of buprenorphine involves the IV injection of pharmaceutic preparations marketed for analgesia.[16] However, abuse also occurs as a result of the illicit diversion and IV use of buprenorphine during buprenorphine drug maintenance treatment programs. In an Australian study of currently injecting drug users, the primary abusers (i.e., 10% of the cohort) injected buprenorphine approximately 10 times per week as a less-expensive alternative to heroin.[12] The abuse of buprenorphine in opioid-dependent addicts participating in treatment programs is limited by the addition of naloxone to the buprenorphine. This combination produces withdrawal symptoms following the IV injection of the combination drug in some, but not all, addicts.[17,18] In a study of opioid-dependent volunteers, the intramuscular administration of up to 16 mg buprenorphine and 4 mg naloxone produced dose-related increases on indices of opioid antagonist effects consistent with naloxone-precipitated withdrawal that resolved relatively quickly;[14] the IV use of buprenorphine/naloxone combination is frequently associated with dysphoria ("bad experience") in contrast to the use of

buprenorphine alone.[19] Similar doses of sublingual buprenorphine and naloxone did not cause withdrawal symptoms. As a result of the relatively mild euphoria associated with IV buprenorphine use compared with IV doses of heroin, the concomitant use of other drugs by IV drug abusers is frequent, particularly benzodiazepines.[20] Insufflation is an alternative route of buprenorphine abuse by injecting heroin users.[13]

DOSE EFFECT

The final daily sublingual maintenance dose of buprenorphine/naloxone for the treatment of opioid dependence ranges from 4 mg buprenorphine/1 mg naloxone to 24 mg buprenorphine/6 mg naloxone with a typical target dose of 16 mg buprenorphine/4 mg naloxone.[21] The usual dose adjustment of the 4:1 formulation involves the increment or decrement of 2 mg/0.5 mg or 4 mg/1 mg. At doses below 12 mg, buprenorphine produces clinical effects similar to opioid agonists (e.g., methadone, morphine). The typical parenteral dose of buprenorphine for analgesia is 0.2–0.6 mg with the duration of action being about 6 hours. Because buprenorphine is a partial μ-opioid receptor agonist, the maximal effects of buprenorphine are less than full agonist (e.g., heroin, methadone). In general, high buprenorphine doses produce fewer adverse effects than heroin or methadone. Additionally, high doses of buprenorphine produce more prolonged pharmacologic effects rather than more serious adverse reactions.[22] The subcutaneous administration of 2 mg buprenorphine to 10 healthy volunteers with histories of opioid abuse produced miosis and mild euphoria without significant changes in body temperature, blood pressure, respiration, or heart rate.[23] The administration of sublingual buprenorphine doses up to 32 mg to healthy volunteers produced miosis, sedation, positive mood, and respiratory depression.[24] However, there are no dose-related increases in the severity of these symptoms with higher buprenorphine doses despite increasing plasma buprenorphine concentrations. The administration of IV buprenorphine in doses up to 16 mg to nondependent opioid abusers are associated with varying degrees of a positive mood, minimal increase in systolic blood pressure, and no significant change in heart rate or oxygen saturation (no capnometry measurements).[25] Most side effects were mild except the development of severe vomiting in one patient. At doses above 12 mg, buprenorphine produces little additional opioid effects, and the dose-response curve for the μ_1-opioid agonist effect flattens. The administration of 0.001–10 mg buprenorphine/kg body weight to rhesus monkeys produced a reduction in respiratory responses (respiratory rate, minute volume, tidal volume) to 5% CO_2,

when compared with control (placebo) values.[26] The response to buprenorphine was dose-dependent, and the maximal effect on these respiratory parameters was about 40–60% of control (placebo) values at a buprenorphine dose of 1 mg/kg. The respiratory depression did not increase with doses above 1 mg/kg, and the administration of up to 10 mg buprenorphine/kg body weight did not cause clinically significant respiratory depression.

The sublingual administration of buprenorphine in doses of 13.2–39.0 μg/kg/day in 3 divided doses to neonates of opioid–addicted mothers is a treatment for neonatal abstinence syndrome.[27] Children ingesting >4 mg buprenorphine usually develop clinical effects of opioid intoxication. The ingestion of an estimated buprenorphine (Subutex®) dose of 4 mg by a 4-year-old girl was associated with bilateral miosis and slight restlessness that resolved by the next day without complications.[28] A 20-month old boy developed lethargy, cyanosis, and respiratory depression after the ingestion of 12 mg buprenorphine (0.97 mg/kg).[29] Any child ingesting >2 mg buprenorphine or any child <2 years of age ingesting more than a taste should be evaluated in the emergency department for central nervous system (CNS) and respiratory depression.[30]

TOXICOKINETICS

Absorption

The oral bioavailability of buprenorphine is low as a result of a large first-pass effect; however, the bioavailability of sublingual doses is substantially higher than oral doses.[31] The systemic bioavailability of oral buprenorphine is about 15% compared with about 30–55% for sublingual doses of buprenorphine, depending on the formulation of the sublingual preparation (i.e., liquid vs. tablet).[32] Sublingual buprenorphine tablets require 2–10 minutes to completely dissolve in the mouth. Although pharmacokinetic studies suggest that the bioavailability of buprenorphine sublingual tablets is 40–50% less than liquid-filled sublingual formulations,[33] pharmacodynamic studies with positron emission tomography (PET) scanning indicate that the equivalent doses of these two formulations produce similar binding to μ-opioid receptors.[34] In a study of 5 postoperative patients receiving 0.4 mg buprenorphine and 5 patients receiving 0.8 mg buprenorphine sublingually, the mean systemic bioavailability was about 55%.[35] The mean bioavailability of sublingual and buccal doses of 4 mg buprenorphine in 6 healthy volunteers was approximately 51% and 28%, respectively.[36] There is substantial variability in the time to maximum buprenorphine plasma concentration following sublin-

gual administration. In a study of postoperative patients receiving low (0.4 mg, 0.8 mg) sublingual doses of buprenorphine, the mean time to peak to plasma buprenorphine concentration was about 3.3 hours (range, 1.5–6 hours).[36] The average peak plasma buprenorphine concentration for this sublingual dose was about 3.3 ng/mL with an approximate range of 1.9–7.2 ng/mL, whereas the average maximum buprenorphine plasma concentration after buccal administration of 4 mg buprenorphine was 1.98 ng/mL (range, 0.25–3.9 ng/mL). Peak subjective effects of buprenorphine occur after peak plasma concentrations of buprenorphine due to a lag in CNS penetration.[37]

Distribution

Buprenorphine is highly protein bound (i.e., 96%), primarily to α- and β-globulins.[38] The volume of distribution of buprenorphine is relatively large. In a study of nondependent heroin users receiving 1.2 mg buprenorphine intravenously, the mean V_d was 335 L (range, 125–771 L).[36]

Biotransformation

Buprenorphine undergoes extensive biotransformation in the liver by oxidative *N*-demethylation. The primary P450 enzymes involved in the biotransformation of buprenorphine are CYP3A4 and, to a lesser extent, CYP2C8 isoenzymes as determined by *in vitro* human liver microsome studies.[39] The main metabolite of buprenorphine is desalkyl-buprenorphine (norbuprenorphine).[40] Norbuprenorphine is an active metabolite with 1/50th the analgesic potency of buprenorphine based on the tail flick test in rats following IV administration of buprenorphine and norbuprenorphine.[41] Buprenorphine and norbuprenorphine undergo extensive phase II metabolism catalyzed by uridine diphosphate glucuronyltransferase 1A1 (buprenorphine), uridine diphosphate glucuronyltransferase 2B7 (buprenorphine), and uridine diphosphate glucuronyltransferase 1A3 (norbuprenorphine).[42]

Elimination

Animal studies indicate that a majority of the orally administered dose of buprenorphine appears in the feces as a result of biliary excretion. After IV administration of 100 μg [³H]buprenorphine/kg body weight to bile duct-cannulated rats, the bile contained over 90% of the administered radioactivity within 48 hours after dosing.[43] In humans, biliary excretion of buprenorphine and buprenorphine glucuronide conjugates account for about 80% of the elimination of buprenorphine, whereas urinary excretion accounts for the rest of the elimination of buprenorphine from the body.[44] Urinary elimination of buprenorphine results from the excretion of inactive glucuronide conjugates of buprenorphine and norbuprenorphine. Very little free buprenorphine appears in the urine.[45] There is substantial variation in the elimination half-lives of buprenorphine and norbuprenorphine both between different individuals and between different routes of administration. Mean elimination half-life of buprenorphine following the IV administration of 1.2 mg buprenorphine to 5 nondependent heroin users was 3.2 hours (range, 1.6–8.2 hours) compared with a mean of 27.7 hours (range, 5.2–49 hours) following the sublingual administration of 4 mg buprenorphine.[36] In a study of 11 male heroin-dependent volunteers participating in a research study, the mean steady-state elimination half-life of sublingual buprenorphine and norbuprenorphine was 42 hours and 57 hours, respectively.[46]

Maternal and Fetal Kinetics

Buprenorphine crosses the placenta during pregnancy, and the drug is excreted in breast milk. Case reports suggest that serum buprenorphine concentrations in the fetus can exceed maternal serum buprenorphine concentrations.[47] These reports also suggest that the excretion of buprenorphine in breast milk is low enough to produce minimal effects in breast-feeding infants, particularly after the first month when CYP3A4 activity reaches 30–40% of adult values. Breastfeeding does not prevent the mild abstinence syndrome associated with infants born to mothers in buprenorphine maintenance programs, and cessation of breastfeeding from mothers in these programs does not induce abstinence symptoms in these infants.

Tolerance

Studies of chronic pain patients receiving long-term buprenorphine therapy via transdermal patches suggest a low incidence of tolerance.[48]

Drug Interactions

Case reports on fatalities associated with the IV use of buprenorphine and benzodiazepines suggest the possibility that these two types of drugs produce synergistic respiratory depression.[49] This interaction is probably pharmacodynamic rather than pharmacokinetic because the lack of significant alteration of flunitrazepam metabolism in the presence of buprenorphine.[50] Drugs that inhibit (ketoconazole, nefazodone, protease inhibitors)

or induce (carbamazepine, phenytoin, rifampicin) CYP3A4 potentially decrease or enhance the *N*-dealkylation of buprenorphine. The protease inhibitors (ritonavir, indinavir, and saquinavir) are extensively metabolized by CYP3A4 isoenzymes,[51] and the selective serotonin reuptake inhibitors (fluoxetine, fluvoxamine) are CYP3A4 inhibitors *in vitro*.[52] Potentially, the concomitant administration of these drugs could alter buprenorphine metabolism, but the clinical significance of this potential interaction is unclear. A case report associated the development of the serotonin syndrome (clonus, agitation, altered mental status, confusion) following ingestion of Suboxone® (buprenorphine/naloxone) by a 54-year-old insulin-dependent diabetic on doxepin and amitriptyline.[53] He recovered after intubation and treatment with cyproheptadine.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

Treatment with sublingual buprenorphine decreases opioid self-administration by humans and animals along with reducing drug-seeking behavior and craving (i.e., motivational measures).[54] The clinical effectiveness of buprenorphine results from the binding of this drug to μ-opioid receptors, thereby decreasing the availability of the μ-opioid receptor to other opioids while alleviating opioid withdrawal symptoms. The slow dissociation of buprenorphine from the μ-opioid receptor results in a long duration of action, whereas the partial agonist effect of buprenorphine causes low intrinsic activity and a plateau in the opioid effects at high doses. Buprenorphine has a high affinity for μ-opioid receptors. In a study of 5 heroin-dependent volunteers, buprenorphine in daily doses of 2 mg, 16 mg, and 32 mg decreased mean whole-brain μ-opioid receptor availability by $41\% \pm 8\%$, $80\% \pm 2\%$, and $84\% \pm 2\%$, respectively, relative to placebo as measured by PET scanning with ^{11}C-carfentanil.[34] Analysis occurred 4 hours after the last buprenorphine dose in areas of the prefrontal cortex, anterior cingulate, thalamus, amygdala, nucleus accumbens, and caudate. This study indicated that buprenorphine rather than the norbuprenorphine metabolite binds to the μ-opioid receptors. The administration of buprenorphine displaces other opioids (e.g., heroin, methadone) from μ-opioid receptors as well as blocking the clinical effects of opioids. Clinical studies suggest that daily doses of 8–12 mg buprenorphine sublingually are more effective than daily doses of 20–35 mg methadone as measured by the risk of discontinuing treatment and positive urine drug screens for opioids.[55] However, buprenorphine may not be as effective as methadone in opioid–dependent individuals requiring high doses (80–100 mg) of methadone.

Mechanism of Toxicity

Buprenorphine is a partial μ-opioid receptor agonist and a weak κ-opioid receptor antagonist that is a relatively safe drug because of the diminished μ_1- and μ_2-opioid agonist actions at high doses. In animal studies, buprenorphine has κ-opioid antagonist activity.[56] The role of κ-opioid receptor in opioid toxicity is unclear, but some κ-opioid agonist produce dysphoria. Some respiratory depression does occur at low doses of buprenorphine. In a study of 10 patients in an intensive care unit, the IV administration of 0.4 mg buprenorphine caused a significant reduction in mean ventilation rate and an increase in mean arterial P_aCO_2 without altering the heart rate, P_aO_2, or pH.[57] Although the partial μ-opioid agonist activity of buprenorphine provides a margin of safety, the concomitant administration of other CNS depressants (e.g., opioids, ethanol, benzodiazepines) can produce serious respiratory dysfunction.

Postmortem Examination

Postmortem examination of fatalities associated with buprenorphine usually demonstrates nonspecific findings of prolonged asphyxiation including pulmonary edema, deep cyanosis, and congestion of multiple organs.[58]

CLINICAL RESPONSE

Adverse effects of buprenorphine are typical of the effects associated with opioids including constipation, nausea, vomiting, and dizziness.[59] Case reports associate the onset of acute icteric hepatitis with buprenorphine treatment of opioid addicts with hepatitis C virus-positive serology.[60] There were no signs of liver failure, and the jaundice resolved with reduction or elimination of the buprenorphine dose. Delayed hypersensitivity reactions may occur following the use of transdermal buprenorphine manifest by generalized skin eruptions and pruritic erythematous plaques.[61]

Illicit Use

In general, buprenorphine intoxication produces less-severe respiratory depression than heroin overdose, but

the coadministration of CNS depressant drugs (e.g., benzodiazepines) with buprenorphine can result in serious respiratory insufficiency.[62] Complications of the parenteral use of crushed buprenorphine tablets include the formation of coagulation necrosis and sterile abscess around the injection site.[63] Cellulitis and phlebitis are potential complications of the parenteral use of crushed buprenorphine tablets as a result of the low water solubility of buprenorphine and the injection of mouth flora and saliva from illicitly diverted pharmaceutic preparations of buprenorphine. High doses of buprenorphine can precipitate prolonged, opioid withdrawal in opioid-dependent individuals. A case report associated the development of severe opioid withdrawal with the parenteral administration of 11 crushed, 8 mg-tablets of buprenorphine.[64] There was no significant respiratory depression; the withdrawal symptoms persisted 4 days. A case report temporally associated the development of a diffuse, symmetrical cystic leukoencephalopathy with the IV injection of crushed buprenorphine tablets dissolved in water.[65] The patient developed bilateral pyramidal dysfunction with spastic quadriparesis, hypertonia, hyperreflexia, and sustained clonus along with diffuse leukoencephalopathic changes in the periventricular, deep, and subcortical white matter of the frontal and parietal lobes. The cerebellum and brainstem were normal. In contrast to methadone, buprenorphine is not usually associated with prolongation of the QTc interval.[66]

Overdose

In a retrospective review of 54 buprenorphine overdoses in children <6 years of age reported to the Research Abuse, Diversion, and Addiction-Related Surveillance System, the most common clinical feature of accidental exposure to buprenorphine was drowsiness or lethargy (55%), followed by vomiting (21%), miosis (21%), respiratory depression (7%), agitation or irritability (5%), pallor (3%), and coma (2%).[30] The onset of symptoms was typically within 1 hour (range, 20 minutes to 3 hours). In general, accidental exposure was well-tolerated by young children; however, significant CNS and respiratory depression occasionally occurs. A case series of 5 toddlers documented the development of respiratory and CNS depression following the accidental ingestion of buprenorphine.[29] The clinical features of buprenorphine in these toddlers were classic of opioid overdose, including miosis, respiratory depression and somnolence. One child in this series developed apnea within 5 hours after ingestion, and the paramedics intubated the child in the field. The report did not indicate that this child received naloxone.

Abstinence Syndrome

The repeated administration of buprenorphine to opioid-dependent individuals produces or maintains physical dependence on opioids; single doses of buprenorphine block μ-opioid receptors for over 24 hours.[67] In a study of 8 opioid-dependent patients on a residential ward, the daily administration of 8 mg buprenorphine sublingually prevented the development of opioid withdrawal symptoms.[68] Withdrawal symptoms developed in these patients following the intramuscular administration of 3 mg naloxone/70 kg body weight. As a partial agonist of the μ-opioid receptor, the withdrawal associated with cessation of buprenorphine therapy is milder in intensity and later in onset than heroin withdrawal. Similarly, in highly opioid dependent patients, the administration of buprenorphine usually, but not always causes milder withdrawal symptoms compared with naloxone.[69] Subjective symptoms and physiologic signs of opioid withdrawal did not develop within 72 hours of the cessation of buprenorphine treatment in 8 buprenorphine-maintained, opioid-dependent patients.[70] Withdrawal from buprenorphine begins more slowly than during heroin withdrawal with peak symptoms occurring about 5 days after cessation of buprenorphine.[71] A majority of neonates born to mothers on chronic buprenorphine maintenance will develop neonatal abstinence syndrome.[72] Compared with infants born to mothers in methadone maintenance programs, neonatal abstinence symptoms are similar or less severe in neonates of mothers in buprenorphine maintenance programs.[73] Analysis of differences in the neonatal abstinence syndrome associated with these 2 heroin substitutes is complicated by the continued abuse of opioid drugs among these mothers. The neonatal abstinence syndrome associated with buprenorphine generally appears within 12–48 hours, peaks at approximately 72–96 hours, and lasts for 120–168 hours.[74]

Reproductive Abnormalities

There are few data on the effects of maternal buprenorphine treatment during pregnancy on birth outcomes and abstinence syndrome in their neonates. A case report on 2 women conceiving on buprenorphine did not reveal any abnormal birth outcomes, such as pregnancy complications, prematurity, low birth weight, or poor neurodevelopmental progress.[75] In a case series of 31 infants with mothers on buprenorphine maintenance treatment, neonatal withdrawal syndrome developed in 13 cases (42%) and 8 of these babies required opioid treatment.[76] A study of 27 full-term neonates born to mothers receiving buprenorphine during their

pregnancy did not detect biochemical evidence (cord artery serum erythropoietin, cardiac troponin T, S100) of asphyxia when compared with substance-abusing and healthy pregnant women.[77] All 27 infants had normal Apgar scores and normal cord blood pH. In general, the neonatal abstinence syndrome is milder in neonates born to mothers on buprenorphine than methadone. In a double-blind, double-dummy, flexible-dosing, randomized, controlled study of 58 pregnant women on buprenorphine and 73 on methadone, the neonates of the former group required less morphine (mean, 1.1 mg and 10.4 mg, respectively; $P < .009$) and shorter duration of treatment (mean, 4.1 days and 9.9 days, respectively; $P < .003$).[78]

DIAGNOSTIC TESTING

Analytic Methods

METHOD

Methods to quantitate buprenorphine and norbuprenorphine in biologic matrices include immunoassays,[79,80] gas chromatography with electron capture (lower limit of quantitation [LLOQ], 0.1 ng/mL),[81] high performance liquid chromatography with fluorescence detection,[82] high performance liquid chromatography with electrochemical detection,[83] gas chromatography/mass spectrometry (GC/MS),[84] liquid chromatography/mass spectrometry,[85] and liquid chromatography/tandem mass spectrometry.[86] The LLOQ for the latter method for buprenorphine and norbuprenorphine is in the range of 0.2 ng/L to 0.5 ng/L,[87] whereas the LLOQ for buprenorphine and norbuprenorphine using GC/MS ranges from 0.2 ng/mL (selective solid-phase extraction by Bond Elut Certify columns and quadrupole mass detector working in EI selected ion monitoring mode)[88] to 4 ng/mL [selective ion monitoring mode with *N,O*-bis(trimethylsilyl)trifluoroacetamide containing 1% trimethylchlorosilane as the derivatizing reagent].[89] The use of liquid chromatography/tandem mass spectrometry eliminates the need for pre-analytic hydrolysis of glucuronide conjugates. These conjugates often have low volatility and require hydrolysis and derivatization when GC/MS is used.

The precision of radioimmunoassay methods depends on the ability of the assay to distinguish between buprenorphine and norbuprenorphine. Some early radioimmunoassay methods for buprenorphine lacked specificity, but newer mass spectrometric methods are able to separate these 2 compounds. Sensitive non-isotopic immunoassays for the detection of buprenorphine include enzyme-linked immunosorbent assays (ELISA) and cloned enzyme donor immunoassays

(CEDIA). These assays have low cross-reactivity with other opioids and with the norbuprenorphine metabolite.[90] With the latter CEDIA method, the sensitivity and specificity of the assay for buprenorphine in 176 unadulterated urine samples from patients receiving buprenorphine was 100% and 87.5%, respectively, as confirmed by liquid chromatography/mass spectrometry.[91] The cutoff for buprenorphine in these urine samples was 5 ng/mL. The LLOQ for buprenorphine and the glucuronide conjugate in urine samples is 5 ng/mL as measured by liquid chromatography/tandem mass spectrometry compared with 25 ng/mL for norbuprenorphine and the related glucuronide conjugate.[92] Intraassay and interassay imprecision with this method is <17%. Following hydrolysis by β-glucuronidase, liquid-liquid extraction at basic pH, and derivatization by *N*-methyl -*N*-(*tert*-butyl-dimethylsilyl)trifluoroacetamide, the LLOQ for buprenorphine and norbuprenorphine in urine samples were 1 ng/mL and 2 ng/mL, respectively, using GC/MS in electron impact mode.[93]

STORAGE

In general, analysis of blood for buprenorphine concentrations should occur within 2 weeks of sampling unless the sample is frozen. Buprenorphine glucuronides are relative stable in refrigerated and frozen samples; however, some degradation occurs after about 3 weeks of storage at 4°C (39.2°F). About 82% of the original buprenorphine concentration remained in the whole blood sample after 3 weeks of refrigerated storage,[86] whereas approximately the same amount remained in a spiked blood sample after 1 year of refrigerated storage in another study.[94]

Biomarkers

BLOOD

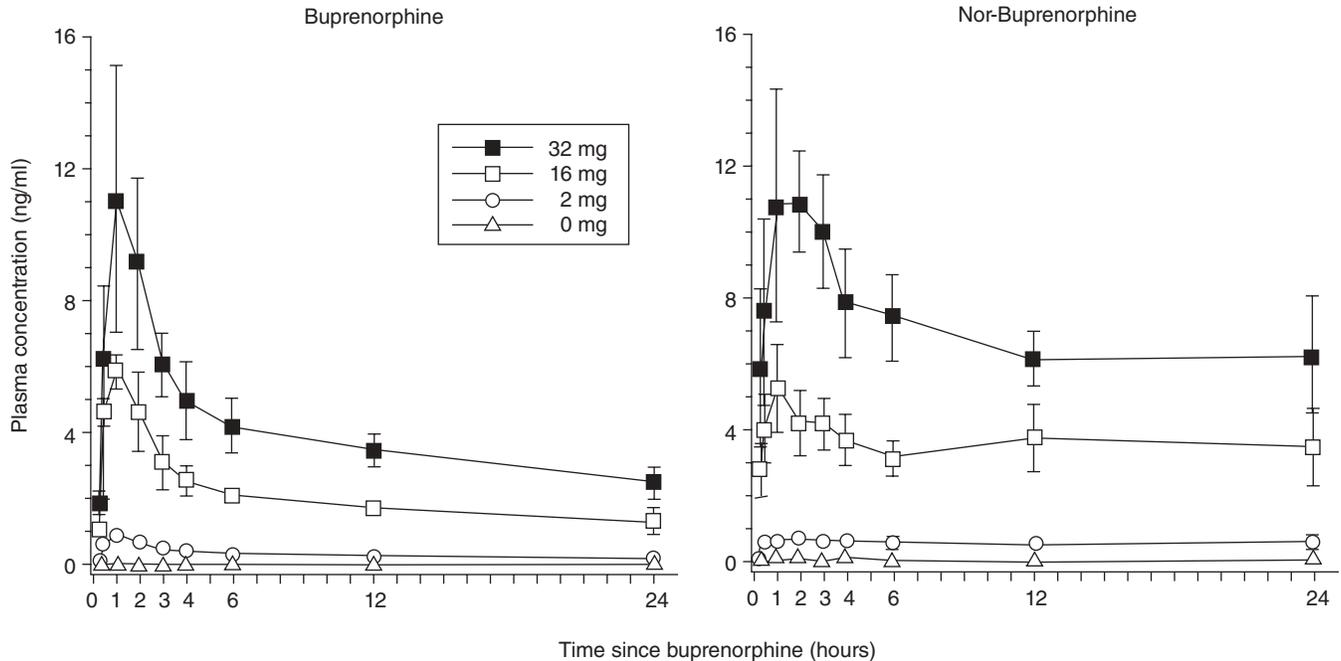
THERAPEUTIC/ILLICIT USE.   There is substantial individual variability in the serum buprenorphine concentrations following sublingual administration of buprenorphine. In a study of 14 volunteers receiving 8 mg buprenorphine sublingually, the peak serum buprenorphine concentration ranged from 1–5 ng/mL.[32] The mean peak plasma concentrations of buprenorphine in 5 opioid-dependent patients receiving daily buprenorphine doses of 2 mg, 16 mg, and 32 mg were approximately 0.5–1 ng/mL, 5–6 ng/mL, and 13–14 ng/mL, respectively.[34] In a study of volunteers receiving a sublingual tablet of 8 mg buprenorphine and 2 mg naloxone, detectable concentrations of buprenorphine and norbuprenorphine appeared in the plasma up to 24 hours after administration as measured by liquid chromatography/electrospray ionization/tandem mass


FIGURE 28.2. Mean (±SEM) buprenorphine and norbuprenorphine concentrations over 24 hours following doses up to 32 mg. (Reprinted by permission from Macmillan Publishers Ltd.: Neuropsychopharmacology, MK Greenwald, C Johanson, DE Moody, JH Woods, MR Kilbourn et al., Effects of buprenorphine maintenance dose on [mu]-opioid receptor availability, plasma concentrations, and antagonist blockade in heroin-dependent volunteers, Vol. 28, Issue 11, p. 2006, Fig. 4, copyright 2003.)

spectrometry.[95] Figure 28.2 demonstrates the plasma buprenorphine and norbuprenorphine concentrations over 24 hours after sublingual administration of placebo, 2 mg, 16 mg, and 32 mg buprenorphine doses. During daily buprenorphine maintenance, steady-state plasma buprenorphine concentrations exceeding 0.7 ng/mL are associated with minimal withdrawal symptoms, when the blood samples are drawn immediately prior to the daily buprenorphine dose.[46]

OVERDOSE. Four hours after the ingestion of 4 mg buprenorphine by a 4-year-old girl, the serum buprenorphine and norbuprenorphine concentrations were 0.64 ng/mL and 7.7 ng/mL, respectively.[28] At that time, she was alert and slightly restless with stable vital signs and miosis. The child was discharged the following day with no sequelae.

POSTMORTEM. Most fatalities associated with buprenorphine involve multiple drugs; deaths associated only with buprenorphine are rare. In a case series of 117 postmortem blood samples positive for buprenorphine, only 1 case involved buprenorphine as a sole agent; postmortem examination of this case revealed pulmonary aspiration. The mean buprenorphine concentration in these cases was about 10–12 ng/mL. Typically, fatalities associated with buprenorphine involve multiple drugs, commonly benzodiazepines, antidepressants, and other drugs of abuse.[58,96] A 25-year-old drug addict was found dead with buprenorphine tablets nearby. Postmortem examination of the blood demonstrated buprenorphine and norbuprenorphine concentrations of 3,300 ng/mL (3.3 mg/L) and 400 ng/mL (0.4 mg/L), respectively, in addition to high concentrations of the flunitrazepam metabolite, 7-aminoflunitrazepam.[97] The bile also contained buprenorphine (2,035 mg/L) and norbuprenorphine (536 mg/L) at concentrations a thousand times greater than blood.

URINE

Buprenorphine and the de-alkylated metabolite, norbuprenorphine are excreted in urine, almost exclusively as glucuronide conjugates. Most immunoassays used to screen urine for drugs of abuse do not reliably detect buprenorphine. Evaluation of 16 urine samples pretreated with glucuronidase from 16 patients in buprenorphine maintenance programs revealed total buprenorphine and norbuprenorphine concentrations ranging from 31–1,080 ng/mL and 48–2,050 ng/mL, respectively, as measured by liquid chromatography/electrospray ionization/tandem mass spectrometry.[98] The total buprenorphine and norbuprenorphine concentrations in urine samples from 33 suspected abusers ranged from 2.3–796 ng/mL and 5.0–2,580 ng/mL, respectively. Maximum buprenorphine and norbuprenorphine

521

concentrations occurred 1 hour and 1.5 hours, respectively, after administration.

Eighteen healthy volunteers received a single dose of 0.4 mg buprenorphine sublingually, and urine samples were collected for 96 hours postingestion. As measured by cloned enzyme donor immunoassay (CEDIA), the mean time of continuous positive results for buprenorphine (5 ng/mL cutoff) in urine samples was 9 hours (range, 4–24 hours).[99] The mean detection time for urinary buprenorphine in this study following analysis by liquid chromatography/tandem mass spectrometry was 76 hours (range, 23–96 hours). The mean time for the norbuprenorphine/buprenorphine ratio to exceed 1 was approximately 7 hours. Four hours after the ingestion of 4 mg buprenorphine by a 4-year-old girl, the urine buprenorphine and norbuprenorphine concentrations were 173 ng/mL and 419 ng/mL, respectively.[28]

Driving

Experimental studies in opioid-dependent volunteers in buprenorphine maintenance programs suggest that single therapeutic doses of buprenorphine cause a slight impairment in gross psychomotor performance, but these buprenorphine doses cause little impairment of more complex cognitive functions when administered to opioid-dependent individuals.[14] The administration of sublingual buprenorphine in doses up to 32 mg caused little impairment on most neuropsychologic tests of psychomotor speed (digit symbol substitution, trail-making A and B), time perception, conceptual flexibility (trail-making A and B), focused attention, and working memory with the exception of mild impairment of long-term memory.[100] The IV infusion of buprenorphine to non-opioid-dependent subjects causes some impairment on performance in neuropsychiatric testing of visual information processing, psychomotor speed, choice reaction time, eye-hand coordination, and attention, when compared with baseline values.[101,102]

TREATMENT

Stabilization

The management of buprenorphine intoxication is similar to the treatment of other opioids. Respiratory depression and pulmonary aspiration are the most common serious complications of buprenorphine overdose. Patients should be evaluated for the adequacy of respiration and monitored for the development of hypoxia with pulse oximetry and arterial blood gases as indicated by clinical examination. Intubation should be considered in patients with inadequate ventilation, when respirations do not improve following the admin-

istration of naloxone. Young children typically tolerate accidental exposure to buprenorphine without serious toxic effects; however, occasionally significant CNS and respiratory depression occurs. Because of the prolonged duration of action, asymptomatic patients with significant exposure to buprenorphine should be observed at least 6 hours after ingestion for evidence of CNS or respiratory depression.

Gut Decontamination

Decontamination measures are usually unnecessary, unless indicated by the concomitant ingestion of other substances. The administration of activated charcoal is a therapeutic option in alert patients presenting within 1 hour of an overdose, but there are inadequate data to determine the effect of this therapeutic measure on clinical outcome.

Elimination Enhancement

Although there are few data on methods to enhance the elimination of buprenorphine, the large volume of distribution and high protein binding likely limit the effectiveness of any measure to enhance the elimination of buprenorphine.

Antidotes

Naloxone is the antidote of choice for buprenorphine intoxication. Although buprenorphine overdose produces an opioid syndrome similar to heroin and methadone, limited data on the use of naloxone for buprenorphine overdose suggests that buprenorphine intoxication is less responsive to naloxone than heroin or methadone intoxication.[103] The relatively high affinity of buprenorphine for the μ-opioid receptor potentially limits the effectiveness of naloxone.[104] Additionally, benzodiazepines are frequently co-ingested with buprenorphine;[103] the effect of benzodiazepines is not affected by the administration of naloxone. Because of the mixed agonist-antagonist μ-opioid receptor activity of buprenorphine, optimization of the naloxone dose depends on the buprenorphine dose. In a study of 16 healthy volunteers, an IV naloxone dose of 0.8 mg did not reverse the respiratory depression from 0.2 mg buprenorphine as measured by ventilation (L/min).[105] Increasing naloxone doses (2–4 mg) given over 30 minutes produced full reversal of the depression in ventilation; however, high naloxone doses (i.e., >5–7 mg) reversed the decline in ventilation associated with effective, lower naloxone doses. Similarly in a placebo-controlled, single-blind study of volunteers, the IV administration of 0.3 mg buprenorphine/70 kg body

weight reduced CO_2 responsiveness by about 50%.[106] The IV administration of 5 mg and 10 mg naloxone, but not 1 mg naloxone produced dose-dependent reversal of the effect of buprenorphine on these respiratory parameters. The maximum effect of naloxone occurred 3 hours after administration, indicating that clinical effect of naloxone during buprenorphine intoxication may be delayed compared with heroin intoxication. Symptomatic patients requiring naloxone for reversal of respiratory depression should be observed for 36–48 hours to prevent oxygen desaturation from delayed effects of buprenorphine on the ventilatory rate.

Chapter 29

DEXTROMETHORPHAN

HISTORY

In 1958, dextromethorphan was approved in the United States as a nonaddictive, safe antitussive, over-the-counter (OTC) replacement for codeine-containing cough preparations. The first tablet form of dextromethorphan, Romilar®, was removed from the US OTC market in the 1970s as a result of abuse.[1] Sporadic episodes of dextromethorphan abuse occurred in Australia during the 1960s[2] and in Sweden during the 1980s. In the early 1990s, dimenhydrinate and cyclizine were popular, nonprescription drugs of abuse among US teenagers.[3] The anticholinergic properties of these drugs produce tachycardia, mild hypertension, and hallucinations similar to dextromethorphan when ingested in excessive doses. During the middle 1990s, caffeine-containing products were popular drugs of abuse among teenagers; later in the 1990s, dextromethorphan became a popular OTC drug of abuse. In 1990, abuse of Robitussin DM by Utah teenagers caused the Utah State Board of Pharmacy to restrict direct access of the public to dextromethorphan. Since the 1980s, abuse of dextromethorphan-containing cough and cold preparation has been relatively common among teenagers as a "poor man's PCP."[4] Analysis of reports to US poison control centers indicate that dextromethorphan abuse among this age group increased significantly in the late 1990s.[3,5]

IDENTIFYING CHARACTERISTICS

Physiochemical Properties

Figure 29.1 displays the chemical structure of dextromethorphan (CAS RN: 125-71-3, d-3-methoxy-N-meth-ylmorphine). This poorly water soluble, white, crystalline substance is the dextrorotatory isomer of the opioid, levorphanol (3-hydroxy-N-methyl morphinan). Levorphanol is the levorotatory isomer of racemic 3-hydroxy-N-methylmorophinan (Dromoran). Levorphanol has significant respiratory depressant, analgesic, and addictive properties.[6] In contrast to levorphanol, dextromethorphan does not stimulate opioid receptors, resulting in the absence of analgesia or respiratory depression at therapeutic doses. Volunteer studies indicate that dextromethorphan is an effective antitussive agent that does not cause euphoria, respiratory depression, or physical dependence to the extent morphine does.[7,8] Other narcotic morphinan derivatives include butorphanol, codeine, levallorphan, and morphine. Commercial dextromethorphan preparations do not contain the (S)-enantiomer.

Terminology

Street names for dextromethorphan-containing medications include the following Coricidin® (skittles, red hots, red devils, triple C) and Robitussin DM® (ro-bowing, robo-copping). Other street names for dextromethorphan include Dex, DXM, and poor man's PCP (phencyclidine).

Form

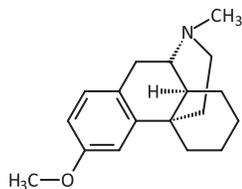
Abuse of dextromethorphan usually involves the ingestion of cough and cold formulations (i.e., gel capsules, tablets, liquid), which contain other active ingredients including antihistamines (e.g., 2–4 mg chlorpheniramine maleate) and analgesics (325–500 mg acetaminophen).


FIGURE 29.1. Chemical structure of dextromethorphan.

Dextromethorphan is available in these medications as the hydrobromide salt, and chronic abuse of large quantities of dextromethorphan hydrobromide increases in the serum bromide concentration. Because the abused dextromethorphan-containing drugs are pharmaceutic preparations, these preparations do not usually contain unknown additives or contaminants.

EXPOSURE

Epidemiology

Dextromethorphan is an ingredient in more than 100 OTC cough and cold preparations in the United States. The abuse of this compound has been recognized since the 1960s; however, abuse of dextromethorphan did not increase significantly until the late 1990s when this compound became a popular drug of abuse with teenagers.[9] Between 1999 and 2004, there was a 10-fold increase in the number of cases of dextromethorphan abuse reported to the California Poison Control System, primarily in the 9- to 17-year-old age group.[10] Similar trends occurred in the data from the American Association of Poison Control Centers (AAPCC) and the Drug Abuse Warning Network (DAWN) databases with the highest frequency among 15- and 16-year-olds. In 2008, the US Substance Abuse and Mental Health Services Administration (SAMHSA) reported that approximately 5% of youth aged 12–25 years used OTC cough and cold preparations for recreational purposes with females overrepresented in the 12–17 year old groups and males overrepresented in the 18–25 year old group.[11] In Korea, zipeprol (CAS No. 34758-84-4) is another centrally acting cough suppressant that is abused with dextromethorphan for stronger hallucinogenic effects, predominantly by teenagers.[12]

Sources

Dextromethorphan hydrobromide (10–30 mg) is present in OTC cough and cold preparations as an antitussive (e.g., NyQuil®, Proctor & Gamble, Cincinnati, OH; Robitussin-DM®, Pfizer Pharmaceuticals, New York, NY; Tylenol-DM®, Ortho-McNeil-Jansson Pharmaceuticals, Titusville, NJ; Coricidin HBP®, Merck & Co., Whitehouse Station, NJ, Vicks Formula 44-D®, Proctor & Gamble). Some liquid dextromethorphan preparations contain ethanol concentrations up to approximately 25%. A novel use of this property is the treatment of drug and alcohol abuse as a means to decrease withdrawal symptoms during acute detoxification and to inhibit the conditioned reactions associated with drug-seeking behavior.[13]

Pure dextromethorphan powder is available on the Internet along with extraction procedures for the manufacture of concentrated dextromethorphan powder from Coricidin HBP™ Cough & Cold tablets.[14] Experienced dextromethorphan abusers use several extraction techniques to eliminate unwanted products (e.g., ethanol, guaifenesin, saccharin, propylene glycol, coloring agents, sweeteners) present in combination cold preparations. These methods include single-phase acid-base extraction with sodium hydroxide into a powder (Crystal Dex) and the two-phase ("Agent Lemon, DXemon Juice") method with ammonia that forms a liquid.[15] The product of the former method is the free-base, crystalline form of dextromethorphan ("Crystal Dex"), whereas the latter method produces liquid dextromethorphan hydrocitrate (DXemon Juice, Agent Lemon). This latter method avoids the use of lye and flammable solvents.

Methods of Abuse

Ingestion is the primary route of dextromethorphan abuse. Rarely, case reports associate dextromethorphan abuse with insufflation.[16]

DOSE EFFECT

Illicit Use

Chronic abusers of dextromethorphan-containing products frequently talk about several levels or plateaus during the ingestion of escalating doses of dextromethorphan. During the first plateau, ingestion of approximately 100–200 mg dextromethorphan produces mild stimulant effects, whereas mild hallucinations develop during the second level following the ingestion of about 200–400 mg dextromethorphan.[17] Dysphoria can occur if dextromethorphan doses exceed 200–250 mg. The third plateau is the "out of body" experience associated with dextromethorphan doses of 300–600 mg; the ingestion of doses > 600 mg are associated with complete disassociation (similar to ketamine). Tolerance develops to the euphoriant properties of dextromethorphan, and chronic abusers can consume 700–1,500 mg daily.[18] A case report documented the daily use of 720 mL of

Tussin DM® (10–15 mg dextromethorphan/5 mL) with daily peak use up to about 1,200 mL (i.e., 2,400–3,600 mg dextromethorphan).[19] Another case reported associated the development of agitation and hallucinations with the chronic ingestion of 3–4 bottles of Robitussin DM® daily for 2 years.[20] The estimated dextromethorphan dose in 3 bottles was 2,160 mg (31 mg/kg body weight). In a retrospective review of 47 patients admitted to an adolescent inpatient psychiatric unit for depression and/or psychosis related to Coricidin HBP® abuse, the number of tablets used per episode ranged from 2–42 with 14% of the patients abusing this product daily.[21] Individual sensitivity to dextromethorphan may vary as a result of pharmacogenetic differences. The ingestion of an estimated 600 mg dextromethorphan hydrobromide within the 12 hours prior to presentation was associated with the development of altered consciousness, seizure, mydriasis, and nystagmus.[22] Phenotyping of this patient demonstrated that he was CYP2D6 deficient (i.e., poor metabolizer of dextromethorphan compared with extensive metabolism of dextromethorphan in normal individuals).

Medical Use

Dextromethorphan is a centrally acting, nonopioid antitussive drug. Recommended dosages are 60–120 mg daily in 3–4 divided doses for adults and children over 12 years of age. Dextromethorphan does not possess expectorant activity, and there are relatively few placebo controlled clinical trials on the efficacy of dextromethorphan as an antitussive agent. As measured by parent questionnaires on the cough-related symptoms during a 3-day upper respiratory tract illness in their children, there was no statistically significant difference in the mean cough and composite symptoms between the dextromethorphan, codeine, and placebo groups.[23]

The administration of a single dose of 2 mg dextromethorphan/kg body weight produced mild cravings as measured by a self-rated visual analog scale in detoxified alcohol abusers, but not in non-alcohol abusers.[24] In a study of opioid addicts on methadone therapy, dextromethorphan (480 mg daily) was associated with mild elevation of blood pressure, heart rate, temperature, and plasma bromide concentration, but none of these effects were clinically significant.[25] The most common adverse effects associated with the highest doses were drowsiness and sleepiness.

Toxicity

Most exposures to dextromethorphan in children do not result in clinically significant symptoms. Patients accidently ingesting more than 7.5 mg dextromethorphan/ kg should be referred to an emergency department for evaluation, whereas patients asymptomatic >4 hours after ingestion can be observed at home.[26]

TOXICOKINETICS

Absorption

Dextromethorphan is rapidly absorbed from the gastrointestinal (GI) tract. As a result of high first-pass metabolism, the concentration of dextromethorphan in the plasma is small compared to the active metabolite, dextrorphan.[27] Following ingestion of dextromethorphan, maximal serum dextromethorphan concentrations occur within about 2–3 hours, whereas peak serum concentrations of dextrorphan occur within approximately 1.5–3 hours.[28,29]

Distribution

Limited data suggest that the volume of distribution of dextromethorphan is relatively large (i.e., about 5–6 L/kg).

Biotransformation

The metabolism of dextromethorphan is extensive based on analysis of urinary metabolites in volunteers receiving the drug orally.[30] Metabolic pathways include O,N-demethylation, O,N-acetylation, and hydroxylation of the phenyl ring with further oxidation. Biotransformation of dextromethorphan results in the formation of the active metabolite, dextrorphan, through CYP2D6-mediated O-methylation and, to a much lesser extent, to 3-methoxymorphinan via CYP3A-mediated N-demethylation. Both of these metabolites are further demethylated to 3-hydroxymorphinan. Dextrorphan has anticonvulsant, sedative, and antitussive properties, as well as an affinity for the phencyclidine site of the ligand-gated channel of the N-methyl D-aspartate (NMDA) receptor complex. The affinity of dextrorphan and ketamine for this receptor is similar.[31] Polymorphism in the expression of the gene for CYP2D6 results in substantial individual variability in the biotransformation of dextromethorphan to dextrorphan. Approximately 7–10% and <1% of the Caucasian and Asians populations, respectively, have deficiencies of CYP2D6 as an autosomal-recessive trait; therefore, these individuals have limited capacity to metabolize dextromethorphan to dextrorphan. In a study of 5 extensive dextromethorphan metabolizers receiving a single oral dose of 30 mg dextromethorphan hydrobromide, the major plasma metabolites were conjugated dextrorphan and conjugated 3-hydroxymorphinan.[32]

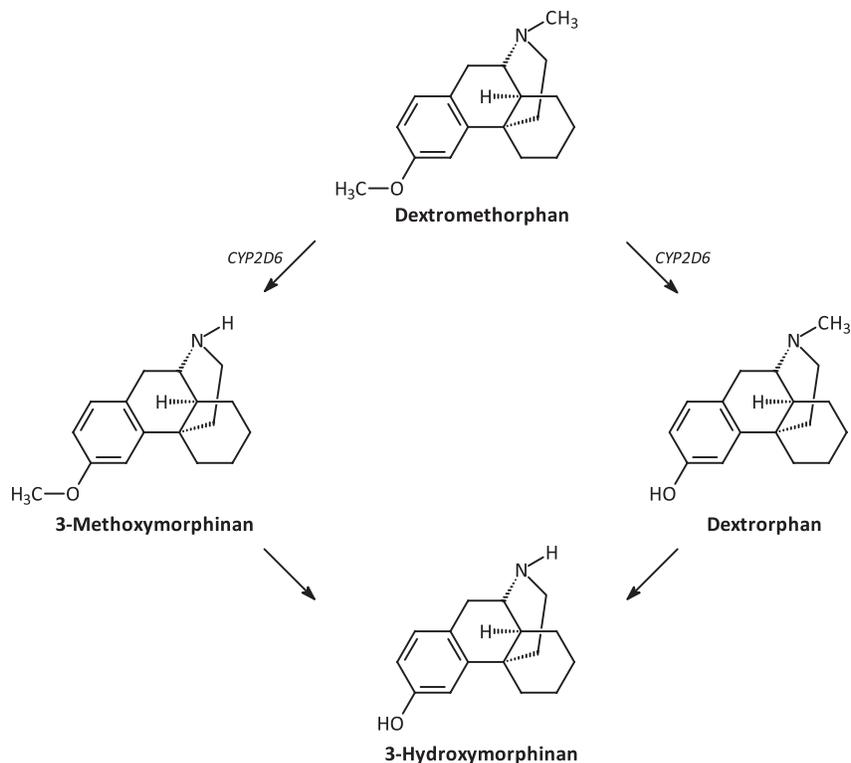
529


FIGURE 29.2. Biotransformation of dextromethorphan.[17] The biologic activities of 3-methoxymorphinan and 3-hydroxymorphinan are unknown. All biologic activity attributed to dextromethorphan resides in dextrorphan.

Free dextrorphan concentrations were about 100-fold less than conjugated dextrorphan. The rapid glucuronidation of dextrorphan results in very small amounts of free dextromethorphan in the plasma. Dextrorphan glucuronide does not cross the blood–brain barrier. In contrast to extensive metabolizers, dextromethorphan was the major component in the blood after the administration of the same dextromethorphan dose to poor metabolizers, while the plasma concentrations of conjugated dextrorphan was 5–10 times less than plasma dextromethorphan concentrations.

Elimination

In a study of 265 unrelated Swiss participants, 9% were poor metabolizers of dextromethorphan and 91% were extensive metabolizers as defined by an antimode at a metabolic ratio of 0.3.[33] The plasma elimination half-life and the amount of dextromethorphan and dextrorphan excreted in the urine depend on the CYP2D6 phenotype. Urinary excretion of dextrorphan following the ingestion of a single 25 mg-dose of dextromethorphan was <6% in all poor metabolizers compared with about 50% in the extensive metabolizers (i.e., the most common phenotype). The typical plasma elimination half-life of dextromethorphan following the administration of single therapeutic doses of dextromethorphan to subjects with normal CYP2D6 concentrations is about 3–4 hours. In a study of 4 poor metabolizers receiving a single dose of 30 mg dextromethorphan, the mean plasma elimination half-life of dextromethorphan was approximately 29 hours.[32] The concentration of dextromethorphan in plasma from 5 extensive metabolizers was near the level of detection; therefore, the plasma half-life of dextromethorphan in the 5 extensive metabolizers could not be calculated. A majority of dextrorphan excreted in the urine appears as free dextrorphan.[34]

Maternal and Fetal Kinetics

There are no data on the placental transfer of dextromethorphan, although the low molecular weight (i.e., about 271 g/mol) suggests that some placental transfer of dextromethorphan occurs.

Tolerance

As with most opioids, tolerance develops after the long-term abuse of dextromethorphan. Case reports

document the ingestion of escalating doses of dextromethorphan despite the development of adverse effects (e.g., constipation, insomnia, weight gain, psychosis) and disruption of personal life. Over 6 months, the ingestion of dextromethorphan by a 38-year-old woman increased from the occasional use of 3 ounces to 40 ounces daily despite the presence of hallucination, paranoia, and delusional beliefs.[19] Cessation of dextromethorphan use was associated with withdrawal symptoms (i.e., vomiting, diarrhea, myalgias, restlessness, night sweats, insomnia, anxiety).

Drug Interactions

Case reports indicate that the most serious drug interaction with dextromethorphan is the development of the serotonin syndrome during concomitant therapy with monoamine oxidase or selective serotonin reuptake inhibitors, particularly following the ingestion of high doses of dextromethorphan.[35,36] Clinical effects associated with the serotonin syndrome include signs of autonomic instability (hypertension, hyperpyrexia, diaphoresis, tachycardia), muscular hypertonicity (tremor, clonus, myoclonus, hyperreflexia), and mental status changes (agitation, disorientation, confusion). In contrast to the bradykinesia and idiopathic reactions associated with neuroleptic malignant syndrome, serotonin syndrome frequently is dose-related and associated with hyperkinesia, clonus, and hyperreflexia. A case report associated the development of serotonin syndrome following abuse of dextromethorphan by a bipolar patient on fluoxetine and lithium.[37] As a weak serotonin reuptake inhibitor, dextromethorphan potentially may interact with meperidine, tramadol, or propoxyphene to produce serotonin syndrome when ingested with monoamine oxidase inhibitors.[38] Several case reports associate the development of altered consciousness (coma, delirium) with the combined use of dextromethorphan with CYP2D6 inhibitors (amitriptyline, methadone), particularly in poor CYP2D6 metabolizers.[39,40]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

The prodrug, dextromethorphan is converted to dextrorphan (CAS No: 125-73-5), which raises the threshold for the cough reflex in the medulla oblongata. The latter compound is a semisynthetic morphine derivative that modulates glutamatergic neurotransmission by noncompetitive antagonism of N-methyl-D-aspartate (NMDA) receptors. These receptors are 1 of 3 types of ionotropic glutamate receptors, which are the primary excitatory neurotransmitter in primates.

Mechanism of Toxicity

The binding affinity (K_i) of the ion channel of the NMDA receptor complex for dextromethorphan is about 3,500 nM compared with 222 nM and 42 nM for dextrorphan and phencyclidine, respectively.[24] Although dextromethorphan binds to NMDA receptors in animal studies, these animal studies suggest that dextrorphan, but not dextromethorphan, has phencyclidine-like properties.[41] NMDA receptors open distinctive membrane channels characterized by voltage-dependent Mg^{++} blockade and high permeability to calcium ions.[42] Activation of NMDA receptors initiate calcium-calmodulin mediated activation of nitric oxide synthase. The active metabolite, dextrorphan, antagonizes these actions, resulting in the enhancement of excitatory neurotransmission and dissociative experiences. Animal studies indicate that dextrorphan and dextromethorphan cause a pronounced enhancement of 5-hydroxytryptamine (5-HT)-induced head-twitch response (HTR) in intact mice, but the clinical relevance of this effect is unclear.[43] Although a pilot study suggested that extensive metabolizers of dextromethorphan have an increased risk of abuse as a result of the positive subjective effects of dextrorphan,[44] there are inadequate data to conclude that extensive metabolizers are overrepresented in samples of dextromethorphan abusers.

Postmortem Examination

The postmortem findings in individuals dying from dextromethorphan intoxication are nonspecific, and similar to opioid poisoning. Postmortem examination of 2 teenagers found dead after ingestion dextromethorphan demonstrated cerebral edema, pulmonary edema, and frothy foam in the major airways without evidence of trauma or antecedent natural disease.[45]

CLINICAL RESPONSE

As an antitussive, dextromethorphan has a wide margin of safety. Adverse drug reactions to therapeutic doses of dextromethorphan are infrequent and mild with recreational abuse of dextromethorphan being the most important drug safety issue associated with this drug.[46] In a study of the neuroprotective effects of dextromethorphan, 181 neurosurgical patients received 212 courses of oral dextromethorphan in doses ranging up to 400 mg.[47] Adverse effects included nystagmus (64%), nausea and vomiting (27%) distorted vision (27%), feeling "drunk" (27%), ataxia (27%), and dizziness (27%). Some patients experienced dysphoria and visual hallucinations.

Illicit Use

Symptoms associated with dextromethorphan abuse include euphoria, altered time perception, lightheadedness, increased perceptual awareness, hallucinations (visual, auditory, tactile), paranoia, visual disturbances, and disorientation. Visual hallucinations involve the appearance of moving swirls and patches of color while the eyes are closed.[14] Case reports indicate that the abuse of dextromethorphan-containing formulations produces nausea, vomiting dizziness, tachycardia, and hypertension along with central nervous system effects (e.g., nystagmus, ataxia, mydriasis, euphoria, lethargy, hallucinations, agitation, seizure, coma).

Dextromethorphan is formulated in cough and cold preparations as the hydrobromide salt. Bromide poisoning is unlikely in episodic, recreational abusers of dextromethorphan hydrobromide. However, chronic, heavy abuse of dextromethorphan may cause chronic bromism presenting with negative anion gap, headache, weakness, lethargy, and altered consciousness.[48] Other clinical effects associated with chronic bromide intoxication include apathy, slurred speech, tremulousness, nystagmus, ataxia, hallucinations, weight loss, acneform rash, and behavioral changes. The differential diagnosis of nystagmus, ataxia and altered mental status includes phencyclidine, lithium, methanol, and anticonvulsant (phenytoin, carbamazepine) intoxication, sedative-hypnotic withdrawal, and thiamine depletion (Wernicke-Korsakoff syndrome). Additionally, chronic dextromethorphan abuse occurs with formulations that include antihistamines (e.g., chlorpheniramine) with anticholinergic effects. Case reports associated dextromethorphan abuse with mania,[49] serotonin syndrome in combination with fluoxetine[50] or chlorpheniramine,[51] and psychosis.[52] Serotonin syndrome may occur during dextromethorphan abuse in patients on therapeutic doses of selective serotonin reuptake inhibitors (e.g., sertraline, escitalopram).[53]

Overdose

Although accidental ingestion of dextromethorphan is a common event, there are few reports of serious toxicity in children following accidental exposure to dextromethorphan; incidental exposures in children may cause mild lethargy, but are typically asymptomatic.[54] Clinical effects commonly associated with mild dextromethorphan overdose include ataxia, drowsiness, hypertension, tachycardia, diaphoresis, mydriasis, vomiting, bidirectional nystagmus, hyperexcitability, and unsteady gait.[17,55] The clinical features of dextromethorphan overdose may simulate the dissociative states associated with ketamine or phencyclidine overdose.

Dextromethorphan intoxication does not simulate classic opioid overdose because this drug lacks strong μ-opioid agonist properties. Miosis and respiratory depression are not a prominent part of dextromethorphan intoxication, which may cause excitation rather than sedation in children.[46] Case reports associate the acute ingestion of dextromethorphan with dystonic reactions (opisthotonus, ataxia, bidirectional nystagmus),[56] psychosis,[57] and the serotonin syndrome (tachycardia, diaphoresis, mydriasis, clonus, hypertonia, confusion, fever).[58]

Dextromethorphan is often formulated in combination with other drugs (e.g., antihistamines, decongestants, expectorants) as part of cough and cold preparations. Consequently, the clinical presentation of intoxication associated with these preparations does not necessarily reflect the classic clinical features of dextromethorphan overdose. Some of these clinical effects also occur following antihistamine intoxication including tachycardia, hypertension, mydriasis, urinary retention, lethargy, agitation, hallucination, and coma. Fatalities due to dextromethorphan intoxication are very rare.

Abstinence Syndrome

A psychologic dependence develops in some patient abusing dextromethorphan over periods ranging from months to years. These patients describe an acute euphoria following dextromethorphan use along with intense craving, insomnia, depression, and dysphoria after cessation of use. Hallucinations and flashbacks can occur within the first few days after the cessation of chronic dextromethorphan abuse.[59] Other clinical features of withdrawal from dextromethorphan include diarrhea, myalgias, restlessness, insomnia, night sweats, chills, and anxiety.[19] Clinical observations suggest that chronic use of dextromethorphan does not produce a classic opioid-like withdrawal syndrome (gooseflesh, yawning, rhinorrhea, lacrimation, arthralgias, tremors, psychomotor agitation);[60] however, minor withdrawal symptoms (nausea, diaphoresis, tachycardia, hypertension) may develop within 24 hours and resolve within 2 days without treatment.[61]

Reproductive Abnormalities

Dextromethorphan is a common antitussive agent for pregnant women. Limited existing data do not indicate that the therapeutic use of dextromethorphan during the first trimester increases the risk of fetotoxicity or congenital malformations. In a study of 128 women ingesting dextromethorphan during the first trimester, there was no statistically significant increase of major

malformation above the expected baseline rate of 1–3%, when compared with pregnant women matched for age, alcohol use, smoking, and upper respiratory tract infection not treated with dextromethorphan.[62] Birth weights and minor malformations were also similar in the two groups. A surveillance study of pharmacy records and pregnancy outcomes in 59 women using dextromethorphan during the first trimester demonstrated similar findings.[63] Dextromethorphan is not generally recognized as teratogenic when used therapeutically during pregnancy (US Food & Drug Administration [FDA] pregnancy category C).

DIAGNOSTIC TESTING

Analytic Methods

Analytic techniques for the quantitation of dextromethorphan and the active metabolite, dextrorphan include high performance liquid chromatography (HPLC) with fluorescence detection,[64] HPLC with ultraviolet detection,[65] gas chromatography with flame ionization detection,[66] and gas chromatography/mass spectrometry (GC/MS).[67] Most of these methods lack the ability to determine the dextromethorphan/dextrorphan ratio. Newer methods provide more accurate determinations of these analytes. The lower limit of quantitation (LLOQ) of dextromethorphan and dextrorphan is 0.002 mg/L and 0.25 mg/L, respectively, following solid-phase extraction of acidified hydrolyzed urine samples and analysis by liquid chromatography/atmospheric pressure chemical ionization/tandem mass spectrometry.[68] The LLOQ for dextromethorphan and metabolites (dextrorphan, 3-methoxymorphinan, 3-hydroxymorphinan) in plasma using ultra performance liquid chromatography/tandem mass spectrometry is near 0.0001 mg/L.[69] The use of capillary electrophoresis on cyclodextrin phases allows the separation of dextromethorphan enantiomers.[70] Analysis of urine or oral fluid samples with enzyme-linked immunosorbent assay (ELISA) and GC/MS allows the determination of dextromethorphan and dextrorphan concentrations with a limit of detection (LOD) and LLOQ of 0.001 mg/L and 0.01 mg/L, respectively.[71] The intraday precision was <5% and the extracted drugs were stable at room temperature for at least 48 hours. The LLOQ for dextromethorphan and dextrorphan in blood samples using dried blood spots technology and HPLC/tandem mass spectrometry is about 0.0002 mg/L.[72] Analysis of cough and cold preparations with HPLC with diode-array UV detection (220 nm) allows the quantitation of various ingredients including dextromethorphan, pseudoephedrine, pheniramine, guaifenesin, pyrilamine, and chlorpheniramine.[73] There are limited human data on the plasma/whole blood ratios of dextromethorphan; however, rodent data suggests that the plasma dextromethorphan concentration is approximately two-thirds the whole blood concentration.[74]

Biomarkers

BLOOD

THERAPEUTIC. The serum dextromethorphan concentrations after oral dextromethorphan doses are relatively low with typical therapeutic concentrations ranging from 0.0005–0.0059 mg/L. The mean peak serum dextromethorphan concentration 2½ hours after administration of 20 mg dextromethorphan to 12 healthy volunteers was 0.0018 ± 0.0022 mg/L when measured as the free dextromethorphan base by gas chromatography.[28] In 181 neurosurgical patients receiving oral dextromethorphan doses ranging from 0.8–9.64 mg/kg (400 mg), the maximum serum dextromethorphan and dextrorphan concentrations were 1.514 mg/L and 0.501 mg/L, respectively. Adverse effects were mild.[47] Figure 29.3 demonstrates the mean plasma concentration of the active metabolite, dextrorphan after the ingestion of 60 mg dextromethorphan in 3 Finnish pharmaceutic cough preparations. In comparison, the mean peak plasma concentrations of the parent compound, dextromethorphan in this study ranged from about 0.002–0.008 mg/L with a mean concentration of approximately 0.0042–0.005 mg/L. Brain dextromethorphan concentrations were up to 68-fold higher than serum dextromethorphan concentrations. In a patient with classic signs of serotonin syndrome following the ingestion of 480 mg dextromethorphan and 64 mg chlorpheniramine, the serum dextromethorphan concentration in an admission blood sample was 0.93 mg/L.[58]

POSTMORTEM. In a case series of 6 infant deaths with detectable dextromethorphan concentrations in postmortem blood, the dextromethorphan concentrations ranged from 0.10–0.95 mg/L.[75] There were insufficient data to separate therapeutic and potentially fatal dextromethorphan concentrations in these cases. In a case series of 8 fatalities involving dextromethorphan, the postmortem dextromethorphan concentration ranged from 7.4–33.55 mg/L.[76] However, the case series did not report specific information on the presence of other drugs or clinical histories. The heart blood of 2 teenagers found dead after abusing dextromethorphan contained dextromethorphan concentrations of 1.89 ng/mL and 3.23 mg/L.[45] One of these teenagers had a therapeutic concentration of diphenhydramine in his postmortem

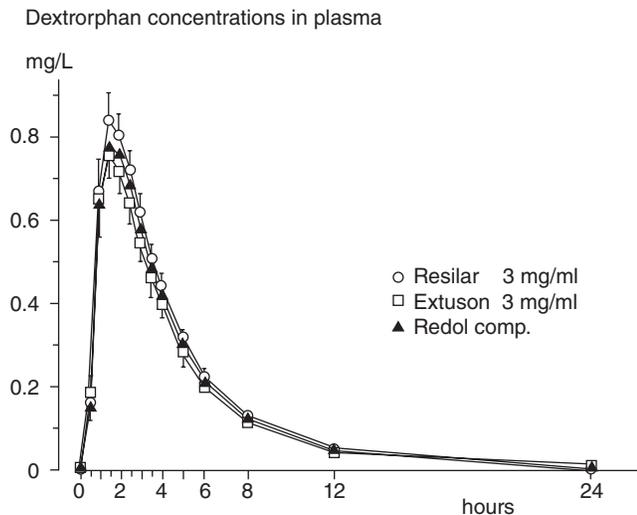
Dextrorphan concentrations in plasma


FIGURE 29.3. Dextrorphan concentrations after ingestion of 3 Finnish cough preparations containing 60 mg dextromethorphan. (Reprinted from M Silvasti, P Karttunen, H Tukiainen, P Kokkonen, U Hänninen, S Nykänen, Pharmacokinetics of dextromethorphan and dextrorphan: a single dose comparison of three preparations in human volunteers, International Journal of Clinical Pharmacology and Therapeutic Toxicology, Vol. 25, p. 495, copyright 1987.)

blood. Femoral blood samples from the postmortem examination of an 18-year-old girl found dead in a lavatory with dextromethorphan in her possession demonstrated dextromethorphan and dextrorphan concentrations of 9.2 mg/L (9.2 μg/g) and 2.9 mg/L (2.9 μg/g), respectively, resulting in a dextromethorphan/dextrorphan ratio of 3.17.[77] She attempted suicide 2 weeks prior to this event and she left a suicide note at that time. In the same report, the dextromethorphan/dextrorphan ratio in femoral blood from a 27-year-old man found dead in his bed was 2.20.

A 19-year-old was found unresponsive after abusing dextromethorphan; he was pronounced dead by paramedics after unsuccessful cardiopulmonary resuscitation. His postmortem iliac blood and vitreous humor contained dextromethorphan concentrations of 1.3 mg/L and 0.7 mg/L, respectively (iliac blood/vitreous ratio, 1.86).

URINE

Routine urine toxicology immunoassays do not typically detect the therapeutic use of dextromethorphan as a result of the low cross-reactivity of dextromethorphan and dextrorphan with opioid and phencyclidine immunoassays; detection of dextromethorphan use by ELISA requires specific immunoassays for dextromethorphan and dextrorphan.[78] The ingestion of single, 20 mg, and

40 mg doses of dextromethorphan did not produce positive results in urine samples from 20 adults, when tested 6 hours after ingestion by the EMIT® opioid screen (Syva Company, San Jose, CA).[79] Occasionally, the ingestion of high doses of dextromethorphan produce false-positive results on urine screens for phencyclidine by immunoassay.[80,81] Confirmation of the presence of dextromethorphan in biologic samples requires analysis by more-specific methods (e.g., GC/MS).

Abnormalities

Mild elevation of serum bromide concentrations may or may not occur following the chronic ingestion of large doses of dextromethorphan hydrobromide-containing formulations.[49] Standard clinical laboratory analytic tests do not distinguish between chloride and bromide. Therefore, the ingestion of bromide produces a false elevation in the serum chloride concentrations as well as a decreased anion gap. A common biomarker for bromide toxicity is a negative anion gap resulting from pseudo-elevation of the serum chloride used to calculate the anion gap. For example, Coricidin HBP Cough & Cold tablets contain 6.9 mg bromide, and the ingestion of 8–16 tablets results in the ingestion of 55–110 mg bromide. The acceptable daily intake of bromide is about 1 mg/kg body weight; consequently, the occasional ingestion of this dose of dextromethorphan hydrobromide probably would not produce chronic bromism. The bromide concentration in a serum sample from a 39-year-old man with a manic state and a history of frequent consumption of 1,500 mg dextromethorphan hydrobromide-containing bottles of cough syrup was 3.4 mEq/L.[49] The serum bromide concentration in a 56-year-old man with chronic symptoms of bromism (lethargy, weakness, alteration of consciousness) was 4.0 mEq/L. Analysis of serum chemistry demonstrated a spurious elevation of chloride and a decreased anion gap. He had consumed 60–120 mL of a cold preparation containing dextromethorphan bromide daily for 4–5 years prior to admission to the hospital for loss of consciousness.[82] A rare case report suggests that dextromethorphan overdose may cause QTc prolongation. A 27-year-old man developed QTc prolongation (i.e., 514 msec after potassium repletion) after ingesting 1,920 mg dextromethorphan and ethanol.[83] His previous QTc following an ethanol binge (no dextromethorphan) was 432 msec.

Driving

In a study of 13,439 blood samples submitted to the Wisconsin State Laboratory of Hygiene from drivers suspected of impairment, blood samples from 108

drivers were positive for dextromethorphan.[84] The mean dextromethorphan concentration was 0.207 mg/L (median = 0.051 mg/L) with a range of 0.005–1.8 mg/L. Although evaluation by drug recognition experts indicated that these drivers had poor psychomotor performance on standardized field sobriety tests and horizontal gaze nystagmus, 96% of these samples contained other drugs. In a case series of 5 known dextromethorphan abusers arrested for driving while impaired, the median dextromethorphan concentration was 0.79 mg/L (range, 0.47–1.22 mg/L).[85] Blood samples from most of these drivers contained other drugs including chlorpheniramine.

TREATMENT

Stabilization

The treatment of dextromethorphan intoxication is supportive. Patients with altered consciousness require intravenous (IV) access, pulse oximetry, and rapid evaluation of blood glucose with the administration of intravenous glucose as necessary. The treatment of agitation involves the IV use of benzodiazepines (lorazepam or diazepam). Hypertension and tachycardia usually respond to sedation, reassurance, and a quiet environment. The presence of clinically significant hyperthermia along with hypertonicity suggests the serotonin syndrome as a result of the interaction of monoamine oxidase inhibitors with dextromethorphan. Decontamination measures include the use of activated charcoal within 1–2 hours of ingestion. If oral activated charcoal is administered, the patient should be observed closely for any alteration of consciousness that would predispose the patient to aspiration. Although some patients with altered consciousness following dextromethorphan ingestion respond to naloxone,[86] the clinical response to naloxone is inconsistent. Similarly, the response of acute dystonic reactions to diphenhydramine is also variable during dextromethorphan intoxication, but some case reports document the resolution of extrapyramidal symptoms after administration of IV diphenhydramine.[56]

Supplemental Care

Most patients with minor acute ingestions of dextromethorphan can be released from the emergency department after 4–6 hours of observation as long as the clinical effects have resolved. In a child developing a dystonic reaction following the ingestion of 38 mg dextromethorphan/kg, the administration of diphenhydramine was associated with resolution of opisthotonus, but not ataxia and nystagmus.[56] The administration

of naloxone did not alter the course of the dystonic reaction. Laboratory assessment of patients with moderate to severe dextromethorphan intoxication includes serum electrolytes, acid-base status, serum creatine kinase, urine myoglobin, serum hepatorenal function, urinalysis, and urine drug of abuse screen if required by the clinical presentation. Many dextromethorphan-containing formulations contain acetaminophen or salicylates. Serum acetaminophen and/or serum salicylate concentrations should be analyzed if the product may contain these drugs or if the patient ingested the drug with suicidal intent. Interpretation of the serum acetaminophen and salicylate concentrations requires a history of the time and chronicity of ingestion because dextromethorphan abuse frequently involves multiple ingestions during the period just prior to presentation.

Chapter 30

FENTANYL ANALOGUES

HISTORY

Paul Janssen and his coworkers synthesized fentanyl in 1960 during their search for analgesics more potent than morphine and meperidine.[1] In 1968, fentanyl was the first of the 4-anilinopiperidine series of opioid agonists introduced into the United States as a synthetic intravenous (IV) anesthetic/analgesic under the trade name Sublimaze® (fentanyl, Janssen-Cilag Ltd, Australia) and Innovar® (fentanyl and droperidol, Janssen-Cilag USA, Titusville, NJ). The latter combination has been discontinued. The rapid onset, short duration of action, and high clinical potency (i.e., about 50–100 times more potent than morphine) led to the acceptance of fentanyl as a commonly used drug for preanesthetic sedation, postsurgical analgesia, and conscious sedation procedures. Fentanyl produces clinical effects (e.g., miosis, bradycardia, respiratory depression, and euphoria) similar to natural opiates. Riley et al. synthesized 3-methylfentanyl from 4-anilino-3-methylpyridine in 1973. In 1979, a powerful, synthetic drug called China White appeared in the illicit drug market; this drug was associated with sudden respiratory arrest and death in opioid addicts.[2] After extensive analysis, the US Department of Justice Special Testing and Research Laboratory identified the drug as the fentanyl derivative, α-methylfentanyl.[3] Later, even more powerful designer opioids appeared in the illicit drug market (e.g., *p*-fluoro fentanyl, 3-methyl fentanyl), which are about 2,000 times more potent than morphine. The illicit use of 3-methyl fentanyl caused at least 100 deaths in California and Pennsylvania during the 1980s.[4,5] Fentanyl derivatives were also involved in the illegitimate administration of doping agents to race horses.[6] Epidemics of fatal 3-methylfentanyl poisonings continue in the Russian Federation, Ukraine, and Estonia.[7]

IDENTIFYING CHARACTERISTICS

Fentanyl and fentanyl derivatives are synthetic opioid analgesics that bind primarily to μ-opioid receptors;[8] there are over 200 fentanyl derivatives.[9] Figure 30.1 displays the chemical structures of fentanyl and common fentanyl analogues. 3-Methyl fentanyl [*N*-(3-methyl-1-(2-phenylethyl)-4-piperidinyl)-*N*-phenylpropanamide, CAS RN: 42045-86-3] is a highly lipid soluble, tertiary amine with a molecular formula of $C_{23}H_{30}N_2O$. The high potency of fentanyl analogues results from the rapid diffusion of these compounds into the brain as well as the high affinity of these drugs for μ-opioid receptors when compared with morphine. There are substantial differences in the potency of the stereoisomers of these drugs. The relative potency of *cis*-(+)-isomer and *trans*-(±)-isomer of 3-methylfentanyl to morphine is approximately 7,000- and 1,000-fold, respectively, based on the tail withdrawal test in rats.[10] Radioreceptor assays indicated that *cis*-3-methylfentanyl is the active isomer of this compound with high affinity ($K_i = 0.24$ nM) for the μ-opioid receptor.[11]

Terminology

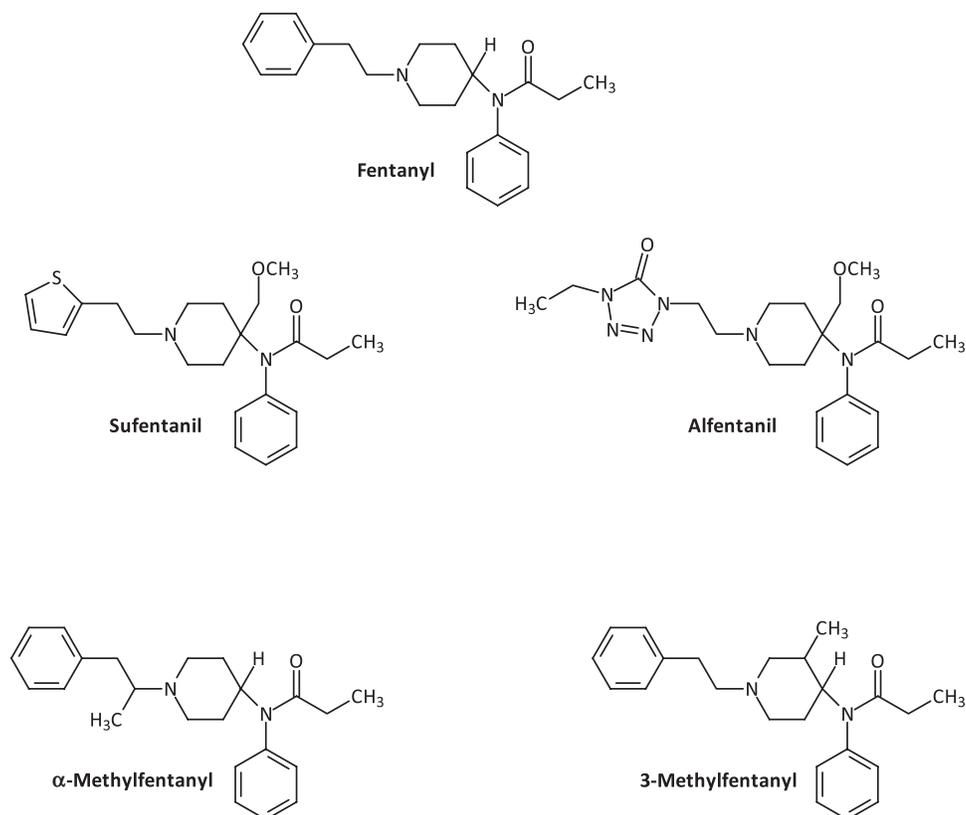
China White refers to 3-methyl fentanyl and α-methyl fentanyl as well as to a very pure form of white heroin, often from Southeast Asia. Other street names for these drugs include China Girl, Persian White, Egg White, Crocodile, Dragon, 999, and Synthetic Heroin.


FIGURE 30.1. Chemical structures of fentanyl and related compounds.

Form

The physical appearance of fentanyl and fentanyl analogues is similar to some types of heroin; the range of colors of heroin range from pure white (Persian White) and off white (China White) to light tan (Synthetic Heroin) and light brown (Mexican Brown). The cost and packaging of fentanyl analogues and light-colored heroin are also similar. Fentanyl derivatives mix poorly with diluents (e.g., lactose) and adulterants, resulting in potentially dangerous, nonuniform distribution of the active drug.[12]

EXPOSURE

Epidemiology

Retrospective analysis of data from the Drug Abuse Warning Network (DAWN) suggests that opioid analgesics are a small part of drug abuse despite the increasing medicinal use of opioids (including fentanyl).[13] Occasional fatalities result from the abuse of fentanyl both by IV injection and insufflation,[14] as well as fatalities from the use of 3-methyl fentanyl as an additive in heroin and/or cocaine during sporadic epidemics in California and Pennsylvania.[15,16] Difficulty diluting this potent drug and the general preference of the opioid-dependent population for heroin accounts for the intermittent use of cis-3-methylfentanyl.[17]

Sources

Illicitly synthesized fentanyl analogues for street use include α-methyl fentanyl, p-fluorofentanyl (CAS RN: 90736-23-5, 4-fluorofentanyl), 3-methyl fentanyl, α-methyl acetylfentanyl, acryl α-methylfentanyl, benzylfentanyl (CAS RN: 1474-02-8), and α-methyl-β-hydroxylfentanyl as well as thienyl and hydroxy derivatives of 3-methylfentanyl. These derivatives are typically available through the same distribution channels as heroin. Because of the high potency of fentanyl and fentanyl analogues, dilution of these illicit drugs is difficult. As a result of the potency of fentanyl and fentanyl analogues, most samples of illicit fentanyl and fentanyl analogues analyzed by law enforcement agencies contain up to 99% lactose and other filler materials.[18] Analysis of confiscated samples of p-fluorofentanyl demonstrated large variability in the dose of this illicit analogue with the p-fluorofentanyl content ranging from 33.8–408.7 μg/tablet (0.14–

1.57%).[19] Caffeine was a common adulterant in these formulations.

Methods of Abuse

Abuse of fentanyl analogues primarily involves the IV administration of these drugs, often as a substitute for heroin and usually administered at about the same frequency as heroin. Most habitual heroin users prefer heroin to fentanyl derivatives as a result of the intense "rush" associated with IV heroin use as opposed to the longer, quieter euphoria associated with fentanyl derivatives.[20] Occasionally, fentanyl analogues are insufflated, chewed, or applied to the oral mucosa with fatal effects.

DOSE EFFECT

The sedative and analgesic dose following the IV administration of fentanyl is approximately 50–100 μg. The potency of *p*-fluorofentanyl and fentanyl is similar, but the potency of *cis*-3-methylfentanyl is substantially greater than fentanyl.[21] There are few clinical data on the dose response of illicit fentanyl analogues; in general, fatal street doses are difficult to predict. Animal studies suggest that the potencies of illicit fentanyl analogues are between the potencies of fentanyl and 3-methylfentanyl.[10]

TOXICOKINETICS

Fentanyl is a potent, short-acting opioid analgesic with a large apparent volume of distribution, extensive first-pass hepatic metabolism, a relatively short plasma elimination half-life, and extensive biotransformation. There are limited data on the toxicokinetics of fentanyl analogues, but the toxicokinetics of these compounds is probably similar (but not necessarily identical) to fentanyl.

Absorption

The usual route of fentanyl analogue exposure is by IV because extensive first-pass hepatic metabolism substantially reduces the oral bioavailability of fentanyl analogues. Following IV administration, serum fentanyl concentrations fall rapidly within 5 minutes. The substantial pulmonary absorption of fentanyl suggests that inhalation is a potential route of exposure to fentanyl analogues depending on the efficiency of the delivery system.[22] The systemic pharmacokinetic parameters of the inhaled fentanyl is similar to IV administration (including onset of action). The dermal absorption of fentanyl analogues depends on their octanol water partition coefficient, which varies among fentanyl derivatives.

Distribution

The initial distribution half-life of fentanyl is 1–2 minutes following the IV administration of high-dose (60 μg/kg) fentanyl for surgical anesthesia.[23] The short duration of action of fentanyl analogues results from redistribution from opioid receptors rather than biotransformation. The high lipophilicity of fentanyl and fentanyl analogues suggests that these drugs accumulate in adipose tissue; the volume of distribution of these drugs increase in obesity.[24]

Biotransformation

Fentanyl and illicit fentanyl analogues undergo extensive biotransformation, primarily by oxidative *N*-dealkylation to the inactive nor-metabolite. *In vitro* studies indicate that CYP 3A4 catalyzes the *N*-dealkylation of fentanyl to the nor-metabolite.[25,26] Minor pathways include amide hydrolysis to the despropionyl metabolite and hydroxylation of the piperidine ring, the phenyl rings, or the propionyl side chain.

Elimination

Metabolism accounts for over 90% of the elimination of fentanyl with most studies indicating that the kidney excretes <4–10% of the absorbed therapeutic dose of fentanyl as unchanged drug.[27]

Maternal and Fetal Kinetics

The high lipid solubility of fentanyl analogues suggests that these compounds easily diffuse across the placenta following IV administration to the mother.

Tolerance

There are few clinical data on tolerance to fentanyl analogues. Like heroin, tolerance develops to some, but not all, of the clinical effects of opioids including (respiratory depression, nausea, analgesia, and sedation).

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

Although fentanyl derivatives are structurally unrelated to opioids, these drugs exhibit similar pharmacologic and toxicologic properties including a high affinity for the μ-opioid receptor. Binding to μ-opioid receptors causes analgesia, sedation, euphoria, respiratory depression, and hypotension as well as tolerance and physical

withdrawal. *In vitro* studies suggest that μ-, κ-, and δ-opioid receptor selectivity between fentanyl and fentanyl analogues vary. A study in cloned human opioid receptors demonstrated that μ- and δ-opioid receptor selectivities of fentanyl and *p*-fluorofentanyl were similar, but κ-opioid selectivity was greater for *p*-fluorofentanyl than fentanyl.[28]

Postmortem Examination

Postmortem examination of fatalities following overdoses of fentanyl analogues are nondiagnostic (e.g., visceral congestion, pulmonary edema), except for the presence of stigmata of IV drug use (recent puncture wounds, chronic active hepatitis, human immunodeficiency virus [HIV], adenopathy).[29] Death following fentanyl injection occurs rapidly as reflected in the lower postmortem lung weights compared with fatal heroin overdose.[30] Bronchopneumonia and aspiration of gastric contents are uncommon postmortem findings.

CLINICAL RESPONSE

Overdose

Fentanyl analogues produce typical symptoms of opioid overdose manifest by respiratory depression, bradycardia, hypotension, nausea, vomiting, and hypothermia. Seizures occur rarely during fentanyl intoxication, typically resulting from hypoxia rather than drug effect.[31] Death results from respiratory depression and subsequent cardiopulmonary arrest. Frequently, the use of illicit fentanyl analogues produces a very rapid death, and the victim may be found with the needle still in his or her arm. Most fatalities occur in known IV drug abusers, and most of these individuals are polydrug users (e.g., morphine, cocaine, diazepam, amphetamine, codeine, methadone).

Abstinence Syndrome

Tolerance and physical dependence following the habitual use of fentanyl, fentanyl analogues, and opioids are clinically similar. Like other opioids, fentanyl analogues cause downregulation of opioid receptors following prolonged exposure. This property produces tolerance and reduction in the inhibitory pathways during withdrawal.

DIAGNOSTIC TESTING

Analytic Methods

The most common methods for the detection of fentanyl and fentanyl derivatives are radioimmuno-assay, gas chromatography, liquid chromatography/atmospheric pressure ionization/tandem mass spectrometry (lower limit of detection [LLOQ], 0.003–0.027 mg/L),[32] and gas chromatography/mass spectrometry (GC/MS).[21] The latter method can detect nor-metabolites of fentanyl and fentanyl analogues with a sensitivity of 2 ng/mL.[33] Liquid chromatography/tandem mass spectrometry allows the quantitation of 9 fentanyl compounds and 16 opioids commonly used medicinally and abused by drug addicts. This method has LLOQ in the range of approximately 0.1–2 ng/mL. The limit of detection (LOD) for *cis*-3-methylfentanyl using liquid chromatography/tandem mass spectrometry is approximately 0.1 ng/mL.[34] Using liquid chromatography/tandem mass spectrometry with electrospray ionization in positive ionization mode, the LLOQ for fentanyl, norfentanyl, and 3-methylfentanyl is about 0.1 ng/mL.[35] The use of liquid chromatography on a reversed-phase column and a gradient consisting of acetonitrile and ammonium acetate at pH 3.2 along with tandem mass spectrometry (quadrupole/linear ion/trap mass spectrometer with a turbo ion spray interface in positive mode using multiple reaction monitoring) allows the detection of illegal fentanyl analogs.[36] Using this technique, the LLOQ for *cis*- and *trans*-3-methylfentanyl, *α*-methylfentanyl, and *p*-fluorofentanyl is approximately 0.1 ng/mL with a bias of 2–5%. Isolation of fentanyl from biologic matrices involves liquid/liquid and/or solid-phase extraction with ethyl acetate, *n*-butyl chloride or heptane/isoamyl as solvents.[8] Analysis of a postmortem blood sample stored frozen for 16 months after the death of a 28-year-old man from a opioid overdose demonstrated the presence of 3.1 ng/mL α-methylfentanyl.[37]

Biomarkers

The presence of small amounts of fentanyl analogues in the stomach does not necessarily imply ingestion of these drugs because of the excretion of these substances into the acid milieu of the stomach. The aqueous solubility of fentanyl increases exponentially with decreasing pH.

Blood

Fatalities from illicit or surreptitious fentanyl analogue use typically involves younger drug addicts dying at their home with multiple drugs (e.g., benzodiazepines, methadone, morphine or 6-acetyl morphine, oxycodone) present in postmortem blood, when compared with deaths from therapeutic fentanyl use.[38] Tolerance, postmortem redistribution, interindividual variation in response, and the presence of multiple drugs complicate

the interpretation of postmortem fentanyl concentrations. Limited data on the postmortem redistribution of fentanyl analogues suggest that postmortem redistribution is variable, but likely significant based on postmortem data on fentanyl.[39]

Urine

Routine urine drug screens do not typically detect fentanyl and fentanyl analogues. The poor cross-reactivity between fentanyl analogues and opioid antigens in urine drug screens results from the lack of structural similarity, low urinary fentanyl concentrations, and the absence of morphine as a fentanyl analogue metabolite. The concentration of the nor-metabolites of fentanyl analogues may be higher in urine samples than the parent drug. The cross-reactivity of fentanyl analogues with immunoassays designed to detect fentanyl and norfentanyl is variable; the lower limit of detection ranges from 0.25–0.5 ng/mL.[40]

TREATMENT

Stabilization

The classic presentation of fentanyl analogue intoxication is similar to heroin overdose including evidence of IV drug use and altered consciousness along with depressed respiratory rate and miotic pupils. Abuse of fentanyl analogues also occurs by insufflation and inhalation. The onset of symptoms after fentanyl analogue overdose is usually more rapid than heroin overdose. Although miosis develops during acute fentanyl analogue intoxication, the presence of severe hypoxia and metabolic acidosis may alter the pupil size. Initial treatment involves the assessment of ventilation and perfusion. Patients with adequate ventilation and oxygen saturations above 91–92% can be observed with cardiorespiratory monitoring until a normal level of consciousness returns. Patients with inadequate ventilation require bag-value-mask ventilation with 100% oxygen and the administration of naloxone 0.2-0.4 mg IV. Although the rate of subcutaneous absorption of naloxone is slower than the IV route, difficulty obtaining IV access may result in similar onset of action via these 2 routes of administration, at least in the prehospital setting.[41] Endotracheal administration of naloxone is an option to parenteral use of this antidote.[42]

If no improvement occurs within 3–5 minutes, additional doses (1–2 mg) of naloxone should be administered parenterally. Criteria for endotracheal intubation include inability to ventilate with bag-valve-mask, poor oxygenation (i.e., oxygen saturation <90%) despite adequate ventilation and supplemental oxygen, and persistent hypoventilation after doses of naloxone exceeding 2–4 mg. The treatment of overdoses of fentanyl analogues requires the administration of naloxone doses sufficient to reverse respiratory depression. High doses of naloxone may be necessary to reverse large overdoses of the potent opioid receptor agonist action of fentanyl derivatives, but all overdoses of fentanyl analogues respond to adequate doses of naloxone when administered before the onset of irreversible damage from respiratory depression and hypoxia.[4] Lack of response to an adequate dose of naloxone indicates hypoxic brain damage or a diagnosis other than opioid intoxication (e.g., head trauma, sepsis, meningitis, aspiration pneumonia). If pulmonary signs or symptoms (e.g., cough, tachypnea, pink frothy sputum, rales) develop, the patient should undergo a chest x-ray to detect radiographic findings of pulmonary edema and/ or aspiration pneumonia.

Pulmonary Edema

A majority of patients with opioid-induced pulmonary edema require only oxygen supplementation. In a case series of 27 patients with pulmonary edema after resuscitation from heroin overdose, 9 patients required mechanical ventilation with extubation usually occurring within 24 hours after intubation. However, severe hypoxia can develop following the administration of naloxone for fentanyl analogue overdose as a result of the occurrence of pulmonary edema.[43] Patients with other complications (e.g., aspiration pneumonia) in addition to pulmonary edema may require intubation including pressure-cycled ventilation for longer periods.

Hypotension

Hypotension from fentanyl analogue intoxication usually responds to fluids and naloxone.

Gut Decontamination

There are few clinical data to guide gut decontamination therapy during fentanyl analogue intoxication. Methods to prevent absorption of fentanyl are not necessary as abuse of fentanyl and fentanyl analogues is usually via injection or inhalation.

Elimination Enhancement

Methods to enhance elimination (e.g., hemodialysis) are not indicated unless renal failure and hyperkalemia complicate acute fentanyl analogue intoxication, usually as a result of rhabdomyolysis.

Antidotes

Naloxone, a pure opioid antagonist, is the antidote of choice for acute fentanyl analogue intoxication. The initial dose of naloxone usually should not exceed 0.4–0.8 mg IV because of the risk of producing withdrawal in opioid-dependent patients. Larger doses of naloxone (e.g., 2–4 mg) may then be administered if the clinical response is inadequate. After restoration of adequate ventilation, repeat doses of naloxone may be necessary for recurrent, clinically significant hypoventilation, particularly following large doses of fentanyl analogues. Fentanyl analogues are usually relatively short-acting. Mild sedation can recur after the administration of naloxone following fentanyl analogue intoxication, in part as a result of the formation of the naloxone metabolite, 6-α-naloxol, which has agonistic and antagonistic effects on opioid receptors. Although μ-opioid receptors mediate respiratory depression, stimulation of both μ- and κ-opioid receptors causes sedation. Hence, persistent κ-opioid stimulation by 6-α-naloxol can cause recurrence of sedation, but recurrence of respiratory depression does not usually occur.

Supplemental Care

Laboratory testing in patients with prolonged coma from acute fentanyl analogue intoxication include analysis of the blood for complete blood count, electrolytes, creatinine, hepatic aminotransferases, and creatine kinase. The presence of rhabdomyolysis (serum creatine kinase >1000 IU) indicates the need for generous fluid replacement and monitoring of renal function; urinary alkalinization probably should not be considered because of the lack of proven efficacy as well as the potential to increase the penetration of the central nervous system and prolong the urinary elimination of the drug.

Chapter 31

HEROIN and THE OPIUM POPPY PLANT
(*Papaver somniferum* L.)

HISTORY

The opium poppy is one of the oldest known medicinal plants. Although the exact time and place of discovery is unknown, the opium poppy probably originated in Asia minor.[1] Sumerian clay tablets in cuneiform script first described the cultivation of the opium plant about 3000 BC. The Sumerian term for opium was *gil* (happiness), and the opium poppy was called the joy plant (*gil hul*). The Assyrians also collected poppy juice in earthen pots during the early morning by scraping the poppy capsule with an iron scoop. The Persian conquerors of Assyria and Babylonia as well as the ancient Egyptians continued the cultivation of the opium poppy, although the Egyptians restricted opium use to cults that included magicians, priests, and warriors.[1] The writings of Hippocrates (460–377 BC) mentioned the use of poppy juice in wine. Opium and hemlock was a common lethal concoction for the execution of condemned Greeks; the Romans continued the use of opium as a medicinal agent and as a poison. Paracelsus (1493–1541) popularized the use of opium in various mixtures (e.g., laudanum) as an analgesic in Europe during the early 16th century. Later in the 17th century, Thomas Syndenham introduced tincture of opium (i.e., laudanum) into Britain as a treatment for plague.

Filling a pacifier with opium poppy seeds was a popular European custom in the 19th century for quieting a noisy baby; several case reports during the middle 19th century attributed poisoning and death of infants to the use of syrup of poppies.[2,3] In 1874, 100 years following the discovery of morphine, a London researcher, C.R. Wright synthesized heroin (diacetylmorphine, diamorphine) along with a series of acetylated morphine derivatives by boiling anhydrous morphine with acetic anhydride.[4] This compound was originally formulated as a cough suppressant. William Osler first described heroin-induced pulmonary edema in 1880.[5] In the latter part of the 19th century, Felix Hoffman of the Bayer Company isolated heroin. Shortly thereafter, the Bayer company began marketing heroin as a cough suppressant and pain remedy with the expectation that acetylation of the morphine molecule would reduce adverse effects. The addictive potential of heroin was not recognized until the early 20th century. The International Opium Commission was founded in 1909; by 1914, 34 nations had agreed to decrease opium production. The Harrison Narcotic Act of 1914 restricted the use of heroin in the United States. The International Narcotics Control Board of the United Nations now regulates the cultivation of opium poppies with India being the only country involved in the legal international trade of opium.

By the 1920s, the illicit use of heroin, primarily via the nasal route, was associated with crimes in many eastern US cities. Heroin smoking with porcelain bowls and bamboo tubes originated in Shanghai during the 1920s; this technique spread across East Asia and to the United States over the next decade.[6] In 1931, an expert report from the League of Nations recommended replacing the medical use of heroin with other opioids because of the abuse potential of heroin and the availability of alternatives.[7] "Chasing the dragon" (i.e., inhaling vapors released by heating heroin on aluminum foil

with a flame) was a refinement of heroin smoking that originated near Hong Kong in the 1950s. This form of heroin abuse spread to other parts of Southeast Asia, and over the next 20 years, to the Indian subcontinent and parts of Europe. During the early 1980s, case reports associated the development of spongiform leukoencephalopathy with the practice of "chasing the dragon."[8] Except in the United Kingdom, diacetylmorphine (heroin) is not approved for therapeutic use; heroin abuse continues to occur in cyclical patterns depending on availability and illicit drug preferences. Heroin use increased dramatically in the early 1970s, but subsequently declined until availability again increased the use of heroin in the late 1980s and early 1990s. Currently, heroin use is increasing, particularly in adolescents using more concentrated heroin formulations, initially via nasal insufflation.[9]

BOTANICAL DESCRIPTION

The opium poppy plant is one of the approximately 100 plant species in the poppy family. The taxonomy of the poppy family is complex; there are a variety of subspecies and strains as a result of the cultivation of these plants over thousands of years. There are several variations of opium poppy plant and related cultivars as a result of the extensive cultivation of this single plant species over many years. Typically, the Indian variety (*album*) has white flowers with white seeds, whereas the European variety (*nigrum*) has purple flowers and slate gray seeds.[1] The Asia minor variety (*glabrum*) has purple flowers with purplish-black seeds.

Common Name: Opium poppy

Scientific Name: *Papaver somniferum* L.

Botanical Family: Papaveraceae (poppy)

Physical Description: These plants are annual herbs with erect stems and alternate, simple, clasping, toothed leaves. The solitary, terminal flowers have showy petals that vary in color from white to purplish-red depending on the cultivars. The fruit is a capsule with an expanded disc at the top that disperses minute seeds. The dried milky exudate of the unripe seed capsule contains morphine. A poppy plant produces one crop (i.e., 5–8 capsules) over a 3- to 5-month period in sunny, rich, moist areas without frost. In northern India, sowing of seeds begins in November (i.e., late fall, early winter); flowering occurs from April to May with capsules maturing in May or June.

Distribution and Ecology: Legal cultivation of poppy plants occurs principally in northern India (Madhya Pradesh, Rajasthan, Uttar Pradesh)

IDENTIFYING CHARACTERISTICS

Structure

Heroin (diacetylmorphine) is a prodrug, which undergoes rapid hydrolysis in the body first to 6-monoacetylmorphine (6-MAM) and then to morphine, especially at alkaline pH. Figure 31.1 demonstrates the chemical structure of heroin and other major alkaloids potentially in illicit heroin.

Physiochemical Properties

The high lipid solubility of heroin allows the rapid distribution of the drug into the central nervous system (CNS). The pK_a of heroin is 7.6; at physiologic pH, approximately 55% of the drug is ionized and the remainder is accessible for membrane-transport. The smokable form of heroin (i.e., heroin base) contains about 91% of the mass of the hydrochloride salt of heroin used for intravenous (IV) administration.

Pyrolytic products from the heating of heroin result from oxidation, de-acetylation, transacetylation, *N*-demethylation, *O*-methylation, and ring cleavage of heroin. Methanol-dichloromethane extraction and gas chromatography/mass spectrometry (GC/MS) analysis of residues from aluminum foils previously used for street heroin smoking of extracts of residues identify about one-half of the compounds in the residues including 6-MAM, 6-acetylcodeine, papaverine, meconine, diacetylmorphine, 4′-acetoxyacetanilide, 4′-methoxyacetanilide, hydrocotarnine, thebaol (degradation product of thebaine), triacetin, caffeine, cocaine, and paracetamol.[10]

During heating, the thermal decomposition of heroin base is much less than heroin hydrochloride. In a study using an experimental device to heat heroin to 200°C (392°F), the loss of heroin base and heroin hydrochloride during volatilization was 11% and 72%, respectively.[11] The heating of diacetylmorphine base and diacetylmorphine hydrochloride up to 310°C (590°F) for about 25 minutes caused the thermal degradation of about 30% and 70% of these compounds, respectively.[10] 6-Monoacetylmorphine is the major degradation product of these 2 compounds among a variety of degradation products.[12] 6-Monoacetylmorphine, 6-acetylcodeine, and morphine were relatively stable under these conditions.

Terminology

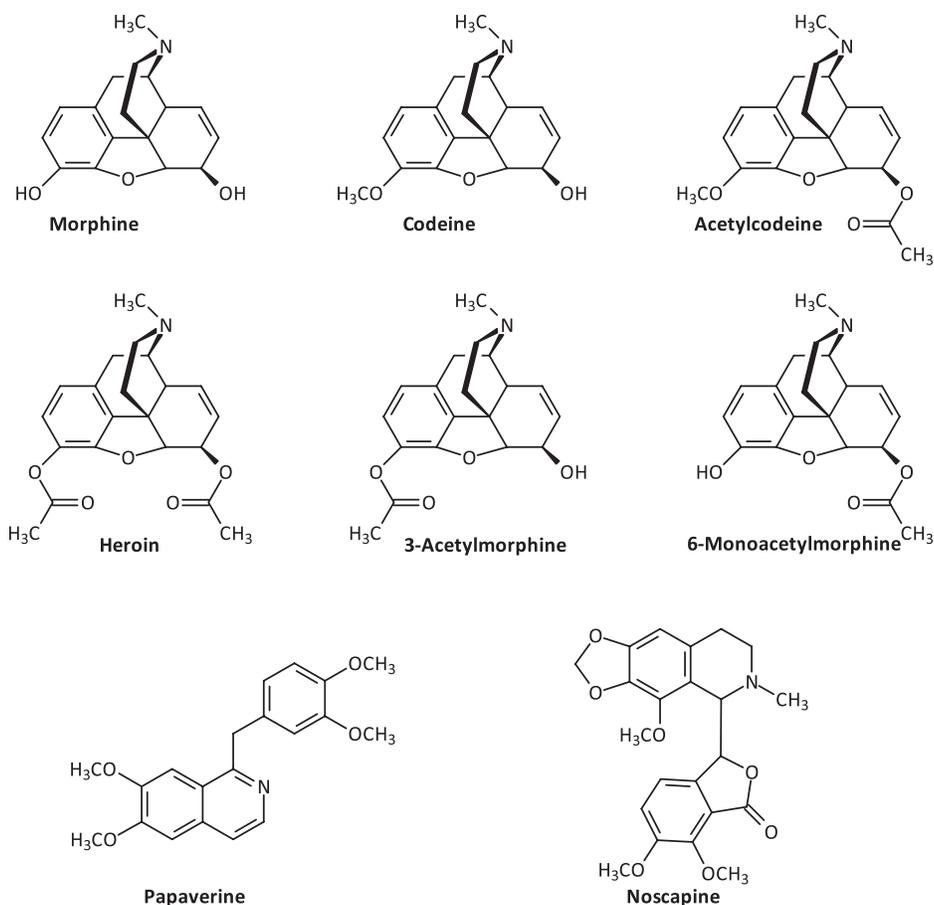
The term *opiate* traditionally refers to opioid-receptor (OR) binding drugs extracted from the opium poppy (*Papaver somniferum* L.) including codeine and


FIGURE 31.1. Chemical structures of heroin and related compounds.

morphine. Opioid is a broader term that includes opium-derived drugs and synthetic substances (fentanyl, propoxyphene) with morphine-like activity as well as substances with OR antagonist activity. "Cheese" is a tan powder suitable for insufflation that is composed of black tar heroin cut with acetaminophen and diphenhydramine to a concentration of approximately 8% heroin.

Form

Heroin is sold in aluminum foil and wax-paper envelopes. A bag (single dose) of heroin typically contains about 100 mg diacetylmorphine with the purity historically ranging from about 1–10%. Recently, the purity of heroin in illicit samples has significantly increased. Illicit heroin varies in chemical and physical appearance depending on the origin of the drug. Figure 31.2 displays confiscated Asian brown and white heroin; Figure 31.3 shows confiscated Mexican black tar heroin.

EXPOSURE

Epidemiology

The estimated number of dependent heroin users among the general Australian population is approximately 7 per 1000 people aged 15–54 years.[13] This prevalence is similar to that of the United Kingdom and within the range (i.e., 3–8 heroin addicts/1000 people) of other European countries. The typical gender distribution of heroin users reveals a male/female ratio of approximately 7:3.[14] In the United States, there are an estimated 200,000 current heroin users (12 years and older) as defined by heroin use within the last month.[15] The estimated lifetime prevalence of heroin use is approximately 3 million (i.e., about 1.4% of Americans). Epidemiologic data indicates that heroin dependence and heroin-related emergency department visits increased substantially within the last 10–20 years in Europe, Australia, and the United States along with

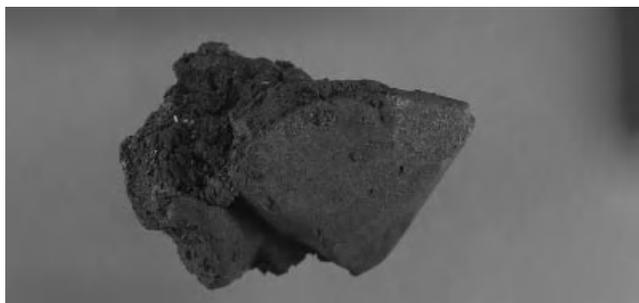
FIGURE 31.2. Confiscated Southwest Asian brown and white heroin. The latter is also produced in Southeast Asia. (Photo courtesy of the US Drug Enforcement Agency)


FIGURE 31.3. Confiscated Mexican black tar heroin. (Photo courtesy of the US Drug Enforcement Agency)

heroin-related deaths.[16,17] Although fatal heroin overdoses occur in both sexes, the typical heroin-related fatality involves 25- to 34-year-old male polydrug abusers.[18]

Sources

Heroin is available illegally in the Black Market and legally in the United Kingdom under strict controls. Government-regulated opium is grown on farms primarily in India, and to a lesser extent in Turkey and Australia; some diversion of this opium to clandestine heroin production probably occurs.[19] Previously, most US illicit heroin was a white powder derived from Asian opium that was processed in France. Now, major sources of illicit US heroin include South America (Colombia), Mexico, Southeast Asia (Myanmar, Burma, and to a lesser extent, India), and Southwest Asia/Middle East (Afghanistan, and to a lesser extent, Pakistan, Iran, Lebanon).[20]

Before the 1990s, most heroin transported to the US originated in Southeast Asia with the amount of heroin in street samples ranging from approximately 1–10%. In the last 10 years of US drug trafficking, less-expensive, undiluted forms of heroin replaced the more dilute Southeast Asian heroin, particularly in the eastern United States. A large portion of Southwest Asian heroin is now consumed in western Europe, Pakistan, and Iran. Mexican brown heroin has been transported from Mexico to the Southwest United States for many decades. Black tar heroin and, to a lesser extent brown powdered heroin from Mexico are prominent forms of heroin in the western United States. Black tar heroin is a viscous to hard black substance that originates in the mountainous regions of Northern Mexico (Durango, Sinaloa, Sonora) and in areas southwest of Mexico City.

Origin/Composition

Opium. Opium is the air-dried, white exudate extracted from the poppy plant that contains at least 40 alkaloids in addition to morphine including codeine, thebaine, narcotine (phthalideisoquinoline noscapine), papaverine, and minor alkaloids (aporphine, benzophenanthridine, protoberberine, tetrahydroprotoberbine, tetrahydroisoquinoline). Pharmaceutic preparations of opium contain about 10% morphine, 5–20% water, 20% sugars, and simple organic acids (fumaric, meconic, lactic, oxaloacetic).[1] Meconic acid occurs in various species in the genus, *Papaver*; the presence of this dibasic acid is not limited to the opium poppy plant. According to 2008 US Drug Enforcement Agency statistics, the wholesale purity of Mexican heroin was 40% compared with 57% for South American heroin.[20] The average purity of heroin from different sources changes annually. For example, the highest average purity in 2000 occurring in South American heroin (48%) followed by Southwest Asian heroin (35%) and Mexican heroin (21%). Compared with Southwest Asian heroin, black tar heroin is much less refined due to the production processes (e.g., use of kerosene rather than acetone). The purity of black tar heroin (i.e., average 35%, range, 20–80%) is substantially greater than Southwest Asian heroin.[21]

Opium Poppy Seeds. Figure 31.4 displays an opium poppy field. The seeds from the opium poppy plant are commonly used in foods. Poppy seeds from *Papaver somniferum* contain significant amounts of morphine and codeine. Although thebaine is typically not present in opioid pharmaceutic preparations, this compound is present in poppy seeds and found in heroin users as measured by GC/MS.[22] The content of morphine

FIGURE 31.4. Opium poppy field. (Photo courtesy of the US Drug Enforcement Agency)

FIGURE 31.5. Opium harvest: Collection of raw opium gum from the poppy. (Photo courtesy of the US Drug Enforcement Agency)

and codeine in processed poppy seeds varies widely depending on the origin of the poppy seeds, variety, time of harvest, external contamination during harvest, harvest technology, and food-processing techniques.[23] Morphine content in poppy seeds may decrease up to 90% during food processing as a result of washing, grinding, and baking.[24,25] Analysis of 3 samples of poppy seeds confiscated by the Singapore Central Narcotics Bureau contained total morphine and total codeine concentrations ranging from 58.4–62.2 µg/g seeds and 28.4–54.1 µg/g seeds, respectively.[26] Washing the seeds in water for 5 minutes with constant agitation followed by decantation of the aqueous layer removed slightly less than half of the free morphine and codeine.

PRODUCTION PROCESSES

Heroin is the diacetylmorphine product derived from the extraction, acetylation, and crystallization of morphine from opium (i.e., dried sap of the opium poppy).

Opium harvest involves 2 steps: 1) the incision (scoring) of the pod allowing the white latex (raw opium gum) to flow externally where the latex hardens, and 2) collection of the dark, solidified latex the following morning by scraping the solidified latex off the pod. Figure 31.5 displays the collection of the white latex from the opium poppy. The latex is kneaded together into balls or stored in perforated pots; the material is then air-dried. More modern techniques involve drying and processing the entire plant (opium "straw"). The clandestine preparation of heroin requires the separation of morphine from opium, typically by the dissolu-

tion of opium in water that contains lime. After pouring the resultant solution over a coarse filter, the addition of ammonium chloride precipitates the morphine base. This solution is filtered, washed with water, and mixed with charcoal and an acid (hydrochloric acid, sulfuric acid). The subsequent precipitate is dried and contains purified morphine.

The second phase of heroin production involves the acetylation of the morphine that uses acetic anhydride and organic bases along with heat. Alternative chemicals to acetic anhydride include ethylidene diacetate and acetyl chloride. Two acetylation methods include the reaction of morphine with acetic anhydride and the acid-catalyzed cross-condensation of morphine with acetic acid. The latter method is slightly less efficient (i.e., <83%) than the former method as a result of the production of more monoacetylmorphine at the 6- and 3-positions (i.e., 6-MAM, 3-MAM). The treatment of morphine at room temperature with a mixture of trifluoroacetic anhydride (TFAA) and acetic acid also produces slightly less heroin and more 6-MAM and 3-MAM than the traditional acetic anhydride method. In an experimental study comparing the TFAA method with the traditional acetic acid method, the yields were as follows: heroin (76.1% vs. 83.55%); 3-MAM (6.9% vs. 0.75%); and 6-MAM (7.13% vs. 0.63%), respectively.[27] Another method ("homebake") involves the conversion of codeine to heroin by the conversion of codeine to morphine by *O*-demethylation with pyridine followed by acetylation with an anhydride. The homebake method is much less efficient than the former 2 methods, resulting in the conversion of 2 g codeine to only 50–200 mg heroin.

Heroin purification involves the separation of the diacetylmorphine as a free base in alkaline medium with subsequent crystallization as the hydrochloride salt after redissolving the crude heroin in acetone and hydrochloric acid. The mixture is filtered and precipitated with sodium carbonate. To form heroin base instead of the hydrochloride salt of heroin, the purification process involves the use of boiling water that contains citric acid and activated charcoal followed by precipitation with sodium carbonate.

IMPURITIES

Heroin is a semisynthetic opioid derived from morphine extracted from the opium poppy plant. Illicit synthesis of heroin does not produce a pure substance due to the presence of other alkaloids extracted from the opium poppy plant along with morphine. The synthetic process also creates other compounds. During the acetylation stage of heroin production, some opiate alkaloids (e.g., codeine) are converted to acetyl derivatives (i.e., acetyl codeine), whereas other opiate alkaloids (e.g., papaverine, noscapine) remain unchanged. In general, street drugs (e.g., heroin) contain a variety of impurities including substituents, contaminants, diluents, and adulterants.[28] Substitution involves the complete replacement of heroin with another drug. Contaminants are unintentional byproducts of the manufacturing process of heroin. Substances (i.e., diluents, adulterants) added to illicit drug after the completion of the manufacturing process are termed additives. Potential additives in illicit heroin include caffeine, lactose, glucose, paracetamol, clenbuterol, scopolamine, phenobarbital, quinine, mannitol, procaine, sucrose, methaqualone, piracetam, and lidocaine.[29,30] Diluents are inert substances with physical characteristics (e.g., taste, form, texture, color) similar to the illicit drug (i.e., heroin) that are intentionally added to reduce the drug concentration while maintaining bulk substance mass. Common diluents of white heroin include sucrose, starches, quinine, and mannitol. Adulterants are pharmacologically active ingredients that are added to the illicit drug (e.g., heroin) to enhance (e.g., phenobarbital) or antagonize (e.g., caffeine) the effect of drug without the knowledge of the user. Although the quinine content of a bag of heroin may exceed 300 mg, lethal serum concentrations of quinine are not usually present postmortem following fatal heroin overdoses, perhaps as a result of the degradation of quinine during preparation of the illicit drug for injection.[31,32,33] The use of scopolamine as an adulterant of heroin caused an epidemic of severe anticholinergic toxicity among heroin users in the latter 1990s.[34] The IV injection of clenbuterol-adulterated heroin was associated with nausea, chest pain, agitation, anxiety, tachy-cardia, palpitations, hypokalemia, hyperglycemia, hypotension, chest pain, myocardial injury, and lactic acidosis.[35,36] Clenbuterol is a veterinary β_2-adrenergic receptor agonist used illicitly by body builders to enhance muscle mass. Another case series reported the development of tremor, hyperreflexia, myalgia, muscle spasm, and elevated serum creatine kinase after the insufflation or injection of clenbuterol-adulterated heroin; however, the cause (i.e., clenbuterol or an unidentified contaminant) of these effects is unclear.[37] In a study of 106 drug-related deaths during 2007, clenbuterol was detected in 12 cases (11%) as measured by GC/MS in full-scan mode (limit of detection [LOD], 2.5 ng/mL).[38]

PROFILING

Impurity profiling of illicit drugs is an intelligence-gathering tool to support and complement the work of law-enforcement agencies. Heroin signature programs (HSP) analyze seized heroin samples to determine drug trafficking and distribution intelligence. The extraction of morphine from opium is never complete; therefore, heroin contains variable amounts of codeine, papaverine, noscapine, and meconine. The chemical composition of heroin depends on the original composition of the opium, morphine extraction methods, acetylation procedures, addition of different solvents (acetone, acetic acid), purification processes, and the amounts of heroin base and hydrochloride salt.[39,40] The type of contaminants and plant chemicals identify the source and manufacturer of the opium.[41,42] For example, enforcement agencies use analysis of phenanthrene (morphine, codeine, thebaine) and benzyl isoquinoline (papaverine, noscapine) compounds as profiles for the source of the heroin. Using data on principal alkaloids (e.g., total codeine, acetyl codeine, papaverine, noscapine, 6-monoacetylmorphine) analyzed by capillary gas chromatography, high performance liquid chromatography, or GC/MS, HSP identifies the geographic origin of seized heroin samples by the following: Southwest Asia, presence of large quantities of papaverine and noscapine; Southeast Asia, absence of papaverine and noscapine; Mexican heroin, unique profile; and South American heroin, high purity and low acetyl codeine content.[43,44] Tasmanian opium accounts for about 25% of the world's legal supply of opium straw based on the development of a cultivar, *Papaver somniferum* Norman. This cultivar has relatively high concentrations of thebaine and relatively low concentrations of codeine and morphine compared with *Papaver somniferum* L. Additionally, this cultivar contains relatively high concentrations of the thebaine metabolite, oripavine; unique markers in heroin derived from oripavine in

551

Papaver somniferum Norman include 3-acetyl-*N*-acetyldesthebaine, 3-acetyl-6-methoxy-4,5-epoxyphenanthrene,3,4-diacetyl-6-methoxyphenanthrene,and 3,4,6-methoxy-5-[2(*N*-methylacetamido)]ethylphenanthrene.[45]

Similar HSP techniques also provide information regarding the method of heroin synthesis. Standard HSP analysis uses acetic anhydride as the principle acetylating agent. Specific markers indicate the use of other acetylating agents including 1-chloroheroin (acetyl chloride) and 3-[1-(1-carboxymethoxyethyl)]-6-acetylmorphine (ethylene diacetate). Specific markers for the trifluoroacetic anhydride method include *bis*-trifluoroacetylmorphine, 3-trifluoroacetyl-6-acetylmorphine, 3-acetyl-6-trifluoroacetylmorphine, and trifluoroacetylcodeine.[27]

Methods of Abuse

In the past decades, most heroin transported to the United States originated in Southeast Asia as the street content of heroin ranged from approximately 1–10%; the preferred route of heroin abuse was IV injection. Over the last decade, the increased availability of high-purity heroin resulted in the increasing use of insufflation and smoking as an alternative to IV heroin. Although the risk of HIV infection associated with IV drug use was avoided, the use of larger quantities of the drug via snorting resulted in more rapid progression to heroin addiction. In parts of Asia, smoking is the most common route of heroin abuse. Methods of smoking heroin include the inhalation of heroin fumes (i.e., chasing the dragon) and smoking tobacco cigarettes dipped in heroin (i.e., *ack ack*) with IV heroin administration. Chasing the dragon involves the heating of heroin powder on aluminum foil and the inhalation of the vapor with a straw or pipe. The molten heroin moves around the foil during heating, and inhalation of the vapor requires movement of the straw or pipe accordingly. This method of delivery is highly efficient.[46]

Preparation of heroin for injection typically involves mixing the drug with water, lemon juice, or other liquids. The solution is heated on a spoon or other utensil until the powder dissolves; then, the solution is filtered through a cotton ball or cigarette filter and drawn into a syringe. Although addicts use all areas of the skin for IV access, the site of injection varies with the duration and intensity of IV drug use. The antecubital fossa and forearms are the common starting sites following in 3–4 years by the upper arms and hands.[47] After 6 years, use of veins in the neck, foot, and legs are necessary to achieve IV access. By 10 years, the toes, fingers, and groin are the remaining sites of injection. Injection into major vessels is an alternative to poor peripheral venous access including attempts to inject into the groin ("groin shot"), upper arm, and neck ("pocket shot"). Subcutaneous injection ("skin popping") is a method of administration designed to avoid the scarring ("track marks") associated with IV drug abuse.

DOSE EFFECT

Because of tolerance, the typical street dose of heroin varies substantially between addicts. The initial dose of heroin to produce euphoria is usually a few milligrams, but tolerance quickly increases the dose required to produce euphoria. The typical single dose of heroin in drug-dependent individuals is approximately 150–200 mg with a highly dependent heroin abuser using 500–750 mg/day.

TOXICOKINETICS

Absorption

Although the absorption of heroin from various sites (e.g., mucosa, lungs, rectum, vagina, soft tissue) is excellent, the preferred route for most heroin addicts is IV administration. Inhaling heated vapors of heroin (i.e., chasing the dragon) is the most efficient drug-delivery method for non-IV routes of administration with bioavailability of approximately 35–45%.[46]

INTRAVENOUS

In experimental studies of IV infusions of diacetylmorphine to heroin addicts, maximal venous concentrations of diacetylmorphine occurred about 3 minutes after cessation of the infusion.[48] Approximately 4–6 minutes after the infusion, diacetylmorphine concentrations were similar in arterial and venous samples. In a study of 4 heroin addicts administered 12 mg heroin via the intramuscular and nasal routes, peak serum diacetylmorphine concentrations occurred about 5 minutes after administration via both routes.[49] Maximum plasma concentrations developed approximately 45–90 minutes after the administration of heroin.

PULMONARY

Experimental studies indicate that popular forms of smoking heroin deliver absorbed morphine doses ranging from approximately 20% (*ack ack*) to about 40% (chasing the dragon) of the external morphine dose.[50] In a study of 10 heroin addicts smoking heroin in doses ranging from 25–100 mg per session, the bioavailability of heroin ranged from about 35–45% as measured by total urinary morphine concentrations.[46] A study of 9 heroin addicts stabilized in a heroin treatment

program indicated that the bioavailability of heroin following inhalation is substantially less than following IV administration.[51] In this double-blind randomized study using 67%, 100%, and 150% of their regular heroin maintenance dose (maximum single dose, 450 mg), the mean bioavailability of heroin via inhalation was 52% (95% CI: 44–61%).

GASTROINTESTINAL

Volunteer studies indicate that the gastrointestinal (GI) absorption of heroin (diacetylmorphine) is good with maximum mean morphine bioavailability ranging from 64–72%.[52] Extensive first-pass deacetylation of heroin results in negligible concentrations of heroin and 6-monoacetylmorphine (6-MAM) in the blood following the oral administration of heroin, except following massive GI absorption during body packing. Consequently, in volunteer studies, detectable concentrations of heroin and 6-MAM do not usually occur after the oral administration of heroin.[53] Some saturation of first-pass metabolism may occur in chronic heroin users, allowing increased bioavailability of oral heroin when compared with heroin-naïve individuals.[54]

NASAL INSUFFLATION

Although the pharmacokinetic profiles of heroin via nasal and intramuscular administration are similar, the relative potency of intranasal heroin is approximately one-half of the potency of intramuscular heroin. Following intranasal administration of 12 mg heroin via the intranasal route, peak plasma heroin and 6-MAM concentrations occurred about 5 minutes and 5–10 minutes, respectively, after administration.[55]

Distribution

Heroin rapidly crosses the blood–brain barrier and into the CNS. Following the IV administration of heroin, animal studies indicate that heroin metabolites (i.e., 6-MAM) rapidly enter the brain.[56] The volume of distribution of heroin ranges from about 60–100 L.[57] Following deacetylation of heroin to morphine, morphine distributes widely into the liver, lungs, kidney, and brain. Parts of the brain with high concentrations of opioid receptors include the thalamus and the brainstem. Morphine easily traverses the blood–brain barrier, but autopsy studies suggest the distribution of morphine following heroin injection is not consistent between different regions of the brain.[58] The apparent volume of distribution for morphine is approximately 3–5 L/kg compared with about 0.3 L/kg for morphine glucuro-

nides.[59] Similar to morphine, approximately 20–40% of heroin binds to serum albumin.[60]

Biotransformation

Heroin is a prodrug that undergoes rapid hydrolysis to the metabolite, 6-monoacetylmorphine (6-MAM), either spontaneously or by serum cholinesterases; then, 6-MAM undergoes further deacetylation to morphine followed by glucuronidation primarily in the liver and kidneys to morphine-3-glucuronide and morphine-6-glucuronide. Figure 31.6 displays the biotransformation of heroin. Pilot studies indicate that diacetylmorphine (heroin) is detectable only shortly after IV administration; oral or rectal administration of heroin do not typically produce detectable amounts of diacetylmorphine.[61] Pharmacologically active metabolites of heroin include 6-MAM, morphine, and morphine-6-glucuronide (M6G), whereas morphine-3-glucuronide (M3G) is inactive. However, M6G is a minor metabolite of diacetylmorphine (heroin) metabolism; therefore, morphine is the major active metabolite of heroin biotransformation in the human body. A small observational study of 8 current IV heroin users suggests that the M6G/M3G ratio may be higher in IV heroin abusers using heroin than in opioid-naïve volunteers administered IV morphine.[62] Other minor metabolites of heroin metabolism include the 3-ether sulfate of morphine and normorphine.[63] Codeine is not a metabolite of heroin or morphine biotransformation,[64] but codeine often appears in blood samples from heroin abusers as a result of the deacetylation of acetyl codeine. This latter compound is an opiate alkaloid that is a constituent of opium, and therefore present in heroin. Peripheral tissues (e.g., human erythrocyte acetylcholinesterase) probably account for a substantial portion of the deacetylation of diacetylmorphine and 6-MAM to morphine.[65]

Elimination

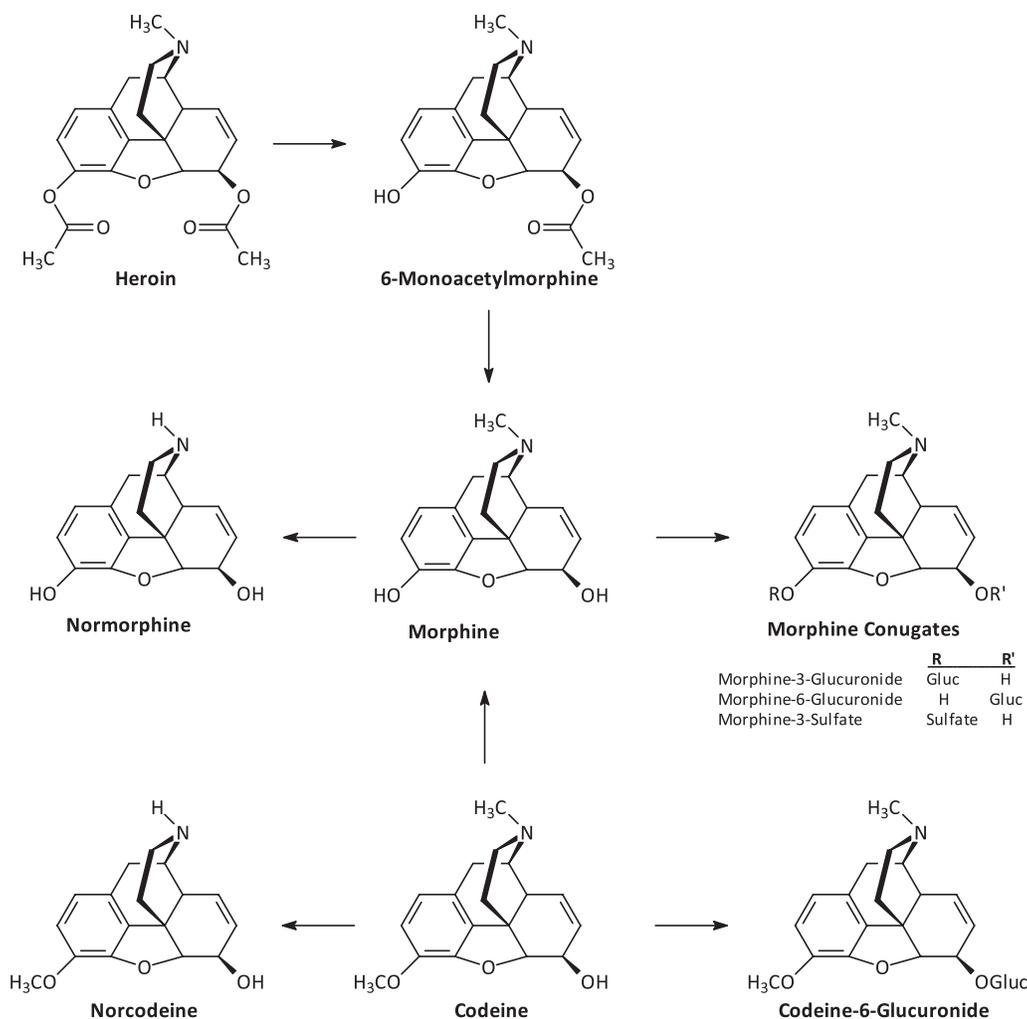
The conversion of heroin (3,6-diaceytlmorphine) to 6-MAM occurs almost instantaneously with peak 6-MAM concentrations in plasma occurring almost simultaneously with peak diacetylmorphine concentrations. In a study of 8 heroin addicts, the kinetic profile of heroin was linear in IV doses up to 210 mg.[48] In a study of 11 chronic pain patients, the mean elimination $t_{1/2}$ of IV heroin from the blood was 3.0 ± 1.3 minutes.[53] The plasma elimination half-life of 6-MAM is slightly longer (i.e., mean, 5–20 min) than heroin. Following the initiation of a 7-hour infusion of 10 mg heroin/hour, analysis of the urine collected over the subsequent 40 hours indicated the presence of a mean of about 45% of the administered dose (i.e., 70 mg) divided as follows: free


FIGURE 31.6. Biotransformation of heroin, morphine, and codeine.[126]

morphine, 4.2%; conjugated morphine, 38.3%; 6-MAM, 1.3%; and unchanged heroin, 0.1%.[66] The excretion of total morphine in urine is highly variable between individual subjects. In a study of 8 subjects given 3–12 mg IV heroin HCl and 4 subjects administered 3.5–13.9 mg heroin base via inhalation, the total morphine concentration in urine samples as a percentage of the administered heroin dose ranged from 12.8–88.5% with a median of 51%.[67] This variability resulted from large variations in the biotransformation and renal excretion of metabolites as well as the route of exposure.

The biotransformation of heroin to metabolites is virtually complete prior to renal excretion. Following intramuscular administration of 6 mg heroin to healthy volunteers, peak urine concentrations of total morphine occurred about 3–4 hours after administration with peak values ranging from 3.31–12 mg/L.[68] Peak concentrations of 6-MAM occurred in the first voided specimen with concentrations ranging from 0.05–0.24 mg/L. Morphine-3-glucuronide is the main urinary metabolite.

Maternal and Fetal Kinetics

Passive diffusion is the major mechanism of transport of drugs from maternal blood to the fetus. For lipid soluble drugs (e.g., heroin) with molecular weights below 600 g/mol, there is no significant barrier to the transfer of the drug through the placenta.[69] In pharmacokinetic studies in primates, heroin diffuses into breast milk and also crosses the placenta.[70]

Tolerance

The development of tolerance to the clinical effects of heroin is dramatic with a few mg of heroin producing

clinical effects in drug-naïve individuals, whereas illicit use of heroin by drug addicts typically involves the injection of up to 750 mg heroin. Experimental studies suggest that signs of physical dependence in human subjects develop after the infusion of heroin 4 times daily for 2–3 days.[71] Tolerance develops to some, but not all of the clinical effects of opioids including heroin. Tolerance develops to respiratory depression, nausea, analgesia, and sedation, but constipation and miosis continue to occur despite tolerance to other opioid effects. These processes result primarily from pharmacodynamic rather than pharmacokinetic changes.

Drug Interactions

Heroin interacts synergistically with other CNS depressants, particularly ethanol.[72] Several drugs (benzodiazepines, chloramphenicol, tricyclic antidepressants, zidovudine) competitively inhibit the glucuronidation of morphine by UGT2B7 *in vitro*, but the clinical significance of this interaction is unclear.[57]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

Heroin is an agonist of the endogenous opioid system with effects on the G-protein-coupled μ-, κ-, and δ-opioid receptors in the brain and spinal cord as well as the nociception (NOR) receptors in the peripheral nervous system. All opioid receptors have endogenous ligands (enkephalins, endorphins). In general, agonists of the μ- (MOP) and δ- (DOP) opioid receptors are analgesic and rewarding, whereas agonists of κ- (KOP) opioid receptors are dysphoric. Table 31.1 summarizes the pharmacologic effects of these opioid receptors. These receptors belong to the large superfamily of

Table 31.1. Pharmacologic Effects of Opioid Receptors.

Opioid Receptor	Pharmacologic Effect
Mu (μ)	Analgesia (supraspinal), euphoria, drowsiness, cognitive impairment, respiratory depression, reduced gastrointestinal mobility (nausea, vomiting, constipation), lowered body temperature, miosis, tolerance, addiction
Kappa (κ)	Analgesia (spinal), sedation, miosis, mild respiratory depression, miosis, dysphoria, diuresis, drug aversion
Delta (δ)	Analgesia, dysphoria, hallucination, delusions

G-protein-coupled receptors involving 7 transmembrane-spanning domains.[73] In addition, these receptors have an extracellular *N*-terminal domain, an intracellular *C*-terminal tail, and 3 extracellular and 3 intracellular loops connecting the 7 transmembrane helical domains. Opioid receptors share about 60% of their structure with the greatest homology in the transmembrane helices and the greatest diversity in extracellular loops and the *N* and *C* termini.[74] Activation of the opioid receptors results in the formation of GTP from GDP and the separation of the G-protein α and βγ subunits. This interaction decreases adenylyl cyclase activity causing a reduction in influx across voltage-gated Ca^{2+} channels and stimulation of G protein-activated inwardly rectifying K^+ channels and phospholipase Cβ. The subsequent hyperpolarization of the cell stops the transfer of afferent nociceptive signals. Activation of the μ-opioid receptor produces calcium influx through the NMDA receptor ion-channel complex, resulting in stimulation of various calcium-dependent, second messenger systems. These μ-opioid receptors are distributed throughout the brain, where they mediate analgesic and addictive effects.

The μ-opioid receptor also displays spontaneous agonist-independent (basal) G protein coupling that causes basal signaling activity in the absence of opioid agonists.[75] The opioid receptors are further divided into subtypes ($μ_1$, $μ_2$, $δ_1$, $δ_2$, $κ_1$, $κ_2$). Mu_1 receptors account for the analgesic effects of heroin, whereas $μ_2$ receptors mediate respiratory depression, miosis, euphoria, physical dependence, and delayed GI motility associated with heroin intoxication. Stimulation of κ-opioid receptors cause analgesia, miosis, respiratory depression, and dysphoria. Delta-opioid receptors are associated with spinal analgesia. The $σ_1$- receptor is not an opioid receptor.[76]

Mechanism of Toxicity

CENTRAL NERVOUS SYSTEM

Heroin produces respiratory depression, and prolonged hypoxia causes postanoxic encephalopathy. The etiology of heroin-induced spongiform encephalopathy remains unclear. The suspected toxin is a thermal degradation product or products of the heating of heroin on aluminum foil. Analysis of residues from aluminum foil do not support triethyl tin as the etiologic agent even though this compound can cause similar neurologic lesions.[77]

RESPIRATORY SYSTEM

Respiratory depression following heroin intoxication results from suppression of brainstem respiratory

centers, primarily via decreases in the ventilatory response to carbon dioxide. Heroin-related pulmonary edema is associated with pulmonary congestion, alveolar edema, pulmonary hemorrhages, and respiratory insufficiency that usually develops following a heroin overdose. The cause of the increased permeability of the alveolar capillary membranes remains unclear. Typical hemodynamic variables during heroin-related pulmonary edema include normal pulmonary capillary pressure, normal or increased cardiac output, and moderately elevated pulmonary artery pressure.[78] Potential mechanisms include hypoxia-induced increase of pulmonary capillary permeability, anaphylactic shock, depressed myocardial contractility, centrally induced respiratory depression, and direct toxic effects on the alveolar capillary membranes. Although pulmonary edema occurs during other opioid overdoses (propoxyphene, codeine, methadone),[79,80] similar degrees of hypoxia occur following barbiturate overdoses without the development of pulmonary edema. In a case-control study of 23 acute heroin fatalities and 12 cases of sudden cardiac death with acute cardiac pulmonary edema, immunohistologic investigation of epithelial and endothelial basal laminae with IgE did not detect a significant difference between the two groups.[81] Although defects of the basal laminae of the alveoli were found in both groups, the poor correlation between IgE-positive cells and heroin use did not suggest an anaphylactic etiology.

TOLERANCE

Potential mechanisms for the development of tolerance and withdrawal include receptor desensitization, endocytosis, functional antagonism, and downregulation of receptors. Receptor desensitization (e.g., phosphorylation of G-protein-coupled receptors followed by binding of regulatory proteins called β-arrestins) involves the alteration of functional coupling of a receptor to the G-protein/second messenger-signaling pathway, whereas endocytosis (internalization) is the translocation of receptors from the cell surface to an intracellular compartment. Extended use of opioids (e.g., heroin) that bind to the μ-opioid receptor result in physical dependence and withdrawal. Chronic use of morphine hypersensitizes norepinephrine receptors in the locus ceruleus, resulting in anxiety, sleep disturbances, and hyperactivity following reduction of chronic morphine doses. Functional antagonism results from the opioid-induced stimulation of the intracellular protein kinase C, which phosphorylates the *N*-methyl-D-aspartate (NMDA) receptor. This effect causes increased Ca^{2+} influx and functional antagonism. NMDA receptor antagonists (ketamine, magnesium, dextromethorphan) and inhibitors of nitric oxide synthase attenuate the effects of

opioid tolerance.[82] Downregulation is the reduction of the number of ligand-binding sites. Downregulation of opioid receptors probably is not solely responsible for the development of tolerance to morphine and heroin.[73]

Postmortem Examination

Heroin is a CNS depressant that causes respiratory arrest and hypoxia following the injection of excessive doses. A wide variety of neuropathologic changes occurs in the postmortem examination of brain specimens from heroin abusers. The primary findings in fatalities following the injection of heroin involve infectious processes that result from bacterial emboli, mycoses, or HIV-1 (human immunodeficiency virus 1) infections.[83] Other complications include cerebral edema and neuronal damage secondary to prolonged heroin-induced respiratory depression and cerebral strokes as a result of thromboembolism, vasculitis, or septic emboli. Autopsies of 18 heroin addicts dying following snorting or smoking of heroin demonstrate nonspecific findings of congestion, edema, and occasionally aspiration of gastric contents, but the complications (e.g. HIV, hepatitis, needle marks) of IV heroin use were absent.[84] Rarely, a toxic spongiform leukoencephalopathy is associated with inhaling heroin via chasing the dragon. Postmortem examination usually reveals the characteristic spongiform degeneration of the white matter along with edema of the myelin sheaths and a vacuolating myelinopathy of the oligodendroglia. Electron microscopy demonstrates that vacuolization in the oligodendroglia forms between the myelin lamellae by splitting at the intraperiod lines.[77] Vascular congestion, ischemic changes, and inflammation of the axons is usually absent, and there is relative sparing of subcortical U-fibers. Pathologic abnormalities in the postmortem examination of hearts from heroin-related deaths include myocardial fibrosis, myocarditis, and contraction bands. These abnormalities do not correlate well to morphine or 6-MAM concentrations in postmortem blood samples.[85]

CLINICAL RESPONSE

Illicit Use

INTOXICATION

Heroin is a highly lipophilic drug that rapidly penetrates the blood–brain barrier; injection of heroin produces an intense euphoria (*rush*) within 1–3 minutes followed by a period of tranquility (*nod*) that persists up to 1 hour. The heroin addict may compare the intense pleasure

and warmth associated with the rush to sexual orgasm. The effects of heroin resolve within 3–5 hours. The addict often injects several times in a day; otherwise, the unpleasant signs and symptoms of opioid withdrawal begin. Heroin addicts are usually polydrug abusers;[112] consequently, the concomitant administration of other drugs of abuse may modify the classic features of heroin intoxication.

MEDICAL COMPLICATIONS

CENTRAL NERVOUS SYSTEM.   Neurologic complications of nonfatal heroin overdoses include acute and sub-acute peripheral mono- and polyneuropathies as a result of prolonged pressure necrosis and compartment syndromes.[86] Rare case reports also associate the use of IV heroin or heroin insufflation with the development of the clinical features of sensorimotor peripheral neuropathy without evidence of compression injury or inflammation.[87] However, most of these cases also had evidence of rhabdomyolysis and dramatic elevations of serum creatine kinase concentrations. Case reports associate a variety of neurologic conditions with IV heroin abuse including spinal cord vasculitis, cerebral vascular accidents, cerebral vasculitis, Brown-Sequard syndrome, neurogenic bladder polyradiculoneuropathy, and transverse myelitis.[88] Infectious neurologic complications of IV heroin use include bacterial meningitis, mycotic aneurysm, mycotic and bacterial brain abscesses, subdural abscess, and epidural abscess. Case reports document the development of wound botulism with the use of parenteral forms of heroin, particularly with the subcutaneous (SC) injection of black tar heroin.[89] Rare case reports associate wound botulism with nasal insufflation.[90] The classical clinical manifestation of botulism includes cranial nerve palsies with bulbar dysfunction (dysarthria, ophthalmoplegia, diminished gag reflex, ptosis) and a symmetrical, descending paralysis (head, chest, upper extremity, lower extremities) in an afebrile patient with a clear sensorium and normal sensation. In severe cases, the muscle weakness progresses to respiratory failure. Blurred vision, diplopia, lethargy, lightheadedness, and dry mouth are early symptoms of botulism.[91] Frequently, these patients have local wound infections following SC injection of the heroin. Heating heroin does not inactivate clostridial spores.

Leukoencephalopathy.   Spongiform leukoencephalopathy is a rare disease characterized by spongiform degeneration of white matter following inhalation of heroin vapors via chasing the dragon; this method is one of several etiologies of this nonspecific neurologic disease.[8] Although less common, spongiform leukoencephalopathy also occurs after insufflation of heroin.[92]

Table 31.2. Stages of Heroin-Induced Encephalopathy.

Stage	Clinical Effects
I	Ataxia, akathisias, apathy, soft (pseudobulbar) speech, paucity of movements, memory loss, inattention
II	Choreoathetoid movements, myoclonus, tremor, spastic paresis, increasing ataxia
III	Hyperpyrexia, paresis, "stretching spasms," hyperventilation, mydriasis, decerebrate posturing, dementia, akinetic mutism, altered consciousness

Prominent clinical features of this disease are progressive motor restlessness, apathy, and cerebellar ataxia. The neurologic deficits are frequently irreversible and the clinical course progresses to death. Rarely, resolution of the white matter lesions may occur along with clinical improvement, but periventricular necrosis may develop.[93] In a case series of 47 cases of heroin pyrolysate-induced spongiform leukoencephalopathy, the clinical presentation of these cases was associated with 3 stages as outlined in Table 31.2.[8] Rarely, case reports associate the development of spongiform leukoencephalopathy with IV heroin use in the absence of hypoxic episodes.[94] Changes in mental status characterized the encephalopathy manifest by neurobehavioral changes ranging from forgetfulness and poor attention span to dementia, coma, and death.[95] In contrast to Alzheimer's disease, language and perception are usually preserved. Cerebellar signs are frequently more prominent than cognitive changes. Muscle strength also remains normal, but marked ataxia may cause an unsteady gait.

Stroke.   Cerebral complications of IV heroin use include hemiplegias, aphasias, hemianopsias, and hemipareses.[96] Potential causes of these complications include cerebral vasculitis with secondary thrombus formation, bacterial or fungal emboli from endocarditis, hypoxic encephalopathy with infarct, acute transverse myelitis, and necrotizing angiitis with rupture of arterial aneurysms. Infarction of the globus pallidus occurred following the insufflation of a large dose of heroin that produced respiratory failure, hypotension, seizures, and hypoxic encephalopathy.[97]

RESPIRATORY SYSTEM.   Common respiratory complications of heroin overdose include acute lung injury, aspiration pneumonia, and hypoxia. Heroin-related noncardiogenic pulmonary edema is an infrequent pulmonary complication (i.e., 1–2%) of overdoses from the

IV, and rarely, intranasal administration of heroin.[98] This syndrome involves the development of diffuse pulmonary infiltrates and hypoxia (oxygen saturation <90% with respiratory rate >12/min) following resuscitation from a clinically apparent heroin overdose. The respiratory insufficiency occurs independent of bronchospasm, pneumonia, or pulmonary embolism. Symptoms of respiratory distress are usually apparent within 1 hour of naloxone reversal of heroin-induced coma and respiratory depression.[99,100] The hypoxia typically resolves within 24–48 hours when other pulmonary complications are absent. Clinical manifestations of heroin-related pulmonary edema in addition to hypoxia include cough, pink frothy sputum, tachypnea, and diffuse rales. Case reports indicate that rarely severe bronchospasm may develop following the IV administration of heroin.[101] Although heroin may contain additives that produce hypersensitivity reactions, case reports indicate that pure heroin can cause acute allergic reactions independent of the direct release of histamine.[102] Other pulmonary complications of IV heroin use include septic emboli, lung abscess, pneumonia, and talc-induced pulmonary hypertension.

GASTROINTESTINAL TRACT.   Heroin body packers may develop intestinal obstruction with perforation and fatal peritonitis. Urine drug screens in these patients may be negative despite the presence of intestinal obstruction secondary to the multiple bags of heroin.[103] Other complications of IV heroin use include hepatitis B, hepatitis C, and chronic active hepatitis.

KIDNEY.   Renal failure may occur as a result of rhabdomyolysis and myoglobin-induced acute tubular necrosis from prolonged pressure necrosis of the limbs during heroin-induced coma. Several renal diseases are associated with the IV use of heroin including glomerulonephritis associated with chronic infections (viral, bacterial, fungal), immune-complex-mediated glomerulonephritis associated with bacterial or fungal endocarditis, HIV-associated nephropathy, and secondary amyloidosis.[104] Case-control studies indicate that heroin users have an increased risk of end-stage kidney disease when adjusted for age, sex, race, socioeconomic status, and history of hypertension or diabetes.[105] Case series from the early 1970s reported a heroin-associated nephropathy that initially was recognized as a complication of IV heroin abuse in the eastern United States. This disease occurred primarily among black men aged 18–45 years.[106] Heroin-associated nephropathy is a nephrotic syndrome that is manifest by massive proteinuria, azotemia, hypertension, renal atrophy, and anemia. Renal biopsies usually demonstrate focal and segmental glomerular sclerosis, variable focal and diffuse interstitial nephritis, membranoproliferative glomerulonephritis, and PAS-positive mesangial deposits (IgA, IgG, IgM, C1q, C3).[107] Progression to end-stage renal disease typically occurs within a few months to a few years. The exact role of heroin, adulterants, hepatitis B and C, and HIV in the etiology of this disease remains unclear. As the purity of heroin increased substantially during the 1990s, the incidence of heroin-associated nephropathy dramatically decreased.[108]

MUSCULOSKELETAL SYSTEM.   Acute rhabdomyolysis associated with life-threatening hyperkalemia, hypocalcemia, and myoglobinuric renal failure may develop after prolonged limb compression secondary to heroin-induced coma. Typical clinical manifestations of heroin-induced rhabdomyolysis are muscle pain and swelling.[109] A compartment syndrome may complicate cases of heroin-induced rhabdomyolysis as a result of severe limb swelling. Vascular insufficiency can cause peripheral neuropathies and transverse myelitis. Infectious complications of IV drug use include osteomyelitis, septic arthritis, infectious sacroiliitis, and Pott disease (i.e., vertebral osteomyelitis secondary to tuberculosis or other infectious agents).

IMMUNE SYSTEM.   HIV infection and opportunistic infections are common complications of the IV use of heroin, particularly in heroin addicts who share needles (e.g., "shooting galleries").[110] Common complications of HIV infection includes oral candidiasis, candida- or cytomegalovirus-induced esophagitis, and *Pneumocystis carinii* pneumonia. Other opportunistic infections include disseminated tuberculosis, atypical mycobacteria, histoplasmosis, viral pneumonia, disseminated herpes zoster or simplex, and cryptococcal encephalitis. Dermatologic diseases include Kaposi sarcoma and cutaneous herpes infections.

SKIN.   Acute cutaneous complications of chronic IV heroin abuse include cutaneous infections, necrotizing fasciitis, necrotizing ulcers (e.g., levamisole-contaminated heroin), thrombophlebitis, intra-arterial injection, and mycotic aneurysm.[111] Edema, peripheral ischemia, and compartment syndrome may result from emboli and vasoconstriction. Hypopigmented or hyperpigmented scars result from chronic IV drug abuse including linear cords ("railroad tracks") and irregular round or oval scars ("pop scars"). The latter is frequently associated with the simultaneous injection of heroin and cocaine ("speedballing"). Tattoos ("shooting tattoos") are often used to hide skin discolorations that result from the deposition of debris in SC tissue.

Overdose

The classic triad of opioid overdose is the combination of abnormal mental status, substantially decreased respiratory rate, and miotic pupils. In a study of patients with heroin intoxication treated in an urban emergency department, this triad demonstrated 92% sensitivity and 76% specificity for the diagnosis of acute heroin intoxication; the response to naloxone did not increase the sensitivity for detecting heroin overdose.[16] Most heroin overdoses occur in experienced users in combination with other drugs (benzodiazepines, ethanol, cannabis); repeat overdoses are common in some heroin addicts.[112] Complications include acute respiratory distress syndrome, pulmonary aspiration, hypoxic encephalopathy, sepsis, shock, and death.[113] Most heroin overdoses are relatively benign if the patient receives supportive care. Other clinical manifestations of serious opioid intoxication include cyanosis, hypotension, hypothermia, and bradycardia.

Fatalities

Acute heroin intoxication is a major cause of death among IV heroin addicts along with HIV.[114] Most deaths following the IV administration of heroin occur as a result of hypoxia in regular, dependent users within 1–3 hours after injection.[115,115] Immediate death following heroin administration is less common than death within 3 hours of administration. In a study of 152 heroin-related deaths in Australia, only 14% were associated with instantaneous death following IV heroin administration.[116] The exact cause of heroin-related overdose deaths is unclear, but risk factors include loss of tolerance, concomitant drug use, and the presence of systemic diseases.[117] The use of naltrexone is probably not a risk factor for fatal heroin overdose.[118] Heroin users often are polydrug users, administering tranquilizers, cocaine, and ethanol in addition to heroin.[119,120] Although autopsy studies suggest that multiple-drug use is a major risk factor for adverse effects of acute heroin intoxication including death, data from a prospective cohort study of heroin overdose patients during the late 1990s did not detect an increased number of complications in heroin overdose with and without multidrug use.[121] Rarely, fatal anthrax is associated with heroin abuse.[122]

Abstinence Syndrome

Acute opioid withdrawal from heroin typically involves autonomic hyperactivity with early signs including tachycardia and hypertension. Symptoms include lacrimation, rhinorrhea, diaphoresis, mydriasis, tremor, goose flesh, restlessness, insomnia, irritability, myalgias, anorexia, yawning, abdominal cramps, vomiting, diarrhea , and feverishness. In contrast to patients experiencing ethanol withdrawal, withdrawal from heroin does not typically cause seizures (except in neonates), dysrhythmias, delirium tremens, or death. The physical symptoms of heroin withdrawal typically begin about 4–6 hours after the heroin injection, peak within about 24–48 hours, and persist up to 7–14 days.[123]

Reproductive Abnormalities

Although there is little evidence for the teratogenic effects of heroin use, obstetrical complications result from the maternal use of heroin.[124] Complications of heroin use by pregnant heroin addicts during labor and delivery include premature rupture of membrane, neonatal sepsis, pre-eclampsia, placenta previa hemorrhage, abruptio placentae, and vaginal hemorrhage. Respiratory depression may occur in the neonate. After birth, withdrawal symptoms occur in almost all infants born to addicted mothers including hyperactivity, hyperirritability, coarse tremors, poor feeding, and poor weight gain. Other symptoms of heroin withdrawal include sneezing, yawning, sweating, vomiting, and diarrhea. Seizures also occur in some infants. The differential diagnosis of seizures in infants from heroin-dependent mothers include hypoglycemia, hypocalcemia, and hypomagnesemia.

DIAGNOSTIC TESTING

Analytic Methods

As with most opioid analyses, analysis of heroin in biologic samples requires both screening technologies (e.g., thin-layer chromatography, immunoassays) and confirmatory techniques (e.g., GC/MS, liquid chromatography/mass spectrometry). The extraction of whole blood with organic solvents yields only free morphine, whereas the same extraction after glucuronide hydrolysis yields both free (unconjugated) and conjugated morphine. Although acid hydrolysis of glucuronides is faster and more effective than hydrolysis with β-glucuronidase, 6-monoacetyl morphine is unstable under these conditions.[125] Confirmation techniques usually require extraction of opioids from biologic matrices either by solid-phase extraction (SPE) or liquid-liquid extraction. Most methods now use SPE. Some current radioimmunoassay (RAI) methods are highly specific for free morphine with low cross-reactivity to other opioids and morphine glucuronides.

METHODS

SCREENING.   Although a variety of methods are available to detect opioids in body fluids, including thin-layer chromatography, gas chromatography with flame ionization or electron capture detection and liquid chromatography, immunologic methods are the initial screening test of choice. Immunoassays reliably detect opioids and metabolites in urine specimens above the cutoff specified by Federal Workplace Drug Testing Programs.[126] In general, urine opioid immunoassays are highly sensitive for compounds (e.g., 6-monoacetylmorphine, codeine, dihydrocodeine) that demonstrate structural similarity to morphine, whereas more structurally dissimilar compounds (e.g., fentanyl, meperidine, methadone, oxycodone) are less reactive. The ingestion of some cough syrups (e.g., ethyl morphine), codeine-containing compounds, and paregoric may cause innocent positive opioid drug screens as a result of the presence of opioid compounds.

CONFIRMATORY.   Although a number of methods exist to quantify opioids and their metabolites, liquid chromatography (LC) does not require pretreatment of the analytes of heroin or heroin metabolites. When used with mass spectrometry (MS) as a detector for liquid chromatography, this analytic method (LC/MS) can separate the lipophilic and hydrophilic analytes of heroin and heroin metabolites in biologic fluids.[127] Isotope-dilution GC/MS or LC/MS are the methods of choice for the quantitation of opioids (6-monoacetylemorphine, morphine, codeine) in biologic fluids.[128] Although acidic hydrolysis is more rapid and technically easier than enzymatic hydrolysis for the determination of total (free plus conjugated) opioid compounds, acid hydrolysis of urine samples destroys biomarker (i.e., 6-MAM) for heroin use.[126] Specific analytic techniques for the determination of 6-MAM in urine include gas chromatography/electron impact/mass spectrometry, which has a LOD near 0.001 mg/L.[129] Analytic methods for the detection of codeine and acetyl codeine as biomarkers of illicit heroin use include liquid chromatography/atmospheric pressure chemical ionization/mass spectrometry[130] and liquid chromatography/tandem mass spectometry (LLOQ, 0.005 mg/L, interassay CV <20%).[131]

STORAGE

In experimental studies, morphine and morphine glucuronide metabolites are stable in spiked fresh blood and plasma samples up to 6 months when stored at −20°C (−4°F), 4°C (39.2°F), and 20°C (68°C).[132] Studies indicate that elevated free morphine concentrations develop in postmortem samples as a result of hydrolysis of morphine glucuronides, particularly M3G at room tempera-

ture (e.g., 20°C/68°F) and to a lesser extent during refrigeration (e.g., 4°C/39.2°F). Freshly collected and refrigerated blood samples stored in sodium fluoride containing M3G produce minimal amounts of free morphine, but increased storage time, room temperature, light, and the present of high concentrations of bacteria (e.g., during putrefaction) cause the hydrolysis of M3G to free morphine, particularly in liver tissue.[133] During prolonged interment, case reports indicate that morphine glucuronides are slowly converted to free morphine in buried corpses, particularly after 3–4 years.[134] Consequently, the free morphine/morphine glucuronide ratio varies depending on the degree of putrefaction and the collection site, when compared with the ratio at the time of death. Heroin remains detectable in corpses after embalming, particularly in bile and liver samples.[135] 6-Monoacetylmorphine is stable in frozen urine samples up to at least 2 years,[136] but 6-MAM undergoes deacetylation to morphine at room temperature with the rate of conversion being pH-dependent.

Biomarkers

Heroin is excreted in saliva transiently following IV administration. In a study of 2 volunteers, heroin remained detectable (i.e., >0.001 mg/L) in saliva for ~1 hour.[137]

BILE

Postmortem concentrations of morphine and morphine glucuronides in bile are typically substantially higher than blood with the bile/blood morphine ratio averaging up to ~100–150. In a case series of 5 postmortem examinations with morphine concentrations in both bile and femoral blood (cause of death not specified), the mean morphine concentration in femoral blood was 0.74 mg/L (range, 0.201–1.71 mg/L) compared with 40.86 mg/L (range, 0.477–181 mg/L) in bile.[138] The presence of high concentrations of morphine in bile suggests chronic heroin use; morphine concentrations may persist in bile following heroin use after blood morphine concentrations are nondetectable as a result of enterohepatic cycling. A 44-year-old heroin addict died in the hospital 144 hours after his last heroin injection.[139] The postmortem bile concentration of morphine was 21.3 mg/L, whereas morphine was not detectable in postmortem blood or urine specimens as measured by GC/MS.

BLOOD

Morphine distributes relatively evenly between plasma and erythrocytes.[140] In a study of 20 heroin-related

deaths, the plasma total morphine concentration was higher than total whole blood morphine concentration in 17 of the 20 cases.[141] These cases included deaths both immediately after injection and within a few hours of injection.

ILLICIT USE.   Heroin has a very short elimination half-life in the blood, and most blood samples from heroin users do not contain detectable amounts of heroin. The heroin metabolite, 6-monoacetylmorphine (6-MAM) has a slightly longer mean half-life of 5–20 minutes; 6-MAM is detectable in blood samples for up to 1–2 hours after heroin administration depending on the dose, analytic method, route of administration, and frequency of heroin use. Because of a variety of factors including tolerance, there is substantial overlap in the morphine concentration in functioning heroin addicts and in blood samples from heroin-related fatalities. Data from case series indicate that some serum samples from heroin addicts in police custody contain total morphine concentrations that exceed the median total morphine concentration in series of postmortem whole blood samples from heroin-related fatalities.[142] In a study of 100 current heroin abusers using heroin within the last 24 hours, the median total morphine concentration in blood samples was about 0.090 mg/L (range, 0.050–1.45 mg/L) compared with 0.350 mg/L (range 0.080–3.20 mg/L) in postmortem blood from 39 heroin-related deaths.[143] Although the median postmortem concentration of total morphine in the 39 heroin-related fatalities was substantially higher than the current heroin users, approximately 7% of the blood samples from the current heroin users contained total morphine concentrations exceeding the median postmortem total morphine concentration (0.35 mg/L) of the 39 heroin-related deaths.

Acetyl codeine is an impurity that is present in opium and in almost all heroin samples, but this compound is not present in pharmaceutical preparations of diacetylmorphine. Deacetylation of this compound in the human body produces codeine. Therefore, acetyl codeine and, to a lesser extent, codeine are biomarkers for the use of illicit heroin, and detectable amounts of codeine commonly occur in the blood samples from heroin users. Analysis of plasma samples from impaired drivers testing positive for 6-MAM indicate that a morphine/codeine ratio greater than unity suggests recent heroin use.[144] In contrast to the recent injection of heroin, the morphine/codeine ratio in plasma is usually less than unity following the recent ingestion of codeine. The volumes of distribution for the morphine glucuronides are approximately 1/10 of the volume of distribution for morphine; therefore, the estimation of absorbed dose based on the total morphine concentration in blood is inappropriate.

POSTMORTEM.
Concentrations.   Heroin is a diester compound that is rapidly hydrolyzed to 6-MAM and subsequently to morphine. Postmortem morphine concentrations vary widely in fatal heroin intoxication as a result of a variety of factors including tolerance, the time between exposure and death, use of supportive care, loss of tolerance from a period of opioid abstinence, and coadministration of other drugs. As a result of these factors, there is frequently an overlap between morphine concentrations in fatal and nonfatal heroin intoxications; consequently, all postmortem morphine and morphine glucuronide concentrations must be interpreted in relation to associated clinical and anatomic factors in the case. Although morphine-6-glucuronide (M6G) is biologically active, the major glucuronide metabolite of morphine is morphine-3-glucuronide (M3G), which is inactive as an opioid and does not cross the blood–brain barrier. There are inadequate data to determine the time of death based on the M3G/M6G ratio. Consequently, interpretation of fatal free (unconjugated) morphine concentrations in postmortem blood samples is more reliable than total morphine concentrations (free or unconjugated plus conjugated morphine). In a study of 87 heroin only-related deaths, the median free morphine and total morphine concentrations in postmortem heart blood samples were 0.170 mg/L (range, nondetected to 2.80 mg/L) and 1.032 mg/L (range, 0.034–4.66 mg/L), respectively, as analyzed by GC/MS with solid-phase extraction.[145] By comparison, the median free morphine concentration in 5 survivors with no other drugs in their blood was 0.065 mg/L (range, 0.028–0.093 mg/L). Free morphine concentrations in postmortem blood exceeding 0.20–0.30 mg/L are often fatal.

When present, 6-MAM concentrations in postmortem samples of femoral blood are usually approximately one order of magnitude lower than free morphine concentrations.[85] Concentrations of 6-MAM and morphine do not correlate well to the time between heroin administration and death.[85] Factors that favor immediate death after heroin administration include detectable concentrations of 6-MAM in postmortem blood, high free morphine concentrations (>0.5 mg/L), high ratio (>0.5–0.6) of free to total morphine, and low urinary concentrations of 6-MAM and free morphine.[146] The morphine glucuronides (M3G, M6G)/morphine ratio increases as the time between administration and blood sampling increases, depending on individual pharmacokinetic parameters (e.g., elimination half-lives, volumes of distribution).[147] This ratio is not dependent on dose. The presence of low free morphine concentrations (<0.2 mg/L) in postmortem blood, total blood morphine >1.0 mg/L, and ratios of free morphine/morphine glucuronides and free morphine plus M6G/M3G in

postmortem blood <1 suggest delayed death (i.e., >3 hours).[148] Codeine frequently occurs in the postmortem blood samples of heroin-related fatalities because codeine is a metabolite of acetyl codeine formed during heroin synthesis. The morphine/codeine ratio in postmortem blood samples is wide, but the ratio is always >1 after use of codeine alone; a morphine/codeine ratio <1 indicates a source of codeine in addition to heroin.

Redistribution.   A several-fold difference in morphine, morphine-3-glucuronide, and morphine-6-glucuronide postmortem blood concentrations may occur between different sampling sites depending in part on the time between injection and death, chemical stability of morphine conjugates, hemoconcentration, diffusion between different compartments, and incomplete distribution of the drug.[149,150] In a study of 32 morphine-related deaths (i.e., mostly IV administration of heroin), the postmortem free morphine concentration in peripheral and central sites did not vary significantly with time based on an average time between death and autopsy <36 hours as measured by a specific radioimmunoassay for free morphine.[151] However, morphine concentrations were consistently higher (i.e., average about double) in heart blood compared with femoral or iliac sites. In this study, the difference between morphine concentrations in central and peripheral samples usually increased as the blood morphine concentration increased, particularly when morphine concentrations in heart blood exceeded 0.30 mg/L. However, there were relatively few samples and no statistical analysis of the trend. Similarly, in a postmortem study of 21 cases with matched postmortem admission and autopsy blood specimens, there was no statistically significant difference between matched samples for concentrations of free morphine, total morphine, M3G, or M6G.[152] The mean postmortem interval was 59 hours. The total morphine concentration in postmortem samples from the femoral vein and the femoral artery is usually similar. In a study of 44 suspected heroin-related deaths with detectable postmortem morphine concentrations, the mean free morphine concentration in femoral vein samples was 0.17 mg/L (95% CI: 0.12–0.22 mg/L) compared with 0.20 mg/L (95% CI: 0.13–0.27 in femoral artery samples.[153] In a study of 50 individuals dying of heroin overdose soon after injection based on urine free morphine concentrations <0.025 mg/L, the mean heart to peripheral blood ratio was 1.4 (range, 0.4–6.9).[154] The ratio of free morphine in peripheral and heart blood does not predict the time between heroin administration and death. Although the metabolism of heroin is too rapid to detect increased concentrations of heroin metabolites in the veins near the injection site, morphine concentrations may remain elevated in the tissue surrounding the site of the fatal injection.[155] The interpretation of the significance of free morphine concentrations requires consideration of storage methods and the time interval between death and analysis because of the hydrolysis of M3G under some storage conditions.[132]

Hair

Hair analysis for illicit drugs potentially provides long-term information about drug use. Heroin and 6-MAM are frequently detectable in hair samples from regular heroin users. However, there are limited data on the length of time heroin and 6-MAM remain detectable in hair samples and on the amount of heroin necessary to produce positive hair samples for heroin or 6-MAM. Following regular heroin use, 6-MAM concentrations in hair samples predominate over heroin and morphine concentrations.[156] However, the dose of administered heroin does not correlate to heroin or 6-MAM concentrations in hair samples collected from the proximal root zone (i.e., about 100 days of hair growth).[157] The presence of morphine/codeine hair ratios >5:1 for low-morphine concentrations (<1 ng/mg hair) or >2:1 for morphine hair concentrations (>1 ng/mg) suggests the use of heroin or morphine.[158] A number of variables complicate the interpretation of the heroin dose based on 6-MAM concentration in hair or route of exposure based on the heroin/6-MAM ratio including site of sampling, technique, and distance from skin.[159] Highly alkaline extractions may degrade heroin and 6-MAM to morphine.[160]

Stomach

Postmortem stomach morphine concentrations are not reliable measurements to distinguish between the IV and oral administration of heroin, probably as a result of postmortem diffusion of morphine from bile in the duodenum to the stomach following the hydrolysis of conjugated morphine present in the bile. In a study of 29 fatal IV heroin overdoses, the mean total morphine concentrations in blood and stomach contents was 0.60 mg/L and 1.16 mg/L (mg/kg), respectively.[161] Detectable morphine concentrations were present in the stomach contents of all 29 cases; the total morphine concentrations in stomach contents were higher than total blood morphine in 83% of the cases.

Urine

6-Monoacetylmorphine.   Analysis of urine samples documents exposure to illicit drugs, but the concentration of specific drugs in the urine do not correlate to

blood concentrations or to impairment. Urine immuno-assays are the most common screening methods for the detection of opioids. Heroin is not usually detectable in urine as a result of the rapid hydrolysis of this drug. Hydrolysis of heroin produces 6-monoacetylmorphine (6-MAM), which is a specific biomarker of heroin use.[162] Although 6-MAM has a short half-life in the blood, this compound is present in urine samples for at least several hours (i.e., first voided urine specimen) after the use of heroin as measured by GC/MS.[163] The CEDIA Heroin Metabolite Immunoassay (Microgenics™, Fremont, CA) is a specific immunoassay for 6-MAM with a confirmation rate of 98% in a study or 525 samples from a criminal justice drug-testing program.[164] Cross-reactivity with opioid analgesics occurred only at high concentrations including morphine at 10 mg/L, oxycodone at 61 mg/L, codeine at 60 mg/L, hydromorphone at 10 mg/L, hydrocodone at 60 mg/L, and pentazocine at 35 mg/L. The cutoff for 6-MAM was 0.01 mg/L. In contrast, morphine is the target analyte for the CEDIA DAU opioid assay with cross-reactivity with other structurally similar opioids including 6-MAM (81%), codeine (125%), hydrocodone (48%), and hydromorphone (57%).[165]

The detection time for 6-MAM and total morphine depends on a variety of factors including the LLOQ of the analytic method, the specific cutoff, the heroin dose, the time since the bladder was emptied, rate of urine formation, and frequency of heroin use. Additionally, there is substantial interindividual variation in the excretion of total morphine after the administration of similar doses of heroin. Consequently, following the chronic use of heroin, the occurrence of a positive urine opioid drug screen within 24 hours following a negative opioid drug screen does not necessarily imply the use of heroin between the two specimens.[166] If the urine sample is collected immediately after heroin use, the urine sample may contain 6-MAM without detectable amounts of some morphine metabolites (e.g., M3G).[167] As a result of individual pharmacogenetics, certain heroin-using individuals may escape detection when urine screening involves only the detection of morphine at the current cutoff.[168]

ACETYL CODEINE. Acetyl codeine is one of the alkaloids present in opium; therefore, this compound occurs in almost all (i.e., about 95%) of heroin samples. The plasma elimination half-life of acetyl codeine is about 4 hours with <1% appearing in urine unchanged.[169] Peak urine concentrations occur ~2 hours after heroin administration. Using GC/MS with a LLOQ of 0.0002 mg/L, acetyl codeine was detectable for about 8 hours after administration. The coadministration of heroin and codeine may result in the formation of detectable concentrations of acetyl codeine.

FREE AND TOTAL MORPHINE. In 1998, the Federal Workplace Drug Testing Program changed urine screening and confirmation cutoff concentrations for opioid testing from 0.300 mg morphine/L to 2.000 mg morphine/L. In addition, positive urine samples require the presence of 6-MAM in concentrations ≥0.001 mg/L as measured by GC/MS. Although this new cutoff decreases detection times, these requirements were necessary to reduce the innocent positive rates for individuals ingesting poppy seed-containing foods. Detection times in urine for heroin use via IV and pulmonary routes are similar.[170] In volunteer studies, the administration of 3–12 mg heroin hydrochloride via inhalation or injection resulted in similar detection times (i.e., ~12 hours) as determined by immunoassay screening and confirmation by the 2.000 mg/L cutoff for morphine and 0.001 mg/L cutoff for 6-MAM.[171] The median detection time (i.e., time to last positive sample) for total morphine after inhalation and IV administration of ~12 mg heroin for the low cutoff (0.300 mg/morphine/L) and the high cutoff (2.000 mg/L) was about 34 hours (range, 10.7–53.5 h) and about 8 hours (range, 2.3–22.3 h), respectively.[67] Changes in urine osmolality can cause fluctuations above and below the cutoff, resulting in positive screens following negative results. Following intramuscular (but not inhalation or IV) administration of heroin, the detection time for free morphine in the urine is substantially shorter than for total morphine. In a study of healthy volunteers administered 3 mg- and 6 mg-doses of heroin intramuscularly, the mean detection time for the 0.300 mg/L cutoff of free and total morphine in urine samples was about 3½ hours and 8 hours, respectively.[68] Although the intranasal route of heroin use produces ~50% of the potency of an intramuscular dose, the pharmacokinetic profiles of the two routes of exposure are similar. Using larger heroin doses (i.e., 6 mg and 12 mg) than the previous study, detection times for total urine morphine by immunoassay and GC/MS confirmation at the 0.300 mg morphine/L- and 2.000 mg/L-cutoff concentrations were about 24–36 hours and <12 hours, respectively.[172] However, the detection times for 6-MAM were highly variable and short with detection times for the ≥0.010 mg/L-cutoff averaging about 2–3 hours (range, 0–6.5 hours) following intranasal administration. Most commercial opioid immunoassays (e.g., Emit® d.a.u.™ Opiate Assay, Syva Company; TDx® Opiates, Abbott Laboratories, Abbott Park, IL; Abuscreen® Radioimmunoassay for morphine, Roche Diagnostic Systems, Inc., Nutley, NJ) detect both free and conjugated morphine as well as free and conjugated codeine. These tests do not distinguish between free and conjugated drug, but codeine use is usually associated with total codeine concentrations exceeding total morphine concentrations.[173] The Coat-A-Count®

Morphine in Urine immunoassay (Siemens Medical Solutions Diagnostics, Los Angeles, CA) is much more specific for free morphine with little cross-reactivity with morphine glucuronides or codeine.[174] Total morphine concentrations in postmortem urine samples from heroin addicts found dead after IV heroin use may be undetectable despite β-glucuronidase or acid hydrolysis as a result of death prior to the excretion morphine and morphine metabolites in the urine.[175]

Cross-Reactivity/False-Positive Urine Opioid Screens. A few compounds cross-react with common opioid urine screening assays including rifampin (i.e., kinetic interaction of microparticles in solution method)[176] and some quinolone compounds (gatifloxacin, levofloxacin, ofloxacin).[177,178] Innocent positive opioid urine screens following ingestion of poppy seeds results from the detection of small amounts of opiates; however, recent reductions in the morphine content of poppy seeds used in foods (e.g., pretreatment of seeds with washing and grinding) and the higher total morphine cutoff have decreased the risk of innocent positive opioid screens, particularly following the ingestion of poppy seed buns.[25] The ingestion of poppy seeds from 1–2 bagels can potentially produce a positive urine drug screen for opioids up to 24 hours after ingestion *depending* on the cutoff.[23] In a study of 3 volunteers consuming as many poppy seeds as possible within approximately 1 hour, the urine drug screen was positive (2.000 mg/L cutoff) up to 4 hours after ingestion in all 3 volunteers and up to 8 hours in one volunteer.[179] Peak urine concentrations of opioids occur within 6–8 hours of ingestion. However, poppy seeds do not contain the synthetic chemical, 6-MAM,[180] and the ingestion of poppy seed-containing food typically does not produce detectable amounts of free morphine in serum samples as analyzed by GC/MS before hydrolysis.[181] There is substantial variation in the content of codeine and morphine in different poppy seeds as well as substantial interindividual variation in urinary excretion of codeine and morphine. Consequently, the presence of a positive urine drug screen after ingesting poppy seeds is highly variable. Other opiates present in poppy seeds based on thin-layer chromatography include thebaine, papaverine, and narcotine.[182] Thebaine is not usually present in the urine of heroin abusers, whereas the consumption of poppy seeds typically produces low concentrations of thebaine detectable in urine up to 36 hours, depending on the dose and individual excretion profile.[183] The absence of thebaine in a urine sample positive for opioids does not exclude the possibility of poppy seed ingestion, particularly when the urine sample is collected 12–24 hours after consumption.

Vitreous Humor

In general, postmortem vitreous humor samples contain substantially lower (i.e., 2- to 3-fold) morphine concentrations than postmortem blood samples following fatal heroin overdoses.[184] In a case series of 10 heroin-related deaths, the mean free morphine concentration in vitreous samples as measured by radioimmunoassay was 0.08 ± 0.04 mg/L compared with 0.32 ± 0.17 mg/L in blood (site not specified).[185] However, the 6-MAM concentration is usually higher in vitreous humor than in blood during postmortem examination of heroin-related deaths.[186] In a study of 25 deaths associated with heroin use, vitreous samples from all 25 cases had detectable concentrations of 6-MAM, whereas only 13 of 25 blood samples were positive for 6-MAM.[187] The mean 6-MAM vitreous humor/blood ratio in these 13 samples was 11.3 (range, 1.7–27). The wide range of values and the lack of data limits correlation of postmortem vitreous humor to blood concentrations following fatal heroin intoxication. Furthermore, there is a lack of correlation between 6-MAM concentrations in urine, vitreous humor, and cerebrospinal fluid.[188] Postmortem cerebrospinal fluid typically contains slightly higher concentrations of morphine compared with vitreous humor, but the morphine concentrations are substantially less than postmortem blood.[189] Because hydrolysis of 6-MAM continues in blood after death, analysis of 6-MAM in vitreous humor and cerebrospinal fluid samples provide an alternative to urine samples for the postmortem detection of heroin use.

Abnormalities

Blood

Numerous laboratory abnormalities occur in IV drug addicts resulting from a variety of diseases including hepatitis, osteomyelitis, cutaneous abscesses, thrombocytopenia, septicemia, endocarditis, tetanus, botulism, tuberculosis, malaria, renal dysfunction, and HIV infections. Laboratory manifestations of heroin-induced rhabdomyolysis include hyperkalemia, hypocalcemia, metabolic acidosis, and increased serum creatinine concentrations. A 5-fold increase in serum creatine kinase concentrations without evidence of cardiac and cerebral damage indicates the presence of rhabdomyolysis. Elevation of serum and urine myoglobin concentrations also suggests the presence of muscle injury, but the rapid clearance of serum myoglobin limits the usefulness of this laboratory abnormality as a measure of ongoing muscle injury.[190]

Cardiac

Acute heroin overdose is associated with nonspecific electrocardiographic changes (e.g., nonspecific ST-T

wave changes, sinus tachycardia, right atrial enlargement), frequently related to hypoxia.[191] More serious dysrhythmias (atrial fibrillation, ventricular tachycardia) occur occasionally in the absence of adulterated heroin (e.g., quinine) usually as a result of acute hypoxia. In contrast to methadone, unadulterated heroin is not usually associated with QT_c prolongation or torsade de pointes. In a study of 15 patients admitted to methadone treatment program after using heroin within the previous 4 hours, 2 patients had increased QT_c intervals as defined by Ashman-Hull criteria.[192] Seven additional patients had bradycardia or tachycardia. By comparison, QT_c prolongation was present in 14 (34%) of the 41 patients on methadone in the treatment program.

ENCEPHALOPATHY

Spongiform leukoencephalopathy differs from other encephalopathies by the histopathologic hallmark of vacuolar degeneration of cerebral white matter. Electron microscopy of the white matter demonstrates fluid entrapment between the myelin lamellae and an absence of demyelination. Heroin-induced toxic leukoencephalopathy is a bilateral, symmetrical disease primarily of white matter; therefore, magnetic resonance imaging (MRI) is the noninvasive diagnostic study of choice because of superior resolution of white matter compared with computerized tomography (CT).[193,194] The head CT scan is usually normal until late in the course of this disease. The lesions typically involve the white matter of cerebellum, cerebrum, and midbrain with selective involvement of the corticospinal tract, the solitary tract, and the lemniscus medialis.[195] Characteristic abnormalities on T2-weighted MRI include symmetric hyperintense lesions of the cerebellar and occipital white matter, corpus callosum, internal capsule, and the medial lemniscus of the brain stem.[196,197] Gray matter is typically preserved with occasional involvement of deep gray matter.[198]

The lack of involvement of the cerebellum in a clinically normotensive patient suggests a diagnosis other than heroin-induced toxic leukoencephalopathy, as spongiform toxic leukoencephalopathy excluding cerebellar and brainstem involvement is a rare complication of the IV or nasal use of heroin.[92] Changes in the frontal lobe are usually minimal to mild. T1-weighted scans demonstrate corresponding hypointensities, and IV gadolinium does not usually enhance the lesions.[94] Restricted diffusion in the cerebral white matter on diffusion-weighted images helps distinguish heroin-induced toxic leukoencephalopathy from other encephalopathies.[199] MR spectroscopy may help differentiate heroin leukoencephalopathy from other encephalopathies associated with drug abuse (e.g., cocaine) or demy-elinating diseases. Demyelination does not typically occur in heroin-induced toxic leukoencephalopathy. The pathologic process of this encephalopathy involves disruption of cellular metabolism, mitochondrial dysfunction, and loss of neurons with gliosis manifest by increased lactic acid and myo-inositol, normal to slightly decreased choline, normal lipid peak, and decreased N-acetyl aspartate and creatine.[200] The reduction of choline and N-acetyl aspartate suggests the presence of axonal injury.

PULMONARY

Radiographic abnormalities following heroin overdose include pulmonary edema, aspiration pneumonia, pulmonary emboli, cardiomegaly, cardiac failure from valvular disease, and rarely hyperaeration from bronchospasm. Heroin-related pulmonary edema typically presents with diffuse, bilateral, fluffy infiltrates that appear symmetric. Occasionally, unilateral or lobar infiltrates may appear, and the pulmonary edema may shift rapidly from lobe to lobe and from one lung to the other.[201] Radiographic evidence of pulmonary edema usually resolve within 24–48 hours. Other pulmonary complications of IV drug use include bronchopneumonia and lung abscesses.

Driving

In blood samples from 5 drivers arrested for driving under the influence, the median free and total morphine concentrations were 0.065 mg/L (range, 0.028–0.093 mg/L) and 0.918 mg/L (range, 0.230–1.451 mg/L), respectively.[132] No other drugs were detected in these blood samples. The presence of 6-MAM indicates the recent use of heroin. When 6-MAM is detected in urine samples from drivers suspected of driving under the influence, urine concentrations of free morphine usually exceed 1 mg/L. Analysis of 212 6-MAM-positive urine specimens from drivers apprehended for driving under the influence of drugs, 92% of these specimens contained morphine concentrations exceeding 1 mg/L as measured by isotope-dilution gas chromatography/mass spectrometry.[202] In an experimental study of 10 heroin addicts, the administration of 25 mg, 50 mg, and 100 mg doses of heroin via inhalation produced a dose-dependent decrease in the simple reaction time as demonstrated in Figure 31.7.[46] The decline in simple reaction times began about 30 minutes after inhalation with peak reduction occurring about 30–60 minutes after inhalation began.

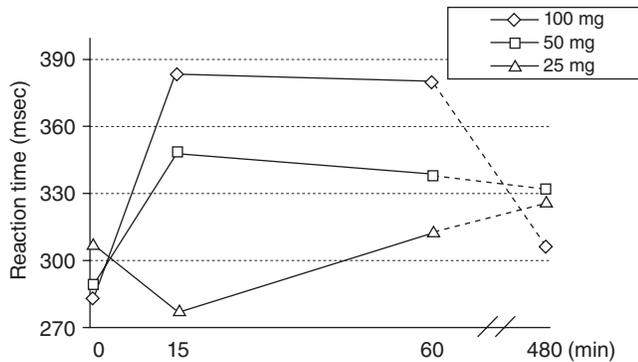
Experimental studies in heroin addicts receiving up to 95 mg IV daily in an observation ward demonstrated that the IV administration of heroin reduced activity and


FIGURE 31.7. Mean decline in simple reaction times of 5 volunteer addicts administered various doses of heroin via inhalation. (Reprinted from European Neuropsychopharmacology, Vol. 11, Issue 3, VM Hendriks, W van den Brink, P Blanken, IJ Bosman, JM van Ree, Heroin self-administration by means of 'chasing the dragon': pharmacodynamics and bioavailability of inhaled heroin, p. 250, copyright 2001, with permission from Elsevier.)

responsiveness to ambient stimuli.[203] However, there was no statistically significant decline in performance on pursuit rotor testing when compared to testing during the daily administration of one IV dose of 8 mg heroin.

TREATMENT

Stabilization

The classic hallmarks of heroin intoxication include evidence of heroin use and altered consciousness along with depressed respiratory rate and miotic pupils. Although pinpoint pupils usually occur during acute heroin intoxication, the presence of severe hypoxia and metabolic acidosis may alter the pupil size. Initial treatment of acute heroin intoxication involves the assessment of ventilation and perfusion. Patients with adequate ventilation and oxygen saturations >91–92% can be observed with cardiac monitor and pulse oximetry (capnography if available) until normal level of conscious returns. Patients with inadequate ventilation require bag-value-mask ventilation with 100% oxygen and the administration of naloxone 0.2–0.4 mg IV. Although the rate of SC absorption of naloxone is slower than the IV route, difficulty obtaining IV access may result in similar onset of action via these two routes of administration, at least in the prehospital setting.[204] Atomized intranasal naloxone is available in some emergency settings.

If no improvement occurs within 3–5 min, additional doses (0.4 mg) of naloxone should be administered parenterally titrated to the maintenance of adequate ventilation. Criteria for endotracheal intubation include

inability to ventilate with bag-valve-mask, poor oxygenation (i.e., oxygen saturation <90%) despite adequate ventilation and supplemental oxygen, and persistent hypoventilation after doses of naloxone exceeding 2–4 mg. If patients with acute heroin intoxication ingested oral opioid compounds, larger doses of naloxone or a naloxone drip may be required. Otherwise, the lack of an adequate response to naloxone indicates hypoxic brain damage or another diagnosis (head trauma, sepsis, meningitis, aspiration pneumonia). If pulmonary signs or symptoms (e.g., cough, tachypnea, pink frothy sputum, rales) of pulmonary edema develop, the patient should receive a chest x-ray to detect pulmonary complications of acute heroin intoxication including acute pulmonary edema and aspiration pneumonia.

A majority of patients with heroin-associated pulmonary edema require only oxygen supplementation. In a case series of 27 patients with pulmonary edema after resuscitation from heroin overdose, about one-third of the patients required mechanical ventilation; most of these patients were extubated within 24 hours. Patients with other complication (e.g., aspiration pneumonia) in addition to pulmonary edema may need intubation including pressure-cycled ventilation for longer periods. Hypotension from heroin intoxication usually responds to fluids and naloxone unless sepsis is present.

Gut Decontamination

Methods to prevent absorption of heroin are not usually necessary unless the patient is a body packer (See Supplemental Care, Body Packing).

Elimination Enhancement

Methods to enhance elimination (e.g., hemodialysis) are not indicated for heroin intoxication. The use of dialysis is limited to the presence of renal failure and hyperkalemia, usually as a result of rhabdomyolysis.

Antidotes

Naloxone, a pure narcotic antagonist, is the antidote of choice for acute heroin intoxication. The initial dose of naloxone usually should not exceed 0.4–0.8 mg IV because of the risk of producing withdrawal in opioid-dependent patients. Larger doses of naloxone should be titrated to effect when the clinical response is inadequate. After restoration of adequate ventilation, repeat doses of naloxone are necessary only for recurrent, clinically significant hypoventilation. Mild sedation may recur after the administration of naloxone following heroin intoxication, in part as a result of the formation of the naloxone metabolite, 6-α-naloxol, which pos-

sesses agonistic and antagonistic effects on opioid receptors. Although μ-opioid receptors mediate respiratory depression, both μ- and κ-opioid receptors mediate sedation. Hence, persistent κ-opioid stimulation by 6-α-naloxol may cause recurrence of sedation, but not respiratory depression.

Supplemental Care

Laboratory testing in patients with prolonged coma from acute heroin intoxication include analysis of the blood for complete blood count (CBC), electrolytes, creatinine, hepatic aminotransferases, and creatine kinase. The presence of rhabdomyolysis (serum creatine kinase >1,000 IU) indicates the need for generous fluid replacement with monitoring of renal function and serum potassium. Urine alkalinization is occasionally recommended in the older medical literature, but the efficacy of this method is unclear.

Acute Intoxication

Complications of an IV heroin overdose are usually clinically apparent soon after treatment begins with naloxone. Based on retrospective studies, patients requiring observation for >3–4 hours had intoxication by other drugs (ethanol, methadone, propoxyphene) or medical problems (e.g., pneumonia, pulmonary edema, hypoxic encephalopathy).[205] Clinical characteristics of patients with an adequate response to naloxone and stable medical condition include Glasgow Coma Scale of 15, heart rate 50–100 beats/min, temperature 35.0–37.5°C (95–99.5°F), oxygen saturation >92%, and respiratory rate 10–20 breaths/min.[206] Consequently, following an IV heroin overdose, patients with normal mental status and normal physical examination 4 hours after the administration of naloxone may be discharged.

Body Packing

Figure 31.8 outlines a treatment plan for heroin body packers. In contrast to body packers (swallowers, couriers, mules, internal carriers), body stuffers swallow small amounts of loosely wrapped drugs, usually to avoid arrest by police. Typically, body packers carry about 1 kg of heroin divided into 50–100 packets of about 10 g each.[207] Although previous packets were loosely wrapped, current smuggling of illicit drugs involves an automated process that densely packs the drug into a latex sheath (condom, balloon) covered with several layers of latex and sealed with a hard wax coating.[208] These processes also use aluminum foil, carbon paper, plastic food wrap, or other material to alter the radiodensity of the packet. Frequently, the body packers ingest

constipating agents (loperamide, diphenoxylate) prior to transport with unaided passage of the packets being delayed 1–2 days to 2–3 weeks.[209]

The radiologic detection of heroin packets depends on the number, density, air-packet interface, size, and position in the GI tract. Plain abdominal x-rays are usually sensitive to the presence of heroin packets by demonstrating oval or round soft tissue densities highlighted by a gas halo or direct visualization of the packets. Case reports suggest that the use of contrast-enhanced plain abdominal radiography or contrast-enhanced CT increases the sensitivity and specificity of abdominal imaging for the detection of heroin packets.[210] There are few data on the sensitivity and specificity of CT for the detection of heroin packets. In a study of 124 body packers who passed heroin packets, noncontrast abdominal and pelvic CT detected heroin packets in all 124 body packers, whereas 2 of the 42 body packers undergoing abdominal plain x-rays had false-negative results.[211] However, case reports suggest that contrast-enhanced CT may miss a single packet of heroin, particularly homogeneous isodense packets.[212] The latter packets have Hounsfield units (HU) in the range of −40 to 30 HU compared with water (0–20 HU) and soft tissue (40–60 HU). Altering the typical window width and level settings for abdominal CT imaging to 600–800 HU and −150 to 300 HU, respectively, improves the sensitivity of noncontrast CT for the detection of isodense packets.[211] Opium packets are less dense than heroin packets, typically in the range of 150–200 HU. In a preliminary study of 12 opium body packers, noncontrast CT detected packets in all 12 body packers.[213] The density of these packets ranged from 127–300 HU. The use of contrast-enhanced plain abdominal radiography may interfere with subsequent imaging of the abdomen with CT scans.

There are few data on the sensitivity of ultrasound for the detection of packets of illicit drugs, but in general, both ultrasound and MRI are not sensitive techniques for the detection of heroin packets in the GI tract.[214] The progress of the packets along the GI tract can be monitored by the use of amidotrizoate-meglumine (Gastrografin, 0.9 mL/kg) and plain abdominal films taken at least 5 hours after ingestion of the contrast if CT scans of the abdomen are not indicated.[215]

The lack of sensitivity and specificity of urine drug screens for the detection of body packing limits the usefulness of the urine drug screen for determining the presence of heroin packets in the GI tract. Heroin packets are frequently not accessible to endoscopy and the risk of breakage limits the usefulness of this removal technique. Oral feeding should be restricted until the packets pass into the large intestine. Depending on the size of the packets, the use of syrup of ipecac may be complicated by esophageal obstruction.[216] Alternatives

567

to the use of whole bowel irrigation include the administration of bisacodyl suppositories (Dulcolax®, Boehringer Ingelheim Pharmaceuticals, Ridgefield, CT), activated charcoal mixed with 3% sodium sulfate cathartic, and phosphosoda enemas after passage of the packets into the large intestine.[217] Oil-based laxatives are not recommended because of the potential of these laxatives to reduce the tensile strength of the packets. There are theoretical concerns that the administration of polyethylene glycol solution can increase the GI absorption of heroin either by solubilizing heroin released from packets or suspending the heroin in solution and increasing the surface area; however, there are inadequate clinical data at the present time to determine the clinical significance of these concerns or the efficacy of these 2 regimens. Confirmation of the elimination of packets by contrast-enhanced CT or contrast-enhanced plain abdominal radiography should be done after decontamination measures and following the passage of 2 or 3 stools without packets. Multiple stools devoid of packages or an absence of symptoms after 24 hours of observation are reasonable endpoints for observation of these patients. Rare patients may have retained packets despite negative abdominal imaging.[211]

ADDICTION

Medical detoxification of heroin addicts involves the substitution of long-acting agonists (methadone, buprenorphine) or α_2-adrenergic agonists (clonidine, lofexidine) for heroin as well as psychosocial treatments (behavioral modification, counselling, family therapy).[218,219] Chronic heroin use produces relative endogenous opioid deficiencies as a result of downregu-

lation of opioid production. This opioid deficiency creates an intense craving that causes a preoccupation with obtaining opioids rather than pursuing more productive interests. Methadone relieves these narcotic cravings. Levomethadyl acetate (LAAM) is also an alternative to methadone and buprenorphine for the treatment of heroin addiction, but the concerns about the cardiotoxicity (i.e., torsade de pointes) associated with high doses of LAAM limits the use of this agent.[220] Although ultrarapid or anesthesia-assisted opioid withdrawal and antagonist induction procedures are promoted as relatively symptom-free alternatives to more traditional methods of withdrawal, there are inadequate data to justify the risks associated with these procedures. A randomized clinical trial of 106 healthy (American Society of Anesthesiologists physical status I or II) treatment-seeking, heroin-dependent patients compared 1) anesthesia-assisted, rapid opioid detoxification/naltrexone induction; 2) buprenorphine-assisted, rapid opioid detoxification/naltrexone induction; and 3) clonidine-assisted opioid detoxification with delayed naltrexone induction.[221] The mean withdrawal scores were similar between the 3 groups, and the treatment retention rates at 12 weeks were not statistically different between the 3 groups (20%, 24%, 9%, respectively). There were 3 potentially life-threatening adverse events during the anesthesia procedure.

METHADONE. Methadone is a long-acting μ-opioid receptor agonists that produces peak blood concentrations in about 2–4 hours with a serum elimination half-life of about 24–36 hours. Opioid withdrawal frequently complicates the hospitalization of opioid-dependent addicts for medical illnesses. During inpatient opioid detoxification programs, heroin addicts usually receive an initial daily methadone dose of 5–20 mg orally in 5-mg increments depending on the severity of the withdrawal symptoms and the size of the heroin habit; subsequently, an additional 5–10 mg methadone is added as required to control abstinence symptoms and until a stabilizing dose is reached. Typically, control of abstinence symptoms in hospitalized heroin addicts respond to daily methadone doses of 10–40 mg; however, some highly dependent heroin users require substantially higher doses. Because of the long duration of action and the difficulty determining the appropriate methadone dose based on history, the methadone dose during the first 24–48 hours must be titrated carefully. After about 2–3 days, the methadone dose is tapered ~5 mg/day or 20% per day. Adverse effects associated with methadone use include constipation, irregular menstrual periods, decreased libido, weight gain, and diaphoresis. For maintenance programs, daily methadone doses begin at 25–35 mg with adjustment of the dose to allevi-

ate withdrawal. Typically, the lowest dose of methadone effective for maintaining a heroin addict is about 60 mg with the dose usually increased gradually to 80–120 mg/day.[222] In general, a trough (i.e., 24-h postdose) serum methadone concentration of 0.4 mg/L correlates to adequate methadone dosing, although symptoms of withdrawal may occur in some heroin addicts despite maintenance doses that produce serum methadone concentrations near these trough concentrations.[223]

A major problem with brief opioid detoxification programs is the extremely high rate of relapse to illicit heroin use. Although maintenance therapy with naltrexone is effective in a minority of highly motivated heroin addicts, poor compliance with this regimen limits the efficacy of naltrexone in most opioid addicts.[224] The daily dosage of methadone administered to pregnant women ranges from 10–90 mg with a mean of about 50 mg. Approximately 60% of infants born to women on methadone maintenance demonstrate opioid withdrawal with the severity of these symptoms depending on the maternal methadone dose.[222] Mixed agonist-antagonists (e.g., nalbuphine, butorphanol, pentazocine) should be avoided because of the potential of these drugs to cause opioid withdrawal symptoms. The administration of rifampin, carbamazepine, isoniazid, barbiturates, and phenytoin also reduce the plasma methadone concentrations; therefore, the use of these two drugs with stable methadone doses may precipitate opioid withdrawal. Although dysrhythmias do not usually occur in patients treated with methadone, a case series of 3 patients administered >600 mg daily[225] and a case series of 17 patients (i.e., mean daily dose 397 ± 283 mg)[226] associated torsade de pointes with high-dose methadone therapy. All these patients had markedly prolonged QTc intervals (mean 615 ± 77 msec for series of 17 patients), and most of these patients had predisposing factors (coronary heart disease, hypokalemia, bradycardia) for the development of dysrhythmias. Because of the long half-life of methadone, withdrawal symptoms from the abrupt cessation of methadone treatment beings within 36–72 hours. Peak symptoms methadone withdrawal peak about 4–6 days after cessation of treatment, and the withdrawal symptoms resolve over the subsequent 10–12 days.

BUPRENORPHINE. Buprenorphine is probably more effective than clonidine for the treatment of heroin addiction; the use of buprenorphine may offer some advantages over methadone. A Cochrane review of buprenorphine and methadone suggested that the severity of heroin withdrawal during the use of buprenorphine and methadone was similar, but symptoms resolved more quickly with buprenorphine and patients were more likely to complete withdrawal

569

treatment with buprenorphine.[227] However, there are limited data comparing these 2 treatments and more studies are needed to confirm these preliminary observations. Buprenorphine is a partial opioid agonist-antagonist that requires sublingual administration because of poor oral bioavailability. This drug is a partial μ-opioid receptor agonist and a weak κ-opioid receptor antagonist that has less depressant effects on respiration and no significant effect on the QT_c interval. As the dose of buprenorphine increases, this drug behaves more like an antagonist; withdrawal symptoms can occur, particularly in highly dependent, heroin addicts (i.e., >60 mg methadone/daily). The opioid-antagonist activity limits the maximal analgesic effects as well as respiratory depression associated with buprenorphine use. In the United States, the approved sublingual drug is marketed as Suboxone® (Reckitt Benckiser, Berkshire, UK) in 2 mg and 8 mg tablets combined with naloxone 0.5 mg and 2 mg, respectively. Because the absorption of oral naloxone is poor, the presence of naloxone does not cause withdrawal reactions following sublingual administration, whereas the presence of naloxone theoretically limits diversion of the tablets for IV abuse. The administration of buprenorphine is a treatment both for opioid detoxification and for the maintenance of opioid-dependent users. Clinical studies suggest that the use of buprenorphine-naloxone for the treatment of heroin addiction is more efficacious than rapid detoxification based on lower opioid use and higher retention rate in the treatment program.[228] The typical dose of buprenorphine for detoxification from opioids is 8–12 mg sublingually daily for 5–7 days with some studies using buprenorphine doses as small as 12 mg intramuscularly in 8 divided doses over 24 hours.[229] Limited data in neonates suggest that buprenorphine may be an alternative to methadone or barbiturates for the neonatal abstinence syndrome at doses of 0.5–1.0 µg/kg orally every 6 hours; however, larger trials are required to define the efficacy of this treatment in neonates.[230]

Therapy with buprenorphine-naloxone should not begin until withdrawal symptoms occur. In a randomized clinical trial of buprenorphine for the treatment of concurrent opioid and cocaine dependence, a sublingual buprenorphine dose of 16 mg daily was well tolerated and reduced concomitant opioid and cocaine use.[231] Maintenance doses are 4–32 mg/day with dosing extended to every 2–3 days as tolerated. The initial induction of detoxification with buprenorphine usually occurs under the observation of a physician because of the potential for withdrawal symptoms. For inpatients, the initial dose typically is 4–8 mg sublingually with careful observation for withdrawal symptoms. Recent studies indicate that less-than-daily dosing schedules of buprenorphine are equally efficacious as daily dosing schedules.[232] In a pilot study of 30 heroin users, there was no statistically significant difference in the Clinical Opiate Withdrawal Scale between the high-dose buprenorphine regimen (8 mg, 8 mg, 8 mg, 4 mg, and 2 mg on days 1–5, respectively) and the low-dose regimen (2 mg, 4 mg, 8 mg, 4 mg, and 2 mg on days 1–5, respectively).[233] Both regimens were superior to clonidine without serious treatment-related adverse events.

The slow release of buprenorphine from opioid receptors results in a long duration of action. A buprenorphine dose of 8 mg sublingual is equivalent to an oral methadone dose of 60 mg for the treatment of opioid-dependent patients. Advantages of buprenorphine over methadone include milder withdrawal symptoms, longer duration of action, lack of QT_c prolongation, and lower risk of serious overdose.[234] Clinical studies suggest that buprenorphine and buprenorphine-naloxone have similar efficacy to moderate doses of methadone when used as maintenance therapy for opioid dependence,[235] and buprenorphine-assisted withdrawal from heroin has similar efficacy in specialty clinics and primary care settings.[236] Buprenorphine is probably more effective than clonidine for the reduction of opioid withdrawal symptoms with less adverse effects.[237] There are limited data on adverse effects (e.g., insomnia, vomiting, headache) following excessive doses of buprenorphine. Although there are case reports of deaths associated with buprenorphine use,[238] these fatalities usually occur following the concomitant use of high doses buprenorphine and other drugs (e.g., benzodiazepines).

AMELIORATING AGENTS. Other medications for the treatment of the symptoms of heroin withdrawal include antiemetics, oxazepam (30–60 mg every 6 hours) for muscle spasms, nonsteroidal antiinflammatory drugs for myalgias, benzodiazepines for insomnia, and clonidine for symptoms of excessive sympathomimetic stimulation. Clonidine is an α-adrenergic agonist that effectively blocks much of the autonomic symptoms associated with opioid withdrawal by decreasing norepinephrine secretion in the locus coeruleus. This drug does not alleviate the subjective symptoms of anxiety, muscle cramps, insomnia, or drug craving as much as reducing doses of methadone. A review of the 24 studies of 1,631 opioid addicts concluded that opioid withdrawal following clonidine and reducing doses of methadone are similar; however, adverse effects (hypotension, dizziness, dry mouth, lack of energy) was higher with clonidine than reducing doses of methadone.[239] A typical dose of clonidine is 0.1–0.2 mg orally every 4–6 hours for mild to moderate withdrawal with careful monitor-

ing of blood pressure. Tapering of the clonidine dose begins with reduction of the dose by 0.2 mg/day starting on the third day of cessation of opioid use.

Chapter 32

METHADONE

HISTORY

In the 1930s, scientists at the pharmaceutic laboratories of the I.G. Farbenkonzern, a subsidiary of Farbwerke Hoechst (Frankfurt am Main, Germany) discovered a number of basic, substituted diphenylmethane compounds with analgesic properties. In 1939, these German scientists first synthesized the compound methadone [2-dimethylamino-4,4-diphenylheptanon-(5)], which was then numbered Va 10820. Limited clinical testing of Va 10820 occurred in Germany during World War II under the code name Amidon, but this compound was not distributed to field hospitals or civilians because of side effects during clinical testing.[1] After the war, German patents and research records on Amidon were brought to the United States; in 1947, the Council on Pharmacy and Chemistry in the American Medical Association gave the generic name, methadone, to Amidon.[2] In the same year, Eli Lily initiated commercial production of methadone in the United States under the name Dolophine®. In 1949, Hoechst AG released methadone in Germany under the trade name Polamidon®. Methadone exists under a variety of trade names throughout the world including Adanon®, Adolan®, Althose®, Amidone®, AN-148®, Anadon®, Biodone®, Butalgin®, Diskets®, Dolamid®, Dolophine®, Dopridol®, Eptadone®, Heptadon®, Heptalgin®, Heptanal®, Heptanon®, Ketalgin®, Mephenon®, Metasedin®, Methadone®, Methadose®, Methox, Miadone®, Pallidone®, Petalgin®, Phenadone®, Physeptone®, Sedo Rapide®, Symoron®, Tussol®, and Westadone®.[1] In the 1940s, clinical studies on the analgesic properties of methadone demonstrated the potential for severe respiratory depression and death.[3]

Although the mortality from self-poisoning decreased in the 1980s and 1990s, the total number of deaths from methadone increased as the availability of methadone as a prescription drug increased.[4] However, the increase in methadone-related deaths was substantially lower than the increase in heroin-related deaths.[5] In the first decade of the 21st century, methadone fatalities increased substantially, primarily in the setting of polydrug use along with the dramatic increase in the abuse of prescription opioid analgesics.[6]

IDENTIFYING CHARACTERISTICS

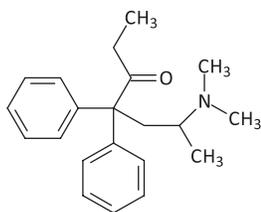
Methadone (CAS RN: 76-99-3, 6-dimethylamino-4,4-diphenyl-3-heptanone) is a synthetic diphenylpropylamine compound with a chemical structure similar to propoxyphene (Figure 32.1). Methadone and morphine differ chemically and pharmacokinetically, but their actions and analgesic properties are similar. The comparative analgesic potency of methadone and morphine is variable, depending on the route of exposure, tolerance (i.e., opioid-naïve or opioid-tolerant), and dose (decreasing at higher doses). In a study of 38 advanced cancer patients switched from oral morphine to oral methadone, the median oral daily dose of morphine before the switch was 145 mg and after the switch the median equianalgesic oral methadone dose was 21 mg (median morphine/methadone ratio = 7.75; range, 2.5–14.3).[7] Methadone is a racemic mixture of R-(-)- and S-(+)-methadone enantiomers in most countries with the exception of Germany.[8] Volunteer experiments indicate that R(-)-methadone (l-methadone) has euphoriant properties and suppresses the physical signs of opioid dependence, whereas the S-(+)-enantiomer


FIGURE 32.1. Chemical structure of methadone.

TABLE 32.1. Physical Properties of Methadone.

Physical Property	Value
pK$_a$ Dissociation Constant	8.94 (25°C/77°F)
log P (Octanol-Water)	3.93
Water Solubility	48.5 mg/L (25°C/77°F)
Vapor Pressure	1.12E-06 mm Hg (25°C/77°F)

(*d*-methadone) is inactive.[9,10] Based on limited clinical data, the analgesic potency of *R*(-)-methadone is about 50 times higher than *S*(+)-methadone as measured by the Hardy-Wolff-Goodell apparatus;[11] there is substantial interspecies variation in experimental tests on the analgesic potency of methadone.[12] Although the (*R*)-enantiomer accounts for most of the opioid effects of racemic methadone, pharmaceutic preparations of methadone are racemates due to cost. Methadone is highly lipid soluble. Clinical studies indicate that blockade of the human ether-à-go-go (hERG) voltage-related potassium channel is isomer-dependent with the (*S*)-methadone isomer being substantially more potent than the (*R*)- methadone isomer.[13]

Methadone is a schedule II drug (US Controlled Substances Act) for use in the treatment of opioid addiction and chronic pain, primarily in oral preparations. An intravenous (IV) formulation of methadone is available for the palliative treatment of cancer pain; however, the propensity of the preservative (i.e., chlorbutanol) in this formulation to enhance the delayed cardiac repolarization associated with methadone limits the use of this preparation.[14] Oral methadone contains sucrose as a means to prevent the IV abuse of oral methadone mixtures.[15] The hypertonic sucrose causes local tissue necrosis if injected. Most illicit methadone is diverted from pharmaceutic uses; therefore, illicit methadone typically contains few impurities.

EXPOSURE

Epidemiology

Methadone maintenance treatment for opioid dependence is an effective method for reducing opioid abuse and criminality, when compared with untreated opioid addicts.[16] Methadone intoxication usually involves multiple drug use in opioid addicts.[17] Accidental methadone poisoning also occurs in children, particularly in households with family members in methadone maintenance programs.[18] Since 1987, methadone-related deaths have increased in the United Kingdom as a result of several factors including the greater availability of medically prescribed drugs and prescribing practices that allow 2 or more prescription sources.[19] Overall, methadone is an uncommon cause of drug-related deaths.[20] In a study of fatal intoxication in Sweden from 1992–2002, methadone ranked 38th out of 50 drugs associated with fatal intoxications.[21] However, among unintentional pharmaceutic overdose fatalities, methadone is common. In a study of unintentional pharmaceutic drug overdoses in West Virginia, methadone was a contributory drug in 112 (40%) of the 295 deaths in 2006.[6] Methadone was a prescribed drug for only 32% of the methadone-related deaths. The mortality of heroin abusers in methadone treatment is about 8 times higher than the general population, but substantially lower than the mortality of heroin abusers without methadone treatment as a result of the relative decrease in death from natural causes and overdose.[22,23]

Sources

Indications for methadone include the detoxification of individuals with physical dependence on opioid drugs and the maintenance of sobriety in opioid addicts.[24] Methadone is a centrally acting opioid analgesic, which is a heroin substitute that significantly reduces the risk of death from accidental heroin overdose for patients participating in a methadone maintenance program.[25] Forms of prescription methadone include methadone tablets (5 and 10 mg methadone hydrochloride), Dolophine 40 mg (methadone hydrochloride diskets), oral solutions (5 mg and 10 mg/5 mL, 10 mg/mL), and parenteral (Dolophine hydrochloride, 10 mg/mL). Methadone is available commercially in the United States as a hydrochloride salt of the racemic mixture. The form of methadone containing only the (*R*)-enantiomer is available in the European Union and is widely prescribed in Germany. The usual source of illicit methadone is the diversion of prescribed methadone.[26] Rarely, methadone contaminates prescription medication as a result of inadvertent errors during the filling of prescriptions.[27]

Methods of Abuse

Abuse of methadone occurs via ingestion and IV injection. Inhalation of methadone is rare. Most cases of

methadone intoxication and abuse are associated with polydrug use. Abuse of benzodiazepines by methadone maintenance patients is very common with a majority of these patients using benzodiazepines in addition to methadone, particularly by patients with concomitant psychiatric disorders and histories of polydrug use.[28,29] In a cross-sectional study of urine drug screens from 2 US drug treatment centers, 65–70% of the drug screens were positive for benzodiazepines.[30] Based on self-reported drug use, the median daily dose of diazepam (i.e., the most common benzodiazepine) was 40–45 mg with the dose usually ingested in the hour before methadone treatment to enhance the effect of methadone.

DOSE EFFECT

Because of the variability in response to methadone, the initial outpatient dose of methadone in maintenance programs is ≤30 mg with an upper range of 25–40 mg in highly tolerant individuals.[15] For patients with uncertain or low tolerance, the initial methadone dose is 10–20 mg. The dose is increased 5–10 mg/day depending on the development of withdrawal symptoms and the craving for heroin with close physician supervision. Patients in methadone maintenance programs typically receive about 50 mg daily, but daily doses range up to 180–300 mg daily. Volunteer studies indicate that 100 mg of methadone blocks the euphoriant effects of 25 mg of heroin in most participants for 48 hours, whereas all participants developed euphoria after receiving 25 mg heroin 72 hours after ingesting 100 mg methadone.[31] The IV administration of 75 mg heroin produced euphoria in 4 of 6 participants despite the ingestion of 100 mg of methadone 48 hours prior to the heroin injection.

Doses greater than 30 mg of oral methadone consistently cause sedation in opioid-naïve individuals.[32] In a study of healthy opioid-naïve volunteers, adverse effects associated with the ingestion of 10–15 mg methadone included nausea, vomiting, and lightheadedness.[33] Only 4 of 17 opioid addicts developed adverse effects (nausea, vomiting, sedation) after receiving a mean methadone dose of 39 ± 17 mg (range, 15–80 mg). Case reports suggest that 1 mg/kg of methadone may cause fatal apnea in children.[34,35] Therefore, the potentially fatal dose in young children is ~10–20 mg. Case reports indicate that some tolerant individuals can receive up to 400 mg methadone subcutaneously without serious adverse effects, whereas some nontolerant adults develop severe respiratory depression after receiving 40 mg methadone intravenously or 70 mg methadone orally.[36] These studies also indicate that opioid-dependent adults lose their tolerance to methadone after 5 weeks of abstinence.

TOXICOKINETICS

Absorption

The absorption of methadone following ingestion is rapid and almost complete with detectable methadone concentrations appearing in plasma within 30 minutes of oral administration.[37] The low hepatic extraction ratio of oral methadone accounts for relatively high bioavailability (i.e. about 70–90%); absorption of methadone is not stereoselective. In a study of 8 opioid abusers receiving 20 mg methadone, the bioavailability of methadone was 0.79 ± 0.21 with a range of 0.41–0.99.[38] The gastric absorption of oral methadone doses is slower in opioid users than opioid-naïve individuals. In a study of 13 opioid-naïve individuals and 17 opioid users receiving oral methadone, the mean absorption half-lives were 0.2 hour and 0.73 hour, respectively.[33] Following the regular daily administration of 100–120 mg methadone to 5 opioid-dependent individuals, the peak plasma methadone concentrations occurred about 2–4 hours after ingestion.[39] Rectal administration of methadone is an alternative to oral use in cancer patients as the absorption of methadone by this route is rapid with high bioavailability. In a study of 7 healthy volunteers receiving 10 mg d_5-methadone-HCl rectally, the mean absolute rectal bioavailability of methadone was 0.76 (95% CI: 0.69–0.82) compared with 0.86 (95% CI: 0.72–0.99) for a similar oral dose.[40] The mean time to peak plasma methadone concentration was more rapid for rectal administration (mean, 1.4 h; 95% CI: 0.83–2.0 h) than ingestion (mean, 2.8 h; 95% CI: 1.3–4.3 h). The bioavailability of methadone via insufflation is sufficient to cause death when methadone is surreptitiously substituted for other drugs of abuse used intranasally.[41] In a cross-over study of 8 healthy volunteers, the mean bioavailabilities of 10-mg doses of methadone administered orally and nasally were approximately 0.85.[42] The maximum plasma methadone concentration and the time of maximum effects as measured by dark-adapted pupil diameter following the nasal dose occurred at 7 minutes and 30 minutes after administration, respectively.

Distribution

Methadone undergoes a rapid distribution phase into a large volume of distribution followed by a slow elimination phase. This drug is widely distributed to fat, lung, liver, kidney, spleen, blood, and urine.[43] The mean apparent volume of distribution was approximately 3.5 L/kg after the IV administration of 10–30 mg methadone to 8 chronic pain patients including 5 cancer patients.[44] A study of 5 opioid addicts receiving daily methadone

doses of 10–60 mg demonstrated a mean steady-state volume of distribution of approximately 6.7 L/kg with range of 4.2–9.2 L/kg.[45] Methadone is highly bound to plasma protein, predominately to the α_1-acid glycoprotein portion with a bound fraction ranging from about 71–89%.[46,47] Methadone binds strongly to orosomucoid 2 (α_1-acid glycoprotein variant) and to a lesser extent to orosomucoid 1.[48] The free fraction of methadone varies directly with plasma α_1-acid glycoprotein concentrations with a range of about 6–14%. Interindividual variation in binding to α_1-acid glycoprotein contributes to the differences in individual response to racemic methadone in addition to variability in cytochrome P450 activity.[49]

Biotransformation

The biotransformation of methadone is stereoselective with large interindividual variation, primarily involving N-demethylation and cyclization of methadone in the liver to inactive pyrrolidine metabolites. Figure 32.2 displays the major metabolites of methadone. Methadone metabolites include 2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine (EDDP) and 2-ethyl-5-methyl-3,3-diphenylpyrroline (EMDP), pyrrolidone, pyrroline, hydroxymethadone, hydroxypyrroline, methadol, and hydroxypyrrolidine.[50,51] Methadone also undergoes hydroxylation and dealkylation of the N-methyl groups. The dealkylated metabolites are unstable, resulting in spontaneous cyclization to form EDDP. N-demethylation of EDDP also occurs. Because of the large first-pass effect, the peak EDDP plasma concentration occurs prior to the peak methadone plasma concentration. In a study of 20 opioid-dependent individuals on chronic methadone therapy, the mean time to peak EDDP and methadone concentrations in plasma were about 2.5 hours (range, 1.0–6.7 h) and 3.7 hours (range, 1.8–6.8 h), respectively.[52]

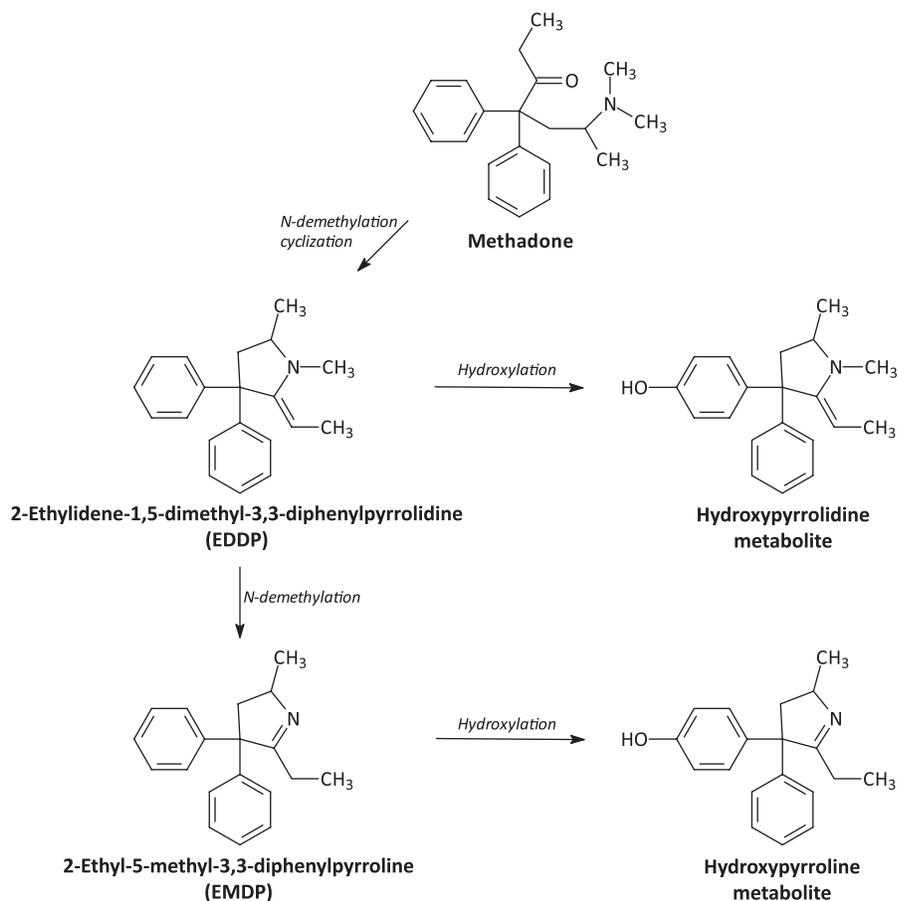
Minor metabolic pathways include the formation of the active metabolites, hydroxymethadone and various methadol metabolites.[53] Figure 32.3 displays the minor metabolites of methadone. Methadone biotransformation involves several cytochrome P450 isoenzymes, but there is a lack of consensus on the exact role of each isoenzyme. Initial *in vitro* studies suggested that CYP3A4 is the primary hepatic CYP450 isoenzyme


FIGURE 32.2. Major metabolites of methadone (adapted from Kreek, 1976).[53]
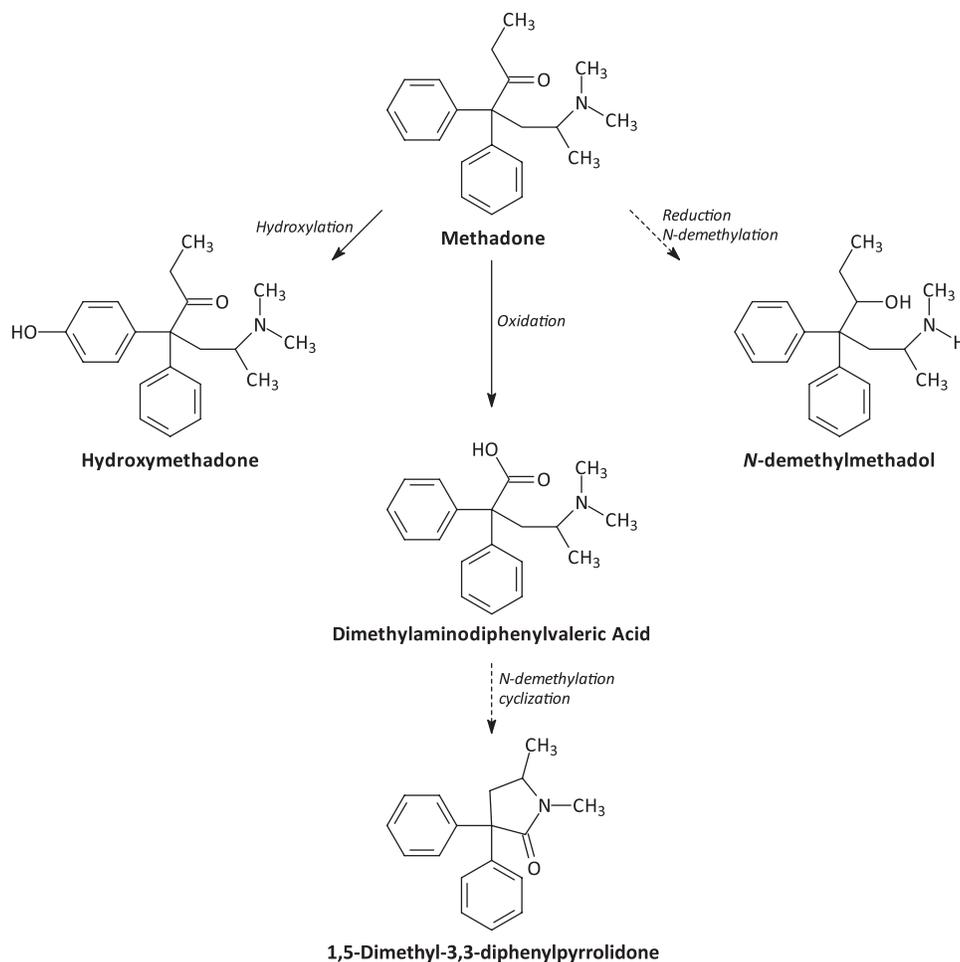

FIGURE 32.3. Minor metabolites of methadone (adapted from Kreek, 1976).[53]

involved with the biotransformation of methadone, whereas other cytochrome P450 isoenzymes (e.g., CYP2B6, CYP2D6, CYP2C9, CYP2C19) participate in the biotransformation of methadone to a lesser extent than CYP3A4.[54,55] However, *in vivo* studies indicate that CYP2B6 has a prominent role in the biotransformation, particularly the chiral *N*-demethylation of methadone.[56] There is substantial variation in the individual expression of CYP3A4; this isoenzyme is inducible resulting in modest individual variation in the biotransformation of methadone. The methadone dose accounts for <50% of the variation in plasma methadone concentrations in studies of methadone maintenance patients, whereas CYP3A4 activity accounts for approximately 20% of the variation in plasma methadone concentrations based on pharmacokinetic studies of CYP probes.[57] CYP3A4 is not stereoselective, whereas CYP2C19 prefers the *R*-(-)-enantiomer. Case reports suggest that CYP3A5 polymorphism may account for rapid methadone clearance and relatively low methadone concentrations in some individuals.[58]

Elimination

The kidney excretes unchanged methadone and glucuronide metabolites with about one-half of a single, methadone dose appearing in the urine as unchanged methadone and metabolites over the first 96 hours after ingestion.[59] Methadone has a long elimination half-life. In a study of healthy volunteers receiving an oral methadone dose of 8–15 mg, the median terminal plasma elimination half-life of methadone ranged from 33–46 hours (depending on the method of calculation).[33] There is wide individual variation (i.e., 15–55 h) in the terminal plasma elimination half-life of methadone. In a study of 5 opioid addicts stabilized on 10–60 mg methadone daily, the mean plasma elimination half-life was about 27 hours (95% CI: 14–39 h).[45] The terminal plasma elimination half-life of the 2 methadone enantiomers was similar in some studies,[60] but the elimination half-life of the (*R*)-enantiomer was slightly longer than the (*S*)-enantiomer in another study (37.5 h and 28.6 h, respectively).[61] In a study of a 44-year old man found

583

comatose with depressed respiration after ingesting an estimated 240 mg methadone, the plasma elimination half-life of the (*R*)- and (*S*)-enantiomers was 16.1 hours and 13.2 hours, respectively.[62]

Increasing plasma methadone concentrations occur when repeat doses of methadone are administered within 6 hours. The induction of P450 isoenzymes requires about 2–3 weeks; therefore, the clearance of methadone gradually increases during this induction period.[63] The urinary excretion of methadone is pH dependent as a result of reduced renal tubular reabsorption of methadone with decreasing urine pH.[59] Hence, the renal clearance of methadone increases in acidic urine. Above a urinary pH of 6, the renal excretion of unchanged methadone is 4% of the absorbed dose, but renal excretion increases substantially when urinary pH is <6.[8] The plasma elimination half-life of methadone in a study of 8 opioid abusers receiving 20 mg methadone orally was 19.5 ± 3.6 hours following urinary acidification and 42.1 ± 8.8 hours following urinary alkalinization.[38] Methadone remains in the plasma long after the analgesic effects of methadone subside. [64]

Maternal and Fetal Kinetics

Methadone crosses the placenta and may cause respiratory depression in the fetus. Methadone metabolism increases during pregnancy, resulting in lower plasma methadone concentrations. Case reports suggest that symptoms of withdrawal can occur in women during pregnancy despite maintaining the same methadone doses that suppressed withdrawal symptoms prior to pregnancy.[65] In general, methadone concentrations in breast milk of lactating mothers in methadone maintenance programs are low and remain stable over time with relative infant dose usually <5% of the maternal weight-adjusted dose.[66] In a study of 12 breast-feeding women on daily methadone doses of 20–80 mg, the mean milk/plasma ratio was 0.44 (95% CI: 0.24–0.64).[67] The mean infant dose as a percentage of the maternal dose was 2.79% (95% CI: 2.07–3.51%) with an estimated mean methadone dose for the infant of 17.4 μg/kg (95% CI: 10.8–24 μg/kg) assuming 100% bioavailability. Case reports suggest that secretion of methadone into breast milk from lactating mothers in methadone maintenance programs is minimal,[68] and the American Academy of Pediatrics lists methadone as a maternal medication usually compatible with breast-feeding.[69] A retrospective study suggested that high-dose (i.e., >100 mg daily) methadone maintenance therapy is not associated with an increased risk of adverse fetal outcomes (neonatal abstinence, infant hospitalization) when compared with low-dose (i.e., <100 mg daily) methadone maintenance therapy.[70]

Tolerance

The development of tolerance to methadone results in cross-tolerance to other opioids with similar properties. However, the cross-tolerance is not complete because methadone acts at several central nervous system (CNS) receptor sites in addition to the μ-opioid receptor including the δ-opioid and NMDA receptors, whereas heroin acts primarily at the μ-opioid receptor. The cross-tolerance of methadone to other opioids varies between individuals and predicting the degree of cross-tolerance is difficult. Consequently, tolerance to heroin does not guarantee tolerance to all the effects of methadone or other opioids.

Partial tolerance develops to the respiratory and pupillary effects of methadone, but the tolerance to the respiratory depressant effects of methadone does not necessarily occur at the same rate as the tolerance to the euphoriant or analgesic effects.[71,72] The development of tolerance requires more time for methadone than for morphine with tolerance to the methadone-induced respiratory effects occurring over 1 year in some individuals.[73] Tolerance develops to reductions in tidal volume, but not to reductions in CO_2 sensitivity.[74]

Drug Interactions

The biotransformation of methadone is complex, involving several CYP450 isoenzymes; therefore, there are a substantial number of potential drug interactions based on *in vitro* studies. A substantial portion of the *in vitro* methadone metabolism occurs by the inducible P450 isoenzyme, CYP3A4, whereas most *in vivo* metabolism of methadone in humans occurs via CYP2B6. The clearance of methadone increases severalfold between the initial dose of methadone and steady-state concentrations.[63] Concomitant administration of certain drugs (e.g., phenytoin, rifampicin, zidovudine, barbiturates, spironolactone, verapamil, diethylstilbestrol, and amitriptyline) induces CYP3A4 and potentially increases methadone clearance. Rifampin lowers plasma methadone concentration, increases methadone urinary excretion, and increases fecal excretion of the major pyrrolidine metabolite.[53,75] The initiation of phenytoin or rifampin accelerates methadone clearance and can cause withdrawal symptoms in the first several days of drug administration.[76] Protease inhibitors (e.g., indinavir, ritonavir) are potent inhibitors of hepatic and intestinal CYP3A isoforms including CYP3A4. However, the clinical significance of this potential drug interaction is unclear. In an *in vivo* study, 12 healthy volunteers received IV and oral methadone alone and in addition to 100 mg ritonavir/800 mg indinavir twice daily.[77] The ritonavir/indinavir dose was sufficient to produce >90%

inhibition of hepatic and first-pass CYP3A activity. There was no statistically significant effects of the administration of ritonavir/indinavir on plasma methadone concentrations, bioavailability, renal methadone clearance, or plasma methadone concentration-effect relationships when compared with baseline values of each volunteer. The lack of a significant drug interaction in this study reflects the importance cytochrome P450 isoenzymes (e.g., CYP2B6) other than CYP3A4 in the biotransformation of methadone. *In vivo* volunteer studies of fosamprenavir 700 mg/ritonavir 100 mg twice daily for 14 days and methadone indicate that this combination causes a small reduction (i.e., mean, 18%) in total plasma (*R*)-methadone concentration without a significant change in free plasma (*R*)-methadone concentration; therefore, no reduction in methadone dosage is recommended when administered with this antiviral agent, consistent with the importance of CYP2B6 compared with CYP3A4.[78]

Ketoconazole, erythromycin, paroxetine, cimetidine, and fluoxetine can increase plasma concentrations of methadone by inhibiting CYP3A4 based on *in vitro* studies, but the relevance of this potential drug interaction is limited because of the importance of other cytochrome P450 isoenzymes (e.g., CYP2B6) in *in vivo* human metabolism of methadone. These potential inhibitory effects last only a few days compared with the 2–3 weeks required for the induction of CYP3A4 isoenzymes. Case reports suggest that potential drug interaction between methadone and fluvoxamine (but not fluoxetine) may be clinically significant.[79,80] Diazepam (10–40 mg) enhances some of the subjective and physiologic effects of methadone (drug-liking, high, goodness) in some opioid addicts.[81,82] However, the concomitant administration of diazepam and methadone does not significantly alter methadone metabolism.[83,84] Central nervous system depressant drugs (e.g., alcohol, sedative-hypnotic, barbiturates) synergistically enhance the respiratory depression of methadone depending on individual tolerance and pharmacogenetics.[85] Although disulfiram enhances *N*-demethylation of methadone and increases urinary excretion of the major pyrrolidine metabolites of methadone, the interaction between methadone and disulfiram is not clinically significant.[86]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

Methadone is a central-acting analgesic with high affinity for μ-opioid receptors and some affinity for the δ-opioid receptors. Morphine (K_i, 1.41 nM) has a higher affinity for the μ-opioid receptor than methadone (K_i, 3.51 nM).[87] Stimulation of these opioid receptors increases potassium channel opening by reducing production of cAMP as a result of the inhibition of adenylate cyclase activity. Inhibition of inward Ca^{++} currents results from the opening of voltage-operated calcium channels. The increased K^+ conductance, decreased Ca^{++} conductance, and the subsequent reduction in membrane excitability provide a molecular mechanism for the analgesic activity of methadone and other opioids.[88] Mu and delta receptor agonist activity produce synergistic effects on respiratory depression. Table 32.2 lists the pharmacologic properties of opioid receptor subtypes. Naloxone has lower affinity for the δ-opioid receptors compared with the μ-opioid receptors. The miosis associated with opioid intoxication results from increased cholinergic stimulation of the nucleus of the oculomotor nerve (cranial nerve III). Blockade of acetylcholine release in the reticular activating system by methadone produces CNS depression. In contrast to morphine, hydromorphone, and naltrexone, animal studies suggest that methadone and the *d*- and *l*-enantiomers of methadone have noncompetitive antagonist activity at the NMDA receptor similar to dextromethorphan.[89]

Mechanism of Toxicity

Methadone and heroin are the major opioids associated with respiratory depression and death following opioid overdose. The medullary centers control respiration with peripheral input from chemoreceptors and other sources. Opioids reduce chemoreceptor sensitivity via μ-opioid receptor stimulation and depress medullary centers via μ- and δ-opioid receptor stimulation. Opioids (e.g., methadone) initially reduce tidal volume and decrease CO_2 sensitivity of the respiratory center chemoreceptors. Larger doses of methadone depress both tidal volume and respiratory rate.[90] Glutamate and GABA are the major excitatory and inhibitory neurotransmitters, respectively. Alcohol facilitates opioid-induced respiratory depression by decreasing the excitatory effect of glutamate at NMDA receptors.[91]

During myocardial repolarization, potassium ions exit the myocardial cells via the slow component (I_{Ks}) and rapid component (I_{Kr}) potassium channels. The human ether-a-go-go-related gene (HERG) encodes the rapid channel protein, and methadone blocks the human ether-a-go-go-related gene potassium current (I_{HERG}) with an IC_{50} <3 μM similar to L-α-acetylmethadol.[92] Subsequently, QT_c prolongation occurs because of the reduced potassium efflux during repolarization, similar to over 100 other drugs.[93] Potential factors contributing to the development of

TABLE 32.2. Pharmacologic Properties of Opioid Receptor Subtypes.[15]

Receptor Type	Mu₁ (μ_1)	Mu₂ (μ_2)	Delta₁ (δ_1)	Delta₂ (δ_2)	Kappa (κ)
Analgesia	Supraspinal/spinal	Spinal	Spinal synergistically with μ-opioid receptors	Peripheral independent of μ-opioid receptors	Spinal

Abbreviations: GI, gastrointestinal; NE, norepinephrine; DA, dopamine.

sudden death in methadone users with relatively low postmortem methadone concentrations include cardiac dysrhythmias and drug-induced respiratory failure. The cause of death in these situations is probably multifactorial, and the causal role of methadone is not well defined.

Postmortem Examination

Deaths in patients receiving methadone typically involve drug abuse-related causes (overdose), liver failure, pulmonary emboli, sepsis, human immunodeficiency virus (HIV), trauma (self-inflicted, accidents, homicide, burns), and other causes (kidney failure, cancer, infections).[94] The postmortem findings in patients dying from methadone intoxication are nonspecific and usually include evidence of IV drug abuse (e.g., hyperplasia of the lymph nodes of the porta hepatis, hepatic triaditis, cutaneous stigmata).[95] The most frequent postmortem finding during autopsies of methadone-related fatalities is pulmonary congestion and edema.[96] Findings of severe pulmonary edema are typical during postmortem examination of methadone-induced fatalities. In a study comparing 39 methadone-related fatalities with a control group of 75 homicide victims with a history of opioid abuse, the mean lung weights were 1306 g and 914 g, respectively.[97] Other findings include bronchopneumonia, aspiration pneumonia,[98] cerebral edema,[99] and medical complication of IV drug abuse (e.g., viral hepatitis, bacterial endocarditis, pulmonary fibrosis).[100,101] In most, but not all postmortem examinations of methadone-related deaths, the cardiovascular system appears normal, and there is no anatomic evidence of other potential causes of death.[102] The lack of unique pathologic changes complicates the determination of the cause of death in relation to the roles of fatal dysrhythmias and respiratory depression.

CLINICAL RESPONSE

Medical Use

Adverse effects associated with the use of methadone include headache, constipation, pruritus, lightheadedness, dry mouth, anorexia, drowsiness, blurred vision, sweating, myoclonus, confusion, and hallucinations[103] along with hypotension and bradycardia following high methadone doses.[104] Peak effects (e.g., sedation, altered perception, analgesia, CNS depression) occur approximately 3 hours after ingestion of therapeutic doses, but in some cases the onset of peak effects may be delayed. Rare case reports associate high doses of methadone during palliative therapy with myoclonus[105] and toxic leukoencephalopathy manifest by high-intensity changes in the T2-weighted magnetic resonance images of cerebral white matter with sparring of the subcortical U-fibers and posterior fossa structures.[106,107]

Overdose

Methadone overdose produces classic symptoms of opioid intoxication including CNS depression (lethargy, stupor, coma), respiratory depression, and miosis.[108]

Symptoms of intoxication usually develop within 2–3 hours of ingestion; onset of symptoms after 9 hours is unusual. In a retrospective study of poison center data on 44 calls related to methadone, all symptoms developed within 9 hours after ingestion.[109] The mean estimated dose of methadone was about 100 mg; all symptoms resolved within 24 hours. Miosis is not a sensitive sign of methadone poisoning, particularly in children.[34] Normal or increased pupillary diameter can occur with high plasma methadone concentrations and/or hypoxia. The level of consciousness ranges from drowsiness to profound coma. Respiratory depression is the most common, serious complication of methadone intoxication, particularly in weakly tolerant individuals initiating high-dose methadone therapy.[110] Respiratory depression persists several days during methadone intoxication, and severe methadone intoxication frequently requires naloxone administration for several days. A case report of a 22-year-old man, who ingested 420 mg methadone, was observed sleeping with normal respirations 41 hours after ingestion.[111] Shortly thereafter, the naloxone infusion was stopped, and ½ hour later he was observed sleeping. The patient was found dead in his bed 3 hours later. Other complications of opioid overdose include hypotension, bradycardia, hypothermia, rhabdomyolysis, and renal dysfunction.[112] Rarely, case reports associate the development of acute respiratory distress syndrome with methadone toxicity following IV or oral use.[113,114] The development of pulmonary edema occurs in patients during methadone intoxication prior to the use of naloxone. Case reports document transient, acute bilateral sensorineural hearing loss during methadone overdoses that resolved within 24–96 hours.[115,116]

Fatalities

OVERDOSE

Deaths from methadone overdose typically involve one of the following 3 scenarios: 1) excessive or repetitive doses of illicit methadone used to obtain euphoria, 2) drug interaction of licit or illicit methadone and other CNS depressants (ethanol, benzodiazepines, opioids), and 3) accumulation of fatal concentrations of methadone following treatment for dependency or chronic pain.[117] Fatalities related to methadone frequently occur in individuals who obtain the drug without medical supervision.[118,119] Fatalities from the sole ingestion of methadone are relatively rare compared with fatalities from IV heroin use.[120,121] Case reports suggest that the highest risk of death during methadone maintenance for heroin addiction occurs in the first few days to 2 weeks after the initiation of methadone treatment, pri-

marily as a result of individual differences in methadone tolerance and pharmacokinetics. The initial plasma elimination half-life of methadone in opioid addicts can be substantially longer than later in the treatment program, and the initial prolonged elimination half-life allows the accumulation of methadone along with potential adverse effects.[122] Other risk factors for methadone intoxication include persistent use of other illicit drugs, consumption of illicit methadone, poor compliance with methadone dosing schedule, inadequate hepatic clearance of methadone secondary to liver disease, and inappropriate or rapid escalation in methadone dosing.[123,124]

The common scenario of a methadone-related overdose is a methadone-treated heroin addict found dead in the morning after being seen the preceding night appearing intoxicated (euphoria, ataxia, slurred speech).[97] Death is rarely sudden, and the toxicity following oral methadone is delayed in contrast to the more immediate toxicity of IV heroin and fentanyl derivatives.[125] In a study of 87 adult fatalities with positive drug screens for methadone, the mean time between methadone use and death was about 5–6 hours.[126] Polydrug use (e.g., alcohol, benzodiazepines) potentiates the respiratory depressant actions of methadone.[127] Although the use of benzodiazepines by patients in methadone treatment programs is frequent, comparison of unintentional fatal overdoses of methadone and other opioid analgesics does not demonstrate increased benzodiazepine use in the methadone group.[128] Occasionally, fatalities occur in children of patients in methadone maintenance programs, when the child ingests the patient's medication.[129]

SUDDEN DEATH

The risk of fatal cardiac dysrhythmia during methadone maintenance therapy appears relatively low; however, determination of the prevalence of fatal dysthymias is complicated by the lack of clinical data in patients dying while being treated with methadone.[130] Occasional case reports associate the therapeutic postmortem methadone concentrations with sudden death as defined by death within 24 hours of being seen alive and asymptomatic or within 1 hour of the witnessed onset of symptoms. In a case series of 22 sudden cardiac deaths in patients in methadone maintenance programs, the prevalence of detectable cardiac abnormalities was 23% ($n = 5$).[131] All these patients had postmortem blood methadone concentration <1 mg/L; however, the appropriateness of the antemortem doses cannot be accurately determined from postmortem data. The prevalence of cardiac abnormalities (coronary artery narrowing >50%, left ventricular hypertrophy >95% of the

upper limit of normal, dilated cardiomyopathy, myocarditis) was higher than the number of cardiac abnormalities ($n = 64, P = .002$) in a comparison series of 106 cases of sudden death with no evidence of methadone use. Cases with evidence of recreational drug use or drug overdose were excluded from both comparison groups. No other drugs were reported in the toxicology screen for blood samples from 8 of the 17 individuals without evidence of cardiac disease; none of the blood samples had detectable concentrations of benzodiazepines.

Abstinence Syndrome

The onset of withdrawal symptoms following cessation of drug use is slower for methadone than heroin. Additionally, methadone withdrawal is less intense and more prolonged compared with heroin withdrawal. Observational studies indicate that the abstinence symptoms associated with methadone begin about 24–48 hours after cessation of methadone with peak symptoms about 2–6 days after initial withdrawal symptoms of vomiting and diarrhea.[132] The subjective effects of methadone and heroin withdrawal are similar except that muscle cramps and arthralgias are not typically prominent during methadone withdrawal. Manifestations of methadone withdrawal include nausea, vomiting, diarrhea, weakness, anxiety, insomnia, abdominal discomfort, headache, sweating, and hot and cold flashes. Although lethargy may persist for 6–8 weeks, withdrawal symptoms usually subside within 10 days and resolve completely within 2–3 weeks.

Withdrawal symptoms occur 7–10 days after birth in neonates born to mothers chronically receiving methadone, and these withdrawal symptoms typically require treatment for about 1 month.[89] A meta-analysis of the medical literature indicates that the severity of the neonatal abstinence syndrome depends on several factors; the incidence of neonatal withdrawal is not clearly related to the methadone dose.[133] In a study of 450 singleton pregnancies of women prescribed substitute methadone for drug abuse during pregnancy, 48.5% developed neonatal abstinence syndrome requiring morphine therapy.[134] Neonatal withdrawal symptoms include tremors, irritability, hyperactivity, excessive crying, vomiting, and elevated temperature.[135,136] Disturbance of sleep patterns, poor fine motor coordination, and excessive crying can persist in these neonates for several months after withdrawal ceases.

Reproductive Abnormalities

Adverse fetal outcomes associated with opioid-dependent women on methadone during their pregnancy include preterm birth, low birth weight, and neonatal abstinence syndrome.[137] Methadone treatment is continued through pregnancy in opioid-dependent mothers to prevent fluctuating opioid concentrations and withdrawal episodes in the fetus. Birth weights of neonates born to methadone-dependent mothers are lower than neonates born to nonopioid-dependent mothers of similar socioeconomic backgrounds, but are higher than the birth weight of neonates born to opioid-dependent mothers without methadone treatment programs. The risk of preterm delivery and stillbirth for this group of mothers on methadone maintenance is also higher than overall rates in general hospitals.[134] In a study of 141 infants born to opioid-dependent mothers in methadone treatment programs and 127 infants born to nonopioid-dependent mothers, the mean birth weights were $2{,}953 \pm 438$ g and $3{,}210 \pm 488$ g, respectively.[138] The difference was statistically significant ($P < .001$). The control group was matched for socioeconomic status, race, and maternal age. At 6-month follow-up, there was no statistically significant difference between the 2 groups in the scores on the Bayley Scale of Mental Development.[89] Some neonates born to mothers in methadone maintenance programs develop moderate to severe opioid withdrawal symptoms (see Abstinence Syndrome). In general, methadone is not considered teratogenic; no specific congenital abnormalities are associated with methadone treatment during pregnancy with the exception of Pierre Robin sequence in methadone-exposed mothers in a retrospective Irish cohort study of 61,030 singleton births at an urban maternity hospital.[139]

DIAGNOSTIC TESTING

SI Units:

$$1 \text{ ng/mL} \approx 3.75 \text{ nmol/L}$$
$$1 \text{ nmol/L} \approx 0.266 \text{ ng/mL}$$

Analytic Methods

Methods for the quantitation of methadone and the main metabolite, 2-ethyl-1,5-dimethyl-3,3-diphenylpyrrolinium (EDDP) in biologic samples include the following: high performance liquid chromatography with UV detection following liquid-liquid extraction (interassay bias <10%; CV <15%),[140] high performance liquid chromatography with diode array detection after solid phase extraction (lower limit of quantitation [LLOQ], 1 ng/mL; accuracy, ±8%),[141,142] liquid chromatography/mass spectrometry after solid-phase extraction and separation with a Sunfire column using a

gradient mode (limit of detection [LOD], 0.5–1 ng/mL; CV <10%),[143] capillary electrophoresis/atmospheric pressure ionization/mass spectrometry,[144] gas chromatography/electron impact mass spectrometry,[145] and gas chromatography/mass spectrometry (GC/MS) in selected ion monitoring with solid phase extraction at pH 6.0.[146] High injector-port temperatures in gas chromatography potentially induce the thermal conversion of methadone to EDDP as an artifact. Reducing the GC injector-port temperature reduces the observed EDDP concentrations, but other methods (e.g., liquid chromatography/mass spectrometry) may be necessary if such conversions occur.[147] Methods to quantitate the enantiomers of methadone and EDDP include chiral liquid chromatography/tandem mass spectrometry.[148,149] The LOD and LLOQ for this method are 0.001 mg/L (mg/kg) and 0.003 mg/L (mg/kg), respectively, with a coefficient of variation <6.3%. Enantioselective liquid chromatography/mass spectrometry allows the quantitation of both free and total enantiomers of methadone and EDDP with accuracy and precision <5–10%.[150,151] Meconium is a more complex media than blood as a result of the presence of bile acids and other excretory products; liquid chromatography/ atmospheric pressure chemical ionization/tandem mass spectrometry allows the quantitation of methadone and EDDP after solid-phase extraction with LLOQ in the range of 5 ng/g.[152] The placenta is an alternative sampling site to meconium for determination of methadone and EDDP concentrations, when meconium is unavailable; however, the placental methadone/ EDDP concentrations and sampling time are substantially less than those in meconium.[153] Methods for the quantitation of methadone and EDDP in breast milk include high performance liquid chromatography with UV detection after liquid-liquid extractions,[67] liquid chromatography/atmospheric pressure chemical ionization/tandem mass spectrometry following protein precipitation and solid-phase extraction,[154] and gas chromatography/electron impact mass spectrometry after protein precipitation (acetonitrile) and solid-phase extraction.[155]

Most of the uncertainty in analytic techniques results from preanalytic (e.g., clotting, heterogeneity, water content, sampling technique, storage) rather than variation in analytic processes. In a study of the preanalytic variation of postmortem methadone measurements from left and right femoral vein samples, preanalytic variation (CV%) for R-(-)- and S-(+)-enantiomers was 3–4% compared with 19–21% for preanalytic variation.[156] For EDDP enantiomers, the CV% was higher (4–6% vs. 30–38%, respectively). Methadone is unstable when stored at room temperature for 24 hours due to the formation of N-oxides.[53] Additionally, pyrrolidine

undergoes degradation to pyrrolidine metabolites when stored at room temperature.

Biomarkers

Some secretion of methadone into the acid environment of the stomach occurs as a result of the diffusion of methadone from surrounding blood vessels in addition to the postmortem diffusion of methadone from fat. Typically, the stomach fluid/postmortem blood methadone ratio is ≤4 following IV methadone use, whereas this ratio is ≥10 following the ingestion of methadone.[125] Hence, a postmortem stomach fluid/blood methadone ratio exceeding 10 suggests antemortem ingestion of methadone. The postmortem methadone concentrations in urine and bile typically exceed the postmortem blood concentration of methadone.[43] In a series of 22 cases with methadone present in postmortem blood samples, the mean bile/femoral blood methadone ratio was 15.25.[157] The concentration of the metabolite, EDDP usually exceeds the methadone concentration in bile.[43,158] Methadone concentrations in vitreous humor do not correlate well to postmortem blood concentrations of methadone.[159]

Blood

Following the administration of IV methadone, the mean whole blood/plasma ratio was 0.75 ± 0.03 as measured by radioimmunoassay.[160]

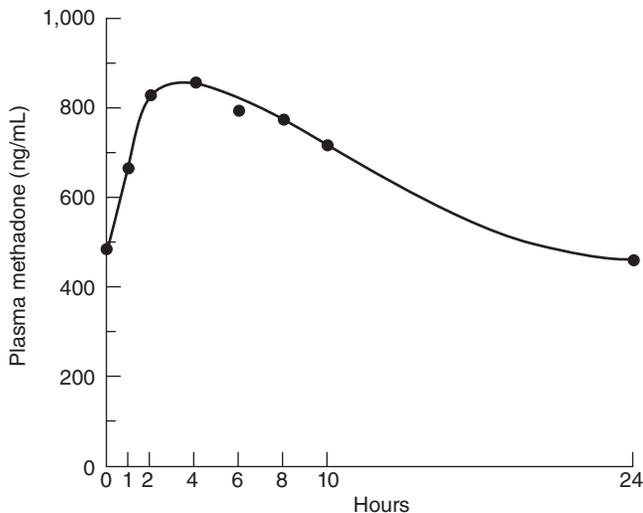
THERAPEUTIC USE. Following the administration of 15 mg methadone to 5 healthy individuals, the mean peak total methadone plasma concentration was 74 ng/ mL 4 hours after ingestion; the mean plasma methadone concentration decreased to 29 ng/mL 24 hours after ingestion.[59] The mean trough methadone concentration in plasma samples from 6 individuals receiving daily methadone doses of 80 mg in a methadone maintenance program was 420 ± 97 ng/mL.[161] The mean peak plasma methadone concentration 4 hours after daily administration of 100–120 mg methadone was approximately 860 ng/mL.[39] Figure 32.4 displays the methadone timeconcentration from this study. In a study of 50 opioid addicts treated with a mean, daily racemic methadone dose of 95 ± 44 mg, the mean methadone plasma concentration just prior to dispensing the daily methadone dose was highly variable (296 ± 176 ng/mL; range, 97–1,094 ng/mL).[162] In a study of 20 long-term opioid addicts receiving mean daily methadone doses of 60 mg (range, 10–225 mg), the steady-state plasma methadone concentration ranged from 65–630 ng/mL with peak concentrations ranging from 124–1,255 ng/mL as measured by GC/MS after solid-phase extraction.[52] The


FIGURE 32.4. Time-concentration curve of mean plasma methadone concentration after ingestion of 100–120 mg methadone by 5 individuals in a methadone maintenance program. (Reprinted by permission from Macmillan Publishers Ltd.: Clinical Pharmacology and Therapeutics, Vol. 13, CE Inturrisi, K Verebely, The levels of methadone in the plasma in methadone maintenance, p. 635, 1972.)

plasma concentration of the primary metabolite (EDDP) ranged from 5–55 ng/mL with peak concentrations ranging from 10–301 ng/mL.

In a methadone maintenance program, 31 patients received daily methadone doses ranging from 3–100 mg. The plasma methadone concentration at steady state increased approximately 263 ng/mL for each 1 mg/kg increase in the methadone dose.[163] However, these patients were not under direct observation, and some patients were excluded because of obvious noncompliance. Consequently, this value is an approximation. Plasma methadone concentrations prior to the next methadone dose of 150–200 ng/mL are sufficient to suppress withdrawal symptoms; plasma concentrations below 50 ng/mL are associated with withdrawal symptoms.[164,165] Withdrawal symptoms are unlikely when the plasma methadone concentration exceeds 500–700 ng/mL. Some patients are highly tolerant of methadone. A 25-year-old heroin addict on a daily methadone dose of 360 mg had a plasma methadone concentration of 2,800 ng/mL associated with drowsiness, but no other adverse effects.[166] As a result of the large variability in clinical response to methadone, most patients in methadone maintenance programs are monitored for clinical effects rather than plasma methadone concentrations.

OVERDOSE.   There are few data on the plasma methadone concentration during methadone overdose. In general, treatment is guided by the clinical presentation, and plasma methadone concentrations confirm exposure rather than guide treatment.

POSTMORTEM.   Interpretation of the significance the postmortem methadone blood concentrations requires careful analysis of several factors including the timing and dose of methadone, prior drug use and tolerance, concomitant medications, clinical history immediately prior to death, disease states, postmortem interval and redistribution, condition/storage of blood samples, site of sampling, and analytic methods in addition to the blood methadone concentration. Similar to other lipophilic bases with large volumes of distribution, methadone pharmacokinetics suggest the possibility of substantial postmortem redistribution. Other factors that contribute to uncertainty relating postmortem to antemortem methadone concentrations include interindividual variation in the active/inactive enantiomer (R/S) ratio and preanalytic variation. Although the mean R/S ratio is near unity, the range extends at least from about 0.5–2.5.[167,168] The median R/S ratio in 10 samples of postmortem femoral blood was 1.46 (range, 1.00–2.62).[148] Methadone was a cause or contributing factor to the death of most of these 10 individuals. Additionally, multiple drugs are frequently present during analysis of postmortem blood samples, particularly morphine, benzodiazepines, and cocaine.[169]

Concentrations.   Even though some authors associate postmortem blood concentrations exceeding 400–1,000 ng/mL in nontolerant adults with apnea and death,[170] interpretation of postmortem methadone concentrations must always include an evaluation of the circumstances surrounding the death and the clinical history. Plasma methadone concentrations >1,000–3,000 ng/mL can occur in patients receiving chronic methadone therapy.[15,171] Consequently, determination of the significance of postmortem methadone concentrations in any situation depends on a variety of factors as listed in the first part of the Postmortem section. In 96 postmortem cases with positive drug screens for methadone, the mean postmortem blood concentrations of methadone for methadone-related and nondrug-related deaths in members of methadone maintenance programs were 1,310 ng/mL (range, 180–3,990 ng/mL) and 1,160 ng/mL (range, 180–3,030 ng/mL), respectively.[171] The mean methadone concentration in postmortem blood from chronic pain patients dying of natural causes was 520 ng/mL. Substantial overlap in postmortem methadone concentrations between drug-related and traumatic deaths also occurred in a case series from Palm Beach County, Florida.[172] The mean methadone concentration in postmortem samples from methadone-only related deaths was 559 ng/mL (range, 114–1,949 ng/mL)

compared with a mean methadone concentration of 605 ng/mL (range, 72–2,700 ng/mL) in traumatic deaths with positive drug screen for methadone. In a case series of 11 methadone-related deaths, the mean methadone concentration in postmortem blood was 725 ng/mL with a range of 200–2,400 ng/mL.[173] The mean methadone concentration in postmortem blood samples from 8 deaths in this study involving only methadone and benzodiazepines was similar (mean, 548 ng/mL, range, 200–1,000 ng/mL). Although benzodiazepines are commonly found in blood samples from patients dying from methadone-related causes,[170,174] there are inadequate data to determine a specific postmortem benzodiazepine concentration that contributes significantly to death. Consequently, each case involving both benzodiazepines and methadone must be interpreted considering all the data available.

Methadone concentrations in postmortem samples from children dying of methadone intoxication are usually lower than adult cases. Postmortem blood samples from 5 methadone-induced fatalities of children under the age of 14 years contained blood methadone concentrations ranging from 200–489 ng/mL (mean, 332 ng/mL).[175] A 5-month-old girl was pronounced dead at home after the mother placed methadone in the child's bottle for sedation.[176] The postmortem methadone and EDDP concentrations in femoral blood samples were 1,071 ng/mL and 148 ng/mL, respectively.

The methadone/EDDP ratio does not clearly separate methadone-related and methadone-incidental deaths. 2-Ethyl-5-methyl-3,3-diphenylpyrroline (EMDP) is a less common methadone metabolite in postmortem samples than EDDP; when present, the EMDP concentration in postmortem blood is usually <10 ng/mL. In 46 autopsy cases that screened positive for methadone, no postmortem peripheral blood samples contained detectable EMDP concentrations (LLOQ, 10 ng/mL); however, 17 liver samples contained EMDP concentrations above 40 ng/mL.[177] As during life, the *R*-enantiomer concentrations of methadone in postmortem blood samples exceed the *S*-enantiomer. In a study of 90 postmortem femoral blood samples containing methadone, the *R/S*-enantiomer ratio was 1.38, slightly higher than that in a living person.[178] This study did not detect a significant contribution of polymorphism in the expression of CYP3A4, CYP2B6, or P-glycoprotein on the variability in the response to methadone. There were no statistically significant differences in the *R*-enantiomer/total methadone ratios between deaths associated with methadone or between methadone plus benzodiazepines or other drugs.

Redistribution. Postmortem redistribution accounts for most of the postmortem blood concentration increases over antemortem blood trough concentrations, depending on site-variation,[179] time between death and withdrawal of the sample, and the presence or absence of unabsorbed drug reservoirs in the lungs and stomach.[180] Postmortem methadone concentrations at specific sites can increase severalfold during the postmortem period. In a study of 15 autopsy cases with two sampling sites, the ratio of subclavian/heart blood ranged from 0.30–2.03 (mean, 1.10; *n* = 9) with the highest ratio recorded from a trauma-related death.[181] The inferior vena cava/heart blood ratio for 2 cases was 0.81 and 4.13, whereas the single femoral/heart blood ratio was 0.90. Postmortem methadone concentration in urine and bile typically exceeds the postmortem concentration of methadone in blood.[43] Furthermore, methadone is not distributed evenly between plasma and whole blood; as noted above, the approximate *antemortem* ratio of whole blood/plasma methadone ratio is about 0.75. The postmortem methadone whole blood/plasma ratio will vary substantially based on the water content at the specified site. A prolonged perimortem period between the administration of methadone and death, as suggested by the development of bronchopneumonia, may account for relatively low postmortem concentrations. As a result of these factors, the postmortem methadone blood concentration following methadone overdoses overlap the range of plasma methadone concentrations of healthy individuals in methadone maintenance programs.

Hair

Daily doses of methadone produce the highest hair methadone concentrations in axillary hair followed by pubic hair and scalp hair. In a study of 10 patients receiving daily oral doses of 10–25 mg methadone, methadone concentrations in axillary hair ranged from 1.3–8 ng/mg hair compared with 1–4 ng/mg for pubic hair and 0.5–2.7 ng/mg for head hair as measured by radioimmunoassay.[182] The methadone concentration in a convenience sample of scalp hair from methadone patients in a detoxification center ranged from 0–15 ng/mg as measured by GC/MS after a methanol wash and solid-phase extraction.[183] Stereoselective analyses of methadone in hair samples indicate a relatively higher concentration of the *R*-enantiomer than the *S*-enantiomer. In a study of 9 methadone patients from a detoxification center, the concentrations of *R*- and *S*-enantiomers of methadone ranged from 2.58–10.22 ng/mg and 1.89–9.53 ng/mg, respectively, whereas the *R*- and *S*-enantiomers of EDDP ranged from 0.42–1.73 ng/mg and 0.40–2.10 ng/mg, respectively.[184] Analysis of the enantiomers involved enzymatic hydrolysis, solid phase extraction, and quantitation by liquid chromatography/ion

spray/mass spectrometry. The methadone concentration in hair does not correlate well to the methadone dose or concentration in blood as measured by gas chromatography/ion trap/mass spectrometry after acid hydrolysis and solid phase extraction.[185] EDDP was detectable in only about 50% of 26 hair samples (9 blond, 6 brown, 4 light brown, 4 unknown, 1 red, 1 gray, 1 red/brown) from methadone patients in this study at a LLOQ of 0.2 ng/mg. The location of the hair samples was not reported. Potential external contamination complicates the interpretation of methadone and EDDP in hair samples as a means to determine multiple episodes of prior methadone ingestion.[186]

SALIVA

Methadone accumulates in saliva as a result of the ionization of methadone (pKa = 8.9, 25°C/77°F) in the acidic saliva (pH = 5.6–7.0); however, the salivary pH does not alter the salivary concentration of EDDP. Consequently, changes in salivary pH alter the diffusion of methadone into saliva, resulting in higher methadone concentrations at lower pH and a poor correlation between salivary and plasma methadone concentrations. Studies of saliva/plasma methadone ratios in methadone maintenance patients range from <1–10.[187] Additionally, the type of collection method also alters the saliva/plasma methadone ratio.[188] Although the presence of methadone in oral fluid can document exposure to methadone, the salivary methadone concentration does not imply behavioral or motor impairment.[189]

URINE

As excretion of methadone into urine is pH dependent, the ratio of methadone to the metabolite, 2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine (EDDP) varies substantially between individuals; additionally, the EDDP/creatinine ratio displays inter-individual variation.[190] Urine immunoassays for methadone are specific for methadone; however, many urine drug screens do not include methadone in the urine drug panel. Immunoassays with a methadone cutoff of 300 ng/mL are common methods of screening opioid abusers in methadone maintenance programs. The EMIT-ETS™ d.a.u. (Syva Co., San Jose, CA) immunoassay screens meconium samples specifically for methadone at a cutoff of 200 ng/mL (ng/g) with little cross-reactivity for the methadone metabolites such as EDDP and 2-ethyl-5-methyl-3,3-diphenylpyrroline (EMDP).[191] The CEDIA EDDP immunoassay (Microgenics Corporation, Fremont, CA) is a sensitive and reliable screening technique for determining EDDP in urine samples at a cutoff of 100 ng/mL. In a study of 1,381 urine specimens

screened with CEDIA urinary EDDP immunoassay and the EMIT® (Dade Behring, Siemens Healthcare Diagnostics, Erlangen, Germany; cutoff calibrator concentration of 300 ng/mL) urinary methadone immunoassay, the positive rates for the 2 screening methods were 46% and 39%, respectively.[192] Of the 108 samples positive for EDDP and negative for methadone by immunoassay, GC/MS confirmed the presence of methadone in all 99 samples tested. There are few data on the methadone metabolite/methadone ratio in urine specimens from acute fatalities or chronic methadone therapy. A case series of 4 autopsies of methadone-related fatalities indicated that the methadone metabolite/methadone ratio was <1, whereas the ratio in urine samples from 4 patients on chronic methadone therapy ranged from 1.28–5.45 (mean, 3.8).[193]

The chemical structure of methadone and verapamil are similar, resulting in cross-reaction of some verapamil metabolites with some immunoassays (e.g., Diagnostic Reagents, Inc., Dearborn, MI) for methadone.[194] However, false-positive cross-reactivity does not usually occur if the individual is ingesting methadone therapeutically. A 9-year-old boy with diphenhydramine intoxication had a positive rapid urine drug screen (One Step Multi-Drug, Multi-Line Screen Test Device; ACON Laboratories, San Diego, CA) for methadone; GC/MS failed to confirm the presence of methadone.[195] Case series suggest that false-positive methadone urine drug screens may occur during quetiapine therapy. In a series of 10 inpatients on quetiapine including 2 patients on only quetiapine, the COBAS® Integra Methadone II test kit using KIMS (kinetic interaction of microparticles in solution) methodology (Roche Pharmaceuticals, Nutley, NJ) was positive; GC/MS did not confirm the presence of methadone.[196]

Abnormalities

BLOOD

Rhabdomyolysis, hyperkalemia, hypocalcemia, hyperphosphatemia, and myoglobinuric renal failure can develop from muscle damage secondary to prolonged immobilization and coma. However, case reports suggest that myoglobinuric renal failure can occur during methadone intoxication without coma or prolonged immobilization.[197] Rarely, the chest x-ray demonstrates evidence of pulmonary edema secondary to the acute respiratory distress syndrome after IV or oral administration of methadone.[198] The most common radiologic finding is a bilateral patchy alveolar pattern with nonuniform, asymmetrical infiltrates.[199] The distribution of the infiltrates can be lobar and unilateral, requiring clinical signs/symptoms to differentiate pulmonary edema from

pneumonia. The radiographic abnormalities associated with methadone-induced pulmonary edema usually resolve within 24–48 hours. The development of pulmonary edema is not related to the dose of methadone.

CARDIAC

Cardiac dysrhythmias during methadone intoxication are unusual, and sudden death is rare. The sources of data linking methadone and serious ventricular dysrhythmias are case reports, case series, and small retrospective studies with inadequate data from systematic prospective studies to establish methadone as a sole, specific cause of fatal ventricular dysrhythmias (i.e., torsades de pointes). Current evidence indicates that the occurrence of torsade de pointes in opioid-dependent patients usually occurs in the presence of multiple co-existing risk factors for QT_c prolongation.[200,201] Case reports suggest that these risk factors potentially include the presence of high-dose therapy (>100 mg daily), recent increase in methadone dose,[202] concomitant therapy with drugs (e.g., citalopram, clarithromycin, cocaine, fluconazole, olanzapine, sertraline) that prolong the QT_c interval, unrecognized congenital long QT interval syndrome in individuals without the phenotypic expression of the prolonged QT interval under normal conditions,[203] and associated electrolyte abnormalities (hypokalemia, hypomagnesemia).[204,205] In a 17-week, randomized clinical trial, the mean QT_c interval increased approximately 30 msec in the high-dose methadone group (60–100 mg daily), when compared with baseline at intake.[206] Approximately 23% of the 55 participants in this group had prolonged QT_c intervals at the end of the study as defined by QT_c exceeding 470 msec in men or 490 msec in women. These abnormalities occur most commonly in patients with daily methadone doses of 600–700 mg, particularly in association with hypokalemia. Significant risks of serious ventricular dysrhythmias occurs when the QTc interval exceeds 500 msec; however, clinically significant QTc prolongation (i.e., QTc >500 msec) is unusual, even in patients monitored because of known risk factors (hypokalemia, hypomagnesemia, QT-prolonging drugs, inhibitors of methadone metabolism).[207,208] In a study of 109 patients from an outpatient methadone clinic, 2 patients (1.8%) had clinically significant QTc prolongation (>500 msec) and the methadone dose correlated to QT_c prolongation.[209] All of these patients had received stable doses of methadone for at least 2 months before testing. Serious ventricular dysrhythmias can occur during these episodes of QT_c prolongation including torsades de pointes and ventricular tachycardia.[210,211] Case reports associate the development of ventricular fibrillation following torsades de pointes with severely hypokalemic patients on therapeutic doses of methadone.[212] Episodes of ventricular fibrillation in these cases may spontaneously revert to sinus rhythms.

Driving

Although experimental tests indicate that some impairment of psychomotor skills occurs in chronic methadone users, the reduction in driving skills is probably not sufficient to cause major driving impairment in the absence of excessive or other drug use. In general, opioid-dependent individuals in methadone maintenance programs perform significantly worse than age-, gender-, and education-matched controls in a variety of neuropsychologic domains including information processing, attention, short-term visual memory, delayed visual memory, short-term verbal memory, long-term verbal memory, and problem solving.[213] Interpretation of the significance of these studies is complicated by confounding variables including the concomitant use of drugs (e.g., heroin, benzodiazepines, ethanol) and medical complications (e.g., IV drug use, head injuries) that may impair driving skills. Preliminary studies suggest that at least some of the cognitive impairment associated with methadone results from comparing matched groups of abstinent opioid users and opioid-dependent individuals in methadone maintenance programs.[214] Neuropsychologic testing of patients in methadone maintenance programs suggests some impairment relative to controls in psychomotor speed (digit symbol substitution and trail-making tests), attention, tachistoscopic tasks, sensorimotor coordination, working memory (two-back task), and decision making (gambling task).[215] In general, these changes are within <0.5–0.7 standard deviations of the control groups, and there is no correlation between methadone dose and the test performance of stabilized methadone maintenance patients.[216] Enrollment in a methadone maintenance program was not associated with impairment in time estimation, conceptual flexibility, or long-term memory. In non-opioid users, methadone causes some impairment of psychomotor skills and perception, primarily in reaction time, information processing, and visual acuity. However, most patients, who are stabilized in chronic methadone treatment programs for at least 1 month, do not demonstrate similar impairment, probably due to tolerance.[217]

The driving ability of methadone maintenance patients depends more on the presence of polydrug use and personality (self-control, self-reliance, apprehension, psychiatric disorders) rather than methadone therapy or dose.[187] Examination of driving records suggests that accident rates of abstinent heroin addicts in methadone maintenance programs and age- and sex-matched controls are similar.[218] In a Norwegian study of

635 drivers apprehended for suspected driving under the influence of drugs with methadone present in their blood, methadone was the only psychoactive drug in 10 cases.[219] The mean whole blood methadone concentration in those 10 drivers was 460 ng/mL (range, 190–650 ng/mL) as measured by liquid chromatography/mass spectrometry (LLOQ, 30 ng/mL). Of the 8 drivers receiving clinical tests of impairment soon after apprehension, 5 drivers were considered impaired. There was no correlation between the whole blood methadone concentrations and the test results (impaired/not impaired).

TREATMENT

Stabilization

Treatment of methadone overdose is similar to the general treatment of opioid intoxication (see Heroin Treatment). The main life-threatening complications are respiratory depression and hypotension. Patients should be carefully monitored for the development of respiratory insufficiency with pulse oximetry, capnometry, and arterial or venous blood gases as needed. Patients with inadequate ventilation require bag-value-mask ventilation with 100% oxygen and the administration of naloxone 0.2–0.4 mg IV. Although the rate of subcutaneous absorption of naloxone is slower than the IV route, difficulty obtaining IV access may result in similar onset of action via these 2 routes of administration, at least in the prehospital setting.[220] If no improvement in respiration or hypotension occurs within 3–5 minutes, additional doses (0.4–2 mg) of naloxone should be administered parenterally. Criteria for endotracheal intubation include inability to ventilate with bag-valve-mask, poor oxygenation (i.e., oxygen saturation <90%) despite adequate ventilation and supplemental oxygen, and persistent hypoventilation after doses of naloxone exceeding 2–4 mg. Because of the long half-life of methadone, naloxone infusion (0.2 mg/h or two-thirds of the effective naloxone dose/h) is usually necessary for up to 48–72 hours along with close monitoring of oxygen saturation and mental status. If pulmonary signs or symptoms (e.g., cough, tachypnea, pink frothy sputum, rales) of pulmonary edema develop, a chest x-ray should be obtained to detect pulmonary edema and aspiration pneumonia. Hypotension usually responds to adequate doses of naloxone and IV fluid therapy.

Gut Decontamination

Theoretically, activated charcoal is an option if the patient presents within 1–2 hours of methadone ingestion, but there are few data to guide management. The presence of altered mental status increases the risk of aspiration of the activated charcoal.[221]

Elimination Enhancement

Hemodialysis is unlikely to increase methadone elimination because of high protein binding and the exceedingly large volume of distribution of methadone. Hence, hemodialysis is indicated only in the presence of hyperkalemia and renal failure to treat the complications of renal dysfunction rather than to remove methadone.

Antidotes

Because of the prolonged elimination half-life of methadone, serious methadone intoxication may require continuous naloxone infusion to prevent recurrence of respiratory depression and alteration of consciousness, particularly during the first 12–24 hours.[222] The usual infusion dose is two-thirds of the effective naloxone dose per hour as a continuous infusion. Close monitoring of mental status and oxygenation for at least 2–4 hours in a monitored setting after discontinuation of the naloxone infusion is required to ensure that altered mental status and respiratory depression do not recur.

Supplemental Care

Most patients with serious methadone intoxication should be hospitalized for 48–72 hours to detect delayed respiratory depression, particularly children. Reversal of methadone-induced respiratory depression with naloxone may be followed by recurrence of respiratory depression when the opioid antagonist effects of naloxone are no longer present. Elevated serum creatine kinase, myoglobinuria, and renal dysfunction can complicate methadone intoxication; all seriously intoxicated patients should be evaluated for electrolyte imbalance, renal dysfunction, and myoglobinuria. Treatment options for patients in methadone maintenance programs with QT_c prolongation include reduction of the methadone dose, substitution of buprenorphine, and insertion of an implantable cardioverter-defibrillator.[223]

WITHDRAWAL

Withdrawal symptoms of neonates born to opioid-dependent mothers on methadone are highly variable, ranging from none to severe.[224] In general, the neonatal abstinence syndrome associated with methadone withdrawal is more moderate and prolonged than similar heroin or morphine addiction as a result of the long plasma elimination half-life of methadone. Treatment of

neonatal withdrawal involves the administration of oral doses of methadone from 0.1–0.5 mg/kg/d depending on the severity of withdrawal symptoms. The methadone dose is tapered over 2–4 weeks.

Addiction

Compared to detoxification programs, methadone maintenance treatment more effectively reduces heroin use, decreases risky HIV-associated behavior and criminal activity, and improves life functioning.[225] However, high rates of illicit heroin use and diversion of methadone persist despite enrollment in methadone maintenance treatment programs. There is substantial regional variation in the doses of methadone administered by methadone maintenance programs.[226] In general, low daily doses (20–35 mg) of methadone are less effective than moderate doses (50–80 mg). A study of steady-state, moderate- (40–50 mg) and high-dose methadone (80–100 mg) suggests that the high-dose group had lower rates of positive opioid drug screens (53% and 62%, respectively, $P = .047$).[227] Both doses substantially reduced the rates of illicit opioid use. Federal regulations in the United States discourage the use of methadone doses exceeding 100 mg, although some studies suggest the methadone doses over 100 mg reduce illicit opioid use among heroin abusers unresponsive to moderate methadone doses.[228]

Because of clinically significant variation in the tolerance and individual pharmacokinetics of methadone, the induction dose of methadone for the first few weeks is low (i.e., 20–30 mg up to 40 mg) depending on the estimated degree of previous opioid use and tolerance. For patients with uncertain or low tolerance, the initial methadone dose is 10–20 mg. The dose is increased 5–10 mg daily, depending on the development of withdrawal symptoms and craving for heroin. Adverse effects associated with methadone therapy, particularly at high doses, include sweating, constipation, insomnia, somnolence, decreased libido, and difficulty with orgasm.

Chapter 33

1-METHYL-4-PHENYL-1,2,5,6-TETRAHYDROPYRIDINE (MPTP)

HISTORY

In 1979, Davis et al reported the development of a parkinsonian illness in a 23-year-old graduate student, who injected a synthetic meperidine congener, 1-methyl-4-phenyl-4-N-propionoxypiperidine (MPPP, 4-propyloxy-4-phenyl-N-methylpiperidine) for several months prior to becoming ill.[1] While experimenting with this synthetic drug, the student began increasing the temperatures of the illicit process to reduce reaction times. This change introduced a contaminant (MPTP or 1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine) that later was identified as the cause of his parkinsonian condition. During the 18-month course of his illness, the drug-induced motor disturbances initially responded to dopamine receptors agonists. Following a fatal cocaine overdose, postmortem examination of this patient revealed marked loss of nigrostriatal cells in the midbrain. In 1983, Langston et al reported the development of a similar parkinsonian illness in 4 intravenous (IV) drug abusers within 1 week of injecting a "synthetic heroin."[2] Subsequent criminal investigations traced the source of this synthetic heroin to a clandestine laboratory that was formulating a structural analog of meperidine and alphaprodine, called MPPP (desmethylprodine). Analysis of samples from the material injected by 2 of these patients demonstrated primarily 1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine (MPTP) with trace amounts of MPPP. As a contaminant of MPPP synthesis, MPTP was subsequently identified as the etiologic agent responsible for the development of the parkinsonian illness.

IDENTIFYING CHARACTERISTICS

Figure 33.1 displays the chemical structure of MPTP (CAS RN: 28289-54-5), which has a molecular formula of $C_{12}H_{15}N$. MPTP is a 4-phenyl piperidine derivative that is structurally related to meperidine and alphaprodine. The lipophilic properties of MPTP allow diffusion of this protoxin across the blood–brain barrier before detoxification; once in the brain, MPTP is converted to the toxic metabolite, 1-methyl-4-phenylpyridinium (MPP^+, cyperquat, CAS RN: 48134-75-4). MPTP along with a variety of MPTP analogs display high potency for monoamine oxidase B. However, there is no definite structure-activity relationship for MPTP analogs; most MPTP analogs studied to date have less neurotoxicity than MPTP despite strong affinity for monoamine oxidase B.[3] Table 33.1 lists some of the physical properties of MPTP.

MPTP is a contaminant of the clandestine synthesis of MPPP (CAS RN: 13147-09-6). At that time, MPPP was a potent analgesic that could be synthesized legally from unrestricted chemicals as the reverse ester of meperidine.[1] Figure 33.2 demonstrates the synthetic pathway for MPPP. Phenyl lithium catalyzed the conversion of the starting material N-methyl-4-piperidone (MP) to 4-hydroxy-4-phenyl-N-methylpiperidine (HPMP).[4] The reaction of this intermediate with propionic anhydride produced the esterified end product, MPPP. Although the production of initial batches of this ester was successful, subsequent modifications of the temperatures and reaction times used in this process resulted in dehydration of HPMP and

MPPP to the toxic contaminant, *N*-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP).[1]

EXPOSURE

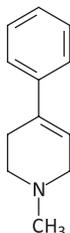
In 1982, a group of young drug abusers developed a severe parkinsonian illness after the IV injection of a new synthetic heroin that was contaminated by MPTP. Of approximately 300 individuals exposed to this contaminant, only a few developed a severe, permanent form of the illness. Since the 1982 epidemic, there have been no reports of MPTP in street samples of illicit drugs. However, sporadic cases of MPTP-induced parkinsonism developed in individuals injecting material from the attempted synthesis of MPPP.[5] All these cases resulted from the IV injection of MPTP-contaminated MPPP.


FIGURE 33.1. Chemical structure of 1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine (MPTP).

TABLE 33.1. Physical Properties of MPTP.

Physical Property	Value
Melting Point	40°C (104°F)
log P (Octanol-Water)	2.71
Water Solubility	2930 mg/L (25°C/77°F)
Vapor Pressure	9.45E-03 mm Hg (25°C/77°F)

DOSE EFFECT

Animals

There is substantial variability in the sensitivity of different animal species to the neurotoxic effects of MPTP with humans and dogs being very sensitive. Rats do not develop MPTP-induced neurotoxicity. Mice require high parenteral doses of MPTP (100 mg/kg body weight) to produce neurotoxicity; the subsequent neurotoxicity is relatively mild compared with primates receiving parenteral MPTP.[6] In primates, the subcutaneous injection of 2.5 mg MPTP/kg body weight produces motor deficits and a 60–70% reduction in neuronal cells in the substantial nigra within 5–10 days of administration.[7]

Humans

Determination of the amount of MPPP injected by patients developing permanent MPTP-associated parkinsonism is complicated by the lack of analytic samples. Typically, the period of IV injection of MPTP-contaminated material lasted 3 days to 1 month.[8] In a case series of 4 patients with severe MPTP-associated Parkinsonism, the estimated dose of contaminated MPPP material ranged from 5 g over 4 days to 20 g over 5–8 days.[2] Analysis of powder used for injection by 2 patients demonstrated MPPP and MPTP concentrations of 0.3% and 3.2% by weight, respectively, whereas analysis of brown granular material used by the other 2 patients revealed MPPP and MPTP concentrations of 22–27% and 2.5–2.9% by weight, respectively. There is some individual variability in the response to the injection of MPTP-contaminated material because the parkinsonian symptoms resolved in some individuals within 2–3 weeks after injections of this material ceased.

TOXICOKINETICS

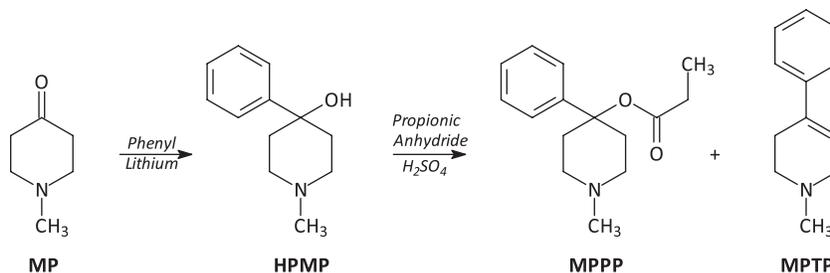
Chronic oral administration of relatively low MPTP concentrations (i.e., 2 μg/kg/d) produce low concentra-


FIGURE 33.2. Chemical synthesis of MPPP. MP = *N*-methyl-4-piperidone; HPMP = 4-hydroxy-4-phenyl-*N*-methylpiperidine; MPPP = 4-propionyloxy-4-phenyl-*N*-methylpiperidine.

tions of the toxic metabolite, MPP[+] in brain tissue as a result of the extensive first pass metabolism of MPTP. Detoxification of MPTP involves the biotransformation of this compound to PTP (4-phenyl-1,2,3,6-tetrahydropyridine). The hepatic *N*-demethylation of MPTP to PTP is mediated at least in part by CYP2D6 based on *in situ* hybridization studies.[9] There is circumstantial evidence linking a deficiency in CYP2D6 with an increased risk of Parkinson disease. A case-control study of 229 patients with Parkinson disease and 720 controls suggested that individuals (i.e., poor metabolizers) with a metabolic defect in the CYP2D6-debrisoquine hydroxylase gene had about a 2.5-fold (95% CI: 1.51–4.28) increased risk of Parkinson disease when compared with individuals with the normal isoenzyme.[10] Inhibitory studies also suggest that CYP1A2 and, to a lesser extent CYP3A4 also contribute to the demethylation of MPTP to PTP. 4-Phenyl-1,2,3,6-tetrahydropyridine is not neurotoxic because the oxidation of PTP does not readily proceed beyond the dihydropyridine structure.[11] MPTP is a lipophilic compound that diffuses across the blood–brain barrier and enters the brain. Once in the brain (i.e., substantia nigra), the formation of the toxic metabolite involves two selective oxidation steps by monoamine oxidase B to yield the intermediate, 1-methyl-4-phenyl-2,3-dihydropyridinium ion (MPDP[+]) and then the toxic cation, 1-methyl-4-phenylpyridinium ion (MPP[+]).[12] The primary difference between MPTP-sensitive species (e.g., primates) and MPTP-insensitive species (e.g., rats) is the plasma elimination half-life of MPP[+], which varies from a few hours in the former to 10–28 days in the latter.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

MPTP is a lipophilic protoxin, which traverses the blood-brain barrier and undergoes metabolic transformation to a toxic metabolite.[13] Inside the endothelial cells of the blood–brain barrier, monoamine oxidase B catalyzes the 2-electron transfer from the oxidized flavin that results in the conversion of MPTP to the dihydropyridine, MPDP[+]. Spontaneous oxidation of MPDP[+] results in the formation of the toxic cation, 1-methyl-4-phenyl pyridine (MPP[+]), which cannot diffuse back across the blood–brain barrier. The MPTP not processed by monoamine oxidase enzymes in the endothelial cells of the blood brain barrier enters adjacent glial cells. Like the endothelial cells of the blood–brain barrier, glial cells contain large stores of monoamine oxidases capable of converting MPTP to MPP[+]. The

production of MPP[+] in the astrocyte stimulates the upregulation of TNF-α, interleukin-1β, and interleukin-6 with the subsequent up-regulation of inducible nitric oxide synthase.[14] After the release of MPP[+] into the extracellular space, dopaminergic uptake carriers (i.e., dopamine transporter) actively transfer MPP[+] to the dopamine neurons in the zona compacta region of the nigrostriatal. MPP[+] is a mitochondrial toxin that migrates into the mitochondria of dopaminergic neurons and decreases the production of cellular ATP by inhibiting NADH CoQ1 reductase (complex I) and possibly other electron transport enzymes (Complex III, IV) in the mitochondrial respiratory chain. The complex interaction of mitochondrial dysfunction, depletion of ATP, oxidative stress, excitotoxicity, and activation of the apoptotic pathway ultimately causes cell death. Degeneration of the axons and neuronal terminals follows the death of the cell bodies.

Postmortem Examination

The main anatomic feature of Parkinson disease is the reduction of neuromelanin-containing neurons in the substantia nigra pars compacta with clinical symptoms appearing after loss of over 60% of the neurons in this area of the midbrain.[15] The selective MPP[+]-induced destruction of nigrostriatal dopamine neurons causes the movement disorder associated with the IV injection of MPTP. Pathologic examinations of patients dying of MPP[+]-associated parkinsonism primarily demonstrate a diffusely pale, depigmented substantia nigra with associated loss of nerve cells and nerve fibers. Electron microscopy confirms nerve cell loss and gliosis in the substantia nigra. Although the degree of cell loss is similar to Parkinson disease, the Lewy bodies commonly present in Parkinson disease are absent in MPP[+]-induced parkinsonism. Occasionally, extraneural melanin is present in MPP[+]-induced parkinsonism along with microglial activation suggestive of an active, ongoing process of cell death. Senile plaques and neurofibrillary tangles are absent in MPP[+]-induced parkinsonism; the locus coeruleus is usually unaffected by this disease.[5]

The degenerative process of Parkinson disease destroys neurons in the brain containing norepinephrine. In contrast to Parkinson disease, the areas of the brain (e.g., locus coeruleus) associated with catecholamine production are usually unaffected by MPP[+]-induced illness; increased central noradrenergic activity occurs in MPP[+]-induced parkinsonism. However, animal models of MPP[+]-induced parkinsonism suggest that some damage may occur in the noradrenergic neurons of the locus coeruleus,[16] but the clinical significance of these changes for humans is unclear.

CLINICAL RESPONSE

The injection of MPTP-contaminated material produces dysphoria, hallucinations, blurring or dimming of vision, a metallic taste in the mouth, jerking of the extremities, and a burning pain at the injection site.[8] According to case reports, these symptoms were distinctly different than symptoms associated with heroin injection. Within 1 week, the intermittent muscle jerks resolve and a movement disorder develops characterized by awkward postures and bradykinesias that can progress to lead pipe rigidity and loss of extremity function (i.e., "frozen addict").[17] Physical findings associated with this illness include dysarthria, dysphagia, drooling, increased muscle tone, and cogwheel rigidity of the upper extremity. After 2–3 weeks, resolution of these parkinsonian symptoms occurs in some patients, particularly those with less-severe clinical symptoms. Other exposed patients develop mild symptoms of parkinsonism (bradykinesia, muscle rigidity, postural instability).[18] More severely affected patients develop a chronic, permanent parkinsonian syndrome manifest by bradykinesias, muscle rigidity, loss of postural reflexes and facial expressions, impaired rapid alternating movements, and stooped posture. Widespread central nervous system (CNS) dysfunction is absent due to the preservation of cerebellar, corticospinal, and autonomic function.

In contrast to idiopathic Parkinson disease, dementia and a resting tremor are not prominent parts of the clinical presentation of MPP$^+$-induced parkinsonian illness.[18] However, resting tremor similar to idiopathic Parkinson disease occurs in some patients with more severe forms of MPP$^+$-induced parkinsonian disease. In a study of 7 patients with moderate to severe MPP$^+$-induced parkinsonism, 4 of these patients exhibited a tremor indistinguishable from the characteristic rest tremor of Parkinson disease.[19] Although dopamine agonists initially improve the symptoms associated with MPP$^+$-induced parkinsonism, the efficacy of these drugs decreases over time and the symptoms progress in severity.

DIAGNOSTIC TESTING

Analytic Methods

Highly sensitive methods for the detection of MPTP-contaminated material include the use of high performance liquid chromatography/tandem mass spectrometry. The limit of detection for MPP$^+$ using this method was 1 fmol on columns with a signal-to-noise ratio of 3:1.[20] High performance capillary electrophoresis is an alternative to high performance liquid chromatography for the determination of MPTP.[21]

Abnormalities

In a study of 6 patients with MPP$^+$-induced parkinsonism and 8 patients with Parkinson disease, the cerebrospinal fluid concentrations (CSF) of homovanillic acid (i.e., the major metabolite of dopamine) were decreased in both groups, whereas the concentrations of the serotonin metabolite, 5-hydroxyindoleacetic acid were normal in both groups.[22] The main difference in CSF fluid between these 2 illnesses is the concentration of 3-methoxy-4-hydroxyphenylethylene glycol (MHPG), the major metabolite of norepinephrine in the brain. After adjustment for plasma MHPG concentrations, the values were elevated (i.e., >6.0 ng/mL) in MPP$^+$-induced parkinsonism, whereas MHPG levels were reduced (<6.0 ng/mL) in Parkinson disease. Assessment of nigrostriatal dopaminergic function by 6-fluorodopa positron emission tomography (PET) suggests that short-term exposure to MPTP causes a progressive decline in nigrostriatal dopaminergic function similar to the protracted loss of dopaminergic function associated with idiopathic Parkinson disease.[23] A case series suggested that subclinical damage to the nigrostriatal pathway can occur in individuals without overt clinical evidence of MPP$^+$-induced parkinsonian disease based on abnormal PET scans.[24] Typically, these individuals injected lower doses of MPTP than individuals with moderate to severe illness.

TREATMENT

The treatment of MPP$^+$-induced parkinsonism is similar to the treatment of idiopathic Parkinson disease. Even severely affected patients initially respond to L-dopa therapy. However, dyskinesias can begin within several weeks of the initiation of the treatment of severe cases. Typically, these cases become less responsive to carbidopa/L-dopa and bromocriptine with subsequent progression to severe immobility and marked hypophonia.

Chapter 34

PHENCYCLIDINE and PHENCYCLIDINE ANALOGUES

PHENCYCLIDINE (PCP)

HISTORY

Despite the synthesis of phencyclidine (PCP) in 1926, clinical use of this compound did not begin until the mid-1950s when Parke, Davis and Company chemists discovered the anesthetic properties of PCP during the exploration of chemicals formed by the addition of Grignard reagents to nitriles.[1] The combination of anesthesia and profound analgesia with preservation of normal laryngeal and pharyngeal reflexes initially encouraged the clinical use of PCP. Early primate studies indicated that PCP produced mild stimulation, ataxia, peaceful sedation, and anesthesia without cardiorespiratory depression.[2] The British government issued a patent to Parke, Davis and Company in 1960 for phencyclidine under the trade name Sernyl; in 1963, the US Food and Drug Administration (FDA) approved the clinical use of PCP. However, soon after introduction of PCP into the US markets, reports of adverse psychologic reactions (e.g., hallucinations, delirium, disorientation, dysphoria, muscle rigidity, agitation) following PCP-induced anesthesia resulted in the voluntary withdrawal of PCP by Parke, Davis and Company. The US Drug Enforcement Agency (DEA) reclassified PCP as a schedule II drug (existing medical use, high abuse potential), but there is no current medical indication for the use of PCP. Subsequent to the recognition of the severe emergence psychosis associated with PCP,

the development of a phencyclidine derivative, ketamine, was released for clinical use as a safer substitute for PCP. Until 1979, distribution of PCP for veterinary use continued under the trade name Sernylan (BioCentrics Laboratory, St. Joseph, MO) because of the efficacy of PCP as an animal tranquilizer.

In 1967, phencyclidine (PCP) was sold as the "peace pill" in San Francisco's Haight-Ashbury district; however, the adverse psychologic reactions associated with the ingestion of PCP limited the popularity of PCP as an illicit drug. Reintroduction of PCP during the early 1970s resulted in more widespread use as the route of abuse changed from ingestion to inhalation, particularly in major metropolitan centers (e.g., Los Angeles, New York, Detroit). Frequently, PCP was an adulterant of other popular street drugs (e.g., tetrahydrocannabinol, lysergic acid diethylamide, cocaine, mescaline, psilocybin). By the middle 1970s, the popularity of PCP increased, while the use of PCP as an adulterant in other street drugs substantially decreased.[3] Legal manufacturing of PCP ceased in April 1979; the US federal government is now the only legitimate source in the United States. During the 1980s, PCP use declined along with the use of most other drugs of abuse.[4] Phencyclidine use remained relatively constant in the United State during the 1990s. Despite well-publicized adverse reactions, PCP remains a popular street drug in certain areas of the United States. However, the use of PCP remains relatively infrequent compared with other drugs of abuse (e.g., cocaine, heroin, methamphetamine, club drugs). PCP is not a popular drug of abuse in most other countries.

IDENTIFYING CHARACTERISTICS

Structure

Phencyclidine [1-(1-phenylcyclohexyl)piperidine, PCP] is an arylcycloalkylamine compound structurally related to the less potent and shorter-acting dissociative anesthetic, ketamine. PCP is not a chiral compound, so stereospecific effects will not occur. Figure 34.1 displays the chemical structures of PCP and some PCP analogues.

Physiochemical Properties

PCP is a lipophilic, water soluble, weak base. Table 34.1 lists some physiochemical properties of PCP. The heating of the hydrochloride salt of PCP at 300°C (573°F) for 5 minutes decomposes about 95% of the salt.[5] Pyrolysis of PCP results in elimination of methylamine and deprotonation to produce the thermal degradation

TABLE 34.1. Physiochemical Properties of Phencyclidine (PCP).

Name	Phencyclidine
IUPAC	1-(1-Phenylcyclohexyl) piperidine
CAS RN No.	77-10-1
Molecular Formula	$C_{17}H_{25}N$
Molecular Weight	243.39 g/mol
Melting Point	46–46.5°C (114.8–115.7°F)
pKa	8.5
Log P (Octanol-Water)	4.7
Salts	Hydrochloride (MP = 233–235°C/451.4–455°F, MW = 279.83) Hydrobromide (MP = 214–218°C/417.2–424.4°F, MW = 324.28)

product, 1-phenylcyclohexene (CAS RN: 771-98-2). Experimental studies indicate that pyrolysis of PCP at 400°C (752°F) results in the formation of phenylcyclohexane and 1-phenylcyclohexene with about 60–70% of the PCP remaining intact, whereas with pyrolysis at 600°C (1,112°F) only trace amounts of PCP survive.[6] At these high oven temperatures (i.e., >600°C/1,112°F), pyrolytic products of PCP include a variety of polycyclic aromatic compounds (e.g., styrene, alpha-methylstyrene, naphthalene, 2-methylnaphthalene, 1-methylnaphthalene, biphenyl, cyclohexylbenzene, acenaphthene, phenanthrene, anthracene). However, at the temperatures present during smoking (i.e., 635°C/1,175°F at the burning tip), these polycyclic aromatic compounds do not form.[7]

Terminology

Street names for phencyclidine include angel dust, killer weed, hog, dust, peace, peace weed, peace pill, goon, cyclone, elephant tranquilizer, embalming fluid, rocket fuel, PCP, super grass, super joint, super weed, green tea leaves, aurora borealis, surfer, LBJ, Peter Pan, love boat, horse tranquilizer, mad man, purple rain, mean green, mint weed, crystal joint, zoom, and Polvo de angel (Spanish). The street monikers "Sherman" and "super cool" refer to cigarettes soaked with PCP. Synonyms for liquid preparations that contain PCP dissolved in embalming fluid or other solvents include wet, dry, tecal, dust, illy and matrix.[8] These preparations are added to cigarettes or marijuana sticks and smoked for hallucinogenic effects; however, these preparations may contain other drugs of abuse (e.g., cocaine).[9]

Form

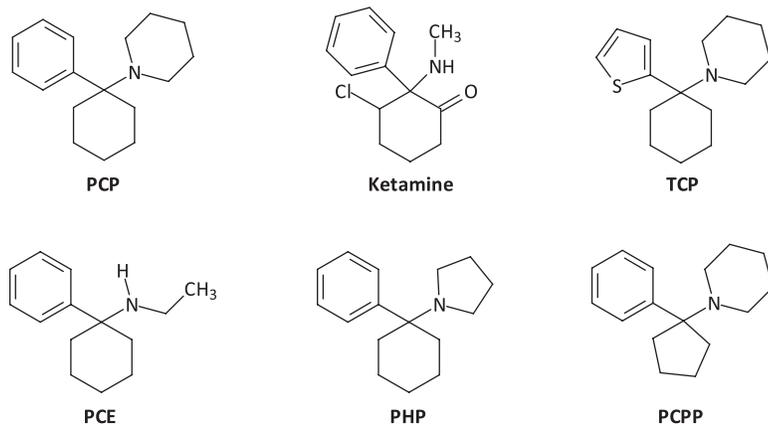
PCP usually appears as the readily soluble hydrochloride salt because PCP base is not water soluble. On the


FIGURE 34.1. Chemical structures of phencyclidine (PCP) and some structural analogs.

street, illicit PCP appears as a liquid or solid. Although PCP is frequently sold as a white, crystalline powder containing 1–6 mg PCP, the color of PCP street samples varies substantially including green, yellow, gray, and pink.[10] Rarer street forms of PCP include liquid, rock crystal, paper squares, and paste. Often PCP is incorporated into a leafy mixture of marijuana ("angel dust") or used in combinations with hallucinogens (LSD, mescaline, psilocybin) or cocaine. Figure 34.2 displays a bottle containing PCP and a cigarette (Sherman) used to dip into the liquid PCP.

EXPOSURE

Epidemiology

Among polydrug abusers, phencyclidine use remains high, particularly in urban settings (e.g., Washington, DC,; Philadelphia, PA; Newark, NJ; Baltimore, MD); however, the prevalence of PCP use is relatively low compared with cocaine.[11] Between 1999 and 2002, PCP-related emergency department visits increased 109% based on Drug Abuse Warning Network (DAWN) data.[12] Although the percentage of the population using illicit drugs increased from 6.3% in 1999 to 7.1% in 2001, the overall use of PCP did not increase significantly during this period. By 2002, PCP was the most frequent *hallucinogen* found in patients presenting to the emergency department based on reports to the DAWN, exceeding emergency department visits related to LSD and MDMA (Ecstasy). Between 2004 and 2006, emergency department visits associated with PCP use based on DAWN data decreased from 31,342 to 21,960, but these visits increased to 36,719 in 2009.[13] In compari-

son, ED visits associated with ecstasy use increased from 10,220 in 2004 to 22,816 in 2009.

Sources

ORIGIN/COMPOSITION

The purity of phencyclidine sold as "angel dust" is high (80–100%) compared with the surreptitious adulteration of other street drugs with phencyclidine (range, 10–30%). Typical street doses of PCP range from 1–9 mg with an average of about 5 mg.[14] In a simulated smoking study, 1-phenylcyclohexene and PCP in mainstream smoke accounted for approximately 30% and 40%, respectively, of the inhaled dose of PCP.[15] About 15% of the inhaled PCP dose remained in the cigarette butt and about 16% off-gassed into sidestream smoke.

PRODUCTION PROCESSES

The US government is the only legal source of phencyclidine for research; the diversion of PCP from legal sources remains limited. Synthesis of phencyclidine as originally developed by Parke, Davis and Company chemists in 1965 involves the use of benzene, piperidine, and *p*-toluenesulfonic acid.[16] Description of the synthesis of PCP using 1-piperidinocyclohexanecarbonitrile (PCC, CAS RN: 3867-15-0) as a chemical intermediate is readily available on the Internet, requiring only moderate technical training and readily available precursors. Clandestine phencyclidine synthesis is a relatively simple, inexpensive process that produces large profits from a few chemicals and limited space. An older method for the clandestine synthesis of PCP is the condensation of 1-phenylcyclopentylamine with pentamethylene dibromide (1,5-dibromopentane, CAS RN: 111-24-0).[17] Alternative methods of clandestine PCP production include the direct conversion of piperidine to PCP, and the condensation of piperidinium chloride (CAS RN: 6091-44-7) with cyclohexanone followed by conversion to the PCC intermediate with a cyanide salt as demonstrated in Figure 34.3. Treatment with a phenyl Grignard converts the intermediate to PCP. To reduce the illicit synthesis of PCP, the United States banned PCP precursors (e.g., piperidine). The use of volatile solvents during the synthesis of PCP may cause explosions or fires in clandestine PCP laboratories.

IMPURITIES AND PROFILING

A major contaminant of illicit synthesis of PCP is the chemical intermediate, 1-piperidinocyclohexanecarbonitrile (PCC, CAS RN: 3867-15-0). In a study of the

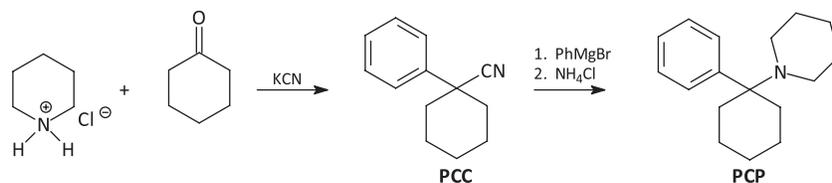
FIGURE 34.2. Liquid phencyclidine (PCP) and cigarette (Sherman) used to dip into the liquid PCP. (Courtesy of *Drug Bible*)


FIGURE 34.3. Chemical synthesis of PCP *via* condensation of piperidinium chloride and cyclohexanone to 1-piperidinocyclohexanecarbonitrile (PCC).

pyrolytic fate of radiolabeled PCC impregnated in marijuana cigarettes, approximately 47% of the PCC appeared unchanged in mainstream smoke. During the smoking study, about 58% of the unchanged PCC in the mainstream smoke was cleaved to form cyanide and 1-(1-piperidino)-1-cyclohexene.[18] The latter compound further decomposed to cyclohexanone, *N*-acetylpiperidine, and piperidine (which has a strong fishy smell). PCC contamination and subsequent cyanide release are not usually clinically significant, except in a massive PCP overdose.[19] Other potentially volatile by-products of PCP synthesis include ether, cyclohexanol, and isopropyl alcohol. Phenyl lithium or phenyl magnesium halides are unstable in atmospheric moisture; these organometal compounds are fire hazards rather than inhalation hazards.

Analytic techniques (e.g., GLC, spot tests) can detect PCC contamination in solid or liquid samples of phencyclidine. However, in a study analyzing 11 confiscated phencyclidine samples with purity ranging from 3–59%, PCC contaminated one specimen.[20] Rapid tests for the presence of PCC with minimum interference from other drugs of abuse include the impregnation of filter paper with sodium picrate that has a detection limit of about 2.5 mg/L.[21] The use of embalming fluid (formaldehyde, methanol, glutaraldehyde, ethanol) as a solvent for dissolving powdered PCP probably does not result in toxicity from smoking the PCP dipped in the PCP-containing liquid ("getting wet") because the volatility of these chemicals during the smoking process substantially reduces exposure to the constituents of the embalming fluid.[22]

Methods of Abuse

Most novice phencyclidine users begin PCP use when introduced to the drug by fellow drug users in a social setting.[23] Frequently, naive users consume phencyclidine while mistakenly believing that the drug was another, more desirable illicit drug. The chronic phencyclidine user is usually a polydrug abuser, who experiments with PCP after using alcohol, sedatives, stimulants, marijuana, and sometimes heroin.[24] Attractive feelings associated with PCP intoxication for these polydrug users include a state of dreamy estrangement and comical incoordination along with feelings of strength, power, and invulnerability. However, increased belligerence, emotional lability, and social isolation complicate chronic PCP use.

The most popular method of using PCP is by smoking thickly wrapped cigarettes in liquid PCP. Alternatively, powdered PCP is mixed with marijuana or tobacco leaves, and rolled into a cigarette (Sherman or Cool brands). Occasionally, the smoking of parsley leaves soaked with PCP is substituted for the use of PCP-soaked marijuana. Less-common methods of abuse include "getting wet" (soaking tobacco or marijuana cigarettes in liquid PCP produced from dissolving powdered PCP in commercial embalming fluid or other solvents), ingestion of PCP-laced food ("dusted food"), nasal insufflation, and IV injection. However, these methods are associated with more undesirable reaction because of the difficulty with titration of illicit PCP doses to desired effects.

DOSE EFFECT

Prediction of adverse reactions based on the PCP dose consumed is complicated by the effect of several variables including the absorbed dose, the route of administration, sample contaminants and adulterants, concomitant drug use, social setting, personality traits, individual variability, and tolerance. The unpredictability of these effects is one of the attractive features for chronic PCP users. Desired effects of illicit PCP use include euphoria, sense of power, analgesia, reduced inhibition, and altered perception of time, space, and body image.[25] Increasing doses of PCP result in amnesia, sensory illusions, altered body images, agitation, panic attacks, obsession with trivial matters, and bizarre behavior. In preclinical drug trials, IV phencyclidine doses of 0.25 mg/kg produced good surgical anesthesia associated with elevated blood pressure and tidal volumes, increased heart rate, occasionally increased muscle tone, bilateral ptosis with decreased pupillary reactivity, impaired visual identification and pinprick sensation, and vertical/horizontal nystagmus.[1]

Postoperatively, most patients were dissociated and euphoric, but approximately 10–20% experienced violent "emergence" reactions. Intravenous PCP doses of 0.5 mg/kg produce agitation in most patients. In healthy volunteers receiving 0.75 mg phencyclidine/kg, perceptual distortions occur rather than hallucinations. The altered mental state resembled schizophrenia and included depersonalization, distortion of body image, slowed time perception, memory loss, and concrete thinking.[26] Intravenous PCP doses of 1 mg/kg resulted in muscle rigidity, catatonia, and convulsions.

The typical street dose of PCP is about 3–5 mg. An approximation of the dose-related effects of PCP depending on the variables listed above is as follows: 1) low doses (1–10 mg): slight elevation of blood pressure and pulse rate may occur along with mild agitation, ataxia, nystagmus, confusion, decreased sensation, euphoria, emotional lability, analgesia, muscle rigidity, blank stare; 2) moderate PCP doses (10–20 mg): profound muscle rigidity, vomiting, hypersalivation, elevated blood pressure, excited or stuporous catatonia, toxic psychosis, bizarre behavior, coma; and 3) high doses (20–100 mg): prolonged coma, convulsions, decerebrate rigidity, opisthotonus, alternating periods of consciousness.[27] Patients emerging from PCP-induced altered consciousness manifest the behavioral toxicity seen at lower phencyclidine doses, characterized by paranoid delusions, agitation, delirium, hypersalivation, and hallucinatory experiences.[28]

TOXICOKINETICS

Table 34.2 lists some approximate toxicokinetic parameters for PCP. These parameters vary with factors such as dose, route of administration, and interindividual differences.

TABLE 34.2. Approximate Toxicokinetic Parameters for Phencyclidine (PCP).

Parameter	Value
Routes of Administration	Oral, Insufflation, Smoking, Intravenous
Typical Dose	Oral: 2–6 mg
	Insufflation, Smoking, Intravenous: 1–3 mg
T_{max}	2.5 hours*
C_{max}	2.7 ng/mL*
$T_{1/2}$	7–46 hours (mean, 17 hours)†
V_d	5.3–7.5 L/kg (mean, ~6 L/kg)
Protein Binding	60–80%
Plasma/Whole Blood Ratio	1.0

Abbreviations: C_{max} peak plasma = PCP concentration; T_{max} = time between exposure and peak plasma PCP concentrations; $T_{1/2}$ = terminal plasma elimination half-life; V_d = volume of distribution.
*1 mg dose.
†↑ up to 4 days during overdose.

as dose, route of administration, and interindividual differences.

Absorption

PCP is well absorbed by all routes with effects beginning within several minutes following insufflation or inhalation.

ORAL

The gastrointestinal absorption of phencyclidine is high. In a study using small doses (i.e., 1 mg) of radiolabeled phencyclidine hydrochloride administered to healthy volunteers, the oral bioavailability was about 72% ± 8% with the average time to peak PCP plasma concentration (2.7 ± 0.4 ng/mL) occurring approximately 1.5–2.5 hours after ingestion.[29] Because PCP is a basic drug, absorption occurs primarily in the small intestine rather than in the acidic medium of the stomach.

INHALATION

The bioavailability of PCP after smoking is high. Case reports indicate that acute PCP intoxication may occur following passive inhalation in both children[30] and adults.[31] During smoking, pulmonary absorption accounts for approximately 30–40% of the PCP dose in a cigarette, whereas heat degrades about 30% of the PCP dose to 1-phenylcyclohexene (PC).[32,33] About one third of the PCP dose remains in the butt or off-gases in the sidestream smoke.[15] Phencyclidine rapidly crosses the alveolar membrane and the blood–brain barrier. In volunteer studies, peak PCP plasma concentrations occur 5–20 minutes after inhalation.[15] A second plasma PCP peak may appear 1–3 hours after inhalation as a result of delayed absorption of PCP depots in the tissues of the upper or lower respiratory tract.

CUTANEOUS

Animal studies in hairless mice suggest that clinically significant percutaneous absorption of phencyclidine hydrochloride may occur within a few hours.[34] Anecdotal experience suggests that percutaneous absorption also occurs in humans (e.g., law enforcement officers handling confiscated material).

Distribution

After equilibrium, PCP distributes widely into the tissues resulting in a large volume of distribution and relatively small plasma concentrations compared with tissue PCP concentrations. Because of high lipid solubility and intracellular ion trapping, phencyclidine is highly

tissue bound. In a study of volunteers administered 1 mg PCP intravenously, the volume of distribution averaged 6.2 ± 0.3 L/kg.[35] Plasma protein binding of PCP ranges from about 60–80%.[35,36] Food deprivation, stress, and weight loss can mobilize phencyclidine from fat stores in experimental animals.[37]

Biotransformation

Biotransformation is the major route of PCP elimination in humans with a variety of metabolic pathways for PCP biotransformation as demonstrated in Figure 34.4.[38] The primary metabolic pathways involve oxidative hydroxylation of the alicyclic (i.e., nonaromatic) rings at several carbon atoms by cytochrome P450 isoenzymes. The major metabolite is the *trans* isomer of 4-phenyl-4-(1-piperidinyl) cyclohexanol (4-PPC). *In vitro* studies of PCP metabolism in human liver microsomes indicate that several CYP isoenzymes contribute

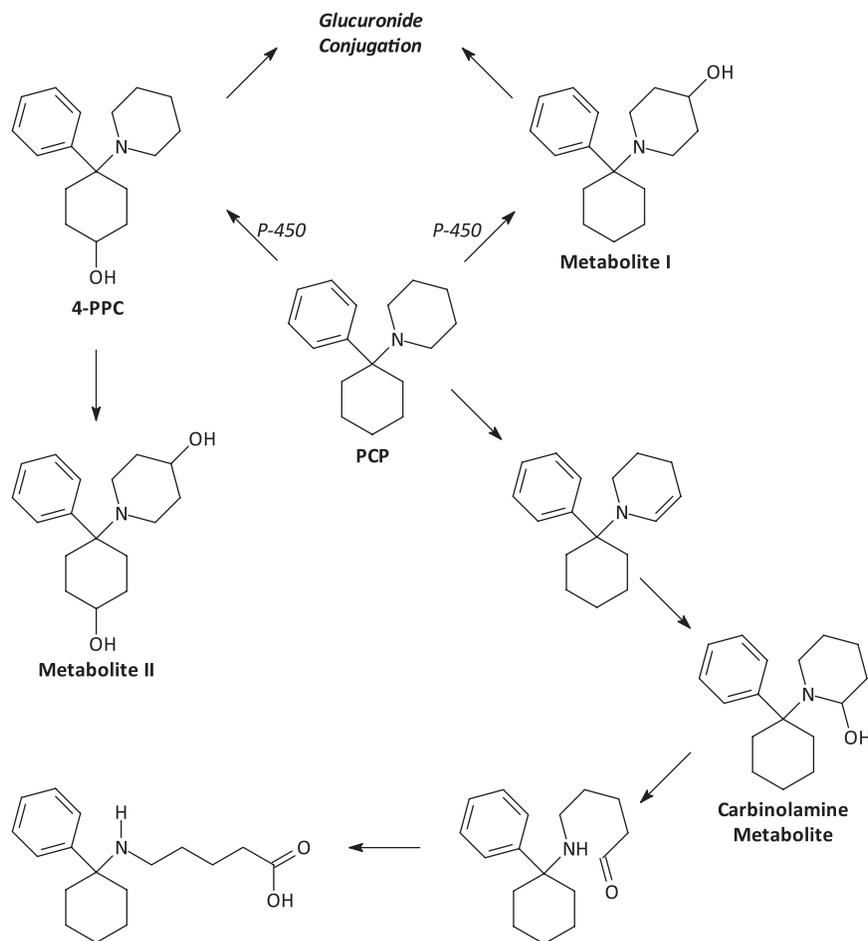
to PCP metabolism, particularly CYP3A.[39] However, there was a large degree of interindividual variation in the metabolite formation. Hydroxylation at C4 of the piperdine or cyclohexane rings forms both mono-hydroxylated metabolites [4-phenyl-4-piperidinocyclohexanol, 1-(1-phenylcyclohexyl)-4-hydroxy-piperidine] as well as the dihydroxy metabolite, 4-(4′-hydroxypiperidine)-4-phenylcyclohexanol. Hydroxylation of PCP at C2 of the piperidine ring forms an unstable carbinolamine that decomposes to form a series of polar, ring-opened compounds.[40] Following the administration of 1 mg PCP to healthy volunteers with normal urinary pH, the ratio of these three metabolites was 6.4/2.5/1, respectively.[29] Primary amine (1-phencyclohexylamine) and amino acid [5-(1-phenylcyclohexylamino)-valeric acid] metabolites are minor products of phencyclidine metabolism in humans.[41] In general, PCP metabolites display less pharmacologic activity than PCP.


FIGURE 34.4. Biotransformation of PCP. 4-PPC = of 4-phenyl-4-(1-piperidinyl) cyclohexanol; Metabolite I = 1-(1-phenylcyclohexyl)-4-hydroxypiperidine; Metabolite II = 4-(4′-hydroxypiperidine)-4-phenylcyclohexanol.

Elimination

Elimination of PCP occurs primarily by the renal excretion of conjugated hydroxylated metabolites; PCP elimination kinetics are relatively complex. Mono-hydroxylated and di-hydroxylated PCP metabolites are conjugated with glucuronic or sulfuric acid before renal excretion. Renal excretion of these metabolites depends on both urine pH and volume. Following the IV administration of 1 mg PCP, excretion of unchanged PCP in urine with normal pH (i.e., 6.0–7.5) is also relatively small (i.e., <10% of the absorbed dose).[35] Reducing the mean urine pH from 7.4 to 6.1 in human volunteers increases renal excretion of small, IV doses of phencyclidine by 50%.[42] The fecal excretion of PCP metabolites is relatively small (<3–5%) compared with renal elimination.[29]

In human volunteers administered 1 mg PCP, the mean terminal (β) elimination half-life of PCP following inhalation and ingestion were similar averaging 24 ± 7 hours and 21 ± 3 hours, respectively, with a range up to 51 hours.[29,32] In a study of 3 volunteers administered 100 μg ^{3}H-PCP intravenously, the mean α-elimination half-life was 4.6 hours compared with a mean β-elimination half-life of 22 hours based on a three-compartment model.[43] During PCP intoxication, the elimination of PCP displays first-order kinetics over a wide range of doses. The estimated initial PCP plasma elimination half-life (i.e., after he passed the last 2 bags of PCP on hospital day 11) in a body packer with a massive PCP overdose producing PCP concentrations near 1,000 ng/mL was approximately 12.5 hours[44] compared with 11 hours in a patient with PCP-induced psychosis.[45]

Drug Interactions

In vitro studies indicate that PCP inhibits the activity of CYP2B6 and CYP2C19 activity.[46] There was little effect on the activity of other CYP isoenzymes. The clinical relevance of these potential interactions is unclear.

Maternal and Fetal Kinetics

Animal studies indicate that PCP crosses the placenta and distributes into fetal tissues including the brain,[47, 48] whereas *in vitro* studies suggest that some PCP metabolism occurs in the placenta.[49] PCP is detectable in cord blood from neonates born to mothers chronically using PCP. In a study of about 200 cord blood samples drawn from neonates born in a large urban teaching hospital, 12% of the samples contained PCP in concentrations ranging from 0.1–5.8 ng/mL.[50] In animal studies, detect-able concentrations of PCP and PCP metabolites do not persist in the brains of fetuses beyond 24 hours after maternal administration of PCP.[51] Animal studies indicate that PCP also rapidly enters breast milk in concentrations substantially higher (i.e., 10 times) than maternal blood concentrations.[52] Thirty-six days after the hospitalization of a pregnant woman for a toxic psychosis secondary to chronic PCP abuse, she delivered a healthy infant.[53] Five days later her breast milk contained 3.9 ng PCP /mL.

Tolerance

Animal studies including primate studies in monkeys indicate that tolerance to the behavioral effects of PCP develops and dissipates rapidly.[54] Animals will self-administer sufficient amounts of PCP to maintain gross intoxication up to 50 days; following chronic administration, a 2- to 4-fold increase in PCP dose is necessary to produce the original behavioral effects.[55] Following a continuous infusion of 45 mg PCP/kg/d for 7 days to rodents, cessation of the infusion produced withdrawal signs (piloerection, increased audiogenic seizures, reduction in exploratory behavior, impaired performance) in unrestrained rats.[56] Withdrawal signs developed 4 hours after termination of the infusion and resolved by 24 hours. After 3.5 days of infusion, a test dose of 2 mg PCP /kg produced the same motor performance as a 1 mg/ kg dose in drug-naive rats. Tolerance in humans after chronic PCP use is not well defined. Anecdotal accounts suggest that the chronic use of high doses of PCP use produce some tolerance, resulting in the need for substantially larger doses to achieve the same subjective effects.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Although classified pharmacologically as a dissociative anesthetic, phencyclidine has stimulant, depressant, hallucinogenic, and analgesic properties depending on personality, dose, route of administration, and possibly genetic predisposition. Phencyclidine is a potent psychotropic drug that currently provides the best available drug-induced model of schizophrenia. Phencyclidine blocks selected sensory inputs, and interferes with the sensory association pathways in a way that diminishes the user's ability to integrate sensory input into meaningful behavior.[57] Psychoactive doses of phencyclidine produce significant increases in glucose metabolism within areas of the brain associated with emotional behavior including the frontal cortex, the caudate-

putamen, and the hippocampus.[58] Smaller increases in glucose metabolism were detected in the substantia nigra.

Mechanism of Action

Phencyclidine affects several receptors in the brain including the glutamate N-methyl-D-aspartate (NMDA), dopamine D_2, and sigma receptors. Animal studies indicate that this drug is a noncompetitive antagonist of the glutamate NMDA receptor.[59] PCP interacts with several binding sites in the brain including a PCP-binding site involving a NMDA ionophore receptor complex and a sigma binding site with affinity for neuroleptics (e.g., haloperidol).[60] The affinity of classical neuroleptic drugs is much lower for the PCP binding site than the sigma binding site. The sigma receptors (σ_1, σ_2) are single transmembrane-spanning proteins that bind hallucinogenic drugs (PCP, ibogaine), antipsychotic drugs (haloperidol), and antidysrhythmic drugs (amiodarone). These receptors modulate a number of central neurotransmitters including noradrenergic, dopaminergic, and glutamatergic receptors.[61] The functions of sigma receptors involve a variety of cardiovascular effects, but the exact role remains undetermined.[62] PCP selectively reduces the excitatory action of glutamate on spinal neurons mediated by the NMDA receptor subtype. Animal studies suggest that functions of the NMDA receptor include glutamate-activated excitatory synaptic transmission, sensory transduction,[63] learning,[64] coordination of rhythmic movements (e.g., swimming), induction of seizures, and perhaps neuronal plasticity and growth. Sensitivity of the NMDA ion channel to ambient levels of Mg^{++} results in voltage dependence. This voltage sensitivity allows the receptor to respond to intense synaptic activation and the channel to respond to long-term processes (i.e., long-term potentiation) by admitting Ca^{++}.[65] However, not all behavioral effects of PCP result from the interaction of PCP with the NMDA-operated ion channel or the sigma receptor.[66]

In rodent models, PCP has indirect dopaminergic effects that result from the inhibition of striatal dopamine reuptake and the facilitation of dopamine release. *In vitro* studies indicate that the affinity of PCP for the dopamine D_2 receptor is greater than the glutamate NMDA receptor. The dissociation constants (K_i) for these two receptors in an *in vitro* study were 2.7 nM and 313 nM, respectively.[67] Electrophysiologic effects in the nigrostriatal and mesolimbic dopaminergic pathways correlated to enhanced locomotor activity and stereotypical behavior. In addition to indirect dopaminergic properties, PCP possesses mild cholinergic properties resulting from weak inhibition of acetylcholinesterase and binding to the muscarinic acetylcholine receptor.[68] In muscle and electric organ membrane preparations, PCP interacts with the nicotinic receptor, but the structure-activity relationship indicates that this interaction is not behaviorally significant in humans.[69] Although phencyclidine produces a pressor response at low dose,[70] the effect of PCP on norepinephrine synthesis and metabolism in the brain is unclear.[66]

Mechanism of Toxicity

PCP intoxication results from a combination of central nervous system (CNS) effects, anticholinergic/cholinergic effects, and adrenergic agonist activity. During large PCP overdoses, phencyclidine possesses brief, dose-related cholinergic (e.g., hypersalivation, diaphoresis) and anticholinergic (e.g., urinary retention) properties, but the anticholinergic effects of phencyclidine are too weak to account for behavioral abnormalities. Most serious adverse effects associated with PCP use result from trauma when altered behavioral and thought patterns lead to poor judgment and high-risk actions. As the PCP dose increases, medical complications (e.g., catatonia with rhabdomyolysis) develop and major medical effects predominate (e.g., coma, respiratory depression, hyperthermia, renal failure secondary to rhabdomyolysis). In a dog model, fatal doses of PCP cause hyperthermia and primary respiratory failure before cardiovascular collapse.[71] Rhabdomyolysis and myoglobinuria may cause renal dysfunction during severe PCP intoxication, particularly when hypotension and metabolic acidosis develop. The etiology of rhabdomyolysis during PCP intoxication is multifactorial including direct muscle trauma, hyperthermia, prolonged coma, hypotension, and isometric muscle contraction.[72] There are few data to suggest that PCP causes direct muscle toxicity. In a study of rats using a restraint cage with a strain gauge, pathologic damage to skeletal muscle occurred in the restrained, PCP-treated rats. However, these abnormalities did not occur in denervated areas of skeletal muscle in these rats.[73,74] Although delayed psychotic episodes occur in patients abusing PCP, a postmortem study of brains from chronic PCP users did not demonstrate alterations in the affinity or the maximum number of PCP or sigma binding sites.[75]

Postmortem Examination

Postmortem examination of deaths associated with the use of PCP is nonspecific, other than trauma secondary to behavioral effects.[76,77] The pathologic changes associated with rhabdomyolysis during PCP intoxication are

also nonspecific. Typically, muscle biopsies from these patients demonstrate scattered necrosis of muscle fibers and myofibrillar disruption.[78] Hyaline degeneration, edema, and loss of cross striations also occur in the muscle cells.[72]

CLINICAL RESPONSE

Illicit Use

Classically, phencyclidine produces behavioral abnormalities, impaired thought processes, and altered consciousness along with elevated blood pressure, increased pulse rate, and mild temperature increase.[79] Although tachycardia occurs during the acute phase of intoxication, the pulse rate is usually <120–130 beats/minute and pulse rates above these levels suggests the ingestion of other sympathomimetic drugs or concurrent illness. The clinical effects are highly variable depending on a variety of factors including the absorbed PCP dose, sample contaminants and adulterants, concomitant drug use, social setting, personality traits, and tolerance. Additionally, the intensity of the symptoms often waxes and wanes. Table 34.3 lists the common clinical features of PCP intoxication in a case series of 1,000 PCP-intoxicated patients. Adverse effects associated with PCP use include intense paranoia, panic, memory loss, delirium, sensory isolation, and flashbacks.[80] Neuromuscular abnormalities include bizarre posturing, dystonia (torticollis, opisthotonos), and choreoathetosis. Following the smoking of usual illicit doses of PCP, peak effects occur in about 15–30 minutes. Despite the prolonged elimination half-life of PCP, the psychologic effects following usual illicit doses of PCP typically resolve within 4–6 hours as a result of the redistribution of PCP from drug receptors. The persistence of symptoms of PCP intoxication beyond 24 hours after exposure is unusual.

Vertical and/or horizontal nystagmus is a common sign of PCP intoxication with nystagmus being present in a majority of patients in a large case series of PCP intoxication,[81] but the presence of vertical and/or horizontal nystagmus is not a unique sign of PCP use. Hyperacusis may develop. Occasionally, cholinergic signs (miosis, bronchospasm, hypersalivation, diaphoresis) develop during PCP intoxication. The main differential diagnosis of PCP intoxication includes stimulant use (e.g., amphetamine, cocaine), hallucinogen ingestion (e.g., mescaline, LSD, psilocybin) psychologic disorders (e.g., catatonia, bipolar disorder, paranoid schizophrenia), and medical conditions (hyperthermia, neuroleptic malignant syndrome, intracranial hemorrhage, thyrotoxicosis, sepsis, meningitis, hypoglycemia, hypoxia).

TABLE 34.3. Incidence of Clinical Features of Phencyclidine (PCP) Intoxication in 1,000 Patients.[81]

Category	Clinical Effect	%*
Behavior	Violent	35.4
	Agitated	34.0
	Bizarre	28.8
	Hallucinating/delusional	18.5
	Mute and staring	11.7
	Nudism	3.3
	No behavioral effects	3.5
Sensorium	Alert and oriented	45.9
	Acute brain syndrome	36.9
	Unconscious	10.6
	Lethargy/stupor	6.6
Neuromuscular Signs	Nystagmus	57.4
	Generalized rigidity	5.2
	Grand mal seizures	3.1
	Localized dystonias	2.4
	Facial grimacing	1.7
	Athetosis	1.3
Cholinergic Signs	Profuse diaphoresis	3.9
	Bronchospasm	2.1
	Pupils ≤1 mm	2.1
	Hypersalivation	1.7
	Bronchorrhea	0.6
Anticholinergic Signs	Pupils >4 mm	6.2
	Urinary retention	2.4
Vital Signs Abnormalities	Hypertension	57.0
	Tachycardia	30.0
	Hypothermia	6.4
	Apnea/respiratory arrest	2.8
	Hyperthermia	2.6
	Cardiac arrest	0.3

*Percentage of 1,000 patients with this clinical effect of PCP intoxication.

BEHAVIORAL ABNORMALITIES

Exposure to mild to moderate doses of PCP results in a wide spectrum of behavioral responses. Although euphoria similar to mild ethanol intoxication may develop during PCP intoxication, behavior is unpredictable. Intoxicated patients may be agitated with a clear sensorium, ataxia, and increased motor activity. Behavior abnormalities include stereotypical behavior manifest by repetitive motor movements (e.g., sucking, picking), involuntary repetition of words (echolalia), and speechless, blank stare. Unusual behavior (e.g., nudity, obscene gestures, socially uninhibited behavior, unprovoked agitation) may occur without disordered thought process or confusion. The behavioral abnormalities and analge-

sic properties of PCP predispose the patient to traumatic injuries during acute PCP intoxication. Most of the behavioral abnormalities associated with PCP intoxication resolve within a few hours; often these patients are amnesic to the events associated with PCP intoxication.

Most mortality and morbidity associated with PCP intoxication results from accidental and self-inflicted trauma during destructive behavior. The combination of PCP-induced cognitive disorganization, impaired senses, paranoia, and hyperactivity predisposes the user to significant risk of traumatic injury. Delusions of invulnerability and the decreased pain perception contribute to the inability to perceive imminent danger. Traumatic deaths associated with phencyclidine use include falls, automobile accidents, self-inflicted injuries, failure to flee fires, and shallow-water drowning. Although threatening or combative behavior is common even without hallucinations, delusions, or disorientation, violence directed at another person does not usually occur in a PCP user without a violent predisposition.[82] Trauma may be difficult to detect in these patients because of the sensory impairment that precedes psychologic effects. Many phencyclidine users become progressively more irritable, angry, and violent following chronic PCP use.[83]

Mental Disorders

A variety of adverse mental status changes occur during PCP intoxication depending on the dose and individual predisposition. These effects include confusion, disorientation, inappropriate affect, belligerence, delusions, auditory and visual hallucination, agitation, violence, and severe dysphoria. Patients are often lethargic with slow, bizarre responses to verbal or tactile stimuli that include blank stares, mutism, and catatonia. High doses of PCP produce the rapid onset of coma, persisting minutes to days. Case reports indicate that the level of consciousness may fluctuate dramatically with the patient developing coma after an apparent period of recovery.[84] These patients may not respond to painful stimuli, but respiratory depression and apnea do not usually occur, except with concomitant ingestion of respiratory depressant drugs. The whole spectrum of behavioral abnormalities (agitation, hallucination, aggressive behavior, disorientation, catatonia) may develop after emergence from PCP-induced coma in adolescents and adults. Medical complications associated with PCP-induced coma include aspiration pneumonia, rhabdomyolysis, grand mal seizures, and apnea. Severe psychologic reactions associated with PCP intoxication include acute toxic psychosis and catatonia.

Toxic Psychosis. After high doses or chronic use, some PCP abusers develop an acute psychosis that closely resembles schizophrenia.[85] The clinical features of the acute psychosis include distorted body images, estrangement, disorganized thought patterns, delusions, and hallucinations along with behavioral abnormalities excluding catatonia. These psychotic reactions most often occur in young male patients following chronic PCP use. In contrast to amphetamine-induced psychosis, PCP-induced psychosis incorporates both positive (e.g., hallucinations, paranoia) and negative (e.g., emotional withdrawal, motor retardation) symptom of schizophrenia.[86] Additionally, PCP-induced psychosis uniquely incorporates the formal thought disorder and neuropsychologic deficits associated with schizophrenia. These patients demonstrate depersonalization, a sense of unreality, and inability to distinguish between internal and external stimuli. Phencyclidine intensifies thought disorders in schizophrenic patients.[87]

The hallucinations associated with PCP intoxication are both visual and auditory, but are not associated with the vivid imagery common during LSD intoxication.[88] The initial phase of the acute psychosis involves violent, aggressive, and/or disorganized behavior and may last up to several days. Paranoid ideations also can occur. During the first week the patient may remain agitated. Restoration of normal behavior and thought patterns usually begins within 1 week, but in some severe cases of PCP-induced psychosis up to 1 year may be necessary before the return to baseline personality. Case reports suggest that bizarre traumatic events may occur as a result of the psychosis and profound analgesic effects of PCP.[89] Although the presence of an acute psychosis predisposes the patient to traumatic injuries, these mental status changes do not necessarily predispose the patient to criminal behavior, which is goal-directed and which usually occurs in a person with a criminal history.

Catatonia. As a result of the chaotic and disturbing feeling associated with PCP intoxication, a stuporous or excited catatonia may develop.[90] These patients are often motionless with arms and head in bizarre positions. Characteristically, these mute patients are expressionless and do not respond to painful stimuli, but a few of these patients will follow simple commands.[91] Clinical features associated with stuporous catatonia include mutism, grimacing, repetitive and/or bizarre posturing, rigidity, blank stare, constant repetition of nonsense, and echolalia. Excited catatonia involves agitation, impulsiveness, nudism, destructive behavior, incoherent and profuse speech, and unpredictable destructive behavior. Symptoms of catatonia usually resolve in 4–6 hours, but some patients require several days to reintegrate their personalities.

MEDICAL COMPLICATIONS

CENTRAL NERVOUS SYSTEM.   Generalized tonic-clonic seizures are the most common neurologic complication of acute PCP intoxication. In a case series of 1,000 patients presenting to a large urban emergency department with acute PCP intoxication, about 3% developed generalized seizures.[81] Rarely, case reports associated focal seizures and hemiparesis with PCP intoxication.[92] Case reports also associate status epilepticus,[93] spontaneous intracerebral hemorrhage,[94] and acute subarachnoid hemorrhage[95] with evidence of PCP in blood and urine samples, but the causal link between PCP use and these neurologic lesions is unclear. The sensory blockade with blank stare and muscle rigidity during PCP intoxication suggests a toxic rather than a structural lesion as a cause of neurologic and behavioral abnormalities.[96]

CARDIOVASCULAR SYSTEM.   Elevation of blood pressure (systolic >140 mm Hg and/or diastolic >90 mm Hg) occurs in about 50% of PCP intoxications based on a case series of PCP intoxication presenting to a large, urban teaching hospital.[81] Despite the occasional presence of severe hypertension, neurologic and cardiac complications are unusual. Hypertension usually resolves within several hours, particularly when agitation ceases. During severe intoxications, hypertension waxes and wanes similar to behavioral abnormalities with return to normal blood pressures over several days to a week.[97]

HYPERTHERMIA.   Mild to moderate temperature elevations occur during PCP intoxication. In a series of 1,000 patients presenting to a large, urban teaching hospital with PCP intoxication, 20 patients with drug screens positive only for PCP had temperatures above 102°F (38.9°C).[81] The highest recorded temperature in this case series was 107.4°F (41.9°C) rectally. Case reports associate PCP-induced hyperthermia with multiple seizures, hypertension, combative behavior, and secondary rhabdomyolysis.[98] Other serious complications of PCP-induced hyperthermia include multiorgan failure manifest by severe metabolic and respiratory acidosis, acute hepatorenal failure, coma, respiratory insufficiency, hypoglycemia, hyperkalemia, and cardiac arrest.[99] A fatal case of submassive liver necrosis and disseminated intravascular coagulopathy developed in a patient with severe PCP intoxication, respiratory failure, rhabdomyolysis, and hyperthermia (initial rectal temperature of 108°F/42.2°C).[100] Two other patients in this series of PCP-induced hyperthermia and submassive liver necrosis survived.

RHABDOMYOLYSIS AND RENAL FAILURE.   Rhabdomyolysis is the most common serious medical complication of phencyclidine intoxication, but the incidence of rhabdomyolysis-induced acute renal failure during severe PCP intoxication is relatively infrequent (i.e., <1% of PCP cases).[101] The renal failure associated with PCP intoxication results from myoglobinuria rather than direct nephrotoxicity, particularly following the prolonged use of restraints and dramatic elevation of serum creatine kinase concentrations.[102] Hyperuricemia frequently occurs during rhabdomyolysis along with hyperphosphatemia and hypocalcemia, but these abnormalities probably do not contribute to the renal failure associated the rhabdomyolysis.[103] Although hemodialysis may be necessary, spontaneous recovery usually begins within 10–14 days. Recovery of renal function is usually complete.[78]

Overdose

In addition to interindividual differences in response to PCP intoxication, the adverse effects associated with PCP intoxication are dose-related with higher PCP doses causing more severe adverse effects (coma, acute toxic psychosis, bizarre behavior, seizures, rhabdomyolysis). Complications associated with a massive PCP overdose included respiratory failure, hyperthermia, rhabdomyolysis, and protracted seizures. One patient was released from the hospital 24 days after ingesting a leaking plastic bag of PCP.[44] At discharge he had a clear sensorium and normal cognition, but dystonic muscle jerks in the extremities remained 24 days after admission.

Fatalities

Behavioral toxicity accounts for most deaths associated with PCP use, in part, from delusions of invulnerability and the inability to perceive imminent danger. PCP-related traumatic deaths include shallow-water drowning, automobile accidents, self-inflicted trauma, and failure to flee dangerous situations (e.g., fires). In a study of 2 northern California counties from July 1970 to June 1976, 19 coroner's cases were associated exclusively with PCP intoxication.[76] In 13 of these cases, the cause of death was drowning or trauma, whereas PCP overdose accounted for only 2 of these deaths. PCP-intoxicated patients are vulnerable to drowning as a result of PCP-induced reduction in sensation and muscular control. In a Los Angeles County study of 104 PCP-related fatalities, PCP overdose was attributed to only 15 deaths.[104] From 1981 to 1986, PCP was an incidental finding in 96% of 104 deaths reported to the St. Louis Coroner's Office where the vast majority of these

cases involved homicide.[105] The deaths of only 4 of the 104 coroner's cases with detectable concentrations of PCP were attributed to overdose.

Sudden death during apprehension for PCP-induced behavioral abnormalities occurs less commonly than during cocaine and methamphetamine intoxication. The cause of death in these situations is complex, particularly whether or not physical restraint and/or positional asphyxia may be contributory. Potential causes of death in these situations include trauma, illicit drug use, hyperthermia, mental and physical stress, natural diseases, and excited delirium.[106] Unexpected cardiac arrest can occur in patients undergoing psychologic stress without the presence of underlying structural heart disease[107] and in actively psychotic patients without obvious medical explanations.[108] Case reports indicate that death occurs during PCP-induced psychosis without the use of methods (e.g., physical restraint, handcuffs, hog tying, taser) to restrain the patient.[109] Medical causes of death in phencyclidine overdose include status epilepticus, respiratory arrest, hyperpyrexia with cardiovascular collapse, and coma with multiple end-organ failure.

Accidental Exposure

Following accidental PCP intoxication, children usually demonstrate ataxia and nystagmus along with altered mental status (diminished response to tactile and verbal stimuli, depressed sensorium, stupor associated with a blank, expressionless stare).[30] Miosis, choreoathetosis, and seizures are more common during PCP intoxication in children than adults.[110] The triad of a blank stare, miosis, and hypertension in a child is strongly suggestive of phencyclidine intoxication. In contrast to adolescents and adults, severe agitation, aggressive behavior, and psychosis do not usually occur in children with PCP intoxication.[111] Respiratory depression is more common during PCP intoxication in comatose children than comatose adults.[112,113]

Abstinence Syndrome

Although an abstinence syndrome develops in animals chronically administered PCP, a PCP withdrawal syndrome in humans is not well defined. In studies of laboratory animals, physical dependence develops within approximately 1 week of PCP administration as manifest by piloerection, bruxism, lethargy, and seizures.[114] These withdrawal effects begin about 4 hours after cessation of PCP administration with resolution occurring within ~24 hours. Clinical reports suggest that symptoms of depression, increased appetite, hypersomnia, lethargy, and drug craving occur approximately 1 week to 1 month after the cessation of chronic PCP use.[111]

Reproductive Abnormalities

Case-control studies suggest that the incidence of poor attention, hypertonia, and depressed neonatal reflexes may increase in infants born to mothers using PCP during pregnancy.[115] Case reports also suggest that a neonatal withdrawal syndrome can occur following the maternal use of PCP during pregnancy that includes jitteriness, hypertonicity, vomiting, and diarrhea.[116] In a study of 7 mothers with a history of chronic PCP use and 27 drug-free controls, the most characteristic features of the PCP-exposed infants were lability of mood (i.e., sudden outbursts of agitation, rapid changes in level of consciousness) and difficulty consoling the infant.[117] At 3 months of age, scores on the Bayley Scales of Infant Development revealed no significant differences between the 2 groups of infants.

Case reports also associate cerebral palsy, neonatal depression, behavioral abnormalities, and facial dysmorphogenesis with chronic maternal use of PCP.[118] However, reporting bias and the presence of confounding variables (e.g., drug use, poor nutrition) limits conclusions regarding the role of PCP use in these reproductive abnormalities. Another retrospective case-control study did not demonstrate a statistically significant difference in low birth weight (<2500 g) between mothers testing positive for PCP at birth and the control group of mothers without evidence of PCP use based on urine drug screens at the time of obstetrical admission.[119] Most animal and human data do not indicate that PCP is a clinically significant teratogen.[50,120]

DIAGNOSTIC TESTING

Analytic Methods

Table 34.4 lists screening and confirmatory methods for the detection of PCP in various human samples along with associated limits of detection (LOD).

SCREENING

Methods for screening urine for PCP abuse primarily involve the use of enzyme immunoassays including enzyme-linked immunosorbent assay (ELISA; Syva EMIT® II, (Syva Co., San Jose, CA) and polarized immunofluorescence (Abbott TDx FPIA®, Abbott Diagnostics, Abbott Park, IL).[124] Sensitivities and imprecision vary between different immunoassays. In a comparison of ELISA tests (Immunalysis Corp., San Dimas, CA; STC Diagnostics Inc., Bethlehem, PA), the lower limit of quantitation (LLOQ) was <1 ng/mL and 25 ng/mL, respectively.[125] The total coefficient of variance was 26% and 8.8%, respectively. Antibodies for these tests

TABLE 34.4. Methods for the Detection of Phencyclidine (PCP).

Method	LOD	Sample
Spot Test	*	†
Gas chromatography/ FID	5 ng/mL[121]	CSF, urine, serum
Gas chromatography/ MS	10 ng/mL[122]	Urine
Radioimmunoassay	<0.5 ng/mL[123]	Serum

are raised against phencyclidine rather than PCP metabolites. PHP is preferred by drug users wishing to escape detection of PCP and PCP analogue use.[126] Alternative methods involve GC with nitrogen-phosphorus detection or capillary electrophoresis.

CONFIRMATORY

Methods for the detection and quantitation of PCP include radioisotopic and enzyme immunoassays, gas chromatography with nitrogen detection,[127] liquid chromatography/mass spectrometry,[128] gas chromatography/ mass spectrometry (GC/MS) following derivation with *N*,*O*)-bis(trimethylallyl)trifluoroacetamide,[129] and GC/ MS using SIM mode with deuterated PCP as internal standard.[130] The limit of detection for PCP by radioimmunoassay (RIA) ranges down to 2 ng/mL.[131] The cross-reactivity of some phencyclidine analogues occasionally limits the correlation between RIA test results and clinical presentation. However, PCP metabolites and most other illicit drugs do not crossreact with RIA assays for PCP. For confirmation of the presence of PCP in urine samples, PCP concentrations above the federally mandated cutoff concentration of 25 ng/mL are required. Gas chromatography/electron impact quadrupole/mass spectrometry is the official method of choice in either selected ion monitoring or full-scan modes for US federal testing mandatory guidelines.[132] GC/MS involves the addition of a deuterated internal standard to the urine, followed by solid-phase or by liquid-liquid extraction and GC/MS analysis. In most chromatographic methods, preanalytic chemical derivation is not necessary.[133]

STORAGE

PCP is stable in storage over at least 3–5 years, even when stored at room temperature and particularly when refrigerated or frozen.[134] Over 6 months, PCP deteriorates (20–40%) in urine specimens when stored at room temperature, but the deterioration in frozen specimens is nominal.[135] A study of 50 urine samples containing a mean PCP concentration of 128 ng/mL demonstrated approximately a 12% decrease in the mean PCP concentration during storage at –20°C (–4°F) for 12 months.[136] In a 3-year study of PCP stored at 4°C (39.2°F) and –20°C (–4°F), samples stored for 1 year did not demonstrate a significant change in PCP concentrations when compared with initial PCP analyses. The average reductions in PCP concentrations in samples stored 2 years and 3 years were approximately 10% and 18%, respectively. Blood phencyclidine samples stored in glass vials with Teflon-lined screw caps, preservative (sodium fluoride), and anticoagulant (potassium oxalate) did not deteriorate significantly over 18 months despite the lack of refrigeration.[137] Eleven of the 45 specimens in this study demonstrated >10% loss of PCP, but PCP was still detectable in all specimens. In another study, most specimens stored over 3 months in gray-top Vacutainer® (BD Diagnostics, Franklin Lakes, NJ) tubes containing sodium fluoride and potassium oxalate at ambient temperature had reduction in PCP concentrations >10%; those stored 4–5 years had losses >70%, but PCP remained detectable in all specimens.[138]

Biomarkers

Urine and blood are the most common fluids used to detect PCP use. Alternate sample matrices for detecting PCP include saliva and cerebrospinal fluid (CSF). Although PCP is usually detectable both in saliva and in blood samples, the PCP concentrations in these 2 samples do not correlate well to one another in animal models.[139] PCP concentrations in CSF often exceed plasma PCP concentrations following complete absorption. The PCP CSF/plasma ratio remains relatively constant for several days after equilibrium, particularly following serious PCP intoxication.[140,141]

BLOOD

The distribution of PCP between plasma and erythrocytes is relatively even with whole blood/plasma ratios near unity.[29,142]

ILLICIT USE. Phencyclidine blood concentrations confirm exposure to PCP, but PCP concentrations in blood samples do not correlate well to behavioral abnormalities. In general, high blood PCP concentrations (i.e., >100 ng/mL) occur in comatose patients, whereas PCP concentrations usually, but not always are lower (<100 ng/mL) in patients with catatonia or toxic

psychosis.[143] In a case series of 46 patients with detectable serum PCP concentrations and abnormal behavioral patterns (lethargy, bizarre, violent, agitation, euphoria), the serum PCP concentrations ranged from 5–300 ng/mL (median, ~25–50 ng/mL).[143] These patients did not have clinically significant abnormalities of their vital signs. Case series suggest that high PCP concentrations in the plasma are associated with increasing risk of serious complications (seizures, hyperthermia, coma, rhabdomyolysis), particularly when the plasma PCP concentration exceeds 400–500 ng/mL.[142] A case series of 10 occasional PCP users suggested that physical findings of PCP intoxication do not correlate to plasma phencyclidine concentrations except for systolic blood pressure.[144] However, the incidence of signs of PCP intoxication (nystagmus, hypertension, hypersalivation, hyperreflexia) increased substantially when the plasma PCP concentration exceeded 100 ng/mL.

OVERDOSE. Massive oral PCP overdoses produced plasma PCP concentrations exceeding 1,000 ng/mL.[44,145] These patients developed severe agitation and coma that required intubation for respiratory support; altered mental status did not improve until the plasma PCP concentrations declined below 100 ng/mL. However, a case report also documented a PCP concentration of 1,100 ng/mL in a postmortem blood sample (location not specified) from a homicide victim.[146]

POSTMORTEM
Blood. Postmortem examinations indicate that the highest postmortem phencyclidine tissue concentrations occur in liver, brain, bile, and kidney while the postmortem blood PCP concentrations are comparatively low.[146] The incidence of fatal PCP intoxications secondary to medical complications is low compared with the number of individuals dying from PCP-related trauma.[105] Although PCP concentrations in postmortem blood samples are usually lower in victims of PCP-induced behavioral toxicity than in fatalities from acute PCP intoxication, some overlap in postmortem PCP concentrations occurs between these two groups. In a case series of 37 autopsies with detectable amounts of PCP in postmortem blood, the demise of 2 individuals found dead was attributed to acute PCP intoxication when alternate explanations for death were not apparent based on autopsy and drug screens.[147] The postmortem blood PCP concentrations of these 2 individuals were 1,500 and 25,000 ng/mL as measured by gas chromatography. In 29 of the 37 cases, the cause of death was attributed to homicide or accidental trauma. The mean blood PCP concentration in postmortem samples from this group was approximately 190 ng/mL (range, 20–700 ng/mL). Two case reports of individuals with histo-

ries of substance abuse associated death from PCP intoxications with postmortem blood PCP concentrations (one femoral, one heart) in the range of 360 ng/mL.[148] Both these individuals were found unresponsive and declared dead in the emergency department. The autopsies revealed mild cardiomegaly and no other cause of death.

In a case series of 5 deaths associated with phencyclidine intoxication and no other detectable drug, the blood PCP concentrations ranged from 300–3,300 ng/mL (mean, 1,000 ng/mL; median, 500 ng/mL) as measured by GC/MS.[149] In 6 additional cases with detectable PCP concentrations in postmortem blood, death was attributed to trauma. The mean PCP concentration in postmortem blood from this group was ~450 ng/mL (range, 60–800 ng/mL). Similarly, in another case series of 10 trauma-related deaths with detectable PCP concentrations in postmortem blood, the mean blood PCP concentration was ~600 ng/mL (range, 100–1,200 ng/mL).[76] There are few data on the postmortem redistribution of PCP, but the large volume of distribution suggests that some elevation (i.e., up to at least 3-fold) may occur in postmortem PCP heart/femoral blood ratio depending on factors related to postmortem redistribution (e.g., amount of tissue degradation, diffusion, postmortem interval).

Liver. In a case series of 5 deaths associated with phencyclidine intoxication and no other detectable drug, the liver PCP concentrations ranged from 0.9–20.5 µg/g (mean, 6.8 µg/g; median, 3.0 µg/g) as measured by GC/MS.[149] Trauma accounts for the death of 6 additional cases with detectable PCP concentrations; the mean concentration of PCP in the liver from these cases was 2.2 µg/g (range, 0.6–3.9 µg/g). The range of PCP concentration in postmortem liver samples from 4 fatalities associated with PCP intoxication and no other discernible cause of death at autopsy was 5–36 µg/g (mean, 13.75 µg/g) compared with 0.32–3.9 µg/g (mean, 1.7 µg/g) for 5 trauma-related deaths with detectable PCP concentrations as measured by gas chromatography.[150] However, occasional case reports of traumatic deaths associate high liver PCP concentrations (e.g., 6.3 µg/g) with substantial PCP concentrations (4,000 ng/mL) in postmortem blood.[76]

VITREOUS HUMOR

Limited data indicate that PCP distributes into vitreous humor with the PCP concentrations in vitreous humor typically being lower than postmortem blood. As measured by gas chromatography/flame ionization detection, the vitreous humor PCP concentrations in a case series of 18 cases testing positive for PCP by

immunoassay (cutoff, 25 ng/mL) ranged from 30–290 ng/mL compared with 50–600 ng/mL in postmortem blood.[151] In a study of 26 deaths involving PCP as an incidental finding, the mean postmortem heart blood/vitreous humor and subclavian blood/vitreous humor ratios were 2.85 ± 1.82 and 2.51 ± 1.49, respectively.[152] There was substantial interindividual variation as reflected in the standard deviations. The equilibrium between vitreous humor and blood is relatively slow compared with other fluid compartments; consequently, some of this variation may reflect difference in the state of equilibrium between blood and vitreous humor.

URINE

Urine PCP concentrations do not correlate to the severity of PCP intoxication.[171] PCP concentrations in urine are high enough during PCP intoxication to detect recent use with commercially available immunoassays, depending in part upon urine pH. Typically, urine PCP concentrations of recent PCP users exceed 100 ng/mL, when measured by RIA techniques that crossreact with PCP and monohydroxylated metabolites.[153] The use of common illicit drugs are unlikely to cause false-positive results for PCP using the EMIT® d.a.u. (Syva Co., San Jose, CA) immunoassay, when the urine concentrations of these drugs are below <100 mg/L.[124,154] Potential false-positive results for the PCP immunoassays can occur as a result of crossreactivity from high urine concentrations of dextromethorphan, ketamine, diphenhydramine,[155] venlafaxine (massive overdose),[156] and tramadol (fatal overdose).[157] Analysis of urine specimens for PCP should include determination of urine pH because the surreptitious addition of sodium bicarbonate or sodium hypochlorite to alter urine pH. The latter reduces the ability to detect PCP concentrations in urine using EMIT®, RIA, or Abbott TDx®, whereas the addition of sodium bicarbonate to urine samples reduces the detection of PCP using Abbott TDx®.[158]

Following PCP use, urine PCP concentration initially declines rapidly during the first 9–10 days; then, urine PCP concentrations decrease more gradually depending on the chronicity of PCP use. On average urine samples remain positive for PCP for about 2 weeks after cessation of chronic PCP use, but the urine from some chronic PCP users may remain positive for 1 month after the last use of PCP.[159] Separation of abstinence from new use during this period may be difficult. Case reports associate surgical procedures within this 30-day period with the development of positive PCP urine drug screens in urine samples from chronic PCP users despite abstinence, probably as a result of the release of PCP from tissue stores.[160]

HAIR

PCP occurs in hair samples from chronic PCP users based on RIA screening techniques and GC/MS confirmation.[161] However, *in vitro* experiments suggest that passive exposure to PCP smoke may produce detectable amounts of PCP in hair samples as measured by gas chromatography/tandem mass spectrometry.[162] As a result of potential external contamination of hair samples following passive exposure to PCP smoke, the detection of PCP metabolites is necessary to confirm the use of PCP using analysis of hair samples. In a study of hair samples from 8 chronic PCP users for PCP metabolites, the major metabolite was *trans*-1-(1-phenyl-4-hydroxycyclohexyl)-4′-hydroxypiperidine (t-PCPdiol), whereas 1-(1-phenylcyclohexyl)-4-hydroxypiperidine (PCHP) was a minor metabolite as measured by GC/MS following acidic methanol extraction.[163] The concentrations of PCP, PCHP, and t-PCPdiol in the hair samples ranged from 0.33–14 ng/mg, 0.02–0.12 ng/mg, and 0.09–0.45 ng/mg, respectively.

Driving

Unlike blood–ethanol concentrations, blood PCP concentrations do not correlate well to a specific degree of impairment; the determination of impairment by blood PCP concentrations alone is difficult.[164] Physical evaluation helps confirm the degree of impairment suggested by the blood PCP concentration. In a group of 259 drivers arrested for driving under the influence, 120 blood samples were PCP positive (cutoff, 5 ng/mL) by GC/MS.[165] For the 55 individuals testing positive only for PCP and that were identified as impaired by drug recognition experts (DRE), the mean blood PCP concentration was 51 ± 26 ng/mL (range, 12–118 ng/mL). However, there was no dose-response relationship between the PCP concentration and the degree of impairment. Of the 129 individuals arrested for driving under the influence and testing negative for PCP, 4 (3%) were suspected by the DRE as being under the influence of PCP. In a case series of 50 PCP-intoxicated drivers arrested for driving under the influence (DUI), the blood PCP concentration ranged from 10–180 ng/mL with a similar lack of correlation between blood PCP concentration and the degree of impairment.[166] Urine PCP concentrations confirm exposure, but urine PCP concentrations do not correlate to impairment.

Abnormalities

Abnormalities associated with rhabdomyolysis during PCP intoxication include myoglobinuria, elevated serum creatine kinase, hyperuricemia, hypocalcemia, and

hyperphosphatemia along with renal dysfunction. Hypercalcemia may occur during the diuretic phase of acute renal failure induced by rhabdomyolysis associated with dramatic elevation of serum creatine kinase.[167] These changes typically occur 1–3 days after PCP intoxication develops, particularly in patients with severe agitation requiring restraints.[168] However, dramatic elevation of serum creatine kinase can occur in the absence of restraint.[167] Coagulopathies can develop during severe PCP intoxication associated with coma and hyperthermia, particularly during the terminal phase of excited delirium.[169] During PCP-induced coma, phencyclidine produces a characteristic electroencephalogram (EEG) pattern similar to deep ketamine anesthesia characterized by sinusoidal theta activity interrupted every few seconds by periodic slow-wave complexes.[170] These periodic complexes are unrelated to visual, auditory, or tactile stimuli during coma, but synchronization with repetitive stereotyped movements occurs on emergence. With neurologic recovery, symmetric, reactive 8.5 Hz alpha activity returns.

Neuropsychologic abnormalities present during PCP intoxication include severe impairment of symbolic cognition (e.g., proverb interpretation) and sequential thinking (e.g., serial sevens). Time distortion also occurs during PCP-induced psychosis with these patients consistently underestimating a 30-second time span.[171] Although some studies of chronic PCP users suggest impairment on neuropsychologic tests (abstraction, perceptual motor skills) when compared with national standards,[172] the question of neuropsychologic sequelae following chronic PCP use remains unresolved.

TREATMENT

Stabilization

The most serious early complications of PCP intoxication include coma, respiratory depression, seizures, and trauma to internal organs. Although relatively infrequent, respiratory depression and aspiration pneumonia may complicate the clinical presentation of PCP intoxication. All patients should be evaluated for adequacy of oxygenation with pulse oximetry, capnometry, and arterial/venous blood gases as needed. Although laryngospasm and prolonged duration of succinylcholine-induced paralysis are potential complications of PCP intoxication, intubation should proceed as required with rapid sequence intubation as determined by the physical examination and diagnostic testing. All comatose or catatonic patients should have IV access, IV naloxone (0.4 mg titrated up to 2 mg) if the concurrent use of opioids is suspected, bedside evaluation of glucose, cardiac monitoring, pulse oximetry, and vital signs including a rectal temperature. The patient should be examined for the presence of occult head and abdominal trauma with radiographic and computed tomography imaging performed as clinically indicated.

SEIZURES

Seizures are a relatively rare complication of PCP intoxication; seizures are usually responsive to IV benzodiazepines (diazepam 5–10 mg up to 30 mg, lorazepam 2–5 mg up to 10–15 mg). Continuing seizures necessitate an evaluation of oxygenation, electrolyte balance, acid–base status, blood glucose concentration, core temperature, and rhabdomyolysis. The persistence of seizures despite the administration of anticonvulsants may require rapid sequence intubation and neuromuscular blockade.

HYPERTHERMIA

Mild temperature elevation usually requires no treatment other than reduction of agitation with the use of benzodiazepines (e.g., lorazepam). Rapidly rising temperatures or temperatures exceeding 102–103°F (38.9–39.4°C) should be treated with standard cooling measures (i.e., evaporative cooling) and sedation as needed. Core temperatures above 105°F (40.6°C) require aggressive cooling measures including cooling blankets, ice packs to the groin and axilla, and ice baths with constant monitoring of core temperatures. Concurrent presence of persistent seizures and hyperthermia may require intubation and neuromuscular blockade with monitoring of the EEG. Although the similarity between PCP-associated hyperthermia and neuroleptic malignant syndrome suggest that dantrolene is a therapeutic option, there are no controlled clinical data to indicate that dantrolene controls the hyperthermia associated with severe PCP intoxication. Hyperthermic patients require daily monitoring of serum hepatic aminotransferases, serum creatine kinase, renal function, and appropriate coagulation studies (e.g. INR, aPTT, D-dimer, platelet count, fibrinogen) for disseminated intravascular coagulation at least during the first several days after the development of the hyperthermia.

HYPERTENSION

Hypertension associated with PCP intoxication is usually mild to moderate; complications from PCP-induced hypertension are rare. The elevation in blood pressure is usually self-limited, and the blood pressure typically returns to the normal range following resolution of the agitation with behavioral abnormalities

resolving within several hours. Standard drug treatment of hypertensive crisis (IV nitroprusside, IV labetalol, or esmolol) is appropriate when clinically indicated by the condition of the patient (e.g., presence of end-organ damage).

CARDIAC DYSRHYTHMIAS

Cardiac dysrhythmias are uncommon during PCP intoxication; the presence of dysrhythmias suggests underlying cardiovascular disease or the use of other drugs of abuse (e.g., cocaine, methamphetamine).

Gut Decontamination

The most common route of exposure to PCP is via the lungs; therefore, decontamination measures are usually unnecessary. Agitated and violent behavior during PCP intoxication often limits the use of gastric decontamination measures following the ingestion of PCP. The difficulty associated with the administration of activated charcoal to agitated patients restricts the usefulness of activated charcoal in this setting unless the patient is comatose and has a protected airway. Whole bowel irrigation may be appropriate for PCP body packers with retained packets, but there are inadequate data to determine the efficacy of this procedure in this circumstance.

Elimination Enhancement

The possibility of a significant enterohepatic circulation suggests that serial-activated charcoal may interrupt recirculation, but there are no data to confirm the efficacy of this procedure. Nasogastric suction theoretically removes the phencyclidine secreted into the acid environment of the stomach, but there are inadequate data to indicate that the amount of PCP removed by this technique is clinically significant. The recommendation for acid diuresis during PCP intoxication is based on the enhanced renal excretion of free PCP following reduction of the urine pH rather than clinical data. Although urinary acidification theoretically enhances the renal excretion of PCP by trapping PCP in the renal tubules, the kidney is not the major route of PCP elimination.[173] Additionally, the use of urinary acidification is associated with potentially serious complications (e.g., metabolic acidosis, exacerbation of myoglobin-induced renal failure). Consequently, the use of urinary acidification for PCP intoxication in *not* recommended for the treatment of PCP intoxication. Although there are few clinical data, the toxicokinetics (i.e., large volume of distribution, extensive biotransformation) of PCP indicate that hemodialysis and hemoperfu-

sion will not remove clinically significant amounts of PCP.

Antidotes

There are no specific antidotes for PCP intoxication.

Supplemental Care

Most patients with mild to moderate PCP intoxication can be discharged after their mental status returns to normal and physical examination demonstrates no evidence of significant trauma. Because the symptoms associated with PCP intoxication can wax and wane, patients should be observed at least until their mental status remains normal for several hours. Indications for hospitalization of patients with PCP intoxication include coma, respiratory distress, hyperthermia, seizures, rhabdomyolysis, and clinically significant trauma.

AGITATION

Intravenous diazepam (5–10 mg in an adult) or lorazepam (2–4 mg) are excellent pharmacologic options for the initial management of agitation associated with PCP intoxication. The latter drug may be administered intramuscularly if IV access is impracticable. Medicated patients should be observed for respiratory depression. Haloperidol (5–10 mg intramuscularly) is another option,[174] particularly if significant hypertension is present. Some authors prefer diazepam to haloperidol because of the potential risk of dystonic reactions, decreased seizure thresholds, and orthostatic hypotension associated with the administration of haloperidol, but there are no clinical trials to assess the difference in efficacy or complications associated with the use of these 2 drugs during PCP intoxication. Unexpected aggressive behavior can occur; the use of restraints and a coordinated show of force may be necessary to subdue the patient, along with sedation. Struggling patients in restraints should receive sufficient sedation to limit the agitation and reduce the potential for hyperthermia and rhabdomyolysis. Persistent, prolonged struggling during PCP intoxication may be associated with excited delirium and hyperthermia. Additional treatment measures involve isolation with a minimum of sensory stimuli (quiet room and few procedures) other than the measurement of body temperature. PCP-intoxicated patients do not respond well to attempts by concerned individuals to verbally calm (i.e., "talk-down") them, especially when these individuals are alone with the patient. Medical observation of the phencyclidine-intoxicated patient should continue until the patient remains symptom-free for several hours.

The urine of all patients with coma, toxic psychosis, catatonia, or acute brain syndrome should be evaluated for the presence of heme on the urine dipstick. Heme-positive urine samples that contain no red cells under microscopy should be considered positive for myoglobin, and a urine specimen evaluated for the presence of myoglobin. PCP-intoxicated patients with evidence of rhabdomyolysis should be hospitalized, and blood samples analyzed for serum creatine kinase, electrolytes, calcium, phosphorus, uric acid, and creatinine at least daily for several days. Myoglobinuria should be treated with adequate fluid replacement and the maintenance of good urine output, especially in the hyperthermic, diaphoretic, and agitated patient. In normovolemic patients with normal renal function, initial creatine kinase levels exceeding 14,000 IU/L suggests the need for IV furosemide (40 mg). Although there are limited clinical data, urinary alkalinization for myoglobinuria probably should not be used because of the decreased renal clearance of phencyclidine in alkaline urine. The presence of myoglobinuria is a contraindication to acid diuresis. Bronchospasm is treated with the usual bronchodilators (inhaled albuterol and ipratropium). Generalized muscle rigidity does not usually respond to diphenhydramine. Urinary catheterization may be necessary, particularly in comatose patients because of the increased incidence of urinary retention during PCP intoxication. The clinical presentation of major trauma may be occult because of the analgesia and altered consciousness associated with PCP intoxication. Therefore, each PCP patient should be carefully evaluated for signs of trauma.

Psychosis

Patients with PCP-induced psychosis should be managed in a quiet room with minimal external stimulation. Haloperidol and chlorpromazine are effective neuroleptic agents for PCP-induced psychosis. There are few clinical data on the adverse effects of these antipsychotic drugs during PCP intoxication including newer atypical antipsychotic drugs, but these reactions probably are similar to the treatment of chronic schizophrenia with the potential exception that PCP-intoxicated patients may develop hyperthermia as a result of the reduced ability to dissipate heat; drugs with anticholinergic effects (e.g., diphenhydramine) should be avoided in these patients.[175] The clinical response of patients with PCP-induced psychosis to haloperidol (i.e., dopamine DA_2 receptor antagonist) may be more effective than to chlorpromazine (i.e., mixed DA_1/DA_2 receptor antagonist) based on a clinical trial of 20 PCP-intoxicated patients.[176] Diazepam is a treatment option for the agitation associated with PCP-induce psychosis, and the use of diazepam or other benzodiazepines probably does not prolong phencyclidine toxicity. Physical restraints often are necessary to prevent self-inflicted trauma. Continuous sedation (e.g., IV midazolam or propofol drip) may be necessary to prevent additional muscle injury and rhabdomyolysis. Psychotic patients should be admitted to a psychiatric or medical facility after medical clearance for concomitant overdose and trauma.

PHENCYCLIDINE ANALOGUES

During the late 1970s, synthetic PCP analogues (TCP, PHP, PCC, ketamine) appeared in street samples. There are limited data to determine the incidence of the use of PCP analogues; however, analysis of street samples suggests that the use of PCP analogues is much less than PCP. There are over 30 PCP analogues with behavioral and pharmacologic effects similar, but less intense, than the effects of PCP. At least 6 analogs appear as illicit drugs including TCP (thiophene analog), PCE (*N*-ethyl analog), PHP (phenylcyclohexyl pyrrolidine analog), *N*-(1-phenylcyclohexyl)-propanamine (PCPR),[177] *N*-(1-phenylcyclohexyl)-2-methoxyethanamine (PCMEA), and *N*-(1-phenylcyclohexyl)-2-ethoxyethanamine (PCEEA).[178] Figure 34.1 displays the chemical structure of some analogs of PCP. Similar to illicit PCP synthesis, the use of volatile solvents during the synthesis of PCP analogues may cause explosions and/or fires in clandestine laboratories. Treatment of PCP analogue intoxication is symptomatic and supportive, similar to PCP.

Dizocilpine

MK-801 (dizocilpine, CAS RN: 77086-21-6) is a potent non-competitive antagonist at the *N*-methyl-D-aspartate (NMDA) family of glutamate receptors in the CNS that shares similar pharmacologic properties with phencyclidine and ketamine. This drug is commonly used as a NMDA receptor antagonist in pharmacological studies. Behavioral sensitization involves persistent enhancement of the locomotor stimulant, stereotypic, and positive reinforcing effects of drugs of abuse following repeated use. Cross sensitization is the enhancement of the effects of drugs of abuse following the use of another drug. Initial animal studies suggested that MK-801

prevented the development of behavioral and cross sensitization;[179] however, subsequent research indicated that the actions of this drug are complex.[180] MK-801 possesses reinforcing properties, induces behavioral sensitization to itself, and induces cross sensitization to other drugs of abuse.[181] A case report associated the death of a 45-year old man found dead with the intentional ingestion of an estimated 25 mg of this compound (heart blood, 150 ng/mL) along with ethanol (heart blood, 20 mg/dL) and diazepam (heart blood, 1,000 ng/mL) plus metabolites (nordiazepam, 1,100 ng/mL; oxazepam, 100 ng/mL; temazepam, 100 ng/mL) as measured by gas chromatography/mass spectrometry.[182]

Ketamine

Ketamine [2-(*o*-Chlorophenyl)-2-(methylamino)cyclohexanone] is a dissociative anesthetic, which is structurally similar to PCP and is marketed in the US under the name Ketalar®. Emergence psychosis (vivid imagery, hallucinations, disorientation, delirium) also occurs in adults after the use of ketamine as an anesthetic. The postanesthesia emergence reactions associated with ketamine are stereospecific with R(-)-ketamine having a stronger association with psychic disturbances. Additional risk factors for emergence reactions include age >16 years, female gender, people who frequently dream during sleep, IV doses of ketamine >2 mg/kg or IV administration rates exceeding 40 mg/min and a history of personality disorders. The effects are typically short-lived (<24 hours) and are not associated with any permanent personality changes. The *S*(+)-isomer is 3–5 times more potent as an anesthetic agent than the *R*(-)-isomer. There are inadequate data to determine if the risk factors associated with ketamine-induced anesthesia emergence are also risk factors for intensified psychic disturbance in PCP users.

1-(1-Phenylcyclohexyl) pyrrolidine (PHP)

1-(1-Phenylcyclohexyl)pyrrolidine (rolicyclidine, CAS RN: 2201-39-0) is a pyrrolidine analogue of PCP with similar adverse behavioral and physiological effects as PCP.[183] PHP is a DEA Schedule I drug. PHP is more difficult to detect in urine drug screens than PCP; determination of the presence of psychoactive phencyclidine analogues (e.g., PHP) requires more rigorous analytic

techniques (gas chromatography/mass spectrometry) than commercial immunoassays for PCP. Analytic methods to detect the presence of PHP include thin layer chromatography[184] and gas chromatography/mass spectrometry.[185] The use of the latter method resulted in the detection of 100 ng PHP/mL in postmortem blood from a 35-year old man shot by police while acting in a bizarre manner and resisting arrest. In a study of 20 patients with PHP-induced psychosis, the administration of 5 mg haloperidol intramuscularly was more effective as a sedative than placebo.[186]

1-(1-[2-Thienyl]cyclohexyl) piperidine (TCP)

1-(1-[2-Thienyl]cyclohexyl)piperidine (TCP, CAS RN: 1867-65-8) is a Schedule I substance in the United States that has been investigated in clinical trials for the treatment of traumatic brain and spinal cord injuries.[187] TCP is not usually an impurity in samples of illicit PCP as analyzed by gas chromatography/chemical ionization/mass spectrometry.[20] Rodent studies suggest that the toxicokinetics of PCP and TCP are similar. In rodent studies, the mean unbound TCP is $42 \pm 6\%$ and mean apparent volume of distribution is large $(27 \pm 17$ L/kg).[188] The clearance of TCP from the blood is rapid with a plasma elimination half-life of about 2 hours. Little (i.e., <1% administered dose) unchanged TCP appears in the urine. Animal data suggest that the physiological properties of TCP and PCP are probably similar in animals and humans, but the behavioral effects of TCP are less intense than PCP or other PCP analogues (dizocilpine, PCE, cyclohexamine).[189] TCP is a high-affinity, non-competitive antagonist of *N*-methyl-ᴅ-aspartate (NMDA) receptors that prevents ion influx through the associated channel. This compound is now the preferred radioligand for the displacement assays of PCP.[190] As measured by a test for ataxia (rotarod) in mice, TCP is about 30–50% more potent than PCP; however, the LD_{50} of TCP was about 1/3 lower than the LD_{50} of PCP.[191] In rodent studies, PCP and TCP have a similar number of high affinity binding sites, but there were twice as many PCP low binding sites as TCP low binding (PCP_3) sites.[192] The number of PCP and TCP high and low binding sites were similar in the cerebellum; however, the density of high binding sites in the cerebrum was 7 times higher than the cerebellum. Methods to detect PCP designer drugs include GC/MS in both electron ionization and positive-ion chemical ionization modes.[193]

Chapter 35

VOLATILE SUBSTANCE ABUSE

HISTORY

Although inhalants were used before the 1700s and chloroform parties were fashionable in the 19th century, medical reports of volatile substance abuse in the United States first appeared in the 1950s with descriptions of adolescents in remote areas sniffing gasoline as a substitute for ethanol.[1] Volatile substance abuse spread from California to the Midwest and the East Coast; the popularity of glue sniffing increased substantially by the mid-1960s. In the late 1970s, nitrite inhalation became a popular method of enhancing sexual pleasure in male homosexuals.[2] Case reports documented fatalities following the inhalation of volatile substances during acts of atypical autoeroticism.[3] Between 1975 and 1990s, the prevalence of inhalant use by US high school students increased, but the prevalence rate stabilized in the early 2000s.[4] During the last decade, inhalant use among females increased compared with males, but inhalant use among some high-use populations (e.g., American Indian adolescents, Mexican American youth) decreased.[5]

IDENTIFYING CHARACTERISTICS

Structure

The abuse of volatile substances involves pharmacologically diverse liquid or pressurized gas products, which contain a high portion of volatile chemicals that easily vaporize at room temperature.[6] These products are rarely single compounds; the major component in the vapor phase may not be the primary constituent of the liquid. Volatile solvents are the largest group of substances associated with inhalant use. Table 35.1 lists the types of chemicals and sources of substances involved with the abuse of volatile substances.

Physiochemical Properties

The amount of a chemical inhaled during volatile substance abuse depends on several factors including the vapor pressure of the compound, the method of abuse, the physical properties of the product, and minute ventilation. Almost all of the common substances associated with inhalant abuse are lipophilic. The release of vapors from viscous material (e.g., glues) is slower than pure liquids. Pressurized liquids (e.g., butane in cigarette lighter refills) can deliver almost all of the substance with little oxygen. At room temperature, one volume of liquid propellant generates up to 200–300 volumes of vapor.[7] Table 35.2 lists the maximum airborne concentrations of some common volatile substances at room temperature.

Terminology

The National Institute on Drug Abuse defines inhalant use as the deliberate inhalation of volatile substances to induce a psychoactive or mind-altering effect.[8] Table 35.3 lists some street terms associated with volatile substance abuse.

TABLE 35.1 Classification and Sources of Volatile Substances of Abuse.[32]

Class	Common Chemical	Some Sources
Aliphatic Hydrocarbons	Propane	Bottled fuel, aerosol propellants
	Butane	Cigarette lighter fluid, aerosol propellants
Alkyl Halides	1,1,1-Trichloroethane	Correction fluid, dry cleaning products, degreasing agent
	Trichloroethylene	Dry cleaning agent, degreaser, spot remover, PVC cement, gum remover
	Trichlorofluoromethane*	Refrigerant, aerosol propellant (hairspray, spray paint, deodorants, room freshener, medical drugs)
	Bromochlorodifluoromethane	Fire extinguisher
	1,1-Difluoroethane	Dust remover
	Dichloromethane	Paint stripper
Aromatic Hydrocarbons	Gasoline†	Automobile fuel
	Toluene	Adhesives, spray paint, glues, rubber cement, paint thinner, nail polish remover
	Xylene	Wood glues, lacquer thinner
Alkyl Nitrites	Amyl nitrite ("poppers")	Vasodilator
	Butyl nitrite, isobutyl nitrite	Room air freshener
Ethers	Diethyl ether	Laboratory solvent
Esters	Ethyl acetate	Nail polish remover, industrial solvent
Ketones	Acetone	Nail polish, solvent
	Methyl ethyl ketone (MEK)	Adhesives, general solvent
	Methyl n-butyl ketone	Paints
	Methyl isobutyl ketone	Spray paint

*Freon 11 is one of several Freon compounds used as propellants including Freon 12 (dichlorodifluoromethane), Freon 22 (chlorodifluoromethane), and Freon 114 (dichlorotetrafluoroethane).
†Blended product with many aliphatic, aromatic, and cycloalkane compounds as well as additives (methyl tertiary butyl ether, methylcyclopentadienyl manganese tricarbonyl, ethanol).

TABLE 35.2. Maximum Possible Air Concentrations of Some Volatile Compounds at Room Temperature (20°C/68°F).[6]

Compound	Physical State (20°C/68°F)	Maximum Vapor Concentration (mg/L)
Toluene	Liquid	121
Tetrachloroethylene	Liquid	136
Methyl Ethyl Ketone (MEK)	Liquid	324
Trichloroethylene	Liquid	426
Acetone	Liquid	635
1,1,1-Trichloroethane	Liquid	767
Dichloromethane	Liquid	1831
n-Butane	Gas	2412
Dichlorodifluoromethane	Gas	5033
Trichlorofluoromethane	Gas	5719

EXPOSURE

Epidemiology

Intentional inhalation of volatile substances is a worldwide problem, particularly common among youth.[9] Most epidemiologic data on the use of inhalants are derived from cross-sections studies; therefore, the lack of longitudinal studies limits conclusions about the normally episodic course of inhalant use. According to the 2000 and 2001 US National Household Surveys on Drug Abuse, about 3.4% US adolescents aged 12–17 years were inhalant users in the past year during the end of the 1990s, and 0.4% of the adolescent population met the criteria for inhalant use disorder during this time.[27] During the 2000s, the number of US persons aged 12 or older who had used inhalants for the first time within the past 12 months remained relatively stable at approximately 800,000.[10]

TABLE 35.3. Terms Associated with Volatile Substance Abuse.[1]

Term	Definition
Bolt, bullet, climax, locker room, rush	Small bottles butyl nitrite
Poppers, snappers	Ampules amyl nitrite
Whippets	Balloons or small bags nitrous oxide
Texas shoe shine	Toluene-containing shoe shine spray
Torch, fire-breathing	Ignition of exhaled flammable gases

Peak inhalant use occurs at age 14–15 years with use significantly declining at age 17–19 years; the onset of inhalant use is earlier when associated with juvenile delinquency. In a study of 285 adjudicated adolescents, the median age of first-time inhalant use was 13 years.[11] In 2005, about 72% of new volatile substance users between the ages of 12 years and 49 years were under the age of 18 years; the mean age of new inhalant users was 16.1 years.[12] By 2007, the mean age of new volatile substance users increased to 17.1 years and remained near 17 years at the end of the 2000s.[10]

The prevalence of inhalant abuse in certain parts of the population are particularly high. In a study of 723 Missouri adolescents in residential care for antisocial behavior, the prevalence of lifetime computer duster spray use was 14.7%.[13] Although inhalant abuse occurs in many demographic areas (rural, suburban, urban) and among all ethnic groups, inhalant abuse is more prevalent among a geographically isolated and socio-economically disadvantaged population. Such populations include American Indian and Alaska Native youth.[5] In a study of 376 Native Alaskan children aged 10–19 years of age living in 14 isolated villages in the Bering Strait, the reported use of inhalants at least once in this group was 48%.[14] Most inhalant use in this group was sporadic and occurred in social settings; the risk of progression to inhalant substance abuse disorders is highest with the first year of use and much lower thereafter.[15]

In the first decade of 2000, the prevalence of inhalant abuse among adolescents has been relatively stable with a slight decrease in inhalant use among youth aged 12–17 years between 2003 (4.5%) and 2007 (3.8%).[16] Progression from inhalant use to abuse or dependence was associated with early first inhalant use, use of multiple inhalants, and weekly inhalant use. The prevalence of mental illness, antisocial personality, multiple drug abuse, and criminal behavior was particularly high among adolescent inhalant users;[17,18] anecdotal reports associate volatile substance abuse with a variety of criminal behaviors.[19] These reports include a substantial number of cases of recidivism.[20] In a retrospective study

of data from about 73,000 respondents to the 2002 and 2003 US National Survey on Drug Use and Health, the prevalence of inhalant abuse and inhalant dependence among all adults using inhalants in the last year was 6.6% and 1.1%, respectively.[28] This study demonstrated that approximately 1 in 10 adults use inhalants as a psychoactive drug at least once in their lives; about 0.5% of the adult population used inhalants within the last year. Compared with the adult population, the prevalence of inhalant use within the past year was increased in young adults (aged 18–25 years), alcohol abusers, lifetime drug users, Asians, white women, and men with serious mental illnesses. In the young adults (i.e., 18–25 years old), 15% of this group reported inhalant use at least once in their lifetime, and 2% of this group used inhalants in the last year. Approximately 44% of the lifetime adult inhalant users initiated inhalant use after the age of 17 years. Inhalant use disorder was more frequent in adult inhalant users aged 35–49 years, particular in individuals with mental illness, suffer from alcohol abuse, or who had a poor education. The profile of the adult inhalant user is distinct from the adolescent inhalant user. Inhalant use in adults is less often associated with criminal activity than adolescent inhalant use, and these adults tend to use fewer inhalants less often than adolescents do.

Sources

The US National Institute on Drug Abuse classifies volatile substances of abuse in the following 4 categories: 1) volatile solvents (adhesives, cleaning fluids, correction fluids, felt-tip markers, gasoline and other fuels, glues, paint thinners, paint removers, shoe polish); 2) aerosols (household products, personal hygiene products, spray paint); 3) gases (butane lighters, propane tanks, refrigerants, medical anesthetics); and 4) nitrites (amyl nitrite, butyl nitrite, cyclohexyl nitrite).[21] Based on data reported to the Toxic Exposure Surveillance System (TESS) of the American Association of Poison Control Systems from 1996–2001, the top 5 volatile substances of abuse are gasoline (41%), paint (13%), propane/butane (6%), air fresheners (6%), and formalin (5%).[22] The type of inhalant abused varies with the population and time studied. In an analysis of inhalant abuse reported to TESS from 2000–2005, the top 5 volatile substances abuse categories in order of frequency were freon/propellant (15.4%), gasoline (11.4%), paint (9.4%), automotive hydrocarbons (8%), and propane (4.5%).[23] A majority (i.e., about 60%) of past-year inhalant users report the inhalation of multiple types of inhalants.[24] Updating of US Poison Control Center data indicated that propellants, gasoline, and paint remained the most popular volatile substances of abuse with only

TABLE 35.4. Inhalants Used during the Past Year by New Inhalant Adolescent Users.[12]

Type	%
Glue, shoe polish, toluene	30.3
Gasoline, lighter fluid	24.9
Nitrous oxide ("whippets")	24.9
Spray paints	23.4
Correction fluid degreaser, cleaning fluid	18.4
Amyl nitrite ("poppers"), locker room deodorizers ("rush")	14.7
Lacquer thinner, other paint solvents	11.7
Lighter gases (butane, propane)	9.4
Anesthetics (halothane, ether, etc.)	3.4

propellants increasing in popularity.[25] A majority of the propellants were computer or electronic dusters, frequently containing 1,1-difluoroethane. Butane, propane, and air fresheners had the highest fatality rates. Some subsets of the general population prefer specific volatile substances (e.g., nitrite inhalant use by homosexuals).[26] Female adolescents often prefer spray paints, correction fluid, glue and shoe polish, whereas male adolescents frequently use lighter fluid, gasoline, and nitrous oxide.[27] Nitrous oxide and amyl nitrite are the most frequently abused inhalants in adults.[28] Solvent abuse in industry is rare among solvent workers.[29]

Table 35.4 lists the specific type of inhalants most commonly used by first-time inhalant users between the ages of 12–17 years. Typically, products preferred by inhalant abusers contain a relatively high volume of propellants (e.g., topical analgesics, deodorants, fly sprays). Unpopular sources for inhalant abuse include natural gas (methane lacks narcotic properties) and petroleum distillates (most have limited volatility) with the exception of gasoline. The formulation of household products changes over time, and chemical analysis or current material data safety sheets (MSDS) are necessary to confirm the composition of these products.

Methods of Abuse

Methods of inhaling volatile substances include sniffing, snorting, bagging, and huffing. The most common method of volatile substance abuse involves the inhalation of vapors from original containers either through the nose (*snorting*, *sniffing*) or the mouth (*huffing*), primarily in a social setting.[30] Adhesives may be poured into a plastic bag and the vapors inhaled while the top of the bag is placed over the mouth and nose. *Huffing* is also a term for the inhalation of vapors from a rag saturated with the chemical and held over the face. Another method to intensify the effects of inhalants is the placement of small amounts of the volatile substance in a paper or plastic bag and covering the mouth and nose with the bag (*bagging*). Other methods of inhalant abuse include spraying the aerosol directly in the mouth or nose, inhaling vapors from a nearby surface (collar, cuff, fingernail), inhaling air-freshener aerosols (*glading*), and placing the canister straw of aerosol computer or personal electronics cleaning products directly into the mouth or nose (*dusting*). Occasionally, the chemical product is heated (e.g., glue) to increase volatilization, bubbled through water to remove irritants (e.g., aluminum chlorohydrate in antiperspirants), or combined with ethanol prior to inhalation.

DOSE EFFECT

Typically, 10–15 inhalations of a volatile solvent produce euphoria and subsequent drowsiness within seconds to minutes.[31] The rebreathing of exhaled air (e.g., *bagging*) causes hypoxia and hypercarbia that enhance the effect of the inhaled solvent.

TOXICOKINETICS

Absorption

The absorption of most chemicals associated with volatile substance abuse is rapid. Pulmonary uptake of these chemicals depends on a variety of factors including the concentration in inspired air, the air/blood and blood/tissue partition coefficients, ventilation, pulmonary blood flow, and the distribution of fat.

Distribution

Most substances associated with volatile substance abuse are lipophilic; consequently, these compounds distribute rapidly into lipid-rich tissues (e.g., brain, bone marrow, kidney, liver). The volume of distribution of most volatile substances is large because of high lipid solubility.

Biotransformation/Elimination

Most inhaled chemicals are rapidly excreted in the breath; metabolism occurs in the liver, primarily by the cytochrome P450 isoenzymes. Typically, metabolites are more polar and less volatile than the parent compound. The biotransformation of these chemicals produces more hydrophilic compounds that diffuse less easily across membranes, but the kidney excretes the metabolites more easily than the parent compounds. Although

metabolites are usually less toxic than the parent compounds, some toxic metabolites may form from volatile substances (e.g., carbon tetrachloride, chloroform, dichloromethane, *n*-hexane). The biotransformation of volatile substances involves both phase I (oxidation, reduction, hydrolysis) and phase II (conjugation with glucuronic acid, sulfate, amino acids, or acetate) reactions. The metabolic rate depends on age, health, dose, and the presence of other drugs.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

The exact mechanism of action of volatile substances used in inhalant abuse is not well-understood. Potential mechanism of action of volatile substances other than nitrites include the generalized slowing of axonal ion channel transport by alteration of brain membranes and the hyperpolarization of gamma-aminobutyric acid (GABA) receptors.[32] In animal models, the inhibition of the *N*-methyl D-aspartate (NMDA) receptor is a common mechanism of action for several commonly abused inhalants. Prolonged exposure modulates the expression of these glutamatergic receptor subtypes depending on the experimental model, the area of the brain studied, and the dose.[33]

Mechanism of Toxicity

Volatile substances of abuse are simple asphyxiants and pulmonary irritants. The inhalation of these chemicals causes varying degrees of hypoxia as a result of the displacement of oxygen and the subsequent decrease in the partial pressure of oxygen. Pulmonary irritation may cause bronchospasm and reduced oxygen exchange. Potential causes of death during inhalant use include ventricular fibrillation, respiratory depression, asphyxia, pulmonary aspiration of stomach contents, and trauma from risky behavior.

Postmortem Examination

The postmortem changes in the examination of patients dying suddenly from volatile substance abuse are usually minimal including passive congestion of the organs, cerebral edema, and pulmonary edema.[34] Evidence of tracheitis, bronchitis, or marked pulmonary congestion may be present, but these common features are nonspecific.[35] The presence of perioral eczema or the characteristic odor of volatile substances is frequently absent at postmortem examination.

CLINICAL RESPONSE

Illicit Use

Acute intoxication with volatile substances and ethanol is similar. Desirable effects of inhalant use include the rapid onset of a pleasurable sensory experience (*high*) followed by the swift resolution of the central nervous system (CNS) effects with minimal adverse symptoms. The immediate effects of inhaling vapors during volatile substance use are similar to early stages of anesthesia with an initial stimulatory phase involving lightheadedness, excitement, disinhibition, and impulsive behavior. Central nervous system symptoms begin within a minute of inhaling the vapors, and resolve within minutes after exposure ceases. However, the *high* can be maintained for hours by continual inhalation of the vapors.[36] As the dose of the inhalant increases, slurred speech, diplopia, dizziness, ataxia, and disorientation occurs similar to ethanol intoxication. Auditory or visual hallucinations may occur following the use of high doses of inhalants; the presence of terrifying hallucinations helps distinguish inhalant use from ethanol intoxication.[36] Without repeated use of the inhalant, the euphoria fades into drowsiness, sleepiness, and headache. Coma occurs rarely during volatile substance abuse. Adverse effects include mucous membrane irritation (rhinorrhea, salivation, sneezing, cough, conjunctival erythema, nausea, vomiting, abdominal pain) and irritation of the respiratory tract (dyspnea, wheezing).

Neurologic sequelae following inhalant use are relatively rare, and the appearance of neurologic abnormalities depends on a variety of factors including the type of substance abused, duration of use, and individual susceptibility.[37] Peripheral neuropathy following chronic volatile substance abuse is usually associated with the inhalation of *n*-hexane, particularly in association with exposure to methyl *n*-butyl ketone. Cranial nerve abnormalities are rarely associated with volatile substance abuse. Chronic heavy inhalant use is associated with behavioral changes including apathy, malaise, poor school grades, poor hygiene, and changes in social activity and acquaintances along with depression, irritability, hostility, and paranoia.[38,39] Stains or paint may appear on the clothing. Complications of chronic inhalant abuse include halitosis, conspicuous odor on the breath, weight loss, chronic rhinitis or epistaxis, ulcerations of nose or mouth, perioral or paranasal dermatitis with pyoderma (huffer's rash), and tremor.[40] Occasionally, mucosal burns result from the spraying of rapid-cooling aerosols directly into the mouth.

Fatalities

The most serious risk for inhalant abusers is sudden death, and most of these deaths occur in individuals under the age of 20 years, primarily in males.[41,42] Common compounds associated with these deaths include butane, fluorinated alkanes, 1,1,1-trichloroethane, trichloroethylene, and ether. Based on data from the Toxic Exposure Surveillance System (TESS) of the American Association of Poison Control Systems, the most common substances associated with fatalities following inhalant use were gasoline (45%), air fresheners (26%), and propane/butane (11%).[22] In 2009, the annual report of the American Association of Poison Control Centers' National Poison Data System listed 4 deaths in adults from intentional inhalation of volatile substances (butane, fire extinguisher vapors, fluorochlorocarbon propellants).[43] There were no reported deaths from deliberate gasoline inhalation. The risk of sudden death is not related to chronic volatile substance abuse as about one-third of the sudden deaths associated with inhalant use occur in first-time users of these substances.

Abstinence Syndrome

In general, volatile substances are not considered physically addictive, but the effects of volatile substances are strongly self-reinforcing and the chronic use of these substances may cause psychologic addiction.[44] The progression from inhalant use to dependence is associated with early first-time use, weekly inhalant use, use of multiple inhalants, polydrug use, comorbid psychiatric disorders, and delinquent behaviors.[24] Case reports of withdrawal following chronic volatile substance abuse are uncommon.[45] In a study of 162 community-recruited inhalant users as defined by using any type of inhalant >5 times, about 11% of the participants reported some withdrawal symptoms based on structured interviews.[46] The reported symptoms included headaches, nausea or vomiting, hallucination, tearing or rhinitis, anxiety, depressed mood, trembling, fatigue, and trouble concentrating.

DIAGNOSTIC TESTING

Analytic Methods

TECHNIQUES

Methods for the detection of volatile organic compounds in postmortem samples typically involve gas chromatography after extraction with static and dynamic headspace or pulse-heating and solvent extraction.[47] The typical limit of detection (LOD) for volatile substances using headspace gas chromatography is in the range of 0.1 mg/L for biologic samples.[48] Headspace gas chromatography with split flame ionization/electron capture detection is a relative simple analytic method for the screening of biologic samples for volatile substances. The most difficult compounds to separate with this analytic method are isobutane/methanol and paraldehyde/toluene.[49] Other techniques to detect volatile substances in biologic samples include capillary gas chromatography/ Fourier transform infrared spectroscopy. The LOD for the latter method ranges from 0.05–10 mg/L depending on the structure of the analyte.[50] Detection of inhalant abuse (e.g., toluene) with traditional urinary biomarkers (e.g., hippuric acid) may require at 10-fold dilution to maintain linearity and avoid contamination with standard analytic techniques.[51]

STORAGE

Samples should be stored in gas-tight, well-sealed, inert containers with minimal headspace. Some loss of volatile organic compounds may occur by evaporation during handling, storage, or analysis of biologic samples, resulting in reduced or nondetectable concentrations of these compounds.

Biomarkers

The ability to detect volatile substances in biologic samples depends on the time since inhalation, dose, and the handling and storage of the specimen. In a study of 125 samples of suspected exposure to volatile substances, headspace gas chromatography detected the substance or the metabolite in 87% of samples from volatile substance abusers when analysis occurred within 10 hours of exposure.[38] Detection of components of blended petroleum distillates is complicated by the low concentrations of these components even after exposure to massive amounts of gasoline vapors. Routine drug screens do not detect inhalant use. Detection of metabolites is useful for only a few volatile substances (e.g., toluene, trichloroethylene, xylene).[7]

Abnormalities

The chronic inhalation of vapors from household products (e.g., paint remover, some paints) containing methylene chloride may cause increased carboxyhemoglobin concentrations depending on the concentration of methylene chloride in the headspace above the substance. Despite the abuse of large doses of these products, the carboxyhemoglobin concentrations are usually relatively low (i.e., <10%).[52] A 14-year-old boy was found unconscious by his mother.[53] On admission to the

emergency department 1½ hours later, he was drowsy, but oriented with slurred speech and some euphoria. He was placed on 100% FiO$_2$, and his carboxyhemoglobin 4 hours after being found by his mother was 13%. He had no evidence of metabolic acidosis (arterial pH = 7.38, HCO$_3$ = 23 mEq/L); he recovered without sequelae. The inhalation of nitrites is associated with methemoglobinemia that may cause serious clinical effects (hypoxia, altered consciousness). Neuropsychologic testing of chronic adolescent inhalant users suggests some deficits in executive functioning compared with drug-using controls (cannabis); however, establishment of causation is limited by methodologic issues (reporting bias, confounding, acute drug effect, classification bias).[54]

TREATMENT

Stabilization

The treatment of the adverse effects of acute inhalant intoxication is primarily supportive, and symptoms of intoxication typically resolve within ~20 minutes after exposure ceases. The initial treatment of the acutely intoxicated patient involves stabilization of any cardiac or respiratory abnormalities. Patients with depressed consciousness should be monitored for adequacy of respiration, hypoxia, and rhythm disturbances. An intravenous (IV) line should be started and the patient placed on a cardiac monitor and pulse oximeter. Hypotension should be treated with fluid replacement and vasopressors as indicated. Although there are theoretic concerns that the use of vasopressors or bronchodilators (e.g., albuterol) potentially may induce dysrhythmias in these patients, there is no direct evidence that these complications occur during the treatment of inhalant abuse. The development of cardiac dysrhythmias should be treated with conventional antidysrhythmic drugs including the use of epinephrine as indicated during cardiopulmonary resuscitation and the correction of any hypoxia or hypokalemia. Seizures are treated with benzodiazepines; these patients should be evaluated for alternate causes (e.g., head trauma, infection, co-ingestion of seizure-inducing drugs) of seizures. The elimination of volatile substances associated with inhalant use is rapid, and the persistence of symptoms more than a few hours after the cessation of use suggests an etiology other than inhalant use.

Elimination Enhancement

The metabolism of most substances involved with inhalant use is rapid; methods to enhance elimination are usually unnecessary.

Antidotes

There are no specific antidotes for inhalant use with the exception of methylene blue for methemoglobinemia associated with nitrite abuse, high flow oxygen for the carboxyhemoglobin associated with exposure to dichloromethane, and sodium bicarbonate and potassium for certain renal tubular syndromes.

Supplemental Care

INTOXICATION

Routine laboratory tests include complete blood count, serum electrolytes, blood urea nitrogen, blood glucose, serum creatinine, serum hepatic aminotransferases, urinalysis, and urine drug screen for the concomitant use of other drugs of abuse. Chest x-ray, arterial blood gases, and carboxyhemoglobin concentrations should be obtained following exposure to dichloromethane.

ADDICTION

There are limited data on the treatment of inhalant abuse. Consequently, treatment involves the application of methods used to treat other addictive disorders including multisystem and family therapy, 12-step facilitation, motivational enhancement techniques, and cognitive-behavioral therapy.[30]

A   Anesthetics

Chapter 36

CHLOROFORM

HISTORY

Chloroform and ether were popular euphoriants in the 19th and early 20th centuries. In 1831, Dumas first prepared chloroform, and he purified this substance by 1834. Both chloroform and ether were introduced as anesthetics in 1847. James Simpson, Professor of Midwifery at the University of Edinburgh, published a report in that year on the use of chloroform for general anesthesia.[1] He previously used ether to relieve the pain associated with childbirth, but he was dissatisfied with the technical difficulties (respiratory irritation, unpleasant odor, slow induction/prolonged recovery) and gastrointestinal effects associated with the use of ether.[2] Soon thereafter, a druggist apprentice intentionally became intoxicated by inhaling chloroform vapors, and he subsequently died.[3] Queen Victoria received chloroform for the birth of her eighth child, Prince Leopold, in 1853.[4] Fatalities and complications (cardiac dysrhythmias, hepatotoxicity) from the use of chloroform-induced general anesthesia were reported during the 19th century, resulting in the general preference for ether-induced anesthesia.[5] The first recorded death from chloroform anesthesia occurred in 1848, when a 15-year-old girl died suddenly shortly after receiving chloroform for the removal of an infected toenail. Various authors attributed her death to several factors including an overdose, fatal dysrhythmia, aspiration of food, and complications of the use of water and brandy to revive her; however, review of the data indicated that a definitive conclusion regarding the cause of death was not possible with the available data.[6] Chlorodyne was a popular narcotic that was formulated in 1846 by Dr. John Collis Browne.[4] This patent medicine contained chloroform, morphine tincture of Indian hemp (cannabis), prussic (hydrocyanic) acid, and other substances. In the US medical literature, Schneck reported the chronic inhalation of chloroform for euphoriant effects in 1945.[7] In the same year, Heilbrunn et al collected 29 cases from the medical literature dating back to 1830; he suggested that chloroform addiction resembled chronic alcoholism.[8] Clinical effects reportedly associated with chloroform addiction included emaciation, depression, anxiety, irritability, delusions, hallucinations, tremors, and paresthesias.

IDENTIFYING CHARACTERISTICS

Chloroform is a simple trihalogenated compound (Figure 36.1). This compound is a colorless, volatile liquid with a sweet, burning taste and characteristic odor. Chloroform (CAS RN: 67-66-3, trichloromethane) possesses moderately high vapor pressure, high lipid solubility, and a slight, but comparatively greater, solubility in water compared with other haloalkanes. Table 36.1 displays some physiochemical properties of chloroform. This compound also has irritant effects on the skin, conjunctiva, and mucous membranes.

EXPOSURE

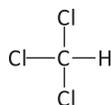
The abuse of chloroform is relatively rare. In some alcohol abusers, the habitual use of chloroform is a substitute for ethanol. Chloroform abusers equate sniffing chloroform with a stiff drink of whiskey or paraldehyde, and the use of chloroform is associated with feelings of tranquility and exhilaration, a sense of well-being ("world seems rosier"), and an inclination to daydream.[7]


FIGURE 36.1. Chemical structure of chloroform.

TABLE 36.1. Physiochemical Properties of Chloroform.

Parameter	Value
Density	1.48 g/mol
Water Solubility	7.5–9.3 g /L (20°C/68°F)
Viscosity	5.63 millipoises (20°C/68°F)
Boiling Point	61.2°C/142.2°F
Odor Threshold	50–200 ppm
Vapor Pressure	159.6 mm Hg (20°C/68°F)
	199 mm Hg (25°C/77°F)
Vapor Density	4.1 (Air = 1)
Surface Tension	27.1 dynes/cm (20°C/68°F)
Relative Evaporation Rate	11.6 (Butylacetate = 1)
Flash Point	None
Air Partition Coefficient	
Blood	10.3
Water	3.5
Oil	401

With continued chloroform use, drowsiness, irritability, and eventually sleep occur.

DOSE EFFECT

There are few data on plasma chloroform concentrations during the abuse of chloroform. Vertigo, fatigue, and nausea develop in volunteers following inhalation of 1,000 ppm chloroform for several hours; dizziness and salivation occur after exposure to approximately 1,500 ppm for several minutes. Lightheadedness, near syncope, and vomiting appear soon after exposure to 4,000 ppm chloroform. Concentrations of 10,000–20,000 ppm produce anesthesia, but higher levels are associated with an increased incidence of cardiac dysrhythmias and hypotension.[9] In patients breathing spontaneously, 2–2.5% chloroform is necessary for adequate surgical anaesthesia.[10]

TOXICOKINETICS

Absorption

The uptake of chloroform by the pulmonary vasculature depends on the ventilatory rate and the solubility of chloroform (i.e., blood–gas partition coefficient) as well as the inspired chloroform concentration. In a study of 16 patients undergoing surgical anesthesia with chloro-

form, the initial uptake of chloroform was rapid with a plateau after 40–50 minutes.[10] The arterial concentration reached approximately 25% of the inspired concentration in a patient breathing spontaneously after ~1 hour of exposure.

Distribution

Absorbed chloroform rapidly distributes into the tissues based on lipid content and on the blood partition coefficients of individual tissues. The highest concentrations of chloroform appear (i.e., highest first) in fat, brain, kidney, and blood.[11] Hydrophobic sites on blood proteins (e.g. hemoglobin) are probably the main carriers of circulating chloroform.[12]

Biotransformation/Elimination

The oxidative cytochrome P450 pathway in the liver is the principal site of chloroform metabolism. The major end products of chloroform metabolism are carbon dioxide and chloride ion with phosgene identified as an intermediate precursor metabolite from *in vitro* studies via spontaneous dehydrochlorination of trichloromethanol.[13] The primary cytochrome P450 isoenzymes involved with the metabolism of chloroform at lower concentrations are CYP2E1 and to a lesser extent by CYP2A6. The importance of the latter isoenzyme increases following the saturation of CYP2E1-mediated reactions.[14] The biotransformation of chloroform at high concentrations also involves CYP2B1.[15]

Detoxification of phosgene occurs either via reaction with water to produce carbon dioxide or via conjugation with thiols (e.g., glutathione, cysteine). Human studies indicate that metabolism is dose dependent. The elimination of chloroform is rapid.[10] Figure 36.2 displays the elimination of chloroform in 8 patients receiving chloroform anesthesia.

Maternal and Fetal Kinetics

There are few humans data on maternal or fetal kinetics of chloroform. In animal studies, chloroform diffuses across the placental barrier, but fetal uptake is low, primarily as a result of the low fat content in the fetus.[16] Based on these animal studies, there is minimal accumulation of chloroform in the fetus.

Drug Interactions

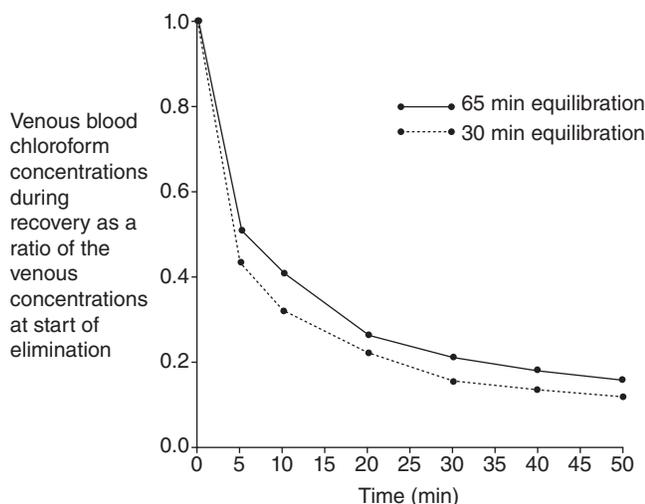
There are few data in humans on drug interactions during chloroform abuse. The simultaneous exposure of chloroform and central nervous system (CNS) depressants would be expected to cause additive or synergistic effects.


FIGURE 36.2. Elimination of chloroform from central venous blood in 4 patients after receiving 30 minutes of chloroform anesthesia (broken line) and in another 4 patients after receiving 65 minutes of chloroform anesthesia (solid line) as a ratio to the central venous blood at the start of elimination. (Reprinted from N Poobalasingham, JP Payne, The uptake and elimination of chloroform in man, British Journal of Anaesthesia, 1978, Vol. 50, p. 327, by permission of Oxford University Press.)

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

The major target organs of chloroform toxicity are the liver and kidney based on animal studies. The hepatotoxicity of chloroform probably results from the cytochrome P450-dependent production of reactive metabolites (e.g., phosgene) that covalently bind to cellular lipids and proteins.[17,18] At the high chloroform concentrations present during abuse, this compound is a central nervous system (CNS) depressant that may cause respiratory arrest and subsequent hypoxia. Similar to other volatile anesthetic agents, chloroform produces vascular dilatation both by direct effects on the vessels and by depression of the vasomotor center.[9]

Postmortem Examination

Typical pathologic findings during autopsies include submucosal hemorrhage, hyperemia and erosion of the trachea, esophagus, and stomach along with marked congestion of various organs including the lungs and brain. A 39-year-old woman with a history of inhaling chloroform monthly for 7 years died shortly after the inhalation of chloroform from a saturated towel.[19]

Postmortem examination demonstrated a few petechiae in the conjunctiva, moderate submucosal hemorrhage in the trachea and esophagus, mild to moderate edema of the lungs with alveolar hemorrhage, moderate vacuolar degradation of the endocardium, and moderate focal fragmentation of the myocardium. Schmorl staining demonstrated large numbers of lipofuscin pigments in the myocardium and focal lipofuscin pigmentation around the central veins of the liver. A 33-year-old man died of diphtheria after a 12-year addiction to chloroform.[8] The postmortem examination demonstrated moderate pathologic changes in the putamen (lipofuscin in a reduced population of large ganglion cells) and cerebellum (reduced Purkinje cells with poor staining). The autopsy of an elderly woman found dead after inhaling chloroform demonstrated marked pulmonary edema and extensive contraction band necrosis of the cardiac muscles.[20]

CLINICAL RESPONSE

Chloroform is a CNS depressant and anesthetic that causes respiratory depression, altered consciousness, coma, and dysrhythmias. A 23-year-old chemistry student was found unresponsive with respiratory distress.[21] A bottle of laboratory-grade chloroform was next to his bed. In the emergency department, he was reactive only to deep painful stimuli, mitotic, mildly acidotic (pH = 7.26), and hypoxemic (pO$_2$ = 51 mm Hg on 70% O$_2$). His respiratory insufficiency necessitated intubation and ventilatory support. He was extubated on the second hospital day; subsequently, he developed nausea, anorexia, jaundice, and mild intravascular hemolysis (serum free haptoglobin = 29.9 mg/dL with normal <10 mg/dL). Large ingestions of chloroform are associated with hepatotoxicity manifest by elevated serum hepatic aminotransferases, hyperbilirubinemia, jaundice, and hypoprothrombinemia with peak effects occurring about 3–6 days after exposure.[22,23] Chloroform is an irritant of the gastrointestinal tract that causes chest pain, abdominal pain, nausea, and vomiting after ingestion.

Withdrawal symptoms following chronic chloroform abuse are occasionally reported in the medical literature. An emaciated 33-year-old man with chloroform addiction (1–2 ounces daily for 12 years) developed a seizure, hallucinations, and paranoia 3 days after cessation of chloroform use in the hospital.[8] Additionally, he had pronounced cerebellar signs (dysarthria, ataxia, coarse intention tremor, positive Romberg's sign, nystagmus, past-pointing). These cerebellar signs gradually diminished over 6 weeks, but he died of diphtheria.

DIAGNOSTIC TESTING

Analytic Methods

Analytic techniques for the determination of chloroform are similar to other volatile drugs of abuse including headspace gas chromatography with flame ionization detection[24] and headspace solid-phase microextraction followed by gas chromatography/mass spectrometry (GC/MS).[25] Potential causes of perimortem and postmortem loss of chloroform from the body include prolonged resuscitation, improper storage in poorly sealed containers, and long postmortem interval. Chloroform concentrations rapidly decline during storage at room temperature. Over 1 week, chloroform concentrations in glass containers decreased over 80% compared with about 10% at 4°C (39.2°F) and approximately 2% at –20°C (–4°F) as measured by headspace GC/MS.[26] By 1 month, little chloroform remained in the glass bottles stored at room temperature, whereas approximately 60% of the original chloroform concentration remained in the glass vials stored at 4°C (39.2°F). Over approximately 1 year, ~58–65% of the chloroform in glass bottles stored at 4°C (39.2°F) was lost.[27]

Biomarkers

Experimental studies indicate that chloroform may be detected in formalin-fixed tissues at least 14 days after death. A 14-day study of rabbits compared the chloroform concentrations in tissues fixed in formalin immediately after death with chloroform concentrations in unpreserved tissues collected at the same time.[28] Two days after death from a mixture of ether, chloroform, toluene, and ethanol, the chloroform concentrations in formalin-fixed brain and liver tissues were 54% and 73%, respectively, of the chloroform concentrations in unpreserved samples analyzed immediately postmortem. Over the next 12 days, the concentrations of chloroform in the formalin-fixed brain and liver tissues declined to 22% and 17%, respectively, of the concentrations in unpreserved tissues. *In vitro* studies of human erythrocytes exposed to 500 ppm chloroform for 2 hours suggest that the average whole blood/plasma ratio of chloroform is about 3.[12] There are few data on serum chloroform concentrations following exposure. A comatose 19-year-old man with stable vital signs survived the ingestion of 75 mL chloroform after intubation and treatment with *N*-acetylcysteine. He developed mild hepatocellular toxicity; his serum chloroform concentration on admission was 91 mg/L.[22]

BLOOD

ILLICIT USE.   Based on the blood/gas partition coefficient of chloroform, the chloroform concentration at equilibrium after inhaling 1% chloroform is 367 mg/L.[10] In patients undergoing surgical anesthesia with chloroform, the mean chloroform concentration in arterial samples from patients receiving 1 hour of 1% chloroform via artificial ventilation was about 150 mg/L compared with approximately 230 mg/L for surgical patients spontaneously breathing 2–2.5% chloroform. Patients regained consciousness when the chloroform concentrations in venous samples were between 20–40 mg/L.

OVERDOSE.   Ten hours after accidental ingestion, the chloroform concentration in a blood sample from a 19-year-old adolescent was 200 mg/L.[29] At that time, the patient was comatose and intubated for respiratory insufficiency.

POSTMORTEM.   A 26-year-old man was found dead with evidence of the use of chloroform during autoerotic activities.[25] Postmortem heart blood, adipose tissue, and brain specimens contained chloroform concentrations of 150.6 mg/L, 79.4 mg/L, and 107.4 mg/L as determined by headspace solid-phase microextraction and GC/MS. A 39-year-old woman had a cardiopulmonary arrest shortly after inhaling chloroform vapors, and she was pronounced dead after 30 minutes of cardiopulmonary resuscitation.[19] The heart blood drawn about 9 hours after her death contained a chloroform concentration of 32.5 ± 0.9 mg/L. Analysis of heart blood drawn 30 hours and 36 hours after the suicides of an elderly couple demonstrated chloroform concentrations of 29.1 mg/L and 41.4 mg/L, respectively, as measured by headspace gas chromatography with flame ionization detection.[20] Postmortem blood from this couple did not contain clinically significant concentrations of any other drugs.

Abnormalities

Abnormalities of hepatic and renal function may occur following exposure to high concentrations of chloroform. Serum hepatic transaminases peak approximately 3–4 days following exposure and return to normal within 6–8 weeks.[30] In general, the alteration of serum hepatic aminotransferase concentrations and prothrombin times are greater than changes in serum bilirubin or alkaline phosphatase concentrations.

TREATMENT

Respiratory depression and cardiac dysrhythmias represent the immediate life-threatening complications of

chloroform exposure; immediate attention should be directed towards the maintenance of ventilation and blood pressure with intubation, mechanical ventilation, intravenous (IV) fluids, and cardiac monitoring as indicated by history and physical examination.[30] Methods to enhance elimination of chloroform have not been studied. Although no antidotes have been studied for the treatment of chloroform intoxication, the depletion of glutathione stores suggest that *N*-acetylcysteine may be effective similar to poisoning with carbon tetrachloride. However, there are limited clinical data at the present time to support the use of *N*-acetylcysteine in this situation. A 19-year-old man survived the ingestion of 75 mL chloroform without developing severe liver failure after treatment with standard IV doses of *N*-acetylcysteine (150 mg/kg over 1 hour, then 50 mg/kg over 4 hours followed by an IV drip at 6.25 mg/kg/h until a decline in serum hepatic aminotransferases).[22] If severe hepatorenal dysfunction develops, supportive care includes the treatment of renal failure with dialysis and hepatic failure with fresh frozen plasma, vitamin K, low protein diet, neomycin, lactulose, and careful fluid and electrolyte balance. Hepatic and renal function should be followed daily for at least 3 days after serious exposure to chloroform.

Chapter 37

ETHERS

DIETHYL ETHER

HISTORY

The effects of diethyl ether (ether) on the level of consciousness were probably known for centuries before the first documented use of ether in anesthesia in the middle of the 19th century. Paracelsus observed the anesthetic effects of ether on chickens in the 16th century with no apparent harm.[1] The exhilarating effects of inhaled diethyl ether vapors ("ether frolics") have been known since soon after the synthesis of ether in the early 19th century.[2] After Faraday demonstrated that diethyl ether had similar anesthetic properties as nitrous oxide in 1815, ether-parties (ether-jags) became popular both in Europe and in the United States. In the 1830s, ladies in Philadelphia would vaporize a little ether in a bladder; for amusement, they would then inhale the vapors from a tube with a stopcock.[3] Dr. Crawford W. Long used diethyl ether during the first surgical anesthetic procedure in 1842.[4] Shortly thereafter, physicians began dispensing diethyl ether in water as a nonalcoholic libation. In Germany, Hoffmann's drops (1 part diethyl ether to 3 parts alcohol) were a treatment for feeling depressed, whereas *perles d'éther* gelatin capsules were a "morning pick-me-up" for French ladies in high position. Before 1846, diethyl ether was widely available from dealers in pharmaceuticals; recognized effects of this compound included exhilaration and dulling of the senses. Morton first successfully demonstrated diethyl ether anesthesia in the Bullfinch Operating Theater at the Massachusetts General Hospital in October 1846.[5] The use of diethyl ether anesthesia quickly spread across the United States and to the United Kingdom.[6,7] Ether anesthesia typically was delivered by dropping the liquid from a suitable bottle unto a wire frame covered with gauze (Schimmelbusch mask). Later advances included vaporization of ether in a glass container by the flow of air or oxygen (draw-over vaporizer). The major problem with these devices was the difficulty delivering a constant amount of anesthetic because vaporization cooled the liquid (latent heat of vaporization). In general, diethyl ether anesthesia was not widely accepted because of the anesthesia risks resulting in part from the need for frequent adjustments of the anesthetic and religious beliefs that pain resulted from Divine Will as a means to understand suffering, insight, meaning, and salvation.

As the illegal distillation of alcoholic spirits (*poteen*) became more difficult in Ireland, diethyl ether drinking became a substitute for alcoholic beverages in the latter half of the 19th century.[8] The immediate effects of diethyl ether were considered similar and more rapid than ethanol.[9] Adverse effects were also similar including hangover (headache, nausea, malaise), cough, mid-epigastric distress, and gastrointestinal reflux. In 1890, the British government classified diethyl ether as a poison, and the sale of diethyl ether was severely limited. More sophisticated diethyl ether drinkers switched to morphine (morphia), which was more readily available and did not have the unpleasant smell associated with the use of diethyl ether. However, diethyl ether remained popular as an alternative to alcohol in lower economic areas of Ireland, East Prussia, Norway, Russia, France, and Hungary.[3] Diethyl ether dependence was first reported in the latter 19th century; the abuse of diethyl ether remains an uncommon form of volatile substance abuse.[10]

H₃C⌒O⌒CH₃
FIGURE 37.1 Chemical structure of diethyl ether.

TABLE 37.1. Some Physiochemical Properties of Diethyl Ether.

Physical Property	Value
Melting Point	–116°C (–178.6°F)
Boiling Point	34.5°C (94.1°F)
log P (Octanol-Water)	0.89
Water Solubility	6.04E + 04 mg/L (25°C/77°F)
Vapor Pressure	538 mm Hg (25°C/77°F)

IDENTIFYING CHARACTERISTICS

Diethyl ether (CAS RN: 60-29-7, ether) is an oxygenated hydrocarbon (Figure 37.1). Diethyl ether is a highly flammable, volatile liquid at room temperature that is relatively insoluble in water. The molecular formula is $C_4H_{10}O$ and molecular weight is 74.12 g/mol. This chemical is not readily ionizable (pKa = –3.59). Table 37.1 lists some of the physiochemical properties of diethyl ether.

The relative high blood/gas solubility of diethyl ether results in slow induction and prolonged recovery from anesthesia. The potency of diethyl ether is relatively low compared with modern inhaled anesthetics; additionally, diethyl ether is a respiratory irritant.

EXPOSURE

The abuse of diethyl ether is relatively rare, and the intentional inhalation of this ether for euphoriant effects usually occurs in the setting of polydrug use (e.g., ethanol). Methods of abuse include both the inhalation of vapors and ingestion. Diethyl ether abuse remains a rare cause of death.[11] Case reports document the inhalation of diethyl ether vapors by soaking a pad with ether and holding the ether-soaked pad by the knees while lying in bed.[12] Over the course of a few hours, the vapors are inhaled until the user becomes unconscious. After sleeping several hours, the user awakens with a sense of elation and hypomania. This phase is followed by a depressive phase that is associated with agitation, irritability, and restlessness. This process is repeated numerous times during the day.

DOSE EFFECT

Following chronic abuse of diethyl ether, daily use of this ether may increase to 0.5–1 liter.[10] In animal studies (e.g., dogs), the administration of 2–2.5 times the

minimum alveolar concentration (MAC) of diethyl ether causes apnea.[13] The mean MAC for this ether in a study of rabbits was about 2.7% ± 0.2%.

TOXICOKINETICS

The absorption of diethyl ether is relatively rapid, and this compound is distributed quickly to the tissues. Hydrophobic sites on blood proteins (e.g., hemoglobin) are probably the main carriers of this ether in the blood.[14] Elimination is also relatively rapid with the lungs excreting the vast majority (i.e., >90%) of an absorbed dose into expired air unchanged. The primary metabolic pathway probably involves the cleavage of ether to acetaldehyde and ethanol followed by oxidation to acetate via cytochrome P450 isoenzymes.[15,16] The formation of acetaldehyde varies substantially between individuals.[17] The urine contains minor amounts of unchanged diethyl ether. The use of escalating doses of diethyl ether during volatile substance abuse indicates the presence of tolerance in the chronic ether abuser.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

Diethyl ether is a central nervous system (CNS) depressant similar to other inhaled anesthetics. Experiments in animals suggest that the acute intoxication produced by abused volatile inhalants (e.g., diethyl ether, toluene, 1,1,1-trichloroethane, halothane) and ethanol is similar. Ether is a relatively safe anesthetic because respiratory depression occurs before serious cardiac depression; subsequently, the depth of anesthesia decreases with progressive respiratory depression without supplemental respiratory support.[18] In mice, subanesthetic concentrations of diethyl ether cause ethanol-like discriminative stimulus effects greater than other common anesthetics (i.e., desflurane, isoflurane, enflurane).[19] Animal studies also indicate that diethyl ether activates the hypothalamic–pituitary–adrenal axis similar to physical stressors (e.g., cold, electric shock); thus, ether is used as a research tool to study hormonal parameters associated with stress.[20]

Postmortem Examination

Similar to other volatile substances of abuse, case reports associate the chronic abuse of diethyl ether with fatalities. Typically, these cases involve an individual found dead with evidence of volatile substance abuse.[21] The postmortem findings are nonspecific including

passive congestion of the organs, pulmonary edema, and cerebral edema.

CLINICAL RESPONSE

The high solubility of ether in the blood and tissues results in a slow induction and prolonged recovery from anesthesia compared with newer anesthetics. Clinical effects of diethyl ether intoxication include euphoria, blurred vision, ataxia, lightheadedness, visual illusions, and hallucination. Adverse effects following the intentional inhalation of ether include headache, nausea, and cough. The odor of diethyl ether is commonly present during the chronic use of this compound. Although the classical effects of addiction develop during the chronic abuse of diethyl ether, physical withdrawal symptoms do not usually occur following the cessation of ether use.

DIAGNOSTIC TESTING

Analytic Methods

Techniques to quantitate diethyl ether concentrations in blood include gas chromatography (head space or direct injection)[22] and headspace capillary gas chromatography/mass spectrometry.[23] The limit of detection and lower limit of quantitation for diethyl ether using the latter method are ~2 mg/L and 7 mg/L, respectively. In a stoppered grey-top tube (1% sodium fluoride, 0.2% potassium oxalate) stored at 3°C (37.4°F), diethyl ether concentrations of 100–5,000 mg/L remained stable in blood samples for 2 months.[24]

Biomarkers

Experimental studies indicate that diethyl ether may be detected in formalin-fixed tissues at least 14 days after death. A 14-day study of rabbits compared the concentrations of ether in tissues fixed in formalin immediately after death with concentrations in unpreserved tissues collected at the same time.[25] One day after death from a mixture of diethyl ether, chloroform, toluene, and ethanol, the diethyl ether concentrations in formalin-fixed brain and liver tissues were 22% and 13%, respectively, of the concentrations in unpreserved samples analyzed immediately postmortem. Over the next 13 days, the concentrations of diethyl ether in the formalin-fixed brain and liver tissues declined only slightly compared with the diethyl ether concentrations in the unpreserved tissues. *In vitro* studies of human erythrocytes exposed to 500 ppm diethyl ether for 2 hours indicate that the average whole blood/plasma ratio of diethyl ether is about 1.8.[14]

Typical plasma diethyl ether concentrations during surgical anesthesia range between 500–1,500 mg/L with deep surgical anesthesia occurring at ~1,200 mg/L.[26] Analgesia is associated with plasma diethyl ether concentrations in the range 100–500 mg/L. A 20-year-old man was found unresponsive in his dormitory room with 2 black plastic trash bags secured over his head by a rubber band.[27] Two saturated rags and a clear resealable bag containing diethyl ether were found inside the black trash bags. The postmortem heart blood and peripheral blood contained diethyl ether concentrations of 319 mg/L and 304 mg/L, respectively. A 49-year-old was found dead with a plastic bag over his head and a towel soaked with ether inside the plastic bag.[28] The postmortem blood diethyl ether concentration was 1,277 mg/L.

Driving

Experimental studies indicate that evidential breath analyzers detect only very low concentrations of diethyl ether, depending on the type of analyzer. Interference of diethyl ether with ethanol determination occurs primarily with infrared analyzers exclusively using the 9.5-μm region.[29] A simulated test of the inhalation of 0.044 mg diethyl ether/L was associated with a 4% increase in the estimated breath ethanol concentration.[30]

TREATMENT

Similar to other inhaled anesthetics, respiratory depression and cardiac dysrhythmias potentially represent the most immediate life-threatening complications of diethyl ether exposure; immediate attention should be directed toward maintenance of ventilation and blood pressure with intubation, mechanical ventilation, intravenous fluids, and cardiac monitoring as indicated by the history and physical examination. The lungs excrete most of the absorbed dose of diethyl ether unchanged; consequently, there are no methods to enhance elimination.

DIMETHYL ETHER

HISTORY

In 1867, Richardson investigated the anesthetic properties of dimethyl ether in rabbits and pigeons; later he successfully used this compound as an anesthetic agent in humans.[31] Although he considered dimethyl ether an

effective anesthetic agent, this compound was never accepted as a reliable anesthetic drug. In the early 1920s, Brown obtained adequate anesthesia with 65% dimethyl ether in cats, and the administration of 85% dimethyl ether produced profound anesthesia with respiratory arrest.[32] Undesirable properties of dimethyl ether included a feeling of suffocation during induction, excessive salivation, and persistent muscle activity during anesthesia. In 1925, Davidson reported the effects of dimethyl ether anesthesia in humans.[33] The administration of 20% dimethyl ether produced unconsciousness within 17 minutes, but prolonged recovery from the depressant effects of the anesthesia occurred after cessation of administration.

IDENTIFYING CHARACTERISTICS

Dimethyl ether (CAS RN: 115-10-6, methyl ether, MW 46.07 g/mol) is a colorless, inflammable, water-soluble gas with an unpleasant odor resembling chloroform. The molecular formula of dimethyl ether is C_2H_6O; the chemical structure is displayed in Figure 37.2. Table 37.2 lists some physiochemical properties of dimethyl ether. This compound is used as a liquid refrigerant, solvent, aerosol dispersant, rocket fuel, and method to rapidly freeze meat and fish. Dimethyl ether was considered as a substitute for liquid petroleum gas because the physical properties of these 2 compounds are similar. In experimental studies, dimethyl ether produces an explosion more intense than propane with a detonation concentration of 5.5–9.0%.[34]

EXPOSURE

Dimethyl ether is a compound in common household aerosol, spray, and liquid products including arts and

$$H_3C \diagdown O \diagup CH_3$$
FIGURE 37.2. Chemical structure of dimethyl ether.

TABLE 37.2. Some Physiochemical Properties of Dimethyl Ether.

Physical Property	Value
Melting Point	−142°C (−223.6°F)
Boiling Point	−24.8°C (−12.64°F)
Vapor Density	1.617 (Air = 1)
log P (Octanol-Water)	0.1
Water Solubility	4.60E + 04 mg/L (25°C/77°F)
Vapor Pressure	4450 mm Hg (25°C/77°F)

crafts, auto products, home maintenance, home office, and personal care products (see Table 37.3).

DOSE EFFECT

There are few data on the dose response of dimethyl ether. Older medical studies suggest that the acute toxicity of dimethyl ether is relatively low. In mice, the median lethal concentration (LC_{50}) following 15-minute exposure was 494 ppm.[35] Studies in cats indicate that 65% dimethyl ether produces anesthesia, whereas the administration of 85% causes profound anesthesia with gradual cessation of respiration.[32] The administration of 50% dimethyl ether to volunteers produced unpleasant side effects including a feeling of suffocation.

TOXICOKINETICS

There are limited data on the toxicokinetics of dimethyl ether.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

There are few data on the toxicity of dimethyl ether. In a rodent study, exposure of Wistar rats to 2% v/v ether 6 hours daily for 5 days a week for 30 weeks produced some elevation of serum hepatic alanine aminotransferase as well as a reduction of liver weight compared with unexposed controls.[36] Histologic examination of the organs including the liver demonstrated no abnormalities.

CLINICAL RESPONSE

Dimethyl ether is a CNS depressant and asphyxiant that potentially causes hypoxia following high acute exposure. Although there are few clinical data on the effects of dimethyl ether, potential serious effects include respiratory insufficiency and altered consciousness. There are no human data on dysrhythmias associated with acute dimethyl ether exposure.

DIAGNOSTIC TESTING

Headspace gas chromatography with split flame ionization/electron capture detection is a simple method for screening a wide range of volatile substances in biologic fluids including dimethyl ether.[37] An initial column temperature of 40°C (104°F) followed by programming to 200°C (392°F) allows the differentiation of dimethyl ether from other low-boiling chemicals (e.g., butane, propane, bromochlorodifluoromethane).

TREATMENT

There are few data on the treatment of dimethyl ether exposure. Treatment is supportive, similar to other inhaled anesthetics with respiratory depression and cardiac dysrhythmias potentially representing the most immediate life-threatening complications of exposure. Immediate attention should be directed toward maintenance of ventilation and blood pressure with intubation, mechanical ventilation, intravenous fluids, and cardiac monitoring as indicated by the history and physical examination.

Chapter 38

HALOGENATED ETHERS (ENFLURANE, ISOFLURANE, METHOXYFLURANE, SEVOFLURANE)

Robbins first reported the anesthetic properties of several fluorinated hydrocarbons in 1946.[1] In the 1950s, advances in organic fluorine chemistry allowed the development of fluorinated anesthetic alkanes and ethers that replaced the variety of gas and volatile liquids introduced as anesthetics in the first half of the 20th century. Trifluoroethyl vinyl ether (fluroxene, Ohio Medical Products, Cleveland, OH) was the first fluorinated anesthetic and was marketed from 1951 until 1974, when this anesthetic was withdrawn because of the discovery of a toxic metabolite.[2] Halothane was introduced by Ayerst Laboratories (New York, NY) and Imperial Chemical Industries, PLC (London, UK) into clinical practice in 1955–1956, about 5 years after the discovery of halothane by Charles Suckling in 1951; however, the subsequent use of halothane declined dramatically as newer, safer anesthetics became available. Methoxyflurane (Abbott Laboratories, Abbott Park, IL) was introduced into clinical practice in 1960. Within a decade, concerns about dose-related nephrotoxicity limited the use of this anesthetic. Over the next 10–15 years, Louise Croix and Ross Terrell synthesized several hundred new fluorinated compounds at Ohio Medical Products.[3] Terrell synthesized enflurane in 1963, and he introduced this anesthetic into clinical practice in 1966. Enflurane was approved as an anesthetic in the United States in 1972. In 1965, Terrell discovered the enflurane isomer, isoflurane. He introduced isoflurane into clinical practice in 1971, but approval of isoflurane in the United States was delayed until 1980 because of early concerns about carcinogenicity. Desflurane is a relatively new volatile halogenated ether anesthetic with minimal bio-transformation and lower solubility in blood and fat than most of the other volatile anesthetics.[4]

ENFLURANE

IDENTIFYING CHARACTERISTICS

Halogenated ethers represent a group of anesthetic agents along with halogenated hydrocarbons (halothane) and nitrous oxide. Inhalational anesthetics are either gases or vapors from volatile liquids. A substance is a gas when the ambient temperature is above the critical temperature (i.e., the temperature at which the substance cannot be liquified no matter how high the pressure). Below the critical temperature, the substance is a vapor. Enflurane (2-chloro-1,1,2-trifluoroethyldifluoromethyl ether, CAS RN: 13838-16-9) is a colorless, nonflammable, volatile liquid with a pleasant ether odor. The lipid solubility of enflurane is relatively low compared with halothane; therefore, the depth of anesthesia and the recovery from anesthesia occur more rapidly than halothane anesthesia. Figure 38.1 displays the chemical structure of enflurane along with other common halogenated ethers (isoflurane, methoxyflurane), halothane, and nitrous oxide.

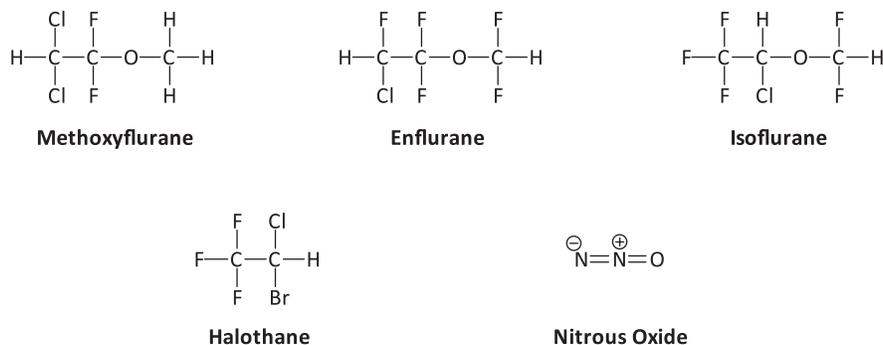
The blood/gas partition coefficient is a measure of solubility and the amount of vapor that must be transferred from alveolar gas to the blood to achieve a given tension. The most soluble anesthetics (e.g., halothane,


FIGURE 38.1. Chemical structures of halogenated ether anesthetics.

TABLE 38.1. Comparison of the Physical Properties of Halothane, Halogenated Ethers, and Nitrous Oxide.[13]

Anesthetic	MAC (%)	Vapor Pressure(mm Hg at 25°C/77°F)	Blood/Gas Partition Coefficient (37°C/98.6°F)	Oil/Gas Partition Coefficient (37°C/98.6°F)
Methoxyflurane	0.16	49.1	12.0	970
Halothane	0.75	302	2.3	224
Enflurane	1.68	591	1.9	98
Isoflurane	1.40	591	1.4	99
Nitrous Oxide	105	gas	0.47	1.4
Sevoflurane	2.6*	197	0.69	47–54

Abbreviation: MAC = minimum alveolar concentration.
Note. The concept of MAC assumes that the alveolar partial pressure of an anesthetic is the same as arterial blood; however, uniform mixing within the alveolus may not occur for anesthetics with high molecular weight (e.g., flurane/isoflurane).[6]
*Age 25, the MAC decreases with age (MAC = 1.7% at 60 years).

methoxyflurane) are associated with the slowest induction and recovery, assuming the same inspired concentrations and stable cardiac output. The oil/gas partition coefficient is a measure of the uptake of the gas in adipose tissue and the elimination rate of the gas after cessation of the anesthetic; this coefficient correlates to potency and the MAC. Table 38.1 compares these physical properties among halothane, halogenated ethers, and nitrous oxide. In general, a compound with a vapor pressure below 0.76 mm Hg at room temperature will attain an ambient concentration <1,000 ppm, which is below concentrations generally observed for narcotic or anesthetic effects.[5]

Carbon monoxide forms when volatile anesthetics pass through dry CO_2 absorbents, more so with Baralyme® (Allied Healthcare Products, Inc., Stuyvesant Falls, NY) than dry soda lime.[7,8] A structural requirement for the formation of carbon monoxide from halo ether degradation is the presence of a difluoromethoxy group. *In vitro* experimental studies suggest that carbon monoxide production is highest with enflurane, intermediate with isoflurane, and insignificant with sevoflurane and halothane. In a patient simulation model using desiccated soda lime, the peak carbon monoxide produc-

tion was as follows: enflurane, 10,654 ppm; isoflurane, 2,512 ppm; halothane, 210 ppm; and sevoflurane, 121 ppm.[9] The amount of carbon monoxide production depends on the amount of desflurane in contact with the dry absorbent, the absorbent water content, and fresh gas flow.[10] The first anesthetic cases involved enflurane, isoflurane, and desflurane with rare case reports documenting carboxyhemoglobin concentrations exceeding 30%.[11] Carbon monoxide formation may occur during the use of sevoflurane in the presence of dry CO_2 absorbents.

EXPOSURE

Abuse of halogenated ethers typically involves medical or veterinary personnel using halothane or enflurane.[12] The abuse of these volatile compounds usually occurs along with the abuse of other drugs (e.g., ethanol).

DOSE EFFECT

The minimum alveolar concentration (MAC) is a measure of the concentration of an inhaled anesthetic required to block purposeful movement in an individual

patient. A dose of 1 MAC will prevent muscle movement following surgical incision in 50% of patients. Typically, anesthetics are administered in concentrations of 0.3–1.5% along with a carrier gas (e.g., oxygen or oxygen plus nitrous oxide).[13] Table 38.1 compares the minimum alveolar concentration (i.e., potency) of enflurane with other halogenated ethers.

TOXICOKINETICS

The elimination of halogenated ethers depends on the individual compound. Compared with halothane, the biotransformation of enflurane is low (i.e., about 8.5%).[14] The lungs excrete most of the absorbed dose of enflurane unchanged in exhaled air; <10% of the absorbed dose of enflurane undergoes biotransformation with inorganic fluoride being the major metabolic product.[15] In a study of 7 healthy female patients undergoing enflurane anesthesia, 82.7% ± 18.8% of the absorbed drug was excreted unchanged by the lungs.[16] Enflurane elimination followed a 3-compartment model with half-times of 17.8 minutes, 3.2 hours, and 36.2 hours. The biotransformation of enflurane produces substantially less fluoride than methoxyflurane.[17] About 2.4% of the absorbed dose of enflurane appeared in the urine as nonvolatile fluorinated metabolites with inorganic fluoride accounting for 0.5% and organic fluoride for 1.9%. Maximum excretion of inorganic fluoride (20–60 mg/d) occurs 3–7 hours after the cessation of anesthesia. The mean half-time of inorganic and organic fluorine was 1.55 days and 3.69 days, respectively.

All inhaled anesthetics potentially interact with neuromuscular blocking agents (e.g., atracurium, pancuronium, vecuronium) to increase the intensity and duration of neuromuscular blockade.[18] Furthermore, benzodiazepines and opioids may decrease the MAC of inhaled anesthetics. Enflurane displaces diazepam from serum proteins *in vitro*; this interaction potentially increases the pharmacodynamic response of diazepam.[19] However, the clinical relevance of this drug interaction is unclear. The presence of nitrous oxide does not alter the metabolism of enflurane.[20]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

The major molecular targets of halogenated ether anesthetics are protein receptors rather than surrounding lipid membranes.[21] Halogenated ethers affect the GABA and NMDA brain receptor systems similar to ethanol. These anesthetics act nonselectively at a number of molecular targets to produce amnesia, hyp-

nosis, and immobility including the molecular targets of propofol (gamma-aminobutyric acid type A receptors) and nitrous oxide (glutamate and nicotinic receptors, potassium leak channels).[22] Halogenated ethers probably produce anesthesia by some part or combination of enhancing inhibitory postsynaptic channel activity (GABA$_A$, glycine receptors) and inhibiting excitatory synaptic channel activity (glutamate, serotonin, nicotinic acetylcholine receptors). At clinically effective concentrations, certain ion channels are sensitive to volatile anesthetics including the superfamilies of cysteine-loop neurotransmitter receptors (GABA$_A$, serotonin type 3, glycine, nicotinic acetylcholine) and glutamate receptors (i.e., activated by *N*-methyl-D-aspartate or α-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid).[23] Volatile halogenated anesthetics enhance GABA$_A$ activity,[24] inhibit glutamate and nicotinic acetylcholine receptors,[25] and activate potassium leak channels (e.g., TREK-1, TREK-2, TASK-1, TASK-2, TASK-3, TRESK).[22] In contrast to hypoxia, volatile halogenated ether anesthetics open potassium channels including the TASK-1 and K$_v$ potassium channels in the membrane of carotid body type I cells.[26] Additionally, volatile halogenated anesthetics act on glycine receptors and mediators of neurotransmitter release. GABA$_A$ receptors are the most abundant inhibitory neurotransmitter receptors in the brain, but alternate pathways to anesthesia probably include the inhibition of excitatory ligand-gated ion channels (NMDA-sensitive glutamate, neuronal nicotinic acetylcholine receptors).[23]

Mechanism of Toxicity

All volatile anesthetics are concentration-dependent myocardial depressants as a result of reductions in trans-sarcolemmal calcium entry and alterations in sarcoplasmic reticulum function.[27] These fluorinated compounds cause respiratory depression manifest by decreased responsiveness to hypoxia and increased carbon dioxide concentrations even at subanesthetic doses.[28] Additionally, these anesthetics depress the central respiratory centers, eliminate conscious respirations, and reduce the responsiveness of peripheral chemoreceptors (oxygen-sensitive glomus type I cells) in the carotid bodies. All halogenated ether anesthetics also reduce pharyngeal reflexes, and relax skeletal muscles following the administration of anesthetic doses.

Postmortem

Autopsy findings in patients dying from the abuse of halogenated ethers are nonspecific (e.g., congestion of viscera, pulmonary edema, cerebral edema) and may demonstrate signs of asphyxia or irritation of the

bronchial mucosa.[29] Autopsy tissues may contain strong odors (e.g., enflurane), depending on the odor threshold of the anesthetic.

CLINICAL RESPONSE

Like other volatile halogenated ethers, enflurane is a central nervous system (CNS) depressant that produces an ethanol-like intoxication that is associated with abuse in some individuals. Malignant hyperthermia is a rare complication of anesthesia with halogenated ethers.[30] Clinical features of malignant hyperthermia include muscle rigidity, elevated body temperature, cardiac dysrhythmias, hypotension, and metabolic acidosis. Rhabdomyolysis also may occur along with renal failure and pulmonary edema.[31] The incidence of hepatotoxicity following enflurane anesthesia is extremely rare (1/800,000).[10]

DIAGNOSTIC TESTING

Analytic Methods

Methods for the analysis of halogenated ethers (e.g., enflurane) in biologic samples include headspace gas chromatography with flame ionization detection or electron capture detection, gas chromatography/Fourier transformation infrared spectroscopy,[32] and headspace gas chromatography/mass spectrometry.[33] The limits of detection and quantitation of the latter method were 1.2 and 4.7 mg/L, respectively. Methods for sampling halogenated ethers include headspace,[34] pulse-heating,[35] solid-phase microextraction,[36] purge-and-trap, and cryogenic oven trapping.[37] Halogenated ethers do not significantly interfere with the determination of breath ethanol concentrations unless the analytic machine uses a single wavelength of 9.5 μm to determine the ethanol concentration in expired air.[38] Like other volatile substances of abuse, storage of the biologic samples in headspace vials that are sealed and stored immediately at −20°C (−4°F) minimizes loss of the halogenated ether, including enflurane, from the container.

Biomarkers

In a study of 10 patients undergoing enflurane anesthesia (0.5–2% v/v), the mean peak blood concentration of enflurane was about 95 mg/L in central venous blood 30 minutes after the beginning of induction; the blood enflurane concentration declined to <0.5 mg/L 90 minutes after the termination of anesthesia.[39] The mean concentration of enflurane in venous blood samples from 12 patients undergoing anesthesia with 1.5% enflurane and 0.75% halothane was 64.8 ± 35.7 mg/L

immediately after the end of anesthesia.[40] A 21-year-old anesthesiology student was found dead with 2 empty bottles of enflurane and a breathing mask nearby. Postmortem blood samples drawn during autopsy 3½ days after death contained 130 mg enflurane/L.[41] Samples of fat and brain tissues also contained high concentrations of enflurane (100 mg/L and 350 mg/L, respectively) as measured by gas chromatography/mass spectrometry. A 29-year-old surgical technician was found dead in his bed with his bedclothes pulled over his head and an empty bottle of enflurane nearby.[42] The postmortem blood enflurane concentration was 71 mg/L as measured by headspace gas chromatography with flame ionization detection. There was no detectable enflurane in the gastric contents.

Abnormalities

Renal dysfunction following enflurane anesthesia is unlikely because serum inorganic fluoride concentrations following enflurane anesthesia seldom exceed the 50 μM concentration associated with renal dysfunction.[43] Isoflurane may prolong the QT_c interval similar to isoflurane and sevoflurane. In a study of 6 healthy adults undergoing anesthesia with only enflurane (2.16 ± 0.13 mM), the QT_c interval increased from 400 ± 10 msec to 460 ± 140 msec. The QRS duration and the PR interval remained unchanged from baseline; there were no dysrhythmias.[44]

TREATMENT

The treatment of complications from enflurane abuse is similar to the abuse of other inhaled anesthetics. Respiratory depression potentially represents the most immediate life-threatening complication of enflurane exposure; immediate attention should be directed toward maintenance of ventilation and blood pressure with intubation, mechanical ventilation, intravenous (IV) fluids, and cardiac monitoring as indicated by the history and physical examination. The lungs excrete most of the absorbed dose of enflurane unchanged; consequently, there are no efficacious methods to enhance elimination.

ISOFLURANE

IDENTIFYING CHARACTERISTICS

Isoflurane (1-chloro-2,2,2-trifluoroethyldifluoromethyl ether, CAS RN: 26675-46-7) is a nonflammable, clear, colorless, volatile liquid anesthetic with a low blood/gas

solubility coefficient that produces the rapid induction of anaesthesia with small volumes. Isoflurane is a structural isomer of enflurane with a chemical formula of $C_3H_2ClF_5O$ (Figure 38.1). The vapor has a slightly pungent, ether-like odor that irritates the airways more than other halogenated ether anesthetics.

EXPOSURE

With the increasing use of isoflurane, the abuse of this anesthetic also increased. In volunteer studies, isoflurane can function as a reinforcer and produce abuse liability-related subjective (i.e., pleasant, psychedelic-like, euphoria) effects in some, but not the majority of participants.[45,46] In general, these subjective effects are less intense than nitrous oxide. In abusers, the immediate effects of inhaling anesthetics are feelings of elation and euphoria followed soon thereafter by hypersensitivity to noise.[47] Continued use produces effects similar to ethanol including loss of inhibition, loquaciousness, agitation, and dysarthria. Sleepiness limits the continued use of the anesthetic. Recovery typically occurs within 30 minutes.

DOSE EFFECT

The minimum alveolar concentration (MAC) is a measure of potency as defined by the concentration of an inhaled anesthetic required to block purposeful movement in an individual patient. A dose of one MAC will prevent muscle movement following surgical incision in 50% of patients. Typically, anesthetics are administered in concentrations of 0.3–1.5% along with a carrier gas (e.g., oxygen or oxygen plus nitrous oxide).[48] Table 38.1 compares the minimum alveolar concentration (i.e., potency) of isoflurane with other halogenated ethers. Isoflurane causes minimal cardiovascular depression at MAC values below 2.[10]

TOXICOKINETICS

Volunteer studies indicate that the percutaneous loss of isoflurane is too small to affect pharmacokinetic studies or to produce clinical effects during anesthesia.[49] Compared with halothane, the biotransformation of isoflurane is minimal (i.e., <1%).[14] The lungs excrete most of an absorbed dose of isoflurane unchanged in expired air. Metabolism of isoflurane primarily involves the formation of trifluoroacetic acid and, to a lesser extent, fluoride ions. The kidneys excrete these metabolites in the urine. Volunteer studies of patients undergoing coronary artery bypass grafting surgery indicate the following 2 distinct components: 1) initial 5-minute fast component reflecting the initial washout of isoflurane

from the functional residual capacity of the lungs, and 2) a 15-minute slow component reflecting the passage of isoflurane across the alveolar-pulmonary capillary membrane and the blood–brain barrier.[50] The elimination of isoflurane from the mixed venous blood (pulmonary artery) as a measure of isoflurane elimination from the body was mono-exponential with a mean half-life of 32.2 ± 11.9 minutes. Isoflurane elimination from the well-perfused brain was more rapid as reflected in a mean isoflurane half-life of 18.9 ± 7.2 minutes in jugular bulb venous blood. End-tidal isoflurane concentrations are higher than arterial isoflurane concentrations at a constant 2% inspired isoflurane concentration, but the difference is relatively constant.

Animal studies indicate a lack of tolerance to chronic doses of halogenated ether anesthetics. Mice continuously exposed to 0.15% and 0.30% isoflurane did not demonstrate either autotolerance or cross-tolerance.[51] However, these studies suggest that some cross-tolerance to halogenated ethers develops following the chronic administration of nitrous oxide or ethanol.[52] Cross-tolerance to isoflurane in these mice persisted 80 days following the cessation of ethanol.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

The mechanism of action of isoflurane is similar to enflurane (see the Histopathology and Pathophysiology section under Enflurane). Isoflurane is a respiratory tract irritant in high doses that can cause laryngospasm; this property limits use of this agent for anesthesia induction. *In vitro* studies suggest that isoflurane is a potent modulator of extrasynaptic $GABA_A$ receptors in the ventrobasal thalamus of mice. Isoflurane enhances fast synaptic inhibition in the brain mediated by $GABA_A$ receptors at anesthetic concentrations similar to other halogenated ether anesthetics. These receptors also occur at extrasynaptic sites in the CNS, such as the thalamocortical relay neurons. The thalamo-corticothalamic loop is a key target for the induction of sedation and hypnosis for anesthetic effects. These extrasynaptic $GABA_A$ receptors contain primarily α_4, β_2, and δ subunits in contrast to α_1, β_2, and γ_2 in synaptic $GABA_A$ receptors. The extrasynaptic $GABA_A$ receptors are particularly sensitive to low isoflurane concentrations.[53]

CLINICAL RESPONSE

Like other volatile halogenated ethers, isoflurane is a CNS depressant that produces an ethanol-like intoxication and is associated with abuse in some individuals. The clinical effects of isoflurane are similar to enflurane with the exception of some difference in potency. Rare case

reports associate fulminant malignant hyperthermia with combined nitrous oxide and isoflurane anesthesia.[54]

DIAGNOSTIC TESTING

In a study of isoflurane anesthesia, the concentration of isoflurane in venous blood ranged between 85.2 mg/L at the beginning of induction and 104.9 mg/L during the operation.[33] A 36-year-old operating room assistant was found dead in a hospital locker room with a plastic bag over his head and an almost empty bottle of isoflurane in his locker.[29] No resuscitation was attempted. The mean concentration of 6 samples of cardiac blood stored in sealed headspace vials was 47.9 ± 0.9 mg/L. The postmortem blood also contained a nordiazepam concentration similar to nordiazepam concentrations in patients with therapeutic plasma diazepam concentrations; the postmortem gastric contents contained unexpectedly high isoflurane concentrations (252 ± 16.05 mg/L [mg/kg]). Renal dysfunction following isoflurane anesthesia is unlikely because serum inorganic fluoride concentrations following isoflurane anesthesia seldom exceed the 50 µM concentration associated with renal dysfunction.[55] Isoflurane may prolong the QT_c interval similar to enflurane and sevoflurane. In a study of 8 healthy adults undergoing anesthesia with only isoflurane (1.04 ± 0.11 mM), the QTc interval increased from 420 ± 10 msec to 470 ± 140 msec. The difference in the QRS duration, the PR interval and the QT interval during anesthesia were not statistically different than baseline.[56]

TREATMENT

The treatment of complications from isoflurane abuse is similar to the abuse of other inhaled anesthetics. Respiratory depression potentially represents the most immediate life-threatening complication of isoflurane exposure; immediate attention should be directed toward maintenance of ventilation and blood pressure with intubation, mechanical ventilation, IV fluids, and cardiac monitoring as indicated by the history and physical examination. The lungs excrete most of the absorbed dose of isoflurane unchanged; consequently, there are no efficacious methods to enhance elimination.

METHOXYFLURANE

IDENTIFYING CHARACTERISTICS

Methoxyflurane (2,2-dichloro-1,1-difluoroethylmethyl ether, CAS RN: 76-38-0) is highly soluble in blood; con-

sequently, the induction of anesthesia is slower than halothane and many other halogenated ether anesthetics. Methoxyflurane is also highly fat soluble.

EXPOSURE

Methoxyflurane is now primarily a general anesthetic for animals because of the nephrotoxicity associated with the use of this compound as an anesthetic.

DOSE EFFECT

The mean alveolar concentration of methoxyflurane necessary to induce the first plane of surgical anesthesia is about 0.3%. A 39-year-old gynecologist developed hepatitis after sniffing about 2 mL methoxyflurane once or twice daily for 6 weeks (i.e., total 125 mL) as a treatment for insomnia.[57] His clinical symptoms and laboratory abnormalities resolved completely following cessation of use.

TOXICOKINETICS

The elimination of methoxyflurane primarily involves biotransformation. Compared with other halogenated ethers, a relatively large part of the absorbed dose of methoxyflurane is metabolized. In a study of 6 Japanese patients undergoing anesthesia with nitrous oxide and 0.31% methoxyflurane, the lungs excreted about 35% of the absorbed methoxyflurane dose unchanged in expired air.[58] The kidneys excreted approximately 46% of the dose in the urine, primarily as organic fluoride, and to a lesser extent inorganic fluoride. Peak serum fluoride concentrations occurred about 6 hours after the end of anesthesia; serum fluoride concentrations may exceed the 50 µM concentration associated with renal dysfunction.[59] *In vitro* studies of microsomes from human livers indicate that CYP2E1 is the principal cytochrome P450 isoenzyme involved in methoxyflurane biotransformation.[60] However, these studies indicate that there are several other isoenzymes involved including CYP1A2, CYP2C9/10, and CYP2D6.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

The chronic abuse of methoxyflurane is associated with hepatorenal damage. A needle biopsy of the liver from 39-year-old man with methoxyflurane-induced hepatitis demonstrated centrilobular to midzonal confluent hepatic necrosis with few inflammatory cells.[57] Portal tract changes were minimal. On electron microscopy, there were many irregularly shaped vacuoles with partially enveloped structures resembling fat droplets and

increased lysosomes in the hepatocytes. Nephrocalcinosis may develop in patients abusing methoxyflurane.[61] The most striking feature seen on renal biopsy of these patients is the deposition of birefringent crystals within tubular lumens, particularly in the cortical lumens. Thickening of the Bowman capsule and focal widening of the mesangial spaces occurs with some glomeruli becoming sclerotic. These changes are similar to the renal damage caused by secondary oxalosis.

A 42-year-old veterinary assistant developed fatal hepatic failure with submassive hepatic necrosis after sniffing methoxyflurane for the preceding 2 months.[62] Postmortem examination of the liver revealed centrilobular liver necrosis with some mononuclear cells infiltrates. There were regenerating liver cells in the peripheral and periportal areas.

CLINICAL RESPONSE

Like other volatile halogenated ethers, methoxyflurane is a CNS depressant that produces an ethanol-like intoxication and is associated with abuse in some individuals. Hepatorenal damage may occur following the chronic inhalation of methoxyflurane. Case reports associate jaundice, hepatic encephalopathy, and fulminant hepatic failure with the chronic abuse of methoxyflurane.[57,62] The clinical features of the hepatitis associated with methoxyflurane are typical of acute hepatitis including general malaise, nausea, vomiting, pruritus, scleral icterus, confusion, encephalopathy, and hepatic failure. A toxic nephropathy is associated with elevated serum fluoride concentrations following methoxyflurane anesthesia.[63] The chronic abuse of methoxyflurane may cause a progressive renal and bone disease similar to fluoride toxicity. A 27-year-old nurse developed painful periostitis, osteosclerosis, hypertension, and renal dysfunction following the long-term, intermittent abuse of methoxyflurane.[64] Symptoms included severe bone pain, headache, polyuria, polydipsia, and epigastric distress. Nephrocalcinosis and secondary oxalosis may complicate the chronic abuse of methoxyflurane as a result of the metabolism of this compound to oxalic acid and fluoride.[61] These changes may cause renal dysfunction, hypertension, edema, anemia, and electrolyte imbalance.

DIAGNOSTIC TESTING

Radiographic abnormalities associated with bone changes from chronic abuse of methoxyflurane resemble periostitis deformans associated with fluorosis from drinking fluorinated wine.[65] These individuals develop multiple crops of hyperostotic periosteal nodules, particularly in the phalanges, as a result of osteoblastic stimulation caused by excessive fluoride concentrations. In severe cases of chronic methoxyflurane abuse, sequelae of hepatic and renal damage may occur including elevation of serum hepatic aminotransferases, hyperbilirubinemia, hyperammonemia, hyperphosphatemia, chronic anemia, and coagulation disorders.

TREATMENT

Respiratory depression represents the most immediate life-threatening complication of methoxyflurane exposure; immediate attention should be directed toward maintenance of ventilation and blood pressure with intubation, mechanical ventilation, IV fluids, and cardiac monitoring as indicated by the history and physical examination. Methods to enhance elimination of methoxyflurane have not been studied. Although *N*-acetylcysteine is a potential antidote for carbon tetrachloride-induced liver damage, there are no clinical data currently available to determine of efficacy of *N*-acetylcysteine for the treatment of methoxyflurane-induce liver damage. If severe hepatorenal dysfunction develops, supportive care includes the treatment of renal failure with dialysis and hepatic failure with fresh frozen plasma, vitamin K, low protein diet, neomycin, lactulose, and careful fluid and electrolyte balance. Hepatic and renal function should be followed daily for at least 3 days after serious abuse of methoxyflurane.

SEVOFLURANE

IDENTIFYING CHARACTERISTICS

Sevoflurane is a methyl isopropyl ether anesthetic that is poorly soluble in blood. This volatile anesthetic has a less pungent odor and less airway irritation than other halogenated anesthetics. Sevoflurane is a colorless, nonflammable liquid, which has a vapor pressure of 160 mm Hg at room temperature. Compound A [fluoromethyl-2,2-difluoro-1-(trifluoromethyl) vinyl ether] is a degradation product of sevoflurane resulting from the interaction of sevoflurane with absorbents used to remove carbon dioxide during anesthesia.

EXPOSURE

Like isoflurane, sevoflurane is a reinforcer in volunteer studies; this anesthetic produces abuse liability-related subjective (i.e., pleasant, psychedelic-like, euphoria) effects in some individuals. In general, these subjective effects are less intense than nitrous oxide. Continued

sniffing of sevoflurane causes effects similar to the ingestion of ethanol including loss of inhibition, loquaciousness, agitation, and dysarthria. Sleepiness limits the continued use of halogenated anesthetics.

DOSE EFFECT

Inspired concentrations of sevoflurane during the induction of anesthesia range from 1–8%. The minimum alveolar concentration of sevoflurane necessary to prevent movement in 50% of patients (MAC) is about 1.7–2.1%.[66] In a study of 42 elective adult surgical patients, the estimated MAC was 1.58% (95% CI: 1.14–1.98%).[67] Rapid induction of anesthesia occurs following the inhalation of 6–8% sevoflurane. The administration of 1.5–3% sevoflurane maintains surgical anesthesia. Compound A is nephrotoxic in rats; mild, reversible renal abnormalities (e.g., transient albuminuria, enzymuria) occur in humans when the dose of Compound A exceeds 240 ppm-hour (e.g., >30 ppm for 8 hours).[68]

TOXICOKINETICS

The alveolar equilibration of sevoflurane is rapid (i.e., 85% complete within 30 minutes), similar to desflurane (90%) and more rapid than isoflurane (73%) and halothane (58%).[69] The lungs excrete most of an absorbed dose of sevoflurane unchanged into expired air with a mean total body clearance (3.5 L/minute) similar to isoflurane. Like all fluorinated volatile anesthetics, sevoflurane undergoes limited biotransformation to organic and inorganic fluoride metabolites. Similar to isoflurane and enflurane, about 2–5% of an absorbed dose of sevoflurane is metabolized via CYP2E1 isoenzymes.[70] In a study of 32 healthy Japanese patients undergoing elective surgery, the estimated mean degradation rate of sevoflurane was 3.3%.[71] The major metabolites are hexafluoroisopropanol (HFIP) and fluoride; these 2 metabolites form in equimolar concentrations. Peak serum fluoride concentrations following sevoflurane anesthesia are about 1.5–2 times higher than those following enflurane anesthesia, but the decline of the fluoride concentrations is much more rapid (i.e., a few hours) following sevoflurane anesthesia than after the administration of enflurane. The metabolism of sevoflurane does not produce trifluoroacetylated liver proteins, which are associated with halothane-induced hepatitis. After conjugation of hexafluoroisopropanol with glucuronic acid, the kidney excretes the glucuronide metabolite with a urinary elimination half-life of about 20 hours. Unlike methoxyflurane, sevoflurane undergoes minimal defluorination in the kidney.[72] The terminal plasma elimination half-life of sevoflurane is approximately 1 day. The renal clearances of the metabolites, fluoride and HFIP are prolonged with apparent elimination half-lives of 21.4 ± 2.8 hours and 20.1 ± 2.6 hours, respectively, in a study of 10 patients receiving 1.3 MAC (2.7% end-tidal) sevoflurane in oxygen for 3 hours.[73] There is substantial variation in the biotransformation of sevoflurane between animal species; therefore, extrapolation of animal data to humans is limited.[60]

In volunteer studies, the administration of disulfiram, which is a potent CYP2E1 inhibitor, substantially decreases the formation of fluoride ion and hexafluoroisopropanol.[74] Other drugs induce the formation of CYP2E1 including phenobarbital, phenytoin, isoniazid, and chronic ethanol use. However, the clinical significance of these potential interactions remains unclear, in part because of the limited metabolism.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Sevoflurane is a CNS depressant that causes respiratory depression and hypotension in high doses (i.e., >1 MAC). The dose-dependent cardiac, respiratory, and CNS depressant effects are similar to the effects of isoflurane.[69] The use of sevoflurane during surgery prolongs the QTc interval similar to isoflurane.[75] In a study of 18 women undergoing sevoflurane anesthesia with prior medications, the QTc interval increased from 434 ± 5 msec at baseline to 459 ± 6 msec 10 minutes after anesthesia began.[76] Although case reports associate sevoflurane abuse with ventricular fibrillation,[77] the role of QTc prolongation in these cases of sudden death is unclear. Sevoflurane produces no significant reactive intermediates; therefore, sevoflurane is not associated with the immune-mediated hepatotoxicity that occurs following halothane anesthesia.

CLINICAL RESPONSE

Like other volatile halogenated ethers, sevoflurane is a CNS depressant that produces an ethanol-like intoxication and is associated with abuse in some individuals. The cessation of these effects is rapid (i.e., within 30 minutes).

DIAGNOSTIC TESTING

Following the 3-hour administration of 2.7% sevoflurane to 10 patients, blood samples were collected 1 hour and 8 hours after cessation of anesthesia.[73] The mean sevoflurane concentrations were 38 mg/L and 7.2 mg/L, respectively.

The postmortem sevoflurane concentration depends on a number of factors including losses during perimor-

tem resuscitation, postmortem interval, collection, storage, and analysis (e.g., absorption into plastic, head-space losses). Comparison of postmortem and anesthetic data is complicated by the ventilatory support surgical patients receive during and after the cessation of anesthesia. A 31-year-old anesthetist was found dead in the break room of the surgery floor near a bottle of sevoflurane.[78] No drugs were detected in postmortem femoral blood except the estimated sevoflurane concentration of 15 mg/L. The autopsy was normal except for pulmonary edema and 50% occlusion of the left main coronary artery. A 44-year-old man was found dead with an oxygen mask containing a gauze pad connected to his face and a variety of medications near his body.[79] The postmortem femoral blood samples contained a high concentration of methamphetamine (7.02 mg/L) and a valproic acid (60.8 mg/L) concentrations consistent with therapeutic concentrations. The concentrations of sevoflurane in postmortem femoral blood and vitreous humor were 26.2 mg/L and 86.7 mg/L, respectively. The author suggested that the concentration of sevoflurane was higher at the time of death because of the high sevoflurane vitreous humor/femoral blood ratio of 3.31. A 47-year-old man was found dead in bed with an empty container of sevoflurane near him.[80] He was last seen alive by his mother 4 days earlier. Postmortem heart and subclavian blood samples contained sevoflurane concentrations of 16 mg/L and 8 mg/L, respectively.

TREATMENT

Similar to other inhaled anesthetics, respiratory depression potentially represents the most immediate life-threatening complication of sevoflurane exposure; immediate attention should be directed toward maintenance of ventilation and blood pressure with intubation, mechanical ventilation, IV fluids, and cardiac monitoring as indicated by the history and physical examination. The lungs excrete most of the absorbed dose of sevoflurane unchanged; consequently, there are no efficacious methods to enhance elimination.

Chapter 39

HALOTHANE

HISTORY

Halothane was introduced into clinical practice in 1956 and by the 1970s, this volatile chemical was the most common general anesthetic agent. In the 1960s, cases reports of postanesthetic jaundice following halothane anesthesia appeared in the medical literature; soon thereafter, the National Halothane Study began an investigation the mechanism of the hepatotoxicity associated with halothane.[1] The incidence of massive hepatic necrosis in the National Halothane Study was 1:10,000.[2] The cause of the liver damage remains controversial with several proposed mechanism including hypersensitivity reaction, toxic metabolites, and nutritional factors. The use of halothane as an anesthetic has dramatically declined because of the introduction of safer drugs.

IDENTIFYING CHARACTERISTICS

Figure 39.1 displays the chemical structure of halothane (2-bromo-2-chloro-1,1,1-trifluoroethane, CAS RN: 151-67-7). This compound is the only modern volatile anesthetic that is not a halogenated methyl ethyl ether. This compound (Freon 123B1) is a nonflammable, colorless liquid with a pleasant, sweet, chloroform-like odor. The vapor pressure at 20°C (68°F) is 241 mm Hg. Table 39.1 lists some physiochemical properties of halothane. Halothane is the most soluble modern anesthetic; the blood/gas solubility of halothane is 2.3, resulting in slow induction and recovery characteristics. This paradoxical property causes the slow equilibrium of alveolar-arterial tension as a result of the rapid removal of halothane from alveolar air and the prolonged equilibration of inspired and alveolar air.[3] The minimum alveolar concentration (MAC) of halothane is 0.74%, but this concentration decreases in the presence of 70% nitrous oxide to 0.29%.[4]

Halothane is less stable in light than enflurane and isoflurane; consequently, the storage of halothane requires the use of a stabilizing agent (e.g., thymol). Ultraviolet light oxidizes halothane to free chlorine and bromine ions, HCl, HBr, and phosgene ($COCl_2$). Rubber readily absorbs halothane, resulting in the decreased delivery of halothane through rubber tubing.

EXPOSURE

Halothane abuse occurs primarily among medical personnel. Reported desired effects of halothane abuse include euphoria similar to sniffing glue; the route of exposure typically involves sniffing from a rag soaked in halothane or inhalation of vapors from a plastic bag containing halothane.[5] The abuse of halothane may continue until the individual becomes unconscious. Severe hepatic necrosis is a rare, immune-related complication of halothane anesthesia that occurs at a ratio of about 1:35,000.[6]

DOSE EFFECT

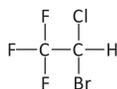
The minimum alveolar concentration (MAC) is a measure of the concentration of an inhaled anesthetic required to block purposeful movement in an individ-


FIGURE 39.1. Chemical structure of halothane.

Table 39.1. Physiochemical Properties of Halothane.

Physical Property	Value
Melting Point	–118°C (–180.4°F)
Boiling Point	50.2°C (122.36°F)
log P (Octanol-Water)	2.3
Water Solubility	4070 mg/L (25°C/77°F)
Vapor Pressure	302 mm Hg (25°C/77°F)

ual. This measure is the accepted standard measure of the clinical potency of inhaled anesthetics. A dose of 1 MAC will prevent muscle movement following surgical incision in 50% of patients. Typically, anesthetics are administered in concentrations of 0.3–1.5% along with a carrier gas (e.g., oxygen or oxygen plus nitrous oxide). The MAC for the first plane of surgical anesthesia with halothane is approximately 0.7% compared with 1.4% for isoflurane and 0.16% for methoxyflurane. In animal studies, the administration of 2–2.5 times the minimum alveolar concentration (MAC) of halothane causes apnea.[7]

TOXICOKINETICS

Biotransformation

The liver metabolizes up to approximately 20–40% of the absorbed dose of halothane via an oxidative pathway and, to a much lesser extent, via a reductive pathway.[8] Under sufficient oxygen tension, metabolites of oxidative dehalogenation of halothane include trifluoroacetic acid, trifluoroacetyl chloride, inorganic bromide, and chloride. Following acetylation, trifluoroacetyl chloride reacts with nucleophilic centers near the site of generation, forming covalent bonds with liver proteins and phospholipids. The cytochrome P450 isoenzymes, CYP2E1 and to a lesser extent CYP2A6, catalyze the oxidative pathway. A minor metabolic pathway (i.e., 1–6%) involves the reduction of halothane via CYP2A6 and to a lesser extent CYP3A4.[9] *In vitro* studies indicate that CYP inhibitors do not reduce the formation of reductive metabolites.[10] The metabolites formed by the reductive pathway include inorganic fluoride, 2-chloro-1,1,1-trifluoroethane, and 2-chloro-1-1-difluoroethylene.[11] The reductive biotransformation of halothane is more extensive in women than in men.[12] Hypoxia substan-

tially increases the reductive biotransformation of halothane.[13] During halothane anesthesia, the concentration of fluoride in venous samples remains relatively stable.[14]

Elimination

The elimination of halothane is relatively rapid following cessation of exposure, primarily by pulmonary excretion in expired air. About 20–50% of the absorbed dose of halothane is metabolized in a dose-dependent manner. In a study of 5 patients undergoing halothane anesthesia (mean, 0.93%), the mean percentage of halothane recovered in expired air was 72.8% ± 9.2%.[15] The mean percentage of the absorbed dose of halothane recovered in the urine as metabolites was 17.7%. At lower alveolar concentrations, more halothane is metabolized, but the percentage of unchanged halothane excreted in expired air increases as the metabolic enzymes become saturated.[8] Saturation of these metabolic enzymes occurs at about 2–10% of the MAC.[16] In a case series of 10 patients undergoing halothane anesthesia (0.75%), the mean halothane concentration in venous blood decreased from 68.2 ± 35.7 mg/L at the end of anesthesia to 7.3 ± 5.0 mg/L 3 hours later.[14] Peak concentrations of halothane metabolites occur about 24 hours after the cessation of anesthesia.[17]

Drug Interactions

Synergistic depression of the central nervous system (CNS) may occur following the concomitant use of CNS depressants (e.g., ethanol) and halothane.[18] *In vitro* and *in vivo* animal experiments suggest halothane alters the pharmacokinetics of many drugs by inducing enzyme activity and changing drug-protein binding. Enzyme-inducing drugs (e.g., phenytoin, phenobarbital) enhance the reductive biotransformation of halothane, whereas the ingestion of ethanol does not alter reductive halothane metabolism.[19] Potentially, the halothane metabolite, trifluoroacetic acid may displace drugs (e.g., phenytoin, diazepam) from binding sites on serum albumin and increase the amount of free (active) drug.[20] The presence of nitrous oxide does not significantly affect the pharmacokinetics of halothane.[21]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

The administration of halothane causes a dose-dependent reduction in systemic arterial pressure as a result of a 20–50% reduction in cardiac output with

665

a corresponding reflex tachycardia.[22] There is minimal reduction in the total peripheral vascular resistance. Halothane depresses the ventilatory response to carbon dioxide and hypoxia, resulting in carbon dioxide retention and decreased sensitivity of peripheral chemoreceptors.[23]

Volatile halogenated anesthetics affect most of the molecular targets of general anesthetics including enhancement of $GABA_A$ activity, inhibition of glutamate and nicotinic acetylcholine receptors, and activation of potassium leak channels (e.g., TREK-1).[24] Additionally, volatile halogenated anesthetics act on glycine receptors and mediators of neurotransmitter release. Animal studies indicate that halothane depresses glutamatergic synaptic transmission in the hippocampus by the presynaptic inhibition of transmitter release and postsynaptic depression of glutamate currents.[25]

Mechanism of Toxicity

Halothane exhibits the most negative inotropic and myocardial sensitizing effects of all the modern inhaled anesthetics. *In vitro* studies indicate that halothane inhibits muscarinic receptor regulation of myocardial adenylyl cyclase activity and stimulates G protein-dependent adenylyl cyclase activity.[26,27] The most common injury in halothane-treated patients is mild, transient hepatocellular injury usually manifest by asymptomatic elevation of serum hepatic aminotransferase concentrations that reflect alterations of cellular integrity seen by electron microscopy. Halothane anesthesia is not associated with renal impairment except in the setting of fulminant hepatic failure. The hepatic lesions result from reactive intermediates (e.g., trifluoroacetyl chloride) produced by the oxidative and reductive pathways of halothane in combination with local hypoxia. The generation of reactive intermediates via CYP2E1-mediated oxidation of halothane causes trifluoroacetylation of intracellular proteins. In animal studies, the histologic damage is dose-dependent.[28] In susceptible individuals, the formation of antibodies directed toward the acetylated neoantigens (i.e., trifluoroacetylated proteins in the endoplasmic reticulum) produced by reactive intermediates causes the more severe form of hepatic injury. Current evidence suggests that exposure to halothane anesthesia causes the formation of a wide variety of trifluoroacetylated proteins, but only a small subset of susceptible individuals produce an immunologic reaction to these proteins.[29] Histologic examinations of liver biopsies from patients with severe halothane anesthesia-associated hepatitis demonstrate massive hepatocellular necrosis. The pathologic findings are virtually indistinguishable from fulminant viral hepatitis.[30]

Halothane is a respiratory depressant that reduces tidal volume as the concentration of halothane increases. This compound is also a cardiac depressant that reduces myocardial contractility in a dose-dependent manner. Dysrhythmias result primarily from hypercarbia secondary to respiratory depression.[30]

Postmortem Examination

Postmortem findings of patients dying following halothane abuse are nonspecific, typical of volatile substance abuse. The most common abnormalities in these patients are pulmonary congestion and edema without evidence of hepatorenal damage.[5,31]

CLINICAL RESPONSE

Illicit Use

Halothane anesthesia is associated with the following 2 types of liver damage: 1) type I halothane hepatitis—a common asymptomatic elevation of serum hepatic aminotransferases, and 2) type II halothane hepatitis—a rare, idiopathic, severe hypersensitivity-mediated hepatitis directed against hepatocyte.[32] The more severe form occurs in about 1 in 35,000 halothane exposures, whereas the mild form of hepatitis occurs in up to one-fourth of halothane-induced anesthesia.[33] Major risk factors for the hypersensitivity hepatitis are repeated exposure to halothane anesthesia and the use of halothane in middle-aged, obese women. Clinical features of halothane-associated hepatitis are typical of acute hepatitis including fever, anorexia, vomiting, malaise, jaundice, light-colored stools, tea-colored urine, and right upper quadrant tenderness.[34] Signs and symptoms of an immune reaction (e.g., fever, arthralgias, rash, peripheral eosinophilia) may also occur. Typically, symptoms appear about 5–21 days after anesthesia with the abrupt onset of fever and chills followed in several days by jaundice. Cirrhosis does not usually develop following type II halothane hepatitis. Case reports associated both fulminant hepatic failure and asymptomatic elevation of serum hepatic aminotransferases with halothane abuse.[35]

Malignant hyperthermia is a rare complication of halothane anesthesia.[36] This pharmacogenetic disorder of skeletal muscle presents as a hypermetabolic response to potent volatile anesthetic gases including halothane. Classical features of malignant hyperthermia are muscle rigidity, hyperthermia, tachycardia, tachypnea, hypercarbia, increased oxygen consumption, and acidosis. Rhabdomyolysis may also occur along with renal failure and pulmonary edema.

Reproductive Abnormalities

There are few data on the effect of halothane abuse on reproductive outcomes. Animal studies do not indicate that halothane is teratogenic in typical anesthetic doses. There were no major or minor teratologic effects in the offspring of pregnant Sprague-Dawley rats exposed to 0.8% halothane 6 hours daily for 3 consecutive days in 1 of 3 periods (i.e., pregnancy days 14–16, 11–13, or 8–10).[37] In a study of Swiss/ICR mice, the incidences of major malformations and minor anomalies did not increase following exposure to subanesthetic concentrations of halothane.[38] Daily anesthetic exposure to 4.0 MAC hours was lethal to both dams and embryos, and this exposure resulted in major developmental malformations in surviving fetuses.

DIAGNOSTIC TESTING

Analytic Methods

Techniques to quantitate halothane and other halogenated ether anesthetics include clinical infrared gas analyzer,[39] gas chromatography with flame ionization detection (GC/FID),[40] headspace solid-phase or capillary gas chromatography/mass spectrometry,[41,42] and gas chromatography/mass spectrometry in selected ion monitoring mode.[43] The detection limit of simple gas chromatography ranges from 0.010–0.100 mg/L, whereas the accuracy (% CV) of GC/FID ranges between 0.8–9.5%.

Biomarkers

In a case series of 10 patients undergoing halothane anesthesia (0.75%), the mean halothane concentration in venous samples at the end of 1 hour of anesthesia was 68.2 ± 35.7 mg/L.[14] Paramedics on the scene began cardiopulmonary resuscitation of a 19-year-old man who was found comatose. On admission to the emergency department, he had clinical features of severe hypoxic encephalopathy and the blood halothane concentration was 200 mg/L.

Following analysis by gas chromatography, the halothane concentrations in postmortem blood samples from 2 men abusing halothane were 0.36% and 0.50% compared with halothane concentrations of 1–2% during halothane anesthesia.[5] Both men were found in cardiopulmonary arrest; resuscitation measures continued for 1 hour and 2 hours, respectively. A 26-year-old anesthetist was found dead holding a polyvinyl bag with a gauze pad in his mouth. The postmortem blood halothane concentration was 200 mg/L.[44] Similar to other volatile substances of abuse, the halothane concentration present on analysis depends on the analytic method, storage conditions (container, temperature), and postmortem interval. The concentration of halothane in erythrocytes is slighter greater than plasma; the whole blood/plasma ratio of halothane is ~1 based on *in vitro* studies.[45]

Abnormalities

Halothane hepatitis is associated with elevations of hepatic serum aminotransferases and bilirubin along with variable increases in serum alkaline phosphatase concentrations. Hepatic encephalopathy may occur along with severe liver failure, elevated serum ammonia, coagulation abnormalities, and hypoglycemia. A case series of patients undergoing oral surgery with halothane-nitrous-oxide anesthesia reported the development of cardiac dysrhythmias in 44 of the 103 procedures.[46] There were 2 episodes of transient ventricular tachycardia that did not require treatment. Two other patients required treatment for cyanosis that promptly resolved with ventilation. The study did not report potential confounding factors including pre-existing heart disease, electrolyte imbalance, pH, or oxygen saturation. Anesthetic doses of halothane prolong the action potential of the heart. In a study of 8 healthy adults undergoing anesthesia with only halothane (0.81 ± 0.06 mM), the mean QT interval increased from 380 ± 10 msec to 450 ± 10 msec, while the mean QTc interval increased from 390 ± 10 msec to 440 ± 20 msec.[47] Halothane administration did not significantly alter the PR interval or QRS duration. There were no clinically significant dysrhythmias. Inorganic fluoride concentrations are not direct measures of the reductive biotransformation of halothane because of variation in the dietary fluoride intake and the equilibrium of fluoride between bone stores and the systemic circulation.

Driving

Although high concentrations of halothane are detectable by some breathalyzers, these readings are unlikely to interfere with the estimation of breath alcohol concentration at halothane concentrations likely to be present in ambulatory individuals. For example, under experimental conditions a 1% concentration of halothane produced an alcohol reading of 0.029 mg/dL on an older Camic breathalyzer.[48]

TREATMENT

Respiratory depression and cardiac dysrhythmias represent the most immediate life-threatening

complications of halothane exposure; immediate attention should be directed toward maintenance of ventilation and blood pressure with intubation, mechanical ventilation, intravenous fluids, and cardiac monitoring as indicated by the history and physical examination. Methods to enhance elimination of halothane have not been studied. If severe liver dysfunction develops, supportive care includes fresh frozen plasma, vitamin K, low protein diet, neomycin, lactulose, careful fluid and electrolyte, and the use of dialysis as needed for associated renal dysfunction. Hepatic and renal function should be followed daily for at least 3 days after serious abuse of halothane. Liver transplantation (orthotopic, auxiliary partial orthotopic, heterotopic) is the only therapeutic option for advanced fulminant hepatic failure.

Chapter 40

NITROUS OXIDE

HISTORY

Priestley discovered nitrous oxide in 1776. In 1868, pressurized liquid nitrous oxide was available in metal cylinders, and the use of nitrous oxide as an adjunct to diethyl ether anesthesia began. Humphry Davy recognized the anesthetic and euphoric properties of this compound in the latter part of the 18th century.[1] Some of his study participants experienced pleasurable effects from the inhalation of nitrous oxide. However, Humphry Davy also reported that chronic heavy use of nitrous oxide was associated with sensory abnormalities and a mental disorder. The lack of availability and the low potency of nitrous oxide limited the abuse of this compound. In the latter 19th century, this compound was inhaled at social gatherings similar to diethyl ether (ether).[2] Of the early anesthetics (chloroform, diethyl ether), nitrous oxide is the only anesthetic remaining in regular use; however, the use of nitrous oxide has decreased in recent years.

IDENTIFYING CHARACTERISTICS

Nitrous oxide (CAS RN: 10024-97-2, N_2O) is a nonflammable, stable, colorless, odorless gas that is heavier than air (vapor density = 1.53, air = 1). The molecular weight of nitrous oxide is 44.01 g/mol. This gas has a slightly sweet taste. The low blood/gas solubility of nitrous oxide results in rapid equilibration between alveoli and blood along with rapid penetration of the blood–brain barrier. Nitrous oxide achieves approximately 90% equilibration between inspired gas and alveoli within 10 minutes.[3]

Whippets refers to whipped cream dispensers used recreationally for the abuse of nitrous oxide.

EXPOSURE

Epidemiology

Nitrous oxide is an occasional drug of abuse among medical and dental personnel. Adolescents and young adults also abuse the nitrous oxide present as a propellant in dairy products (e.g., whippets). In a study of juveniles in a correctional facility, nitrous oxide was 1 of the 5 most abused volatile substances after gasoline, Freon, butane lighter fluid, and glue.[4]

Sources

Nitrous oxide is an anesthetic and analgesic gas that has been investigated as a drug (psychotropic analgesic nitrous oxide) to reduce the cravings associated with withdrawal from alcohol, cocaine, and methaqualone.[5,6] This gas is the only inorganic gas used for clinical anesthesia. Nitrous oxide is also a propellant in whipped cream.

Methods of Abuse

Abuse of nitrous oxide typically involves the inhalation of the contents of nitrous oxide-containing containers or inhalation from a balloon filled with the gas. The euphoria usually begins within 15–30 seconds of the beginning of inhalation with peak effects occurring in

~2–3 minutes.[7] The euphoria is associated with a sensation of warmth in the head and auditory illusions. Rebreathing the nitrous oxide prolongs these effects. Case series suggest that chronic nitrous oxide use is associated with medical and psychiatric complication of addiction, but the incidence of addiction to nitrous oxide is extremely low.[8]

DOSE EFFECT

Illicit Use

The minimum alveolar concentration (MAC) is a measure of anesthetic potency as reflected in the concentration or percent of inspired gas at 1 atmosphere (atm) necessary to render 50% of patients unresponsive to surgical stimulus. Because the MAC reflects an adequate dose for only 50% of the patient, successful clinical anesthesia requires 0.5–2 MAC for an individual patient. Nitrous oxide is the least potent anesthetic in modern practice with a MAC of 105; however, MAC is a measure of anesthetic potency rather than a precise measure of respiratory or cardiac effects. The effect of chronically inhaling nitrous oxide depends, in part, on the current intake and the pool of vitamin B_{12} at the time of abuse. The inhalation of approximately 40–60 whipped cream bulbs daily for the preceding 6 months was associated with the development of paresthesias, gait disturbance, and signs of an axonal peripheral neuropathy.[9] In a case series of 13 dentists with nitrous oxide abuse and myeloneuropathy, the reported period of abuse ranged from 3 months to several years.[10]

Toxicity

Subanesthetic concentrations of nitrous oxide for sedation, amnesia, and analgesia in dentistry and minor surgical procedures range from about 20–30% atm. At these concentrations, human behavioral studies indicate that some impairment of psychomotor function (tapping rate, choice reaction time),[11] learning,[12] cognition (word recall, arithmetic tests.),[13] and memory[14] occurs. These effects resolve rapidly (i.e., within minutes) after cessation of use. The anesthetic potency of nitrous oxide is low, and satisfactory anesthesia is not possible without simultaneous anoxia. At least 30% oxygen under normobaric conditions are necessary to overcome ventilation perfusions changes associated with general anesthesia; typical concentrations of nitrous oxide for anesthesia with controlled ventilation is 65–70%.[15] The maximum tolerable mixture of nitrous oxide and oxygen for prolonged inhalation is 65% and 35%, respectively. The inhalation of 85% nitrous oxide with oxygen is tolerable only for brief exposures.

TOXICOKINETICS

Kinetics

The rate of uptake of a gas depends on the following factors: 1) ventilation, 2) blood/gas solubility coefficient, 3) alveolar/blood partial pressure difference, 4) cardiac output, and 5) diffusion of the gas across the alveolar membrane.[16] Based on measurements of nitrous oxide at the mouth, the estimated uptake of nitrous oxide is inversely proportional to the square root of the time elapsed from the start of administration.[17] Using this equation, the estimated uptake of nitrous oxide during the first minute is about 1L compared with 129 mL/min after 60 minutes and 90 mL/min after 2 hours of anesthesia.[18] The lungs excrete nitrous oxide unchanged in exhaled air; the rate of elimination is rapid after inhalation ceases. The nitrous oxide concentration in expired air drops rapidly to about 25% of the initial value; then, the decline is more gradual. Cardiac output has little effect on the elimination of nitrous oxide because of the low solubility of this gas. The placental transfer of nitrous oxide is time-dependent and slower than the maternal uptake of nitrous oxide.[19]

Tolerance

There are few human data on tolerance to the chronic use of nitrous oxide. In rodent studies, tolerance develops to the effects of nitrous oxide in the animals after prolonged exposure (e.g., 18 h exposure to 70% nitrous oxide in Plexiglas chambers followed by a 30-minute recovery before testing).[20]

Drug Interactions

Nitrous oxide is an effective adjunct to the administration of other anesthetics because the concomitant inhalation of these anesthetics with nitrous oxide reduces the MAC of the other anesthetics. However, the reduction of MAC is not consistent between studies, and the effect of nitrous oxide on the MAC of other anesthetics does not correspond to a simple additive relationship.[21] In very high concentrations, nitrous oxide is a cardiorespiratory depressant; consequently, exposure to other central nervous system depressants would be expected to enhance these depressant effects. Nitrous oxide activates supraspinal opioid receptors via corticotropin-releasing factor; however, existing studies are inadequate to determine if the potential interaction of nitrous oxide and opioids is clinically significant.[22]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

The anaesthetic action of nitrous oxide remains unclear. The mechanism of action of nitrous oxide probably involves the release of β-endorphins and the binding of μ-, δ-, and κ-opiate receptors. Animal studies suggest that the analgesic effects of nitrous oxide result from opioid peptide release in the periaqueductal gray area of the midbrain and the subsequent activation of the descending inhibitory pathways and noradrenergic neurons.[23] This action modulates the nociception process in the spinal cord. Implicated receptors include dopamine receptors, benzodiazepine (GABA) receptors, α_2-adrenoceptors, and N-methyl-D-aspartate (NMDA) receptors.[24] Experimental studies indicate that nitrous oxide inhibits NMDA-activated currents, while GABA-activated currents are unaffected.[25] Nitrous oxide may also be a dopamine agonist.[26] Positron emission tomography (PET) scans of volunteers receiving nitrous oxide demonstrate activation in the anterior cingulate cortex (psychomotor and cognitive processes), and deactivation in the posterior cingulate, hippocampus, parahippocampal gyrus, and visual association cortices in both hemispheres.[27] The former two regions mediate learning and memory.

Mechanism of Toxicity

Nitrous oxide is an anesthetic and respiratory depressant. This gas is a mechanical asphyxiant that causes hypoxia by displacing oxygen. In addition, nitrous oxide increases the alveolar-arterial difference of oxygen in the alveoli. Both of these properties cause hypoxia; therefore, prolonged inhalation of pure nitrous oxide will cause asphyxia. Nitrous oxide abuse may cause a posterior column myelopathy (e.g., subacute combined neurodegeneration of the spinal cord) by inactivation of vitamin B_{12} dependent enzymes. Nitrous oxide oxidizes the monovalent cobalt in cobalamin to the bivalent ion, resulting in the inactivation of the vitamin B_{12}-dependent enzyme, methionine synthase. This enzyme catalyzes the formation of tetrahydrofolate and methionine from homocysteine and methyltetrahydrofolate. The purpose of these chemical reactions is the formation of 10-formyl tetrahydrofolate for DNA synthesis and the replenishment of the one-carbon pool. The effect of reduced methionine synthase activity depends, in part, on the pre-existing pool of vitamin B_{12}; individuals with vitamin B_{12} deficiency will experience more adverse effects from the use of nitrous oxide than patients with normal vitamin B_{12} stores.[28] Recovery of methionine synthase activity requires the synthesis of new enzymes (i.e., 3–4 days); however, full recovery may be delayed several weeks.[29] Animal studies suggest that the euphoric effects of nitrous oxide are mediated by the partial opioid agonist properties of this gas.[30]

Postmortem Examination

The postmortem examinations of individual dying during the abuse of nitrous oxide are nonspecific including contraction band necrosis in the myocardium.[31] In a case series of 4 fatalities related to the use of nitrous oxide, the only postmortem finding was visceral congestion.[32]

CLINICAL RESPONSE

The clinical response to nitrous oxide varies with some patients experiencing euphoria, while others experience little or even unpleasant effects. Descriptions of the euphoric effects associated with nitrous oxide include numbness, lightheadedness, tingling, warmth, stiffness, and auditory hallucinations. In a study of volunteers receiving 30% nitrous oxide, inhalation was associated with a dreamy, detached state characterized by euphoric mood, changes in body image, and alteration of time perception.[33] Adverse effects of nitrous oxide anesthesia include hypoxia, claustrophobia, and nausea.

Complications

Nitrous oxide abuse is associated with a sensorimotor polyneuropathy characterized by broad-based gait, ataxia, and sensory loss (vibration, position sense). The clinical presentation of these neurologic changes is virtually identical to subacute combined degeneration with posterior and lateral column injury associated with pernicious anemia. Case reports associate chronic abuse of nitrous oxide (whippets) with an ascending sensorimotor neuropathy and gait disturbances similar to Guillain-Barré syndrome.[34] Clinical features include paresthesias in the extremities, loss of coordination, gait disturbances, generalized weakness, brisk reflexes in the distal portion of the extremities, a positive Romberg sign, impotence, sphincter disturbances, and reduced proprioception with preservation of temperature and pain sensation.[9,35] Occasionally, Lhermitte sign (i.e., an electric sensation transmitted down the spine during neck flexion or rotation) is present. Cognitive ability is usually unaffected in the absence of acute intoxication. However, some case reports of nitrous oxide abuse document both impairment of cognitive function (recall, word list generation) and reduced temperature and pain sensation in a stocking-glove distribution.[36] Typically, the peripheral neuropathy gradually improves with cessation of exposure.

Abstinence Syndrome

Withdrawal symptoms are usually not associated with nitrous oxide abuse.

Reproductive Abnormalities

Some epidemiologic studies of medical personnel suggest that spontaneous abortions may increase following chronic low-level exposure to nitrous oxide in surgical or dental operating suites.[37] However, these studies are limited by failure to control for confounding variables and poor exposure data (e.g., the use of job title as a surrogate for nitrous oxide exposure). More recent studies in hospitals using scavenger equipment to reduce nitrous oxide concentrations have not detected an increased incidence of reproductive abnormalities in exposed women.[38,39] There are few data on the effect of nitrous oxide abuse in pregnant women.

DIAGNOSTIC TESTING

Analytic Methods

Methods for the determination of nitrous oxide in biologic samples include gas chromatography with microionization cross-section detection,[40] gas chromatography with thermal conductivity detection,[41] capillary gas chromatography/mass spectrometry in selected ion monitoring,[42] and headspace gas chromatography/mass spectrometry.[43]

Biomarkers

The nitrous oxide concentration in operating theater personnel depends on the effectiveness of scavenging devices.[44] The mean nitrous oxide concentrations in the breathing zones of anesthesiologists practicing in operating rooms with and without scavenging devices were 57 ppm (range, 6–203 ppm) and 534 ppm (range, 52–2,385 ppm), respectively.[45] The mean nitrous oxide concentrations in the blood of the anesthesiologists in rooms with scavenging devices was ~12 mg/L (~12 ppm), whereas the nitrous oxide concentration in the blood of anesthesiologists in the operating rooms without scavenging devices was up to 10-fold higher. In a study of 80 operating theater personnel, the mean nitrous oxide concentration in air at the end of the operation was 0.049 mg/L as measured by personal passive samplers at collar height.[46] The mean concentrations of nitrous oxide in blood and urine samples collected simultaneously with the air samples was 0.023 mg/L and 0.026 mg/L, respectively. Isolated urine samples of exceptionally high urinary nitrous oxide were attributed to asymptomatic urinary tract infections.

In a case series of 4 individuals found dead following the use of nitrous oxide inside a car, the concentration of nitrous oxide in postmortem blood samples (location not specified) ranged from 46,000 to 93,000 ppm (reported as 4.6–9.3 mL/dL) as measured by headspace gas chromatography with thermal conductivity detection.[32] A 26-year-old man in the same series was found dead in bed with a tube connected to his mouth from a tank of nitrous oxide. His postmortem blood nitrous oxide concentration (site not specified) was 89,700 ppm as measured by the same method.[41]

Abnormalities

Electrodiagnostic testing of patients with peripheral neuropathy associated with nitrous oxide abuse is consistent with patients who have an axonal peripheral neuropathy. Nerve conduction studies demonstrate reduced amplitude and delayed motor/sensory conduction along with prolonged F wave latencies and absent H reflexes.[47] Sensory evoked potentials reveal prolonged latency of scalp-evoked potentials from tibial nerve stimulation, but median nerve values may be normal. Denervation potentials may also appear. The somatosensory evoked potentials from tibial nerve stimulation may be normal to the lumbar spine, but slow conduction often occurs to the cortex.[9] Substantial clinical improvement in these parameters occurs within a year, but minor conduction delays, loss of H reflexes, denervation potentials, or reduced posterior tibial sensory evoked potentials may remain.[48] Abnormalities on sural nerve biopsy are nonspecific, characterized primarily by axonal degeneration.[49] Magnetic resonance imaging (MRI) of the brain is usually normal. MRI findings in patients with neurologic changes suggestive of a demyelinating process include symmetrical T2-weighted hyperintensities and T1-weighted hypointensities of the posterior and lateral columns of the spinal cord, primarily in the cervical and thoracic regions.[50] These MRI changes are not specific to nitrous oxide abuse as these changes occur in other diseases (e.g., human immunodeficiency virus [HIV], lupus, syphilis, Devic disease). Other abnormalities include megaloblastic anemia with increased mean red cell volume, reduced serum vitamin B_{12} concentrations, and low serum folate; however, serum vitamine B12 concentrations may be normal despite the presence of a prominent sensorimotor neuropathy.[34]

Driving

Based on volunteer studies, the effect of nitrous oxide on driving skills diminishes rapidly after cessation of exposure. In a study of 10 dental students, increased errors on a driving simulator were demonstrated within

15 minutes of cessation of exposure to 50–70% nitrous oxide with oxygen.[51] However, the driving of some students improved compared with no exposure. Following the inhalation of self-administered nitrous oxide/oxygen as a sedative/analgesic medication for colonoscopy, scores on psychomotor function returned to normal within 30 minutes.[52] These tests included multiple-choice reaction time, hand–eye coordination, and letter deletion tests. In a study of 80 patients undergoing colonoscopy with a 50% nitrous oxide/50% oxygen mixture, the scores on the adaptive tracking task were compared with baseline scores prior to self-administered analgesia.[53] The mean time between screening and re-testing was approximately 11 minutes (range, 2–30 minutes). There was no statistically significant decline in test scores, and improvement in testing scores of the exposure group was similar to the age-matched control group (no nitrous oxide).

TREATMENT

The treatment of acute exposure to nitrous oxide is supportive with primary focus on the detection and treatment of any respiratory insufficiency. Case reports suggest that supplementation with methionine and vitamin B_{12} may improve the clinical course of the neuropathy associated with nitrous oxide abuse.[54] The dose of methionine is 1 gram 3 times daily. Suggested regimens for the peripheral neuropathy include vitamin B_{12} 100–1,000 µg intramuscularly (IM) daily for 5 days followed by 100–1,000 µg weekly for 5 weeks, then 100 µg to 1,000 µg monthly by mouth until resolution or stabilization of the patient.[55] Other regimens include IM vitamin B_{12} 100 µg daily for 5 days followed by 250 µg daily by mouth for 1 month.[36] Folate supplementation is necessary only when there is a documented folate deficiency.

B   Fluorinated Alkanes

Chapter 41

FLUORINATED ALKANES

HISTORY

Medgley and Henne first reported the synthesis of fluorinated aerosol propellants (i.e., dichlorodifluoromethane, Freon 12) in 1930. These compounds were introduced as a less-toxic refrigerant gas to replace ammonia and sulfur dioxide. Aerosol insecticides (Freon 12) were introduced by the military during World War II, and these insecticides were released to the civilian market in 1947.

IDENTIFYING CHARACTERISTICS

Structure

Trichloromonofluoromethane (FC11) and trichlorotrifluoroethane (FC113a) are liquids at room temperature and standard pressure, whereas dichlorodifluoromethane (FC12) is highly volatile under these conditions. The lipid solubility of FC11 and FC113 are similar and greater than the lipid solubility of FC12 and FC114. The boiling point of chlorodifluoromethane (FC22) is −40.7°C (−41.3°F); this compound is typically stored as a liquid at a pressure of 150 psi. The temperature of the vapors released from these containers is below the boiling point; therefore, exposure to the vapors may cause severe frostbite. At 25°C (77°F) and 760 mm Hg, the relative density of air saturated with FC22 (42.1%) is 3.3 (air = 1), and the vapor pressure is 334 mm Hg. Bromochlorodifluoromethane (FC1211) is a volatile liquid with a boiling point of −3.7°C (25.3°F) that forms a noncombustible cloud over fires and interferes with the chemical reactions within the fire. The boiling point of 1,1-difluoroethane is −24.9°C (−12.8°F), and the rapid evaporation of the liquid causes frostbite as the tissues are cooled below 0°C (32°F). This compound is colorless, odorless, water insoluble, and highly flammable.

Table 41.1 lists identifying data and the boiling points of common fluorocarbons.

Terminology

Fluorinated alkanes are frequently identified by number (e.g., Freon 113). The first digit on the right indicates the number of fluorine atoms, the second digit from the right is one less than the number of hydrogen atoms, and the third digit (absent if zero) is one less than the carbon atoms. Letters identify isomers with "a" denoting the isomer containing the smallest mass difference on each carbon atom. Other letters are added as masses of other isomers diverge from the "a" isomer. For example, Freon 113a is 1,1,1-trichloro-2,2,2-trifluoroethane (trichlorotrifluoroethane).

EXPOSURE

Epidemiology

Fluorinated alkane propellants were popular volatile substances of abuse during the late 1960s and early 1970s, particularly FC11, FC12, and FC114.[1] Abuse of fluorocarbons includes the chronic inhalation of freon-containing refrigerant as well as the abuse of medical inhalers containing Freon propellants.[2] The excessive use of these inhalers even involves children as young as 4 years of age.[3] The abuse of products containing fluo-

TABLE 41.1. Fluorocarbon Identification.

Fluorocarbon	CAS Number	Names	Molecular Formula	Boiling Point
Bromochlorodifluoromethane	353-59-3	FC1211, Freon 12B1, Halon 1211, Fluorocarbon 1211,	$CBrClF_2$	−3.7°C

1,1,1-Trichloro-2,2,2-trifluoroethane (Trichlorotrifluoroethane)	354-58-5	FC 113a, Freon 113a, fluorocarbon 113a	$C_2Cl_3F_3$	46.1°C

rinated alkanes propellants has declined as other compounds (e.g., alkanes) have replaced these products.

Sources

Halogenated fluorocarbons are used as solvents, aerosol propellants, refrigerants, plastics manufacturing, foam blowing, and components of fire extinguishers with the fluorocarbon concentration varying depending on the use. Aerosols contain propellants, solvents, and active ingredients along with additives (e.g., perfumes, emollients). The use of halogenated hydrocarbons as propellants has decreased because of concern about the effect of these relatively inert compounds on the ozone layer. Bromochlorodifluoromethane and bromotrifluoromethane are constituents of fire extinguishers used to suppress electrical fires. 1,1-Difluoroethane is a component of airbrush propellants and refrigerants.

Methods of Abuse

Methods for abusing volatile halogenated hydrocarbons primarily involve the pouring of the substance on a rag or in a container followed by the inhalation of the vapors. Alternate methods include attempting to inhale vapors from air conditioner fluid (chlorodifluoromethane) directly from the air conditioner unit.[4] At times, a plastic bag is placed over the person's head to increase the concentration of the vapors. Dusting is the inhalation of halogenated hydrocarbons (e.g., difluoroethane, tetrafluoroethane) found in office products containing compressed air. Volatile substance abuse of bromochlorodifluoromethane typically involves the discharge of the fire extinguisher into a plastic bag and the subsequent inhalation of the vapors from the bag.

DOSE EFFECT

Animals

Animal studies demonstrate observable narcotic effects (loss of coordination, tremor, disequilibrium, irregular breathing, lacrimation) at concentrations around 50,000 ppm FC113, whereas anesthetic effects (unconsciousness, convulsions, and death) occur after exposure to ~100,000 ppm FC113 for several hours.[5] Other animal

studies indicate that guinea pigs develop disequilibrium after a 1-minute exposure to 165,000 ppm FC113, whereas rats exposed to 220,000 ppm FC113 developed convulsions, coma, cyanosis, and death within 3–15 minutes; however, these concentrations are sufficient to reduce the oxygen concentration to levels causing asphyxia.[6]

Humans

In volunteer studies, short-term exposure (i.e., <30 minutes) to 40,000 ppm FC1301 caused lightheadedness, confusion, ringing in the ears, and impaired coordination; exposure to 60,000 ppm was associated with increased heart rate, depressed T waves, and premature ventricular contractions.[7,8]

TOXICOKINETICS

Absorption

Halogenated hydrocarbons are rapidly absorbed following inhalation. However, the relatively low peak arterial concentrations of fluorocarbons compared with the total doses administered suggest the amount of fluorocarbons absorbed by the lungs is low. In a study of asthmatic patients inhaling bronchodilators with fluorinated hydrocarbon propellants, peak concentrations of trichlorofluoromethane (FC11) in venous blood occurred 30–90 seconds after inhalation.[9] Similarly, the peak concentration of FC11 in arterial blood from 6 volunteers occurred with 30 seconds after inhalation of this substance.[10] The absorption of FC12 and FC114 are relatively slow compared with FC11 and FC113.[11] Based on [38]Cl-labeled fluorocarbon studies in volunteers following the single-breath inhalation, the retention of fluorocarbons 30 minutes after inhalation ranged from 10% for FC114 to 23% for FC11 as demonstrated in Table 41.2. In a study of 3 volunteers, the lungs absorbed only about 2% of the inhaled dose of FC22 during the

TABLE 41.2. Percentage of Inhaled Fluorocarbon Vapors Retained by Three Volunteers 30 Minutes after Inhalation.[11]

Fluorocarbon	Retention Range (%)	Retention Mean ± Standard Deviation (%)
FC11	19.8–26.6	23.0 ± 2.2*
FC12	8.8–14.2	10.3 ± 2.2
FC113	18.7–21.0	19.8 ± 0.9
FC114	9.2–18.1	12.3 ± 4.1

*Four volunteers.

4 hours of the study.[12] The estimated pulmonary retention of FC113 was about 14% (95% CI: 12–16%) following exposure of 7 volunteers to 1,000 ppm FC113 for 4 hours.[13] Following exposure of 4 pairs of volunteers to 10,000 ppm FC1301 for 24 hours, steady-state concentrations of FC1301 occurred about 2 hours after the beginning of exposure.[14]

Distribution

In volunteer studies, the estimated fat/blood partition coefficient of FC22 was ~10 with a mean blood/air partition coefficient of 0.76 at 20 mg/L,[12] whereas the fat/blood partition coefficient of FC113 was approximately 146 at 20 mg/L.[13] Rodent studies indicate that FC152a is distributed to the brain and blood within seconds after the inhalation of high concentrations of FC152a with intoxication occurring within 20 seconds.[15]

Biotransformation/Elimination

In general, the metabolism of fluorinated alkanes is minimal. Because of low lipid solubility, most inhaled fluorocarbon vapors are exhaled without diffusing across alveolar membranes. Animal and human studies indicate that the elimination of fluorocarbons from the blood is rapid.[16] The blood elimination half-life of trichlorofluoromethane (FC11) in 5 asthmatic patients and 1 control ranged between 0.3–1.5 minutes. In a study of 3 dogs receiving FC11, the mean terminal half-life of FC11 in arterial blood was approximately 3–5 minutes.[17] The elimination of FC22 from venous blood was rapid following exposure of 3 volunteers to 518 ppm FC22 for 4 hours, characterized by a mean initial half-life of 0.23 hour and a mean terminal half-life of 2.8 hours.[12] The lack of an increase in serum fluoride suggests that the biotransformation of FC22 is minimal. In this study, the amount of FC22 excreted in the urine was small. The mean initial and terminal elimination half-lives following exposure of 4 pairs of volunteers to 10,000 ppm FC1301 were 4.5 minutes (range, 2.5–8.1 minutes) and 200 minutes (range, 131–347 minutes), respectively.[14]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

Close contact with the vapors of halogenated hydrocarbons released from containers containing pressurized liquid may cause severe local tissue damage. The temperature of these vapors close to the container is typically below the boiling point of the substance, which is

substantially lower than freezing. Therefore, direct contact with these vapors causes severe frostbite.

There are few human data on the mechanisms associated with sudden death during volatile substance abuse. Animal studies suggest that halogenated alkanes may sensitize the heart to the development of dysrhythmias.[18,19] Ventricular fibrillation was an uncommon rhythm during these experiments as the most common dysrhythmia in mice that were asphyxiated after inhaling fluorocarbon propellants was a bradyarrhythmia initiated during asphyxia.[18] There were marked differences in the dysrhythmogenic potential of fluorocarbons between animal species and between different fluorocarbons.[20,21] These studies used anesthetics to depress consciousness, oxygen deprivation, and large doses of epinephrine (5–6 µg epinephrine/kg by central venous catheter over 10 seconds) that substantially exceed the maximum endogenous rate of human epinephrine secretion. Typically, these changes occur only a few minutes after the administration of the epinephrine.[22,23] In a study of 16 anesthetized dogs receiving intravenous pentobarbital, normal arterial oxygen tensions, carbon dioxide tension, and pH were maintained during exposure to high concentrations of fluoroalkane propellants (FC11, FC12).[24,25] The most common scenario was an immediate, dramatic slowing of the heartbeat (sinus bradycardia), followed by A-V dissociation with progressively lower escape rhythms and ultimately electrical and mechanical asystole. Only 2 of the dogs developed ventricular fibrillation. Consequently, the conditions of these studies do not necessarily simulate the conditions present during volatile substance abuse. Animal studies indicate that there is substantial variation in the cardiac effects between both animal species and fluorocarbon compounds.[26] Other possibilities for the effects of fluorocarbons include the general phenomenon of disruption of normal cellular function by chemically inert lipid-soluble compounds.

Postmortem Examination

The postmortem findings in cases of sudden death associated with the abuse of halogenated hydrocarbons are usually nonspecific (pulmonary congestion, cerebral edema, hyperemia of the trachea). A 15-year-old adolescent with a history of inhaling fumes from electrical fire extinguishers (bromochlorodifluoromethane) collapsed and died later that day in the hospital.[27] Postmortem examination confirmed exposure to bromochlorodifluoromethane along with cerebral edema, anoxic brain damage, pulmonary congestion, and blood-stained foam in the airways. Postmortem examination may reveal alternate causes of death (e.g., aspiration of stomach contents, laryngeal obstruction)[28,29] or evidence of cold injuries on the hands or mouth.[4]

CLINICAL RESPONSE

Illicit Use

Adverse effects associated with the inhalation of vapors from halogenated hydrocarbons include nausea, vomiting, disorientation, altered consciousness, and dysrhythmias including ventricular fibrillation. A 15-year-old adolescent discharged a fire extinguisher into a plastic bag and then placed the bag over his head. He inhaled vapors from the bag numerous times, then, he collapsed.[30] Medical personnel found him pulseless and apneic. Cardiac monitoring demonstrated ventricular fibrillation; he was defibrillated and intubated. He regained consciousness in the hospital; by the sixth day he was conversant without focal neurologic signs.

Complications

Complications of the intentional abuse of halogenated products include loss of consciousness, seizures, frostbite (2nd/3rd degree burns), and dysrhythmias.[31] Severe local burns of the hand may require amputation of the affected digits.[32] Local tissue damage to the mouth and airway may cause edema and obstruction that requires intubation or tracheostomy, particularly following exposure to liquid freon when the container is inverted.[33,34] A 16-year-old adolescent presented to the emergency department after losing consciousness while inhaling vapors from an open container that was releasing a propellant containing 1,1-difluoroethane.[35] After regaining consciousness, he noted that his lips were cold and blistered. About 4 hours after presentation to the emergency department, he developed respiratory distress that required nasotracheal intubation. Endoscopy revealed first- and second-degree burns of the larynx with involvement of the vocal cords along with first-degree burns of the proximal esophagus and trachea. Second- and third-degree burns were present on the lips, tongue, and oral cavity. Fluorosis (diffuse sclerosis, increased bone density) of the boney skeleton is a potential complication of chronic fluorocarbon abuse. Most common fluorinated alkanes are listed by the International Agency for Research on Cancer (IARC) as Group 3 compounds (not classifiable as to its carcinogenicity to humans).[36,37,38]

Fatalities

Death immediately following volatile substance abuse with halogenated alkanes may result from respiratory

depression, ventricular fibrillation, suffocation, airway obstruction (laryngeal spasm/edema), or aspiration of gastric contents. Case reports document sudden death following the intentional inhalation of fluorinated alkanes, primarily involving dichlorodifluoromethane (FC11)[39,40] and trichlorofluoromethane (FC12).[41] In a few of these cases, ventricular fibrillation was documented as the initial rhythm during the course of resuscitation.[42] Typically, these individuals feel unwell shortly after inhaling the vapors and then collapse. A case series documented the sudden deaths of 5 youth following the inhalation of vapors from fire extinguishers (bromochlorodifluoromethane).[43] Postmortem examinations did not demonstrate natural causes of death, and postmortem blood confirmed exposure to bromochlorodifluoromethane. Animal studies and case reports suggest that the risk of sudden death occurs during or shortly (i.e., <5–10 minutes) after cessation of exposure to fluorinated alkanes.[44]

DIAGNOSTIC TESTING

Analytic Methods

Methods for the detection of halogenated propellants in biologic samples include headspace gas chromatography with flame ionization or electron capture detection,[45] direct injection gas chromatography/mass spectrometry (GC/MS), headspace mass spectrometry without separation,[46] and headspace GC/MS.[47] The lower limit of quantitation for 1,1-difluoroethane following analysis with headspace GC/MS with flame ionization detection was approximately 4 mg/L (4,000 µg/L).[48]

Proper specimen collection in sealed containers within a timely manner after death is necessary to detect fluorocarbons in postmortem samples. The high volatility of halogenated hydrocarbons requires careful handling of tissue samples with storage in air-tight containers at −30°C (−22°F). Separation of samples, standards, and glassware in separate freezers helps prevent cross-contamination.

Biomarkers

PHARMACEUTIC USE

FC11 was detectable in blood samples 1 hour after the use of an inhaler containing FC11 at a concentration of ~0.120 mg/L, as measured by gas chromatography with electron capture detection.[10] By 2 hours after the use of the inhaler, the FC11 concentration was nondetectable. Following exposure of 3 volunteers to 92 ppm and 518 ppm FC22 for 4 hours, the mean peak FC22 con-

centrations in venous blood samples were 0.25 mg/L and 1.36 mg/L, respectively.[12] Peak concentrations in venous blood occurred approximately 1 hour after exposure began. Following exposure to 10,000 ppm FC1301, the steady concentration of FC1301 was about 3–4.5 mg/L beginning 2 hours after exposure began.[14]

POSTMORTEM

The dichlorodifluoromethane concentration in postmortem blood samples from a man found dead following autoerotic activities was 3.2 mg/L.[49]

1,1-DIFLUOROETHANE. Analysis of postmortem blood samples from 2 adolescents, who died in a crash immediately after their car crossed the median of a four-lane highway, detected 1,1-difluoroethane (FC152a) concentrations of 78 mg/L (driver) and 35 mg/L (passenger).[50] The blood sample from the driver also contained ethanol (13 mg/dL). A 42-year-old man was found dead in his car surrounded by approximately 40 canisters of aerosol duster (difluoroethane).[51] His postmortem femoral blood contained difluoroethane (136.3 mg/L), and the postmortem examination demonstrated myocardial fibrosis and an acute infarction in the left ventricle. A 20-year-old man was found dead with dust remover next to his body, and his postmortem femoral blood contained 1,1-difluoroethane (83.5 mg/L) as measured by headspace gas chromatography with flame ionization detection.[52] In contrast to the blood sample from the previous man, the postmortem blood sample from this man was not sealed in headspace vials at autopsy. A 24-year-old woman died immediately after a single-vehicle accident.[53] The passenger survived, and reported that the driver was inhaling Dust Off Duster (Dupont, Wilmington, DE) while driving shortly before the accident. The femoral blood and vitreous humor contained 1,1-difluoroethane concentrations of 29.8 mg/L and 21.3 mg/L, respectively. The postmortem distribution of difluoroethane in the body suggested that she was in the distribution phase after inhaling this compound. The chest cavity and aortic blood contained 1,1-difluoroethane concentrations of 79.9 mg/L and 85.6 mg/L, respectively.

CHLORODIFLUOROMETHANE. A 22-year-old man developed coughing and wheezing after inhaling fluorocarbon vapors; he presented to the emergency department in ventricular fibrillation.[54] He was pronounced dead 1 hour after being found by his roommates, and the autopsy demonstrated only nonspecific findings. The cans of fluorocarbons found near him contained a 50:50 mixture of chlorodifluoromethane (FC22) and chloropentafluoroethane (FC115). The concentrations of FC22

and FC115 in postmortem blood samples were 71 mg/L and 0.30 mg/L, respectively. The difference in the concentrations of these 2 fluorocarbons may reflect differences in pharmacokinetics, inhaled concentrations, and/or vapor pressures in alveolar blood. Two crew members collapsed while entering a compartment filled with FC22, and they died at the scene.[55] At autopsy 16 hours later, blood samples from the 2 victims contained FC22 concentrations of 37,100 ppm (reported as 37.1 μL/mL) and 26,000 ppm. The concentrations of FC22 in postmortem blood samples were approximately 37 times higher than in vitreous humor.

Dichlorofluoromethane.   A 29-year-old man with a history of fluorocarbon abuse was found dead with a tube in his mouth connected to a Freon dispenser.[56] The postmortem blood contained 8,600 ppm FC21.

Trichlorofluoromethane.   A   23-year-old   factory worker was found dead in a room, which contained a leaking reservoir of FC11.[57] The postmortem examination did not demonstrate a cause of death other than FC11 intoxication. The postmortem blood sample contained 62.8 ppm FC11 compared with 108.9 ppm in the brain and 406.6 ppm in the heart tissue, as measured by gas chromatography/mass spectrometry.

Urine

Detection of fluorocarbons in the urine depends on the dose and time since exposure. In a study of 3 volunteers exposed to 518 ppm FC22, this compound was detectable in urine samples for at least 22 hours, as determined by gas chromatography/flame ionization detection (limit of detection, 0.003 mg/L).[12] FC113 concentrations in urine samples following exposure of volunteers to 1,000 ppm FC113 was below the limit of detection (<1 mg/L).[13]

TREATMENT

First Aid

Animal studies indicate that ocular contact with FC113 produces only mild conjunctivitis and minimal corneal dullness 24 hours after exposure.[58] Splashes to the eye of FC113 should be irrigated copiously with water and medical   attention   sought   if   redness   persists. Decontamination measures are usually unnecessary following oral exposures because FC113 is not well absorbed from the gastrointestinal tract. The main danger results from the inhalation of large concentrations of FC113 or other fluorocarbons that produce narcosis and rarely dysrhythmias. The victim should be removed from the contaminated environment as soon

as safely feasible. Respiration and pulses should be immediately checked and artificial respiration and chest compression begun as necessary. Frostbite of the mouth may cause airway obstruction in severe cases. All patients with altered mental status should receive supplemental oxygen. The primary treatment for frostbite is rapid rewarming, such as a 30-minute warm water bath   (38°C–43°C/100°F–108°F)   for   frostbite on the extremities. Manipulation of tissue in the area of the frostbite should be avoided because this tissue is very sensitive to trauma unless necessary to secure an airway.

Acute Management

Respiratory depression and dysrhythmias represent the principal threat to patients abusing fluorinated alkanes, particularly FC11, FC12, and FC113. The adequacy of ventilation should be evaluated immediately and supplemental oxygen and/or intubation initiated as needed. The patient should be monitored for dysrhythmias. Patients in cardiac arrest should be resuscitated with the standard advanced cardiopulmonary resuscitation protocols including the use of epinephrine; there are inadequate clinical data to recommend specific dysrhythmic drugs. Patients usually recover rapidly as the body quickly eliminates these compounds within 6–24 hours following acute exposure. Hepatorenal dysfunction does not usually result from exposure to fluorinated alkanes. There are no methods to enhance elimination other than ensuring adequate ventilation because the lungs excrete almost all of the absorbed dose of fluorinated alkanes. Blood gases or pulse oximetry should be measured in all patients with altered mental status or symptoms of dyspnea. Usually, no direct sequelae result from exposure to fluorinated alkanes; however, sustained respiratory depression may produce hypoxic damage to the brain or heart.

Supplemental Care

Treatment is supportive. Asymptomatic patients or patients with mild symptoms that resolve may be discharged several hours after they become asymptomatic. Patients with evidence of dysrhythmia should be monitored for 4–6 hours. If all abnormalities resolve, asymptomatic patients may be discharged. Patients remaining symptomatic after observation should be observed overnight with cardiac monitoring.

BUTANE, ISOBUTANE, and PROPANE

BUTANE AND ISOBUTANE

IDENTIFYING CHARACTERISTICS

n-Butane and isobutane are colorless, odorless, and flammable gases at room temperature. Odorants are added to natural gas and liquified petroleum gas (LPG) as a means of identifying potentially explosive concentrations. *n*-Butane and isobutane are the 2 isomers of the 4-carbon aliphatic hydrocarbon, butane (C_4H_{10}). Butane is highly lipid soluble. Table 42.1 lists some physiochemical properties of *n*-butane and isobutane.

EXPOSURE

Epidemiology

Butane is 1of the 5 most common volatile substances of abuse;[1] additionally, this compound is 1of 3 compounds most often associated with sudden death secondary to volatile substance abuse along with propane.[2]

Sources

Items containing butane include cigarette or charcoal lighter fluid (75%–89%), pressurized fuel tanks, liquefied petroleum gas, natural gas, hairspray, and aerosol antiperspirants. Liquefied petroleum gas (LPG) is a mixture of butane and propane that varies in composition with season and type of product. Common LPG mixtures contain 60% propane and 40% butane with the relative butane percentage increasing in summer and the relative propane percentage increasing in winter.

Methods of Abuse

The abuse of butane occurs both in solitary and social situations. Methods of butane abuse include using the cover of the gas canister as a mask, filling a plastic bag with the liquid ("bagging"), and spraying the liquid on a towel before inhaling ("huffing").[3] Inhaled concentrations of volatile substances, including butane, depends on the mode of administration. Sniffing delivers the lowest concentration of butane and bagging the highest. Huffing these chemicals produces an inhaled butane concentration between that of sniffing and bagging. The desired effects of abusing volatile products with butane are euphoria, loss of inhibition, altered perception of body form, sense of slowing of time, illusions, lightheadedness, ataxia, and hallucinations.[4] These effects persist up to 15–20 minutes.[5] The rapid resolution of these effects results in repeated inhalation to maintain the desired effects; often, this pattern of use continues for 3–4 hours.

DOSE EFFECT

Animal studies indicate that *n*-butane and isobutane are central nervous system (CNS) depressants at very high concentrations; these compounds possess relatively less toxicity compared with pentanes.[6] These studies also

TABLE 42.1. Some Physiochemical Properties of *n*-Butane and Isobutane.

Physical Characteristic	*n*-Butane	Isobutane
CAS Registry Number	106-97-8	75-28-5
Molecular Formula	$C_4–H_{10}$	$C_4–H_{10}$
Molecular Weight	58.12 g/mol	58.12 g/mol
Melting Point	−138.4°C (−217.1°F)	−159.4°C (−254.9°F)
Boiling Point	−0.5°C (31.1°F)	−11.73°C (10.9°F)
Water Solubility	61 mg/L (Relatively Insoluble, 25°C/77°F)	49 mg/L (20°C/68°F)
Vapor Density	2.07 (Air = 1 @ 20°C/68°F)	2.07

suggest that the CNS depressive effects of *n*-butane are somewhat greater than the effects of isobutane. Exposure of human volunteers to 10,000 ppm butane for 10 minutes causes some drowsiness, but no other systemic symptoms.[7] Exposure of volunteers to 500 ppm isobutane 8 hours a day, 5 days per week for 4 weeks did not produce any abnormalities on continuous monitoring of the cardiac rhythm, electrocardiogram, neurologic exam, visual evoked response, memory tests, pulmonary function tests, or serum hepatic transaminase concentrations.[8]

TOXICOKINETICS

There are limited data on the toxicokinetics of butane isomers. Because butane isomers are gases, pulmonary absorption is the primary route of exposure. Dermal absorption is limited by the volatility of butane isomers. Based on similarities in animal studies with other alkanes, elimination of butane isomers is probably rapid with little accumulation in tissues.[9] *In vitro* studies indicate that hydrolysis of *n*-butane produces 2-butanol, which may be conjugated with glucuronic acid, oxidized to methyl ethyl ketone, or expired as 2-butanol in air.[10] These studies also demonstrate that *tert*-butanol is the primary hydrolytic product of isobutane metabolism; elimination of *tert*-butanol occurs either by conjugation with glucuronic acid or by excretion unchanged in expired air and urine. In rodent studies, metabolism of *n*-butane yields *sec*-butanol and methyl ethyl ketone, whereas the biotransformation of isobutane produces *tert*-butanol.[11] Presumably, microsomal enzymes oxidize butane to the corresponding secondary or tertiary alcohol; then, alcohol dehydrogenase catalyzes the oxi-

dation of these alcohols to the corresponding ketones. In mice, *tert*-butanol is the primary metabolite following inhalation of isobutane; there is no oxidation of *tert*-butanol to a ketone by alcohol dehydrogenase.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

n-Butane and isobutane are simple asphyxiants and mild CNS depressants with a very narrow safety margin between anesthetic and lethal concentrations. Potential mechanisms for sudden death following the inhalation of butane or isobutane vapors include asphyxia, trauma after dangerous behavior, respiratory depression, aspiration, and cardiac dysrhythmia. Although some authors suggest that myocardial sensitization causes sudden death during butane or isobutane abuse based on experimental studies and case reports, this theory is difficult to prove in individual cases because of the presence of confounders (e.g., hypoxia, respiratory and myocardial depression, concomitant drug use). Animal studies indicate that high doses of epinephrine and high concentrations of isobutane (50,000 ppm)[12] predispose dogs to develop cardiac dysrhythmias. However, the clinical relevance of these abnormalities is unclear because of the difference in blood concentrations between these experiments and volatile substance abuse with the exception of bagging. Aspiration of liquid petroleum by a performer (e.g., during placement of flaming objects in their mouth) may cause hydrocarbon pneumonitis.

Postmortem Examination

Postmortem examinations of victims dying while inhaling products containing butane typically demonstrate nonspecific findings, similar to other volatile substances of abuse, such as findings consistent with suffocation (pulmonary edema, cerebral edema, general congestion of organs) or aspiration.[13] These abnormalities include conjunctival petechiae, edema of the lungs with subpleural hemorrhages, laryngeal edema, cerebral edema, passive congestion of the viscera, white to reddish frothy fluid in the airways, deep purple lividity, and terminal aspiration of stomach contents.[14] Vomiting is a common complication of butane abuse, and postmortem examination often demonstrates evidence of gastric aspiration.[13] Diffuse interstitial fibrosis of the myocardium may also be present on postmortem examination along with intrasarcolemmal accumulation of fibronectin and intracellular loss of the cardiac antigen, troponin C in myocardial fibers.[15] Herniation of the

685

cerebellar tonsils into the foramen magnum may also occur.[16]

CLINICAL RESPONSE

Illicit Use

Adverse effects associated with the acute inhalation of butane include eye, nose, and throat irritation, nausea, vomiting, abdominal pain, anorexia, ataxia, diplopia, fatigue, hallucination, confusion, weakness, and headache. Case reports associate encephalopathy with butane abuse, both as a result of chronic abuse[17] and postresuscitation sequelae of cardiopulmonary arrest during inhalant use.[18] The acute encephalopathy (i.e., disorientation, drowsiness) associated with high butane doses may persist for several days after cessation of use.[17] Psychiatric abnormalities include behavioral disturbances, mood swings, impulsive actions, social isolation, dependency, violence, irritability, delusions of persecution, and hallucination.[19] In some case reports, these psychotic symptoms persist months after the cessation of butane use.[20] A 16-year-old adolescent developed confusion, lethargy, hallucination, and agitation within 2 days after inhaling vapors from butane lighter fluid.[21] He was noncommunicative and ambulated slowly. Magnetic resonance imaging revealed severe bilateral thalamic injury; he remained profoundly mute and apathetic 3 months after the event.

Case reports associate myocardial infarction and ventricular fibrillation with butane abuse in adolescents.[22,23] Ventricular fibrillation may develop immediately following butane abuse in the absence of myocardial infarction.[24,25] Typically, these patients have normal coronary arteries and the presumed etiology of the myocardial infarction is butane-induced coronary artery vasospasm.[26] Asystole may occur during volatile substance abuse. A 16-year-old adolescent collapsed while surreptitiously inhaling butane in his bedroom; he was found unconscious by his parents.[27] The initial rhythm obtained by medical personnel on the scene about 5–10 minutes after his collapse was asystole. He was resuscitated at the scene, and he developed no other dysrhythmias in the hospital prior to discharge.

Ignition of butane during volatile substance abuse may cause severe burns of the hands, arms, and face. In a case series of 48 patients hospitalized at a Korean burn unit for injuries related to butane abuse, 22 patients required split-thickness skin grafts.[28] Five patients with major burns died of respiratory failure and/or septicemia. Flash fires in enclosed spaces (e.g., car) during butane abuse may cause inhalation injuries resulting in adult respiratory distress syndrome, septicemia, and death.[29]

Fatalities

Sudden death is a well-described complication of volatile substance abuse with butane.[30] Most deaths occur outside the hospital, and most of these cases involve asphyxia.[31] Causes of death during volatile substance abuse besides asphyxia include respiratory depression, aspiration of gastric contents,[32] asystole, and trauma (drowning, falls, motor vehicle accidents).[33] In several cases, ventricular fibrillation was the initial rhythm documented by medical personnel in case reports of intentional inhalation of butane; however, ventricular fibrillation is a rare complication of the intentional abuse of butane.[18] A 14-year-old boy inhaled butane gas from a portable fuel canister in a vacant lot for about 1½ hours.[34] He fled when police arrived; he was found collapsed about 15 minutes later. The initial cardiac rhythm obtained by medical personnel on the scene was ventricular fibrillation. Resuscitation was unsuccessful and postmortem examination 12 hours after death revealed no evidence of asphyxia.

DIAGNOSTIC TESTING

Analytic Methods

Methods for the analysis of butane and isobutane in biologic specimens include headspace gas chromatography with flame ionization detection,[35] headspace gas chromatography/mass spectrometry,[16] and solid-phase microextraction gas chromatography/mass spectrometry.[36] Because of loss during storage, samples should be analyzed as soon as possible after storage in gas-tight, well-sealed, inert containers with minimal headspace.

n-Butane and isobutane vaporize at room temperature and standard atmospheric pressures. However, samples stored in properly sealed containers designated for volatile substance and stored at −30°C (−22°F) will retain these gases within the coefficient of variation (10%) for 2 weeks.[34] Suitable containers include a preservative-free Vacutainer® or a tightly closed glass vial with a screw cap lined with Teflon septum.[37]

Biomarkers

The presence of butane and isobutane in postmortem tissue confirms exposure to this compounds antemortem, but interpretation of postmortem concentrations is complicated by perimortem and postmortem changes. These changes include volatilization during resuscitation efforts, loss during storage, postmortem losses (i.e., postmortem interval), and postmortem contamination. 2-Methyl-2-propanol is a metabolite of isobutane; the presence of this metabolite in blood samples confirms

the antemortem presence of isobutane. Following completion of the distribution phase, the highest butane concentrations occur in adipose tissues and brain. A 16-year-old boy was found dead at his home with a gas cylinder of cigarette lighter fluid near his body.[38] Analysis of subclavian blood revealed the presence of 0.090 mg/L *n*-propane, 0.246 mg/L isobutane, and 0.846 mg/L *n*-butane. A 13-year-old boy collapsed suddenly after sniffing the vapors of a gas lighter refill fluid from a vinyl bag; he was pronounced dead in the emergency department after unsuccessful resuscitative efforts.[14] During postmortem examination the following day, the concentrations of butane and propane were highest in fatty tissue and lowest in the lungs. The concentrations of *n*-butane and isobutane in blood samples (site not specified) were 0.94 mg/L (reported as 0.94 μL/g) and 0.37 mg/L (0.37 μL/g), respectively.

TREATMENT

Patients with altered mental status should be monitored for respiratory insufficiency and cardiac dysrhythmias. All symptomatic patients should receive supplemental oxygen. Depressed consciousness is an indication for intubation to protect the airway because of the risk of vomiting and aspiration associated with volatile substance abuse. Although some authors suggest that epinephrine should not be administered during the resuscitation of cardiopulmonary arrests associated with butane abuse,[39] case reports document the successful resuscitation of these patients with protocols that included the use of intravenous epinephrine.[18,22,23,24] Paramedics found a 15-year-old girl in coarse ventricular fibrillation and cardiopulmonary arrest after collapsing following 2 hours of intermittent inhalation of vapors from butane gas lighter refills.[40] After a single 200 J-direct current shock, she developed asystole that responded to 1 mg of intravenous epinephrine with conversion to sinus tachycardia. There were no further dysrhythmias reported. Antiarrhythmic agents for the treatment of recurrent ventricular dysrhythmias include amiodarone and lidocaine.

Myocardial infarction may complicate the course of volatile substance abuse with butane along with hypotension and dysrhythmias. Standard treatment for hypotension includes fluid infusions and dopamine despite the concerns about the use of catecholamines after volatile substance abuse. There are few data on the use of other inotropic agents (e.g., glucagon) or on the use of atropine and glucagon for hemodynamically significant bradycardia in these patients. Seizures should be treated with standard doses of benzodiazepines. Rhabdomyolysis, electrolyte imbalance, or renal dysfunction may complicate the course of severely intoxicated patients. Patients

who remain asymptomatic for 4 hours with no cardiac abnormalities may be discharged.

PROPANE

IDENTIFYING CHARACTERISTICS

n-Propane is a colorless, odorless, and flammable gas at room temperature. Odorants are added to natural gas and to LPG as a means of identifying potentially explosive concentrations of these gases. Propane concentrations of 2–10% are highly explosive. Table 42.2 lists some physical and chemical properties of *n*-propane.

EXPOSURE

Propane abuse is substantially less common than butane abuse. In a survey of 285 adolescents in juvenile correctional facilities, the reported intentional use of propane as inhalant was 6.4% compared with 38.3% for butane.[1]

Sources

Products that may contain propane include cigarette or charcoal lighter fluid, pressurized fuel tanks, LPG, natural gas, hairspray, and aerosol antiperspirants. Charcoal lighter fluid contains relatively small concentrations (i.e., <6%) of *n*-propane, whereas propane gas bottles contain mostly propane (95%) along with ethane (4%) and trace amounts (<1%) of butane and isobutane plus ethyl mercaptan for odor warning properties. Propane occurs in natural gas at concentrations of approximately 3–18%.

TABLE 42.2. Physical and Chemical Characteristics of *n*-Propane.

Physical Characteristic	*n*-Propane
CAS Registry Number	74-98-6
Molecular Formula	$C_3–H_8$
Molecular Weight	44.09 g/mol
Melting Point	−189.7°C (−309.5°F)
Boiling Point	−42.1°C (−43.8°F)
Water Solubility	62.4 ppm (25°C/77°F)
Vapor Density	1.56 (Air = 1 @ 20°C/68°F)
Vapor Pressure	760 mm Hg

Methods of Abuse

The abuse of propane occurs both in solitary and social situations, similar to butane and isobutane. Propane abuse involves inserting a line from the bottle to the mouth and inhaling the gas for 10–15 seconds during inspiration.[41] The breath is held for up to 1 minute before expiration. The metal valve may freeze and cause burns if the value has direct contact with the skin. The desired effects of propane abuse are similar to butane including euphoria, loss of inhibitions, altered perception of body form, sense of slowing of time, illusions, lightheadedness, ataxia, and hallucinations. Repeat inhalation is necessary as a result of the rapid resolution of effects following cessation of use; frequently a session of propane abuse continues 3–4 hours. Propane gas contains ethyl mercaptan to improve the odor warning properties of propane. The presence of ethyl mercaptan in inhaled gas causes noxious taste and unpleasant odors; propane inhalant abusers frequently drink sodas and expectorate to relieve the effects of inhaling ethyl mercaptan.

DOSE EFFECT

Propane is a simple asphyxiant like *n*-butane, but animal studies indicate that the CNS depressant effects of propane are substantially less than the effects of *n*-butane.[42] Exposure of volunteers to 10,000 ppm propane for 10 minutes was not associated with any adverse symptoms; however, exposure of these volunteers to 100,000 ppm propane for 2 minutes caused vertigo.[7] Exposure of volunteers to 1,000 ppm propane 8 hours per day 5 days per week for 4 weeks did not produce any abnormalities on continuous monitoring of the cardiac rhythm, electrocardiogram, neurologic exam, visual evoked response, memory tests, pulmonary function tests, or serum hepatic transaminase concentrations.[43]

TOXICOKINETICS

There are little data on the kinetics of propane in humans or animals. Absorption of propane vapors through the skin is probably small compared with pulmonary absorption. The metabolism and elimination of propane is probably similar to the kinetics of butane isomers.[10] In mice, inhalation of propane yields isopropanol and acetone as a result of oxidation by microsomal enzymes and alcohol dehydrogenase.[11] Case reports suggest that tolerance to the effects of propane may develop after continued, high-dose abuse based on the use of increasing quantities of propane and/or butane.[44]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

n-Propane is a simple asphyxiant and mild CNS depressant that displaces oxygen. The mechanisms of toxicity of *n*-propane and butane are similar. Although some authors suggest that myocardial sensitization causes sudden death during *n*-propane or butane abuse based on experimental studies and case reports, this theory is difficult to prove in individual cases because of the presence of confounders (e.g., hypoxia, respiratory and myocardial depression, concomitant drug use). Animal studies indicate that high doses of epinephrine and high concentrations of *n*-propane (150,000 ppm)[45] predispose dogs to develop cardiac dysrhythmias. However, the clinical relevance of these abnormalities is unclear because the doses are substantially higher than the doses achieved during *n*-propane or butane abuse. Most fatalities associated with propane abuse involve asphyxia rather than dysrhythmias,[46] and postmortem examinations are consistent with asphyxia (e.g., petechiae of the conjunctiva, epicardium, pleural surfaces).[47] Aspiration of liquid petroleum during a maneuver such as "fire-eating" may cause a hydrocarbon pneumonitis. Liquid propane may produce cold injuries to the skin without ignition as a result of evaporative heat loss.[48]

CLINICAL RESPONSE

Complications of propane and butane abuse are similar, although case reports of butane abuse are more common. Ignition of propane during volatile substance abuse may cause severe burns of the hands, arms, and face; flash fires following ignition of propane may cause severe inhalation injuries of the upper airways and lung. Sudden death is a less common complication of propane abuse than butane abuse.[49] Most deaths occur outside the hospital and usually involves asphyxia. These fatalities include the intentional use of propane during auto-erotic activities.[50,51]

DIAGNOSTIC TESTING

Analytic methods for the detection and quantitation of propane and butane are similar. *n*-Propane vaporizes at room temperature and standard atmospheric pressures similar to butane; proper storage of samples requires sealed container designated for volatile substance and stored at −30°C (−22°F). The presence of propane in postmortem tissue confirms antemortem exposure to this gas, but interpretation of postmortem concentrations is complicated by perimortem and postmortem changes including volatilization during resuscitation efforts, loss during storage, postmortem losses (i.e., post-

mortem interval), and postmortem contamination. A 23-year-old man was found dead with a plastic bag over his head and a propane cylinder near him.[52] Postmortem blood propane concentration was 2.8 mg/L. Charcoal lighter fluid contains higher concentrations of butane and isobutane than propane; consequently, the propane concentrations in postmortem samples from deaths associated with charcoal lighter fluid are lower than butane or isobutane concentrations.[38] Following completion of the distribution phase, the highest propane concentrations occur in adipose tissues and brain, similar to butane.

TREATMENT

The treatment of propane intoxication is supportive and similar to the treatment of butane and isobutane intoxication (see Butane and Isobutane—Treatment).

Chapter 43

ETHYL CHLORIDE

HISTORY

The anesthetic properties of ethyl chloride were described by Flourens in 1847, and the following year Heyfelder anesthetized 3 patients with ethyl chloride.[1] However, he abandoned the use of ethyl chloride for this purpose because of high volatility and cost. McCardie reintroduced ethyl chloride as an anesthetic in the early 1900s after a Swedish dentist inadvertently produced unconsciousness in a patient while spraying the gums during a dental extraction.[2] Ethyl chloride was administered as a convenient and easy-to-use general anesthetic in the United Kingdom from 1945 to 1964; however, the use of ethyl chloride as an anesthetic was abandoned as safer anesthetics became available.[1]

IDENTIFYING CHARACTERISTICS

Ethyl chloride (chloroethane, C_2H_5Cl) is a colorless, flammable gas with a pungent, somewhat unpleasant, ether-like odor at ambient pressure and temperature. This volatile liquid has a boiling point of 12.3°C (54.1°F) and a vapor pressure of >1,000 mm Hg at 20°C (68°F). Table 43.1 lists some the values for the physical properties of ethyl chloride. At room temperature and ambient pressure, the release of 1 mL of ethyl chloride produces 560 mL of vapor.[1] Evaporation of ethyl chloride from the surface of the skin produces rapid cooling (−20°C/−4°F) of the surrounding area; rapid surface cooling also limits the concentration of ethyl chloride in inspired air.

Like other volatile substances of abuse, ethyl chloride is highly lipid soluble. Street terminology for ethyl chloride includes head cleaner, ethyl gaz, and ethyl four star.

EXPOSURE

There are relatively few case reports in the medical literature involving volatile substance abuse associated with ethyl chloride. The abuse of ethyl chloride typically occurs in polydrug abusers (alcohol, marijuana) including use a substitute for amyl nitrite in homosexual men.[3] Ethyl chloride is used as a solvent for the manufacture of perfumes, as well as a refrigerant, alkylating agent, topical anesthetic, and chemical intermediate in the production of tetraethyl lead. In the past, ethyl chloride was an anesthetic agent. Ethyl chloride is a constituent of VCR head cleaners, and these products are intentionally inhaled for euphoria and the enhancement of sexual pleasure.[4] Brand names for some of these products reflect these uses including Maximum Impact, Jungle Juice Plus, Macho, Ethyl Four Star, Head Cleaner, Ethyl Gas, Ethyl Gaz, Rush, and Black-Jac. These products are available in stores and over the Internet.

DOSE EFFECT

Pre-World War II anesthesiology literature indicate that 4% (40,000 ppm) ethyl chloride produces rapid general anesthesia within 1–4 minutes.[1] Case reports associate the daily sniffing of an estimated 100–300 mL ethyl chloride over 4 months with the development of cerebellar dysfunction and hallucinations that resolved over several weeks.[5,6]

TOXICOKINETICS

The high lipid solubility of ethyl chloride results in the rapid absorption of ethyl chloride from the lungs. The biotransformation of ethyl chloride is not well studied in humans. Rodent studies suggest that there are 2 major pathways: 1) cytochrome P450-dependent dechlorination resulting in the formation of acetaldehyde and acetic acid, and 2) glutathione-*S*-transferase-dependent conjugation of ethyl chloride followed by metabolism.[7,8] These pathways are dose- and species-dependent. Oxidation of ethyl chloride in rodents primarily involves CYP2E1. Figure 43.1 displays the proposed pathways of ethyl chloride metabolism.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Ethyl chloride is a central nervous system depressant with anesthetic properties. Autopsy finding in individuals dying during ethyl chloride abuse are nonspecific. Postmortem examination of a 30-year-old man found dead with rag over his mouth and empty cans of ethyl

TABLE 43.1. Physical Properties of Ethyl Chloride.

Physical Property	Value
CAS Number	75-00-3
Density	0.9214 g/cm^3 (0°C)
Melting Point	−139°C (−218.2°F)
Boiling Point	12.3°C (54.1°F)
log P (Octanol-Water)	1.43
Water Solubility	6710 mg/L (25°C/77°F)
Vapor Pressure	1010 mm Hg (20°C/68°F)
Conversion Factor	1 ppm = 2.64 mg/m^3 (25°C/77°F)

chloride containing-VCR head cleaner near him demonstrated general visceral congestion and cerebral edema without a specific cause of death other than ethyl chloride abuse.[9]

CLINICAL RESPONSE

Illicit Use

The effects of the acute inhalation of ethyl chloride vapors resemble ethanol intoxication with behavioral disinhibition, euphoria, and perceptual changes. The intentional inhalation of ethyl chloride vapors may cause lightheadedness, confusion, impaired short-term memory, elation, slurred speech, auditory and visual hallucinations, ataxia, lower extremity weakness, gait spasticity, diplopia, blurred vision, and altered consciousness.[10] Abnormal neurologic signs include positive Romberg test, poor heel-to-shin, and hyperreflexia. Other adverse effects of the abuse of ethyl chloride include disorientation, paranoia, and unpleasant hallucinations.[5] A 41-year-old man with human immunodeficiency virus (HIV) presented to the emergency department with tremor, ataxia, dysarthria, ataxia, gait disturbances, hallucinations, and generalized weakness.[4] He had been inhaling 2 canisters of VCR head cleaner (ethyl chloride concentration not reported) several times weekly including the day of admission. The weakness, hallucinations, and ataxia resolved over 5 days of hospitalization; he was lost to follow-up after hospital discharge.

Fatalities

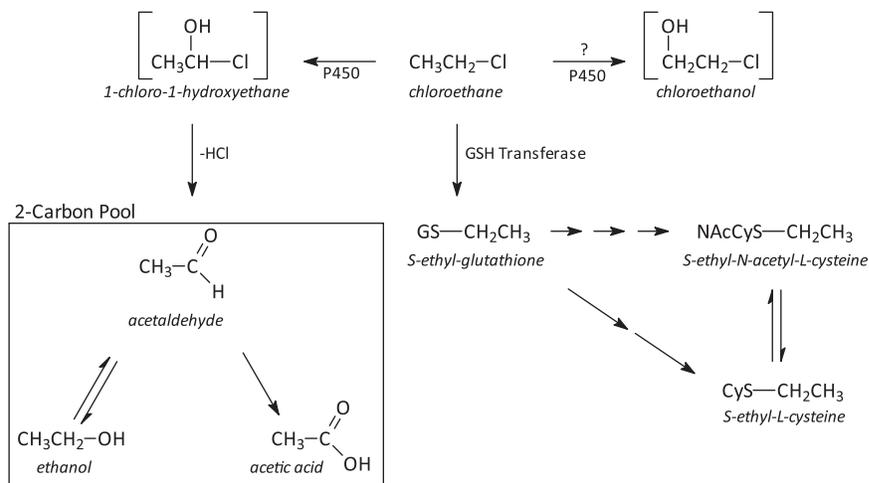
Several case reports associate fatalities with the abuse of ethyl chloride. A college student was found unconscious with a metal canister containing ethyl chloride near his right hand.[11] On arrival of the paramedics, his


FIGURE 43.1. Proposed pathways of ethyl chloride (chloroethane) metabolism.[8]

initial rhythm was ventricular fibrillation. He was transported to the hospital where he was pronounced dead after 1 hour of resuscitative efforts including intubation and advance cardiac life support.

Abstinence Syndrome

Several case reports associate cessation of chronic abuse of high doses of ethyl chloride with withdrawal-like symptoms including ataxia, tremor, weakness, dysarthria, gait disturbances, and hallucinations.[5] These symptoms abate over the first few days after cessation of the abuse of ethyl chloride, but the authors were unable to determine if the etiology of these effects were related to withdrawal, intoxication, or other withdrawal syndromes. A 52-year-old man developed hypotension, impaired consciousness, and suffered a grand mal seizure within approximately 12 hours after admission to the hospital for confusion and disorientation.[6] Over the next 10 days, disorientation, short-term memory impairment, visual hallucinations, ataxia, gait disturbances, amnesia with confabulation, and visual hallucinations occurred. By 2 weeks, most of these abnormalities resolved. He had a 30-year history of ethyl chloride, ethanol, and benzodiazepine abuse. Although the clinical course suggests withdrawal from ethyl chloride, withdrawal from ethanol or benzodiazepine may also have contributed to these abnormalities.

DIAGNOSTIC TESTING

Analytic Methods

Methods for the quantitation of ethyl chloride primarily involve headspace gas chromatography.[9] The co-elution of ethanol with ethyl chloride or the internal standard, *t*-butyl methyl ether, indicated the importance of using a second complementary analytic technique for ethyl chloride analysis. Using gas chromatography/flame ionization detection, ethyl chloride may be indistinguishable from ethanol because the peaks may co-elute. This result may be particularly confusing when the presence of ethyl chloride abuse is not obvious.[12] Analysis with gas chromatography/mass spectrometry allows the separation of these 2 compounds.

The low boiling point of ethyl chloride requires the storage of biologic samples in tightly sealed, glass containers that are refrigerated or frozen. Blood may be collected in gray top tubes (sodium fluoride, potassium oxalate) with minimal headspace. Repeated opening and recapping of stored samples may result in the loss of ethyl chloride from the sample through volatilization, particularly at room temperature.

Biomarkers

A 30-year-old man was found dead in a locked apartment with a rag held loosely in his mouth and 3 empty cans of VCR head cleaner near his body.[9] Postmortem blood samples contained ethyl chloride concentration of 423 mg/L along with diazepam (0.064 mg/L) and nordiazepam (0.126 mg/L). Analysis of vitreous humor also demonstrated the presence of ethyl chloride (12 mg/L), but loss of ethyl chloride may have occurred because the vial was opened several times for prior analysis. Hospital blood from a college student found unconscious with a canister of ethyl chloride next to him contained 200 mg ethyl chloride/L.[11] He was pronounced dead after about 1 hour of resuscitation; the postmortem heart blood ethyl chloride concentration was 650 mg/L. Some loss of ethyl chloride from the hospital blood sample may have occurred during storage because of repeated opening of the antemortem blood. The ethyl chloride concentration in vitreous humor was 410 mg/L.

TREATMENT

Acute intoxication with ethyl chloride is associated with central nervous system depression and possibly with cardiac dysrhythmias. Most patients with altered consciousness recover rapidly by the time of presentation to the emergency department. The lack of improvement in the level of consciousness suggests the presence of other drugs of abuse, underlying trauma, or hypoxic brain damage. These patients should be carefully evaluated and monitored for dysrhythmias, hypoxia, and electrolyte imbalance. Treatment is supportive; there are no antidotes or methods to enhance the elimination of ethyl chloride. Frequently, volatile substance abuse involves the use of other drugs of abuse. Rehabilitation includes referral to chemical dependence centers and counseling.

Chapter 44

GASOLINE

HISTORY

Medical reports on the intentional inhalation of gasoline first appeared in the English medical literature in 1941, when a review of gasoline by Machle mentioned the intentional inhalation of gasoline for pleasurable effects.[1] In the early 1950s, case reports documented the abuse of gasoline by children[2] and adults.[3] The popularity of gasoline abuse is primarily limited to remote areas (e.g., Indian reservations, Australian aborigines).[4,5] Lead has been an octane-boosting additive in gasoline since the 1920s. The abuse of leaded gasoline by Aboriginal peoples in Northern Canada began in the late 1960s and intensified in the 1970s.[6] The organolead encephalopathy from leaded gasoline abuse was first recognized in 1968.[7] The misuse of leaded gasoline declined in the early 1980s, and the use of leaded gasoline in the United States and Canada was banned by the 1990s.

IDENTIFYING CHARACTERISTICS

Structure

In formulating gasoline, the primary goal is specified physical characteristics rather than a specific chemical composition. Therefore, gasoline (CAS RN: 8006-61-9) is a petroleum distillate containing a variable mixture of at least 150–200 C_4–C_{12} alkane, cycloalkane, alkene, and aromatic hydrocarbons obtained by "cracking" heavy fractions of crude oil in the boiling range 40–225°C (104–437°F).[8] Regular-grade gasoline contains substantial portions of C_8 and C_9 alkenes and cycloalkanes. Appreciable amounts of aromatic hydrocarbons

(e.g., xylene) are found in commercial fuels from California and Texas, especially those with high octane ratings. The exact mixture of this volatile liquid depends on the origin of the petroleum, the boiling point used to refine the petroleum, and the compounds added to the mixture during the refining process. Because of the greater volatility of low-molecular-weight hydrocarbons, the composition of vapor from gasoline differs from the composition of the liquid. Gasoline vapor contains up to 90% C_3–C_5 nonaromatic hydrocarbons with only about 2% C_6–C_8 aromatic hydrocarbons.[9] Tetraethyl lead (CAS RN: 78-00-2, MW: 323.44) was previously added in the United States as an antiknocking agent; newer additives to boost the octane rating include methyl tertiary-butyl ether (MTBE) and alcohols. Tetraethyl lead is a colorless, oily liquid that frequently has dyes (blue, orange, red) added. This compound has a musty odor; tetraethyl lead is soluble in most organic solvents and is minimally soluble in water. In the United States, the use of tetraethyl lead as an additive routinely occurred from 1921 until 1986. Over the next 6 years, the use of this compound was gradually eliminated; however, the use of tetraethyl lead still occurs in some developing countries.

Gasoline has a distinctive odor that is detectable by most people in the range of 1–2 ppm. The odor threshold depends, in part, on the composition of the gasoline and the odor of gasoline is identifiable in the range of 0.15–0.25 ppm.[10] The vapor density of gasoline is 3–4 times heavier than air, and the vapor pressure ranges from 400–775 mm Hg at 20°C (68°F). The volatility of gasoline depends on the physical characteristics of the particular grade of gasoline. In general, gasoline

possesses intermediate volatility and low viscosity compared with other hydrocarbons.

EXPOSURE

Gasoline sniffing remains a major form of substance misuse, particularly in isolated communities (e.g., Aboriginal communities across Australia and Canada, Native American communities in the United States).[11] Aboriginal victims accounted for about one-quarter of the deaths associated with volatile substance abuse in a retrospective study (1983–2002) of South Australia.[12] In a study of cases of volatile substance abuse reported to the Toxic Exposure Surveillance System (TESS) of the American Association of Poison Control Systems from 1996–2001, gasoline was the most commonly abused volatile substance.[13] The top 5 categories of volatile substances abused were gasoline (41%), paint (13%), propane/butane (6%), air fresheners (6%), and formalin (5%). Among adolescents, gasoline remained one of the most popular volatile substances of abuse in the latter 2000s.[14] Gasoline was the most common volatile substance of abuse among incarcerated youth (mean age, 15.5 years) in a Missouri study based on questionnaires; about one-third of these youth reported lifetime use of inhalants, and 22% of these youth reported gasoline sniffing.[15] Leaded gasoline from the 1970s contained 0.8–2.65 g of organic lead compounds/gallon, primarily as tetraethyl lead. Canada phased out leaded gasoline in 1990, whereas the United States eliminated lead from gasoline in 1996. Gasoline sniffers are typically polydrug users, who use other drugs of abuse when gasoline is not available.[16]

DOSE EFFECT

The toxicity of gasoline depends on the composition of hydrocarbons within this mixture. The C_6–C_8 alkanes and cycloalkanes have relatively stronger narcotic properties (e.g., ataxia, lightheadedness, altered consciousness, headache) and some irritant properties, whereas the corresponding alkenes are relatively weak anesthetics. Eye and throat irritation is the most sensitive symptom of exposure to gasoline. Exposure to ambient concentration of gasoline vapors exceeding 900 ppm causes central nervous system (CNS) symptoms within a few minutes. Volunteer studies indicate that exposures to 500–1,000 ppm gasoline vapors for 30–60 minutes causes mild mucous membrane irritation (eyes, nose, throat) and lightheadedness, whereas exposure to 1,000–3,000 ppm for the same duration causes nausea, lightheadedness, headache, numbness, and impaired coordination.[17] During this study, exposure to gasoline vapors above 10,700 ppm for <5 minutes caused the rapid onset of anesthetic effects including dizziness, ataxia, confusion, and altered consciousness. Exposures to gasoline vapors above 1,000 ppm produced more severe ocular symptoms including lacrimation and conjunctival erythema.[18] Volatile substance abusers typically inhale 15–20 breaths of vapor from open gasoline containers or from gasoline saturated rags to experience hallucinations and euphoria.[19,20] During binges, gasoline abusers inhale for 3–5 minutes every 3–4 hours over 48 hours.[21]

TOXICOKINETICS

Absorption

In general, the highly volatile C_5–C_7 compounds (alkanes, cycloalkanes, aromatic hydrocarbons) readily cross alveolar membranes. Animal studies suggest the absorption of higher-numbered hydrocarbons by the lungs is more limited and the effects of these compounds are primarily local.[22] In the range of C_3–C_9, the absorption of unsaturated hydrocarbons (alkenes, aromatics) through the lungs is greater compared with similar saturated compounds.[23] The lungs readily absorb organic tetraethyl lead.

Distribution

There is substantial differences in the distribution pattern between aliphatic, alicyclic, and aromatic components of petroleum distillates. Although aromatics produce the highest concentration in blood, their concentration in brain is lower than the concentration of aliphatic and alicyclic hydrocarbons.

Biotransformation

The metabolism of most petroleum distillates is complex and involves hepatic biotransformation. The metabolic fate of individual compounds is difficult to predict because of potential saturation of substrates and competitive inhibition or enhancement of various enzyme systems. Monooxygenases in the liver oxidize aliphatic hydrocarbons to their respective alcohols. In rodents, cytochrome P450 isoenzymes rapidly convert tetraethyl lead to the relatively stable compound, triethyl lead.[24] Within 24 hours, triethyl lead accounted for 40–50% of lead in internal organs and 70% of the lead in muscle. Ultimately, most triethyl lead is converted to inorganic lead and stored in bone. Excretion of organic lead in urine and feces is small. The elimination half-life of tetraethyl lead in blood is a few days.[25] In a case of occupational organolead exposure, the elimination of triethyl lead followed a 2-compartment model with an elimination half-life of 35 days and ~100 days.[26]

Elimination

In a patient found unconscious in his gasoline vapor-filled car, the estimated half-life of gasoline was about 17 hours over the week prior to his death from multiorgan failure.[27] Generally, the kidney excretes a portion of alkanes unchanged, whereas most aromatic hydrocarbons appear in the urine as metabolites. Because of high vapor pressure and low blood/air coefficients, alkanes and cycloalkanes with low molecular weight appear in relatively high concentrations in expired air compared with aromatic compounds.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

Chronic exposure to gasoline (i.e., sniffing) produces cerebellar abnormalities and intellectual impairment; organic and inorganic lead encephalopathy accounts for most of these changes, but the exact causal role of organolead in gasoline-induced encephalopathy is not well-defined.[4,28] Most chronic studies of animals exposed to unleaded gasoline vapors at doses up to 2,000 ppm do not demonstrate behavioral changes or histopathologic abnormalities in the central and peripheral nervous system.[29] Tetraethyl lead and triethyl lead (metabolite) are much more lipid soluble than inorganic lead.[30] Consequently, tetraethyl lead can accumulate in the CNS much more rapidly than inorganic lead, causing the rapid onset of neurologic dysfunction and encephalopathy. The contribution of tetraethyl lead to the short-term effects of gasoline intoxication is unclear. Although inhalation of tetraethyl lead alone may cause hallucinations and behavioral changes,[31] tetraethyl lead may potentiate the effects of other volatile hydrocarbons in gasoline. Chronic inhalation of petroleum distillates (e.g., gasoline sniffing) does not usually produce a chemical pneumonitis, perhaps because of relatively low alveolar concentration and limited duration of exposure.

Postmortem Examination

Postmortem findings in patients dying suddenly following gasoline sniffing are usually nonspecific.[32] The most common abnormalities on postmortem examination are pulmonary and cerebral edema. A 21-year-old man died in the hospital after his fourth admission for toxic psychosis associated with gasoline sniffing; the blood lead concentration at admission during this visit was 197 μg/dL.[31] Postmortem examination revealed mild cortical atrophy with ventricular dilation and patchy cerebellar atrophy. Histologic examination of the brain demonstrated loss of pyramidal neurons from the hippocampus and patchy loss of Purkinje cells along with dentate neurons. There was also mild, diffuse astrocytic gliosis of the pons, striatum, pallidum, and thalamus.

CLINICAL RESPONSE

Illicit Use

Gasoline sniffing causes 2 distinct clinical syndromes: 1) an acute intoxication, and 2) an organolead-associated encephalopathy.[33] The acute intoxication associated with gasoline sniffing is similar to ethanol intoxication, manifest by giddiness, excitement, restlessness, dizziness, loss coordination and ataxia, feelings of numbness, confusion, disorientation, hallucination, and loss of consciousness. These effects persist for several hours (i.e., up to 5–6 hours).[16] Organic lead may contribute to the acute effects of gasoline sniffing, and serious gasoline abusers often prefer high-octane-leaded gasoline, when available, because of the perception of the more rapid onset of intoxication.[34]

Complications

Complications associated with gasoline sniffing include organic lead encephalopathy, aspiration pneumonia, and burns from the ignition of gasoline vapors or clothes soaked in gasoline.[35] The encephalopathy (i.e., alteration of consciousness or orientation) associated with the chronic abuse of leaded gasoline vapors is distinct from the classic features of inorganic lead poisoning and similar to the encephalopathy associated with tetraethyl lead intoxication following occupational exposure.[30,36] In mild cases of encephalopathy from chronic leaded gasoline sniffing, symptoms include anorexia, nausea, vomiting, insomnia, headache, fatigue, irritability, anxiety, agitation, and emotional lability.[37] Other neurologic complications of chronic leaded gasoline abuse include abnormal jaw jerk, poor memory, nystagmus, hyperreflexia, gait disturbances, movement disorders (ataxia, myoclonus, choreoathetosis, postural or intention tremor), confusion, impaired thinking, depression, poor abstraction, and short attention span.[38,39] In contrast to solvent abuse, acute and persistent organic psychosis is a frequent complication of leaded gasoline sniffing.[6] Psychiatric symptoms are particularly common in organolead toxicity compared with inorganic lead poisoning. More severe cases of organolead-associated encephalopathy involve frank psychosis, delirium, cerebellar ataxia, seizures, and coma along with fluctuating levels of consciousness, illusions, auditory and visual hallucination, paranoia, and delusions.[7,40] Although most of the chronic effects of leaded gasoline sniffing resolve with abstinence, case reports associate recurrent

or progressive encephalopathy with the chronic abuse of leaded gasoline.[31] Continued leaded gasoline sniffing may cause progressive dementia and cerebellar ataxia that results in permanent dysmetria, dysarthria, ataxic gait, and severe impairment of thought processes.[31] Although the encephalopathy associated with leaded gasoline sniffing typically presents with gastrointestinal and psychiatric disturbances, occasionally cerebellar signs (chorea, ataxia, resting tremor) and myoclonus are the prominent parts of the clinical presentation.[41,42]

Nausea, vomiting, abdominal pain, and anorexia may occur during organolead intoxication; however, gastrointestinal symptoms are not as prominent in organolead intoxication compared with inorganic lead poisoning. Rare case reports of chronic gasoline sniffing are associated with myopathy, elevated serum creatine kinase, and myoglobinuria in the absence of CNS effects.[43] Symptoms included muscle weakness and myalgias. Rare case reports also associate gasoline sniffing with sudden death; case series of death related to volatile substance abuse include fatalities attributed to gasoline sniffing.[44] The 2009 Annual Report of the American Association of Poison Control Centers' National Poison Data System did not list any deaths from intentional inhalation of gasoline.[45]

Abstinence Syndrome

There are few data on the existence of an abstinence syndrome in gasoline sniffers. Physical dependence and withdrawal symptoms are not usually associated with gasoline sniffing.[46] However, in a case series of 9 adolescents inhaling gasoline fumes daily, all subjects reported a withdrawal syndrome including irritability, psychomotor retardation, anhedonia, dry mouth, sleep disturbances, craving, and increased lacrimation.[47] Other complaints included headache and palpitations. Leaded gasoline use remained legal during the time of this study. Although some observations of gasoline sniffers suggest that some tolerance develops to the effects of gasoline sniffing based on the need to use larger amounts of gasoline to achieve the desired effects,[48] other case reports do not document tolerance to the hallucinogenic effects of gasoline sniffing.[49]

DIAGNOSTIC TESTING

Analytic Methods

TECHNIQUES

Gasoline is a mixture of hydrocarbons that varies depending on the refinery techniques; quantitation of gasoline is complicated by the complexity of this mixture.

However, gasoline does have a characteristic aromatic, aliphatic, and naphthalenic profile. Methods for analysis of gasoline in biologic samples include gas chromatography with flame ionization detection (GC/FID),[32] and gas chromatography/mass spectrometry (GC/MS) after liquid-liquid extraction.[50] The limit of detection and the lower limit of quantitation were 0.3 mg/L and 1.0 mg/L, respectively, for the latter method. Different authors select different peaks in the chromatograph to estimate the concentration of gasoline in blood or postmortem tissues including isopentane, *n*-pentane, 2-methylpentane, 3-methylpentane, *n*-hexane, benzene, toluene, *m,o*-xylene, *m,p*-xylene, and propylbenzene. The gasoline concentration is estimated by comparing the peak area of the selected marker with the concentration of that marker in the gasoline standard. Selection of the peak depends on the volatility of substance (i.e., risk of loss during storage) and the abundance of the substance in gasoline; the estimated concentration of gasoline will vary depending on the substance selected. A study of the estimated gasoline concentration in heart blood compared the following 6 markers: isopentane, *n*-pentane, 2-methyl-2-butene, 2-methylpentane, 3-methylpentane, and *n*-hexane.[51] The calculated gasoline concentration ranged from 0.051 mg/L (isopentane) to 0.447 mg/L (*n*-hexane). The use of higher boiling point compounds (e.g., C_0–C_2 naphthalene profiles) facilitates comparison of samples with substantial amount of evaporation compared with the original sample.[52]

Factors that affect the chemical composition of gasoline include the source (e.g., refinery), season (i.e., winter blend vs. summer blend), location, time of month, and the amount evaporated from the original sample. Analytic methods are available to determine the similarity of gasoline samples include visual inspection of target compounds in the profile of the gas chromatograph, covariance mapping and GC/MS, and principal component analysis of the GC/MS profiles of the gasoline samples.[53] Covariance mapping and GC/MS can discriminate the source of 2 samples following analysis of 3 replicate samples with test power of >99% ($\beta < 0.01$) at a significance level (α) of 0.05.[54] Collection of blood samples (e.g., gray-top tube with minimal headspace) for analysis of gasoline content is similar to other volatile substances. The choice of an analytic method for gasoline analysis in biologic specimens should be done in consultation with an analytic toxicologist to determine the optimal technique for the specific clinical situation.

Biomarkers

Lipophilic substances (e.g., gasoline) do not easily diffuse into the vitreous humor; therefore, the concen-

trations of substances used to estimate the gasoline concentration are low compared with blood.[50]

BLOOD

ILLICIT USE.   Blood lead concentrations reflect exposure to both organic and inorganic lead; the trend in these blood concentrations is more useful than a single value for determining the extent of leaded gasoline abuse. High blood lead concentrations (i.e., >100 μg/dL) suggest recent, high-dose exposure to leaded gasoline because of the rapid decline over hours to days.[6] Moderately elevated blood lead levels (30–50 μg/dL) remaining relatively stable over several days suggest the presence of inorganic lead and the absence of organic lead exposure in the previous few days to a few weeks, depending on the amount of bone lead stores. These moderately elevated blood lead concentrations decline rapidly in patients with limited leaded gasoline exposure and no significant bone lead stores. Free erythrocyte protoporphyrin (FEP) concentrations do not correlate well to blood lead concentrations in gasoline sniffers.[55]

OVERDOSE.   The estimated blood gasoline concentration in a 44-year-old man found unconscious inside a gasoline vapor-filled car was 247 mg/L, as measured by headspace gas chromatography/mass spectrometry.[27] He died 9 days later of multiorgan failure.

POSTMORTEM.   A 15-year-old boy collapsed at home with several substances next to his body including gasoline, solvents, paint, glue, and turpentine.[50] Postmortem analysis of peripheral and heart blood demonstrated gasoline concentrations of 22.1 mg/L and 38.3 mg/L, respectively, based on GC/FID analysis using *m*, *p*-xylene as the reference peak for gasoline quantitation. The heart blood also contained high concentrations of toluene (12.5 mg/L) and 6% carboxyhemoglobin. A 34-year-old man was found dead in his bed with a small quantity of liquid fuel near his nose.[56] The estimated gasoline concentration was 4.259 ppm (μg/g) based on GC/MS using several constituents as reference peaks for gasoline quantitation.

Abnormalities

In contrast to inorganic lead poisoning, organolead toxicity is not associated with lead lines in the long bones, nail bed changes, or gingival lead lines. Anemia and basophilic stippling does not typically occur with organolead intoxication. In a case series of 50 patients referred to a pediatric neurology clinic for gasoline sniffing, the most common abnormality on electroencephalography

was very low voltage and diffuse slow wave activity.[39] Evaluating the effect of chronic gasoline sniffing on cognitive function is complicated by multiple confounding factors including education, age, gender, baseline intelligence quotient, polydrug use, acute intoxication, and the effect of lead in the gasoline. A cross-sectional study of 50 current indigenous Australian gasoline sniffers and 96 health indigenous Australians suggested that gasoline sniffers performed below controls on complex psychomotor tasks, learning, executive function, and spatial awareness after controlling for demographic factors.[57] The size of the deficit ranged from 0.7–1.5 standard deviations. Simple psychomotor tasks and working memory were less affected by gasoline sniffing. The groups were not matched for gender (i.e., more women in the control group), and most of the gasoline sniffers inhaled daily (i.e., up to 12 hours prior to testing).

TREATMENT

Stabilization

The treatment of acute gasoline intoxication is supportive. Respiratory depression may complicate the clinical course of organolead poisoning associated with gasoline sniffing, particularly if seizures occur. These patients should be evaluated for the presence of hypoxemia and dysrhythmias. Aspiration pneumonia is a common complication of severe organolead toxicity; sepsis may occur.[58]

Elimination Enhancement

There are no clinically effective methods to enhance the elimination of lead other than chelation.

Antidotes

Case reports associate clinical improvement with the use of chelating agents,[59] and some authors recommend the use of chelating agents to remove inorganic lead.[4] However, the improvement in the abnormalities associated with the encephalopathy does not closely correlate to blood lead concentrations, and there are inadequate data to determine whether or not the use of chelating agents alters clinical outcome of gasoline-induced encephalopathy. Most patients improve over several weeks to months with abstinence from gasoline sniffing. The use of chelating agents increases the excretion of inorganic lead, but inorganic lead is not clearly responsible for the psychosis associated with organolead toxicity.[6] In a series of 25 patients admitted with intentional gasoline sniffing and altered mental status (delirium, drowsiness, stupor), 18 of 20 patients were chelated for

lead intoxication.[38] Despite high blood lead concentrations, chelation of inorganic lead did not appear to alter outcome significantly.

Chapter 45

n-HEXANE

IDENTIFYING CHARACTERISTICS

Commercial hexane, often labeled as the plural "hexanes," is a mixture of hexane isomers including *n*-hexane, cyclohexane, and methyl cyclopentane along with small amounts of pentane isomers, heptane isomers, ketones (acetone, methyl ethyl ketone), dichloromethane, and trichloroethylene.[1] The concentration of *n*-hexane in commercial mixtures generally ranges from about 20–80%. Small amounts (<0.3%) of phthalate esters (dimethyl, diethyl), adipate esters (dibutyl), and organophosphorus compounds may also contaminate some commercial hexanes.[2] *n*-Hexane is an aliphatic alkane with a structural formula of $CH_3(CH_2)_4CH_3$; the "*n*" refers to the "normal" or unbranched isomer. This compound is a colorless, highly volatile liquid with a mild gasoline-like odor. Table 45.1 lists some physical properties of neat *n*-hexane.

EXPOSURE

n-Hexane is a constituent of some glues, rubber cement, stove and lantern fuels, and gasoline. This substance occurs naturally in petroleum products (natural gas, crude oil) and petroleum distillates (gasoline, jet fuel, naphtha, benzine).

DOSE EFFECT

Acute

The acute toxicity of *n*-hexane in animals is relatively low. Short-term, high-dose *n*-hexane exposure produces narcosis with headache, mild nausea, and eye irritation occurring following exposure to 1,500 ppm; confusion and dizziness develops in volunteers exposed to 5,000 ppm *n*-hexane for 10 minutes.[3] Older studies in humans suggest that exposure of individuals to 1,000–5,000 ppm *n*-hexane for 10–60 minutes produces drowsiness, vertigo, and giddiness.[1,4] Exposure of volunteers to 5,000 ppm for 10 minutes produces vertigo, whereas volunteers remain asymptomatic following exposure to 2,000 ppm for 10 minutes.[5] In animal studies, the intratracheal instillation of 0.2 mL *n*-hexane produces a fatal chemical pneumonitis.[6]

Chronic

Case reports document the development of peripheral neuropathies in Japanese sandal workers, Taiwanese press proofers, and Italian shoemakers following chronic occupational exposure to *n*-hexane concentrations ranging from 30–2,500 ppm.[1] Accurate exposure data are not available because many of the measurements did not reflect the cumulative exposure of the affected workers. However, these data suggest that most of the workers were chronically exposed to *n*-hexane in poorly ventilated rooms with *n*-hexane concentrations in air that substantially exceeded 500 ppm.[7] Additionally, most of these industrial exposures involved the use of mixtures of hydrocarbons including methyl ethyl ketone, toluene, acetone, ethyl acetate, and other aliphatic hydrocarbons (pentanes, hexane isomers). Case reports suggest that a peripheral neuropathy may develop after the chronic inhalation of naphtha containing 20% *n*-hexane[8] and high doses of gasoline containing at least 5% *n*-hexane.[9]

TABLE 45.1. Physiochemical Properties of *n*-Hexane.

Property	Value
CAS Number	110-54-3
Molecular Formula	C_6H_{14}
Molecular Weight	86.177 g/mol
Relative Density	0.659 (Water = 1 @ 20°C)
Vapor Pressure	
20°C/68°F	124 mm Hg
25°C/77°F	150 mm Hg
Vapor Density	2.97
Saturated Air (760 mm Hg)	
20°C (68°F)	16.3%
25°C (77°F)	19.7%
Boiling Point	68.74°C (155.73°F)

TOXICOKINETICS

Absorption

Volunteer studies indicate that the steady-state pulmonary retention of *n*-hexane is about 15–30% as measured by the difference between inhaled and expired air at concentrations up to 200 ppm.[10,11] There are few data on retained concentrations of *n*-hexane associated with volatile substance abuse.

Distribution

Studies in animals indicate that *n*-hexane tissue concentrations are highest in the brain followed by liver, kidneys, and adrenal glands.[12] *n*-Hexane does not accumulate easily in tissues; however, the high partition coefficient and the relative long half-life of *n*-hexane in fat suggests that some accumulation may occur following exposure to the high doses of *n*-hexane associated with misuse of *n*-hexane containing products.

Biotransformation

The metabolism of *n*-hexane in humans and rats is qualitatively similar;[1] however, metabolism of *n*-hexane in rats becomes saturable and nonlinear following exposure to *n*-hexane concentrations exceeding 300 ppm. Saturation of metabolic enzymes and the resulting nonlinear kinetics in humans are not well defined, but limited data suggest nonlinear kinetics begin above *n*-hexane concentrations of 300 ppm.[13] The cytochrome P-450 system metabolizes *n*-hexane first to 2-hexanol and then to 2,5-hexanedione, which is a common neurotoxic metabolite shared with methyl *n*-butyl

ketone (MBK) as displayed in Figure 45.1. Animal studies suggest that the metabolism of *n*-hexane involves several cytochrome P450 isoenzymes;[14] CYP2B6 catalyzes the formation of 2-hexanol, whereas CYP2E1 is the major isoenzyme responsible for the formation of 2,5-hexanedione.[15,16] 2,5-Hexanedione, 2,5-dimethylfuran, and γ-valerolactone are the major metabolites present in the urine of humans exposed to *n*-hexane.[17] The kidneys excrete these metabolites primarily in the form of conjugates (glucuronides, alcoholic sulfate esters).[18] 2-Hexanol, free 2,5-hexanedione, and free 2,5-dimethylfuran are minor metabolites that are detectable in urine after exposure to *n*-hexane.[19] Following exposure of Wister rats to 2,000 ppm *n*-hexane, 4,5-dihydroxy-2-hexanone is a major urinary metabolite that is excreted primarily as a glucuronide; acid hydrolysis of the glucuronide metabolite of 4,5-dihydroxy-2-hexanone increases the presence of 2,5-dimethylfuran and 2,5-hexanedione.[20]

Elimination

The lungs excrete about 10% of the absorbed dose of *n*-hexane unchanged based on occupational studies of *n*-hexane exposure.[21] In both animals and humans, the elimination of *n*-hexane from the lungs and the blood is relatively rapid with a biphasic elimination half-life of ~0.2 and 1.5–2 hours, respectively.[11,22] The calculated half-life of *n*-hexane in fat was about 64 hours based on a mathematical model of *n*-hexane distribution.[23] The urinary elimination half-life of 2,5-hexanedione is ~13–14 hours, and the maximum urinary excretion of 2.5-hexanedione occurs about 3–5 hours following cessation of exposure.[1] Animal studies indicate that the formation of 2,5-hexanedione is not proportional to dose following exposure to high *n*-hexane concentrations (500–1,000 ppm) associated with volatile substance abuse.[22]

Chemical Interactions

Methyl ethyl ketone (MEK), methyl isobutyl ketone, and lead acetate enhance the neurotoxicity of *n*-hexane, whereas exposure to toluene reduces the neurotoxicity of *n*-hexane. Animal experiments indicate that MEK enhances the neurotoxicity of *n*-hexane;[24] however, this effect is dose-dependent. Following chronic exposure (12 h/d, 6 d/wk, for 20 weeks) of Wistar rats to 2,000 ppm MEK and 2,000 ppm *n*-hexane, changes in the urinary excretion of 2,5-hexanedione is biphasic with the initial excretion rate of this compound being below the excretion rate of the positive control (2,000 ppm *n*-hexane alone).[25] After about 4 weeks, the 2,5-hexanedione concentration in the urine of rats exposed to both *n*-hexane

FIGURE 45.1. Proposed metabolic pathway for *n*-hexane in animals.[1]

and MEK was twice as high as the urinary concentration of 2,5-hexanedione in rats exposed to *n*-hexane alone. Following a 15-minute exposure to MEK (200–300 ppm) and *n*-hexane (60 ppm), volunteer studies indicate that MEK inhibits the biotransformation of an intermediate step in the conversion of *n*-hexane to the neurotoxic metabolite, 2,5-hexanedione.[26] These results suggest that the interaction of *n*-hexane and MEK may decrease the toxicity associated with exposure to *n*-hexane at concentration near ambient air concentration associated with workplace standards; however, animal studies suggest that enhancement of *n*-hexane neurotoxicity occurs following exposure to MEK at concentrations associated with volatile substance abuse. Animal and human studies indicate that toluene may inhibit the metabolism of *n*-hexane, and thus reduce the excretion of the neurotoxic metabolite, 2,5-hexanedione.[27] Exposure to acetone and *n*-hexane may increase the urinary concentration of free 2,5-hexanedione, but there are few data on the clinical consequence of these metabolic changes.[28]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

The neurotoxic substance causing the development of *n*-hexane neuropathy is the toxic metabolite, 2,5-hexanedione.[29] *n*-Hexane neuropathy is primarily an axonal polyneuropathy with secondary demyelination.[30] Similar pathologic findings occur in other toxic neuropathies (e.g., acrylamide, triorthocresyl phosphate, inherited giant axonal neuropathy, vinca alkaloids, colchicine). Sural nerve biopsies demonstrate axonal swelling, loss of large myelinated fibers with focally enlarged "giant" axons containing neurofilaments, widening of nodes of Ranvier, and thinning of the overlying myelin secondary to retraction by axonal swelling.[31] Occasionally, segmental demyelination may occur. Paranodal demyelination occurs at the sites of swelling, and Wallerian degeneration of the axons develops distal to the swollen sites.[32] Aspiration with subsequent chemical pneumonitis is a potential complication of the ingestion of *n*-hexane based on animal studies; however, there is a lack of case reports documenting the pulmonary toxicity of *n*-hexane following aspiration. There are few data on postmortem examination of chronic *n*-hexane abusers.

CLINICAL RESPONSE

Peripheral neuropathy is a rare complication of hexane-containing glue sniffing. Glue-sniffer's neuropathy is a subacute, symmetrical, ascending, predominately motor polyneuropathy associated with the chronic intentional inhalation of *n*-hexane containing products.[33] The neurologic manifestations of this disease are uniform and similar to the sensorimotor neuropathy resulting from chronic occupational exposure to excessive concentrations of *n*-hexane. Weakness begins in the distal lower extremities along with a stocking-glove distribution of paresthesias and hypesthesias; neurologic effects may progress to gait disturbances, difficulty ambulating, and tetraplegia.[34,35] Abnormalities on neurologic examination include diminished deep tendon reflexes, muscle weakness, atrophy, and sensory loss (i.e., reduced pinprick, light touch, temperature, position, and vibration).[36] Often, the earliest symptom of *n*-hexane peripheral neuropathy is the gradual onset of distal numbness in the toes and fingers.[37] Paresthesias rarely spread beyond the knees or wrists. For 2–4 months after cessation of exposure to these products, the neuropathy progresses (i.e., "coasting"). Recovery is slow and variable with some persistent effects (e.g., foot drop) following severe intoxications. Associated symptoms include muscle cramps, anorexia, and weight loss. *n*-Hexane is a mild skin irritant.

DIAGNOSTIC TESTING

Analytic Methods

Techniques for the quantitation of *n*-hexane in biologic samples includes headspace capillary gas chromatography with flame ionization detection and cryogenic oven trapping,[38] liquid chromatography/atmospheric pressure chemical ionization/mass spectrometry,[39] and headspace with gas chromatography/mass spectrometry (GC/MS) solid-phase microextraction.[40] The latter method allows the determination of *n*-hexane in the general population with a limit of detection (LOD) of 0.089 ng/mL. The LOD for *n*-hexane using gas chromatography with flame ionization detection is about 2.4 and 1 ng/mL for whole blood and urine, respectively, whereas the LOD using liquid chromatography/atmospheric pressure chemical ionization/mass spectrometry is about 50 ng/mL. *n*-Hexane is an ubiquitous chemical found in many laboratory materials and processes including the collecting of blood in a Vacutainer®. Boiling the Vacutainer® stoppers in methanol followed by vacuum baking removes the residue of *n*-hexane in these containers.[40] Gas chromatography with flame ionization detection and GC/MS are the most common analytic methods for the quantitation of the toxic metabolite, 2.5-hexanedione in urine samples. Using headspace solid-phase microextraction and gas chromatography with flame ionization detection, the LOD for this metabolite is 25 ng/mL with the coefficient of variation <7%.[41]

Biomarkers

BLOOD

n-Hexane is frequently detectable in blood samples from the general population without known exposure to *n*-hexane. In a study of patients presenting to an infirmary without known occupational exposure to *n*-hexane, about 86% of the blood samples had detectable concentrations of *n*-hexane.[42] The mean blood concentration of *n*-hexane was 0.61 ng/mL (range, 0.015–7.68 ng/mL); 95% of the blood samples contained *n*-hexane concentrations <1.47 ng/mL. The *n*-hexane concentration is higher in whole blood than plasma because of the uneven uptake of *n*-hexane by erythrocytes. *In vitro* studies indicate that the uptake of *n*-hexane from whole blood by the human erythrocyte fraction was about 66%.[43] Following exposure to low *n*-hexane concentrations (<10 ppm) in ambient air, the serum *n*-hexane concentration was about 30% of the whole blood *n*-hexane concentration.[44]

URINE

The neurotoxic metabolite, 2,5-hexanedione, is a biomarker for the biologic monitoring of exposure to *n*-hexane from inhalant abuse.[45] In human urine, 2,5-hexanedione is present as 2 chemical species: a free form that represents about 8% of the total and the remainder as 4,5-dihydroxy-hexan-2-one. Acid hydrolysis increases the concentration of 2,5-hexanedione in the urine because of the formation of 2,5-hexanedione from 4,5-dihydroxy-hexan-2-one. Small quantities of 2,5-hexanedione may occur in the urine of individuals without occupational exposure to *n*-hexane. Environmental exposure to *n*-hexane accounts for maximum excretion of ~500–800 ng 2,5-hexanedione/mL urine.

Abnormalities

n-Hexane polyneuropathy is one of the few toxic neuropathies that causes electrophysiologic features of both axon loss and demyelination with abnormal spontaneous activities (positive sharp waves, fibrillation potentials, long polyphasic motor unit potentials) and decreased motor and sensory conduction velocities.[46,47] Although *n*-hexane neuropathy is primarily an axonal neuropathy, electrophysiologic abnormalities often meet the criteria for demyelinating neuropathy as a result of secondary demyelination.[31] Electrophysiologic findings depend on the severity of the neuropathy. Nerve conduction studies typically demonstrate reduced conduction velocities, prolonged distal latencies, and decreased amplitudes of both motor and sensory responses that are characteristic of a mixed axonal and demyelinating process.[9] Motor conduction velocities usually increase steadily from distal to proximal segments (e.g., wrist to upper arm); the slowing of proximal conduction velocities is usually mild. F waves are usually absent. Occasionally, nerve conduction studies demonstrate partial conduction block in the median and ulnar nerves.[37] Abnormalities on electrophysiology testing typically resolve within 1 year.[48]

TREATMENT

Because of the limited data on the human toxicity of *n*-hexane, treatment of toxicity is supportive. Exposure to very high *n*-hexane concentrations may cause obtundation and coma. The victim should be removed to fresh air after adequate ventilation of the site. *n*-Hexane is a mild to moderate central nervous system depressant; thus, the adequacy of respiration should be evaluated and assisted ventilation and supplemental oxygen administered as needed. Contaminated clothing should be removed and the skin washed with soap and lukewarm water. Eye contact should be treated with warm saline or water irrigation for 15 minutes.

After the patient has been removed from the source, medical attention should be directed toward evaluation and support of cardiorespiratory function including the potential development of aspiration pneumonia. Ingestion of pure *n*-hexane is rare. Gastrointestinal decontamination is not recommended because of the low acute toxicity of *n*-hexane and the aspiration potential of this liquid. There are no antidotes to *n*-hexane toxicity. The body eliminates *n*-hexane rapidly; therefore, no measures to enhance elimination are indicated. Peripheral and central nervous system symptoms resulting from chronic exposure are treated symptomatically.

Chapter 46

METHANOL

IDENTIFYING CHARACTERISTICS

At room temperature, methanol (CAS RN: 67-56-1, CH_4O) is a clear, colorless liquid with a faint odor resembling ethanol and a boiling point of 64.6°C (148.3°F). Methanol is soluble in water, ethanol, and many organic solvents. The concentration of methanol in the air above a liquid product is not the same as the methanol concentration in the liquid phase, and the composition of the vapor phase of a liquid mixture containing methanol does not usually match the vapor concentration above the liquid because of differences in vapor pressures. For example, the partial pressure of each solvent in the vapors inhaled from carburetor cleaner depends on saturated vapor pressures rather than the molar concentrations of the liquid in the container. The vapor pressure of methanol is 127 mm Hg at 25°C (77°F) compared with 28 mm Hg at 25°C (77°F) for toluene. Consequently, the vaporized state of the carburetor cleaner at room temperature contains higher concentrations of methanol than toluene.[1] Analysis of a glue used for sniffing contained 82.5% toluene and 6.6% methanol; however, the vapor phase above the liquid contained 3,067 ppm toluene and 12,350 ppm methanol.[1]

EXPOSURE

Epidemiology

Most cases of serious methanol poisoning result from ingestion rather than inhalation, particularly from the substitution of methanol-containing solutions for etha-nolic beverages.[2] Rare cases of significant pulmonary exposure to methanol include exposure to methanol vapors during firefighting[3] and spraying methanol-containing material.[4] Deliberate abuse of methanol-containing products is relatively rare.

Sources

Major commercial applications of methanol include use as an intermediate in chemical manufacturing, an octane booster in gasoline, and a solvent. Other sources of methanol include cleaning solutions, printing and duplicating solutions, varnish, shellac, dyes, stains, paint removers, antifreeze, canned heating fuel for camping stoves and chafing dishes, de-icing products, windshield washer fluid, gasoline additives, formalin, and adhesives. Methanol is a common ingredient in carburetor cleaners along with toluene, methylene chloride, and butane/propane. The typical composition of carburetor cleaner is about 5–25% methanol, 45–80% toluene, 20% methylene chloride, and propellants (isobutane, propane).

Methods of Abuse

The abuse of methanol-containing compounds typically involves the inhalation of vapors from a plastic bag containing the liquid portion of the product, primarily from carburetor cleaning fluid. The central nervous system (CNS) effects of methanol are relatively mild, but the effect on consciousness depends on the dose and concomitant ingestion of other CNS-altering substances. Consequently, the desired effects associated with the intentional inhalation of methanol-containing

products are primarily the result of toluene rather than methanol.

DOSE EFFECT

Exposure of volunteers to 200 ppm methanol for 4 hours does not cause a statistically significant increase in serum formate concentrations or a decrease in blood pH.[5]

TOXICOKINETICS

There are substantial differences in the toxicity of methanol between various species. Primates are particularly sensitive to methanol toxicity, whereas rodents detoxify methanol via a catalase-peroxidase system that prevents the formation of toxic metabolites (formaldehyde, formic acid).[6] Consequently, extrapolation of rodent dose-response data on methanol to primates is inappropriate.

Absorption

The lungs absorb methanol rapidly; the absorption rate constant (i.e., the percentage of the methanol in the lungs absorbed per hour of time) for a 4-hour exposure of volunteers to 200 ppm was 0.87 ± 0.67/hour.[7] In a study of volunteers exposed to 200 ppm for 2 hours, the relative uptake of methanol was approximately 50%.[8] The bioavailability of methanol is limited, in part, by the adsorption of this water-soluble compound onto mucous in the upper respiratory tract.

Distribution

Similar to ethanol, the volume of distribution (V_d) of methanol approximates total body water. Based on volunteer studies, the V_d of methanol is about 0.60–0.77 L/kg, depending on the amount of body fat.[9] The distribution of methanol into tissues is rapid with peak serum methanol concentrations occurring within 1 hour.

Biotransformation

Endogenous metabolism involves the oxidation of methanol to carbon dioxide and water, primarily in the liver. Alcohol dehydrogenase catalyzes the formation of formaldehyde from methanol. The former compound is rapidly converted to formic acid via formaldehyde dehydrogenase within a few minutes of formation.[10] Formaldehyde does not accumulate in blood after the absorption of methanol, whereas formate is the toxic metabolite that accumulates as a result of the low rates of formate oxidation in humans. The conversion rate of formate to carbon dioxide and water depends on the activity of the hepatic tetrahydrofolate-dependent enzyme, 10-formyl-tetra-hydrofolate dehydrogenase. The activity of this enzyme is high in rodents; therefore, methanol toxicity is minor in rodents compared with humans.[11]

Elimination

Following exposure to methanol concentrations associated with volatile substance abuse, zero-order (saturation) kinetics best describe the elimination of methanol.[12] As a result of the saturation of metabolic pathways involved with the oxidation of formate in humans, the plasma elimination half-life of methanol ranges between a few hours at low methanol concentrations and approximately 24 hours in methanol-poisoned patients. Following exposure of volunteers to 800 ppm methanol for 2 hours, the mean plasma elimination half-life of methanol was 1.44 ± 0.33 hours.[13] In an otherwise healthy, methanol-poisoned patient, the total body clearance rate of methanol was 11.3 mL/minute, while methanol metabolism was blocked by the concomitant ingestion of high doses of ethanol.[14] The pulmonary and renal clearance rates in this patient were 5.6 mL/minute and 5.7 mL/minute, respectively. These data indicate that the pulmonary clearance of methanol is low even in poisoned patients. The plasma elimination half-life of the metabolite, formate increases up to ~20 hours in methanol-poisoned patients, but hemodialysis reduces this half-life to 2–3 hours.[15]

Maternal and Fetal Kinetics

Case reports indicate that methanol diffuses across the placenta and into the fetal circulation. Three days after birth by emergency cesarean section because of methanol poisoning in the mother, the plasma methanol concentration of the neonate was 61.6 mg/dL.[16] The child had a persistent metabolic acidosis with an initial pH of 6.9. He died the following day after developing an intraventricular hemorrhage. The mother died 10 days after delivery from complications of methanol poisoning.

Drug Interactions

At serum concentrations >20 mg/dL, ethanol causes almost complete blockade of methanol metabolism.[17] Consequently, the amount of methanol from endogenous sources increases following the consumption of ethanol at doses sufficient to increase the blood ethanol concentration above this concentration. In a study of 5 volunteers with blood ethanol concentrations near 80 mg/dL, the blood methanol concentration increased to 0.12–0.34 mg/dL from baseline methanol concentrations of 0.04–0.08 mg/dL as measured indirectly by analysis of end-expired alveolar air with gas chromatog-

raphy.[18] Below ethanol concentrations of 20 mg/dL, the elimination of methanol becomes exponential (i.e., first-order) rather than linear with an elimination half-life of approximately 1.5–3 hours.[19] Case reports suggest that the simultaneous ingestion of methyl ethyl ketone with methanol also inhibits methanol metabolism.[20]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

The metabolic acidosis and visual changes associated with methanol toxicity result from the biotransformation of methanol to the toxic metabolite, formic acid.[21] The serum formate concentration correlates closely to the metabolic acidosis and the severity of methanol poisoning.[22] 10-Formyl tetrahydrofolate dehydrogenase catalyzes the oxidation of formate; the rate of oxidation depends on the presence of adequate stores of folic acid and the regeneration of tetrahydrofolate during the oxidation of formate. *In vitro* studies indicate that formate inhibits cytochrome c oxidase activity in intact mitochondria and isolated cytochrome aa_3.[23] Inhibition of the cytochrome oxidase complex at the terminal end of the respiratory chain in the mitochondria leads to cellular hypoxia, similar to other cellular toxins (carbon monoxide, cyanide, hydrogen sulfide).[21] Both formate and lactic acid contribute to the metabolic acidosis associated with methanol poisoning. Formate accounts for the early metabolic acidosis, but lactic acidosis occurs later as a result of cellular hypoxia and inhibition of cellular respiration.[24] Direct toxicity by formate probably causes the optic nerve damage associated with methanol toxicity. Undissociated formic acid produces edema, the breakdown of the myelin sheaths, and lesions in the optic disk and retrolaminar section of the optic nerve.[25] Neurotoxicity also results from damage in the basal ganglia (e.g., putamen) and subcortical white matter. Imaging studies suggest that local cellular edema secondary to inhibition of the Na-K ATPase pump and cytochrome oxidase causes the observed edema and necrotic lesions.[26]

Postmortem Examination

The pathologic findings in postmortem examination of fatal cases of methanol poisoning are not unique.[27] Autopsies of patients dying of methanol intoxication typically demonstrate congestion of the lungs and brain, as well as cerebral edema and petechial hemorrhages of the brain and cerebellum.[28] Classic neuropathologic findings include pallor of the myelin of the retrolaminar

optic nerves, and acute hemorrhage and necrosis in the putamen and subcortical white matter.[29,30]

CLINICAL RESPONSE

Illicit Use

Intentional inhalation of methanol may cause clinically significant metabolic acidosis, visual disturbances, CNS depression, altered mental status, and respiratory impairment depending on the duration of use and the absorbed dose of methanol.[31] Symptoms of methanol poisoning include headache, nausea, vomiting, abdominal pain, lethargy, and dyspnea. The development of methanol toxicity is typically delayed 12–18 hours during the metabolism of methanol, and the clinical effects may be delayed over 24 hours as a result of the concomitant ingestion of ethanol. Products that contain methanol usually contain other compounds (e.g., toluene, methylene chloride, acetone) that contribute to the CNS and renal toxicity following abuse. Occasional case reports indicate that metabolic acidosis and decreased visual acuity may occur following the intentional inhalation of methanol-containing household products, but the occurrence of visual disturbances following the abuse of these products is uncommon.[32] A 21-year-old habitual glue-sniffer began inhaling vapors from a new paint thinner that contained 20% methanol, 20% methyl acetate, and 57% toluene.[33] Within 1 week, he developed central vision defects, central scotomata, visual loss (i.e., unable to see a moving hand), dysesthesias of the feet, ataxia, gait disturbances, and loss of coordination. Improvement in the visual defects occurred after hospitalization. The case report did not document the serum methanol concentration, acid-base status, or imaging studies. Other case reports associate the abuse of methanol-containing solvent with nausea, vomiting, thirst, sleeplessness, weakness, fatigue, and blurred vision that resolved within 4 days after cessation of solvent abuse.[1] Ophthalmologic exam of this patient did not detect any abnormalities. An observational study of 7 people presenting to an emergency department after abuse of methanol-containing products did not detect visual abnormalities; the highest formate concentration was 25 mg/dL.[34] Genotoxicity studies and oncogenicity studies in rodents indicate that the inhalation of methanol is unlikely to produce cancer in humans.[35]

Fatalities

A 26-year-old itinerant was found pulseless with several cans of a methanol-containing carburetor cleaner (43.8% toluene, 23.2% methanol, 20.5% methylene chloride, 12.5% propane) and soaked rags nearby.[44] As

reported by companions, he inhaled approximately 9 cans in the 2 days preceding his death. Analysis of postmortem blood indicated that he died of respiratory depression secondary to combined toxicity from very high ethanol concentration (440 mg/dL) in combination with methanol (90 mg/dL), and toluene (5.6 mg/L).

Reproductive Abnormalities

There are few data on the reproductive abnormalities associated with intentional inhalation of methanol-containing products. These products usually contain a variety of other compounds in addition to methanol. Metabolic acidosis, dehydration, and electrolyte disturbances potentially contribute to adverse fetal effects. Consequently, the determination of the causal role of volatile substance abuse and methanol in the development of reproductive abnormalities is difficult. Case reports associate chronic maternal abuse of methanol-containing products with premature delivery[36] and bilateral frontal cortical leukomalacia with cerebral infarcts.[37] In both case reports, the mothers were hospitalized multiple times during their pregnancies for complications of volatile substance abuse including metabolic acidosis, electrolyte imbalance, anemia, and toxic serum methanol concentrations requiring hemodialysis and ethanol infusion.

DIAGNOSTIC TESTING

Analytic Methods

Methods for the quantitation of formic acid primarily involve the use headspace gas chromatography with flame ionization detection.[38] Similar to other volatile substances, storage requires a tightly sealed container along with refrigeration or freezing. Substantial loss of methanol may occur following repeated opening and recapping of the container.

Biomarkers

Some endogenous production of methanol occurs in humans. In a study of volunteers exposed to 200 ppm methanol for 4 hours, the mean serum methanol concentration at the end of the exposure period was 0.65 ± 0.27 mg/dL compared with 0.09 ± 0.06 mg/dL for the sham exposure group.[7] Following exposure of 26 volunteers to 200 ppm methanol for 4 hours, there was no statistically significant difference in the mean serum formate concentration between the methanol exposure (1.43 ± 0.89 mg/dL) and the sham exposure (1.27 ± 0.64 mg/dL).[5]

The intentional inhalation of methanol-containing products may cause clinically significant metabolic aci-

dosis, serum methanol concentrations, and serum formic acid concentrations.[39] In an observational study of 7 patients using methanol-containing carburetor cleaner as a volatile substance of abuse, 4 patients had serum methanol concentrations exceeding 24 mg/dL and 5 patients had elevated serum formic acid concentrations (>12 mg/dL).[34] The anion gap for these patients ranged between 13–31 mEq/L. The methanol concentration in blood samples drawn 4 hours after arrival to the emergency department ranged between 10–86 mg/dL. The patient with a serum methanol concentration of 86 mg/dL had a serum formate concentration of 25 mg/dL and an anion gap of 16 mEq/L.

Abnormalities

In a case series of methanol-abusing patients presenting to an emergency department with elevated serum methanol concentrations (50.4 mg/dL, 128.5 mg/dL), other abnormalities included elevated blood formic acid concentrations (12 mg/dL, 19.3 mg/dL, 48 mg/dL) and metabolic acidosis (pH 7.19).[44] The severity of the acidosis depends on the methanol dose, duration of use, the presence of ethanol, and the time since exposure. A normal anion gap does not necessarily exclude potentially significant serum methanol concentrations, particularly in the period shortly after inhalation. Exposure to methanol also may cause a significant osmolal gap. For each milligram of methanol per deciliter, the osmolal gap increases by about 0.34 mOsm; a methanol concentration of 50 mg/dL increases the osmolal gap by about 17 mOsm/kg H_2O.[21] The presence of severe metabolic acidosis with increased anion and osmolar gaps strongly suggests the presence of methanol or ethylene glycol intoxication.[21] The maximum osmolal gap correlates to the peak absorption of methanol. During the metabolism of methanol, the osmolal gap decreases as the anion gap increases and the metabolic acidosis worsens. Consequently, the osmolal gap does not correlate to the severity of methanol poisoning late in the clinical course, and the absence of an osmolal gap at that time does not exclude the diagnosis of methanol poisoning. The differential diagnosis of this set of laboratory abnormalities includes chronic renal failure, critical illness, diabetic ketoacidosis, and alcoholic ketoacidosis.[40] Visual outcomes do not correlate well to computed tomography (CT) abnormalities during hospitalization for methanol poisoning.[41]

Driving

Experimental studies indicate that evidential breath analyzers (e.g., Dräger 7110 Evidential breathalyzer;

Draeger Safety UK Ltd., Blyth, Northumberland, UK) detect methanol at low concentrations, but the presence of methanol triggers the interfering compound alert. A simulated test of the inhalation of 0.019 mg methanol/L was associated with an 8% increase in the estimated breath ethanol concentration.[42]

TREATMENT

Stabilization

The most common serious complications of methanol poisoning are metabolic acidosis, visual changes, and CNS depression. Initial attention should be directed at evaluating and correcting any cardiopulmonary and acid–base abnormalities. Poor prognostic factors include severe metabolic acidosis and acidemia (pH < 7.0), coma on admission, and >24 hours delay from exposure to admission.[43] Patients with an arterial pH < 7.3 should receive intravenous (IV) sodium bicarbonate to correct the acidosis back to the normal range (7.35–7.45). Most patients presenting after intentionally abusing methanol-containing products respond well to supportive measures alone. Volatile substance abuse associated with methanol-containing products (i.e., huffing) rarely causes toxic methanol concentrations (>50 mg/dL) and metabolic acidosis (pH < 7.2) requiring therapeutic interventions (sodium bicarbonate, ethanol infusion/fomepizole, hemodialysis).[31,44]

Elimination Enhancement

Hemodialysis during methanol intoxication effectively removes formate and methanol, while correcting the metabolic acidosis associated with methanol poisoning. The mean clearance rate of methanol during this procedure is high (i.e., ~125–215 mL/min).[45] Potential indications for hemodialysis in this setting include persistent metabolic acidosis (<7.25–7.30) or electrolyte imbalance unresponsive to conventional therapy, visual changes, renal failure, and deteriorating vital signs despite intensive supportive care.[21] The use of fomepizole obviates the need for dialyzing high methanol concentration (>50 mg/dL) unless the rapid elimination of methanol is necessary. In this situation, folate should be administered and the acid–base status closely monitored. The typical dose of folate is 1 mg/kg/body weight, up to a total dose of 50 mg, administered intravenously over 30–60 minutes in dextrose and water, every 4–6 hours until normalization of the acid–base status and the elimination of methanol. The endpoint of dialysis is a methanol concentration below 20 mg/dL and normalization of the acid–base status.

Antidotes

Both ethanol and fomepizole inhibit alcohol dehydrogenase activity. If administered soon after exposure, ethanol and fomepizole reduce the formation of toxic metabolites and limit the development of metabolic acidosis.[46] Ethanol or fomepizole should be administered as soon as possible after methanol ingestion to prevent the development of formate and metabolic acidosis. There are inadequate data to determine the exact serum methanol concentration necessary to cause toxicity, in part as a result of the dynamic kinetic process involved with the metabolism of methanol to formate. Table 46.1 lists the recommendations of the American Academy of Clinical Toxicology for the administration of antidotes during methanol poisoning.

The loading dose of fomepizole is 15 mg/kg administered intravenously followed by IV doses of 10 mg/kg every 12 hours for 4 doses. After 48 hours, the bolus doses are increased to 15 mg/kg every 12 hours as a result of the self-induction of fomepizole metabolism. This dose of fomepizole is administered until the methanol concentration is <20 mg/dL. There are few clinical data to confirm the superiority of fomepizole over ethanol in terms of efficacy or cost-effectiveness for the treatment of methanol poisonings. Although the acquisition cost of fomepizole is high, the administration of fomepizole does not necessarily require intensive care or frequent laboratory monitoring because of the lack of the metabolic and CNS depressant effects associated with ethanol use. The exact serum methanol concentration that requires treatment with fomepizole is not well defined. Some patients (i.e., huffers) with serum methanol concentrations exceeding 20 mg/dL following inhalation may respond to supportive care only.[34] The presence of visual abnormalities or persistent metabolic

TABLE 46.1. American Academy of Clinical Toxicology Clinical Guidelines on Antidote Administration.

Criteria
Documented plasma methanol concentration >20 mg/dL (>200 mg/L)
or
Documented recent history of ingesting toxic amounts of methanol and osmolal gap >10 mOsm/kg H_2O*
or
History or strong clinical suspicion of methanol poisoning *and* at least two of the following criteria: A. Arterial pH < 7.3 B. Serum bicarbonate <20 mEq/L(mmol/L) C. Osmolal gap >10 mOsm/kg H_2O*

*Laboratory analysis by freezing point depression method only.

713

acidosis is an indication for the treatment of these patients with fomepizole or ethanol, if fomepizole is unavailable.

Supplemental Care

Diagnostic testing for patients exposed to toxic concentrations of methanol include complete blood count, serum electrolytes and anion gap, urinalysis, arterial blood gases to assess acid–base status, serum calcium, serum lipase, serum amylase, serum creatinine, serum creatine kinase, serum osmolality, and serum ethanol. If available, serum methanol concentrations help guide management decisions regarding hemodialysis and the administration of fomepizole. Patients with elevated serum methanol concentrations should be followed for the development of persistent or worsening metabolic acidosis and visual symptoms. All patients should be evaluated with a funduscopic examination and visual acuity. The presence of neurologic signs including altered mental status indicates the need for CT or magnetic resonance imaging of the brain.

Chapter 47

NAPHTHALENE and *para*-DICHLOROBENZENE (MOTHBALLS)

NAPHTHALENE

IDENTIFYING CHARACTERISTICS

Similar to *para*-dichlorobenzene (*p*-dichlorobenzene, 1,4-dichlorobenzene), naphthalene is a clear, colorless, lipid-soluble crystalline compound. Figure 47.1 displays the chemical structure of naphthalene. Placing a mothball in a water bath heated to 60°C (140°F) will separate naphthalene and *p*-dichlorobenzene as a result of the melting of *p*-dichlorobenzene (melting point, 52.7°C/126.9°F); naphthalene melts at a higher temperature (melting point, 80.2°C/176.4°F) as displayed in Table 47.1. In addition, the difference in densities between these 2 compounds allows separation. Camphor floats in water, whereas both *p*-dichlorobenzene and naphthalene sink.[1] However, naphthalene mothballs float in a saturated solution of table salt, whereas *p*-dichlorobenzene-containing mothballs sink. Failure to stir the salt solution sufficiently to produce a saturated salt solution may result in suspension the naphthalene mothballs in the solution, leading to false interpretation. A 50% dextrose solution is an alternative to the saturated salt solution because of similar specific gravities.[2] The odor threshold of naphthalene is about 0.44 mg/m³. This compound is soluble in alcohol, benzene, acetone, and ether. Naphthalene is moderately volatile with low water solubility as demonstrated in Table 47.2; the affinity for lipid tissue is also moderate.

EXPOSURE

Distillation and fractionation of coal tar is the most common source of naphthalene; production of naphthalene also results from the dealkylation of methyl naphthalenes.[3] The principal use of naphthalene is feedstock in the production of phthalic anhydride for the synthesis of phthalate plasticizers and resins, pharmaceuticals, insect repellents, and dyes. Other uses include the production of surface-active agents (naphthalene sulfonates), organic chemicals, carbaryl (1-naphthyl-*N*-methylcarbamate), alkylated naphthalene solvents, and synthetic leather tanning agents. There are few data on the prevalence of the use of mothballs as a volatile substance of abuse, but abuse of mothballs is relatively rare. Naphthalene is a constituent of ambient air as a result of the combustion of wood and fossil fuels as well as cigarette smoking, particularly in urban areas.

DOSE EFFECT

Inhalation

The minimum risk level (MRL) for chronic exposure to naphthalene in air is 0.0007 ppm based on an uncertainty factor of 300 and lowest-observed-adverse-effect level (LOAEL) of 10 ppm for hyperplasia of the nasal olfactory and respiratory epithelium in chronic rodent studies.[3] Exposure of rats to 60 ppm naphthalene (6 h/d, 5 d/wk) for 2 years did not affect survival, when compared with unexposed controls.[4] Approximately 300–500

TABLE 47.1. Distinguishing Physical Characteristics of Mothballs.

Physical Characteristic	Naphthalene	*para*-Dichlorobenzene	Camphor
Water bath 60°C (140°F)	Solid	Liquid	Solid
Water bath 25°C (77°F)	Sinks*	Sinks*	Floats

*p-Dichlorobenzene is more dense than naphthalene. In a salt solution, p-dichlorobenzene sinks, whereas naphthalene floats.

Vapor Pressure	0.085 mm Hg (25°C/77°F)

naphthalene-containing mothballs were distributed around an apartment; analysis of air samples from the apartment by gas chromatography with flame ionization detection demonstrated naphthalene concentrations of about 0.020 ppm.[5] The naphthalene concentration was potentially higher when the mothballs were initially distributed. Visitors to the apartment complained of headache, nausea, and vomiting. Individuals with G-6-PDase deficiency are substantially more susceptible to hemolytic anemia following naphthalene exposure than individuals with normal G-6-PDase activity.[6]

Ingestion

A case report associated the ingestion of 2 naphthalene mothballs by a 2-year-old with the development of acute hemolytic anemia and slight jaundice.[7] The G-6-PDase status of the patient was not reported. A case report associated the intentional ingestion of 6 g naphthalene (estimate, 109 mg/kg) by a 16-year-old girl with hemolytic anemia.[8] She developed vertigo, abdominal and flank pain, hemolysis, jaundice, and fever (41.6°C/106°F); she eventually recovered. The G-6-PDase status of the patient was not reported. A 19-year-old woman developed hemolysis, anemia (7.5 g/dL) and methemoglobinemia (13%) after ingesting 12 mothballs containing naphthalene (percentage not reported).[9] Her hemoglobin electrophoresis suggested hemoglobin E α-thalassemia (glucose-6-phosphate dehydrogenase was present).

TOXICOKINETICS

There are few data on the toxicokinetics of naphthalene. The extensive biotransformation of naphthalene produces a variety of reactive and nonreactive metabolites including 1-naphthol (α-naphthol), 2-naphthol (β-naphthol), 1,4-naphthoquinone (α-naphthoquinone), and 1,2-naphthoquinone (β-naphthoquinone). Cytochrome P450 isoenzymes catalyze the first step in naphthalene metabolism by producing the reactive electrophilic arene epoxide intermediate, 1,2-naphthalene oxide as demonstrated in Figure 47.2. There are multiple CYP450 isoenzymes involved with the biotransformation of naphthalene. *In vitro* studies indicate that CYP2E1 enhances the conversion of naphthalene to 1- and 2-naphthol; however, further metabolism of 1- and 2-naphthol requires other P450 isoenzymes.[10] Based on *in vitro* and rodent studies, these isoenzymes include CYP1A1, CYP1A2, CYP1B1, CYP3A7, CYP3A5, CYP2F2, and CYP2B4.[11,12] These studies indicate that there are both gender and species differences in the metabolism of naphthalene.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

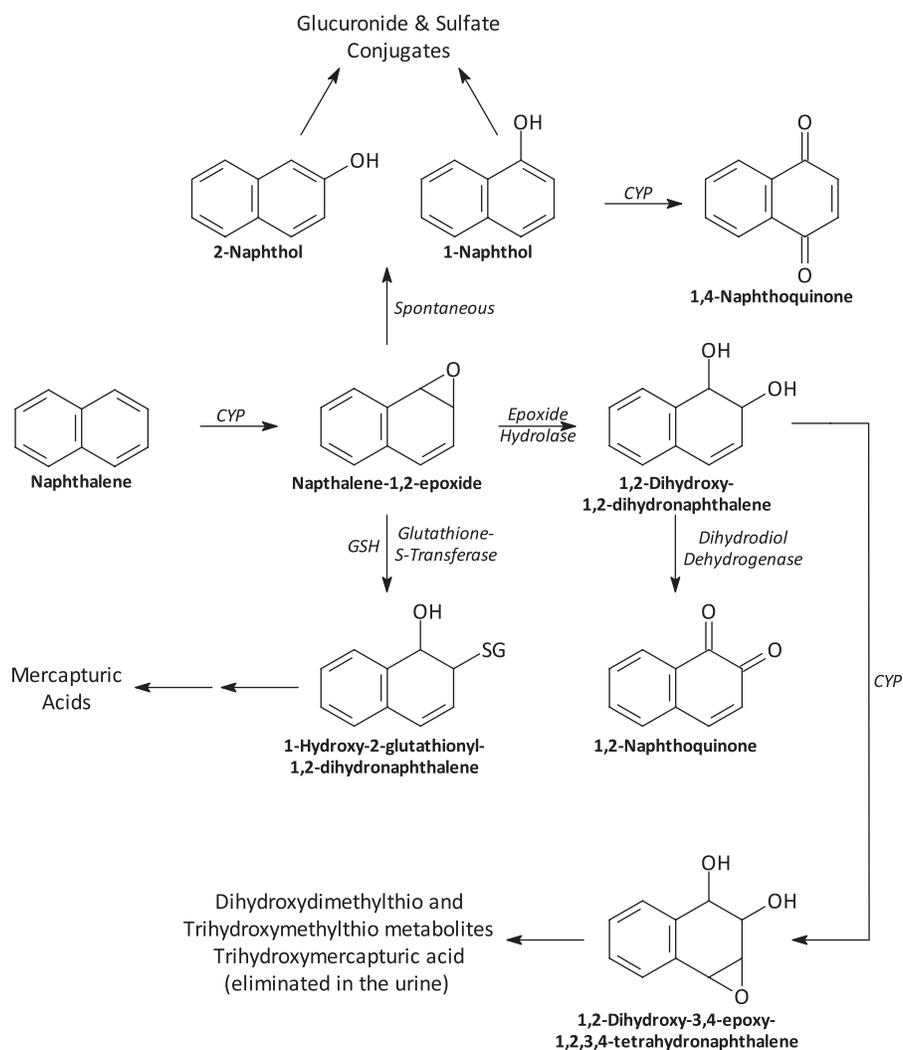
Although naphthalene does not possess hemolytic properties, the naphthalene metabolite, α-naphthol can produce hemolysis, particularly in G-6-PDase-deficient patients. Glucose-6-phosphate dehydrogenase deficient patients have a diminished capacity to produce the NADPH necessary for the stability of the red cell membrane. These patients are susceptible to increased red


FIGURE 47.2. Proposed metabolic pathways of naphthalene.[3] CYP = cytochrome P450 enzyme(s); GSH = reduced glutathione; SG = glutathione.

cell hemolysis following exposure to oxidizing agents. Oxidation of iron in the heme results in the formation of Heinz bodies, and the formation of free radicals increases red cell membrane fragility and lysis. The destruction of red blood cells causes anemia, increased hematopoiesis (i.e., increased reticulocyte count), and increased bilirubin (jaundice). The exact role of naphthalene in causing hemolysis is unclear. Potential mechanisms include direct oxidation of hemoglobin and reduction of glutathione stores. The development of hemolysis following exposure to naphthalene is highly variable between species with hemolysis occurring in dogs, but not in rodents.[3] A 30-year-old woman presented to the emergency department 2 days after the reported ingestion of 40 mothballs; she died 3 days later.[13] Antemortem cultures demonstrated peritonitis and Gram-negative sepsis. Postmortem examination demonstrated 25 intact mothballs in the stomach, bilat-

eral pleural effusions, pulmonary congestion, and renal tubular dilation and necrosis; however, no necrosis or perforation of the gastrointestinal tract was detected.

CLINICAL RESPONSE

There are limited data on the clinical effects of chronically inhaling vapors from mothballs; most of these data are case reports. Often, these reports rely on historical accounts of exposure, and do not contain documentation of the composition of the mothballs. The primary toxic effects of exposure to mothballs in these case reports are hepatic injury and hemolytic anemia, particularly in neonates with fetal hemoglobin or patients with G6PDase deficiency or sickle cell anemia.[6] Clinical manifestations of naphthalene intoxication include nausea, vomiting, diarrhea, abdominal pain, headache, and dysuria. Clinical evidence of hemolysis typically

appears 1–3 days after exposure with weakness, fatigue, pallor, tachycardia, jaundice, and dyspnea. Hemolysis may persist up to ~1 week.[9] A 26-year-old polydrug user (alcohol, cocaine) presented for a preoperative visit with a history of inhaling vapors from mothballs daily for several years.[14] She had mild anemia, hypokalemia (2.6 mEq/L), and minimal elevation of her serum hepatic aminotransferases. Repeat testing 2 weeks after cessation of mothball use demonstrated a normal serum potassium and normal serum hepatic aminotransferases. This case report did not include the chemical composition of the mothballs or laboratory analysis for hemolysis. Another case report describes a 54-year-old woman with a long history of sniffing and chewing mothballs; she did not report the abuse of any other drugs.[15] She had multiple medical problems including insulin-dependent diabetes, chronic renal failure requiring hemodialysis, hypertension, and peripheral neuropathy (gait disturbance, hyporeflexia, symmetrical motor weakness with upper extremities < lower extremities). The chemical composition of the mothballs could not be determined; the causal role of chronic abuse of mothballs was unclear because of the presence of medical diseases capable of causing these abnormalities. A 10-year-old Native American boy developed nausea, vomiting, abdominal distention, and jaundice after a 2-month episode of sniffing naphthalene mothballs.[16] He died 6 months later with extensive centrilobular necrosis of the liver and no evidence of fibrosis or regenerative nodules. The International Agency for Research on Cancer (IARC) lists naphthalene as a possible human carcinogen (2B), whereas the US National Toxicology Program lists this compound as reasonably anticipated to be a carcinogen.

DIAGNOSTIC TESTING

Analytic Methods

Methods to quantitate naphthalene in biologic materials involve gas chromatography with flame ionization detection, gas chromatography with electron capture detection,[17] and gas chromatography/mass spectrometry (GC/MS).[18] The use of headspace capillary gas chromatography with flame ionization detection allows the detection of naphthalene in whole blood and urine at concentrations of 50 ng/mL and 10 ng/mL, respectively.[19] The interday precision for analysis of 5 mg naphthalene/L in these 2 media were <3% and <5%, respectively. For the analysis of naphthalene in residues, analytic methods include gas chromatography after supercritical fluid extraction, GC/MS combined with a purge and trap thermal desorption extraction,[20] and high performance liquid chromatography (HPLC)

coupled with a diode array detector at 220 nm with confirmation by GC/MS.[21] The limit of detection (LOD) and lower limit of quantitation (LLOQ) for naphthalene in honey using HPLC was 23 ppb (0.023 μg/g honey) and 78 ppb (0.078 μg/g), respectively. Naphthalene metabolites are less lipophilic than the parent compound. Methods for the quantitation of naphthalene metabolites (α-naphthol, α-naphthylglucuronide, and β-naphthylsulfate) include gas chromatography with flame ionization detection,[22] and liquid chromatography/electrospray mass spectrometry in selected ion monitoring mode.[23]

Biomarkers

Naphthalene is detectable in the blood of US citizens without known occupational exposure to naphthalene. 1-Naphthol, 2-naphthol, and 1,4-naphthoquinone appear in the urine as a result of the hydroxylation of naphthalene present in ambient air.[24] Following occupational exposure to naphthalene during the distillation of naphthalene oil, the range of 1-naphthol concentration in end of work shift urine samples from these workers was 400–34,600 ng/mL.[25] The maximum excretion rate for 1-naphthol occurs 1 hour after the end of exposure with a urinary elimination half-life of ~4 hours.

Abnormalities

Naphthalene mothballs are substantially less radioopaque than *p*-dichlorobenzene mothballs. Other tests to distinguish *p*-dichlorobenzene from naphthalene include the addition of chloroform along with a small amount of anhydrous aluminum chloride powder to the mothballs and heating a copper wire dipped in the mothball crystals.[26] In the former method, naphthalene produces an intense blue color immediately, whereas *p*-dichlorobenzene produces no reaction. Both compounds produce a fleeting yellow-orange flame with the latter method, but within the next few seconds *p*-dichlorobenzene produces a brief, intense bright green flame. Naphthalene produces no color. Abnormalities associated with exposure to naphthalene include elevated serum hepatic aminotransferases, hyperbilirubinemia, electrolyte imbalance from fluid loss, renal dysfunction, mild methemoglobinemia, and hemolytic anemia with Heinz bodies and schistocytes.[27]

TREATMENT

The primary risk following acute exposure to high doses of naphthalene is central nervous system (CNS) depression and suppression of the respiratory drive. Patients should be removed from further exposure;

contaminated skin should be washed thoroughly with soap and water after removal of contaminated clothing. Symptomatic patients should be monitored for respiratory depression and cardiac dysrhythmias. Patients with altered consciousness may require respiratory support (supplemental oxygen, assisted ventilation). There are no antidotes for naphthalene exposure. If hemolysis is suspected, a blood smear, urinalysis, and serum hepatic aminotransferases should be obtained. Asymptomatic patients may be discharged after 4 hours observation with repeat testing for hemolysis and liver dysfunction 24–48 hours after discharge.

*para-*DICHLOROBENZENE

IDENTIFYING CHARACTERISTICS

Figure 47.3 displays the chemical structure of *p*-dichlorobenzene. This compound is a lipophilic, volatile crystal with a characteristic odor. *p*-Dichlorobenzene is insoluble in water and soluble in diethyl ether. Table 47.3 lists some physiochemical properties of *p*-dichlorobenzene. Volatilization of *p*-dichlorobenzene varies with mothballs from different manufacturers depending on the specific formulation. In a study of Japanese mothballs, emission rates of *p*-dichlorobenzene from these mothballs ranged from 0.0033–0.035 g/h at 25°C (77°F).[28] Even pure grade *p*-dichlorobenzene (i.e., >99.8%) may contain minor amounts of chlorobenzene, *o*-dichlorobenzene, and *m*-dichlorobenzene. The odor

Conversion	1 mg/m³ = 6.01 ppm
Melting Point	52.7°C (126.9°F)
Density	1.46 g/cm³ (20°C/68°F)
Vapor Density	5.07 (Air = 1)
Water Solubility	81.3 mg/L (25°C/77°F)
Vapor Pressure	1.74 mm Hg (25°C/77°F)

threshold of *p*-dichlorobenzene in liquids is about 0.01–0.03 mg/L. Occupational surveys suggest that a faint odor appears at *p*-dichlorobenzene concentrations in ambient air from 15–30 ppm; *p*-dichlorobenzene concentrations in ambient air from 30–60 ppm produce a strong odor, whereas eye and nose irritation occurs at 80–160 ppm.[29]

EXPOSURE

The deodorizing and insecticidal properties of *p*-dichlorobenzene result in the use of this compound as a constituent of mothballs, toilet bowl, and diaper pail deodorizers. Mothballs are relatively pure compounds that are produced as flakes, crystals, and round balls. *p*-Dichlorobenzene is now the primary constituent of mothballs because of the lower toxicity of this compound compared with naphthalene. The treatment of parasitic infections was an antiquated use for *p*-dichlorobenzene.[30] The abuse of *p*-dichlorobenzene by the chronic inhalation of vapors is relatively rare.

DOSE EFFECT

There are few human data on the dose response of *p*-dichlorobenzene; the extrapolation of animal data from different species and strains is limited by substantial differences in the biotransformation of *p*-dichlorobenzene to reactive metabolites including benzoquinone compounds. A serious adverse reaction following exposure to *p*-dichlorobenzene may occur in sensitive individuals (e.g., neonates with fetal hemoglobin, G-6-PDase-deficient patients).

TOXICOKINETICS

There are few quantitative data on the toxicokinetics of *p*-dichlorobenzene in humans. Limited pharmacokinetic studies suggest that the lungs rapidly absorb *p*-dichlorobenzene; rapid distribution into tissues occurs, particularly adipose tissues.[31] Analysis of blood samples from the general population indicate that this compound is absorbed from the environment; in a study of 1,000 adults living throughout the United States, 96% of the samples had detectable concentrations (LOD, 1 ng/mL) of *p*-dichlorobenzene.[32] Biotransformation of *p*-dichlorobenzene primarily involves oxidation by CYP2E1 isoenzymes to 2,5-dichlorophenol.[33,34] Rodent studies indicate that elimination occurs through urinary excretion of this metabolite as the sulfate (50–60%), glucuronide (20–30%), and the free form (5–10%) with minor metabolites accounting for the remaining 10%.[35] These studies suggest that the biliary excretion of glucuronide conjugates of 2,5-dichlorophenol is relative

minor at low doses, but biliary excretion increases with increasing dose. There are substantial species differences in the biotransformation of *p*-dichlorobenzene to reactive metabolites with this conversion being least in human microsomes and greatest in mice; rats were intermediate in conversion rates as reflected in the variable carcinogenic response of this species to *p*-dichlorobenzene.[36]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

The mechanisms of toxicity of *p*-dichlorobenzene or naphthalene exposures in rare cases of the hemolytic anemia are likely similar. The clinical finding of Heinz-body formation in red blood cells and methemoglobinemia during hemolytic anemia suggest the presence of oxidative stress; however, the exact mechanism causing these abnormalities is unclear. Potentially, oxidative metabolites of *p*-dichlorobenzene may inhibit glucose-6-phosphate dehydrogenase (G6PD), resulting in the production of hemolysis, methemoglobinemia, and Heinz bodies.

CLINICAL RESPONSE

Hemolytic Anemia

Rare case reports associate hemolytic anemia with the ingestion or chronic inhalation of vapors from *p*-dichlorobenzene-containing mothballs; symptoms from hemolysis are often delayed several days.[37,38] Three days after the ingestion of an unknown amount of *p*-dichlorobenzene, a 19-month-old boy presented to an emergency department with tachycardia, anemia (hemoglobin, 6.4 g/dL), mild methemoglobinemia (2.5%), and jaundice (total bilirubin, 12.0 mg/dL).[39] He was transfused with 150 mL packed cells; subsequent to discharge, he was asymptomatic. A newborn required a blood transfusion for a Coombs-negative hemolytic anemia after the mother inhaled the vapors from mothballs during her pregnancy.[40] The erythrocyte glucose-6-phosphate dehydrogenase activity for the child was 1.4 units/g hemoglobin compared with 2.8 units/g hemoglobin for the mother. Twenty days later the mother was admitted for a blood transfusion (hematocrit, 23%).

Central Nervous System

Several case reports associated chronic exposure to *p*-dichlorobenzene with neurologic abnormalities (e.g., leukoencephalopathy with gait disturbances and brady-kinesias), but determination of causation in these case reports is limited by poor exposure data and the presence of confounding factors. A case report associated the development of mental slowing, unsteady gait, urinary retention, cerebellar syndrome, and pyramidal signs with the inhaling of mothball (*p*-dichlorobenzene) vapors 10 minutes daily for the preceding 4–6 months.[41] The patient recovered within 6 months following the cessation of *p*-dichlorobenzene abuse. She also had a 1-month history of an ichthyosis-like dermatosis on her lower extremities, elbows, and hands. In a similar case report, a 44-year old man presented to an emergency department with an atypical aromatic body odor; anorexia; cachexia; flat affect; social withdrawal; hyperreflexia; cogwheel rigidity in the lower extremities; and dry, scaly, ichthyotic skin.[42] He continued to deteriorate during the first month of hospitalization with the development of clonus, upper extremity cogwheel rigidity, catatonia, and inadequate food intake. The family confirmed that the patient ingested and inhaled vapors from *p*-dichlorobenzene containing mothballs including the heating of these mothballs to increase vapor formation for at least 4 months prior to admission. The serum *p*-dichlorobenzene concentration ~1 month after hospitalization was 1,200 ng/mL. The patient was transferred to a skilled nursing facility after 3 months of hospitalization with slightly increased responsiveness.

Several other case reports associate the chronic inhalation of *p*-dichlorobenzene-containing mothballs with ataxia, gait disturbances, rigidity, dystonia, bradykinesias, dementia, and mutism.[43,44] In some cases, the resumption of *p*-dichlorobenzene abuse resulted in deterioration in the neurologic abnormalities of the patient.[45] However, the presence of multiple confounding factors (e.g., polysubstance abuse, psychiatric illness) and poor exposure data limit definitive conclusions regarding the causal connection between chronic *p*-dichlorobenzene abuse and neurologic abnormalities. Chronic exposure to high doses of *p*-dichlorobenzene for 6 years was associated with the development of severe cerebellar ataxia, dysarthria, moderate weakness, and hyporeflexia that mostly resolved 6 months after cessation of exposure.[46] The chronic ingestion of mothballs for 7 months by a 21-year-old homeless woman was associated with the development of an acute cerebellar syndrome (ataxia, nystagmus) with stupor and a progressive encephalopathy.[47] Magnetic resonance imaging demonstrated a diffuse leukoencephalopathy with predominance in the periatrial deep white mater and the splenium. She developed diffuse cerebral atrophy, and required a percutaneous gastrostomy tube for nutrition. The patient had a history of heroin abuse. There are inadequate data to link chronic exposure to *p*-dichlorobenzene with cataracts.[29]

Carcinogenesis

The International Agency for Research on Cancer (IARC) lists *p*-dichlorobenzene as a possible human carcinogen (Group 2B) based on sufficient evidence in rodent studies and insufficient human epidemiology data on carcinogenicity.[48] The production of liver cancer in B6C3F$_1$ mice by gavage and in BDF$_1$ mice by inhalation probably results from nongenotoxic (promotional) effects by forcing the growth of spontaneous precancerous lesions.[49]

DIAGNOSTIC TESTING

Analytic Methods

Methods to quantitate *p*-dichlorobenzene in biologic materials include GC/MS combined with a purge and trap thermal desorption extraction.[20] The LOD for *p*-dichlorobenzene in honey using GC/MS was 0.15 μg/kg honey. Methods to quantitate *p*-dichlorobenzene in ambient air and solid material include solid-phase microextraction or ultrasonic extraction coupled to GC/MS[50,51] and gas chromatography with flame ionization detection.[28] The LOD of *p*-dichlorobenzene in honey using GC/MS in selected ion monitoring mode after headspace solid-phase microextraction is 1 μg/kg (ppb) honey with precision below 6.3%.[52]

Biomarkers

There are limited data on the concentration of *p*-dichlorobenzene (1,4-DCB) in blood, but the concentrations range from nondetectable to a few ppb. In a convenience sample of blood from 982 adult participants in the Third National Health and Nutrition Examination Survey (NHANES III), the median 1,4-DCB concentration in whole blood samples was 0.33 ng/mL (ppb).[53] In a study of 1,000 adults from throughout the United States, the concentration of 1,4-DCB in their blood averaged 2.1 ng/mL with a range up to 49 ng/mL.[32] Smoking does not alter the concentration of *p*-dichlorobenzene in the blood.[54] The School Health Initiative: Environment, Learning, Disease (SHIELD) Study of low-income neighborhoods in Minneapolis, Minnesota measured multiple chemicals in children's blood samples 4 times over 2 years.[55] About 65–89% of the samples contained detectable concentrations of 1,4-DCB (LOD, 0.04 ng/mL) with the median and 95th percentile of multiple sampling times ranging from 0.12–0.22 ng/mL and 12–27 ng/mL, respectively.

The *p*-dichlorobenzene metabolite, 2,5-dichlorophenol commonly occurs in urine samples from the general population. In a Japanese study of 119 adults living in an urban area (i.e., Osaka), 2,5-dichlorophenol was detectable in 99% of the urine samples as measured by gas chromatography with electron capture detection (LOD, 20 ng/mL).[56] The median urinary 2.5-dichlorophenol concentration was 0.39 mg/g creatinine with a maximum concentration of 3.32 mg/g creatinine.

Abnormalities

p-Dichlorobenzene mothballs are strongly radiopaque. In a study of 10 commercial products of solid mothballs, deodorizers, and bathroom cleaners containing 99–100% *p*-dichlorobenzene and 0.5% cetrimonium bromide, all 10 substances were strongly radiopaque (5/5) in air overlaid by plexiglas.[57] Case reports associate the chronic inhalation of mothball vapors with anemia, hypokalemia, hyponatremia, and mild elevation of serum hepatic aminotransferases that resolves within a few weeks after cessation of abuse.[58]

TREATMENT

The treatment of both *p*-dichlorobenzene and naphthalene exposure is primarily supportive. The primary risk following acute exposure to high doses of *p*-dichlorobenzene is CNS depression and suppression of the respiratory drive. Patients should be removed from further exposure, and contaminated skin should be washed thoroughly with soap and water after removal of contaminated clothing. Symptomatic patients should be monitored for respiratory depression and cardiac dysrhythmias. Patients with altered consciousness may require respiratory support (supplemental oxygen, assisted ventilation). There are no antidotes for *p*-dichlorobenzene exposure.

Chapter 48

TOLUENE

HISTORY

Reports of glue sniffing were rare before 1960.[1] Glue sniffing became a popular method of volatile substance abuse in the 1960s, when the practice of inhaling fumes from glue and nail-polish remover became popular among American and Canadian teenagers.[2]

IDENTIFYING CHARACTERISTICS

Toluene is a clear, colorless, moderately volatile, flammable liquid.[3] Table 48.1 outlines the physicochemical characteristics of toluene. Pure toluene has a sweet, pungent aromatic odor detectable at a concentration near 0.8 ppm, whereas the odor threshold for a mixture containing 46% toluene along with other short-chained alkanes and cycloalkanes was approximately 2.5 ppm.[4]

Figure 48.1 displays the chemical structure of toluene. The composition of a liquid mixture containing toluene does not usually match the vapor concentration above the liquid because of differences in vapor pressures. Analysis of a glue used for sniffing contained 82.5% toluene and 6.6% methanol; however, the vapor phase above the liquid contained 3,067 ppm toluene and 12,350 ppm methanol.[5]

EXPOSURE

Toluene is one of the most commonly abused volatile substances. Often, toluene is the exclusive volatile substance of abuse. Toluene is an excellent solvent for paints, lacquers, thinners, coatings, and glues; this chemical is a component of glues, paints, lacquer, and varnish as well as a pure commercial solvent. Toluene is part of the production process for polyurethanes, nylon, plastic bottles, pharmaceutics, nail polish, dyes, and synthetic chemicals. Desired effects of toluene abuse include mild euphoria, excitation, delusions, and distorted perception of space and images.[6] Toluene is a constituent of many abused glues, particularly in older case reports; however, the toluene content varies substantially with different glues. Glue sniffing typically involves the inhaling of vapors from a glue-soaked rag held to the nose, a glue-containing bag held to the mouth, or from glue heated in a pan.[1]

DOSE EFFECT

There are few data on the effects of exposure to toluene concentrations associated with volatile substance abuse. A case report associated chronic inhalation of toluene vapors at work with episodes of headache, inappropriate speech, transient memory loss, and loss of consciousness; however, there were no documented abnormalities of heart, liver, or kidney function.[7] Exposure to an estimated 600–800 ppm toluene causes confusion, altered auditory and visual perception, loss of inhibitions, and poor coordination; estimated toluene exposures in chronic toluene abusers may attain 5,000 ppm.[8,9] Acute exposure of animals to toluene produces rapid excitatory effects at moderate concentrations and depressant effects at high concentrations. In mice, motor activity increased following acute exposure to 560 ppm toluene; decreased activity occurred following acute exposure to 3,000 ppm toluene.[10] Brief exposure to high concentrations of toluene also limits the ability of animals to

TABLE 48.1. Physicochemical Characteristics of Toluene.

Physical Characteristic	Data

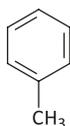
Boiling Point	110.6°C (231.1°F)
Density	0.8669 g/mL (20°C/68°F)
Water Solubility	534.8 mg/L (25°C/77°F)
Vapor Pressure	28.4 mm Hg (25°C/77°F)
	59.3 mm Hg (40°C/104°F)
	291.5 mm Hg (80°C/176°F)
Odor Threshold	
Water	0.04–1 ppm
Air	8 ppm


FIGURE 48.1. Chemical structure of toluene.

perform conditioned neuromuscular responses. The exposure of monkeys to 2,000 ppm toluene for <1 hour increased response time and reduced the accuracy of the response to conditioned stimulus, but there were no overt neurological signs (e.g., ataxia, tremor).[11] Recovery from the effects of toluene is also rapid, although there is some tissue accumulation following repeated high-dose exposures. Following exposure of mice to 12,000 ppm toluene for 5 minutes, the results of unconditioned performance and reflex testing returned to normal by 10 minutes after cessation of exposure.[12] However, a cycle of 5 exposures to the same concentration of toluene separated by 30 minutes of fresh air caused abnormalities on these tests until 60 minutes after the cessation of toluene exposure.

Characteristic white matter changes associated with toluene abuse include atrophy, loss of gray matter-white matter boundaries, and callosal thinning.[13] These changes are typically symmetrical and occur after 5–7 years of inhalant abuse. In a series of 24 toluene abusers (mean age 23 ± 4.4 years) admitted to a Canadian drug-treatment unit, 11 patients had cerebellar abnormalities on neurologic examination.[14] The estimated mean daily dose of toluene for this cohort was 425 ± 366 mg toluene for 6.3 ± 3.9 years.

TOXICOKINETICS

Absorption

The average relative uptake of toluene from alveolar air is rapid, ranging from approximately 40–60% depending on several factors (e.g., ventilation rate, fat distribution).[15] Following exposure of 12 healthy male volunteers to about 80 ppm toluene, the uptake of toluene averaged approximately 50% of the inspired amount at rest.[16] Arterial blood contains detectable amounts of toluene within 10 seconds of airborne exposure to toluene.[17] In 5 incarcerated toluene abusers, the peak whole blood toluene concentrations occurred about 20 minutes after cessation of toluene use.[18]

Distribution

Adipose tissue and bone marrow provide depots for toluene; the storage of toluene in fat accounts for the long terminal elimination half-life.

Biotransformation

The cytochrome P450 isoenzymes catalyze the oxidation of most (i.e., ~80%) of absorbed toluene to benzyl alcohol via side-chain oxidation of the methyl group.[19] In studies of rats, the metabolism of toluene involves at least 6 cytochrome P450 isoenzymes (CYP1A1/2, CYP2A1, CYP2B1/2, CYP2C6, CYP2C11, CYP2E1).[20] *In vitro* studies using human liver microsomes indicate that CYP2E1 is the major isoenzyme involved with the methyl hydroxylation of toluene to form benzyl alcohol; whereas CYP1A2 catalyzes the formation of minor phenolic metabolites.[21] Alcohol and aldehyde dehydrogenases oxidize benzyl alcohol to benzoic acid. Conjugation of benzoic acid with glycine produces hippuric acid, which the kidneys subsequently excrete in the urine. *ortho-*, *meta-*, and *para-*cresols are minor metabolites of toluene metabolism. The kidney excretes these minor metabolites as conjugated cresols. Figure 48.2 outlines the metabolism of toluene.

Elimination

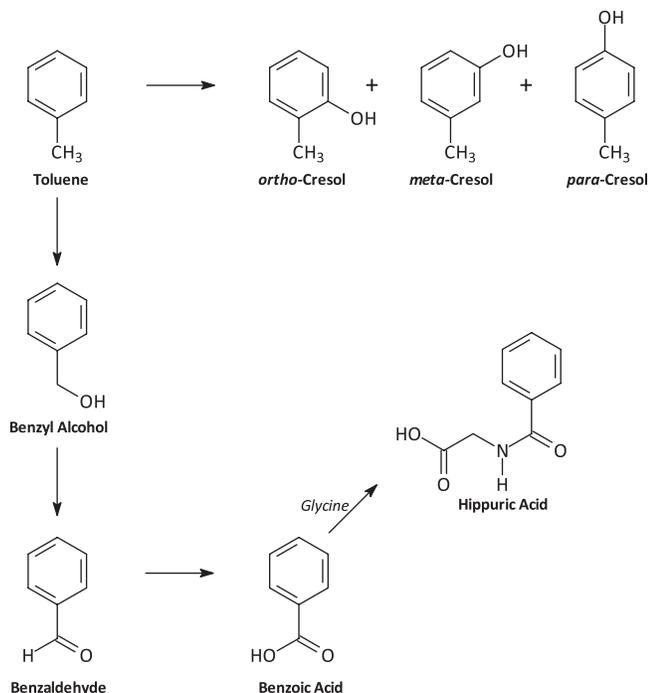
The lungs excrete about 7–14% of an absorbed dose of toluene unchanged following exposure to about 80 ppm toluene for 2 hours.[16] In a study of workers exposed to 50 ppm toluene for 2 hours, the mean excretion of toluene in exhaled air was 13 ± 6.2%.[22] Hippuric acid in the urine accounted for 75 ± 6.4% of the total toluene dose. The kidney excretes minimal amounts of unchanged toluene in the urine. The elimination of toluene following inhalation has a rapid initial distribution phase, an


FIGURE 48.2. Toluene metabolism.[22]

intermediate phase, and a slow phase involving the elimination of a relatively small portion of the initial dose from fat stores. The elimination half-lives of toluene from the blood in a small study of incarcerated toluene abusers ranged from about 35–54 minutes during the first hour after cessation of toluene use to 80–110 minutes during the second hour after toluene inhalation.[18] Following exposure of 2 workers to concentrations of a toluene-containing solvent mixture that was sufficient to produce coma, the elimination half-life of toluene from the blood of these 2 workers was approximately 17 hours and 27 hours.[23] In a cross-sectional study of 37 male printers exposed to toluene, the toluene elimination from venous blood followed a 3-compartment model with the terminal median elimination toluene half-time being 90 hours (range, 50–324 hours).[24] The estimated median percentage of toluene elimination for the slow component was about 17% (range, 3–26%) compared with 42% (range, 22–63%) for the intermediate phase. The median time to reduce the plasma toluene concentrations by 50% during the fast and intermediate components were 9 minutes and 2 hours, respectively.

Maternal and Fetal Kinetics

Toluene readily crosses the placenta. Rodent studies suggest that about 10% of an inhaled dose of toluene

rapidly crosses the placenta and distributes into fetal tissue depending on gestational age.[25] Toluene persists in the fetus at least 24 hours after exposure.

Tolerance

Tolerance to the neurobehavioral changes does not usually develop in animals following repeated exposure to toluene.[26] Case reports suggest that tolerance to the effects of inhaling toluene vapors during glue sniffing may develop within 3 months after weekly toluene abuse.[8,27] In a study of young, glue-sniffing adolescents admitted to a pediatric psychiatric service, some patients reported using up to 25 tubes of glue daily.[28] Toluene is a major constituent of glues in older case reports of volatile substance abuse; however, there is substantial variation in the chemical content of vapors from different glues.

Drug Interactions

Although induction of P450 isoenzymes is unlikely at toluene concentrations commonly present in the workplace, enzyme induction may occur in a toluene abuser.[29] Experimental studies suggest that metabolic interaction may occur between toluene, trichloroethylene, and ethanol as a result of alteration of CYP2E1 isoenzymes that oxidize these compounds;[30] however, the clinical significance of these potential interactions is undefined. The administration of moderate doses of ethanol about 1 hour after exposure to toluene near the Swedish occupational limit increased the peak toluene concentration in blood about 33%.[31] The ethanol concentrations with and without toluene exposure were not significantly different.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

Central Nervous System

In vitro studies suggest that toluene alters neuronal excitation by producing compensatory responses in the functional expression of ion channels. In a study of primary cultures of rat hippocampal neurons, toluene inhibited NMDA-mediated currents (IC_{50}, 1.5 mM) in a dose-dependent relationship, whereas the non-NMDA agonist kainic acid had no effect on GABA-mediated currents.[32] Pathologic changes reported in case studies of toluene abuse include 1) diffuse atrophy of the cerebellum, brainstem, and cerebrum, and ventricular dilation and widening of sulci in the affected areas; 2)

demyelination of white matter; 3) degeneration and gliosis of ascending and descending long-tracts; and 4) ill-defined myelin pallor and discoloration of the white matter.[33] Neuroimaging and neuropsychologic studies of chronic toluene misuse indicate that toluene abuse preferentially affects regions of the brain in a lipid-dependent distribution.[34] These changes are relatively greater in the periventricular and subcortical (e.g., thalamus, basal ganglia) than in cortical areas; abnormalities in white matter regions are greater than gray matter regions.

Analysis of the brains of toluene abusers by proton magnetic resonance spectroscopy suggests that the white matter changes result from axonal damage and gliosis with secondary demyelination rather than direct neuronal damage and primary demyelination.[35] Characteristic white matter changes include atrophy, loss of gray matter–white matter boundaries, and callosal thinning.[13] Case reports of encephalopathic chronic toluene abusers document the reduction in presynaptic dopamine D_2 receptor density as measured by dopamine transporter scans.[36]

CARDIOVASCULAR SYSTEM

Although cardiac dysrhythmias are a suspected cause of some fatalities associated with toluene abuse and sudden death, there is a lack of convincing evidence in animals that toluene causes direct cardiac effects. In a study of 25 dogs breathing lethal toluene concentrations (30,000 ppm) from a plastic bag attached to their endotracheal tube, respiratory movements continued twice as long as death by suffocation using a plastic bag of the same size; there were no terminal respirations.[37] Transient dysrhythmias with fluctuations in blood pressure were observed in a few animals including ventricular fibrillation, but these dysrhythmias were associated with the terminal changes of hypoxia in the electrocardiogram (e.g., depressed ST segment, inverted T wave, widening of the QRS, reduction of the R wave). The authors concluded that most cases of sudden death during toluene abuse result from severe hypoxia secondary to toluene narcosis; however, they suggested that fatal ventricular fibrillation might occur in sensitized individuals. No serious cardiac dysrhythmias developed in 2 workers found stuporous after exposure to high toluene ambient air concentrations (>7,000 mg/m³).[38] The administration of toluene in near lethal concentrations (66,276 ppm for 30 minutes) was devoid of untoward electrocardiographic effect in chloralose-anesthetized rat.[39] Both animal studies and case reports suggest that high toluene concentrations may cause suppression of cardiac conduction (sinus bradycardia, atrioventricular block); however, these dysrhythmias typically resolve within a few hours after toluene exposure ceases.[40,41]

RENAL SYSTEM

The renal tubule is the primary site of injury to the kidneys following volatile substance abuse of toluene and toluene-containing products. Most toluene abusers with renal dysfunction have a reversible, distal renal tubular acidosis that results from impaired hydrogen ion secretion in the distal renal tubule.[42] The metabolic abnormalities associated with renal tubular acidosis depend on the affected portion of the renal tubule (i.e., proximal or distal). Diseases associated with proximal renal tubular acidosis include nephrotic syndrome and the use of acetazolamide, whereas renal transplants and lithium therapy are associated with distal renal tubular acidosis. The proximal tubule is the main site for bicarbonate absorption. Impaired hydrogen ion secretion at this level limits the resorption of bicarbonate and increases the excretion of bicarbonate in the urine. The proximal tubule absorbs the decreased filtered load of bicarbonate, and excessive bicarbonate is not present in the distal renal tubule. However, decreased hydrogen ion secretion in the distal tubule impairs the regeneration of bicarbonate.

Animal studies indicate that toluene decreases proton conductance in the active transport pathway without affecting the force of the proton pump or back-diffusion of hydrogen ions.[43] Reduced urinary ammonium and titratable acid limits net acid excretion and progressive acidosis develops when net acid excretion decreases below the fixed acid production of the body. Impaired sodium-hydrogen exchange in the distal nephrons causes sodium depletion, secondary hyperaldosteronism, and potassium wasting. These changes result in the combination of hypokalemia, dehydration, and acidosis. Overproduction of hippuric acid from the metabolism of large toluene doses may contribute to the formation of the wide anion gap metabolic acidosis by the accumulation of hippurate and the enhancement of sodium excretion with a corresponding decrease in the glomerular filtration rate.[44] Table 48.2 lists the laboratory abnormalities that aid in the diagnosis of proximal and distal renal tubular acidosis.

Postmortem Examination

A chronic toluene abuser died of acute toluene intoxication; postmortem examination demonstrated diffuse, ill-defined myelin pallor in the brain that was maximal in cerebellar, periventricular, and deep cerebral white matter.[45] Neurons were preserved with no axonal swelling or beading; gliosis was minimal. Occasional, scant

TABLE 48.2. Diagnostic Features of Proximal and Distal Renal Tubular Acidosis.[42]

Laboratory Values	Proximal	Distal

Urine pH (Morning)	May be <6.0	>6.0
Bicarbonate Requirement	High	Low

perivascular macrophages were present. Postmortem examination of toluene abusers may demonstrate the smell of volatile substance; a red, scaly perioral rash, and/or paranasal rash; but typically the examination detects only congestion of the organs (e.g., lungs, brain).[46]

CLINICAL RESPONSE

Illicit Use

Toluene produces an initial excitatory phase followed by central nervous system (CNS) depression similar to the ingestion of ethanol. Desirable effects of the deliberate inhalation of toluene include exhilaration, euphoria, disinhibition, and lack of coordination. Other effects associated with the inhalation of toluene include the sensation that time passes quickly, auditory and visual hallucination, illusions, and delusional ideas.[47] Adverse effects include malodorous breath, excessive oral secretions with frequent expectoration, slurred speech, tinnitus, dizziness, impaired judgement, lethargy, gastrointestinal irritation, cough, sneezing, depression, fear, and dangerous delusions (swimming, flying). The effects of toluene inhalation typically resolve within about 30–45 minutes after inhalation ceases. A 14-year-old girl was brought to the emergency department with confusion, disorientation, and agitation after inhaling toluene daily for at least 5 days.[48] These symptoms resolved within 3 hours, but she complained of headache, weakness, and dizziness.

Complications

In a case series of 20 patients with chronic volatile substance abuse (primarily toluene) for over 2 years, 13 of these patients had neurologic abnormalities when examined at least 4 weeks after the cessation of use.[49] These adverse neurologic effects included cognitive (60%), pyramidal (50%), cerebellar (45%), and brainstem/cranial nerve (25%) abnormalities. Case

reports associate cerebellar damage, tremor, and ataxia with toluene abuse.[50] In a series of 24 toluene abusers (mean age 23 ± 4.4 years) admitted to a Canadian drug treatment unit, 11 patients had cerebellar abnormalities on neurologic examination.[14] The severity of the cerebellar signs correlated to the evidence of volume loss in the cerebellum as measured by a computed tomography (CT) scan. There is little evidence that toluene abuse causes peripheral or cranial nerve pathology.[51] A case report associated a history of chronic, heavy abuse of toluene-containing glue with a multiple sclerosis-like syndrome.[52] A 31-year-old man developed progressive incoordination, lower limb weakness, paresthesias, diplopia, urinary incontinence, and diffuse hyperintensities of cerebral white matter on T2-weighted magnetic resonance images (MRIs) that improved with abstinence. During one of his relapses, an acute encephalopathy appeared that also improved after cessation of glue sniffing.

Type I (distal) renal tubular acidosis is a recognized complication of toluene abuse.[53] Symptoms include nausea, vomiting, muscle weakness, and altered mental status. Rhabdomyolysis and myoglobinuria may occur along with severe hypokalemia and hypophosphatemia. Quadriparesis and respiratory failure may occur as a result of severe hypokalemia.[54] The renal tubular acidosis and hypokalemia associated with toluene abuse may mimic familial periodic paralysis. Other renal abnormalities associated with toluene abuse include Fanconi's syndrome. Rarely, case reports associate the development of ureteral calculi with toluene abuse and distal renal tubular acidosis.[42] Hepatotoxicity is not usually associated with toluene abuse.

Case reports associate chronic toluene abuse with dilated cardiomyopathy without coronary artery disease,[55] myocardial infarction with ventricular fibrillation,[56] and recurrent non-Q-wave myocardial infarction.[57] However, the contribution of toluene abuse to the morbidity and mortality associated with these case reports is unclear because of the confounding factors (e.g., ethanol abuse, preexisting congestive heart failure, strong family history of cardiac disease) present in these patients along with the poor documentation of exposure.

Abstinence Syndrome

Sleep disturbances, irritability, tremor, and nausea may occur within 2–5 days after cessation of toluene abuse.[58] However, case reports of withdrawal following the cessation of the inhalation of toluene are rare despite the continued chronic abuse of toluene by patients with serious neurologic and psychiatric abnormalities.[59] A 13-year-old boy reported that his 2-year history of glue

sniffing required progressively larger amounts of glue (i.e., up to 1 pint adhesive/4 h).[60] When hospitalized, he complained of abdominal cramps, myalgias, fatigue, and nausea beginning 36 hours after admission. These symptoms resolved after 5 days as the same symptoms had during a previous episode of abstinence. Withdrawal from the abuse of thinner containing toluene was associated with irritability, agitation, anxiety, irritability, cognitive impairment, tremor, vertigo, nausea, anorexia, insomnia, and paresthesias; however, these case reports do not include analysis of the thinner or confirmation of other drug use.[61,62]

Reproductive Abnormalities

The risk of developmental delay, growth retardation, preterm delivery, and perinatal death increases in infants born to mothers abusing inhalants.[63] Renal tubular acidosis may occur in pregnant mothers or in premature infants born to mothers chronically abusing toluene.[64] In a case series of 5 infants born to women abusing toluene during their pregnancy, 3 infants had growth retardation, 2 infants had hyperchloremic metabolic acidosis, and 2 had congenital anomalies.[65] Case reports associate self-reported toluene abuse with the development of phenotypic facial abnormalities, behavioral abnormalities, and growth deficits in children born to mothers without self-reported ethanol abuse.[66,67] These abnormalities are similar to those of the fetal alcohol syndrome and include growth deficits, microcephaly, attentional impairments, developmental delays (e.g., language), and minor craniofacial and limb defects (small midface, short palpebral fissures, low-set ears, narrow bifrontal diameter, micrognathia, blunted fingertips, small fingernails).[68,69] The causal role of toluene in these congenital and behavioral abnormalities is difficult to determine from case reports based on self-reports and the lack of control of confounding factors.

DIAGNOSTIC TESTING

Analytic Methods

TECHNIQUES

Analytic methods for the quantitation of toluene in biologic samples includes headspace gas chromatography with flame ionization detection or split flame ionization/electron capture detection,[70,71] gas chromatography with Fourier transform infrared detection, and gas chromatography/mass spectrometry (GC/MS).[72] The limit of detection (LOD) and lower limit of quantitation (LLOQ) of toluene in blood samples using gas chromatography with flame ionization detection were 0.030 and

0.10 mg/L, respectively.[73] Interference may occur with some substances (e.g., paraldehyde, n-propanol, degradation products of fatty acids including hexenol). Methods to overcome this interference in the detection of toluene in headspace analysis include the conversion of toluene to benzoic acid via the formation of benzotrichloride and subsequent detection of the trimethylsilyl derivatives with GC/MS.[74] Scanning electron microscopy of lung tissue from patients chronically inhaling paint may reveal particles of inorganic paint pigments, and dispersive x-ray spectral analysis of these particles confirms the presence of pigments (e.g., titanium).[46]

STORAGE

Substantial loss of toluene may occur during storage, even if stored in tightly sealed containers. Following storage of toluene standards in blood containing 2.16 mg/L in glass headspace vials, no significant toluene losses (i.e., <5%) occurred during storage at room, refrigeration, or freezing temperatures for the first week; however, a 19.48-mg/L standard lost 26%, 16%, and 24%, respectively, at these storage temperatures. At 2 weeks, the losses of these 2 standards increased to 40–45% at room temperature (24°C/75°F) and 35–40% at freezing temperature (−18°C/0°F).[75] After 4 years of storage, the losses were 90–95% at room temperature and 83–91% during refrigeration; therefore, toluene was still detectable in blood samples stored 4 years under refrigeration if the initial concentration exceeded 0.40 mg/L. The blood toluene concentrations in frozen samples were not analyzed during this period.

Samples should be stored in gas-tight, well-sealed, inert containers with minimal headspace; transfers of blood should occur under refrigerated conditions with the number of transfers minimized.[76] Examples of suitable containers include glass tubes fitted with a screw-topped cap, a metal foil liner, and an anticoagulant (e.g., EDTA). The tube should be filled up as much as possible with blood to eliminate a large gap between the cap and the blood in the container. Soft rubber tubes are highly permeable to toluene.[77] Teflon bags are unsuitable for the storage of breath samples for the detection of toluene as 1 study documented the loss of 87% of the toluene content over 9 days.[18] Long-term storage at temperatures below −5°C (23°F) should be avoided because of the formation of n-hexenol from the degradation of fatty acids at these temperatures.[70] The production of n-hexanal interferes with the analysis of low concentrations of toluene. False-positive results for toluene and other aromatic hydrocarbons (ethyl benzene, xylene) may potentially result from the use of tubes containing gel separators manufactured with aro-

matic hydrocarbons.[78] Xylene and ethylbenzene may contaminate some containers (e.g., Sarstedt Monovette serum gel blood-collection tubes; Sarstedt, Numbrecht, Germany) as a result of the leaching of these compounds from the tubes. Other sources of positive bias include contamination of butyl rubber materials used in sample preparation consumables (e.g., Vacutainer stoppers, syringe plungers, sample vial septa).[79]

Biomarkers

Toluene is detectable in saliva after experimental and occupational exposure to toluene in ambient air. In a study of 36 synthetic leather industry workers exposed to approximately 5–7 mg/m³ as a time-weighted average (TWA), the geometric mean toluene concentration in their saliva was 0.00096 mg/L (range, 0.00012–0.00549 mg/L) as measured by GC/MS.[80]

BLOOD

Toluene is detectable in the blood of non-occupationally exposed members of the general US population. In a convenience sample of 982 participants from the Third National Health and Nutrition Examination Survey (NHANES III), the median toluene concentration in blood samples from this group was 0.00028 mg/L (0.28 ppb) with an 95th percentile of 0.0015 mg/L (1.5 ppb).[81] Toluene is a component of cigarette smoke and only about one-half of this group were nonsmokers (current smoking status not reported).

Blood toluene concentrations do not correlate well to clinical effects because of the rapid distribution of toluene into the tissues and the rapid toluene elimination from the body. In general, the blood toluene concentration increases as the severity of toluene intoxication increases. Two amnesic workers were found at the bottom of a small swimming pool after using toluene to remove excess glue from tiles; they were stuporous and unable to walk, but their vital signs were normal.[38] The estimated toluene concentration in their ambient air was >7,000 mg/m³. Ninety minutes after the exposure ceased, the blood toluene concentrations were 4.1 mg/L and 2.2 mg/L as measured by headspace gas chromatography with flame ionization detection. Within 1–2 hours, they became fully alert and ambulatory; they were discharged from the emergency department 5 hours after exposure ceased. In a case series of 110 patients referred to a poison control center for volatile substance abuse, 10 patients with blood toluene concentrations exceeding 10 mg/L were either asymptomatic or mildly intoxicated (headache, drowsiness, nausea, vomiting).[82] In a study of 6 habitual toluene abusers, the blood toluene concentrations about 20 minutes after

cessation of inhalation ranged from 9.8–31.2 mg/L.[18] At the time of the sampling, these habitual toluene abusers demonstrated clinical features of moderate intoxication (slurred speech, poor coordination, impaired concentration). Substantial tolerance may develop following the chronic abuse of toluene. In a convenience sample of 62 homeless adolescents from a shelter that provided housing only from 7 PM to 7 AM each day, all admitted to volatile substance abuse and 57 of 62 adolescents had detectable toluene concentrations in their blood (sample time not specified). The blood toluene concentrations ranged from the LOD (0.5 mg/L) to 83.7 mg/L (median, 15.3 mg/L) as measured by gas chromatography with flame ionization detection.[83] Although most of these adolescents displayed signs of intoxication (restlessness, drowsiness, poor focus), this study did not report clinical features of severe toluene intoxication despite high blood toluene concentrations.

The postmortem blood toluene concentration as measured by headspace gas chromatography exceeded 5 mg/L in 22 of 25 deaths attributed to toluene.[82] In a case series of 33 suspected toluene-containing glue sniffers based on clinical history or evidence found at the death scene, the range of the toluene concentration in postmortem blood from suicidal individuals dying of trauma was 1–38 mg/L.[70] The postmortem toluene concentration in samples from individuals dying of drowning ranged from 1.7–54 mg/L, whereas the postmortem toluene concentration in 2 cases of hanging was 8.1 mg/L and 25 mg/L.

URINE

A 14-year-old girl presented to the emergency department after inhaling toluene daily for 5 days.[48] Four hours after presentation, she was alert and cooperative with headache and dizziness. The urinary hippuric acid at that time was 93.9 g/g creatinine. A 32-year-old man was admitted twice for chronic abuse of toluene-containing glue. The initial urinary hippuric acid concentrations at each admission were 24,400 mg/L and 21,800 mg/L.[5] Hippuric acid is a metabolite of toluene, and the concentration of hippuric acid in urine is a biomarker of toluene exposure in environmental and occupational settings.[84] However, hippuric acid is a metabolic product of some dietary components (e.g., benzoate preservatives, prunes, cranberries, plums, black tea); therefore, the presence of hippuric acid in the urine is not specific for toluene exposure. Hippuric acid concentrations up to 1.5 g/g creatinine may occur as a result of dietary exposure, but high concentrations of hippuric acid in the urine indicate toluene abuse. In a study of homeless adolescents in Brazil, urine hippuric acid concentrations exceeding 3 g/g creatinine was associated with intentional toluene exposure.[83] This cutoff had a sensitivity

of ~98% and specificity of 100%, and was below the urine hippuric acid concentrations following occupational exposure to 200 ppm (i.e., 4 times the current occupational limit for toluene in the work environment). The urine concentration of hippuric acid may be <1 g/g creatinine despite the presences of substantial amounts of toluene in the blood.[82]

Abnormalities

NEUROPSYCHOLOGIC TESTING

Presently, there is limited evidence that toluene abuse causes specific or persistent psychiatric or neuropsychologic testing deficits. In general, neuropsychologic tests are highly sensitive, but the specificity of these tests is poor, particularly without premorbid data. Evaluation of the performance of chronic volatile substance abusers on these tests is complicated by small sample sizes, inadequate controls, abuse of multiple drugs and several volatile substances, poor history, residual effects of acute intoxication, and confounding factors (age, educational history, socioeconomic status, psychiatric disorders, poor motivation, delinquency, learning and reading deficits, comorbid mental disorders). A high percentage of chronic toluene abusers have impaired performance on neuropsychologic testing relative to the general population, but there are few data on the premorbid baseline of these patients prior to the onset of volatile substance abuse. Within a cohort of 25 chronic solvent abusers, the patients with white matter changes had a statistically lower performance IQ (but not the verbal IQ) on the Wechsler Adult Intelligence Scale revised compared with other members of the group, particularly in the Digit Symbol Test (sustained attention, response speed, visuomotor coordination).[92] This latter test is less affected by intellectual level and educational background than most WAIS-R tests. There were no data on the premorbid intelligence of this group.

The presence of abnormalities on neurologic examination of chronic volatile substance abusers is often, but not always, associated with impaired performance on neuropsychologic testing including decreased IQ (verbal > performance) compared with population norms, impaired attention/concentration, deficits in short-term memory, and poor insight and judgment.[34] These neuropsychologic deficits are consistent with the white matter pathology detected by MRI. Although earlier studies suggested that toluene did not cause neuropsychologic impairment following mostly experimental use,[85] later studies of more heavily exposed, older adolescents suggests significant impairments in cognitive functioning including speed of information processing, visuospatial reasoning, learning, psychomotor

coordination, sustained attention, and executive abilities (e.g., working memory).[86,87]

A study of 55 volatile substance abusers (mean age 30.1 ± 8.0 years with a mean duration of abuse of 10.7 ± 8.2 years) and 61 chronic drug users (mean age 29.4 ± 6.1 years with cocaine being the drug of choice for 47% of these drug abusers) indicated that both groups scored below the population mean on most neuropsychologic measures.[88] The volatile substance abuse group performed particularly poorly on measures of working memory and executive cognitive functions when compared to the other drug abuse group. There was no clear dose-response relationship between cumulative dose of volatile substances and abnormalities on neuropsychologic tests. MRI data from this study demonstrated a high prevalence of abnormalities in both the inhalant group (44% abnormal) and the control drug group (25.5% abnormal). These abnormalities occurred in the basal ganglia, cerebellum, pons, and thalami of both groups, albeit higher in the inhalant group.

IMAGING STUDIES

Conventional MRI typically demonstrates multifocal white matter T2 hyperintensities and brain atrophy in the subcortical and periventricular white matter, internal capsule, brainstem, cerebellum, and upper cervical cord. Less common MRI abnormalities associated with toluene abuse involve prominent T2 hypointensities in the gray matter of the cortex and cerebellum including the basal ganglia, red and dentate nuclei, substantia nigra, and thalamus.[89,90] In MRI scans, chronic severe toluene abuse is associated with increased cerebellar, basal cistern, and cerebral sulci along with periventricular white matter signal hyperintensity on T2-weighted MR images.[91] In a study of 25 chronic solvent abusers with a mean age of 22.1 ± 4.3 years and mean duration of abuse of 7.5 ± 3.9 years, 10 patients had hyperintensities in cerebral white mater, brainstem, and cerebellum on T2-weighted MR images.[92] The main substance of abuse in 88% of these patients was toluene, occasionally with lacquer thinner and glues. Of these abusers, 9 also had hypointensities in the thalami. However, regression analysis did not demonstrate a statistically significant correlation between atrophy indices and duration of volatile substance abuse. Single photon-emission computed tomography (SPECT) may demonstrate hypohyperperfusion foci and nonhomogeneous uptake of radiopharmaceuticals in the brain.[93]

BLOOD

Multiple metabolic abnormalities may occur following chronic toluene abuse. These metabolic disturbances

include hypokalemia, hyperchloremia, hypophosphatemia, and metabolic acidosis.[94] Debilitating muscle weakness along with rhabdomyolysis may result from profound hypokalemia due to chronic toluene abuse.[95] Metabolic acidosis may occur with either a normal anion gap or a high anion gap. Typically, renal tubular acidosis is associated with a normal anion gap and hyperchloremic metabolic acidosis as a result of impaired renal excretion of ammonium ion; excessive excretion of potassium and sodium in inappropriately alkaline urine (i.e., pH >5.5 in the presence of metabolic acidosis) also occurs.[96] Excessive urinary excretion of hippuric acid may also cause a normal anion gap metabolic acidosis as a result of the rapid excretion of the unmeasured anion, hippurate. Occasionally, a high anion gap acidosis develops along with excessive sodium excretion, prerenal azotemia, and impaired renal excretion of hippuric acid. Although transient distal renal tubular acidosis is a prominent occurrence during these abnormalities, this syndrome does not explain all of the metabolic and renal changes in chronic toluene abusers. These abnormalities may include renal dysfunction. In a case series of 16 episodes of hospitalization for paint sniffing (30–35% toluene), there were 6 episodes of rapidly reversible renal insufficiency with peak serum creatinine concentrations ranging from 1.7–5.4 mg/dL.[97] The urinalysis of chronic toluene abusers may demonstrate glucosuria, proteinuria, or myoglobinuria.[98] An elevated serum osmolal gap may occur in the presence of toluene in the serum.[99]

Driving

In a Norwegian study of 114 drivers arrested for driving under the influence with detectable toluene concentrations in their blood samples, the blood toluene concentration collected 30–90 minutes after apprehension ranged from 0.09–21.5 mg/L.[100] Most of the 29 drivers with blood toluene concentrations exceeding 9.3 mg/L (109 µM) and no other detectable drugs were impaired as determined by a physician's examination. Some decline in the toluene concentration between apprehension and analysis probably occurred because of the rapid toluene elimination rate and the delay between sampling and analysis. In a case series of 6 drivers arrested for suspected driving under the influence with no other drugs of abuse in their blood, the mean blood toluene concentration was 25 ± 12.1 mg/L (median, 23 mg/L, range, 12–45 mg/L).[101] All these drivers displayed moderate intoxication (slurred speech, ataxia, poor concentration) without serious signs of CNS depression. The average time between arrest and collection of the blood sample was approximately 2 hours. The mean toluene blood concentration for glue sniffers

arrested for volatile substance abuse was 10.8 ± 3.9 mg/L (median, 2.4 mg/L; range, 0.2–74.7 mg/L).[102]

TREATMENT

Stabilization

The primary risk following severe acute exposure to high doses of toluene is CNS depression and suppression of the respiratory drive. Severe hypokalemia and profound muscle weakness may result from chronic toluene abuse. Patients should be removed from further toluene exposure; contaminated skin should be washed thoroughly with soap and water after removal of contaminated clothing. Other decontamination measures are usually unnecessary. Symptomatic patients should be monitored for respiratory depression and cardiac dysrhythmias. Patients with altered consciousness may require respiratory support (supplemental oxygen, assisted ventilation). There are no antidotes for toluene exposure.

Supportive Care

The treatment of medical abnormalities associated with toluene abuse is supportive. As a result of the rapid initial elimination of toluene, resolution of CNS symptoms typically occurs within a few hours. Failure of these symptoms to improve within several hours after toluene exposure ceases suggests the presence of other pathology. Correction of renal abnormalities associated with chronic toluene abuse may require longer therapy with most patients responding to fluid and electrolyte replacement within a few days. Blood from these patients should be analyzed for electrolyte (hypokalemia, hypophosphatemia, hypocalcemia) and acid-base disturbances as well as rhabdomyolysis. Patients with a history of chronic toluene abuse should be referred for psychiatric care to encourage abstinence. There is no specific treatment for chronic toluene exposure.

Chapter 49

TRICHLOROETHANE

IDENTIFYING CHARACTERISTICS

1,1,1-Trichloroethane (CAS RN: 71-55-6, methylchloroform; TCA) is a colorless, pleasant smelling liquid with a molecular weight of 1.336 g/mol and a boiling point of 71.1°C (160°F). The viscosity of this liquid at 20°C (68°F) is 0.858 mPa-sec. The vapor pressure at room temperature is 127 mm Hg; the concentration of TCA in ambient air at saturation is 160,000 ppm. The odor threshold of TCA is about 100 ppm; the smell becomes unpleasant at 1,500–2,000 ppm.[1] This highly volatile, nonflammable compound is only slightly soluble in water, but TCA is highly miscible in organic solvents (e.g., carbon tetrachloride, carbon disulfide, chloroform, acetone, methanol, benzene). Trichloroethane is a halogenated aliphatic hydrocarbon as displayed in Figure 49.1. 1,1,2-Trichloroethane (CAS RN: 79-00-5) is an isomer of TCA.

Stabilizers are added to both technical and solvent grades of TCA at concentrations of 3–8% to prevent the corrosion of aluminum and aluminum alloys. These stabilizers include nitromethane, nitroethane, butanols, isobutyl alcohol, methyl ethyl ketone, diisopropylamine, 1,4-dioxane, butylene oxide, 1,3-dioxolane, toluene, and *n*-methylpyrrole.[2] Minor impurities in 1,1,1-trichloroethane include 1,1-dichloroethane and 1,1,2-trichloroethane.

EXPOSURE

Sources

1,1,1-Trichloroethane is a volatile, chlorinated solvent that is used primarily as an industrial degreaser and consumer spot remover. Previously, typewriter correction fluid (e.g., Wite-Out™) contained trichloroethane and trichloroethylene up to about 50–60% of the product. In 1984, mustard oil was added to typewriter correction fluid in the United States to discourage the inhalation of vapors from these products. Mustard oil (allyl isothiocyanate) has an unpleasant smell and irritates the mucous membrane and gastrointestinal epithelium; however, as the abuse continued, trichloroethylene and later trichloroethane were removed from these products. Now petroleum distillates have replaced the chlorinated hydrocarbons in many of these products. Trichloroethane previously was a solvent in cosmetics.

Methods of Abuse

Similar to most volatile substances of abuse, trichloroethane is usually sniffed directly from the container, placed on a rag and inhaled as the rag is placed over the nose and mouth, or placed in a container from which the vapors are inhaled. Typically, the euphoria is compared with the ingestion of large amounts of ethanol. Repeat inhalations are necessary to maintain the desired effects because the euphoria resolves in about 15–30 minutes and the "pleasant" drowsiness by 15–60 minutes.[3]

DOSE EFFECT

Mild acute overexposure (500–1,500 ppm) produces inebriation, headache, weakness, lightheadedness, and irritability, whereas exposure to higher levels (1,500–5,000 ppm TCA) causes slurred speech, loss of coordination, giddiness, confusion, lethargy, and disequilibrium.

Abnormalities of the Romberg Test appear in susceptible individuals following exposure to about 900 ppm.[4] Table 49.1 lists the estimated physiologic response to specific TCA concentrations. The clinical effects of airborne exposures to TCA are both concentration and time dependent. Induction of anesthesia develops within 2 minutes following exposure to a concentration of 10,000–26,000 ppm, and recovery begins within 3–5 minutes after exposure ceases.[5]

TOXICOKINETICS

Absorption

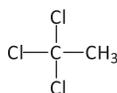
In volunteers, the lungs absorb approximately 25% of the inhaled dose of 1,1,1-trichloroethane (TCA) following exposure to 300 ppm TCA for 6 hours.[6] Similarly, the lungs retain approximately 26–32% following exposure to 213 ppm TCA over 8 hours.[7] The skin is a good barrier to the uptake of TCA vapors; percutaneous absorption of TCA through undamaged, nonoccluded human skin probably is insignificant based on experimental studies and pharmacokinetic modeling.[8] Data are limited on the gastrointestinal (GI) absorption of


FIGURE 49.1. Chemical structure of 1,1,1-trichloroethane.

TCA. The high oral LD_{50} (i.e., approximately 10 gm/kg TCA body weight) and the absence of reported data on systemic toxicity following ingestion of TCA suggest that GI absorption of this chemical may not be substantial; however, data are insufficient to reach definitive conclusions.

Distribution

The high lipid/blood partition coefficient of TCA indicates that TCA distributes relatively more to organs with the highest fat concentrations. Postmortem concentrations document high TCA concentrations in the fat, brain, and blood. Absorbed TCA has the potential to cross both the blood–brain and placental barriers.

Biotransformation

TCA is a relatively stable molecule; humans metabolize only small amounts (i.e., <7%) of TCA, primarily via the cytochrome P450 pathway. The major metabolite is 2,2,2-trichloroethanol, which is also a product of the metabolism of tetrachloroethylene, chloral hydrate, and trichloroethylene. The glucuronide conjugate of trichloroethanol (urochloralic acid) appears in the urine following exposure to TCA. The other significant metabolite is trichloroacetic acid. The metabolism of TCA is saturable; the ratio of trichloroethanol glucuronide and trichloroacetic acid increases above 2:1 as the TCA exposure increases.[9]

TABLE 49.1. Estimated Effects of Single Exposure to the Vapors of 1,1,1-Trichloroethane. [4]

Exposure Time (min)	Air Concentration (ppm)	Expected Human Effect
5	2,000	Disturbance of equilibrium. Odor is unpleasant but tolerable (H)
	5,000	Pronounced loss of coordination (R)
	10,000	Definite incoordination (R,M)
	20,000	Complete incoordination and helplessness (R)
15	1,000	Possible beginning loss of equilibrium (H)
	2,000	Loss of equilibrium (H)
	10,000	Pronounced loss of coordination (R)
30	1,000	Mild eye and nasal discomfort; possible slight loss of equilibrium (H)
	2,000	Loss of equilibrium (H)
	5,000	Incoordination (R,M)
	10,000	Pronounced loss of coordination (R)
60	100	Apparent odor threshold (H)
	500	No detectable effect, but odor is obvious (R,H)
	1,000	Very slight loss of equilibrium (H)
	2,000	Loss of coordination (H)
	5,000	Obvious loss of coordination (R,M)
	10,000	Pronounced loss of coordination (R)
	20,000	Surgical anesthesia, possible death (R)

Note. H = Expected effects are based on human data; M = expected effects based on data from monkeys; R = expected effects based on data from rats.

Elimination

The lungs excrete >90% of an absorbed TCA dose unchanged in expired air following exposure 200 ppm TCA.[7] The relatively low blood/air partition coefficient of TCA compared with other solvents produces relatively slow distribution into tissues, resulting in the rapid elimination of TCA by the lungs.[10] The estimated elimination half-life of TCA follows a 3-compartment model: 1) 44 minutes for highly vascular tissue, 2) 5.7 hours for muscle tissue, and 3) 53 hours for poorly vascularized tissue (e.g., fat). Urinary excretion of TCA metabolites is slow (i.e., days). The kidneys excrete approximately 4.2% of an absorbed dose of TCA as trichloroethanol and approximately 1.8% of the dose as trichloroacetic acid.[7] Following exposure of human volunteers to 350 ppm TCA for 6 hours, <1% of the absorbed TCA dose remained in the body after 9 days.[6]

Tolerance

Tolerance to the effects of TCA occurs in some, but not all animal studies, depending in part on the exposure scenario.[11] These animal studies indicate that tolerance develops to some of the effects of TCA, whereas prolonged exposure to TCA causes sensitization to other effects. Following exposure of mice to TCA (0, 2,000, 6,000, 10,000, 13,300 ppm) 30 minutes daily for 15 days, tolerance developed to measures of forelimb grip strength, number of rears, and inverted screen tests; sensitization occurred to measures of locomotor activity. The development of tolerance was independent of dose.

Drug Interactions

Although pretreatment of rodents with ethanol may induce metabolic enzymes, the elimination rate in ethanol-pretreated and control rats (no ethanol) is similar following exposure to trichloroethane concentration up to 500 ppm for 6 hours.[12] Additionally, pretreatment of mice with isopropanol or acetone does not affect the serum alanine aminotransferase concentration in mice exposed to trichloroethane following injection of 1.5 mL TCA/kg or exposure to 15,000 ppm TCA for 2 hours.[13,14]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

Trichloroethane affects ligand-gated ion channels, particularly the glutamate and GABA$_A$ receptor superfamilies, similar to trichloroethylene. *In vitro* animal studies indicate that trichloroethane reversibly enhances γ-aminobutyric acid (GABA)$_A$ and α$_1$ glycine receptor-mediated synaptic currents, thereby increasing the inhibitory effects of GABA similar to inhaled anesthetics.[15,16] Additionally, these studies suggest that trichloroethane also enhances serotonin-3$_A$ receptor (5-HT$_{3A}$) function.[17] Rodent studies using opioid and nicotinic antagonists/agonists suggest the lack of involvement of the μ-opioid and central nicotinic receptors in the discriminative stimulus effects of TCA misuse.[18] In these rodent studies, the effects of TCA on these receptors are similar to trichloroethylene, toluene, enflurane, and sevoflurane.[19]

Mechanism of Toxicity

Acute exposure to a high dose of 1,1,1-trichloroethane (TCA) produces CNS excitation (1,250–2,500 ppm)[20] and then CNS depression (>5,000–10,000 ppm); most deaths probably result from this depression and the subsequent hypoxia. There are multiple potential causes of death in individuals dying suddenly after inhaling vapors of products containing trichloroethane including asphyxia, aspiration of gastric contents, hypoxia, and cardiac dysrhythmias. Although strenuous exercise frequently precedes sudden death, the question of whether strenuous activity contributes to sudden death or is a consequence of central nervous stimulation or hypoxia remains unresolved.

Postmortem Examination

The autopsies of individuals dying suddenly after trichloroethane abuse demonstrate nonspecific findings including signs of asphyxia (pleural petechiae, subconjunctival hemorrhage/petechiae), irritation of the airways and conjunctiva, congestion of the viscera (brain, lungs), and aspiration of food.[21,22] Histologic examination of the heart from a 14 year old, who died shortly after sniffing Liquid Paper™ correction fluid (composition not reported), demonstrated degenerative changes including swollen and ruptured myofibrils, interfibrillary edema, and a wavy, fibrillar pattern.[23] Although congestion of the liver and kidney may be prominent, acute damage to these organs is not usually present on postmortem examination of cases of sudden death associated with TCA.[24] Rarely, autopsies of cases of sudden death demonstrate severe cerebral edema. A 15-year-old adolescent complained of diplopia and hallucinations after apparently sniffing typewriter correction fluid (Tipp-Ex®, composition not reported).[25] He collapsed and resuscitation was unsuccessful. The autopsy demonstrated severe cerebral edema with marked tonsillar herniation and uncal grooving.

CLINICAL RESPONSE

Illicit Use

The clinical effects of trichloroethane are similar to other volatile substances of abuse and include initial excitement, disinhibition, and euphoria followed by CNS depression. Nausea and vomiting are frequent complications of TCA miuse; other adverse effects include ataxia, slurred speech, hallucination, agitation, and delirium.[26] Exposure to high TCA concentrations produces a rapid onset of CNS depression. Symptoms include dizziness, headache, fatigue, and lethargy. These symptoms may progress to stupor, apnea, coma, or death.[27] The abuse of trichloroethane has not been associated with hepatic or renal damage.

Fatalities

Numerous case reports associate sudden death with TCA and trichloroethylene misuse shortly before their collapse.[28,29] Often, these individuals become agitated and exercise strenuously (e.g., run) prior to death.[30] Many of these case reports involve the misuse of typewriter correction fluid that contains both trichloroethylene and trichloroethane. Although many of the cases involve asphyxia and aspiration of stomach contents, some document the presence of ventricular fibrillation. A 12-year-old girl collapsed shortly after inhaling the vapors from a container of typewriter correction fluid thinner containing trichloroethane.[31] Bystander cardiopulmonary resuscitation was initiated immediately by a nearby physician, and an ambulance arrived within 2 minutes. The initial rhythm was coarse ventricular fibrillation, which converted to normal sinus rhythm with a single 200 J shock. She was extubated in the emergency department after awakening; recovery occurred without sequelae. Although most of these case reports are not associated with myocardial injury, rare case reports associate the development of myocardial injury with the misuse of products containing trichloroethane. A 15-year-old adolescent collapsed 15 minutes after inhaling Liquid Paper™ (composition not reported).[32] The initial rhythm 8–10 minutes after collapse was coarse ventricular fibrillation that converted to sinus rhythm after 2 countershocks. Serial electrocardiograms were consistent with anteroseptal subendocardial injury and the echocardiogram revealed a small area of hypokinesis in the distal interventricular septum. He was discharged 4 days after admission with no further complications.

Abstinence Syndrome

Animal studies suggest that TCA has the potential to produce physical dependence similar to other CNS depressant drugs. Following 4 days of continuous exposure to TCA (500–2,000 ppm), cessation of TCA exposure caused a withdrawal syndrome characterized by increased susceptibility to seizures.[33] Reexposure to TCA attenuated the severity of these seizures, as did exposure to toluene or ethanol. However, there are inadequate data in humans to conclude that an abstinence syndrome occurs in volatile substance abusers using TCA.

DIAGNOSTIC TESTING

Analytic Methods

Techniques for the quantitation of trichloroethane and metabolites in biologic samples include headspace gas chromatography,[34] capillary gas chromatography with electron capture detection,[35] and dynamic headspace with gas chromatography/mass spectrometry.[36] The coefficients of variation for the latter method were below 3.5%, and the lower limit of quantitation (LLOQ) was 0.0008 mg/L. Other methods for the detection of TCA and trichloroethanol were spectrophotometric methods based on the Fujiwara reaction,[37] but these older methods have low sensitivity and specificity.

Biomarkers

1,1,1-Trichloroethane is detectable in the blood of non-occupationally exposed members of the general US population. In a convenience sample of 982 volunteers from the Third National Health and Nutrition Examination Survey (NHANES III), the median TCA concentration in whole blood samples from this group was 0.00013 mg/L (0.13 ppb) with an upper 95% confidence limit of 0.0008 mg/L (0.80 ppb).[38] Following exposure of volunteers to 600 ppm TCA for 1 hour, the TCA concentration in blood from these volunteers averaged 3–4 mg/L; the blood TCA concentration decreased to <1 mg/L within 25 minutes after cessation of exposure.[39] In blood samples, asymptomatic volunteers had TCA concentrations of 7–10 mg/L following approximately 1-hour exposure to 950 ppm TCA.[40] Thirty minutes after exposure, no TCA was detectable in the blood.

The postmortem trichloroethane concentration must be interpreted cautiously because of a variety of factors including the following: 1) potential losses during the postmortem interval and during collection and storage

of the specimen, 2) the presence of contributing factors (dysrhythmias, aspiration, preexisting disease), and 3) perimortem clearance of TCA during resuscitation. Postmortem analysis of blood samples (source not reported) from a 13-year-old girl who died shortly after inhaling vapors from Liquid Paper™, revealed trichloroethane and trichloroethylene concentrations of 2.0 mg/L and 7.5 mg/L, respectively.[41] The postmortem ethanol concentration was undetectable. Two 17-year-old adolescents were found dead with a history of abusing Liquid Paper™. The postmortem blood trichloroethane concentrations were 7 mg/L and 4 mg/L, whereas the trichloroethylene concentrations were 29 mg/L and 19.6 mg/L, respectively.[42] The trichloroethane concentrations in postmortem blood samples from 2 men found dead following autoerotic activities were 29.5 mg/L and 214 mg/L.[43]

Abnormalities

Serum electrolytes, hepatic aminotransferases, and creatinine are typically normal in patients presenting to the emergency department following the inhalation of vapors from products containing trichloroethane.

TREATMENT

The treatment of exposure to TCA is supportive and similar to the treatment of trichloroethylene exposure. Respiratory depression and dysrhythmias represent the greatest dangers to life following exposure to TCA. The adequacy of oxygenation should be immediately evaluated by pulse oximetry, and if necessary, arterial or venous blood gases. Patients with altered mental status or dyspnea should receive supplemental oxygen. Hypotension should be treated initially with fluid expansion and then vasopressor as needed, especially because TCA exposure may decrease peripheral vascular resistance.[44]

Symptomatic patients should be monitored for the development of dysrhythmias. Although sympathomimetic drugs should be administered with caution, their use in the clinical setting should not be avoided, if indicated. Myocardial irritability occurs at ambient TCA concentrations exceeding 5,000 ppm in animal studies; those concentrations are unlikely to occur in the clinical setting because of the rapid elimination of TCA through the lungs.

Potential complications of exposure to TCA are cardiac dysrhythmias, aspiration pneumonia, mild chemical hepatitis (delayed several days), and hypoxic encephalopathy. Otherwise, most patients recover from acute overexposure to TCA without sequelae. Patients exposed to high concentrations of TCA should receive a chest x-ray, electrocardiogram, and measurement of serum creatinine and hepatic aminotransferases. There are no recognized methods to enhance the elimination of TCA.

Chapter 50

TRICHLOROETHYLENE

HISTORY

Fisher synthesized trichloroethylene (TCE) in 1864; this substance has a long history of use as an industrial solvent until recent times when other solvents replaced TCE. Lehman first reported the narcotic properties of TCE in 1911; Jackson first used TCE as an anesthetic in 1933. In the early 1940s, the use of impure TCE in a closed circuit with soda lime for obstetric anesthesia was associated with the development of cranial nerve palsies, primarily trigeminal hypoesthesias, as a result of the formation of a decomposition product (dichloroacetylene).[1] In 1977, the US Food and Drug Administration banned the use of TCE as a food and drug-extraction solvent because of an increased incidence of hepatocellular cancers in rodents gavaged with high TCE doses. Other prohibited uses included the administration of TCE as a general anesthetic, surgical disinfectant, pet food additive, and an extractant of caffeine.

IDENTIFYING CHARACTERISTICS

TCE is a colorless liquid at room temperature with a fruity odor reminiscent of chloroform. The odor threshold in air is approximately 20–80 ppm with clear warning properties present at TCE concentrations above 100 ppm.[2,3] This compound has a sweet, burning taste. TCE is slightly water soluble, but most common organic solvents easily dissolve TCE. Table 50.1 lists the some physical properties of TCE.

The formation of the toxic contaminant, dichloroacetylene, resulted from the use of trichloroethylene (TCE) as an anesthetic in a closed system with alkali absorbers and as a cleaning solvent in submarines and space capsules. Dichloroacetylene may also form as a result of the use of TCE solvents on moist alkaline materials (e.g., concrete).[4] Symptoms of contamination by dichloroacetylene include a sickening sweet sour smell, nasal irritation, anorexia, malaise, vomiting, headache, pruritus, and the development of cold sores.[5] The onset of trigeminal neuralgias and facial herpes has been associated with the formation of dichloroacetylene during trichloroethylene anesthesia.[6,7]

EXPOSURE

Sources

As an excellent solvent for greases, waxes, tars, and oils, TCE has been used primarily as a cleaning and extracting agent in the automotive, metal, and textile processing industries.[8] Consumer products containing TCE include spot removers, paint strippers, typewriter correction fluids, adhesives, and cleaning fluids; however, the use of TCE in these products has been declining. Previously typewriter correction fluid (e.g., Wite-Out™) contained trichloroethane and trichloroethylene at concentrations up to about 50–60% of the product. The malodorous compound, mustard oil (allyl isothiocyanate) was once added to typewriter correction fluid; however, this constituent was later removed along with TCE and trichloroethane.

Methods of Abuse

The abuse of TCE is frequently part of a pattern of polydrug use that includes the abuse of alcohol and other available volatile substances (e.g., ethyl chloride,

TABLE 50.1. Some Physical Properties of Trichloroethene (TCE).

Physical Characteristic	Value
Density	1.47 g/mL (20°C/68°F)
Solubility, Water	1.366 g/L (25°C/77°F)
Boiling Point	87.6°C (189.7°F/760 mm Hg)
Viscosity	0.58 cP (20°C/68°F)
Vapor Pressure	74 mm Hg (25°C/77°F)
	59 mm Hg (20°C/68°F)
Surface Tension	26.4 dyn/cm (20°C/68°F)
Vapor Density	4.54 (Air = 1)
Saturated Air	102,000 ppm TCE (25°C/77°F)
Density, Saturated Air	1.35 (Air = 1)

ether).[9] Addiction to TCE occurs rarely in the workplace following occupational exposure to TCE.[10] These workers may continue to abuse TCE at their home for the soporific and hallucinogenic properties.[11] Methods of abuse include sniffing and huffing as well as the ingestion of TCE.[12] Young abusers pour 20 drops to 15 mL of trichloroethylene on a cloth or handkerchief and inhale the vapors.[13] Most of the addicts describe a pleasant warm feeling, disengagement, relaxation, sleepiness, and euphoria similar to ethanol.

DOSE EFFECT

Human volunteer studies indicate that TCE exposure from 300–500 ppm for >3 hours causes decrements in manual dexterity.[14] At 1,000 ppm TCE, eye and upper respiratory tract irritation appears along with lightheadedness after 6 minutes of exposure. Drowsiness, lethargy, and nausea develop at concentrations of 2,000 ppm TCE after 5 minutes of exposure. Concentrations of 5,000 ppm TCE produce light anesthesia, while concentrations of 20,000 ppm TCE cause much deeper anesthesia in the clinical setting. The minimum alveolar concentration (MAC) of TCE necessary for the first plane of surgical anesthesia is 0.17%. Case reports indicate that chronic abusers of trichloroethylene may consume 120–180 mL trichloroethylene daily.[9]

TOXICOKINETICS

Absorption

Trichloroethylene is well-absorbed through the lungs and gastrointestinal tract, while dermal absorption appears minimal. The pulmonary retention of TCE following inhalation ranges from approximately 20–70% depending upon airborne concentration, duration of

exposure, and tidal volume. Based on sampling of blood and expired air over 44 hours, 6 healthy volunteers exhaled a mean of approximately 22% of the absorbed dose following exposure to 100 ppm TCE over 4 hours.[15] Although the absolute quantity absorbed increases with increasing ventilation, most absorption of TCE following inhalation occurs over the first few minutes as a result of the relatively high blood/air partition coefficient (i.e., about 10).

Distribution

TCE disappears from the plasma as a result of rapid distribution and metabolism.[16] Because of high lipid solubility (oil/blood partition coefficient of approximately 750), accumulation of TCE occurs in organs containing adipose tissue. Animal studies indicate that body fat, adrenals, ovaries, and blood cellular components accumulate the greatest portion of TCE.[17]

Biotransformation

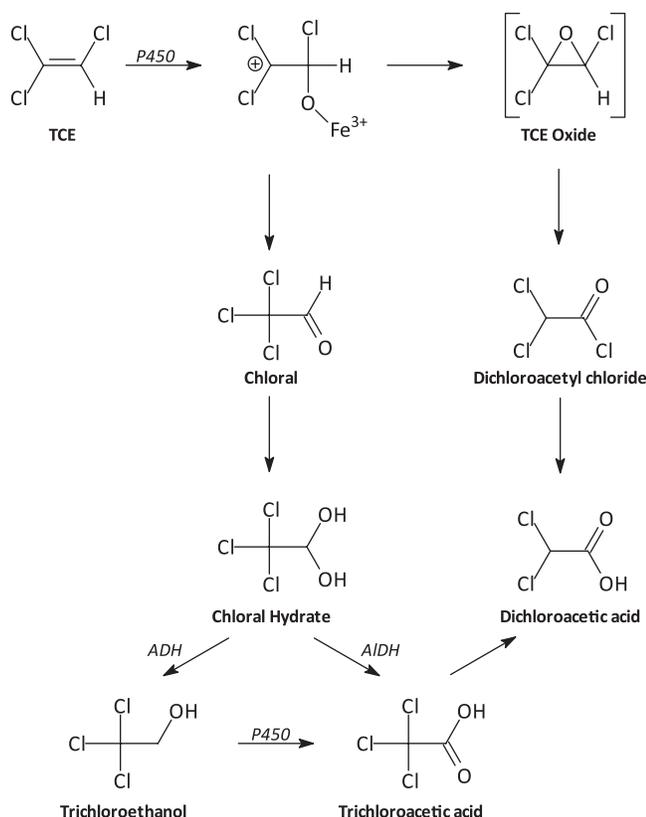
There are two major pathways of TCE metabolism: cytochrome P450-dependent oxidation and conjugation with glutathione. The former pathway is the higher affinity route, whereas the latter becomes more important following exposure to high TCE concentrations. Metabolism occurs primarily in the liver in the presence of cytochrome P450 isoenzymes (e.g., CYP2E1),[18] although other potential sites of metabolism include the lung and kidney. The mixed function oxidase system converts TCE to an epoxide, which subsequently rearranges to trichloroacetaldehyde and then chloral hydrate as displayed in Figure 50.1. The other potential toxins in this pathway include dichloroacetyl chloride and dichloroacetic acid. The latter metabolite forms in animals primarily following exposure to high TCE doses. TCE can also undergo conjugation with glutathione by the catalytic action of glutathione-*S* transferase to form *S*-(1,2-dichlorovinyl)glutathione, and subsequently to the cysteine conjugate [*S*-(1,2-dichlorovinyl)-L-cysteine, DCVC] by γ-glutamyltransferase (GGT). Potentially, nephrotoxic metabolites form from the generation of reactive metabolites by the catalytic action of cysteine conjugate β-lyase on DCVC.[19] The cysteine conjugate, DCVC, also undergoes detoxification by *N*-acetylation to yield mercapturates. Although TCE metabolism in humans and animals is similar, there are substantial quantitative differences in TCE metabolism as a result of sex-, species-, and strain-dependent differences in various enzymes that metabolism TCE.[20,21] Comparatively, the metabolic rate in humans is slowest with the trichloroethanol/trichloroacetic acid ratio greatest in rabbits and smallest in humans.[22]


FIGURE 50.1. Oxidative metabolism of trichloroethylene. This chemical also undergoes conjugation with glutathione and subsequent biotransformation to form potentially toxic reactive metabolites.[20]

Elimination

TRICHLOROETHYLENE

Elimination of TCE involves 2 primary processes: 1) relatively rapid metabolic conversion of TCE followed by excretion of metabolites (e.g., trichloroethanol, trichloroacetic acid), and 2) the pulmonary excretion of unchanged TCE. Following exposure to low doses (<100 ppm), the liver metabolizes about 70–90% of an absorbed TCE dose, whereas the lungs excrete 10–20% of this dose unchanged.[16] Only small amounts of TCE appear in the feces.[23]

During acute TCE intoxication, the kinetics of TCE metabolism varies substantially depending on several factors including the adequacy of alveolar air exchange (i.e., pulmonary edema, pneumonitis, hyperventilation), hemodynamic status (hypovolemia, depressed cardiac output), and hepatorenal function.[24] In these situations, traditional pharmacokinetic models do not accurately describe the kinetics of trichloroethanol or trichloroace-

tic acid excretion. Michaelis-Menten kinetics (i.e., linear at low doses and dose-dependent at high doses) is probably the best model for TCE elimination; this model accounts for the differences in the half-life and elimination pattern of metabolites that occur in TCE metabolism between volunteer studies and TCE-intoxicated patients.[25] The mean half-life of TCE in the blood following an exposure sufficient to cause transient unconsciousness in 3 workers was approximately 20 hours with maximum excretion of urinary metabolites occurring 2–3 days after exposure.[26]

TRICHLOROETHANOL AND TRICHLOROACETIC ACID

The excretion of TCE metabolites is substantially longer than the elimination of TCE from the blood. During a TCE overdose, the plasma half-life of trichloroethanol increases as a result of the continued formation of trichloroethanol from TCE stored in adipose tissues. A 58-year-old worker fell into a vat of TCE, and became comatose after accidentally ingesting TCE. The serum TCE concentration increased up to 4 days postexposure; this elimination pattern followed a 2-compartment model with a half-life of 53 hours and 268 hours.[27] The serum half-life of trichloroacetic acid was similar (50 h and 277 h, respectively). The higher protein binding of trichloroacetic acid results in higher blood concentrations and a longer urinary elimination half-life than trichloroethanol. In a case report of a degreaser addicted to TCE, the renal excretion of TCE metabolites followed a 2-compartment model with the following approximate fast and slow urinary elimination half-life, respectively: 1) trichloroethanol, 6 hours and 50 hours; and 2) trichloroacetic acid, 8 hours and 73 hours.[28] Trichloroacetic acid accounted for >90% of the trichlorometabolites. In a worker comatose from TCE intoxication, the urinary half-life of the fast phase for trichloroethanol was about 26 hours compared with 52 hours for trichloroacetic acid; the urinary elimination half-life of these two metabolites for the slow phase were similar (166 h).[27]

Tolerance

There are few data on the development of tolerance in humans following volatile substance abuse of TCE. Tolerance to the effects of TCE develops in some animal studies, depending in part on the exposure scenario.[29] Rats develop tolerance to the acute behavioral effects of TCE on signal detection when they inhale TCE while performing the task. This tolerance depends more upon learning than upon changes in TCE metabolism; the effects probably result from loss of TCE-induced reinforcement.[30]

745

Drug Interactions

The interaction of ethanol and TCE produces the well-known syndrome of degreaser's flush, which is manifest by erythema of the upper torso and face. The acute ingestion of ethanol increases the TCE concentration in blood and expired air, probably by the inhibition of mixed function oxidases.[31] Exposure to other central nervous system (CNS) depressants probably enhances the CNS effects of TCE.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

Trichloroethylene is a CNS depressant that produces anesthesia in high concentrations. Like other volatile solvents, TCE presumably causes acute CNS depression by changing membrane fluidity, and thereby altering neural transmission. Increased vagal tone during light anesthesia may cause bradycardia, nodal rhythms, or low-grade AV block. Increased myocardial contractility and ventricular dysrhythmias are associated with deeper planes of trichloroethylene-induced anesthesia.[32]

Acute centrilobular necrosis and hepatic failure may occur following chronic abuse of substances with high trichloroethylene concentrations (e.g., Carbona—44% trichloroethylene, 56% petroleum distillates).[33] Liver biopsies of these cases demonstrate acute centrilobular necrosis superimposed on chronic fibrosis.

Postmortem Examination

The postmortem examinations of individuals dying during volatile substance abuse including TCE are nonspecific (e.g., visceral congestion). A 16-year-old adolescent was last seen sniffing plastic cement; he was found dead with a plastic bag and nearly empty tube of glue beside his body.[34] The postmortem examination revealed marked pulmonary edema, severe passive congestion of the liver and spleen, cerebral edema with some herniation of unci and cerebellar tonsils, and a completely obstructed airway with aspirated gastric contents. Analysis of a steam distillate of blood and brain by gas liquid chromatography demonstrated TCE, but this compound was not a known constituent of the plastic cement. A case report documented the development of a fatal congestive cardiomyopathy and hepatorenal failure in a 24-year-old man with a 5-year history of inhaling vapors from shoe-cleaning solvent (trichloroethylene 67%, methylene chloride 18%, dipropylene glycol 10%).[35] Postmortem examination demonstrated

hypertrophied myocardial fibers, focally thickened endocardium, and thickening of the left ventricle. Although the authors attributed the cardiomyopathy to TCE abuse, the causal role of trichloroethylene is unclear because of the presence of confounding factors and the absence of laboratory confirmation of drugs of abuse.

CLINICAL RESPONSE

Illicit Use

Acute trichloroethylene intoxication causes fatigue, visual disturbances, lightheadedness, headache, slurred speech, disorientation, stupor, and altered consciousness. Recovery from the CNS depressant effects of trichloroethylene is rapid in the absence of hypoxia. A 14-year-old adolescent was found unconscious with a bottle of typewriter correction fluid in her hand.[36] Initially, she was responsive only to deep pain, but she was only slightly drowsy on arrival to the emergency department. After 10 minutes of observation, she was fully alert.

Adverse effects associated with TCE abuse include headache, nausea, vomiting, confusion, amnesia, memory disturbances, emotional lability, personality changes, delirium, insomnia, tremor, and unpleasant hallucinations.[9,37] Case reports associate chronic abuse of substances containing high TCE concentrations with hepatic failure.[33] Following cessation of use, hepatic dysfunction usually resolves without sequelae. Cranial nerve palsies may develop following exposure to TCE contaminated with the decomposition product, dichloroacetylene, as a result of demyelination of the sensory trigeminal nucleus. A 35-year-old heroin addict complained of facial numbness, diplopia, and difficulty walking after inhaling TCE continuously for 3 days to alleviate withdrawal symptoms.[38] By the sixth day of hospitalization, all symptoms resolved with the exception of facial paraesthesias and some ataxia. A case report associated the chronic abuse of plastic modeling glue (main ingredient, TCE) with a right middle cerebral artery occlusion, dense hemiparesis, and seizures.[39] Although trichloroethylene was the main ingredient of the glue, the causal role of trichloroethylene in the development of the cerebral infarct is unclear.

Fatalities

Case reports associate sudden death with trichloroethylene abuse.[40,41] Typically, these case reports involve the abuse of typewriter correction fluid, which contains both TCE and trichloroethane.[42,43] Often, these individuals become agitated and exercise (e.g., run) strenu-

ously prior to their death.[44] Although many of the cases involve asphyxia and aspiration of stomach contents, some reports document the presence of ventricular fibrillation. A 12-year-old girl collapsed shortly after inhaling the vapors from a container of typewriter correction fluid thinner containing trichloroethane.[45] A nearby physician initiated cardiopulmonary resuscitation immediately, and an ambulance arrived within 2 minutes. The initial rhythm was coarse ventricular fibrillation, which converted to normal sinus rhythm with a single 200 J shock.

Abstinence Syndrome

There are few data on withdrawal symptoms following chronic abuse of trichloroethylene. A 29-year-old woman was admitted to the hospital for trichloroethylene addiction, somnolence, and hallucination.[11] Most of her symptoms resolved by the third hospital day, but she then developed delirium and bizarre behavior (incoherent, refusal to dress and eat). These psychotic features persisted about 5 days, and her mental status returned to normal within 1 week after resolution of the delirium.

DIAGNOSTIC TESTING

Analytic Methods

Techniques to quantitate TCE and the main metabolites in biologic samples include headspace gas chromatography,[46,47] headspace gas chromatography with electrochemical detection,[48] gas chromatography/mass spectrometry (GC/MS),[49] and headspace solid-phase microextraction with GC/MS.[50] The lower limit of quantitation (LLOQ) for GC/MS is ~0.005 mg/L, whereas the LLOQ for TCE in blood following analysis with GC/MS using headspace solid-phase microextraction was 0.00025 mg/L. Gas chromatography with flame ionization or electron capture detection are the most common analytic methods for the separation of TCE from biologic matrices because of the volatility of TCE. Analysis of TCE metabolites (chloral hydrate, dichloroacetic acid, trichloroacetic acid) typically involves gas chromatography and high performance liquid chromatography (HPLC); ultraviolet detectors are frequently used with HPLC or capillary electrophoresis.[51] Extraction techniques for removing TCE and metabolites from a matrix include liquid-liquid extraction, solid-phase microextraction, protein precipitation, and solid-phase extraction depending on the specific requirements of the extraction. The TCE concentration in whole blood exceeds the plasma TCE concentration. In blood samples from 10 fasting patients scheduled for TCE anesthesia, the plasma/whole blood ratio of TCE averaged approximately 0.76 (range, 0.72–0.81).[52]

Biomarkers

BLOOD

Trichloroethylene is a contaminant of our environment. In Germany, where the estimated mean daily TCE intake ranges from 32–51 μg; 31% of whole blood samples drawn from 39 healthy volunteers demonstrated detectable levels of TCE.[53] None of the volunteers were occupationally exposed to TCE; the TCE concentration in their blood samples ranged from <0.0001–0.0013 mg/L (median <0.0001 mg/L). In a convenience sample of 982 volunteers from the Third National Health and Nutrition Examination Survey (NHANES III), the majority of the whole blood samples contained TCE concentration below the LOD (0.00001 mg/L, 0.010 ppb) with a 95th percentile of 0.000021 mg/L (0.021 ppb).[54] Admission blood from a 35-year-old heroin addict contained 119 mg trichloroethanol/L (no trichloroethylene measurement) after inhaling trichloroethylene continuously for 3 days to alleviate withdrawal symptoms.[38] Clinical effects included facial numbness, diplopia, and difficulty walking. The plasma TCE concentration ranged from 0.2–1 mg/L over the first 5 days in a case series of 4 patients with serious TCE intoxication.[55] These concentrations did not correlate well to symptoms or with the appearance of dysrhythmias.[24] Serum TCE concentrations exceeding 1.5 mg/L are usually associated with coma. Eight hours after admission for TCE intoxication, the serum TCE concentration in a deeply comatose 58-year-old man was 31.4 mg/L.[27] Two hours after exposure to TCE vapors at work, the serum from a 54-year-old man contained 9 mg TCE/L.[56] At that time, his Glasgow Coma Scale score was 7 and his vital signs were stable; he recovered without sequelae.

POSTMORTEM

The postmortem TCE concentration must be interpreted cautiously because of potential losses during the postmortem interval, collection of the specimen, and storage along with redistribution from adipose stores. Most case reports of sudden death in adolescents abusing typewriter correction fluid document the presence of both TCE and trichloroethane. Two 17-year-old adolescents were found dead with a history of abusing Liquid Paper™. The TCE concentrations in postmortem blood (site not specified) were 29 mg/L and 19.6 mg/L compared with trichloroethane concentrations of 7 mg/L and 4 mg/L.[57] A 42-year-old

construction worker was found dead at the bottom of a well that had been painted with TCE.[58] Postmortem examination confirmed the presence of asphyxia (Tardieu spots lungs and heart), and subclavian and femoral blood contained TCE concentrations of 84 mg/L and 40 mg/L, respectively. A 28-year-old man was found dead on the floor of his home with a history of glue sniffing and an empty container of commercial contact cement (95–97% trichloroethylene). Initial analysis of cardiac blood demonstrated 80 mg trichloroethanol/L.[59] Subsequent analysis of cardiac blood after 4 months of storage at 4–6°C (~39–43°F) revealed 1.1 mg TCE/L as measured by headspace gas chromatography with flame ionization detection.

Abnormalities

Conduction abnormalities are uncommon during trichloroethylene intoxication.[60] A case report associated the development of Mobitz type I A-V block with trichloroethylene intoxication secondary to volatile substance abuse.[61] Sinus rhythm returned during abstinence in the hospital. Abnormalities associated with the trichloroethylene abuse include hyperbilirubinemia, elevated serum hepatic aminotransferases, and elevated prothrombin time.[62] In patients with cranial nerve palsies and facial hypoesthesias secondary to the formation of dichloroacetylene, somatosensory evoked potentials may demonstrate impairment of the trigeminal nerve.[63]

TREATMENT

Most mild TCE intoxications respond to removal from the source of exposure and supportive care. Immediate threats to life are respiratory depression and cardiac dysrhythmias. Oxygen, intubation, intravenous lines, and cardiac monitoring should be initiated as dictated by the clinical situation. Patients who demonstrate serious toxicity should be monitored for at least 24 hours because of the potential to develop serious dysrhythmias. Profuse diarrhea may exacerbate electrolyte imbalance and predispose the patient to dysrhythmias. Consequently, generous intravenous fluids should be given to symptomatic patients and the serum electrolytes should be monitored at least daily in these patients. Liver function tests and serum creatinine should be obtained to monitor hepatorenal damage. There are inadequate clinical data regarding the use of antidysrhythmic drugs for serious dysrhythmias to recommend specific drugs other than the usual antidysrhythmic drugs (amiodarone, lidocaine).

Hypotension is unusual following the removal of the victim from exposure; the presence of hypotension necessitates an evaluation of the patient for other causes (trauma, volume depletion). Cautions against the use of sympathomimetic drugs for TCE intoxication are based on animal studies rather than therapeutic experience. Therefore, the use of sympathomimetic drugs in the clinical setting with cardiac monitoring should be based on clinical judgment. No data are available on the enhancement of elimination of TCE or associated metabolites. Sequelae are unusual following acute exposure and the patient should recover fully unless hypoxic damage occurred.

D   Nitrogen Compounds

Chapter 51

AMYL and BUTYL NITRITES

HISTORY

The discovery of the vasodilatory properties of amyl nitrite occurred in 1859 when Guthrie described facial and cervical flushing after the inhalation of amyl nitrite. In 1867, Sir Thomas Lauder Bruton used amyl nitrite to treatment chest pain associated with angina pectoris.[1] He also investigated the properties of butyl nitrite in the 1880s. Although amyl and butyl nitrite had similar properties, butyl nitrite was not used clinically.[2] Generally, amyl nitrite was considered a safe drug, initially marketed as a prescription drug in 1937. In 1960, the US Food and Drug Administration (FDA) removed amyl nitrite from the list of medications requiring a prescription. However, during the 1960s, reports of the abuse of nitrites by apparently healthy young men appeared, and the FDA reinstated the requirement for a prescription of amyl nitrite in 1969. During the 1970s, amyl and butyl nitrite became a popular aphrodisiac, particularly among homosexual males.[3] Butyl nitrites are not classified as drugs by the FDA.

IDENTIFYING CHARACTERISTICS

Nitrites are highly unstable in aqueous solutions and biologic fluids as a result of volatility and hydrolysis to alcohols and nitrite ions. Alkyl nitrites (amyl, butyl) are esters of nitrous acid (HNO_2), whereas organic nitrates (e.g., nitroglycerin) are esters of nitric acid (HNO_3). The alkyl nitrites are highly flammable; fires may result from the synthesis and use of these compounds. Amyl nitrite (CAS RN: 110-46-3, $C_5H_{11}NO_2$) is a yellow liquid with a boiling point of 99.2°C (210.6°F). This compound also occurs as a mixture of isomers (CAS RN: 8017-89-8).

Figure 51.1 displays the chemical structure of amyl nitrite. There are four isomers of butyl nitrite: isobutyl, *n*-butyl, *sec*-butyl, and *tert*-butyl. *n*-Butyl nitrite (CAS RN: 544-16-1, $C_4H_9NO_2$) is a liquid with a boiling point of 78°C (172°F) and a vapor pressure of 81.3 mm Hg at 25°C (77°F). The water solubility of this compound is 1,120 mg/L at 25°C (77°F). Isobutyl nitrite (CAS RN: 542-56-3) is an isomer of *n*-butyl nitrite. These compounds are rarely available as pure substances in commercial preparations.[4] Figure 51.2 displays the chemical structure of *n*-butyl nitrite.

The rather unpleasant smell of *n*-butyl nitrite resembles a men's locker room (i.e., sweaty socks). Hence, one of the common names (Locker Room) for butyl nitrite reflects this smell. Other popular terms for butyl nitrite include Aroma of Men, Ban Apple Gas, Bang, Bolt, Bullet, Climax, Cum, Discorama, Hardware, Heart On, Jac Aroma, Lightning Bolt, Locker Room, Rush, Satan's Scent, Thrust, and Toilet Water. "Poppers" is a popular term for amyl nitrite; this term derives from the sound heard during the crushing of the pearls (glass ampules enclosed in mesh) that contain amyl nitrite. Amyl nitrite is available in pharmaceutic grade; therefore, this compound is relatively pure. Isobutyl and butyl nitrite are commercial preparations that contain a variety of other substances depending on the commercial use.

EXPOSURE

Epidemiology

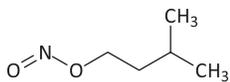
Nitrites are the primary inhalant used by adults, particularly homosexual men and polysubstance drug abusers. In a study of drug abusers in the Baltimore–Washington,


FIGURE 51.1. Chemical structure of amyl nitrite.
FIGURE 51.2. Chemical structure of *n*-butyl nitrite.

DC metropolitan area, the prevalence of lifetime nitrite inhalant use was approximately 11% for recreational drug users and 22% for heavy drug abusers. The mean age of first use was 25.6 years compared with 14.6 years for glue and 17.6 years for marijuana. Sixty-nine percent of a sample of homosexuals in this area used nitrite inhalants at least once. In a study of self-reported drug use by American adolescents aged 12–17 years, the prevalence of nitrite inhalant lifetime use (i.e., at least once in their life) was 1.5%.[5] The prevalence of lifetime nitrite use is higher in incarcerated youth. In a study of 723 Missouri youth confined to residential care for antisocial behavior, the lifetime prevalence of nitrite inhalant use was 1.7% (boys, 1.3%; girls, 4.3%) as determined by face-to-face interviews.[6] As a result of the AIDS (acquired immunodeficiency syndrome) epidemic, nitrite abuse has decreased among homosexual males, but the prevalence of nitrite abuse among recreational drug users remains relatively stable.[7]

Sources

Medical uses for organic nitrites include smooth muscle relaxation during difficult preterm cesarean deliveries, coronary vasodilator prior to thallium scanning, afterload reduction during heart failure, diagnostic aid for the detection of heart murmurs, and an initial antidote for the treatment of cyanide poisoning. Although the use of amyl nitrite requires a prescription in the United States, butyl and isobutyl nitrite are not regulated by the FDA because these compounds do not fit the definition of a food or a drug.

Methods of Abuse

Inhaled nitrites are used to enhance the sexual experience in homosexual men, particularly in men with a history of drug abuse and risky sexual behavior.[8] Purported effects attributed to the use of inhaled nitrites include relaxation of rectal smooth muscle and anal sphincter tone, prolongation of penile erection, prevention of premature ejaculation, and general intensifica-

tion or prolongation of the sexual experience.[7] Both sexes use inhaled nitrites reportedly to induce euphoria in social settings to enhance meditation, stimulate appreciation of music, promote dancing, and expand creativity.[9]

DOSE EFFECT

Following inhalation of nitrites, the desired effects begin within seconds and diminish rapidly within 5 minutes after inhalation ceases. Consequently, nitrites are inhaled as many as 20 or more times over several hours. Most serious cases of nitrite-induced methemoglobinemia result from the ingestion rather than inhalation of nitrites.[10]

TOXICOKINETICS

Absorption

Rodent studies indicate that the absorption of nitrites from air is rapid. In rats exposed to isobutyl nitrite up to 900 ppm for 45 minutes, the average bioavailability was 43%.[11] Following exposure to 3,855 ppm *n*-butyl nitrite for 5 minutes, pulmonary absorption of *n*-butyl nitrite during this period was 44% of the dose.[12] Volunteer studies indicate the bioavailability of sodium nitrite in solution is high (95–98%) after ingestion.[13]

Biotransformation/Elimination

Isobutyl nitrite degrades rapidly in biologic fluids as a result of enzymatic degradation and chemical hydrolysis. *In vitro* and *in vivo* studies indicate that the biotransformation of butyl nitrite in whole blood produces butanol, nitrate, and methemoglobin.[14] These studies also indicate that the nitrite distributes rapidly into total body water. In acidic water, butyl nitrite forms butanol, nitrite, and nitrate. The clearance of isobutyl nitrite is rapid following inhalation. In rats exposed to isobutyl nitrite up to 900 ppm for 45 minutes, the blood clearance was 2.9 L/min/kg (i.e., >>cardiac output) and a half-life of 1.4 minutes.[11] An *in vitro* study of isobutyl nitrite indicated that the average elimination half-life of this compound from blood is about 1 minute.[15]

Drug Interactions

In club scenes, amyl and other nitrites are used in conjunction with phosphodiesterase-5 (PDE-5) inhibitors (e.g., sildenafil).[16] Although there are few clinical data, the concomitant use of nitrites and PDE-5 inhibitors may potentially cause serious hypotension.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

Besides carrying oxygen to the tissues, hemoglobin regulates vascular tone and inflammation via a redox coupling with methemoglobin. In hemoglobin, iron exists in the reduced ferrous state (Fe^{2+}), whereas methemoglobin contains iron in the oxidized ferric state (Fe^{3+}). Nitrite (NO_2) is reduced by deoxyhemoglobin to form methemoglobin and nitric oxide (NO). Nitric oxide is a gas produced by the action of nitric oxide synthetase in the endothelial cells. This compound controls systemic and coronary artery vascular tone by acting locally as an endothelial relaxing factor. The degree of oxidation of hemoglobin reflects the oxygen saturation in the blood and modulates vascular blood flow by producing nitric oxide from nitrite.[17] The action of nitrites results primarily from the formation of nitric oxide (NO). Inhalation of nitrites produces vasodilation and relaxation of smooth muscles as well as vasodilation of cerebral arteries. Although nitrites increase cerebral blood flow, neuroimaging studies of healthy volunteers receiving amyl nitrite do not demonstrate regional differences in cerebral blood flow.[18]

Mechanism of Toxicity

The binding of nitrite to oxyhemoglobin displaces oxygen; this reaction yields methemoglobin, hydrogen peroxide, and nitrogen dioxide in a free radical chain initiation step.[19] Nitrogen dioxide oxidizes ferrous hemoglobin to methemoglobin, whereas hydrogen peroxide oxidizes methemoglobin to a radical (ferryl hemoglobin). Nitrite also reacts with the ferryl hemoglobin radical to produce methemoglobin and nitrogen dioxide. Methemoglobin binds oxygen poorly; thus, oxygen delivery to the tissues decreases. Hydrolysis of alkyl nitrites may occur on contact with epithelial surfaces, and the subsequent formation of nitrous acids may cause inflammation and burns of the skin and tracheobronchial tree.

Postmortem Examination

A 34-year-old man was dead on arrival at the emergency department 1 hour after intentionally ingesting sodium nitrite.[20] The autopsy was performed 5 hours after death, and the abnormalities included dark brown ("soy sauce") blood in all organs and muscles along with hyperemia of the gastric rugal folds. The postmortem blood methemoglobin concentration was 90%. Postmortem examination of a 23-year-old man, who died after the ingestion of isobutyl nitrite in a room deodorizer, demonstrated pulmonary hyperemia with intraalveolar hemorrhage, hyperemia of the liver, and mild, diffuse hyperemia of the gastric mucosa.[21] There was no blue discoloration of the tissues, as no methylene blue was administered prior to death. The postmortem blood methemoglobin concentration was 95%.

CLINICAL RESPONSE

Illicit Use

Desired effects of the inhalation of nitrites include increased cutaneous perception, reduced sexual inhibition, heightened sexual arousal, relaxation of the anal sphincter, and prolonged orgasm.[2] Based on questionnaires, the mean duration of the euphoric effects associated with the use of inhaled nitrites is about 1 minute with a range of a few seconds to 15 minutes.[7] Adverse effects include headache, dizziness, palpitations, nausea, vomiting, weakness, incontinence, blurred vision, facial flushing, periorbital pressure, hypotension, and syncope. The inhalation of amyl nitrite may cause a reduction in systolic blood pressure along with a reflex tachycardia. Local irritant reactions may cause dermatitis, sinusitis, or irritation of the upper respiratory tract (tracheobronchitis) with cough, fever, hemoptysis, and dyspnea.[22] Although uncommon, methemoglobinemia is a potential complication of the abuse of nitrites,[23] particularly in patients with deficiencies of nicotinamide adenine dinucleotide reduced (NADH) methemoglobin reductase (NADH diaphorase).[24] A 31-year-old previously healthy man developed dyspnea and syncope after intentionally inhaling amyl nitrite aerosolized from a compressed gas blower.[25] In the emergency department, he was obtunded and hypotensive with a methemoglobin concentration of 52%; he recovered after the administration of methylene blue. A 28-year-old man was brought by ambulance to the emergency department after collapsing after sniffing amyl nitrite.[26] He was hypotensive, tachycardic, and confused with an elevated respiratory rate and navy blue discoloration of his skin. His methemoglobin concentration was 63%; he recovered after the administration of intravenous methylene blue.

Medical Complications

Yellowish, erythematous, crusted skin lesions ("poppers dermatitis") may appear around the nose, upper lips, face, penis, or scrotum.[27] Pain and swelling may occur in the nasal passages simulating sinusitis. The dermatitis typically resolves within 10 days after cessation of use.[28] Other cutaneous lesions related to the abuse of nitrites

include acrocyanosis (painless, symmetrical, gray bluish macules with edema of underlying skin on nose, ears, or dorsum of hand).[29] Acute hemolysis may occur in patients with glucose-6-phosphate dehydrogenase (G6PDase) deficiency following the abuse of amyl or butyl nitrite.[30] Case reports associate reduction in visual acuity and central differential light sensitivity with the abuse of isobutyl nitrite; however, etiology of the oph-thalmic changes is unclear.[31,32] Four patients developed prolonged visual loss as a result of damage to foveal photoreceptors after inhaling isopropyl nitrites.[33] Resolution of the visual loss occurred in several weeks in some of these patients, but 1 patient had persistent visual loss 1 month after exposure.

There is no clear evidence that the use of inhaled nitrites produces immunodeficiency or enhances the risk of acquiring AIDS; however, there are few data from controlled clinical trials to determine any causal link between the use of nitrites and AIDS.[34] In inhala-tion studies of F344 rats and B6C3F1 mice exposed up to 150 ppm 6 hours/day, 5 days/week for 103 weeks, there was an increased incidence of alveolar/bronchiolar adenoma or carcinomas combined in rats and mice.[35] However, the incidence of mononuclear cell leukemia in rats was decreased. In mice, exposure to isobutyl nitrite produces tissue-dependent alteration in the expression of cancer- and angiogenesis-related genes including hepatic mRNA and protein expression of vas-cular endothelial growth factor (VEGF).[36] The frequent use of poppers is probably a surrogate marker for fre-quent receptive anal intercourse rather than a direct risk factor for AIDS.

Fatalities

Fatalities following the use of nitrites are rare, and most fatalities involve the ingestion rather than inhalation of amyl or butyl nitrite.[37] However, the inhalation of amyl or butyl nitrite may cause severe methemoglobinemia, and potentially death.

DIAGNOSTIC TESTING

Analytic Methods

The volatility and instability of alkyl nitrites complicates the analysis of these compounds. Hydrolysis of alkyl nitrites in aqueous matrices rapidly converts these com-pounds to the corresponding alcohol and nitrite ion. Analytic methods for the analysis of nitrites in blood include gas chromatography with electron capture detection, capillary column gas chromatography/mass spectrometry,[38] solid phase microextraction with gas chromatography/flame ionization detection,[39] liquid

chromatography/mass spectrometry (LC/MS), and gas chromatography/mass spectrometry (GC/MS).[40] The lower limit of quantification (LLOQ) for these methods is approximately 0.001 mg/L. The half-life of butyl nitrites stored at 37.0°C (98.6°F) in whole blood samples from mice ranges from 2–20 minutes.[4] To reduce the formation of other volatiles, samples should be stored at a maximum temperature of 4°C (39°F) with 1–2% w/v sodium fluoride added as a preservative.

Biomarkers

A slate-blue cyanosis and chocolate brown discolor-ation of the arterial blood occurs at methemoglobin concentrations between 15–20%, but symptoms of intoxication are minimal. The administration of oxygen does not improve the cyanosis or chocolate-brown color associated with methemoglobinemia. Methemoglobin concentrations between 20–50% cause headaches, diz-ziness, lethargy, dyspnea, and syncope. Above 50% met-hemoglobinemia, signs of cardiac and cerebral hypoxia develop including confusion, metabolic acidosis, sei-zures, and dysrhythmias. Methemoglobin concentra-tions over 70% are associated with coma, pulmonary edema, and death. A 42-year-old man was deeply cya-notic with a markedly diminished level of consciousness and tachycardia after accidentally ingesting 1 gram of sodium nitrite.[41] His serum nitrite concentration on admission was 0.6 mg/dL.

In the postmortem blood from a 34-year-old man who was pronounced dead 1 hour after ingesting sodium nitrite, the nitrite and nitrate concentrations were 0.55 mg/L and 30.0 mg/L, respectively. The methemo-globin concentration in the postmortem blood was 90%, and the ratio of nitrite to nitrate in stomach contents was 2:1. Nitrite and nitrate were not detectable in vitre-ous humor. The postmortem methemoglobin concentra-tion may fall below fatal ranges as a result of perimortem administration of methylene blue or prolonged post-mortem intervals.[37]

Abnormalities

Unexplained cyanosis suggests methemoglobinemia, particularly when the clinical symptoms are mild com-pared with the degree of cyanosis and oxygen therapy does not improve the cyanosis.[42] Pulse oximetry typi-cally displays oxygen saturations in the range of 80–85% because pulse oximetry measures the light absorbance of deoxyhemoglobin (660 nm) and oxyhemoglobin (940 nm). The oximeter calculates the ratio of the absor-bance at these 2 wavelengths and displays an oxygen saturation based on the ratio of absorbance at these 2 wavelengths (e.g., 100% = absorbance ratio of 0.43).

Methemoglobin absorbs light equally at 660 nm and 940 nm; therefore, high concentrations of methemoglobin cause a spuriously high pulse oximeter reading near 80–85% (absorbance ratio = 1.0). Cooximetry accurately measures oxygen saturation by determining the differential absorbance of oxyhemoglobin, deoxyhemoglobin, carboxyhemoglobin, and methemoglobin at 4 different wavelengths. However, the absorbance of methemoglobin and sulfhemoglobin are similar (630 nm and 614 nm, respectively); therefore, cooximetry does not reliably separate these 2 types of hemoglobin. The potassium cyanide test distinguishes methemoglobin and sulfhemoglobin as a result of the conversion of methemoglobin to cyanomethemoglobin in the presence of potassium cyanide, whereas this reaction does not occur following the addition of potassium cyanide to sulfhemoglobin. The oxygen saturation reported in arterial blood gas analysis might also be misleading because the reported oxygen saturation is a calculated value based on the assumption that all hemoglobin has normal oxygen-carrying capacity. Thus, the presence of high methemoglobin concentrations causes an overestimation of the calculated oxygen saturation. A case report of a 20-year-old woman associated the self-reported sniffing of poppers with the development of radiographic changes consistent with posterior reversible encephalopathy syndrome (PRES).[43] These changes included abnormal, symmetric, high signal intensity on T2-weighted magnetic resonance images of the juxtacortical white matter of the frontal, parietal, occipital, and temporal lobes. Although she had transient loss of consciousness, confusion, paresthesias, and bilateral headache consistent with methemoglobinemia, there was no measurement of the methemoglobin concentration or discussion of how the effect of methemoglobin could be differentiated from PRES.

TREATMENT

Stabilization

Treatment of methemoglobinemia involves evaluation of the adequacy of ventilation, assessment of hemodynamic status, and the provision of supplemental oxygen. Severely affected patients may be hypotensive and hypoxic, and the rapid administration of methylene blue to these patients may be necessary.

Elimination Enhancement

Exchange transfusion is an option for patients unresponsive to maximum therapeutic doses of methylene blue, particularly in severely affected patients.[44] Several case reports document the use of hyperbaric oxygen (HBO) for patients with severe methemoglobinemia.[45] The rationale for the treatment of severe methemoglobinemia with HBO is the enhanced reduction of methemoglobin and the delivery of high oxygen concentrations to the tissues despite the limited oxygen-carrying capacity of the blood secondary to methemoglobinemia. Rodent studies indicate that the administration of HBO (4 ATA) immediately after intraperitoneal administration of sodium nitrite reduces mortality and methemoglobinemia when compared with controls (no treatment).[46]

Antidotes

Intravenous methylene blue is the initial antidote of choice for patients requiring treatment.[47] Methylene blue (toluidine blue) accelerates the enzymatic reduction of methemoglobin by NADPH-methemoglobin reductase, which normally provides a minor pathway for the reduction of methemoglobin. This enzyme reduces methylene blue to leucomethylene blue, which subsequently reduces methemoglobin to hemoglobin. This process requires an adequate supply of NADPH from glycolysis; therefore, the patient requires normal serum glucose and glucose-6-phosphate dehydrogenase concentrations to fully benefit from methylene blue. Patients with G-6-PDase deficiency develop hemolytic anemia following the administration of an oxidizing agent (i.e., methylene blue). Asymptomatic patients with methemoglobin concentrations below 30% usually require only supportive care and removal of the offending agent. The initial intravenous dose of methylene blue (1% solution by weight) is 1–2 mg/kg slowly over 3–5 minutes. Rapid improvement in cyanosis and normalization of methemoglobinemia usually occurs within 30–60 minutes.[48] The response to treatment may be difficult to assess because of the bluish skin discoloration caused by methylene blue; therefore, further treatment should be based on repeat methemoglobin concentrations (measured by cooximetry) and patient response. An initial drop (i.e., about 5%) in pulse oximeter readings may occur soon after the infusion of methylene blue because of the interference of methylene blue with pulse oximeter readings, but these readings usually return to normal within 10–30 minutes after infusion. This spurious drop in oxygen saturation results from the similar absorbance (i.e., 668 nm) of methylene blue and reduced hemoglobin. A second dose of methylene blue may be administered in 1 hour if the methemoglobin concentration does not drop significantly with a maximum total dose of 7 mg/kg. Adverse effects of high doses of methylene blue include headache, dizziness, mental confusion nausea, vomiting, abdominal pain, diaphoresis, hypertension, and possibly paradoxical

methemoglobinemia or hemolysis due to high oxidative stress. Failure to respond to sufficient doses of methylene blue may result from the following: 1) G-6-PDase deficiency, 2) NADPH methemoglobin reductase deficiency, or 3) excessive doses of methylene blue (i.e., >7 mg/kg).

PSYCHOACTIVE PLANTS

Chapter 52

ABSINTHE

HISTORY

Since antiquity, wormwood (*Artemisia absinthium*) has been a constituent of vinous beverages with alleged medicinal properties.[1] Both the Egyptian Ebers Papyrus (1552 BC) and the Old Testament of the Bible (Jeremiah 9:15, 13:15) contain references to wormwood.[2] The Greek philosopher and mathematician, Pythagorus of Samos (569–475 BC) recommended wormwood leaves soaked in wine as a treatment for labor pains; Hippocrates (~460–377 BC) used wormwood extracts for rheumatism and menstrual pains.[3] Several of Shakespeare's plays (e.g., *Merry Wives of Windsor*) also contain references to wormwood.[4] Other *Artemisia* species have been used as herbal remedies for many years including the treatment of intestinal round worms,[5] malaria, tumors, and neonatal jaundice.[6] Artemisinin is an extract of the Chinese herb *Artemisia annua* that has been used for >2000 years as an herbal tea for treatment of fever. This compound has undergone clinical trials as an anti-malarial agent.[7]

Absinthe is historically a highly alcoholic, distilled beverage that contains flavoring extracts from wormwood as well as other herbs. In the late 1700s, a French physician in Couvet, Switzerland developed a medicinal formulation containing absinthe that was sold to Henri-Louis Pernod. The Pernod family continued to manufacture and export this drink well into the 20th century. During the 1844–1847 French military campaign in Algeria, French soldiers received wormwood-containing wine as an antipyretic. The use of absinthe became widespread among all French social classes, particularly in Paris where the summer afternoon between 5–6 PM became the "hour of absinthe." By the late 1860s, France imported almost 2 million gallons of absinthe from Switzerland.[8] Experimental work on the neurotoxic effects of absinthe by Valentin Magnan in the 1870s formed the scientific background for the campaign against absinthe.[9] He described the occurrence of generalized tonic-clonic seizures in absinthe drinkers, and he conducted animal research on the epileptic effects of absinthe preparations. In France and other parts of Europe during the last quarter of the 19th century and the first part of the 20th century, the consumption of absinthe as an ethanol-containing aperitif generated considerable controversy regarding the consequences of heavy use including noisy, aggressive behavior, post-intoxication depression and fatigue, anxiety, hallucinations, nightmares, and emaciation.[10] However, a causal link between the use of absinthe and these adverse effects has not been proven in humans apart from the chronic use of ethanol.

During the 1870s, absinthe was a popular drink of artists, musicians, financiers, and literary figures including Oscar Wilde, Edgar Alan Poe, and Charles Baudelaire. Famous paintings displaying the drinking of absinthe include Absinthe (Edgar Degas, ca. 1877), The Absinthe Drinker (Edouard Manet, ca. 1858–1859), and The Absinthe Drinker and The Poet Cornuti-Absinthe (Pablo Picasso, 1901, 1903). Toulouse Latrec depicted Vincent van Gogh drinking absinthe in a pastel portrait created in 1887. Some scholars believe that an addiction to absinthe along with brandy and turpentine exacerbated the manic depressive mood swings of van Gogh.[1,11] In 1905, the Belgian Parliament banned the manufacture and sale of absinthe; the Swiss (1908), Dutch (1910),

and US (1912) governments prohibited the sale and import of absinthe shortly thereafter. Prohibition of the use of absinthe in France began in 1922. At that time, most other European countries forbade the use of absinthe with the exception of Spain, Portugal, the Czech Republic, and the UK. During the early part of the 20th century, the intravenous administration of thujone, the active ingredient in absinthe, was a chemical model for the study of epilepsy.[12,13]

The lifting of prohibitions against the production and use of absinthe began in the latter part of the 20th century; however, the content of absinthe approved for use differed from the historical formulations of absinthe. In 1988, Council Directive 88/388/EEC reintroduced absinthe into the European Union for bitter spirit drinks with a maximum limit of 35 mg/kg α- and β-thujone. Although this regulation removed limits for the use of *Artemisia absinthium*, *Salvia officinalis*, and other thujone-containing flavoring plants in foods, synthetic thujone is prohibited as a chemical food additive. Switzerland also lifted the ban on absinthe. Importation of absinthe remains legal in Canada. In 2007, the US government approved the first authentic thujone-free (i.e., <10 ppm) absinthe product (Lucid, Viridan Spirits, Inc., Manhasset, NY).

BOTANTICAL DESCRIPTION

Wormwood refers to 2 (*Artemisia absinthium*, *Artemisia pontica*) of over 180 species of the genus *Artemisia* (sagebrush). The active ingredient in absinthe is thujone (ethanol is an additive rather than an ingredient); this compound also occurs in sand hill sage (*Artemisia filifolia* Torr.), tansy (*Tanacetum vulgare* L.), Eastern or Northern white cedar (*Thuja occidentalis* L.), and yarrow (*Achillea millefolium* L.).[14]

Common Name: Bitter wormwood, wormseed, absinth sagewort, absinth wormwood, absinthium, common sagewort, losna, pelin, assenzio, wermutkraut

Scientific Name: *Artemisia absinthium* L.

Botanical Family: Asteraceae (sunflowers, tournesols)

Physical Description: This fragrant perennial herb grows up to 1–4 feet (~30–120 cm) with silver-green leaves containing fine silk hairs. Yellow-green flowers appear between July and September. Figure 52.1 displays the bitter wormwood.

Distribution and Ecology: This introduced, perennial shrub occurs in disturbed areas of the northern United States from Oregon and Washington

FIGURE 52.1. Bitter wormwood (*Artemisia absinthium*). (Richard A. Howard Image Collection. Courtesy of Smithsonian Institution.)

to Maine and South Carolina. This plant species is native to Europe and Asia.

Common Name: Roman or petite wormwood

Scientific Name: *Artemisia pontica* L.

Botanical Family: Asteraceae (sunflowers, tournesols)

Physical Description: The height of this plant is similar to common wormwood, but leaves of Roman wormwood are smaller and more finely cut with narrower segments. The upper leaves are white with fine hairs on both sides. Numerous flowers appear in July at the tops of the branches. The flowers are darker and smaller compared with common wormwood.

Distribution and Ecology: Roman wormwood is a native plant species of temperate climates in southern Europe and Asia that naturalized in eastern Canada and the northeastern United States.

IDENTIFYING CHARACTERISTICS

Structure

α-Thujone (CAS 546-80-5) and β-thujone (CAS 471-15-8) are bicyclic monoterpenes that differ in the stereochemistry of the C4-methyl group as displayed in Figure 52.2. α-Thujone is the active ingredient in cedar leaf oil, whereas β-thujone is the major constituent of wormwood oil.[15] These compounds are structurally similar to tetrahydrocannabinol, the active ingredient in marijuana.[16] Thujone is an isomer of camphor ($C_{10}H_{16}O$).

Physiochemical Properties

In animal models, α-thujone is an epileptic agent that is about 2–3 times more potent than β-thujone.[15] Table 52.1 lists some physical properties of α-thujone.

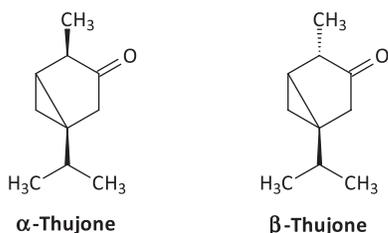
Thujone is a relatively stable compound, except in very alkaline media. Rapid epimerization of α-thujone to β-thujone occurs at pH 11.5, but not in ethanol solutions stored at pH 2.5 or pH 6.5; rapid photodegradation of thujone to corresponding isomeric 5-methylene-6-methylhept-2-ene compounds also occurs within 6–8 hours when stored in 30% ethanol solutions.[17] Little degradation of thujone occurs at ambient temperatures up to 100°C (212°F); no deterioration of thujone occurred in absinthe samples stored at ambient temperatures for 1 year.[18] However, thujone undergoes photodegradation. Irradiating commercial absinthe with UVA doses of 16.9 mW/cm² and UVB doses of 3.9 mW/cm² for 25 hours resulted in the reduction of the β-thujone concentration from 9.7 mg/L to 1.8 mg/L.[18]


FIGURE 52.2. Chemical structures of α-thujone and β-thujone.

TABLE 52.1. Some Physical Properties of α-Thujone.

Physical Property	Value
Boiling Point	203°C (397.4°F)
log P (Octanol-Water)	2.650
Water Solubility	408 mg/L (25°C/77°F)

The taste of absinthe results primarily from the presence of absinthin (CAS RN: 1362-42-1, $C_{30}H_{40}O_6$).[15]

Form

Absinthe (German, *wermut*) is an emerald-green colored spirit that contains ethanol, essential oils of wormwood, and varying amounts of herbs including Florence or sweet fennel (*Foeniculum vulgare* P. Mill.), green anise (*Pimpinella anisum* L.), hyssop (*Hyssopus officinalis* L.), calamus, angelica (*Angelica arguta* Nutt.), lemon or common balm (*Melissa officinalis* L.), nutmeg (*Myristica fragrans* Houtt.), sweet marjoram (*Origanum majorana* L.), and Roman wormwood (*Artemisia pontica*). The green color of absinthe results from the presence of chlorophyll and/or additives.[4]

EXPOSURE

Sources

Wormwood oil is a dark green to blue-brown, bitter-tasting substance extracted from wormwood.

ORIGIN

European companies in Spain, Bulgaria, France, the Czech Republic, and Germany recently began production of absinthe; Switzerland lifted the ban on the consumption of absinthe.[2] In Canada, provincial governments control the sale of spirits, and the limits on absinthe vary between provinces. The Alcohol and Tobacco Tax and Trade Bureau in the United States lifted the ban on absinthe for products containing <10 ppm thujone. Absinthe is available over the Internet. Although the recipes for modern and vintage absinthe are similar, the origin (essential oils/herbs) of the contents of specific absinthe spirits vary by location and distillery.

COMPOSITION

HERBS/ESSENTIAL OILS. Although the whole plant contains thujone, leaves and flowers are the main source of essential oils. The concentration of the principal constituents of essential oils from *Artemisia* species depends on a variety of factors including plant part, season, growing conditions, storage conditions, species, and chemovar with the β-thujone concentration reaching up to about 60% in some cultivars. In a Serbian sample of the essential oil from aerial parts of *Artemisia absinthium*, the main ingredients were β-thujone (19.8%), *cis*-β-epoxyocimene (10.7%), *trans*-sabinyl acetate (8.8%), sabinene (8.1%), and linalyl 3-methylbutanoate (7.5%).[19] α-Thujone was a minor constituent (0.2%). In

763

contrast to the essential oil from aerial parts of wormwood plants, the two main constituents of the essential oil from wormwood roots were α-fenchene (23.3%) and linalyl butyrate (14.4%) with minor concentrations of β-thujone. Although the α-thujone/β-thujone ratio varies with the source and other variables, the concentration of β-thujone usually substantially exceeds the concentration of α-thujone.[20] Some camphor is usually detectable in samples of absinthe because thujone is an isomer of camphor.

ABSINTHE.   Traditional absinthe is an emerald spirit with a bitter taste and a high ethanol concentration. In addition to the high ethanol content, α-thujone probably is the active ingredient in absinthe.[15] Absinthe contained high and variable amounts of ethanol. The ethanol concentration varied with the following types of absinthe: absinthe *suisse* (68–72%), absinthe *demi-fine* (50–68%), and absinthe *ordinaire* (45–50%).[3,10] The estimated total thujone content of old absinthe was up to 260 mg/L (ppm) based on theoretical calculations.[21] However, there are few direct analyses of absinthe products to confirm this estimate. In 1936, Wilson detected thujone concentration from 1.8–45 mg/L in absinthe produced from various essences, whereas absinthe made from wormwood contained 2–34 mg thujone/L as measured by the semiquantitative method of Enz that did not separate thujone isomers.[22] Chemical analysis of 13 vintage samples of absinthe produced before 1915 detected total thujone concentrations (α- and β-thujone) ranging from 0.5–48.3 mg/L (mean, 25.4 ± 20.3 mg/L; median, 33.3 mg/L).[23] The concentration of β-thujone was up to 6-fold higher than α-thujone. There was no statistically significant difference in the total thujone concentrations between vintage (i.e., pre-1915) and modern absinthe. Additionally, this study did not detect toxic concentrations of methanol, fusel oils, copper, or antimony in the vintage absinthe. Theoretically, the chemical composition of vintage absinthe analyzed in this study and cheaper absinthe products mass-produced during the 19th and early 20th centuries may differ significantly. The essential oils of other herbs (e.g., oil of hyssop) used for absinthe production contain convulsant compounds (e.g., pinocamphone, fenchone), but whether these convulsants remain in toxicologically significant concentrations after distillation remains unproven.

PRODUCTION PROCESSES

The absinthe process involves 1) the ethanol-extraction of the aromatic herbs, 2) distillation of the extract, 3) the addition of color and flavors, and 4) dilution with water to reach the final ethanol content.[24] The first step in the production of absinthe with traditional recipes involves the maceration of wormwood and other dried herbs (e.g., fennel, anise) in a concentrated ethanol solution (85–90%). Distillation of the strongly bitter, green-brown macerate produces a light, aromatic, colorless fraction. The addition of *Artemisia pontica* and other herbs during the coloration step introduces the green color (i.e., chlorophyll) and a mild bitter taste. Denaturation of chlorophyll by light and heat results in the characteristic pale green color of traditional absinthe. During the final step, dilution after the coloration step results in the final ethanol concentration.

IMPURITIES

Because the addition of water changes the color of absinthe from emerald to opal, some preban manufacturers added coloring agents (e.g., aniline green, antimony chloride, copper sulfate, hyssop, indigo, nettles, tumeric).[10] These additives are not approved for use in modern absinthe.

Methods of Abuse

Because of the high ethanol content and bitter taste, traditionally absinthe was diluted with water by dripping the water over a perforated spoon (absinthe spoon) containing a lump of sugar and into a glass of absinthe. More elaborate preparation involved the use of a crystal colander (strainer) containing sugar and crushed ice mounted on a wine glass.[4] The absinthe would be poured over the colander followed by essence of anise and then water. The traditional use of absinthe continues; other, less common methods of drinking absinthe include pouring the liquor directly over the sugar cube and lighting the cube with a match and alternately drinking the liquor without dilution.

DOSE EFFECT

There are few modern data on the effect of specific doses of total thujone or specific isomers. Current European regulations limit thujone only in *Artemisia*-derived alcoholic beverage to 35 ppm.[25] Thujone may be added to food only indirectly by the addition of thujone-containing plants; the addition of thujone to food as a chemical is prohibited. The no observable effect level (NOEL) for female and male rats based on the occurrence of seizures was 5 mg/kg body weight and 10 mg/kg body weight, respectively.[26] The estimated tolerable daily intake (TDI) based on a safety factor of 500 is 10 μg/kg body weight. In the European Medicines

Agency *Artemisia absinthium* monograph, the proposed daily thujone intake for adults is 3.0 mg over a maximum of 2 weeks.[27] Using the benchmark dose (BMD) method instead of the NOEL, the estimated acceptable daily intake of thujone is 0.11 mg/kg body weight based on a BMD lower confidence limit (benchmark response of 10%) for clonic seizures in male rats.[28] The calculated amount for benchmark response of 10% was 11 mg/kg body weight/day.

The ingestion of about 10 mL of the essential oil of wormwood by a 31-year-old man was associated with seizures, myalgias, rhabdomyolysis, and acute renal failure.[29] He did not develop hyperkalemia or oliguria; all his laboratory values returned to normal ranges by 17 days after ingestion.

TOXICOKINETICS

There are few data on the toxicokinetics of thujone in humans; *in vitro* studies indicate that hydroxylation via NADPH-dependent pathways account for the biotransformation of α- and β-thujone. The major metabolites of α-thujone and β-thujone are hydroxythujone and dehydrothujone compounds.[30] In rodent studies, the major metabolite of thujone compounds is 7-hydroxy-α-thujone and minor metabolites include 4-hydroxy-α-thujone, 4-hydroxy-β-thujone, and 7,8-dehydro-α-thujone.[31] The major urinary metabolites include hydroxythujone glucuronides and 4,10-dihydrothujone. These studies indicate that there are substantial differences in the metabolism of thujone between animal species.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Absinthe has both sedative and analgesic properties that result in elevated mood and increased sense of perception. Because most of the observations of absinthe drinking resulted from historical accounts, there is limited information on the pharmacologic interactions of thujone and ethanol in absinthe as well as the contribution of each substance to the effect of the spirit. Absinthe may produce hallucination and seizures during acute intoxication, whereas withdrawal rather than acute intoxication causes these complications in chronic alcohol abusers. The cause of absinthism remains unclear with potential contributing factors including α- and/or β-thujone and contaminates [e.g., copper sulfate, antimony chloride, tansy (*Tanacetum vulgare* L.), sweet calamus (*Acorus calamus* L.)]. Analysis of α- and β-thujone in historical recipes and recently produced absinthe detected low thujone concentrations (0–4.3 mg/L) that are far below current absinthe standards (<35 mg/L). This study failed to confirm the high thujone concentrations (260 mg/L) reported in absinthe during the 19th century.[18] In animal studies, α-thujone acts as a convulsant by the noncompetitive inhibition of the γ-aminobutyric acid (GABA$_A$)-gated chloride channel.[15] *In vitro* studies suggest that α-thujone reduces 5-HT$_3$ receptor activity,[32] but the clinical significance of this inhibitory activity remains undefined as absinthe typically contains a lower concentration of this isomer than β-thujone. Although thujone is structurally similar to tetrahydrocannabinol, animal studies indicate that thujone does not bind to the CB$_1$ cannabinoid receptors in the central nervous system as determined by radioligand receptor binding assays.[33]

CLINICAL RESPONSE

Observations of heavy absinthe drinkers by historical accounts suggest that absinthe and acute ethanol intoxication produce different clinical effects. However, the physiologic effects of ethanol and absinthe are difficult to differentiate when both were consumed in the same drink. Heavy absinthe users were boisterous, impulsive, aggressive, paranoid, and violent during periods of intoxication that lasted much longer than pure ethanol intoxication. Reported adverse effects of the chronic use of absinthe included vomiting, gastritis, cachexia, restlessness, anxiety, giddiness, illusions, auditory and visual hallucinations, seizures, delirium, and coma. These effects were associated with absinthe by clinical observations during the late 1800s; therefore, the causal relationship remains unproven. There are few reported data on the adverse effects of current formulations of absinthe.

Exposure to *Artemisia* species may produce allergic manifestations (e.g., allergic rhinitis, contact dermatitis).[34] The incidental ingestion of a large dose of wormwood oil (major ingredient thujone) instead of absinthe causes seizures, rhabdomyolysis, and acute renal failure.[29] A case report associated the development of second-degree atrioventricular block (Mobitz type I) with absinthe intoxication (serum ethanol, 198 mg/dL).[35] Within a few minutes, the rhythm changed spontaneously to an accelerated junctional rhythm that converted to normal sinus rhythm within a few hours with medical treatment (specifics of treatment not reported). The patient remained hemodynamically stable throughout his clinical course. A 2-year carcinogenicity study by the US National Toxicology Program demonstrated some evidence of carcinogenicity in F344/N male rats, but none in female rats, B6C3F1 male mice, or B6C3F1 female mice.[36] There were no significant dose-response

relationships between neoplastic or nonneoplastic lesions.

DIAGNOSTIC TESTING

Methods for the quantitation of thujone, pinocamphone, and fenchone in absinthe include gas chromatography/flame ionization detection, high performance liquid chromatography, and liquid-liquid extraction with gas chromatography/mass spectrometry.[24] The limit of detection is near 80 µg/L.[18] Experimental studies of preban absinthe with UV irradiation up to 200 hours indicate that absinthe stored in green bottles does not decompose, whereas an 18% reduction in β-thujone content and concurrent discoloration occurred in absinthe stored in clear bottles for the same time.[37] Analysis of preban bottles up to 7 years did not detect significant reductions in β-thujone content.

TREATMENT

Treatment is supportive and similar to the treatment of acute ethanol intoxication. The primary focus is airway protection and prevention of withdrawal in chronic users by the liberal use of agents active at the GABA complex in the central nervous system (e.g., benzodiazepines).

Chapter 53

AYAHUASCA, HARMALA ALKALOIDS, and DIMETHYLTRYPTAMINES

AYAHUASCA, HARMALA ALKALOIDS, and *N*,*N*-DIMETHYL-TRYPTAMINE

HISTORY

Indigenous peoples of the Amazon and Orinoco River Basins of South America have used tryptamine-containing concoctions (e.g., ayahuasca) for spiritual and medicinal purposes since before the time of Christ. Ayahuasca and the vessels for drinking this beverage were sacred in these primitive cultures. An experienced healer (*ayahuascero*) conducted the ritual use of ayahuasca after many years of training and preparation (e.g., periods of isolation, dietary restrictions, sexual abstinence). These rituals included special songs (*icaros*) and the use of other plants (e.g., tobacco). Jesuit missionaries recorded the first European references to ayahuasca in the early 18th century.[1] During the middle 19th century, English botanist Richard Spruce compiled an inventory of native plant life in the Amazon.[2] Beside discovering the rubber tree (*Hevea* spp.) and cinchona bark (quinine), he identified *Banisteriopsis caapi* as one of the sources of the psychedelic brew, ayahuasca. In the 1920s, banisterine was introduced as a treatment for Parkinson disease. The source of this hallucinogenic compound was *Banisteriopsis caapi*; subsequent studies demonstrated that the β-carboline, banisterine was identical to the reversible monoamine oxidase inhibitor, harmine. Interest in using this substance as a treatment for Parkinson disease waned in the early 1930s.

During the 20th century, the ritual use of ayahuasca extended to modern syncretic religious movements that combined Christian liturgy and African spiritualism, particularly in Brazil. Raimundo Irineu Serra, a Brazilian rubber tapper founded the Santo Daime in the 1930s after discovering the use of ayahuasca by indigenous peoples in the remote forests of the Brazilian frontier state of Acre. The Barquinha split from the Santo Daime in 1945; this group formed the Uniao do Vegetal with José Gabriel da Costa in 1961. After the death of Raimundo Irineu Serra in 1971, the Santo Daime split into several factions including the Eclectic Centre of the Universal Flowing Light (CEFLURIS). The latter group expanded their church into urban Brazilian areas and also overseas while attracting international visitors to their ritual use of ayahuasca.[3] In 1987, the use of ayahuasca in religious ceremonies was legalized in Brazil. The use of ayahuasca containing *N*,*N*-dimethyltryptamine by members of the Uniao do Vegetal Church is legal in the United States based on the US Supreme Court interpretation of the 1993 Religious Freedom Restoration Act.[4]

BOTANICAL DESCRIPTION

Common Names: Ayahuasca vine, caapi, yagé, yaje, natem, oni, nishi, vine of the dead, vine of the soul

Scientific Name: *Banisteriopsis caapi* (Spruce ex Griseb.) Morton

Botanical Family: Malpighiaceae

Physical Description: This tropical vine has smooth, chocolate-brown bark and opposite, oval-shaped green leaves ranging in size 3.5–8 cm (~1.5–3 inches) wide and 8–18 cm (~3–7 inches) long. The compound inflorescence is axillary or has terminal cymose panicles (i.e., increased, irregular branching in the upper parts with each branch containing a flower). The flowers are about 1 cm (0.4 inches) in diameter with pink petals. The fruit is a samara nut that produces fan-shaped green seeds. Upon ripening, these seeds turn brown.

Distribution and Ecology: The ayahuasca vine grows indigenously in the western parts of the Amazon Basin, primarily Brazil, Colombia, and Peru. This plant is also cultivated in tropical environments.

Common Names: Amiruca panga, chacrona, chacruna, folha, reinha, sami ruca

Scientific Name: *Psychotria viridis* Ruiz & Pav.

Botanical Family: Rubiaceae (coffee)

Physical Description: *P. viridis* is a perennial bush that grows to 5 m (~15 feet) in height and has a unique combination of plant structures (foveolae, stipules) as demonstrated in Figure 53.1.[5] The elliptical, smooth leaves are opposite (i.e., produced in pairs along the stems), growing to about 5–15 cm (~2–6 inches) long and 2–6 cm (~1–2.5 inches) wide. There are 5–10 pairs of secondary veins and occasionally microscopic plant hairs appear on the lower surface. The leaves arise on leaf stalks (petioles) that are about 1–10 mm (~0.04–0.4 inches) long. The leaves are usually gray or red-brown when dried. Foveolae are small pockets found on the lower leaf surface near the junction of the side (secondary) and central veins as demonstrated in Figure 53.1. These distinctive microscopic structures have an opening near a secondary vein that provides shelter for symbiotic mites capable of destroying destructive fungi and herbivorous invertebrates. Each leaf bears at least one pair of foveolae that usually occur near the apex; vegetative stems typically contain more foveolae than reproductive stems.

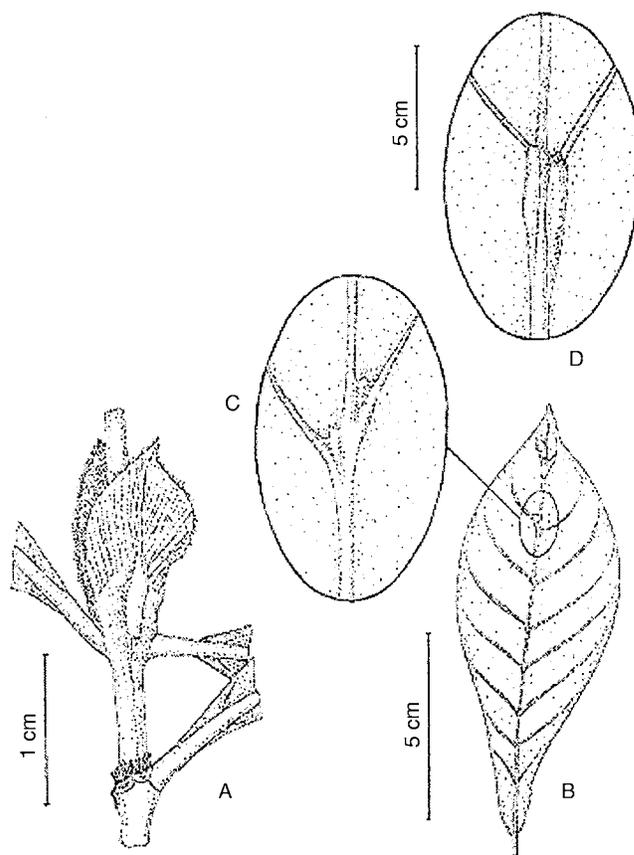
Pairs of distinctive leafy structures (stipules) cover and protect the young, developing leaves. These elliptical, membranous structures are sharply angled at the apex reaching about 5–25 mm (~0.1–1 inch) long and 4–12 mm (~0.15–0.5 inch) wide. As the stipules fall off, a horizontal scar (0.3–1 mm/0.02–0.04 inch wide) develops between the insertion of 2 opposite leaves in the middle


FIGURE 53.1. Distinctive vegetative features of *Psychotria viridis*. (A) upper stem with a pair of well-developed stipules (top to bottom), the bases of a pair of leaves, a stipule scar with a crown of hairs (trichomes) above the scar, the base of another leaf, and the scar from a fallen stipule. (B) Underside of leaf with an encircled pair of foveolae. (C) Enlarged view of encircled foveolae. (D) Enlarged view of foveolae from dried sample.[5]

and lower parts of the stem. A dense line of plant hairs (trichomes) appears above the scar; these trichomes are about 0.5–1 mm (~0.02–0.04 inch) long and turn red-brown when the stem is dried.

Distribution and Ecology: This plant grows in wet lowland tropical forests in Cuba and northern Central America as well as western and central South America, particularly in the Amazonian Basin near Peru and Bolivia.

Common Names: Syrian rue, harmal, African rue, harmal, peganum, harmal shrub, isband, ozallaik, peganum, steppenraute

Scientific Name: *Peganum harmala* L.

Botanical Family: Zygophyllaceae (caltrop)

Physical Description: This perennial glabrous plant grows up to 30 cm (~12 inches) in height. The

narrow, succulent leaves arise from stiff stems arranged in an alternate pattern. The small, 5-petaled flowers are white.

Distribution and Ecology: This plant grows in semiarid conditions in sandy oils in the eastern Mediterranean, Middle East, North Africa, and Central Asia.

IDENTIFYING CHARACTERISTICS

Structure

The ceremonial drink ayahuasca derived from the above plants contains the reversible monoamine oxidase A inhibitors (harmala alkaloids) and the classic hallucinogen, *N,N*-dimethyltryptamine (DMT). Collectively, harmala alkaloids are β-carboline compounds (i.e., harmine, harmaline, tetrahydroharmine). β-Carboline compounds are heterocyclic, dehydrogenated derivatives of tryptophan that occur endogenously in mammals and some plants as a result of the Pictet-Spengler condensation of indolealkylamine compounds with aldehydes.[6] Figure 53.2 demonstrates the structure of these β-carboline compounds, DMT, and serotonin. The tryptophan-derived β-carboline compounds have some structural similarity to *N*-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), which causes irreversible parkinsonism as a result of metabolism to a neurotoxic quaternary ion, 1-methyl-4-phenyl pyridine (MPP+). Tryptamine compounds are tryptophan-derived compounds with a basic indole ring, similar to serotonin; DMT is the prototypical member of the ring-unmodified tryptamine compounds. DMT is structurally related to serotonin and similar to other psychedelic agents (e.g., lysergic acid diethylamide [LSD], mescaline).

Physiochemical Properties

DMT is a serotonergic agonist and classic hallucinogen that produces vivid visual imagery and poorly formed auditory hallucinations following inhalation or intravenous administration to experienced hallucinogen users.[7] Harmine and harmaline are reversible, competitive, type A monoamine oxidase (MAO-A) inhibitors,[8] whereas tetrahydroharmine (CAS RN: 40959-16-8) is a weak inhibitor of serotonin uptake at presynaptic sites.[9] Harmaline and harmine have pK_a values of 9.55 and 7.45, respectively.[10] Ayahuasca contains harmala alkaloids together with DMT; this combination has mild sedative and hallucinogenic properties similar to the classic hallucinogen, 1-(2,5-dimethoxy-4-methylphenyl)-2-aminopropane (DOM).[11] Anecdotal reports suggest that the effectiveness of ayahuasca preparations rapidly degrade after 3 days of storage.[12]

EXPOSURE

Sources

In addition to *Banisteriopsis caapi*, other plants that contain harmala alkaloids include *Peganum harmala* (Syrian rue) and *Passiflora incarnata* L. (passionflower).[13] Plants that contain appreciable quantities of *N,N*-dimethyltryptamine include *Phalaris arundinacea* L., *Phalaris aquatica* L. (canary grass, *Phalaris tuberosa* L.), *Desmanthus illinoensis* (Michx.)MacMill. (prairie bundleflower), and *Psychotria viridis* Ruiz & Pav. (chacruna). Sources of *N,N*-dimethyltryptamine for South American peoples include snuffs from seeds of *Anadenanthera peregrina* (L.) Speg. or the tree bark (*Virola* species) and the brewed tea, ayahuasca (hoasca, daime, yajé, vegetal, caapi, mihi, dapa, natema, pinde).

Harmine   **Harmaline**   **Tetrahydroharmine (THH)**

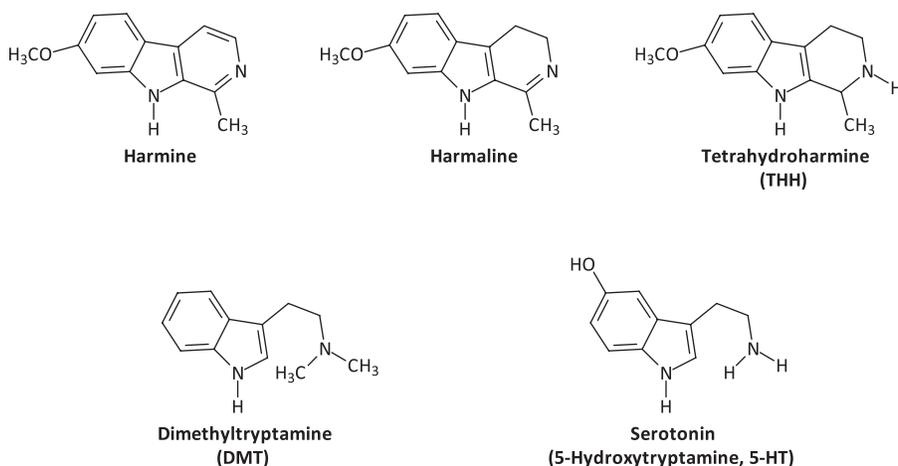
Dimethyltryptamine (DMT)   **Serotonin (5-Hydroxytryptamine, 5-HT)**


FIGURE 53.2. Chemical structures of harmala alkaloids in ayahuasca, dimethyltryptamine (DMT), and serotonin.

Hoasca is the Portuguese transliteration of ayahuasca and the accepted name of this tea in Brazil. Production of this South American tea involves the boiling or soaking of pounded stems from the ayahuasca vine (*Banisteriopsis caapi*) in combination with leaves from other plants (e.g., *Psychotria viridis*). In Ecuador and Colombia, the preparation of ayahuasca typically involves the use of leaves of *Diplopterys cabrerana* (Cuatrecasas) B. Gates [*Banisteriopsis* rusbyana (Nied.) C.V.Morton] rather than *Psychotria viridis*.[14] Traditional uses for *P. harmala* include a red dye for carpets, an abortifacient, and an emmenagogue. Specialty shops and the Internet are common sources for many psychotropic substances including dimethyltryptamine compounds and related designer drugs. A variety of flora (e.g., reed canary grass, *Phalaris arundinacea* L.) contain DMT with instruction for the extraction of smokable freebase DMT available over the Internet.[15] DMT is a schedule I drug in the United States.

Composition

The alkaloid content in the plants used for the production of ayahuasca varies substantially; consequently, the harmala alkaloid content in different ayahuasca preparations also varies. Some sampling studies suggest that the concentration of β-carboline compounds in *Banisteriopsis caapi* range from 0.05–1.95% dry weight, whereas *N,N*-dimethyltryptamine concentrations in *Psychotria viridis* range from ~0.1–0.66% dry weight. [12,14] Table 53.1 displays the mean and range of the major harmala alkaloids detected in 33 samples of *Banisteriopsis caapi* and *N,N*-dimethyltryptamine in 37 samples of *Psychotria viridis* collected from 22 sites throughout Brazil on the same day by experienced members of the União do Vegetal, and analyzed by high performance liquid chromatography.[16] The concentrations of tetrahydroharmine were highly variable in the samples of *Banisteriopsis caapi*, and these concentrations did not correlate to the concentrations of harmine or harmaline. Analysis of lyophilized aqueous extracts of the vine from *Banisteriopsis caapi* demonstrated harmine concentrations of ~20 mg/g extract.[17] Some South American shamanic snuffs derived from bark and bark-extracts of *Virola* species (Myristicaceae) contain substantial amounts of 5-methoxy-*N,N*-dimethyltryptamine in addition to smaller quantities of DMT.[18] Analysis of bark and leaf samples from *Virola* species indicated that the concentration and type of tryptamines varied greatly between samples.[19]

Analysis of an infusion of *P. harmala* associated with acute intoxication indicated that the main active ingredients were harmine, harmaline, and tetrahydroharmine.[20] Minor constituents included vasicine (CAS RN: 6159-55-3, peganine) and 3-deoxyvasicine (CAS RN: 495-59-0, deoxypeganine). In contrast to ayahuasca preparations, concentrations of DMT and 5-methoxy-DMT in the infusion of *P. harmala* were undetectable. Typically, the seeds and roots of *P. harmala* contain the highest concentrations (i.e., about 2–7%) of harmala alkaloids as well as the quinazoline derivatives, vasicinone (CAS RN: 486-64-6) and deoxyvasicinone (CAS RN: 530-53-0). In a Spanish study of various plant parts of *P. harmala* collected from May to December, the highest content of harmine (mean, 4.3% w/w) and harmaline (mean, 5.6% w/w) occurred in dry seeds.[21] Roots also contained substantial quantities of harmine (mean, 2.0% w/w) and harmol (mean, 1.4% w/w), but not harmaline. *In vitro* studies indicated that extracts of the dry seeds were stronger inhibitors of MAO-A than roots; monoamine oxidase B (MAO-B) was not inhibited by either extract.

The alkaloid content of ayahuasca varies substantially with individual recipes, preparation methods, and plant origin/composition.[22] The principal β-carboline alkaloids in this mixture are dimethyltryptamine, harmine, harmaline, and tetrahydroharmine. Analysis of a 100-mL dose of ayahuasca by high performance liquid

TABLE 53.1. Harmala Alkaloid and *N,N*-Dimethyltryptamine Content of Convenience Samples of *Banisteriopsis caapi* and *Psychotria viridis*.[16]

Substance (Source)	Sample Number	Mean ± SD (mg/g)*	Range (mg/g)*
Harmine (*B. caapi*)	33	4.83 ± 2.06	0.31–8.43
Harmaline (*B. caapi*)	33	0.46 ± 0.19	0.03–0.83
Tetrahydroharmine (*B. caapi*)	33	1.00 ± 0.79	0.05–2.94
N,N-Dimethyltryptamine (*P. viridis*)	37	7.50 ± 5.01	0.00–17.75

*Dry weight.

TABLE 53.2. Harmala Alkaloid and DMT Content of Two Samples of Ayahuasca.[1]

Compound	Sample 1 (% Total Alkaloids)	Sample 2 (% Total Alkaloids)
DMT	9.1 mg/dL (14.1%)	8.8 mg/dL (12.5%)
Harmine	47.5 mg/dL (73.1%)	9.2 mg/dL (13.2%)
Tetrahydroharmine	4.2 mg/dL (6.5%)	26.5 mg/dL (37.8%)
N-Methyltetrahydroharmine	4.1 mg/dL (6.3%)	25.5 mg/dL (36.4%)
Harmaline	Trace (<0.1%)	ND
Total Alkaloids	0.65% w/v	0.070% w/v

Abbreviation: ND = none detected.

chromatography using fluorescence detection in one study was as follows: harmine, 170 mg; harmaline, 20 mg; 1,2,3,4-tetrahydroharmine, 107 mg; and *N,N*-dimethyltryptamine, 24 mg.[23] Table 53.2 displays the harmala alkaloid and DMT concentrations in 2 preparations of ayahuasca as measured by GC/MS.

Methods of Use

Shamans in the Amazon Basin use this inebriating tea in traditional medical diagnosis and healing, divination, pathway for access to the supernatural, and rites of passage, particularly in the Brazilian-based syncretic religious groups (Santo Daime, O Centro Espirita Beneficiente União do Vegetal).[24] The latter church uses sacramental brews of ayahuasca as part of a religious ritual (*preparo*), whereas the Santo Daime church uses a decoction (santo daime) of *P. viridis* and *B. caapi* in the ritual called *feitio*.[25] During religious ceremonies, participants typically drink the tea every hour; vomiting frequently accompanies the use of the tea.[12] Piaroa shamans from southern Venezuela use the cambium from *B. caapi* alone (i.e., without DMT-containing decoctions) to heighten empathy among tribal members.[26] The Piaroa people also use *B. caapi* as a hunger suppressant, stimulant, and hunting aid to enhance visual acuity. Limited data on ayahuasca users does not suggest that the ritualistic use of ayahuasca is associated with serious deterioration in the psychosocial interactions typically caused by other drugs of abuse.[27]

Because of the poor oral bioavailability of DMT, DMT is usually smoked after adding the solid brownish material to a marijuana cigarette. Typically, the use of smokable DMT is associated with a pattern of extensive drug use.[28] The rapid intensity and resolution (i.e., about 30 minutes) of the effects associated with smoking DMT results in the eponym, businessman's lunch trip.

DOSE EFFECT

Typical doses of DMT for smoking are 40–50 mg with a range of about 20–100 mg.[13] The administration of 0.1 mg/kg intravenously causes undesirable feeling of physical tension without the euphoria present following the higher dose. In a double-blind, saline placebo-controlled, randomized study of 10 experienced hallucinogen users given DMT intravenously, the threshold for significant physical effects (e.g., increased blood pressure and heart rate, pupillary dilation, increase rectal temperature) was about 0.2 mg/kg body weight.[7] A more intense disorganizing effect, rush, and perceptual perturbations occurred after the administration of 0.4 mg/kg; some users considered these effects unpleasant. Altered perception including the appearance of rapidly moving, brightly colored visual images also occurs in volunteers administered the same intravenous doses.[29] The administration of 0.3 mg/kg followed in 1 minute by a continuous infusion of 0.02 mg/kg/min for 84 minutes produced strong alteration of visual and auditory phenomena along with paranoia and body misperceptions (e.g., body melting away, difficulty sensing the boundaries of their bodies).[44]

The typical infusion of *P. harmala* for sedative effects involves the steeping of 5–10 g crushed seeds. A 41-year-old woman boiled 100 g of seeds in water and she drank the infusion.[30] Subsequently, she developed nausea, vomiting, visual hallucination, diaphoresis, and altered consciousness followed by respiratory failure and mild hepatorenal dysfunction. She eventually recovered without sequelae. The ingestion of 50 g *P. harmala* seeds was associated with nausea, vomiting, and hallucination.[31]

TOXICOKINETICS

Absorption

There is substantial interindividual variability in the bioavailability of harmala alkaloids. Based on clinical effects, the absorption of *N,N*-dimethyltryptamine (DMT) following inhalation is rapid. Smoking DMT produces rapid onset of effects within 5 minutes, and these effects resolve within approximately 30 minutes.[13] The bioavailability of DMT after ingestion is too low to

produce clinical effects, probably as a result of the enzymatic degradation in the gastrointestinal tract to an inactive metabolite.[32] Detectable DMT concentrations following the ingestion of ayahuasca probably result from the inhibition of monoamine oxidases in the gastrointestinal tract and/or liver by the β-carboline metabolites (i.e., harmol or harmalol). These inhibitory effects limit the enzymatic degradation of the simultaneously ingested DMT in ayahuasca, resulting in enhanced absorption of DMT and allow subsequent psychedelic effects.

Volunteer studies indicate that the intense visual imagery associated with the ingestion of ayahuasca correlates to peak plasma concentrations of DMT occurring about 1.5–2 hours after ingestion.[33] Similarly, the mean peak plasma DMT concentrations was about 1.5 hours after ingestion of freeze-dried ayahuasca (0.6 and 0.85 mg DMT/kg body weight) by 18 volunteers.[34]

Biotransformation

The *O*-demethylation of harmine and harmaline to harmol and harmalol, respectively, involves a variety of cytochrome P450 isoenzymes including CYP1A1, CYP1A2, CYP2C9, CYP2C19, and CYP2D6. Kinetic studies indicate that the primary CYP subfamilies involved with the *O*-demethylation of these β-carboline compounds are CYP1A1 and CYP2D6.[35] The glucuronide and sulfate of harmol and harmalol are the main urinary metabolites of harmine and harmaline biotransformation. The metabolism of DMT following ingestion of ayahuasca involves *N*-oxidation (dimethyltryptamine-*N*-oxide) and oxidative deamination.[36] Little unchanged DMT appears in the urine.

Tolerance

Psychologic dependence on ayahuasca or withdrawal symptoms following the cessation of use are not well-documented in the medical literature. Experimental studies suggest potential for the development of some tolerance as reflected in the reduction in platelet 5-HT transporter in regular users when compared with nonusers, assuming that similar effects occur in the central nervous system (CNS).[37] However, observational studies indicate that tolerance does not develop to the psychedelic effects of DMT in contrast to many other psychedelic agents (e.g., LSD, mescaline).[45] In a double-blind randomized study of 13 experienced hallucinogen users receiving saline placebo or 0.3 mg DMT fumarate/kg 4 times at 30-minute intervals, there was no evidence of tolerance as measured by blinded clinical interviews and the Hallucinogen Rating Scale scores.[57] The DMT dose in this study produced typical psychedelic effects.

Similarly, the short-term administration of a psychedelic DMT dose (0.7 mg/kg) twice daily for 5 days did not produce pharmacokinetic or pharmacodynamic evidence of tolerance; however, 3 of the 4 users reported some variation in the response to their subjective "high."[38] Cross-tolerance to a psychedelic dose of DMT did not occur in some users with high tolerance to LSD.[39]

Drug Interactions

Potentially, the ingestion of tyrosine-containing foods along with the MAO-A inhibitors in harmala-containing plants may cause hypertensive crisis similar to monoamine oxidase inhibitor toxicity. Additionally, serotonin syndrome is a potential complication of the concomitant ingestion of selective serotonin reuptake inhibitor (SSRI) antidepressants with the monoamine oxidase-inhibiting harmala alkaloids in ayahuasca.[40]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

In addition to the monoamine oxidase inhibiting activity, *in vitro* assays suggest that β-carboline compounds may contribute to the serotonin-like effects of DMT in ayahuasca by binding with modest affinity at 5-HT_{2c} and 5-HT_{2A} receptors depending on the presence of ring substituents and ring saturation. These studies indicate that harmine and harmaline have minimal to no affinity for 5-HT_{1A} serotonin receptors, dopamine D_2 receptors, or for benzodiazepine receptors with the exception of methyl-β-carboline-3-carboxylate (β-CCM) receptors.[41] β-CCM is a benzodiazepine receptor ligand with inverse agonist properties (i.e., produces an effect opposite to that of an agonist, yet acts at the same receptor). Although tetrahydroharmine (THH) is a weak inhibitor of serotonin (5-HT) uptake,[42] the contribution of THH to the psychedelic effects of ayahuasca is not well-defined.

DMT has nearly equal affinity for the 5-HT_{1A} and 5-HT_2 receptors. In the CNS, rodent studies suggest that DMT binds to 5-HT_{1A} as an agonist and to 5-HT_2 receptors as an antagonist.[43] These relatively short-term effects cause autonomic effects (mydriasis, elevated heart rate, blood pressure, temperature) and a dramatic modification of perception, sense of self, and reality. In healthy volunteers, the administration of DMT produces a dose-dependent, schizophrenia-like state, characterized by formal thought disorder (paranoia, visual hallucinations) and inappropriate affect.[44] Apathy, withdrawal, delusions, and catatonic features are less intense than glutamate antagonists (e.g., phencyclidine). Pindolol is a potent 5-HT_{1A} antagonist, and the

administration of this drug prior to the administration of DMT enhances the psychedelic effects of DMT; these studies suggest that 5-HT$_{1A}$ agonist activity moderates the psychedelic effects associated with 5-HT$_2$ agonist activity.[45]

CLINICAL RESPONSE

The ingestion of ayahuasca containing *N,N*-dimethyltryptamine (DMT) produces mild sedative and hallucinogenic effects that peak approximately 1–1.5 hours after ingestion and resolve within 3–4 hours. The simultaneous ingestion of DMT with Syrian rue (*Peganum harmala*) may prolong the CNS effects and tachycardia up to 12 hours. The intravenous administration of DMT to volunteers was associated with psychedelic effects within 2 minutes of administration and resolution of symptoms within 30 minutes.[45] Adverse effects during ayahuasca use include myalgias, nausea, vomiting, diarrhea, eructations, uncontrollable muscle jerks, and anxiety. The most commonly reported adverse effects in a cross-sectional study of a convenience sample of 32 American members of a branch of the Santo Daime Church were nausea (34%), vomiting (28%), exhaustion 1–2 days after the ceremony (28%), and insomnia (12%).[46] Uncommon side effects included muscle spasm, reduced memory on the following day, headache, visual changes, hypoglycemia, dry mouth, and tachycardia. About 25% reported no adverse effects despite chronic use; physical examinations did not reveal any medically significant disorders. A cross-sectional study of 15 members of the syncretic church using ayahuasca for at least 10 years did not detect any personality or cognitive deterioration as measured by structured psychiatric diagnostic interviews, personality testing, and neuropsychologic testing.[47] Although the test group was compared with a matched control group, the study did not clearly indicate the extent of blinding of the interviewers and testers to the assignment of individuals to the 2 groups.

Effects associated with the ingestion of harmala alkaloids from *P. harmala* include nausea, vomiting, euphoria, visual hallucinations, diffuse tremors, elevated temperature, tachycardia, hypertension, disorientation, agitation, and seizures. An 18-year-old man presented to an emergency department with nausea, vomiting, diffuse tremors, ataxia, visual hallucinations, and agitation after drinking an infusion from *P. harmala* seeds.[20] His urine drugs of abuse screen was negative and analysis of his urine confirmed the presence of harmine and harmaline along with the corresponding metabolites, harmol and harmalol. He recovered rapidly without sequelae. Rodent studies suggest the possibility of fetal abnormalities following the ingestion of ayahuasca doses up to 10 times the typical recreational dose.[48] However, maternal toxicity (decreased maternal and fetal weight gain) at the higher doses and the presence of abnormalities in the control group (albeit lower incidence) limits conclusions regarding the etiology of these abnormalities.

DIAGNOSTIC TESTING

Analytic Methods

Methods for the detection of dimethyltryptamine and β-carboline compounds in ayahuasca include high performance liquid chromatography (β-carbolines) and gas chromatography with nitrogen/phosphorus detection (dimethyltryptamine),[49] gas chromatography/mass spectrometry (GC/MS),[22,50] high performance liquid chromatography/electrospray/mass spectrometry,[51] and liquid chromatography/electrospray ionization/tandem mass spectrometry.[52] The lower limit of quantitation (LLOQ) for these compounds in plasma samples using HPLC and gas chromatography with nitrogen/phosphorus detection is ~1 ng/mL, whereas the limit of detection (LOD) of tryptamines using screening methods based on gas chromatography/mass spectrometry typically ranges from ~5–10 ng/mL.[53] The use of liquid chromatography/electrospray ionization/tandem mass spectrometry allows the detection of β-carboline and dimethyltryptamine compounds with no extraction procedures and LLOQ in the range of 5 ng/mL. The LLOQ for β-carboline and dimethyltryptamine compounds using GC/MS is approximately 20 ng/mL with a precision (relative standard deviation) of <10%.[22]

Detectable concentrations of DMT, 5-hydroxy-DMT (bufotenine), and 5-methoxy-DMT (mexamine) occur in human urine samples as a result of the normal biotransformation of tryptamine by indolethylamine *N*-methyltransferases.[54,55] Simultaneous analytic methods (e.g., gas chromatography/mass spectrometry, liquid chromatography/electrospray ionization/mass spectrometry) can quantitate a variety of tryptamines, β-carbolines, and phenethylamine hallucinogens including α-methyltryptamine, 5-methoxy-α-methyltryptamine, *N,N*-diisopropyl-5-methoxytryptamine, *N,N*-diisopropyl-4-hydroxytryptamine, *N,N*-dimethyltryptamine, 5-methoxy-*N,N*-dimethyltryptamine, bufotenine, psilocin, psilocybin, harmine, and harmaline.[51] In plasma samples, the use of high performance liquid chromatography/ion trap ion trap/mass spectrometry with heated electrospray ionization to reduce matrix effects allows the detection of major alkaloids in ayahuasca with an LOD below 1 ng/mL.[56]

Biomarkers

In a study of 13 volunteers administered 0.3 mg DMT fumarate/kg body weight intravenously at 30-minute intervals for a total of 4 doses, the mean peak DMT plasma concentration after the last dose was approximately 70 ng/mL.[57] In a study of 18 volunteers with prior experience with psychedelic drugs, the ingestion of freeze-dried ayahuasca (0.6 and 0.85 mg DMT/kg body weight) produced mean maximum plasma DMT concentrations of 12.1 ng/mL and 17.4 ng/mL, respectively; peak subjective effects correlated to peak plasma DMT concentrations.[34] A study of 15 volunteers receiving 2 mL ayahuasca/kg detected the following approximate mean peak concentrations of DMT and harmala alkaloids: DMT, 16 ng/mL (range, 11.5–25.5 ng/mL); harmine, 115 ng/mL (range, 36–222 ng/mL); harmaline, 6 ng/mL (range, <1–9 ng/mL); and tetrahydroharmine, 91 ng/mL (range, 49–135 ng/mL).[23] Figure 53.3 displays the plasma concentration-time curve for harmine, tetrahydroharmine, and DMT following the ingestion of 2 mL ayahuasca/kg body weight by 14 regular users during religious practices. All volunteers experienced intricate visual imagery and a general state of heightened awareness; the most intense visionary effects occurred ~1–2 hours after ingesting the tea. Adverse effects included vomiting, a fine tremor, and nystagmus. In a study of 4 healthy men, peak whole blood DMA concentrations of 100 ng/mL were associated with color and spatial distortions, auditory hallucinations, paranoia, and a dissociative state.[38]

A 25-year-old man ingested a preparation from a South American tree bark in the evening followed by the ingestion of 5-methoxy-dimethyltryptamine approximately 4 hours later.[58] He was found dead the following morning, and the autopsy did not demonstrate an anatomic cause of death. Table 53.3 lists the toxicologic findings in postmortem samples from this case as measured by liquid chromatography/electrospray/mass spectrometry. 5-Methoxy-*N*,*N*-dimethyltryptamine (5-MeO-DMT) is typically not detected in ayahuasca, and the presence of such large amounts of 5-MeO-DMT suggests the addition of synthetic 5-MeO-DMT to this preparation.

Urine drugs of abuse screens do not typically detect the use of ayahuasca (DMT, harmala alkaloids) or other tryptamine hallucinogens. DMT and bufotenine are natural products of serotonin or tryptamine metabolism catalyzed by indolethylamine *N*-methyltransferase. Some urine specimens may contain small, but detectable quantities of DMT or bufotenine when analyzed by GC/MS.[59] Although the comparative formation of DMT in schizophrenic and normal patients was investigated in the 1970s with GC/MS, no clear difference in urinary or cerebrospinal fluid DMT concentrations was demonstrated between schizophrenic and normal populations.[60,61]

FIGURE 53.3. Averaged and standard errors of harmine, tetrahydroharmine (THH), and *N*,*N*-dimethyltryptamine (DMT) concentrations following the ingestion of 2 mL ayahuasca/kg by 14 regular users. These volunteers received the following doses of harmala alkaloids: Harmine, 252.3 ± 38.4 mg; THH, 158.8 ± 24.2 mg; and DMT, 35.5 ± 5.3 mg. Reprinted from Journal of Ethnopharmacology, Vol. 65, Issue 3, JC Callaway, DJ McKenna, CS Grob, GS Brito, LP Raymon, RE Poland, EN Andrade, EO Andrade, DC Mash, Pharmacokinetics of Hoasca alkaloids in healthy humans, p. 252, © 1999, with permission from Elsevier.

Abnormalities

The development of serotonin syndrome during intoxication by tryptamine compounds may occasionally cause leukocytosis, rhabdomyolysis (i.e., in association with muscle rigidity), or hepatorenal dysfunction (i.e., in association with hyperthermia). The effect of ayahuasca on an electroencephalogram (EEG) primarily involves a decrease in the absolute power in the classical frequency bands, particularly in the delta and theta bands. Power analysis of EEGs from 18 volunteers receiving 0.85 mg DMT/kg body weight demonstrated reductions in the power densities of the alpha-2, beta-1, delta, and theta frequency bands over the temporal-parietal-occipital junction as well as decreases in theta power over the medial temporal and medial frontal regions of the cortex.[62] These areas comprise the regions of the brain associated with emotion, memory processes,

TABLE 53.3. Toxicologic Analysis of Postmortem Samples from a 25-Year-Old Man.[58]

Compound	Heart Blood	Peripheral Blood	Urine
5-Methoxy-*N,N*-dimethyltryptamine	1,880 ng/mL	1,200 ng/mL	9,590 ng/mL
Dimethyltryptamine	20 ng/mL	10 ng/mL	890 ng/mL
Harmaline	70 ng/mL	40 ng/mL	2,260 ng/mL
Harmine	170 ng/mL	90 ng/mL	1,150 ng/mL
Tetrahydroharmine	380 ng/mL	240 ng/mL	6,020 ng/mL

and integration of sensory information. The EEG findings more closely resemble the stimulant effects associated with LSD use rather than general stimulants (e.g., amphetamine, methylphenidate).

TREATMENT

Life-threatening medical reactions following exposure to tryptamine compounds are extremely rare. All patients should be evaluated for associated diseases with vital signs, physical examination, and a complete history that includes current symptoms, prior medical problems, and previous psychiatric history. Vital signs should include an accurate core temperature that is repeated if the patient deteriorates. The sympathomimetic effects of tryptamines are usually mild and transient, except in patients with underlying cardiovascular disease. Laboratory investigations in patients with severe intoxication or signs of organic disease include complete blood count, electrolytes, hepatic aminotransferases, serum creatinine and creatine kinase, urinalysis, and urine for drugs of abuse screening as well as computed tomography (CT) of the brain if neurologic disease is suspected. The usual methods of decontamination are almost always unnecessary because of the rapid absorption of tryptamine compounds; the use of decontamination measures complicates the treatment of agitated patients. In addition to the use of benzodiazepines, reduction of sensory stimulation, and reassurance that the frightening images are not real are important aspects of the management of tryptamine-related panic attacks. The patient should be placed in a safe, quiet environment, preferably with a familiar person who can provide constant reassurance (i.e., "talkdown"). This person should reorient the patient by interpreting the anxious feelings while attempting to restore a sense of control and well-being to the patient overwhelmed with frightening visions and emotions. Continuous interpretations of sensory misperceptions and pseudo-hallucination are necessary to reduce the anxiety associated with a "bad trip."

5-METHOXY-*N,N*-DIMETHYL-TRYPTAMINE (5-MeO-DMT)

IDENTIFYING CHARACTERISTICS

5-MeO-DMT (*O*-methylbufotenine, CAS RN: 1019-45-0) is the prototypical hallucinogenic, 5-substituted tryptamine. Although 5-MeO-DMT is a natural part of ayahuasca and is approximately 10 times more potent than DMT in rodent behavioral studies,[63] 5-MeO-DMT is a minor constituent of ayahuasca and probably contributes little to the hallucinogenic effects.

EXPOSURE

5-Methoxy-*N,N*-dimethyltryptamine (5-MeO-DMT, *O*-methylbufotenine, CAS RN: 1019-45-0) is a natural constituent of the seeds from *Anadenanthera peregrina* (L.) Speg. (yopo, cohoba tree), which is a native tree of the Caribbean and South America. The seeds from this tree are ingredients in the psychedelic yopo snuff; however, 5-MeO-DMT is a minor constituent in this snuff compared with bufotenin.[64] 5-MeO-DMT is also a minor constituent of the bark from the South American rainforest vine, *Diplopterys cabrerana* (Cuatrec.) B.Gates (chaliponga). Shamanic snuffs (e.g., epéna, nyakwana) derived from South American plants (e.g., *Virola* species) contain 5-MeO-DMT as the primary psychoactive ingredient and *N,N*-dimethyltryptamine (DMT) as the secondary ingredient.[65] As the *O*-methyl analogue of bufotenine, 5-MeO-DMT occurs in animals (e.g., Colorado River toad, *Bufo alvarius* Girard in Baird) that contain bufotenin. In most European countries and the United States, 5-MeO-DMT is a controlled sub-

stance (e.g., schedule I in the United States); however, this substance is available over the Internet.

DOSE EFFECT

Self-experimentation studies suggest that the intranasal administration of 10 mg 5-methoxy-N,N-dimethyltryptamine (0.14 mg/kg body weight) is a threshold dose for the production of psychedelic imagery.[64] Sublingual administration produced effects similar to nasal insufflation. The addition of β-carbolines (e.g., harmaline, harmine) potentiated the psychedelic effects of 5-methoxy-N,N-dimethyltryptamine. Anecdotal studies suggest that the hallucinogenic dose of 5-MeO-DMT is similar to psilocin and substantially lower than DMT.[66] In rodent studies, the intraperitoneal LD_{50} of 5-MeO-DMT is about 6-fold lower than serotonin and about 3-fold lower than bufotenine.[67]

TOXICOKINETICS

There are few data on the toxicokinetics of 5-MeO-DMT in humans. Animal studies indicate that 5-MeO-DMT is rapidly absorbed following ingestion and extensively metabolized and conjugated with glucuronide or sulfate prior to renal excretion.[68] Deamination mediated by MAO-A is the major biotransformation pathway, similar to tryptamine and DMT. Other potential pathways include N-oxygenation, N-demethylation, and O-demethylation. The latter pathway catalyzed by CYP2D6 produces the active metabolite, bufotenine in *in vitro* studies with human liver microsomes.[69] Studies in mice indicate that the CYP2D6-mediated elimination of 5-MeO-DMT is nonlinear (Michaelis-Menten kinetics) at high doses, suggesting that the risk of intoxication does not increase proportionally to the dose.[70] Inhibition of deamination by monoamine oxidase A inhibitors diverts 5-MeO-DMT biotransformation to other metabolic pathways including O-demethylation, resulting in increased production of bufotenine.

HISTOPATOLOGY AND PATHOPHYSIOLOGY

In radiolabeling studies of human 5-HT$_{2A}$ receptors, the binding affinities (K_i) of 5-MeO-DMT and DMT for the 5-HT$_{2A}$ receptor are 25 nM and 230 nM, respectively; thus, the affinity for the 5-HT$_{2A}$ receptor is substantially higher for 5-MeO-DMT than DMT. In general, the affinity of tryptamines for this receptor is lower than phenethylamine compounds (e.g., DOB, LSD).[71] There are at least 7 distinct classes of 5-HT

receptors with some (e.g., 5-HT$_2$) classes including multiple subtypes; most indoleamine and phenethylamine hallucinogens predominately stimulate 5-HT$_{2A}$ receptors. Animal studies suggest that 5-MeO-DMT differs from DOM because the psychedelic effects of the former compound rely on activation of both the 5-HT$_{1A}$ and 5-HT$_2$ receptors, whereas the psychedelic effects of DOM depends primarily on agonist action on the 5-HT$_2$ receptors.[72,73]

CLINICAL RESPONSE

Self-experimentation studies suggest that 5-methoxy-N,N-dimethyltryptamine (5-MeO-DMT) produces similar or more potent psychedelic effects as DMT or bufotenine despite differences in 5-HT$_{2A}$ binding.[64] Following intranasal administration of 5-methoxy-DMT to volunteers, psychedelic effects begin within about 5 minutes, peak within about one-half hour and resolve within ~1 hour. The ingestion of an extract of Syrian rue containing harmaline and the smoking and snorting of about 25–30 mg 5-methoxy-N,N-dimethyltryptamine was associated with the development of disorientation, agitation, hyperthermia, and tachycardia.[74] The patient was extremely combative, and he later developed rhabdomyolysis that responded to fluid administration without the occurrence of renal dysfunction. The differential diagnosis included serotonin syndrome (5-methoxy-DMT) and monoamine oxidase inhibitor toxicity (harmaline).

DIAGNOSTIC TESTING

Thin layer chromatography, gas chromatography, and high performance liquid chromatography are relatively insensitive methods for detecting 5-MeO-DMT, DMT, or bufotenine concentrations compared with gas chromatography/mass spectrometry. DMT may be quantitated using gas chromatography with nitrogen phosphorus detection following liquid-liquid extraction.[23] The LOD and LLOQ for this method are 0.5 ng/mL and 5 ng/mL, respectively. The use of high performance liquid chromatography with fluorescence detection following protein precipitation allows the quantitation of harmala alkaloids with a LLOQ of ~2 ng/mL.[23] Analysis of urine samples by high performance liquid chromatography/electrospray ionization/tandem mass spectrometry allows the detection of 5-MeO-DMT and DMT with LOD of 0.1 ng/mL and a coefficient of variation of 9–11% and 4–5%, respectively.[75] Case reports associate mild hypokalemia, hyperglycemia, and mild hepatorenal dysfunction with 5-MeO-DIPT intoxication.[30]

TREATMENT

Treatment of 5-MeO-DMT intoxication is supportive, similar to 5-methoxy-diisopropyltryptamine (foxy) or *N,N*-dimethyltryptamine (DMT) intoxication.

Chapter 54

BETEL QUID and ARECA NUT

HISTORY

Mastication of the areca nut is an ancient custom dating back at least to Herodotus in 340 BC and the Maharmasa, a Ceylonese document from 504 BC.[1,2] References to the areca nut appeared in the Sanskrit medical literature during the early part of the First Millennium, and later in Hindu and Buddhist writings. The expansion of Buddhist practices brought the areca nut to Tibet and southern China as a stimulant, aphrodisiac, antihelminthic, and digestive agent. The areca nut was a valuable masticatory in the Wei-Chien dynasty in 421 AD,[3] and Arab physicians use it frequently in the 10th century AD. Marco Polo mentioned the use of this nut during his travels in 1298. The Dutch introduced the areca nut into Taiwan during the 18th century from Malaysia. During the 19th century in England, the areca nut was briefly a constituent of toothpaste.[4]

BOTANICAL DESCRIPTION

The areca nut is the ripe seed of the betel palm (*Areca catechu*). Betel nut is not the correct biologically name for the areca nut despite common usage of the term, betel nut. The betel pepper (*Piper betel* L.) is a climbing shrub that is native to the West Indies.

Common Name: Betel palm

Scientific Name: *Areca catechu* L.

Botanical Family: Arecaceae (Palm)

Physical Description: The betel palm grows to 100 feet (~30 m) in height with a slender trunk only 6 inches (~15 cm) in diameter. The ripe areca nut is yellow to scarlet on the surface. Throughout the year, this tropical palm bears ovoid to oblong fruit with a pointed apex 1–2 inches (~3–5 cm) in length.

Distribution and Ecology: Although the betel palm is a native of Malaysia, the betel palm is widely cultivated in Southeast Asia, East Africa, India, Taiwan, and New Guinea.

IDENTIFYING CHARACTERISTICS

Structure

The areca nut contains a variety of alkaloids including arecoline, arecaidine, guvacine, and guvacoline (norarecoline).[5] Figure 54.1 displays the chemical structures of these alkaloids.

Physiochemical Properties

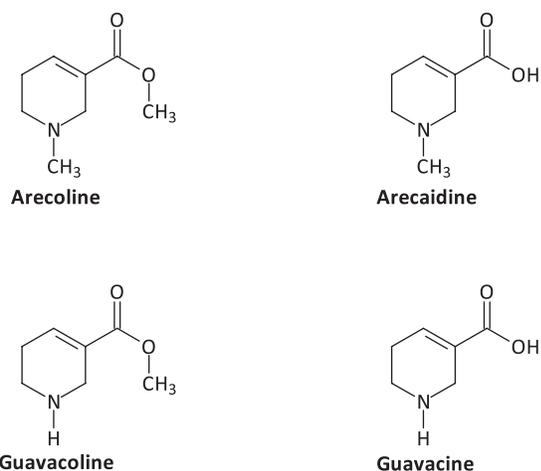
The areca nut has a slightly bitter and stringent taste. The primary alkaloid, arecoline, is a muscarinic (M_1, M_2, M_3) receptor agonist and a weak ganglionic nicotinic agonist, whereas arecaidine is only a M_2 muscarinic receptor agonist.[6] Arecoline is structurally related to methacholine, which produces dose-related bronchoconstriction in asthmatic patients.[7] The bronchoconstrictive properties of arecoline are approximately 10% of the bronchoconstrictive effects of methacholine. Human studies on saliva during the mastication of betel quid (chewable mass of material, See Methods of Abuse for description) indicate that *in situ* nitrosation of compounds from the areca nut produce a variety of


FIGURE 54.1. Chemical structures of common areca nut alkaloids.

nitrosamines including *N*-nitrosoguvacoline (CAS RN: 55557-02-3) and 3-(methylnitrosamino)propionitrile (CAS RN: 60153-49-3). When the betel quid contains tobacco, the chewing of the quid releases volatile nitrosamines into the mouth including *N*-nitrosodiethylamine (CAS RN: 55-18-5) and *N*-nitrosodimethylamine (CAS RN: 62-75-9) along with 1-nitrosoanabasine (CAS RN: 1133-64-8), *N*-nitrosonornicotine (CAS RN: 16543-55-8), and 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (CAS RN: 64091-50-5).[8] Autooxidation of polyphenol compounds in areca nut and catechu during chewing produces reactive oxygen species.

EXPOSURE

Epidemiology

Several hundred million people worldwide use the areca nut as a psychoactive substance, particularly in Southeast Asia and India. The practice of chewing areca nuts is a traditional psychoactive activity of native populations in the Indian subcontinent, south Asia, and Melanesia (Vanuatu, Solomon Islands, Papua New Guinea, Fiji). Migration of these populations resulted in the introduction of betel quid use into Africa, Australia, China, the United Kingdom, and the United States.[9] The use of the areca nut is one of the most commonly used psychoactive substances in the world along with alcohol, nicotine, and caffeine.[10] Betel products with and without tobacco are relatively inexpensive and available in some specialty shops (e.g., East Asian grocery stores) in parts of the United States.[11] The areca nut is a prohibited food product in the United States, but the use of betel quid is not banned. Medicinal uses of the areca nut include the treatment of tapeworms and roundworms in domestic animals as well as the herbal treatment of fever, venereal disease, headaches, stomach pain, and rheumatism in humans.

TABLE 54.1. Approximate Alkaloid Content of Fresh Australian Areca Nuts.[12]

Alkaloid	Content*
Arecoline	0.30–0.63
Arecaidine	0.31–0.66
Guvacoline	0.03–0.06
Guvacine	0.19–0.72

*Estimated % weight/weight (dry).

Sources

Table 54.1 lists the approximate alkaloid content of fresh areca nuts from Australia. The arecoline concentrations in areca nuts from India and New Guinea following steam distillation were slightly higher than the Australian nuts as measured by high performance liquid chromatography.[12] Minor alkaloids include nicotine, methyl nicotinate, ethyl nicotinate, methyl-*N*-methyl piperidine-3-carboxylate, ethyl-*N*-methyl piperidine-3-caroxylate, and ethyl-*N*-methyl-1,2,5,6-tetrahydropyridine-3-carboxyate. The arecoline content of commercial areca nuts varies from 0–1.4%.[13] Areca nut processing reduces the arecoline content, particularly following boiling in water.[14]

The betel leaf and inflorescence (flower, pod) is a frequent constituent of Taiwanese betel quid. Fresh inflorescence from *Piper betle* contains approximately 15 mg safrole/g (wet weight) along with safrole metabolites including dihydroxychavicol (about 9 mg/g) and eugenol (about 2.5 mg/g).[15] Eugenol methyl ester, isoeugenol, and quercetin are minor constituents of these inflorescence. Betel oil is a volatile extract of the betel leaf, which contains psychoactive phenols (chavicol, chavibetol or betel-phenol) eugenol, hydroxychavicol, and the stimulant, cadinene.[16]

Methods of Use

The nut is consumed either fresh or dried by sunshine, baking, or roasting. Although areca nut can be chewed alone, most use of the areca nut involves the addition of other ingredients into a chewable mass called a quid (pan, paan).[16] The betel quid typically consists of areca nut, leaves of psychoactive plants (e.g. betel pepper), and slaked lime (calcium hydroxide) paste. The quid typically is placed in the lateral gingiva for 15–20 minutes with effects occurring within 2 minutes and an average duration of 15–20 minutes.[17] The quid may be held in

the buccal vestibule over a long duration with occasional chewing; alternatively, the quid may be swallowed or expectorated. The source of the betel pepper leaves is an unrelated climbing shrub (*Piper betel*); burnt seashells, reef coral, and/or limestone are the source of the slaked lime paste. Other sources of psychoactive leaves include kratom [*Mitragyna speciosa* (Korth.) Havil.) in Southeast Asia, nutmeg (*Myristica fragrans* Houtt.) in India, and kava (*Piper methysticum* G. Forst.) in Melanesia. The slaked lime increases the pH of the oral cavity, resulting in an increased absorption of nicotine through the oral mucosa. Catechu is a reddish gum produced from the sap of the Malaysian acacia tree [*Acacia nilotica* (L.)Delile] that can be added to the quid.

The method of areca nut use depends on the region. Betel quid is a popular form of areca nut use in India, Pakistan, Bangladesh, and Sri Lanka where fresh, dried, or cured areca nut, slaked lime, catechu, and flavoring ingredients are wrapped in betel leaves. These flavoring ingredients include cloves, coconut, sugar crystals, camphor, amber, nutmeg, mace, saffron, anise, turmeric, mustard, and cardamon. Tobacco is often added to the mass, which is placed in the mouth and masticated during the day. Migrant communities from these areas retain their use of betel quid in their new countries.[18] Similar use of the betel quid occurs in southeastern Asia (e.g., Cambodia, Thailand, Myanmar, The Lao People's Republic, Philippines). In Taiwan and China, the unripe betel quid contains green areca nut, slaked lime, betel inflorescence; occasionally, betel leaves are used in the quid without tobacco. Some aboriginal groups in Asia use betel stems in the quid.[19] In Papua New Guinea, the betel quid often contains wild ginger. Betel leaf is perishable, but nonperishable forms (e.g., supari, mawa, gutka, pan masala) of betel quid are available commercially.[10] *Pan masala* is a preparation of areca nut, catechu, cardamon, lime, flavoring agents, and perfuming material. Gutkha is a variation of *pan masala* that contains tobacco.

DOSE EFFECT

Adverse effects associated with the infusion of 5 mg intravenous arecoline to Alzheimer patients included diaphoresis, flushing, nausea, and Mobitz type II second-degree atrioventricular block with a ventricular rate of 40 bpm.[20] A constant infusion of 1.5 mg/hour was not associated with adverse effects. In dog studies, the oral administration of 1 mg arecoline hydrobromide/kg produced some slowing of the heart rate and respirations, but no obvious changes in behavior, whereas there was no observable effect from the oral administration of 0.1 mg arecoline hydrobromide/kg.[21]

TOXICOKINETICS

Peak plasma concentrations of arecoline occur about 5–10 hours after dermal application of the areca nut, whereas the oral mucosal absorption of arecoline is rapid. The areca nut and tobacco contain secondary and tertiary amines that undergo nitrosation in the saliva during betel quid-chewing following reactions with available nitrites and catalysts (e.g., thiocyanate). These nitrosamines include *N*-nitrosoguvacoline and 3-(methylnitrosamino)propionitrile. The amount of nitrosation depends on several factors, including individual variation and salivary pH.[22] Volatile nitrosamines include *N*-nitrosodiethylamine and *N*-nitrosodimethylamine. Endogenous formation of nitrosamines also results from the ingestion of precursors of nitrosamines (e.g., nitrite, nitrosatable amines), particularly in the acid environment of the stomach. Formation of reactive oxygen species also develops in the oral cavity during betel-quid chewing. Hydrolysis of arecoline and guvacoline to arecaidine and guvacine, respectively, occurs in the mouth during betel-quid chewing, particularly when lime is present in the quid.[23] These latter 2 compounds are potent inhibitors of GABA uptake. Arecoline readily crosses the blood–brain barrier with brain/plasma concentration close to unity.[24] The rapid hydrolysis of arecoline by plasma esterases results in the short plasma half-life of arecoline. In a study of 15 Alzheimer patients receiving 5 mg intravenous arecoline, the mean terminal plasma half-life of arecoline was 9.3 ± 4.5 minutes with plasma arecoline concentrations returning to baseline within ~1 hour.[20] The mean volume of distribution was 2.55 ± 2.05 L/kg (range, 0.63–6.1 L/kg) with a clearance of 13.6 ± 5.8 L/min. The major urinary metabolites of areca nut and arecoline are arecaidine (urinary elimination half-life, ~4 h) and to a lesser extent, *N*-methylnipecotic acid (urinary elimination half-life, ~8 h) as measured by isotope-dilution liquid chromatography/tandem mass spectrometry.[25] The kidney excretes little arecoline unchanged.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

The chewing of areca nut is associated with sympathetic activation including increased heart rate and elevated plasma epinephrine and norepinephrine concentrations.[26] Volunteer studies suggest that areca nut chewing causes transient tachycardia and elevation of blood pressure in novice users, but habituation to the pressor effects occurs with chronic use.[17] Experimental studies indicate that areca nut-chewing modulated metabolic signals regarding appetite consistent with the use of betel quid for reducing hunger and increasing stamina,

but the dose response is nonlinear.[27] The effects of betel chewing are complex and potentially involve parasympathetic, GABAergic, and sympathetic activity in the central nervous system.[23] In the presence of lime, hydrolysis of arecoline and guvacoline to arecaidine and guvacine, respectively, occurs. These hydrolyzed substances are strong inhibitors of GABA uptake. Rodent studies indicate that arecoline is strong M_1- and M_2-muscarinic receptor agonist.[28]

CLINICAL RESPONSE

Betel Quid/Areca Nut Use

Desirable effects associated with the use of the areca nut and betel quid include a sense of well-being, euphoria, increased alertness, warmth, sweating, salivation, reduced hunger, and increased stamina. Table 54.2 lists the initial and subsequent effects associated with betel quid chewing by 170 habitual users during an observational study of recreational betel quid use. Effects reported in experimental studies include tachycardia, flushing, diaphoresis, and heightened alertness.[23] Despite the widespread use of areca nut and betel quid, reports of acute toxicity associated with betel quid use are rare. In a retrospective study of 42,000 calls to the Taiwan Poison Control Center over ~10 years, there were 12

TABLE 54.2. Effects Associated with Betel-Quid Chewing based on Personal Observations of 170 Habitual Users.[23]

Time	Clinical Effects	%
Initial Effects		
	Dizziness	67
	Hot sensation	65
	Palpitation	44
	Sweating	28
	Heightened alertness	16
	Epigastric discomfort	9
Subsequent Effects		
	Heightened alertness	64
	Hot sensation	62
	Palpitation	47
	Combat of cold (increased cold tolerance)	43
	Sweating	41
	Diminished thirst	38
	Diarrhea	34
	Happy feeling	19

	Epigastric discomfort	15
	Prevention of hunger	11
	Increased respiration	10

adults with probable areca nut-related toxicity from intentional use.[29] Of the 7 cases involving only areca nut use, the most common effects were nausea, vomiting, abdominal colic, salivation, sweating, tremor, dizziness, palpitations, hypertension, tachycardia, and tachypnea. Most effects following the use of the areca nut or betel quid are transient and mild with effects beginning within a few minutes to 1 hour after mastication starts. Complete recovery generally occurs within 24 hours. Neophyte users may develop dizziness, vertigo, nausea, diaphoresis, and feeling of throat constriction.[1] Heavy areca nut users can develop cholinergic toxicity manifest by salivation, diaphoresis, lacrimation, diarrhea, urinary incontinence, miosis, gastrointestinal irritation, and tremor.[30,31] Case reports indicate that areca nut chewing in asthmatic patients can cause acute bronchospasm as a result of the muscarinic effects of arecoline.[32] Additionally, heavy use of areca nut has been associated with auditory hallucinations, delusions, transient psychosis, and dystonic reactions in schizophrenic patients on phenothiazine antipsychotic drugs.[33] Rare case reports temporally associate the use of betel quid with the development of acute myocardial infarction,[34] but the contribution of the betel quid use to myocardial ischemia is unclear. In a Taiwanese population-based cohort study of 4,049 participants aged 60 years or older and 2,462 participants aged 50–66 years, there was a weak association between mortality, particularly cerebrovascular death and ever-chewing betel quid.[35] The hazard ratio for the increased risk of cerebrovascular death in ever-chewers was 1.66 (95% CI: 1.19–2.30).

Nonmalignant pathologic lesions of the mouth associated with chronic betel quid use include severe erosion of the teeth, tooth discoloration, gingivitis, dark brown staining of the teeth, and deep brownish red discoloration of the oral mucosa (betel chewer's mucosa).[36] Case reports associate the habitual ingestion of betel quid with the milk-alkali syndrome (metabolic alkalosis, hypercalcemia, nephrocalcinosis, renal insufficiency) resulting from the ingestion of large amounts of slaked lime paste.[37] A retrospective hospital-based cross-sectional study of Taiwanese adults suggested an association between chronic kidney disease and betel quid use.[38] The odds ratio for the betel quid users (9.4% of study group) after adjustment for age, sex, hypertension, and diabetes was 1.812 (95% CI: 1.072–3.061, $P = .026$). However, the mechanism for this possible association remains unclear.

Abstinence Syndrome

Chronic areca nut chewing is associated with habituation, addiction, and withdrawal. These withdrawal symptoms are usually mild, similar to caffeine or nicotine

withdrawal, and include general discomfort, malaise, irritability, sore gums, and poor concentration.[39] Case reports associate chronic betel quid chewing during pregnancy with neonatal withdrawal symptoms (irritability, hypertonia) that persisted up to 5 days after birth.[30,40]

Reproductive Abnormalities

Some studies suggest that the chronic use of betel chewing during pregnancy causes adverse pregnancy outcomes. An observational study of 6 newborns from betel chewing mothers reported 1 neonate with withdrawal syndrome and 1 neonate with low birth weight, hyporeflexia, and hypotonia.[41] In a study of 62 aboriginal women in southern Taiwan with adverse pregnancy outcomes and 124 age-matched women, the prevalence of adverse pregnancy outcomes was greater in the study group.[42] After adjusting for maternal illness and number of previous pregnancies covariates, the prevalence of adverse pregnancy outcome among betel quid-chewing women was 2.8-fold higher (OR = 2.8, 95% CI:1.2–6.8) than nonbetel quid chewers.

A study of 453 pregnant women did not demonstrate a difference in birth weight or congenital abnormalities based on areca nut use.[43] A study compared the pregnancy outcomes of 400 betel chewing Papua New Guinean women with 400 nonbetel chewing controls matched for parity and province of birth.[44] There was a significant difference ($P = .05$) in the mean birth weight between the study group (2,998.5 ± 492.5 g) and the controls (3,079.5 ± 464.1 g). However, there was no statistically significant difference in Apgar scores, congenital abnormalities, or irritability (as a measure of withdrawal syndromes).

Carcinogenesis

The International Agency for Research on Cancer (IARC) lists betel quid (with or without tobacco) and areca nut as human carcinogens (Group 1) based on studies associating betel quid without tobacco with oral cancers.[45] Several case-control and cohort studies associate betel quid-containing tobacco with cancers of the oral cavity, pharynx, and esophagus as well as premalignant oral lesions. The increased risk of these cancers remains after adjustment for smoking and alcohol use. In a community-based nested case-control study of 1,029 volunteers over the age of 30 years in Sri Lanka, the adjusted odds ratio for oral potentially malignant disorders (oral erythroplakia, leukoplakia, submucous fibrosis, lichen planus) in volunteers using betel quid daily was 10.6 with a large 95% confidence interval (95% CI: 3.6–31.0).[46] The risk of these premalignant

lesions in daily betel quid chewers was dose-dependent, and the attributable risk was 90.6%. The chewing of betel quid is strongly associated with the development of oral submucous fibrosis[47] and oral leukoplakia,[48] which are precancerous lesions of the buccal mucosa. The former is a chronic disorder characterized by fibrosis of the mucosal lining of the upper gastrointestinal tract including the mouth, pharynx, and upper one-third of the esophagus. Oral leukoplakia is primarily a homogeneous (i.e., predominately white) patch or plaque on the oral mucosa most often associated with tobacco use. The appearance of the discoloration can also be speckled (red/white) or nodular. A follow-up study of a hospital-based population of 166 patients with oral leukoplakia demonstrated an annual malignant transformation rate of 2.9% over 29 months.[49] Nodular leukoplakia has the highest malignant transformation rate of the 3 types of leukoplakia.[50] In a cohort of 66 patients with oral submucous fibrosis followed an average of 8 years, the malignant transformation rate for oral cancer was approximately 4.5% during this period.[51]

DIAGNOSTIC TESTING

Analytic Methods

Methods for the detection of arecoline in biologic samples (saliva, urine) include capillary gas chromatography with nitrogen phosphorous detection,[52] gas chromatography/mass spectrometry,[53] high performance liquid chromatography/electrospray/quadrupole mass spectrometry,[54] ion-pairing high performance liquid chromatography,[55] and liquid chromatography/tandem mass spectrometry.[56] The lower limit of quantitation (LLOQ) for the latter method is 0.5 ng/mL for both arecoline and arecaidine. The LLOQ for arecoline using high performance liquid chromatography with UV detection is about 12 ng/mL compared with 5–8 ng/mL for other alkaloids (arecaidine, guvacine, guvacoline).[12]

Biomarkers

Serum or plasma arecoline or its metabolite, arecaidine are biomarkers of recent betel quid use. The placement of powdered areca nut in the oral cavity produces a rapid rise in the plasma concentration of arecoline. In a study of 15 fasted, healthy young adults receiving 10 mg arecoline via bioadhesive gels designed to mimic conventional use by allowing arecoline to bypass the portal circulation after sublingual absorption, the mean plasma arecoline concentration approximately 2½ hour after application of the gel to the buccal mucosa was approximately 0.8 ng/mL.[27] After consumption of the gel, the

mean plasma arecoline concentration increased to about 1.4 ng/mL 6 hours after the initial application of arecoline to the buccal mucosa.

Abnormalities

Neuropsychologic testing of chronic areca nut users indicates that the use of traditional amounts of areca nut does not significantly affect visual choice reaction time, digit span, or eye-hand coordination.[57]

TREATMENT

Treatment of acute toxicity associated with areca nut use is supportive, consisting primarily of fluid and electrolyte replacement along with antiemetics as needed. There are few clinical data to guide the use of atropine for obvious cholinergic symptoms (e.g., bradycardia, severe bronchorrhea) during areca nut intoxication. In general, supportive care provides adequate treatment for the transient symptoms associated with areca nut use unless the cholinergic symptoms are life-threatening. Standard treatment for bronchospasm associated with areca nut use includes inhaled β-adrenergic agonists (albuterol), corticosteroids, and ipratropium bromide.

Chapter 55

CAFFEINE

HISTORY

Although the medicinal use of tea in China is commonly thought to date back to the 3rd to 1st century BC,[1] the first clear reference to the medicinal use of the tea plant in China dates back to 750 AD.[2] During the Tang Dynasty (7th–9th centuries), tea became part of ceremonies of the Chinese culture. Lu Yu wrote the classic manual on tea connoisseurship, *The Classic of Tea* during the latter 8th century, incorporating both Taoism and Confucianism. The popularity of tea increased during the Ming Dynasty (1368–1644), when tea was drunk after steeping cured loose tea leaves in boiling water. The first green tea leaves from China arrived in Amsterdam on a ship of the Dutch East India Company in the early 17th century.[2] Although coffee and tea arrived in Europe at similar times, tea became the dominant methylxanthine-containing drink in many parts of Europe.

Cultivation of coffee began in Ethiopia and later Yemen. Coffee drinking probably began around 1000 AD, but the spread of coffee in the Arab world did not begin until after the discovery of the process of roasting in the 14th century.[2] Coffee was a popular beverage in the Islamic world by the end of the 15th century. The use of coffee quickly spread to Arab-controlled territory (North Africa, Spain, Turkey, the Balkans, India). Venetian merchants introduced coffee into Europe in the early 17th century, and the use of coffee in Europe was widespread by the end of the 17th century. Colonization by the Europeans resulted in the introduction of coffee plants to their colonies in Africa and the Americas.

BOTANICAL DESCRIPTION

In contrast to most other natural psychoactive drugs (e.g., nicotine, morphine, strychnine), caffeine is widely distributed in the plant kingdom. Caffeine occurs in 13 orders of the plant kingdom with the most common sources of commercial production being coffee (*Coffea arabica* L., *Coffea canephora* Pierre ex A.Froehner) and tea [*Camellia sinensis* (L.) O. Kuntze].[3] *C. arabica* accounts for about 90% of the current coffee production.

Common Name: Coffee

Scientific Name: *Coffea arabica* L.

Botanical Family: Rubiaceae (coffee)

Physical Description: The coffee tree is an evergreen, glabrous shrub or small tree that reaches up to 5 m (~16 feet) in height. The relatively large, elliptical leaves are opposite, dark green, and glossy with acuminate tips and short petioles. The white, fragrant flowers have a tubular corolla with small, cup-shaped calyx. The fruit is a drupe about 1.5 cm (0.6 inch) long that begins as a green immature fruit and ripens to a crimson black cherry when dried after 7–9 months. There are usually 2 somewhat elliptical seeds.

Distribution and Ecology: Arabic coffee originated in Ethiopia at altitudes of about 1,400–1,800 m (4,500–6,000 feet) and was subsequently cultivated on the Indonesian island of Java. Later, the cultivation of this coffee plant spread to the West Indies, Central America, and favorable climates in

South America, India, and Sri Lanka. This plant prefers temperate to tropical environments with little or no frost and abundant rain.

Common Name: Tea

Scientific Name: *Camellia sinensis* (L.) O. Kuntze

Botanical Family: Theaceae (tea)

Physical Description: This small evergreen tree reaches up to 16 m (~50 feet) in height depending on pruning practices. On the surface, a mat of feeders arise from a strong taproot. The leaves are lanceolate to obovate, usually 4–15 cm (~1.5–6 inches) in length and 7–12 cm (~3–5 inches) wide. The white to pink flowers appear in axillary or subterminal cymes with numerous stamens; brown capsules contain 1–3 seeds per lobe.

Distribution and Ecology: The tea tree is native to Southeast Asia, as well as Sri Lanka, India, and China. Tea is widely cultivated in subtropical and tropical regions up to 2,000 m (~6,500 feet) elevation near the Equator. Production of trees requires warm, humid conditions without frost, such as occurs in the southeastern United States.

IDENTIFYING CHARACTERISTICS

Structure

Caffeine (CAS RN:58-08-2) is a methylxanthine or methylated purine derivative (1,3,7-trimethylxanthine), structurally similar to theophylline (1,3-dimethylxanthine) and theobromine (3,7-dimethylxanthine).

Physiochemical Properties

Caffeine is a soft, white crystal or powder that is odorless and has a slightly bitter taste. This compound is soluble in chloroform, but only partially soluble in water or ethanol. Table 55.1 lists some physical properties of caffeine.

EXPOSURE

Epidemiology

Caffeine is the most widely used stimulant in the world—used by up to 80% of the general population.[4] In the 2004 Canadian Community Health Survey–Nutrition, coffee was the second most common beverage for most Canadians behind water, whereas tea is the most common beverage worldwide.[5] More than 20% of

TABLE 55.1. Some Physical Properties of Caffeine.

Physical Property	Value
Melting Point	238°C (~460°F)
pKa Dissociation Constant	10.4 (40°C/104°F)
log P (Octanol-Water)	−0.07
Water Solubility	2.16E+04 mg/L (25°C/77°F)

men and 15% of women aged 31 to 70 years exceeded the daily recommended maximum of 400 mg caffeine. In a survey of food intakes by a representative sample of the US population ($n = 18,081$), 87% consumed food and beverages containing caffeine.[6] The average daily caffeine intake was 193 mg (1.2 mg/kg body weight). Major sources of caffeine were coffee (71%), soft drinks (16%), and tea (12%). The age group with the highest average caffeine consumption are men and women aged 35 to 64 years. In studies from the late 1970s and early 1980s, the average daily consumption of caffeine by adults in the United States was approximately 2.4 mg/kg with consumption for the upper 95% being >7 mg/kg.[7] The consumption of caffeinated beverages varies with different populations. In a survey of Canadian and US children, 36% and 56% of these children, respectively, drank caffeinated beverages with an average daily caffeine consumption of 7 mg and 14 mg, respectively.[8] These amounts are well within the established levels of safe consumption. Caffeine is a common ergogenic aid. The average daily intake of caffeine by 270 elite Canadian athletes was 0.85 ± 13 mg/kg body weight based on self-reported 3-day food records.[9] These athletes ranged in age from 16–45 years; they competed in 38 different sports.

Sources

ORIGIN

Caffeine is the most abundant purine alkaloid belonging to a group of methylxanthines and methyl uric acids derived from purine nucleotides in the coffee plant. Plants synthesize caffeine from inosinic acid by oxidation with inosine-5-phosphate dehydrogenase to xanthylic acid and subsequent methylation with methylases and the cofactor 5-adenosyl methionine to caffeine. In some plant species, theobromine (3,7-dimethylxanthine, CAS RN:83-67-0) or methyl uric acids including theacrine (1,3,7,9-tetramethyluric acid, CAS RN: 2309-49-1) and liberine (1*H*-purine-6-dione, 7,9-dihydro-2-methoxy-1,9-dimethyl, CAS RN: 51168-26-4) are the major purine alkaloids. Table 55.2 lists the major purine alkaloids in various plant species.

Caffeine is an active ingredient of beverages (e.g., coffee, tea, cola) as well as over-the-counter cold

TABLE 55.2. Major Purine Alkaloids in Various Plant Species and Infraspecies.[3]

Plant	Common Name	Major Alkaloid
Coffea arabica L.	Arabica coffee	Caffeine

Paullinia cupana Kunth	Guarana	Caffeine
Cola spp.		Caffeine
Citrus spp.		Caffeine

preparations, stimulants, analgesics, and appetite suppressants.[10] Table 55.3 lists common commercial sources of caffeine with approximate caffeine content. Energy drinks are commercial beverages that typically contain variable amounts of caffeine and other ingredients (e.g., guarana, taurine, sugar derivatives) with the caffeine content ranging between 50–505 mg per container.[11] Caffeinated alcoholic beverages often contain larger amounts of ethanol per container. The 3 types of tea based on fermentation are the following: green tea (nonfermented), oolong tea (semifermented), and black or red tea (fermented). Production of green tea involves the drying and steaming of fresh tea leaves to inactivate polyphenol oxidase and eliminate oxidation, whereas black tea undergoes postharvest fermentation by polyphenol oxidase before drying and steaming. The fermentation of red tea (*pu-erh*) results from the introduction of microorganisms. Worldwide, black tea accounts for about three-fourths of tea consumption, and most of the remainder of tea consumption involves green tea. Oolong tea accounts for <2% of worldwide tea consumption. Principal areas of black tea consumption are North America, Europe, and North Africa, whereas green tea is consumed primarily in China, Japan, Korea, and Morocco.[12] Oolong tea is popular in Taiwan and China.

COMPOSITION

The caffeine content in plants and beverages varies widely. The synthesis of caffeine in plants involves the conversion of xanthosine → 7-methylxanthine → theobromine (3,7-dimethylxanthine) → caffeine (1,3,7-trimethylxanthine) via the catalytic conversion of these compounds by three *N*-methyltransferase enzymes. The caffeine content of seeds from various *Coffea* species varies from about 0.4–2.4% dry weight, whereas the caffeine content in caffeine-containing *Camellia* species ranges from <0.02% (*C. kissi* Wallich) to 2–3% [*C. sinensis* var. *sinensis* (L.) Kuntze].[3] Young leaves of the first shoots of tea plants contain relatively high concentrations of caffeine. The stems and roots contain minor amounts of caffeine. The caffeine concentration in coffee and tea beverages depends on the preparation methods, as well as the caffeine content of the bean or leaf. Similar concentrations of caffeine occur in coffee and tea beverages, when the tea percolates for at least 20 minutes.[13] In an Australian study of 17 health adults, the average caffeine content per drink over 24 hours was as follows: instant coffee, 60 ± 22 mg; brewed coffee, 80 ± 19 mg; and tea, 29 ± 14 mg.[14] Caffeine intake correlated poorly with the number of coffee and tea drinks during this 24-hour period. The dose of caffeine in analgesic tablets and cold preparations typically ranges from ~30–65 mg.[13]

The chemical composition of green tea is complex, including 15–20% proteins (enzymes) by dry weight, 1–4% aminoacids (arginine, aspartic acid, 5-*N*-ethylglutamine, glutamic acid, glycine, leucine, lysine, serine, threonine, tryptophan, tyrosine, serine), 5–7% carbohydrates (cellulose, fructose, glucose, pectins, sucrose), and 5% minerals/trace elements along with xanthic bases (caffeine, theophylline), pigments (chlorophyl, carotenoids), sterols (stigmasterol), vitamins (B, C,E), and volatile compounds (aldehydes, alcohols, esters hydrocarbons, lactones).[15] The composition of these compounds varies with geographic location, growing conditions, plant strain, and preparation methods.[16] The main polyphenols in tea are flavonoids with the concentration of these compounds

TABLE 55.3. Dietary Sources of Caffeine with Estimated Caffeine Content.[39]

Product	Source	Caffeine Content*
Coffee	Decaffeinated	<5 mg/5 oz cup (150 mL)
	Brewed (ground roasted)	60–180 mg/5 oz cup (150 mL)[†]

substantially higher in green tea than black tea. The major flavonoids in green tea are catechins (flavan-3-ols) with (–)-epigallocatechin-3-gallate being the most common catechin.[17] Less common catechins in green tea include (–)-epigallocatechin, (–)-epicatechin-3-gallate, and (–)-epicatechin. Black tea contains oxidized phenolic compounds, particularly therarubigins and theaflavins, as well as relatively high concentrations of fluoride.[18] Table 55.4 compares the concentrations of phenolic compounds and caffeine in several different beverages as measured by high performance liquid chromatography with photodiode array detection.[19]

Methods of Use

Caffeine acts as a mild positive reinforcer that is not usually considered a drug of abuse. Typically, ingestion of caffeine involves the use of products similar to those listed in Table 55.3. Medically significant misuse of caffeine usually results from the overuse of caffeine-containing weight loss or energy products in pill or powder form. Caffeine is a treatment for apnea of prematurity in neonatal intensive care units.[20] The efficacy of caffeine ingestion for short-term high-intensity exercise is equivocal. Some studies demonstrate decreased performance with caffeine ingestion following repeat cycles, whereas other studies show significant improve-

ments in team sports exercise and power-based sports with caffeine ingestion, particularly in elite athletes without regular caffeine use.[21] Traditional uses of green tea in Chinese medicine include the treatment of headache, body aches, indigestion, depression, and low energy. In Chinese medicine, the use of green tea is believed to prolong life. Other uses of green tea in supplements include the treatment of hair loss and obesity. There is little evidence that the use of green tea prevents cancer.[15]

DOSE EFFECT

The response to caffeine depends on the dose, the time after consumption, and the concomitant ingestion of other substances. In general, moderate doses of caffeine (i.e., 250–300 mg/d) do not produce clinically significant alterations in cardiovascular parameters, even in most patients with coronary artery disease.[22] In some studies of healthy, adult caffeine users, ingestion of 200 mg caffeine in an energy drink was associated with an increase in the mean heart rate of 5–7 beats/min and the mean systolic blood pressure of 10 mm Hg over baseline 4 hours after ingestion.[23] The drink also contained 2,000 mg taurine, and there was no sham control without caffeine. The difference between baseline and postcaffeine heart rate was not statistically significant during

the first 3 hours of the study. Naïve caffeine users may become symptomatic (e.g., tremulous) after the ingestion of 1–2 cups of coffee (<100–200 mg caffeine). Tolerance to the effects of caffeine begins within 1–4 days based on volunteer studies.[24] Heavy caffeine consumption involves the ingestion of >500–600 mg/day (7–8 mg/kg). Consequently, heavy coffee drinkers consume >500 mg/day. Symptoms (i.e., "caffeinism") associated with these high doses include anxiety, headaches, irritability, insomnia, anorexia, lightheadedness, and tremulousness. The number of coffee or tea drinks is not a reliable measure of caffeine consumption because of the wide variation in the caffeine content of these beverages.

In a retrospective analysis of the 38 cases presenting to the Royal Infirmary of Edinburgh after the deliberate ingestion of caffeine-containing products, the median ingested amount of caffeine was 1,040 mg (25–75% interquartile range, 600–1,500 mg).[25] The most common symptoms were nausea, vomiting, and abdominal pain; no patient displayed severe caffeine toxicity. The ingestion of 80–100 mg/kg by children produces serious toxicity, whereas caffeine doses in the range of 150–200 mg/kg are potentially fatal. A one-year-old girl survived the ingestion of 200–300 mg caffeine/kg after developing seizures, coma, and ventricular fibrillation.[26] The ingestion of a caffeine dose in the range of 10 g is potentially fatal in an adult, although recovery occurred after the ingestion of 24 g caffeine following intensive supportive care.[27]

TOXICOKINETICS

Absorption

The absorption of caffeine from the gastrointestinal tract is rapid and complete including absorption through the rectal mucosa. There is no significant hepatic first-pass effect following the ingestion of caffeine. The presence of food in the stomach or ethanol does not significantly inhibit the absorption of caffeine. Peak plasma caffeine concentrations occur within about 1 hour. In a study of 18 healthy adults, the mean peak plasma concentration occurred about 60 minutes after ingesting 250 mg caffeine with a range up to 120 minutes.[24] The peak plasma caffeine ranged from 3.8–14.8 mg/L during the 7-day study with the plasma caffeine concentrations at the end of the study ~2–3 mg/L higher than the first day of caffeine consumption.

Distribution

Caffeine crosses all biologic membranes including the blood–brain barrier, resulting in wide distribution throughout the body. Caffeine distributes relatively evenly between plasma and erythrocytes, and easily crosses the placenta to enter the fetal circulation. Caffeine also enters breast milk, the bile, saliva, and semen.[39] In a study of 11 healthy adults administered an intravenous (IV) dose of 150 mg anhydrous caffeine, the mean volume of distribution was 0.53 ± 0.5 L/kg.[28] Animal studies indicate the absence of long-term accumulation of caffeine or caffeine metabolites in the body.[29]

Biotransformation

The biotransformation of caffeine is complex with at least 17 metabolites.[30] Metabolism of caffeine via demethylation produces dimethylxanthine compounds, primarily paraxanthine (1,7-dimethylxanthine) via N^3-demethylation catalyzed by CYP1A2.[31] This isoenzyme is an abundant cytochrome P450 isoenzyme, accounting for about 15% of the total CYP content. A small portion of the biotransformation reactions results from the catalytic action of CYP2E1, whereas CYP1A2 accounts for most all of isoenzymes responsible for caffeine demethylation.[32] CYP1A1 has similar affinity for caffeine as CYP1A2, but the former isoenzyme is much less abundant than the latter.[33] The dimethylxanthine metabolites are pharmacologically active, and may contribute to the effects of caffeine. There are substantial interindividual differences in the expression of CYP1A2; therefore, there are significant individual differences in the metabolism of caffeine. In humans, there are no significant differences in caffeine metabolism between genders despite the higher activity of CYP1A2 in men.[29] Subsequent pathways involve acetylation, 8-hydroxylation by CYP3A isoenzymes, and the catalytic oxidation of 1-methylxanthine to 1-methyluric acid by xanthine oxidase.

Minor metabolites include theobromine (3,7-dimethylxanthine) via N^1-demethylation and theophylline (1,3-dimethylxanthine) via N^7-demethylation. Figure 55.1 displays the initial demethylation reactions involved with the biotransformation of caffeine. In a study of 17 healthy adults ingesting tea or coffee, paraxanthine, theobromine, and theophylline accounted for about 67%, 24%, and 8% of the total dimethylxanthine compounds in plasma, respectively.[14] Major urinary metabolites of caffeine are 5-acetylamino-6-formylamino-3-methyluracil, 1-methyluric acid, 1-methylxanthine, 1,7-dimethyluric acid, and 1,7-dimethylxanthine.

Elimination

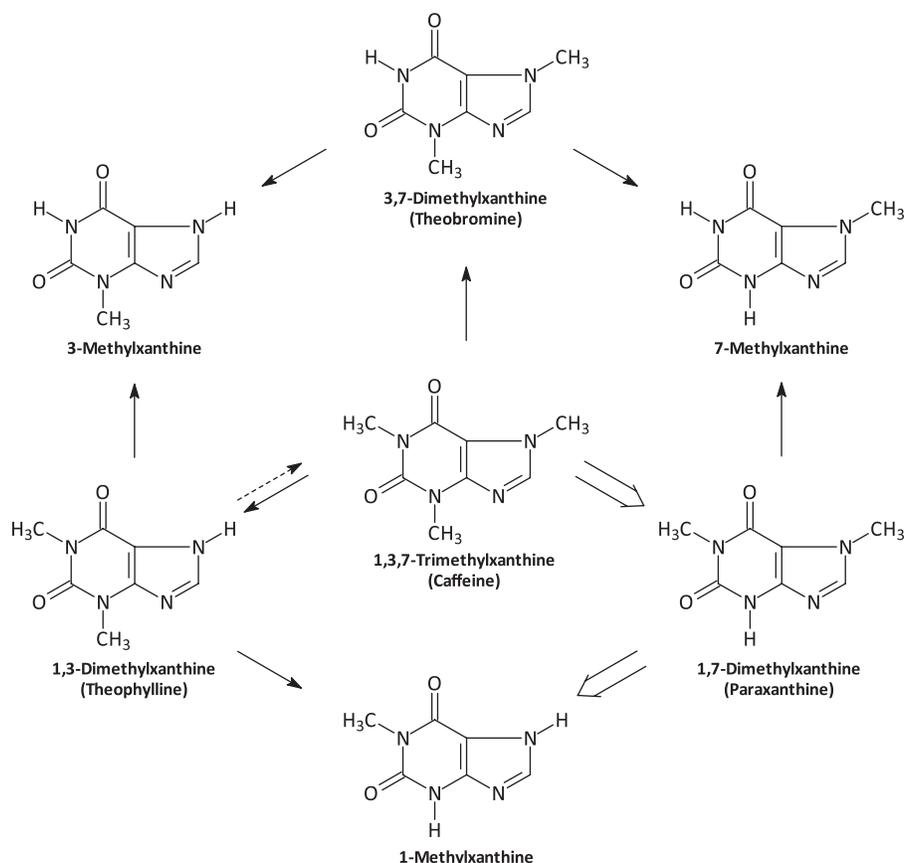
Elimination of caffeine occurs almost exclusively via biotransformation and renal excretion of metabolites


FIGURE 55.1. Initial demethylation reactions of caffeine.[7]

with little caffeine appearing in the urine unchanged. Age, renal function, and dose affect caffeine elimination. In most patients, the kidney excretes minor amounts (i.e., 1–2%) of an absorbed dose of caffeine in the urine as unchanged caffeine. The elimination process from the blood is first-order in the range of 2–10 mg/kg, whereas caffeine follows zero-order (saturation) kinetics in neonates and overdose.[29] The average serum elimination half-life of caffeine in adults ingestion typical recreational doses of caffeine is about 4–6 hours (range, 2–12 h) following typical recreational doses of caffeine. Infants up to the age of 3 months eliminate caffeine primarily by renal excretion rather than biotransformation with elimination half-life markedly prolonged at about 100 hours compared with adults.[34] By the age of 7–9 months, the renal elimination of caffeine accounts for about 2% of the elimination of caffeine, similar to adults. Liver disease and pregnancy prolong the elimination half-life of caffeine, whereas smoking and the induction of hepatic microsomal enzymes reduces the caffeine-elimination half-life. As a result of the saturation of hepatic microsomal enzymes during an overdose, the elimination half-life of caffeine during caffeine intoxication is prolonged compared with the ingestion

of <250–500 mg caffeine.[35] Based on 3 serum samples drawn within 2 days after a 6–8 g overdose of caffeine, the serum elimination half-life of caffeine was ~16 hours.[36]

Maternal and Fetal Kinetics

Methylxanthines including caffeine readily pass the placental barrier and enter fetal tissues. Caffeine elimination in nonpregnant and pregnant women in the first trimester are similar, but elimination decreases in pregnant women during the second and third trimesters with the potential for accumulation of caffeine in the mother and fetus depending on the caffeine dose.[37] The placenta and fetus lack the CYP450 isoenzymes required to metabolize caffeine; therefore, caffeine elimination by the fetus occurs by renal excretion.[38]

Drug Interactions

Various drugs induce CYP1A2 including selective serotonin reuptake inhibitors (fluvoxamine), antipsychotics (clozapine, olanzapine), psoralens, antiarrhythmics (mexiletine, diltiazem, verapamil), proton pump

inhibitors (omeprazole), quinolones (enoxacin, norfloxacin, ciprofloxacin), and theophylline.[39] Other drugs that inhibit caffeine metabolism include acute ethanol ingestion, cimetidine, disulfiram, and oral contraceptives. Smoking increases the clearance of caffeine up to 30–50%. In a study of 16 healthy adults, the ingestion of 75 mg phenylpropanolamine with 400 mg caffeine increased the mean peak plasma caffeine concentration from 2.1 ± 0.3 mg/L (caffeine alone) to 8.0 ± 2.2 mg/L (caffeine + phenylpropanolamine).[40] There are few data on the clinical relevance of these drug interactions. Existing experimental data suggest that the ingestion of caffeine will not ameliorate ethanol-induced impairment of driving skills, even in doses consistent with the use of caffeinated ethanol beverages (e.g., 69 mg caffeine/12 ounce beer with 4.8% ethanol by volume).[41]

Tolerance

Tolerance develops following chronic caffeine use to some of the central and peripheral effects (e.g., anxiety, jitteriness, blood pressure, diuresis), but not all central effects (e.g., attention, wakefulness).[42] In volunteer studies of participants without habitual caffeine use, tolerance to increases in blood pressure, heart rate, plasma epinephrine, plasma norepinephrine, plasma renin activity, and urinary catecholamines develops within 1–4 days of regular caffeine use at a daily dose of 250 mg.[24] Tolerance to the cardiovascular effects of caffeine is lost within 3 weeks after cessation of caffeine use.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

Caffeine is a central nervous system stimulant that produces diverse and complex effects including increased arousal and vigilance, reduced fatigue, and improved performance on some motor tasks.[4,43] Attention is modified by caffeine use, allowing more effective processing of relevant stimulus characteristics during information processing.[44] These effects probably result from caffeine-induced adenosine receptor antagonism.[45] Ergonomic studies in endurance athletes suggest that caffeine improves performance modestly during endurance activities (i.e., 3–4%)[46] and repeated sprint ability,[47] but not during sprint activities with predetermined goals.[48,49] Volunteer studies suggest that the ingestion of coffee does not mimic the positive effects of caffeine on endurance, perhaps as a result of moderation of the caffeine-induced elevation of plasma epinephrine concentrations by other ingredients in coffee.[50] Caffeine also stimulates the medullary respiratory center by increased sensitivity to stimulation by plasma carbon dioxide concentrations. Additionally, caffeine decreases cerebral blood flow as a result of the antagonism of adenosine-induced cerebral vasodilation. Effects on sleep include increased sleep latency and reduced sleep duration.

In commonly ingested doses, the administration of caffeine alone slightly increases blood pressure, minimally reduces heart rate, and causes the release of catecholamines (epinephrine, norepinephrine) and renin in *caffeine-naïve* individuals; however, tolerance limits the effect of these changes following continued caffeine use. In a study of normotensive, caffeine-naïve volunteers, daily administration of 400 mg caffeine produced a 3 mm Hg increase in ambulatory systolic and diastolic blood pressure associated with a 3-beat/minute decrease in heart rate.[51] Both these changes were statistically significant, and these changes resolved soon after administration ceased.

The increased glomerular filtration rate and inhibition of tubular reabsorption of sodium and water results in mild diuresis with sodium and water loss. Caffeine increases minute ventilation; the ingestion of caffeine in asthmatic patients produces much less bronchodilation than theophylline.[52] Stimulation of gastric secretion of acid and pepsin occurs following the ingestion of coffee with some studies suggesting that caffeine also reduces lower esophageal sphincter tone.[4]

Mechanism of Toxicity

The toxic effects of caffeine are an extension of pharmacologic effects. Caffeine increases the synthesis and release of catecholamines as well as increasing intracellular cyclic AMP concentrations by inhibiting phosphodiesterases. These actions result in pharmacologic effects on multiple organ systems. Caffeine is a nonselective adenosine receptor (A_1, A_{2A}) antagonist, which inhibits the action of adenosine in the brain, cardiovascular system, gastrointestinal tract, lung, kidney, and adipose tissues. Adenosine A_1 receptors occur in most areas of the brain, particularly in the hippocampus, striatum, cerebral cortex, and some areas of the thalamic nuclei (e.g., medial and anterior nucleus).[53] Intermediate amounts of these receptors occur in the nucleus accumbens and the caudate-putamen as demonstrated by autoradiography in postmortem brain tissues with N^6-[^{3}H] cyclohexyladenosine. Dopamine-rich regions of the brain contain substantial amounts of adenosine A_{2A} receptors. The interaction of adenosine A_{2A} and dopamine D_2 receptors regulate the GABAergic striatopallidal neurons, whereas the interaction of adenosine A_1 and dopamine D_1 receptors are involved in the regulation of the GABAergic striatonigral and striatoentopeduncular neurons.[54] Enhancement of postsynaptic

dopamine D_2 receptors by adenosine A_{2A} antagonism probably accounts for the central effects of caffeine.[44]

There is no clear evidence that coffee increases the risk of cardiovascular diseases. Moderate ingestion of caffeine does not increase the frequency or severity of cardiac dysrhythmias in normal individuals, patients with ischemic heart disease, or those with preexisting serious ventricular ectopy.[55] Additionally, there is no clinically significant association between coffee consumption and the occurrence of coronary heart disease.[56] Caffeine reduces insulin sensitivity in skeletal muscle and may reduce glucose output from the liver.[57,58] High doses of caffeine produce vasodilation, hypotension, and marked tachycardia. Other effects at high caffeine doses (i.e., serious overdose) include mobilization of calcium from intracellular storage sites in skeletal muscle, cardiac muscle, and neurons.

CLINICAL RESPONSE

Recreational Use

For most people, the ingestion of usual doses of caffeine in beverages produces a subjective feeling of well-being, alertness, and increased energy with minimum adverse effects. Excessive doses of caffeine produce anxiety, irritability, nervousness, palpitations, insomnia, tremulousness, and nausea. A case report of a 47-year-old man associated the development of delusions and paranoid psychosis with the chronic consumption of excessive amounts of coffee (i.e., 36 cups of coffee/d).[59] The psychotic symptoms resolved after a reduction of his coffee consumption without the administration of antipsychotic medication. Behavioral studies in children suggest that acute alteration of their usual dose of caffeine results in some adverse behavior changes (e.g., volatility, inattentiveness, restlessness), but there is little evidence that caffeine produces long-term adverse behavioral effects.[60] A meta-analysis of coffee consumption and the risk of type 2 diabetes suggested that increased coffee use was associated with a dose-related decrease in type 2 diabetes.[61] The relative risk of type 2 diabetes in chronic coffee drinkers using 4–6 cups and ≥6–7 cups daily were 0.72 (95% CI: 0.62–0.83) and 0.65 (95% CI: 0.54–0.78), respectively.

Cardiovascular

There are inadequate data to associate coffee drinking with the development of hypertension. The consumption of coffee by women does not appear to increase the risk of hypertension based on a large cohort study.[62] A longitudinal study of 1,017 male former medical students demonstrated a higher incidence of hypertension in coffee drinkers during follow-up when compared with coffee nondrinkers at baseline (18.8% vs. 28.3%, respectively; $P = .03$).[63] However, the relative risk of hypertension was not dose-related after adjustment of confounding factors. The association between the risk of myocardial infarction (MI) and coffee consumption is complex, and the risk of MI may be related to the interindividual variability in the enzyme activity of CYP1A2. For younger individuals with the rapid caffeine metabolizing genotype (CYP1A2*1A allele), the consumption of 1–3 cups of coffee daily was associated with a lower risk (odds ratio = 0.69; 95% CI: 0.50–0.86) of nonfatal MI than individuals consuming <1 cup coffee daily after controlling for other risk factors.[64] Some studies suggest that individuals with the slow CYP1A2*1F allele are more susceptible to acute, nonfatal MI following chronic coffee consumption. A population case-control study of individuals with their first nonfatal MI demonstrated an increased risk of MI only in carriers of the slow CYP1A2*1F allele.[65] The odds ratio of developing a nonfatal MI in these genotypes for the consumption of ≥4 cups of coffee daily was 1.64 (95% CI: 1.14–2.34), when compared with referents (i.e., <1 cup coffee daily). For normal phenotypes, the odds ratio of acute non-fatal MI for moderate coffee consumption (1–3 cups daily) was less than unity (i.e., ~0.5).

Although typical caffeine doses mildly increase epinephrine concentrations (i.e., 6-fold less than strenuous exercise),[66] most studies do not demonstrate proarrhythmic effects following caffeine use and moderate caffeine doses are well tolerated even in patients with cardiovascular disease.[67] In a study of 18 patients with frequent ventricular premature beats (VPCs), the ingestion of 1 mg caffeine/kg was associated with increased frequency of VPCs (307 ± 350/h) compared with a caffeine-free period (307 ± 414/h, $P < .01$).[68] However, there was no significant difference in the cardiac rhythm, rate, or ventricular repolarization (QTc interval). Studies of patients with cardiovascular disease have not demonstrated an increased incidence of VPCs or other ventricular dysrhythmias during the use of caffeine including patients with histories of recent MI,[69] nonsustained ventricular tachycardia,[70] and multiple types of malignant ventricular dysrhythmias (ventricular fibrillation, recurrent ventricular tachycardia, symptomatic nonsustained ventricular tachycardia).[71] Larger epidemiologic studies have not demonstrated an association between typical caffeine use and the incidence of atrial dysrhythmias (e.g., atrial fibrillation, atrial flutter).[72]

Central Nervous System

Epidemiologic studies of coffee consumption and the risk of stroke are inconsistent, in part as a result of the

differences in study population (healthy, hypertensive patients, diabetics), outcomes (incidence, mortality), and gender. A population-based prospective cohort study of 34,670 healthy Swedish women demonstrated a statistically significant lower risk of total stroke, sub-arachnoid hemorrhage, and cerebral infarction but not intracerebral hemorrhage in coffee drinkers than seldom coffee drinkers, after adjustment for other risk factors.[73] The multivariable relative risk of total stroke for high coffee consumption (≥5 cups/d) was 0.77 (95% CI: 0.63–0.92) compared with controls (<1 cup/d). Similarly, a prospective study of 83,076 healthy women in the Nurses' Health Study demonstrated a 20% lower risk of total stroke in women consuming ≥4 cups/day than seldom coffee drinkers (<1 cup/wk).[74] However, a cohort study of 499 hypertensive, nonsmoking men detected an approximately 2-fold higher risk of isch-emic stroke in men consuming 3 cups coffee/day com-pared with noncoffee drinkers.[75] Most cohort studies of coffee consumption using stroke mortality among healthy participants and diabetics have not detected dose-related effects of coffee consumption on mortality.[76,77]

Gastrointestinal

Several case reports associate the use of green tea in herbal products with hepatotoxicity, more commonly in women. A 41-year-old woman developed jaundice after using a hair loss supplement containing 27% *Camellia sinensis* for 6 months.[78] Although her serum hepatitic aminotransferases were elevated above 1,000 IU/L and her serum bilirubin was 13.6 mg/dL (9.8 mg/dL direct), there was no evidence of liver dysfunction. Liver biopsy was consistent with a drug reaction (periportal inflam-mation with granulocytes, eosinophils, lymphocytes, plasmocytes along with intrahepatic cholestasis); her jaundice resolved with 1 month of cessation of the use of the supplement. A review of worldwide reports of adverse events (published reviews, the US Food & Drug Administration MedWatch Program, United States Pharmacopeia's MEDMARX Adverse Event Reporting System, Australian Therapeutic Goods Administration, UK Medicines and Healthcare Products Regulatory Agency, Health Canada's Canadian Adverse Drug Reaction Monitoring Program) associated with the use of green tea supplements revealed 8 cases of probable hepatotoxicity based on the Naranjo Causality Algorithm Scale.[79] Most suspected cases of hepatotoxic-ity resolve without sequelae following cessation of sup-plement use; rarely, cases reports associate acute liver failure requiring orthotopic liver transplantation with the use of green tea supplements.[80]

Overdose

Adverse effects associated with the IV administration of high doses (36–136 mg/kg) of caffeine in neonates simulate seizures including tachypnea, fine tremor, muscle fasciculations, opisthotonus, tonic-clonic move-ments, and nonpurposeful facial movements.[81] Symptoms of serious caffeine intoxication begin within several hours of ingestion, usually with the onset of vomiting. The clinical effects of severe caffeine intoxication resemble a massive catecholamine release including vomiting, abdominal cramps, weakness, miosis, nystag-mus, weakness, hypertension, tachycardia, respiratory distress, rhabdomyolysis, and cyanosis. Neurologic effects involve myoclonus, opisthotonus, agitation, hal-lucination, hyperreflexia, tremor, anxiety, delirium, and central nervous system depression ranging from leth-argy to coma.

Case reports associate excessive caffeine consump-tion with a variety of supraventricular and ventricular dysrhythmias including paroxysmal supraventricular tachycardia in a 42-year-old man with aortic insuffi-ciency from rheumatic valvular disease drinking 30 cups of coffee daily along with 3–4 cups of tea,[82] and ventricu-lar fibrillation in a 27-year-old hypotensive woman intentionally ingesting 27 g caffeine.[83] A 27-year-old motocross racer developed dull retrosternal chest pain and a cardiac arrest after a day of racing and drinking 7–8 cans of a caffeinated energy drink.[84] Although his coronary angiogram was normal, he had electrocardio-graphic and echocardiographic evidence of transmural ischemia and an elevated serum troponin I. A case report associated the ingestion of a 20-g caffeine over-dose with the development of a subendocardial MI in a 20-year-old bulimic woman.[85] However, no echocar-diography or angiography was performed to document underlying cardiac disease.

Fatalities

There are only a few case reports in the medical litera-ture documenting death following the ingestion of caf-feine alone.[86] Death from caffeine intoxication usually occurs as a result of hypotension, respiratory failure, ventricular fibrillation, and cardiorespiratory arrest.[87,88] Case reports also associate the administration of fatal doses of caffeine with child abuse.[89]

Abstinence Syndrome

Symptoms of the mild abstinence syndrome associated with chronic caffeine use include headaches, fatigue,

decreased energy, and reduced alertness. Headache is the most common withdrawal symptom with an incidence of up to 50% in some volunteer studies.[90] Other symptoms of abstinence include anxiety, depressed mood, reduced concentrating ability, irritability, nausea, vomiting, and craving for caffeine. Tremor, muscle stiffness, confusion, and rhinorrhea occur rarely during caffeine withdrawal. The withdrawal symptoms typically begin within 12–24 hours after the last caffeine dose and maximum effects occur within 20–48 hours of the last dose.[90,91] Symptoms can persist up to 1 week. A study of twins suggested genetic factors in the etiology of caffeine tolerance and withdrawal because of the increased risk of these complications in monozygotic twin pairs when compared with dizygotic twin pairs.[92]

The regular consumption of caffeine produces tolerance to many of the effects of caffeine within a few days; the severity of withdrawal symptoms depends on individual pharmacokinetics, dose, and duration of use. Volunteer studies indicate that minor caffeine withdrawal can occur following the consumption of as little as 300 mg/day for 3 days[93] The administration of 250 mg caffeine daily to 18 volunteers for 1 week did not produce withdrawal symptoms.[24] However, a study of 7 healthy volunteers suggested that mild withdrawal symptoms can occur following the consumption of caffeine doses as low as 100 mg (i.e., one cup coffee) in some, but not all individuals.[94] A volunteer study suggested that the ingestion of caffeine-containing soft drinks moderates the withdrawal symptoms associated with heavy caffeine consumption.[95] Although this abstinence syndrome can encourage the repeated use of caffeine, caffeine use is typically self-limiting because most individuals do not experience positive and pleasant behavioral effects from escalating doses of caffeine. Rodent studies suggest that the addictive potential of caffeine is relatively low based on minimal functional activation of an area (i.e., shell of the nucleus accumbens) involved with addiction and reward at usual caffeine doses.[96]

Reproductive Abnormalities

Reporting bias and multiple confounders (e.g., associated drug/nicotine use, caffeine use other than tea/coffee) complicate the determination of the effect of caffeine on the fetus. Although there are some epidemiologic evidence that caffeine in high doses adversely affects pregnancy outcome, the results are inconclusive and there is insufficient evidence to restrict caffeine intake after the first trimester. In general, most studies of moderate maternal caffeine consumption (<300 mg/d) do not associate maternal caffeine use with miscarriages or reductions in birth weight, gestational age, or fetal growth.[97,98] A meta-analysis of 15 cohort and 7 case-control studies demonstrated a combined odds ratio of 1.11 (95% CI: 0.96–1.28) for the risk of preterm births (<37 weeks gestation) comparing the highest and lowest level of caffeine consumption during the first trimester.[99] Additionally, there were no statistically significant differences in the combined odds ratios for the second and third trimesters.

Some observational studies suggest a relatively small effect from high maternal caffeine use (≥300 mg/d) during pregnancy on fetal growth restriction (number of births <10th percentile for weight, adjusted for confounders). In a prospective longitudinal observational study of 2,635 low-risk pregnant women, the odds ratios for fetal growth restriction and maternal caffeine use were as follows: 100–199 mg/day, 1.2 (95% CI: 0.9–1.6); 200–299 mg/day, 1.5 (95% CI: 1.1–2.1); and >300 mg/day, 1.4 (95% CI: 1.0–2.0).[100] The test for trend comparing maternal caffeine use of >300 mg/day and <100 mg/day was statistically significant ($P < .001$). The evaluation of self-reports of 2,291 mothers with singleton live births detected a small reduction of birthweight (−28 g/100 mg of caffeine consumed daily, 95% CI: −0.10 to −0.46, $P = .001$).[101] However, the authors believed that this reduction was probably not clinically significant unless the mother ingested at least 6 cups of coffee daily. There was no association between maternal caffeine consumption and mean gestational age. Most positive observational studies on the effect of maternal caffeine use and fetal growth restriction do not demonstrate positive associations between maternal caffeine use and other parameters of fetal well-being (e.g., still births, miscarriage, preterm labor, gestational age).[100,102]

There is no evidence that caffeine is teratogenic in humans. The association between caffeine consumption and spontaneous abortion or still-births is equivocal because of methodologic limitations including selection and recall bias, inconsistent exposure measurement, failure to account for caffeine metabolism and the timing of fetal demise, confounding by smoking and other drugs, and the interrelationship between caffeine and nausea.[103] A Danish study of 88,482 pregnant women suggested an increased risk of spontaneous abortion before 20 weeks in women consuming ≥8 cups of coffee daily (adjusted hazard ratio, 1.48; 95% CI: 1.01–2.17), but there was no statistically significant increase in the risk of stillbirth (>196 days gestation).[104] Although developmental abnormalities occur in animal studies at very high caffeine doses, consumption of these doses by pregnant mothers is highly unlikely. Based on rodent studies, the developmental no observable effect level (NOEL) is approximately 30 mg/kg/day, the teratogenic NOEL is 8,100 mg/kg/day, and the reproductive

NOEL approximately 80–120 mg/kg/day, depending on the method of administration and species.[105]

Carcinogenesis

The International Agency for Research on Cancer lists caffeine as not classifiable as to its carcinogenicity to humans (Group 3) based on inadequate evidence for the carcinogenicity of caffeine in humans and inadequate evidence for the carcinogenicity of caffeine in experimental animals.[106] The IARC lists coffee as possibly carcinogenic to humans (Group 2B) based on limited evidence in humans that coffee drinking is carcinogenic in the bladder and inadequate evidence in experimental animals for the carcinogenicity of coffee.[107] There is little scientific evidence associating female breast cancer or colon cancer with coffee drinking. There was a small, but significant increase in mortality (OR = 1.26; 95% CI: 1.05–1.51) during a 25-year study of 27,530 Seventh-Day Adventists, when comparing moderate to heavy coffee drinkers (≥3 cups/d) with non-coffee drinkers.[108] However, the causality of coffee in this increased mortality could not be determined. There is little evidence associating the use of coffee or tea with esophageal cancer; however, the drinking high-temperature mixtures is an independent risk factor for the development of esophageal cancer.[109]

DIAGNOSTIC TESTING

Analytic Methods

Methods for the quantitation of caffeine in biologic fluids include gas chromatography with nitrogen phosphorus detection,[110] capillary electrophoresis,[111] high performance liquid chromatography with UV detection,[28] and gas chromatography/mass spectrometry.[112] The limit of detection (LOD) with the latter method in biologic samples is about 0.001 mg/L with a coefficient of variation of approximately 10%.[113] Quantitation of caffeine metabolites in the subnanomolar range results from separation by high performance liquid chromatography followed by analysis by stable isotope dilution gas chromatography/mass spectrometry.[114] The use of gas chromatography/ion-trap/tandem mass spectrometry allows the detection of caffeine in environmental samples in the range of 0.000001–0.000002 mg/L.[115] High concentrations of caffeine in blood samples from overdoses can produce false-positive elevation of theophylline concentrations when analyzed by enzyme immunoassays or high performance liquid chromatography methods that do not separate paraxanthine from theophylline.[116]

Biomarkers

BLOOD

Caffeine equilibrates evenly between erythrocytes and plasma; therefore, caffeine concentrations in plasma, serum, and whole blood from the same sample are similar (i.e., variation of <5–10%).

RECREATIONAL USE.   In a convenience sample of 600 outpatients presenting to a clinical laboratory for routine blood analysis, the mean plasma caffeine concentration was 2.1 mg/L with a range of 0.2–13.1 mg/L.[117] There were no restrictions on food or drink intake including caffeine consumption. The upper 95% upper confidence limit was 5.6 mg/L. Following the ingestion of 120 mg caffeine by 13 healthy volunteers, the peak plasma caffeine concentration averaged about 3 mg/L (range, 2–4 mg/L) at 1 hour after ingestion.[118] In a study of 4 volunteers ingesting 300 mg caffeine, the mean peak plasma caffeine concentration at 1 hour after ingestion was about 8 mg/L (range, 6–9 mg/L).[119] The ingestion of 500 mg caffeine produces peak plasma caffeine concentrations up to 17 mg/L.[35]

OVERDOSE.   Plasma caffeine concentrations exceeding 30 mg/L are associated with toxicity. Tachycardia and seizures can occur when the plasma caffeine concentration is 50–60 mg/L. Serious toxicity occurs when plasma caffeine concentrations near 100 mg/L; plasma concentrations in the range of 90–180 mg/L are potentially lethal.[120,121] However, survival has occurred in patients with peak plasma caffeine concentrations in the range of 100–400 mg/L with intensive supportive care.[26,122] A 21-year-old woman became comatose, responsive only to pain with a tachydysrhythmia that deteriorated into ventricular fibrillation.[123] The initial serum caffeine concentration was 297 mg/L, but she survived with intensive cardiorespiratory support and hemoperfusion. Three hours after a large caffeine overdose, a serum caffeine concentration of 194 mg/L was associated with agitation, confusion, diaphoresis, tremulousness, hyperreflexia, tachydysrhythmia, and blood-tinged vomitus in a 58-year-old obese woman.[124]

POSTMORTEM.   Postmortem samples containing caffeine usually contain other drugs; death from caffeine alone is rare.[125] In a case report of a 31-year-old man found dead after ingesting a large dose of caffeine tablets, the femoral blood contained a caffeine concentration of 153 μg/g (~153 mg/L).[120] No other drugs were detected in postmortem blood. A 56-year-old man was found dead in his bed. His heart blood contained a caffeine concentration of 150 mg/L along with a blood ethanol concentration of 109 mg/dL and a fluoxetine concentration above usual

antemortem therapeutic concentrations.[86] A 29-year-old man suffered a fatal cardiac arrest while undergoing imaging studies in the emergency department.[126] Postmortem femoral blood contained caffeine at 192 mg/L with no other significant amounts of drugs in his postmortem blood sample. In a study of postmortem redistribution, the heart/femoral blood ratio in 3 cases ranged from 1.0–1.4 with a mean of 1.2.[127] Caffeine penetrates into the vitreous humor. In 2 fatal cases of caffeine/ephedrine intoxication, the postmortem whole blood : vitreous humor ratio was 3.59 (343.9 mg/L, 95.9 mg/L) and 1.84 (184.1 mg/L, 99.8 mg/L).[128]

Urine

The renal tubule resorbs caffeine in equilibrium with unbound caffeine in plasma. There is substantial variation in the renal excretion of caffeine between individuals. In some individuals, the daily intake of 3–6 cups of coffee can produce urine caffeine concentrations exceeding 12 mg/L.[129]

Abnormalities

The most common dysrhythmias associated with caffeine intoxication are sinus tachycardia and paroxysmal supraventricular tachycardia. Other dysrhythmias include wide-complex tachycardia, premature atrial and ventricular contractions, bigeminy, ventricular tachycardia, ventricular fibrillation, asystole, pulseless electrical activity, and asystole.[45,130] Caffeine reduces electroencephalogram power, particularly in the alpha and theta frequencies. The release of large amounts of catecholamines during severe caffeine intoxication produces lactic acidosis, hypokalemia, hyponatremia, leukocytosis, and hyperglycemia.[131,132] Rhabdomyolysis, hyponatremia, and renal dysfunction can complicate large, intentional ingestions of caffeine[133] and massive amounts (15 L/d) of tea.[134] Respiratory alkalosis can occur in association with hyperventilation.[36]

TREATMENT

Stabilization

Serious caffeine intoxication can cause intractable hypotension, seizures, coma requiring intubation, and serious dysrhythmias including ventricular fibrillation. Treatment for these complications requires careful monitoring for the development of dysrhythmias, seizures, and respiratory failure with IV access, cardiac monitoring, and pulse oximetry. Ventricular dysrhythmias may not respond to lidocaine, and supraventricular tachycardias may not respond to adenosine. Case reports suggest that some dys-

rhythmias (supraventricular tachycardias, ventricular tachycardia) may respond to esmolol (500 µg/kg bolus followed by continuous infusion of 50 µg/kg/min)[124] or procainamide.[130] Seizures usually respond to the IV administration of benzodiazepines (lorazepam, diazepam). During severe caffeine intoxication, the associated hypotension can be unresponsive to dopamine (20 µg/kg/min), norepinephrine (20 µg/min), and epinephrine (2 µg/min).[135] Case reports suggest that these patients may respond to vasopressin infusions initiated at 0.2 U/hour and titrated to 1.2 U/hour.[135] Caffeine is an adenosine receptor antagonist that may reduce the effectiveness of adenosine to convert paroxysmal supraventricular tachycardia if ingested <4 hours before treatment.[136]

Decontamination

Caffeine binds to activated charcoal, and patients should receive 50 g activated charcoal (1 g/kg) if the patient presents within 1–2 hours after ingestion of caffeine in tablet form. As with most overdoses, syrup of ipecac is contraindicated because of the potential for sudden loss of consciousness and seizures during severe caffeine intoxication. There are no data documenting improved clinical outcome following gastric lavage or any other measures of decontamination in this setting.

Enhancement of Elimination

Case reports associate clinical improvement in severe caffeine intoxication following the initiation of hemodialysis[135] or charcoal hemoperfusion.[83,137] Persistent hypotension may complicate the use of hemodialysis in severe caffeine overdose, and there are few data on the clearance rates or clinical efficacy of these methods of enhancing caffeine elimination.

Supplemental Care

During severe caffeine intoxication, patients should be monitored for dysrhythmias, electrolyte imbalance (hypokalemia, hypocalcemia), lactic acidosis, and respiratory depression. The catecholamine-induced hypokalemia is not a true potassium deficit; therefore, correction of hypokalemia should be cautious and immediate normalization of serum potassium with large doses of IV potassium avoided. There are no specific antidotes. Agitation may require the use of IV benzodiazepines as needed to calm the patient without causing respiratory depression. Treatment of the gastrointestinal symptoms include antiemetics (promethazine 25 mg IV, metoclopramide 5 mg IV, odansetron 4–8 mg IV) for vomiting and proton pump inhibitors (famotidine 20 gm IV, pantoprazole 40 mg IV) for gastritis.

Chapter 56

COCAINE

HISTORY

As one of the most potent naturally occurring central nervous system (CNS) stimulants, cocaine has a long history of use and abuse.[1] Analysis of material from a 3,000-year-old Egyptian mummy revealed detectable quantities of cocaine,[2] but there is no documentation that ancient Egyptians used cocaine for recreational purposes. Archaeological findings in Ecuador indicate that the pre-Inca inhabitants chewed cocaine long before the Spanish Conquistadors discovered the use of cocaine among the privileged groups of the Inca culture. The Moche culture flourished on the northern coast of Peru from about 100–700 AD; their ceramic sculptures from this period depict the chewing of coca leaves along with the implements to increase the extraction of cocaine from the leaves by holding alkaline powder near the leaves during mastication.[3] The Incas believed this plant was a divine gift created to alleviate hunger and thirst, and they tightly controlled coca cultivation. The Inca ruling class would chew the leaves on special occasions, whereas members of the working class were occasionally rewarded with a gift of coca leaves. In 1507, the European explorer Amerigo Vespucci mentioned the Indian practice of chewing coca with alkaline ash. Despite an early ban by Spanish Conquistadors on cocaine use, Spanish entrepreneurs used coca leaves as an incentive to employ Indians in hard labor. Although Francisco Pizarro probably brought coca leaves to the 16th-century Spanish court, Europeans did not use coca leaves during this period, in part because coca leaves would have lost their potency during the lengthy trip across the Atlantic Ocean.[4]

Sir William Hook published the first English illustration of coca in 1835 along with a translation of a book by the German naturalist, Edward Poeppig that contained warnings about the addictive properties of cocaine.[5] In 1860, Albert Niemann purified cocaine from coca leaves brought from the New World on a frigate of Archduke Ferdinand. Although the anesthetic properties of cocaine were recognized soon after purification, there was little initial interest in the medicinal properties of this compound. Cocaine-containing wines (e.g., vin Mariani), which contained 6 mg cocaine per ounce, were a popular restorative and tonic in Italy and France during the 1860s.[6]

In 1884, Sigmund Freud wrote glowing reports about the ability of cocaine to relieve depression and cure morphine addiction in his famous treatise, "Über Coca." In that same year, Carl Koller recognized the potential of cocaine to anesthetize the cornea during ophthalmologic surgery. Halstead, an American surgeon, demonstrated the peripheral nerve-blocking properties of cocaine injections. Cocaine was soon prescribed for a wide range of medical conditions from hay fever to hemorrhoid surgery. Initially, the use of cocaine was enthusiastically accepted. Robert Louis Stevenson wrote the first draft of *Dr. Jekyll and Mr. Hyde* following 3 days of cocaine administration for the treatment of tuberculosis. Sir Arthur Conan Doyle's character, Sherlock Holmes, used unnamed artificial stimulants until he became tired, wasted, and paranoid. Later, he reappeared in good health, his pipe replacing the use of stimulants.[7] Pharmacist John Styth Pemberton marketed a cocaine-caffeine mixture called Coca-Cola in 1886 after dropping a wine-cocaine product that competed unsuccessfully with vin Mariani.

The first reports of serious complications from cocaine use appeared in the mid-1880s, not long after Freud's treatise.[8] By 1891, there were over 200 reports of serious adverse reactions, including 13 deaths following the use of cocaine.[4] Unfortunately, Halstead became one of the first victims of cocaine dependence when he tried to cure his morphine addiction with cocaine. Freud was accused of unleashing the third great scourge (after ethanol and opiates) on humanity; subsequently, he removed all reference to cocaine abuse from his autobiography.

During the latter 19th century and most of the first third of the 20th century, the production and export of coca leaves were legal in most countries. The export of coca leaves from South America rose steadily during the 1880s, but the loss of potency during the long voyages led to the processing of the leaves into raw cocaine prior to shipping. During the early 1900s, a new source of coca leaves from Java undercut the South American coca trade with high-grade coca (i.e., about 1.5% compared with <1% for most coca leaves).[9] Japan also entered the coca trade with domestically manufactured cocaine and coca grown in Formosa. Coca export records from the major producing sites (Peru, Bolivia, Java, Formosa) indicate that the legal production of coca peaked around 1920; these records also indicate that cocaine consumption was first popular in North America, then in Europe and other parts of the world.

Nations that ratified the Versailles Treaty and the 3 treaties with Austria-Hungary, Bulgaria, and Turkey agreed to implement the provisions of the Hague Opium Convention of 1912.[9] This Convention required that each nation control cocaine exports so that only authorized persons could receive the drug. The United States attempted to control cocaine use through the Pure Food and Drug Act of 1906; consequently, the Coca-Cola Company removed cocaine from the coca leaves prior to formulation of their drink. To comply with the Opium Convention of 1912, the United States implemented the 1914 Harrison Narcotic Act. This legislation labeled cocaine as a narcotic with the same restrictions and penalties as heroin. Eventually, coca exports steadily declined by the 1920s. Although clandestine laboratory books on the synthesis of cocaine have been available since the 1920s,[10,11] the synthetic process is too complex and costly compared with the isolation and purification of cocaine from coca leaves.

Reports of serious cocaine toxicity were rare between the publication of Maier's classic text on cocaine abuse in 1926 and the appearance of reports on cocaine body packing in the late 1970s.[12] In 1970, the Comprehensive Drug Abuse Prevention and Control Act classified cocaine as a schedule II drug (i.e., high abuse potential with limited medical application), but again allowed the medical use of cocaine. Serious complications from cocaine use increased substantially in the 1980s when new forms (e.g., smoking freebase) of cocaine abuse dramatically increased the amount of cocaine used by addicts.[13] Cocaine-associated deaths resulted from all routes of administration, including intravenous (IV), nasal, vaginal, and oral, as well as from unintentional and deliberately inflicted trauma.[14] Beginning in 2003, the South American cocaine cartels began adding the veterinary antihelminthic, levamisole to bulk cocaine shipments as an adulterant, reportedly to potentiate the effects of cocaine; by 2008, about one-fourth of confiscated cocaine analyzed by the United States Drug Enforcement Administration (DEA) contained levamisole.[15] The intended role of levamisole in illicit cocaine remains unknown, although recent data suggest that the stimulant, aminorex is a metabolite of levamisole at least in some animal species (e.g., horses).

BOTANICAL DESCRIPTION

Common Name: Coca plant, Cuca (Peru), Epadu or Ipadu (Brazil), Hayo (Venezuela), Huánuco Coca (Bolivia), Spadic (Colombia)

Scientific Name: *Erythroxylum coca* Lam.

Botanical Family: Erythroxylaceae

Physical Description: This shrub grows to 3–6 m (~9–18 ft) in height with straight, alternate reddish branches. The pointed leaves are smooth, slightly glossy, and green to green-brown. The leaf size ranges from 1.5–3 cm in width and from 0.5–11 cm in length. These leaves contain an areolate portion with the midrib bounded by a curved, longitudinal line on each side, particularly prominent on the undersurface. Red berries form from the flowers and each berry contains only 1 seed. Following pruning of the branches, multiple new branches appear around the cut in a geometric pattern.

Distribution and Ecology: This bush requires the moist, tropical climate found in the eastern Peruvian Andes (Peru, Ecuador, Bolivia), and to a lesser extent, in Mexico, the West Indies, and Java. These plants grow best in lush high valleys of the eastern Andes. Illicit production of the coca plant occurs at elevations of 1,500–6,000 ft (~450–1,800 m) because of the lower cocaine yield at lower elevations. There are 2 recognized infraspecies of the coca plant: *Erythroxylum coca* var. *coca* Lam. and *Erythroxylum coca* var. *ipadu* Plowman. The *E. coca* var. *coca* Lam. variety is the most common source of street cocaine. The less common

source of cocaine, *E. coca* var. *ipadu* Plowman is cultivated primarily in the Amazon Valley. The coca plant should not be confused with the cocoa plant, which contains caffeine rather than cocaine.

Common Name: Columbian Coca plant

Scientific Name: *Erythroxylum novogranatense* (Morris) Hieron.

Botanical Family: Erythroxylaceae

Physical Description: This shrub or small tree grows to about 2.5 m (~8–9 ft) in height with small, obovate to narrowly elliptical, pointed leaves up to 5 cm in length. An intramarginal vein surrounds the midvein on each side. Small, solitary flowers appear throughout the year and they produce a red, oblong drupe that contains a single seed.

Distribution and Ecology: This plant grows in the drier mountainous region of Colombia, the Caribbean coast of South America, and the north coast of Peru. The 2 varieties of *Erythroxylum novogranatense* are *E. novogranatense* var. *novogranatense* (Morris) Hieron. and *E. novogranatense* var. *truxillense* (Rusby) Plowman. The leaves from a strain of *E. novogranatense* grown near Trujillo, Peru are legally exported to the Stephan Chemical Company (Maywood, NJ), which is the only legally recognized manufacturer of cocaine for pharmaceutical purposes in the United States.

IDENTIFYING CHARACTERISTICS

Structure

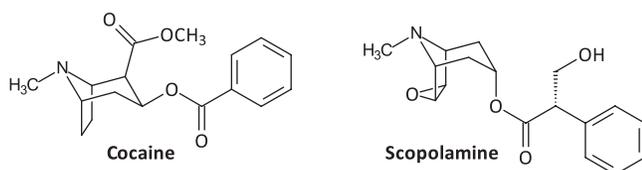
Cocaine (methyl benzoylecgonine) is a tertiary amine that is structurally, but not pharmacologically related to the tropane family of natural alkaloids (e.g., scopolamine, atropine) as demonstrated in Figure 56.1. Although amphetamines and cocaine share similar stimulant properties, cocaine is structurally distinct from phenylethylamine compounds. Cocaine base is methyl benzoylecgonine (CAS RN: 50-36-2, $C_{17}H_{21}NO_4$).


FIGURE 56.1. Chemical structures of cocaine and scopolamine.

Physiochemical Properties

Cocaine is a weak base with a pK_a of 8.6 compared with a pK_a of 8.23 for the more hydrophobic, cocaethylene. The relatively greater hydrophobicity of cocaethylene may contribute to its longer plasma half-life compared with cocaine.[16] In alkaline solutions, the non-ionized or freebase form of cocaine predominates, whereas in acidic solutions cocaine exists as the salt (e.g., hydrochloride in an HCl solution). Pure cocaine base is an odorless, colorless to white crystalline powder with a bitter taste and a melting point of 98°C (208.4°F). Cocaine base is poorly water-soluble (0.00167 g/ mL), whereas cocaine hydrochloride is very soluble in water (2.5 g/mL). The hydrochloride salt has limited volatility (i.e., very low vapor pressure) and a melting point of about 195°C (383°F). Hydrolysis of cocaine hydrochloride occurs rapidly at pH >4.

Terminology

Street names for cocaine include Coke, Snow, Flake, Gold Dust, Green Gold, Blow, Pimp's Drug, Rock, Bernice, Star-Spangled Powder, Root, C, Lady, White, White Girl or Lady, Nose Candy, Speedball (heroin and cocaine), Toot, Tick (smoked with phencyclidine), and Liquid Lady (ethanol and cocaine).

Form

Cocaine exists in illicit samples as the cocaine salt (hydrochloride) or as the cocaine base (crack). The most common form of illicit cocaine is the white crystalline, highly water soluble powder, cocaine hydrochloride as displayed in Figure 56.2. As the vapor pressure of cocaine hydrochloride is very low, vaporization of cocaine hydrochloride requires temperatures >200°C (>392°F), resulting in an unsuitable form for smoking. Unlike the hydrochloride and sulfate salts of cocaine, freebase cocaine vaporizes at 98°C (208°F); therefore, this form of cocaine is suitable for smoking. Crack is the freebase form of cocaine that has a characteristic crackling sound when smoked. Figure 56.3 displays a sample of crack cocaine. This type of cocaine should not be confused with freebasing, which is a process to purify cocaine hydrochloride by mixing aqueous cocaine with baking soda or ammonia and extracting the free form of cocaine with an organic solvent (ether). Legitimate commercial production of cocaine involves the synthesis of cocaine from (-)-ecgonine in the presence of methanol and benzoic acid after hydrolysis of the ester alkaloids extracted from the plant material.

EXPOSURE

Epidemiology

For many years, poverty-stricken Indians of the Andean highlands chewed coca leaves to relieve fatigue and hunger as well as to improve productivity and energy during hard labor in the mines. For 50 years after the Harrison Narcotic Act, the use of cocaine in the United States was limited to the jazz scene. In the 1960s, cocaine emerged as a substance commonly used with heroin (i.e., Speedball) by IV polydrug users,[17] but by the 1970s cocaine had become an expensive drug that was insufflated (sniffed) or smoked rather than injected. By 1980, almost 10 million people over 11 years of age reported

using cocaine during the preceding year, with almost half indicating use within the last month.[18] Members of the middle and upper class were attracted to cocaine because it promotes feelings of exhilaration and ecstasy, enhanced self-confidence, and heightened physical prowess. Concern over the illicit use of cocaine increased dramatically during the early 1980s because of the accelerated use of cocaine among all social classes and the prevalence of more hazardous forms of abuse (e.g., free-basing, crack cocaine). Overall, the number of people in the United States using cocaine doubled from the preceding 2 years. Cocaine use among American high school seniors increased from 6% in 1976 to 20% in 1982.[19]

The number of cocaine users peaked in ~1985. The estimated number of occasional cocaine users (i.e., <12 days in preceding year) decreased from 7.1 million in 1985 to about 2.4 million in 1994 and these statistics remained relatively stable during the next decade.[20,21] Between 2002 and 2009, the estimated number of individuals in the United States aged 12 years or older using cocaine for the first time in the last year declined from ~1 million to 617,000 including a reduction in the number of first time crack cocaine users from 337,000 to 94,000.[22] During this same period, the estimated number of individuals in the United States aged 12 years or older with cocaine dependence or abuse decreased from 1.5 million to 1.1 million. Introduced in the 1980s, crack cocaine was a new method of delivery rather than a new drug. Since the introduction of crack cocaine, there has been a clear trend for first-time cocaine use among polydrug users to smoke crack cocaine rather than inject cocaine.[23] Although cocaine addicts frequently begin with intranasal cocaine use, most of these addicts transition to the smoking route.[24] Patients who smoke freebase or administer IV cocaine rarely revert to insufflation (snorting).

Sources

ORIGIN/COMPOSITION

Cocaine is 1 of at least 14 alkaloids extracted from the leaves of 2 coca shrubs (*E. coca*, *E. novogranatense*) indigenous to the Andean region of South America. The relative amounts of alkaloids in coca leaves vary with age as well as with species and variety.[25] The leaves of the *ipadu* variety of *E. coca* contain much smaller amounts of cocaine compared with other varieties of the coca plant. The seeds of coca plants do not contain cocaine.[26] The lifespan of the plant is over 40 years, but production of an average coca plant declines after about 10 years.[5] The leaves contain between 0.5–2.0% (average <1%) cocaine depending on the strain and weather con-

ditions; harvest occurs in March, June, and November beginning 2 years after planting.[31] After the removal of cocaine, the residual leaf material from the Colombian coca plant (*E. novogranatense*) is a flavoring agent for the soft drink, Coca-Cola.

PRODUCTION PROCESSES

COCOA PASTE.   The processing of cocaine hydrochloride for illicit distribution involves the following 3 steps: 1) extraction of crude coca paste from the coca leaf, 2) extraction of cocaine base from coca paste, and 3) conversion of the cocaine base to cocaine hydrochloride. These steps usually occur in South America near the fields of coca plants, and the techniques are somewhat variable depending on the availability of chemicals.[27] The solvent extraction technique uses limewater and gasoline or kerosene during the maceration of coca leaves. The addition of a dilute sulfuric acid solution allows the separation of the aqueous layer containing cocaine from the gasoline or kerosene. Neutralization of the aqueous layer with alkaline material causes the precipitation of a crude coca paste containing cocaine as well as other alkaloids, basic inorganic salts, and hydrolysis products.

The acid extraction process involves the maceration of the coca leaves in a pit lined with heavy plastic. The pit contains sulfuric acid and stomping by workers causes the cocaine base to leach from the leaves in the form of an aqueous solution of cocaine sulfate. After several extractions and the filtering of the solution to remove insoluble plant materials, the excess acid is neutralized by the addition of basic lime or sodium carbonate. The cocaine sulfate solution then forms a very crude coca paste. This paste contains a variety of chemicals including *cis-* and *trans-*cinnamoylcocaine, cuscohygrine, hygrine, tropine, tropacocaine, ecgonine, benzoylecgonine, methyl ecgonine, truxilline compounds, plant waxes, and benzoic acid. The refining process may include the addition of potassium permanganate to destroy cinnamoylcocaine isomers.[5] This step allows the formation of *n*-formyl cocaine that is not normally present in the paste; this by-product can hydrolyze to norcocaine. Either acetone or ether is added to the coca paste to extract the cocaine base, and the solution is poured into a reaction vessel along with a dilute solution of hydrochloric acid in acetone. The resultant slurry is poured on a bed sheet to filter out the cocaine hydrochloride. After drying, the cocaine hydrochloride is packaged for shipping. Figure 56.4 displays confiscated cocaine bricks.

FREEBASE COCAINE.   To produce the freebase form of cocaine, sodium bicarbonate or household ammonia is

FIGURE 56.4. Confiscated cocaine bricks. (Photo courtesy of the US Drug Enforcement Agency)

mixed in a vessel containing cocaine hydrochloride and water. Diethyl ether is added to the basic aqueous solution; then, the mixture separates into a biphasic solution. The aqueous, lower layer is discarded; the upper (organic) layer containing the cocaine base is decanted and dried.[28] The processing of freebase cocaine removes water-soluble impurities (e.g., sugars) and some inert compounds (inositol, talc, cornstarch), but not basic organic compounds including local anesthetics (e.g., lidocaine, benzocaine) or stimulants (e.g., amphetamines, caffeine, ephedrine).[29] These organic bases are converted to their freebase forms in the same way that cocaine remains in the final product.

CRACK COCAINE.   *Crack* is the term for the tiny crystalline pieces (*rocks*) of freebase cocaine that produce a popping sound (cracking) when heated during smoking. Preparation of crack cocaine involves the mixing of cocaine hydrochloride with sodium bicarbonate (or household ammonia) in sterile water and the heating of the mixture in boiling water until the precipitated cocaine base forms an oily compound. Reduction of the temperature in the reaction vessel by the addition of ice allows the solidification of cocaine base on the bottom of the vessel. The cocaine base precipitates as small pellets (*rocks*) when the water bath cools. These irregularly shaped, off-white to buff-colored fragments of compressed powder are about ¼″ to ⅜″ in width. After collection of the cocaine base from the vessel, the material is dried under a heat lamp or in a microwave oven. The only distinction between processing of crack cocaine and freebase cocaine is the absence of the organic solvent extraction phase in the processing of crack cocaine. As such, incomplete drying may result in high moisture content compared with freebase cocaine.

IMPURITIES AND PROFILING

Similar to many other illicit drugs, street samples of cocaine contain impurities, contaminants, diluents, and adulterants.[30] The extraction of cocaine from the coca leaf results in the presence of other impurities (i.e., natural alkaloids: hydroxycocaine, *cis*-cinnamoylcocaine, *trans*-cinnamoylcocaine, tropacocaine, cuscohygrine, hygrine, and truxilline compounds).[27,31] Truxilline alkaloids (α-, β-, γ-, δ-, ε-truxilline) are precursors of truxillic and truxinic acids that may also occur in illicit cocaine samples.[32] Contaminants are by-products of the manufacturing process of cocaine. Degradation of cocaine during the manufacturing process produces ecgonine, benzoylecgonine, or methyl ecgonine as well as benzoic acid and methylecgonidine. Typically, illicit cocaine hydrochloride is about 30% pure as a result of additives (diluents, adulterants) added after the completion of the manufacturing process.[33] Diluents are inert substances with physical characteristics (e.g., taste, form, texture, color) similar to the illicit drug (i.e., cocaine). Common diluents of illicit cocaine include primarily sugars (mannitol, lactose, sucrose). Adulterants are pharmacologically active ingredients that enhance or antagonize the effect of the illicit drug (i.e., cocaine).

Although increased supplies of cocaine often improve the purity of street cocaine, invariably the street samples of cocaine contain many adulterants including inert compounds (inositol, lactose, mannitol), local anesthetics (benzocaine, lidocaine, procaine, tetracaine), stimulants (amphetamines, caffeine, ephedrine, theophylline, phenylpropanolamine, phendimetrazine, phenmetrazine, phentermine), and toxic compounds (quinine, strychnine).[34] Other adulterants found in cocaine samples include phenobarbital, diphenhydramine, dipyrone, aminophenazone, levamisole (veterinary antihelminthic), noraminophenazone, phenacetin, and salicylamide.[35,36] The presence of adulterants should be considered whenever adverse reactions complicate cocaine use; however, the clinical effects of these impurities are frequently difficult to separate from the effects of cocaine use. Levamisole is a known cause of agranulocytosis in veterinary medicine; analysis of clinical specimens and drug paraphernalia of some cocaine-using patients with agranulocytosis demonstrated the presence of this drug.[37,38] Cocaine use is not usually associated with agranulocytosis.

Figure 56.5 demonstrates the structures of cocaine, cocaine alkaloids, manufacturing by-products of illicit cocaine, and other impurities. Because the coca plant synthesizes only the levorotatory isomer of cocaine (*l*-cocaine), the presence of diastereoisomers or its dextroenantiomer (*d*-cocaine) indicates synthetic production. Although the synthesis of cocaine is quite

sophisticated and beyond the capabilities of most illicit laboratories, gas chromatography, nuclear magnetic resonance, and mass spectrometry methods can distinguish natural from synthetic cocaine in forensic or legal settings.[39,40]

Methods of Abuse

In modern, rural Andean society, coca chewing is a ritualistic part of poverty and hard labor that produces relatively low cocaine blood concentrations.[41] Since pre-Inca times, coca chewing has been a method of cocaine use intended to alleviate hunger, ease fatigue, and improve mood.[42,43] For cocaine users in developed countries, cocaine use is a behavior intended to add excitement to their lives, enhance self-image, or improve performance or productivity. Although these users frequently project outward signs of success, cocaine use initially suppresses feelings of depression, low self-esteem, and boredom. Compulsive cocaine use results from the need to increase the amount of cocaine to sustain the desired effects of the drug. Such drug-oriented behavior causes social, economic, and physical deterioration. Based on admissions to abuse treatment centers, 40% of addicts use cocaine nasally, 30% by freebase smoking, 20% by injection, and 10% by combined routes.[44] Chronic cocaine use does not produce the classical pattern of addiction that occurs following chronic opioid or sedative-hypnotics abuse. However, chronic use of cocaine produces acute tolerance to the euphoric effects of cocaine as well as some physical symptoms of withdrawal including insomnia, irritability, depression, and headaches. These chronic effects usually do not occur following medical or casual cocaine use.

INSUFFLATION

Nasal insufflation (sniffing or snorting) is a popular method of cocaine abuse for recreational cocaine users. These cocaine users form a line of finely crushed cocaine crystals on a hard surface (e.g., a mirror) using a sharp edge (e.g., a razor blade). Depending on the purity of the cocaine, each line represents ~10–35 mg of cocaine. After rolling a paper or using a straw, the cocaine user draws or snorts the line of powder into the nostril. Insufflation is a relatively inefficient method of cocaine use compared with smoking freebase cocaine.

SMOKING

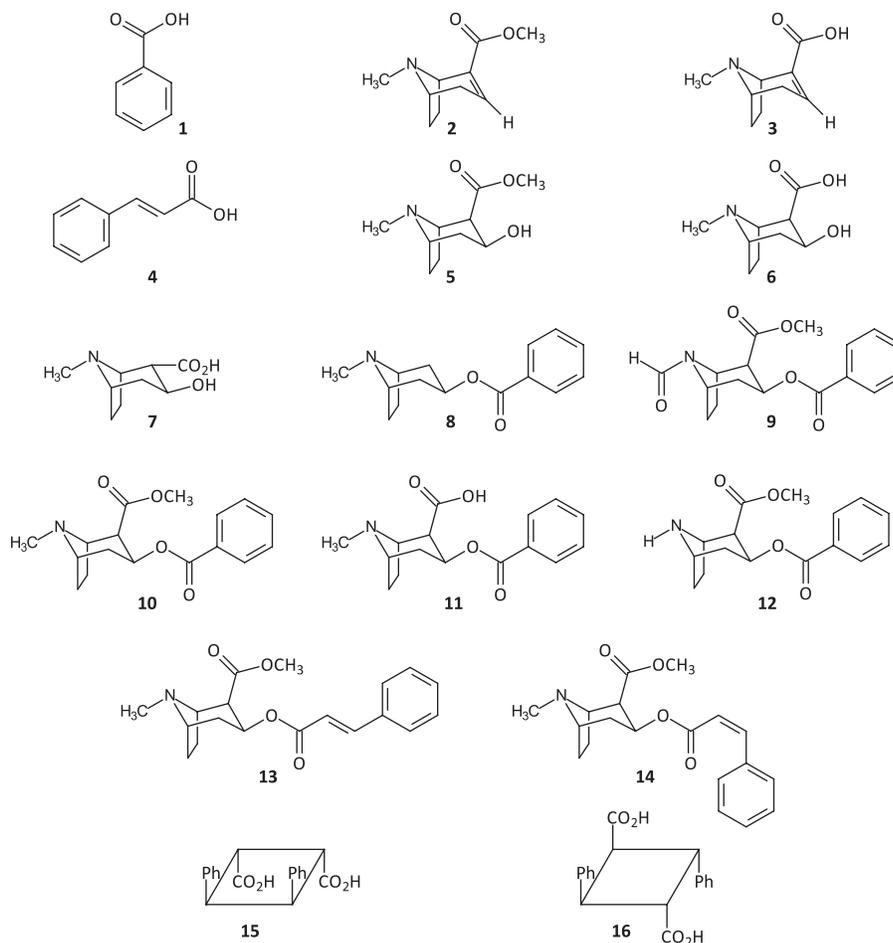
Smoking cocaine base produces a rapid increase in plasma cocaine concentrations with peak concentrations occurring within 5 minutes and the immediate onset of euphoria.[45] As measured by VAS ratings and


FIGURE 56.5. Chemical structures of some alkaloids in coca leaf along with alkaloidal impurities and manufacturing by-products in illicitly refined cocaine. 1 = benzoic acid; 2 = ecgonidine methyl ester; 3 = ecgonidine; 4 = trans-cinnamic acid; 5 = ecgonine methyl ester; 6 = ecgonine; 7 = pseudoecgonine; 8 = tropacocaine; 9 = *N*-formylnorcocaine; 10 = cocaine; 11 = benzoylecgonine; 12 = *N*-norcocaine; 13 = *trans*-cinnamoylcocaine; 14 = *cis*-cinnamoylcocaine; 15 = β-truxinic acid; 16 = α-truxillic acid.

vital signs in pharmacodynamic studies of 10 healthy men, the cardiovascular and subjective effects following the smoking of 50 mg cocaine were similar to the effects following the IV administration of 32 mg cocaine.[46] The exception was higher VAS ratings of "stimulated," "high," and "liking" following smoked cocaine compared with IV cocaine.

FREEBASE. Smoking of cocaine requires the conversion of the cocaine hydrochloride salt to the more volatile, freebase form. The main distinction between crack cocaine and cocaine used in freebasing is the difference in the production processes (i.e., the use of ether in an organic solvent extraction phase during processing of cocaine for freebasing). In the 1970s and 1980s, commercial drug paraphernalia shops sold extraction kits for freebasing. These processes separated the free alkali base with an ether solvent and dried the base as the benzoylmethylecgonine amino alcohol base. This process retained some adulterants (e.g., local anesthetics), but not other additives (e.g., sugars). The volatile product could be smoked in a cigarette or water pipe. However, ether is highly flammable; therefore, explo-sions potentially complicate some of these extraction processes.

An experimental study with model pipes that simulated crack smoking indicated that cocaine smoke generated by this method contains approximately 93% cocaine particles with an average particle size in the respirable range (i.e., 2.3 μm) for primates.[47] A much smaller fraction of the "crack smoke" reaches the alveolar region of rodents compared with humans. The amount of cocaine inhaled during the volatilization of freebase cocaine is highly dependent on flow rate and temperature.[48] In an experimental apparatus, heating crack cocaine to 170°C (338°F) and 225°C (437°F) reduced the amount of cocaine to 73 ± 9% and 62 ± 11%, respectively.[49] Degradation of cocaine increases with increasing temperature and lower flow rates. At a temperature of 260°C (500°F) and a flow rate of 400 mL/min, 39% of the cocaine in the glass pipe appeared in a wool trap compared with <10% when the air flow rate decreased to 100 mL/min.[50] At this temperature, 60% of the cocaine remained intact, whereas only 2% of the cocaine remained intact as the temperature increases to 650°C (1,202°F). Benzoic acid and

methylecgonidine (CAS RN: 43021-26-7, anhydroecgonine methyl ester) were the main thermal degradation products of cocaine as determined by gas chromatography/mass spectrometry (GC/MS).

Smoking freebase cocaine has a high potential for dependency and overdose compared with intranasal use because cocaine smokers are less likely to titrate the dose of cocaine.[51] The important differences between the use of intranasal and smoking freebase are the immediate onset of effects, the magnitude of the euphoria, the duration of use, and the large quantity of cocaine consumed with the latter route of administration.[52] Additionally, more concomitant drug use occurs (e.g., ethanol, sedative-hypnotics, heroin) during the use of freebase cocaine. Escalating doses of freebase cocaine results in binges or runs over 1–3 days, similar to the abuse of methamphetamine. Behavioral complications of chronic cocaine use include diminished interest socialization (family, friends, work, food) as well as physical deterioration (unkempt appearance, exhaustion, insomnia, weight loss, depression). A paranoid or depressive psychosis may develop during this period of cocaine abuse.[53] The nadir of cocaine dependency typically involves family and financial crises. Cost probably is not a factor for the selection of the route of cocaine administration because the cost of powder cocaine and freebase cocaine is similar on a per pure unit basis.[54]

Coca Paste.   Coca paste is the initial product of the cocaine extraction process that contains high concentrations of cocaine sulfate. Abuse of this product involves the smoking of tobacco or marijuana cigarettes laced with this white semisolid. Smoking these cigarettes causes an immediate euphoria similar to the smoking of freebase cocaine, but the relative cost of smoking coca paste is lower. The addiction potential of smoking coca paste and freebase cocaine is similar, and this form of cocaine use is common in South America, particularly among the poor and even among the middle-class.[55] The use of coca paste in the United States is sporadic. Chemical analysis of coca paste indicates that the paste typically contains >60% cocaine along with a variety of other substances including benzoic acid, ecgonine, ecgonine methyl ester, methyl benzoate, manganese, gasoline residues (ethylbenzene, xylene, trimethylbenzene, naphthalene), and other natural alkaloids (tropacocaine, *cis* and *trans*-cinnamoylcocaine).[56]

Intravenous Use

Most IV cocaine users are polydrug users, who use cocaine depending on availability. When cocaine is unavailable, these polydrug users return to their customary drug of abuse. Injecting cocaine alone requires frequent injections; therefore, smoking is a more popular route of abuse because of similar euphoria and the lack of complications of IV drug use. Cocaine use can produce too much hyperactivity and excitement for some addicts, who prefer the combination of heroin and cocaine (Speedballing). An IV cocaine habit is expensive, and this method of cocaine abuse produces reactions and adverse effects similar to those produced by freebase cocaine habits, as well as the other infectious and physical complications associated with IV drug abuse.

DOSE EFFECT

Illicit Use

Significant physiologic and psychologic changes develop after inhalation, injection, or insufflation of cocaine. However, predicting toxic reactions following cocaine use is complicated by a variety of factors including individual sensitivity, acute tolerance, cocaine purity, and the type of impurities and adulterants. Snort, hit, line, and dose are the street terms for individual measures of cocaine; typical doses range up to 200 mg per measure depending on purity with an average dose of cocaine salt being about 25 mg per insufflation.[33] Large quantities of cocaine are sold in grams or spoons (i.e., 0.5–1 g). A 15-mg intranasal dose of cocaine produces slight elevations in systolic pressure and a subjective feeling of euphoria.[57] A 16-mg IV dose simulates the effects of the average dose that individuals self-inject on the street.[58] Intravenous doses of 8- to 32-mg cocaine produce euphoria, stimulation, a feeling of increased vigor, enhanced psychomotor activity, and anxiety similar to the use of amphetamine.[59] Dysphoric reactions can occur following the insufflation of cocaine doses as low as 20–30 mg. A typical adult fatal dose of cocaine is approximately 1 g depending on a number of factors including individual susceptibility. Potentially sensitive individuals include those with hereditary pseudocholinesterase deficiency.

Medical Use

The major clinical indication for the use of cocaine is topical anesthesia and vasoconstriction for ear, nose, and throat surgery. The typical adult dose of intranasal cocaine is 80–200 mg (4 mL of 5% cocaine solution); however, surveys of otolaryngologists indicate that some physicians administer intranasal cocaine doses exceeding 200 mg.[60] Within 2–4 minutes of application, the administration of 20–50 mg produces adequate vasoconstriction for ear, nose, and throat surgery. In an

observational study of cocaine doses of 1.5 mg/kg for local anesthesia prior to intubation for coronary bypass surgery, the use of cocaine did not produce changes in cardiovascular parameters as measured by blood pressure, pulse rate, cardiac index, left ventricular stroke work index, total peripheral vascular resistance, and pulmonary vascular resistance.[61]

Cocaine is not currently used for topical anesthesia of the cornea because chronic cocaine use causes delayed epithelization and corneal opacification. Additionally, pupillary dilation secondary to cocaine use potentially can produce acute angle glaucoma. The Brompton cocktail was a mixture of analgesics for terminally ill patients that often contained cocaine as well as a variety of other drugs (e.g., heroin, morphine).[62] The use of the mixture has been replaced by other analgesics.

TOXICOKINETICS

Absorption

Cocaine is rapidly and efficiently absorbed via the nasal, oral, and pulmonary routes at doses commonly associated with therapeutic use. The pharmacokinetic profile of cocaine in volunteers is similar following smoking and IV use, but the intranasal administration of cocaine produces lower peak cocaine concentrations and longer intervals between intranasal administration and peak concentration compared with the other 2 routes of administration.[63] Figure 56.6 compares the time course of the mean plasma cocaine and benzoylecgonine concentrations following single cocaine doses via the IV, nasal, and pulmonary routes of exposure.

NASAL INSUFFLATION

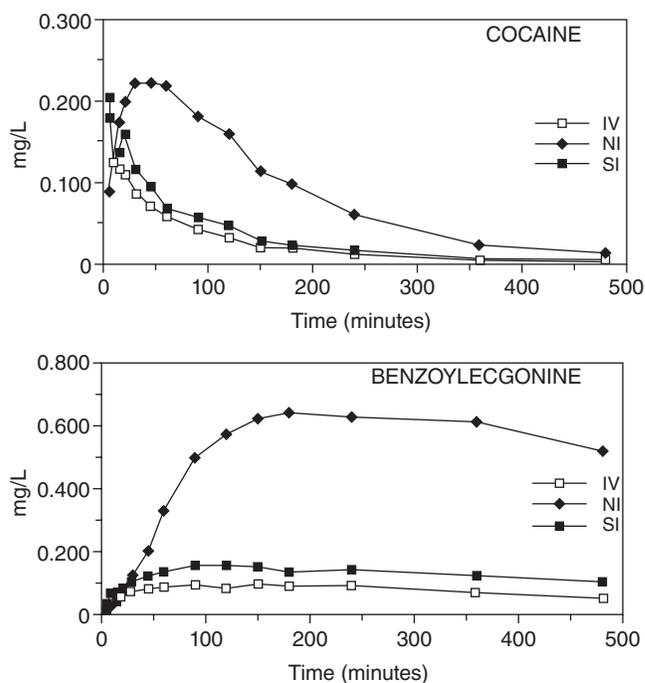
Plasma cocaine concentration increases rapidly for the first 20–30 minutes after insufflation with peak cocaine concentrations occurring approximately 15–60 minutes after administration. Following a 1.5 mg/kg cocaine dose, the peak plasma cocaine concentration ranged from 120–474 ng/mL.[64] Maximum euphoric effects occurred before peak cocaine concentrations (i.e., 15–20 minutes after nasal insufflation), and the effects were greater on the ascending plasma cocaine curve suggesting some tachyphylaxis.[65,66] Some delay in nasal absorption can occur as a result of the vasoconstrictive properties of cocaine, and the nasal mucosa absorbs about 98% of a therapeutic dose of cocaine within 4 hours of nasal administration.[67] The subjective and physiologic effects of 25-mg IV and 100-mg intranasal cocaine doses are similar.[57]


FIGURE 56.6. Time course of mean plasma cocaine and benzoylecgonine blood concentrations after the injection 20.5 mg cocaine (□, IV), nasal insufflation of 94.6 mg cocaine (◆, NI), and the inhalation of 50 mg cocaine freebase (■, SI) in adult volunteers. Reprinted with permission from AR Jeffcoat, M Perez-Reyes, JM Hill, BM Sadler, CE Cook, Cocaine disposition in humans after intravenous injection, nasal insufflation (Snorting), or smoking, Drug Metabolism and Disposition, Volume 17, p. 156, copyright 1989.

ORAL

At least one study suggests that oral and intranasal bioavailability of cocaine is similar (i.e., about 60%) at doses of 2 mg/kg.[68] At this dose, the intranasal and oral administration of cocaine produces statistically similar mean peak plasma concentrations. Oral administration of cocaine produced detectable plasma cocaine concentrations at 30 minutes with peak plasma cocaine concentration occurring between 50–90 minutes. Subsequently, the plasma cocaine concentration declined gradually over approximately 5 hours.[69] In this study, the peak subjective "high" after oral dosing was more intense than the euphoria induced by nasal insufflation, but subjective effects were delayed 45–90 minutes after administration following oral administration compared with 15–60 minutes after intranasal administration. Body stuffers ingest wrapping materials that liberate cocaine at variable rates depending on the type of container and the pH.[70] In the alkaline environment of the small intestine ($pK_a = 8.6$), the relative amount of the ionized form of cocaine decreases, whereas a relatively greater

proportion of the non-ionized form crosses the intestinal mucosa into the systemic circulation compared with the acidic environment of the stomach.

SMOKING

The absorption of freebase cocaine into the pulmonary circulation is rapid and complete with the onset of subjective response occurring soon after the initiation of smoking.[45] Consequently, the onset of action of cocaine is similar following pulmonary and IV administration. Inhalation of 15-mg freebase cocaine produces as much psychologic and physiologic effect as IV administration of 20-mg cocaine hydrochloride. Most of the freebase cocaine is delivered to the lungs within the first 4 puffs with subjective euphoria occurring within 6–11 minutes after initiation of smoking. Up to two-thirds of the cocaine may not reach the alveoli. Figure 56.7 demonstrates cocaine concentrations in volunteers after the smoking of cocaine doses of 10 mg, 20 mg, and 40 mg.

INTRAVENOUS

The IV administration and smoking of equivalent doses of cocaine produce similar cocaine concentrations in venous blood and similar times to peak effect. However, arterial concentrations of cocaine exceed venous cocaine concentrations during the first 15–20 minutes after the administration of cocaine via smoking and IV injection. In a study of 9 chronic cocaine users, the maximal arterial cocaine concentrations were at least 10-fold higher than maximal venous cocaine concentrations after both IV and smoked routes with peak arterial and venous cocaine concentrations occurring about 15 seconds and 4 minutes, respectively, after administration by either route.[71] Therefore, the pharmacokinetics of IV cocaine and freebase smoking are similar with physiologic and psychologic effects appearing several minutes after administration by either route.

DERMAL

There are limited data on the absorption of cocaine though the skin. A 5-mg dose of freebase cocaine was applied to a 20-square-inch area on the volar surface of the forearm of a single individual. The area of application was covered with a long-sleeved cotton shirt until the remaining cocaine was removed by washing 13 hours later.[72] The peak concentration of benzoylecgonine was 55 ng/mL 48 hours after application. The application of cocaine hydrochloride in a similar manner resulted in a peak urinary benzoylecgonine concentration of 15 ng/mL 24 hours after application. All urine specimens remained below the federal cutoff of 300 ng/mL for benzoylecgonine in urine drug screens.

Distribution

Cocaine has a moderate affinity for lipid tissue with an apparent volume of distribution notably smaller (2–3 L/kg) than most psychotropic drugs.[73] Following absorption, cocaine readily diffuses across the blood–brain barrier, resulting in the rapid distribution of cocaine into the brain where cocaine concentrations are several times higher in brain tissue than in the whole blood or plasma shortly after administration.[63,74] Because the serum and plasma cocaine concentrations fall more rapidly than cocaine concentrations in the brain, the cocaine brain/blood cocaine ratio increases 1–2 hours after exposure until brain cocaine concentrations become nondetectable by approximately 6–8 hours after a single cocaine exposure. *In vitro* studies with equilibrium dialysis indicate that both cocaine and cocaethylene are tightly bound to α_1-glycoprotein, whereas low-affinity sites on albumin occur for these 2 compounds.[75] In a study of serum from 12 healthy volunteers, the mean free fraction of cocaine was 0.083 ± 0.018 based on ultrafiltration.[76] The protein binding of cocaine was concentration-dependent with the most pronounced effects occurring above a cocaine concentration of 5 mg/L.

Animal studies indicate that benzoylecgonine persists in the brain at least 1 week after cessation of chronic cocaine use.[77] Animal studies also indicate that

cocaine distributes into genital organs including the epididymis and seminal vesicles. Following the administration of tritiated cocaine hydrochloride to male mice, the highest radioactivity appeared in the kidney and epididymis with sperm accounting for a substantial amount of the radioactivity associated with the epididymis.[78] Typically, the ratio of semen/plasma cocaine concentrations is less than unity.[79] Limited data from volunteer studies suggest that passive exposure to cocaine via the ejaculate of cocaine-using male partners may result from sexual activity, but the benzoylecgonine concentrations from this activity are unlikely to produce positive urine drug screens at the usual cutoff of 300 ng/mL.

Biotransformation

The major metabolic pathways of cocaine metabolism involve 1) human carboxylesterase-1 (hCE-1)-mediated and spontaneous chemical hydrolysis of cocaine to benzoylecgonine and 2) pseudocholinesterase- and human carboxylesterase-2 (hCE-2)-mediated hydrolysis of cocaine to ecgonine methyl ester.[80] These hydrolytic pathways account for the majority of the urinary metabolites of cocaine. Minor pathways include trans-

esterification of cocaine to cocaethylene by a liver cocaine carboxylesterase in the presence of ethanol, demethylation to norcocaine by cytochrome P450 isoenzymes, and the formation of several oxidative metabolites (*p*-hydroxycocaine, *p*-hydroxybenzoylecgonine, *m*-hydroxybenzoylecgonine) as demonstrated in Figure 56.8. Benzoylecgonine is the major metabolite of cocaine in the body. However, there is substantial interindividual and route-dependent variation in the biotransformation of cocaine. Enzymatic (liver methylesterase and carboxylesterase) and, to a lesser extent, spontaneous chemical hydrolysis of cocaine to benzoylecgonine accounts for ~30–45% of the total urinary cocaine metabolite in humans, depending on route of administration and interindividual variation.[81,82] In a study of 6 volunteers administered bioequivalent doses of cocaine by the IV, intranasal, and smoked routes, urinary benzoylecgonine accounted for approximately 39%, 30%, and 16%, respectively, of the administered dose.[80] In a similar pharmacokinetic study of 4 occasional cocaine users receiving IV, intranasal, and inhaled doses of tritiated cocaine, urinary benzoylecgonine represented about 36%, 39%, and 26% of the total cocaine dose, respectively.[73] The enzymatic hydrolysis of cocaine by

plasma and hepatic cholinesterases to ecgonine methyl ester accounts for ~5–40% of the total urinary metabolites of cocaine, depending on the route of exposure, species, and individual pharmacokinetics.[83]

The role of hepatic cytochrome P450 isoenzymes in the metabolism of cocaine is minor.[84] The enzyme-mediated demethylation of cocaine by the CYP3A isoenzymes to norcocaine and sequentially to *N*-hydroxynorcocaine accounts for about 2.6–6.2% of cocaine metabolism.[85,86] Other minor metabolites (<2% total) of cocaine include norcocaine, benzoylnorecgonine, ecgonidine, norecgonidine methyl ester, norecgonine methyl ester, *m*-hydroxybenzoylecgonine, *p*-hydroxybenzoylecgonine, *m*-hydroxycocaine, and *p*-hydroxycocaine.[80,87] The pyrolysis of cocaine during smoking produces benzoic acid and anhydroecgonine methyl ester (methylecgonidine), and the presence of the latter compound in the urine indicates the administration of cocaine by smoking rather than injection or insufflation.[88] Of 81 urine samples testing positive for cocaine using the enzyme-multiplied immunoassay technique, 12 (15%) were positive for anhydroecgonine methyl ester at concentrations ranging from 4–226 ng/mL as measured by GC/MS.[89] In this study, 7 hair samples were positive for anhydroecgonine methyl ester at a mean concentration of 0.6 ng/mg (range, 0.2–2.4 ng/mg).

Elimination

The elimination of cocaine from the blood is rapid with a biologic half-life of approximately 1 hour, and the plasma clearance of cocaine averages about 20–30 mL/kg/min.[59] Early studies of cocaine doses from 0.2–2 mg/kg suggest first-order (i.e., dose-dependent) kinetics,[68] whereas another study of chronic cocaine users demonstrated a 2-compartment system after a 32-mg IV dose.[92] Saturation may occur at very high cocaine dosages, resulting in changes in the elimination kinetics. Additionally, there is substantial intra- and interindividual variation in the elimination half-life of cocaine, probably because of differences in the route of exposure and plasma cholinesterase activity.[90,91] For example, the apparent plasma half-life of cocaine is slightly longer following insufflation than after oral administration, probably as a result of continued nasal adsorption. In chronic cocaine users, the plasma cocaine half-life averaged 48 minutes after a 32-mg IV injection.[92] The mean elimination half-life for cocaine following the intranasal administration of cocaine to 7 recreational users was 75 ± 5 minutes compared with 48 ± 3 minutes for the oral administration of cocaine to 4 recreational users. Cocaine plasma levels remain detectable for approximately 4–6 hours. Recent phar-macokinetic studies with more sensitive analytic methods suggest that lipid-soluble tissues may store small amounts of cocaine, resulting in an extended terminal plasma cocaine elimination half-life (4–5 h).[74]

The hydrolysis of cocaine to benzoylecgonine and ecgonine methyl ester represents ~80–90% of the urinary metabolites of cocaine with the renal excretion of unchanged cocaine accounting for <5% of the absorbed dose, depending on pH.[93] In a study of 3 cocaine users receiving an IV infusion of 253–700 mg cocaine, benzoylecgonine, and ecgonine methyl ester accounted for 14–17% and 12–21% of the cocaine dose during the first 30 hours after administration.[94] Unchanged cocaine accounted for about 2% of the absorbed dose during this period. The elimination of the 2 major cocaine metabolites is slower than the elimination of cocaine from the blood with an average urinary half-life of benzoylecgonine being slightly shorter than the urinary half-life of ecgonine methyl ester.[81] In a study of 5 IV cocaine users, the mean urinary elimination half-life of benzoylecgonine and ecgonine methyl ester was 3.1 hours and 4.5 hours, respectively.[94] Increased renal excretion of cocaine occurs in acidic urine. However, alteration of pH does not result in the accumulation of ecgonine methyl ester because the rate of the hydrolysis of this metabolite exceeds both the rate of formation and the rate of hydrolysis of cocaine to benzoylecgonine.[95]

Maternal and Fetal Kinetics

Case reports of adverse effects in infants born to cocaine-using mothers indicate that cocaine crosses the placenta and that both cocaine and benzoylecgonine enter fetal blood and brain tissue.[96,97] The cocaine concentration in fetal brain tissue exceeds plasma cocaine concentrations within several hours of administration, but the ratio of brain/plasma cocaine concentrations in the fetus is lower than in adults because of the lower lipid content of the fetal brain.[63] At autopsy, the highest cocaine concentrations are found in the urine and kidney, followed by the brain, blood, liver, and bile. A cerebral infarction occurred in the fetus of a cocaine user.[98] Some case reports suggest that cocaine diffuses into breast milk. A 2-week-old, breast-fed neonate developed tremulousness, irritability, and exaggerated startle response 1 week after her mother began using cocaine.[99] During the first day of admission to the hospital, samples of maternal milk and urine from the infant contained both cocaine and benzoylecgonine. Animal studies using ^{3}H-cocaine demonstrated a mean breast milk/maternal blood cocaine ratio of 7.8.[63] However, there are inadequate pharmacokinetic data to determine the extent of cocaine diffusion into breast

milk, particularly given the rapid biotransformation and instability of cocaine in blood.

Tolerance

Although tolerance to the therapeutic effects of cocaine does not occur, most chronic drug users develop tolerance to the euphoric and, to a lesser extent, to the cardiovascular effects of cocaine.[100] Case reports suggest that some chronic users, particularly freebase cocaine smokers, develop tolerance to large doses (>1 g) of cocaine.[101] Animal studies demonstrate that repetitive administration of cocaine produces tolerance to the convulsant and cardiorespiratory stimulatory properties of cocaine.[102]

Acute tolerance (tachyphylaxis) reduces the euphoric and chronotropic effects of cocaine within the same, but not different experimental sessions as demonstrated in volunteers administered cocaine via IV injection, insufflation, or inhalation.[103] Consequently, the cardiovascular and subjective effects of single cocaine doses dissipate more rapidly than expected from the elimination half-life. For cardiovascular effects and some subjective effects measured during these studies, the effects were greater during the ascending curve of the plasma cocaine concentration than during the descending curve (i.e., Mellanby effect).[104] During studies of volunteers maintained on a constant infusion of cocaine (i.e., plasma cocaine concentration = 0.5–0.75 mg/L), the euphoric effect of cocaine peaked at about 1 hour and then declined to baseline about 4 hours after the infusion began.[105] The chronotropic effect peaked at about 10 minutes and then declined to about one-third of the peak value with a half-life of approximately 30 minutes. Within 30 minutes after the initiation of IV cocaine, self-reports of the "rush" associated with initiation of IV cocaine decreased below statistically significant levels with or without the constant cocaine infusion.

Drug Interactions

Ethanol

Many cocaine users ingest ethanol during binges, frequently with the belief that the ingestion of ethanol with cocaine reduces unpleasant side effects of the "crash" associated with cocaine use as well as enhancing or prolonging the euphoria associated with cocaine use.[106,107] Volunteer studies suggest that the simultaneous or recent ingestion of social doses of ethanol with the intranasal administration of cocaine increases peak plasma cocaine concentrations approximately 20% compared with the exposure to cocaine alone.[108] The increased cocaine concentrations were associated with

enhanced subjective feelings of euphoria and well-being compared with the use of cocaine alone. Experimental studies suggest that the ingestion of ethanol 30 minutes after the administration of cocaine significantly reduces the subjective effects associated with the simultaneous ingestion of ethanol and exposure to cocaine.[109] Cocaine, ethanol, and cocaethylene frequently are present in biologic samples from trauma patients. In a study of 415 consecutive admissions to an urban trauma center, approximately one-third of the admission urine samples contained evidence of benzoylecgonine, and blood samples from about one-half of these patients contained cocaethylene.[110] All 114 admission blood samples from the group of trauma patients with positive urine samples for benzoylecgonine were positive for cocaine with the serum cocaine concentrations ranging from 0.04–0.70 mg/L (mean, 0.093 mg/L). About 56% of these 114 blood samples were positive for ethanol (mean, 175 ± 85 mg/dL), whereas 60% of these 114 blood samples tested positive for cocaethylene (mean, 0.041 mg/L; range, 0.003–0.213 mg/L). Plasma cocaethylene concentrations did not correlate well to blood ethanol concentrations.

PHARMACOKINETICS.   Cocaethylene, the ethyl ester of benzoylecgonine, is a marker of the simultaneous use of cocaine and ethanol, and the metabolic pathways of cocaine and cocaethylene are similar.[111] In the presence of a hepatic carboxyltransferase, the transesterification of cocaine with ethanol produces an active, but somewhat less potent metabolite, cocaethylene (ethyl cocaine).[112] Figure 56.8 demonstrates the metabolic pathways for cocaethylene and cocaine. The simultaneous use of cocaine and ethanol increases the serum cocaine concentration and reduces serum benzoylecgonine concentrations compared with the cocaine-only use.

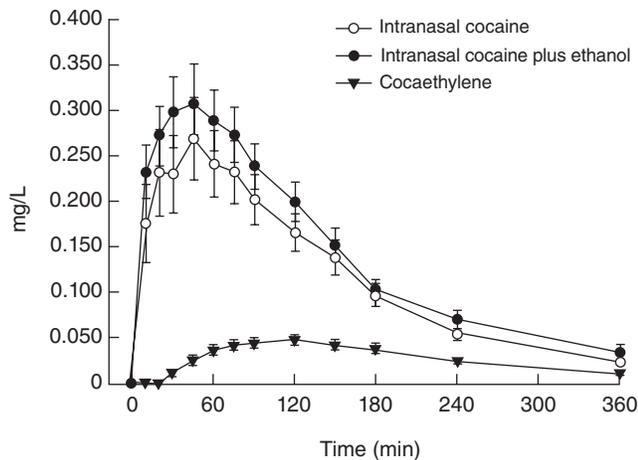
In volunteer studies using social doses of ethanol (0.8 g/kg) and intranasal cocaine (1.25 or 1.9 mg/kg) together, the peak plasma cocaethylene concentration is usually lower (i.e., 15–20%) than the plasma cocaine concentration with the peak cocaethylene concentration occurring about 1 hour later than the peak cocaine concentration.[113] In a study of 8 volunteers receiving 100 mg intranasal cocaine and ethanol simultaneously, the mean peak plasma concentrations of cocaethylene and cocaine were 0.0485 ± 0.0147 mg/L and 0.331 ± 0.112 mg/L, respectively, whereas the mean peak plasma ethanol concentration was approximately 100 mg/dL.[108] The mean times to the peak cocaethylene and cocaine concentrations were 116.3 ± 9.9 minutes and 41.3 ± 22.3 minutes, respectively. Figure 56.9 demonstrates the time course of cocaethylene and cocaine concentrations after simultaneous ingestion of 0.8 g ethanol/kg and


Figure 56.9. Time course comparing plasma cocaine (○) following 100 mg intranasal cocaine with plasma cocaine (●) and cocaethylene (▼) concentrations after administration of 100 mg intranasal cocaine and the simultaneous ingestion of 0.8 g ethanol/kg. Reprinted with permission from M Farré, RDL Torre, ML González, MT Terán, PN Roset, E Menoyo, J Camí, Cocaine and alcohol interactions in humans: neuroendocrine effects and cocaethylene metabolism, Journal of Pharmacology and Experimental Therapeutics, Vol. 283, p. 173, copyright 1997.

intranasal administration of 100 mg cocaine compared with cocaine concentrations following the insufflation of 100 mg cocaine without ethanol. Following intranasal administration of single or multiple doses of cocaine and ethanol, the peak concentration of cocaethylene is about 15–25% of the peak concentration of cocaine.[114] In a study of cocaethylene formation following different routes of deuterium-labeled cocaine and ethanol administration to 6 healthy volunteers, the percentage of cocaine converted to cocaethylene was as follows: oral, 34% ± 20%; intravenous, 24% ± 11%; and smoked, 18% ± 11% (excluding 2 participants with near zero delivery).[115] Only the difference in cocaethylene formation between the smoked and oral routes was statistically significant. The cocaine was administered 1 hour after the ingestion of 1 mg ethanol/kg. Although plasma clearance of cocaine decreases during the combined use of cocaine and ethanol, elimination rates of cocaine and ethanol remain unchanged.

A study of 10 volunteers receiving IV doses of cocaine up to 1.2 mg/kg 1 hour after the ingestion of ethanol (1 g/kg) demonstrated that an average of about 17% ± 6% of the cocaine was converted to cocaethylene and the urine benzoylecgonine excretion decreased by approximately 48%.[116] Although cocaethylene concentrations are relatively low compared with cocaine following single doses of cocaine and ethanol,[117] plasma cocaethylene concentrations can exceed plasma cocaine

concentrations in samples from chronic or binge cocaine abusers as a result of the relatively longer half-life of cocaethylene compared with cocaine. In a series of 41 trauma patients presenting to an urban emergency department with detectable plasma concentrations of cocaethylene, the mean plasma ratio of cocaethylene/cocaine was 1.3 with a range of 0.1–4.7.[118] The longer plasma half-life of cocaethylene compared with cocaine may account for the range of plasma cocaine/cocaethylene ratios present in trauma patients.[118] Volunteer studies indicate that the administration of single, IV, or intranasal doses of cocaethylene produces an elimination half-life for cocaethylene approximately 1.5–2 times longer than the cocaine elimination half-life.[119] Norcocaethylene is a minor *N*-demethylated metabolite of cocaethylene that occurs in relatively small concentrations compared with cocaethylene. Norcocaethylene displays a slightly longer (i.e., ~3 h vs. 2 h) plasma elimination half-life compared with norcocaine.[111] Detoxification of cocaethylene involves the formation of benzoylecgonine and ecgonine ethyl ester, similar to the biotransformation of cocaine.

PHARMACODYNAMICS.   The toxicologic profile of cocaethylene is similar to cocaine, and the effects of cocaethylene are additive to those of cocaine, although somewhat less potent intravenously than intranasally.[111,120] In volunteer studies, the intranasal administration of equivalent doses of cocaine and cocaethylene produced a similar rating of euphoria, although the euphoria tends to last longer following the administration of cocaethylene.[121] The difference in the duration of effect reflects the slower clearance, larger volume of distribution and correspondingly longer elimination half-life of cocaethylene compared with cocaine. Although experimental studies suggest that the effects of cocaine and cocaethylene are similar after intranasal administration, the IV cocaethylene is less potent than IV cocaine.[122] In a study of 6 paid volunteers, the IV administration of 0.25 mg/kg cocaethylene base produced a mean rating of "high" at ~65% of the rating for an IV injection of an equivalent dose of cocaine base.[120]

Cocaine antagonizes some of the deleterious effects of ethanol by reducing the feeling of drunkenness and ameliorating some of the impairment of psychomotor tasks (e.g., digit symbol substitution) caused by ethanol.[123] Cocaethylene binds to the dopamine transporter with the same affinity as cocaine, blocks dopamine uptake and increases extracellular concentrations of dopamine in the nucleus accumbens.[124] However, rodent studies indicate that cocaethylene acts more selectively on serotonin uptake than cocaine as a result of substantially less binding of cocaethylene to the serotonin transporter compared with cocaine.[125]

Drugs that affect catecholamine metabolism (e.g., guanethidine, dopamine, α-methyldopa, tricyclic antidepressants, monoamine oxidase inhibitors) enhance the sympathomimetic effects of cocaine. Potentially, monoamine oxidase inhibitors may augment the hypertensive effects of cocaine, but there are limited data on this interaction. The administration of selegiline, an irreversible monoamine oxidase-B (MAO-B) inhibitor did not enhance the cardiovascular effects of 40-mg IV cocaine in 5 volunteers.[126] In general, the use of tricyclic antidepressants, trazodone, and selective serotonin reuptake inhibitors (e.g., fluoxetine, paroxetine, sertraline) with cocaine does not cause any increased risk of side effects.[127] *In vitro* amitriptyline is a partial competitive inhibitor of human serum butyrylcholinesterase (K_i = 0.01 mM), but there are few clinical data to determine the clinical significance of this potential interaction.[128] Pretreatment of volunteers with haloperidol reduces the cocaine-induced increase in blood pressure, but haloperidol does not change the effect of cocaine on heart rate.[129]

Heroin often is used concomitantly with cocaine (i.e., Speedball) to enhance the cocaine-induced euphoria and reduce the overstimulation of cocaine. The interaction between opioids and the dopaminergic system is complex; opioid antagonist and agonists produce a variable effect on the euphoria associated with cocaine use.[127] Coadministration of cocaine with other stimulants is common because sympathomimetic drugs are frequently adulterants in illicit cocaine. Animal data on the simultaneous administration of cocaine and amphetamines are conflicting with some studies suggesting that cocaine may block the uptake of amphetamines.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Cocaine is a powerful CNS stimulant and sympathomimetic agent that produces effects through the potentiation of neurotransmitters, principally norepinephrine and epinephrine. Cocaine also has demonstrable effects on dopamine and serotonin.

Mechanism of Action

Cocaine has potent sympathomimetic effects in addition to stimulating norepinephrine, serotonin, and dopamine release. Cocaine is also a local anesthetic that reduces sodium ion flux during the depolarization of peripheral nerves by blockade of the voltage-gated sodium channels and thereby increases the threshold required to generate an action potential.[130] The anesthetic and local vasoconstrictive properties of cocaine make topical cocaine an excellent treatment for nasal hemorrhage. However, long-term insufflation of cocaine causes chronic inflammation of the nasal mucosa[131] as well as perforation of the nasal septum.[132] Cocaine causes mydriasis both by local and by central α-adrenergic effects on the radial muscles of the iris. Partial cycloplegia also occurs. Cocaine and amphetamine have similar effects on catecholamine reuptake inhibition, dopamine release, and serotonin release/reuptake inhibition; however, cocaine has marked local anesthetic activity compared with minimal activity for amphetamine. Additionally, cocaine has no monoamine oxidase inhibition (MAOI), whereas amphetamine has mild MAOI activity.

Mechanism of Toxicity

Cocaine exerts toxicity through 2 mechanisms that include 1) potentiation of catecholamine action (i.e., dopamine, norepinephrine) as a result of the inhibition of reuptake at the adrenergic nerve terminals, and 2) the inhibition of voltage-dependent sodium ion channels.[133] The latter effect reflects the local anesthetic properties of cocaine and evidence of blockade of the voltage-dependent sodium ion channels during animal studies occurs at cocaine concentrations 10 times higher than the effects of catecholamine potentiation.[134] Cocaine also stimulates the release of excitatory amino acids and enhances thrombosis by promoting platelet aggregation, impairing thrombolysis via increased TPA-inactivator, and accelerating atherogenesis.

Cocaine inhibits the synaptosomal uptake of catecholamines and serotonin. Blockade of the reuptake of norepinephrine at preganglionic sympathetic nerve endings in the sympathetic system produces an excess of norepinephrine in the synaptic cleft. Neuronal uptake is the primary method of eliminating catecholamines from the synaptic cleft, and cocaine intensifies the catecholamine effects at the nerve endings through blockade of catecholamine reuptake. The dopamine transporter is a transmembrane spanning protein that moves dopamine across the neuronal membrane.[135] Diffusion and binding to the dopamine transporter protein clears dopamine from the neuron after the release of dopamine from presynaptic terminals. Cocaine effectively binds dopamine transporters at low doses; at behavior-altering doses, cocaine occupies a majority of the dopamine

transporters.[135] Cocaine blocks dopamine transporter proteins, particularly in mesolimbic (nucleus accumbens) dopaminergic neurons, and this effect is important to the reinforcing properties of cocaine.[136] The rapid uptake and clearance of cocaine from the brain correlates to the euphoria associated with IV cocaine use, and the inhibition of the dopamine transporter correlates to the reinforcing properties of cocaine.[137]

In the primate brain, cocaine acts primarily on the synaptic dopamine reuptake system by binding to a specific receptor on the dopamine synaptic plasma membrane in both the nigrostriatal (caudate-putamen) and the mesolimbic dopamine neurons rather than on the dopamine synaptic vesicles.[138,139] The prolonged presence of dopamine in the synapse produces simulation of the dopamine receptors in the caudate-putamen and nucleus accumbens.[140] Self-stimulation models in animals suggest that activation of mesolimbic and nigrostriatal dopaminergic pathways may cause the euphoria and compulsive drug behavior associated with chronic cocaine abuse.[28] Chronic cocaine use causes modest elevation of dopamine transporter concentrations in the mesolimbic regions of the brain in acutely (<96 h) abstinent chronic cocaine abusers.[141] Upregulation of the cocaine binding sites in the striatum results in the need for continued cocaine use to experience the reenforcing effects of the drug.

The increase in dopamine neurotransmission from the competitive blockade of high-affinity dopamine uptake mediated by both D_1 and D_2 dopamine receptors is the primary determinant of the acute behavioral effects of cocaine.[142] Although *in vitro* studies indicate that cocaine can potentiate the D_2 receptor-mediated depolarizing effects of dopamine, the hyperpolarizing effect of dopamine acting on the postsynaptic D_1 receptors via increased outward potassium conductance probably accounts for the inhibitor effect of cocaine on postsynaptic cells in the caudate, nucleus accumbens, and medial prefrontal cortex.[143] Extracellular concentrations of serotonin in the nucleus accumbens also increase during cocaine administration and the serotonin system by modulating dopamine release during both the stimulatory and withdrawal phases.[144] In rodent studies, cocaine doses that maintain self-administration behavior inhibit the norepinephrine transporter at peripheral sympathetic nerve terminals.[145]

With increasing doses, cocaine causes a rostral-caudal stimulation beginning with the cortex. Initially, euphoria, hyperactivity, restlessness, and garrulity occur. Progressive activation of the lower brain centers results in tremor, hyperreflexia, and convulsions. Animal studies indicate that cocaine increases extraneuronal levels of aspartate and glutamate in the nucleus accumbens,[146] but the clinical significance of these changes remains undefined. In high doses, a period of depression develops subsequent to the excitatory phase. Mechanisms for the development of seizures following cocaine exposure include direct irritation of epileptogenic foci, toxic effects of adulterants (e.g., lidocaine, amphetamine), and cerebral vasculitis.[147] Seizures may also result from the occurrence of subarachnoid hemorrhage or focal cerebral ischemia. Based on the lack of vascular pathology in cases of cocaine-associated strokes, cerebral vasospasm or vasoconstriction may contribute to the development of cocaine-associated ischemic and hemorrhagic strokes.[148]

Excited delirium shares many similarities to neuroleptic malignant syndrome and potential mechanisms of toxicity, but the pathophysiology of this syndrome is unclear. Suggested hypotheses include chronic alterations of presynaptic proteins (α-synuclein) in dopamine neurons in the midbrain, dopamine transporter, and/or dopamine D_2 receptors in the thermoregulatory centers of the brain.[149,150] Clarification of the mechanism of toxicity producing excited delirium requires further research.

Cardiovascular System

Serious complications (e.g., life-threatening arrhythmias, acute reversible myocarditis, dilated cardiomyopathy, myocardial infarction [MI], sudden death) of myocardial ischemia result from the imbalance between myocardial oxygen demand and supply during cocaine use.[151] The etiology of this imbalance is multifactorial including intracoronary thrombosis, platelet aggregation, and coronary artery vasoconstriction. Animal data and indirect human data suggests that chronic cocaine use accelerates atherosclerosis; however, the degree of atherosclerosis associated with chronic cocaine use remains somewhat controversial. A 15-year longitudinal study of 18- to 30-year-old men and women did not detect an increased prevalence of accelerated atherosclerosis in the subset of individuals with long-term, heavy cocaine use.[152] In an age- and gender-matched cohort study of 412 patients presenting to an urban emergency department with acute chest pain, 44 patients (9%) had a history of chronic cocaine use.[153] These patients had a statistically significant, sixfold higher risk for acute coronary syndrome (OR = 5.79, 95% CI: 1.24–27.02, P = .02); however, cocaine use was not associated with a higher prevalence of any plaque (P > .58), calcified plaque (P > .58), noncalcified plaque (P > .58), or the presence of significant coronary artery stenosis (P = .09).

Cocaine directly inhibits the cardiac ion channels and increases sympathetic stimulation to the heart and coronary vasculature.[154] Cocaine produces a characteristic

voltage- and frequency-dependent inhibition of the cardiac sodium current. Experimental data suggests that this inhibition occurs as a result of the blockade of the pore and the stabilization of the channels in the inactivated state.[155] A cross-sectional study of IV drug users suggests that chronic cocaine use affects some diastolic functional parameters (e.g., increased average deceleration time),[156] but the restriction of the study group to inner city IV drug users including HIV-positive patients limits conclusions regarding the effect of chronic cocaine use on other types of cocaine users. Adrenergic adaptive mechanisms mediate the chronic tolerance of experimental animals to the cardiovascular effects of cocaine.

HEMODYNAMIC CHANGES. The administration of moderate doses of cocaine (2 mg/kg intranasal) to volunteers produces mild (8–12%) coronary artery vasoconstriction and a mean reduction (~8%) in coronary sinus blood flow, even in the presence of increased myocardial oxygen demand.[157] These changes were not associated with chest pain or electrocardiographic (ECG) evidence of ischemia. Recreational doses of cocaine produce modest increases in blood pressure (20 mm Hg systolic/10 mm Hg diastolic) and heart rate (30 beats/min) that are similar to the hemodynamic changes during mild exercise.[158] Animal studies indicate that central stimulation of sympathoadrenal neural axis activity plays an important role in the development of these cardiovascular effects because inhibition of peripheral sympathetic neuronal amine uptake mechanism by cocaine is not critical for initiating hypertension, tachycardia, or release of plasma catecholamine.[159] The sympathomimetic response probably results from the blockade of norepinephrine and epinephrine uptake, which causes increased neurotransmitter concentrations at central adrenergic receptors.[45] α-Adrenergic-mediated actions probably are involved in the development of coronary artery vasoconstriction. During cocaine use, phentolamine blocks this vasoconstriction, whereas nonselective β-adrenoceptor blocking agents enhance α-adrenergic-mediated effects (vasoconstriction, increase systemic vascular resistance).[160] Other potential causes of cocaine-induced vasoconstriction include a direct effect on increased calcium influx in vascular smooth muscle and the release of vasoconstrictive factors (e.g., endothelin).[161]

DYSRHYTHMIAS. The permeability of the cardiac myocyte membrane to various cations (sodium, potassium, calcium) determines the resting conditions across the membrane (phase 4 of the action potential). The sodium-potassium exchange pump, the sodium-calcium exchanger current, and the inwardly rectifying potassium current maintain the resting membrane potential. During resting conditions, the voltage-dependent

sodium channels are closed, and the opening of the sodium channels initiates the action potential (phase 0). Phase 1 (R and S wave on the ECG) involves the inactivation of the sodium channels along with the extracellular movement of potassium and the intracellular movement of calcium. Cocaine slowly binds and disassociates from the sodium channel, resulting in the blocking of these channels in the open state and prevention of the return of the sodium channels to the inactive, resting state.[162] This action is characteristic of Vaughan-Williams Class Ic antiarrhythmic drugs (flecainide, moricizine).

In large doses, cocaine can directly depress myocardial conduction and contractility, similar to other local anesthetic agents.[163] These local anesthetic properties result from the inhibition of sodium influx into myocardial cells and the propagation of the action potential by the blockage of the myocardial fast sodium channels during phase 0 of the cardiac action potential.[164] The resulting QRS widening is similar to the effects of Vaughn-Williams type 1A and 1C antidysrhythmic agents. Cocaine also blocks potassium efflux channels in the heart resulting in QTc prolongation. In addition, increased dispersion of ventricular refractoriness and ventricular effective refractory period occurs. In overdose, the cocaine-induced blockade of cardiac sodium channels in the closed state causes prolongation of the action potential, QRS prolongation, and wide-complex tachydysrhythmias. Although *in vitro* studies indicate that the major cocaine metabolites (benzoylecgonine, ecgonine methyl ester) have little or no effect on the sodium channel, the ethanol-derived metabolite (cocaethylene) produces more potent and prolonged blockade of the sodium channel than cocaine.[165] The inhibition of impulse conduction by alterations of sodium membrane permeability may cause sudden death.[166]

Animal studies also indicate that cocaine has electrophysiologic effects of class I antiarrhythmic agents (prolongation of the effective refractory period, depression of automaticity/phase 0 depolarization).[167] The administration of a continuous 3-hour infusion of cocaine at 0.11 mg/kg/min (total dose: 20 mg/kg) to anesthetized dogs increases the ventricular fibrillation threshold about 50% compared with placebo (lactose dissolved in normal saline).[168] However, large doses of cocaine prolong the QRS complex and QTc duration that along with hypoxia, acidosis, and underlying cardiovascular disease increase the risk of developing ventricular dysrhythmias, including ventricular fibrillation.[169] Both tachycardia and acidosis increase the binding of cocaine to the sodium channels and increase the risk of serious dysrhythmias.[170] Other mechanisms for dysrhythmias include myocarditis, myocardial ischemia, intense sympathetic stimulation (contraction band necrosis), and the development of myocardial fibrosis.

The administration of high-dose cocaine (5 mg/kg) intravenously to dogs produces negative inotropic and potent type I electrophysiologic effects as manifest by decreased blood pressure, cardiac output, and coronary blood flow, as well as prolongation of cardiac conduction (increased PR, QRS, QT intervals).[171] The effects of cocaine on repolarization are biphasic resulting in 2 distinct clinical profiles based on case reports of electrocardiographically documented life-threatening dysrhythmias associated with cocaine.[172] In overdose, a monomorphic slow ventricular tachycardia or idioventricular rhythm develops, reflecting excessive sodium channel blockade. The second type of dysrhythmia reflects potassium channel blockage and is expressed as *torsade de pointes* in recreational users with underlying risk factors (e.g., congenital long QT syndrome).

MYOCARDIAL INFARCTION. The pathophysiology of cocaine-associated myocardial ischemia is multifactorial. Mechanisms of this cardiac complication include 1) increased myocardial oxygen demand in the setting of limited oxygen supply, 2) enhanced platelet aggregation and thrombus formation, and 3) coronary artery vasospasm.[173] Depending on the individual (e.g., preexisting cardiovascular disease, polydrug use, adulterants) one or several of these factors may contribute to the development of myocardial ischemia. Structural narrowing of the coronary arteries is common in patients with cocaine-related MIs.[174] Rarely, patients in substance abuse treatment programs for cocaine dependency may develop signs of silent myocardial ischemia during the first few weeks of withdrawal, but the mechanism for these changes is unclear. In a study of 21 patients with cocaine addiction undergoing Holter monitoring, 8 of these patients developed ST elevation during the first 2 weeks of withdrawal.[175] Sudden death can occur as a result of excited delirium (hyperthermia, psychotic behavior, respiratory arrest) as well as from ventricular dysrhythmias.[176]

RESPIRATORY SYSTEM

The pathologic changes of the lung associated with cocaine abuse are multifactorial, route-dependent, and in some cases idiopathic. These pulmonary changes include vascular lesions (microemboli, spasm with thrombosis, hemorrhage, edema, arterial medial hypertrophy),[177] bronchospasm in asthmatic patients, interstitial disease, hypersensitivity pulmonary disease ("crack lung"),[178] bronchiolitis obliterans,[179] barotrauma (pneumothorax, pneumomediastinum), lung cavitations, pleural empyema, and inhalation injuries (aspiration, thermal damage, foreign body deposits).[180] The etiologies of these changes are diverse and include the follow-

ing: pulmonary hemorrhage/edema from microvascular injury, thermal airway injury, hypersensitivity reactions, interstitial pulmonary fibrosis, and foreign body reactions.[181] In rodent studies, chronic crack cocaine inhalation causes extensive histologic changes in the entire respiratory tract. Following 2 months of daily exposure of 2-month-old BALB/c mice to the smoke of 5-g crack cocaine in an inhalation chamber, histologic changes in the respiratory tract included increased mucus content of the nasal epithelium, alveolar hemosiderin, and alveolar/bronchiolar macrophage cell density as well as reduced thickness of the nasal and bronchial epithelium.[182] Case reports associate crack cocaine use with diffuse histologic changes in the lungs manifest by infected bronchiectasis, interstitial desquamative pneumonia, diffuse alveolar damage, subsegmental arterial thrombosis, and foci of pulmonary infarction.[183] Clinical studies indicate that alveolar hemorrhage occurs frequently in otherwise healthy crack cocaine smokers without obvious evidence of hemoptysis or cough.[184] Histologic changes associated with crack lung include diffuse alveolar damage, alveolar hemorrhage, and eosinophilic interstitial and alveolar infiltrates with deposition of IgE.

TEMPERATURE

Large doses of cocaine produce hyperthermia by one or more of the following mechanisms: 1) increased heat production secondary to muscular hyperactivity and/or seizures, 2) direct pyogenic action on the central thermoregulatory centers in the hypothalamus, 3) reduction of heat loss by vasoconstriction, and 4) increased calorigenic activity in the liver. Volunteer studies suggest that low doses of intranasal cocaine impair thermoregulatory adjustments for the dissipation of heat. In as study of 7 cocaine-naïve volunteers subjected to progressive passive heat stress, the nasal administration of 2-mg cocaine/kg shifts the esophageal temperature threshold for cutaneous vasodilation and sweating as well as reducing the discomfort associated with heat stress.[185] These changes potentially disrupt normal autonomic responses to thermal stress as well as limit behavioral adjustments and predispose patients to hyperthermia in hot environments. However, the administration of this cocaine dose does not cause changes in core temperature in the absence of heat stress.

Rhabdomyolysis is a common complication of cocaine-induced hyperthermia, although rhabdomyolysis may develop without elevated body temperature.[186] Animal studies indicate that antagonism of dopamine receptors, particularly the DA-1 subtype, abolish cocaine-induced hyperthermia;[187] downregulation of brainstem D_1 dopamine receptors by cocaine abuse may

also contribute to the development of hyperthermia and death.[188] In fatal cases of excited delirium, marked hyperthermia usually precedes the development of status epilepticus, hypotension, rhabdomyolysis, disseminated intravascular coagulation, acute hepatorenal failure, impaired cerebral function, and death.[189] Animal models indicate that intrabrain heat production is the primary cause of functional brain hyperthermia; the cerebral circulation dissipates potentially dangerous heat from brain tissue by bringing relatively cooler blood and subsequently removing warmed blood.[190] Although cocaine induces metabolic activation of central neurons, modulations of thermal effects from both behavior and environmental variables result in relative stable brain temperatures, depending upon previous drug effect; however, the vasoconstrictive effects of cocaine during strenuous exercise in a hot, humid environment may cause serious elevation of brain temperatures and fatal hyperthermia.

GASTROINTESTINAL TRACT

Cocaine can produce nausea and vomiting via stimulation of the central vomiting centers with diarrhea and abdominal cramps developing from sympathomimetic effects on the intestinal wall. Cocaine is an intrinsic hepatotoxin in laboratory animals, but there are limited data on hepatotoxicity in humans in the absence of hyperthermia.[191] Potentially, animal models and *in vitro* studies suggest that reduced glutathione stores and the subsequent development of a reactive intermediate metabolite produce hepatic damage similar to acetaminophen toxicity.[192] However, hepatotoxicity is not a well-recognized complication of cocaine intoxication in humans except as a result of hyperthermia. Other gastrointestinal (GI) complications of cocaine abuse include GI perforation/hemorrhage, pneumoperitoneum, and mesenteric ischemia.[193]

KIDNEY

Renal complications associated with cocaine abuse include acute renal failure, renal infarction, and electrolyte imbalance.[194] Causes of acute renal failure associated with cocaine abuse include acute rhabdomyolysis,[195] hypertension,[196] interstitial nephritis,[197] thrombotic microangiopathy,[198] and antiglomerular basement membrane nephritis.[199]

Postmortem Examination

The pathologic findings on the postmortem examination of fatalities associated with recreational cocaine abuse are diverse and nonspecific because of the frequency of polydrug use and the presence of concomitant diseases.

Mechanisms of sudden death include ventricular fibrillation, respiratory arrest secondary to direct CNS effects or hyperthermia, intracerebral hemorrhage, dissecting aortic aneurysm, and disseminated intravascular coagulation with hyperthermia. Except for IV injection sites and bite marks from preterminal seizures, postmortem examination of patients dying suddenly following cocaine use demonstrate nonspecific signs of an asphyxial death (e.g., pulmonary edema, visceral congestion, petechiae). Fresh IV sites of cocaine injection characteristically present as multiple sites of ecchymosis, occasionally with central pallor. Less scarring is present in these lesions than in those of opioid addicts because cocaine abusers usually inject soluble material (e.g., mannitol) as compared with the insoluble talc and starch present in opioids. However, fatalities of cocaine users from urban cities frequently involve other drugs (e.g., heroin, ethanol).[200,201] Postmortem signs of chronic crack smoking include focal burns of varying ages on the mucosa of the lips, tips of the tongue, and opposing surfaces of the fingers (palmer surface of thumb and index finger).[202] These injuries result from burns from the surface of hot pipes or the flames from lighters. Calluses also develop on the palmer surface of the thumbs as a result of the frequent use of a lighter to heat cocaine crystals. Occasionally, singeing of the nasal hairs or eyelashes occurs. The inhalation of carbon particles during chronic crack smoking can produce black deposits in the alveoli.

COCAINE-INDUCED EXCITED DELIRIUM

Fatalities occur following all routes of cocaine administration (smoking freebase, nasal insufflation, vaginal application, ingestion). Several case reports describe the development of intense paranoia after chronic cocaine use followed by hyperthermia, bizarre, sometimes violent behavior, respiratory arrest, and death.[203] Frequently, these cases involve chronic cocaine users restrained while in police custody or during transport to a medical facility. Pathologic findings during postmortem examination of patients who die during cocaine-associated excited (agitated) delirium are usually minimal and nonspecific with or without postmortem evidence of hyperthermia. Depending on the duration of supportive care, pathologic findings during autopsies of fatalities secondary to cocaine-induced excited delirium include skeletal muscle necrosis without evidence of vasculitis, acute tubular necrosis with granular myoglobin casts in the tubules, cerebral edema, and pulmonary congestion.[204] Although these patients are often restrained, traumatic injuries are usually minor. Postmortem measurements of dopamine synaptic markers in the striatum and hypothalamus may help

differentiate deaths from excited delirium from deaths secondary to cocaine overdose or from asphyxiation.[205] However, this evaluation must be conducted by a properly equipped laboratory on adequately preserved brain tissue collected within 12 hours of death.

HISTOLOGIC ABNORMALITIES

Although normal heart tissue on autopsy examination does not exclude chronic cocaine use, endomyocardial biopsies of chronic cocaine users without significant coronary artery disease may demonstrate contraction band necrosis (coagulative myocytolysis), focal (eosinophilic) myocarditis, or dilated cardiomyopathy.[206] The frequency of these abnormalities varies between autopsy series. The presence of contraction band necrosis suggests an acute insult (e.g., elevated blood concentrations of norepinephrine), and patchy microfocal fibrosis indicates the presence of healed areas of contraction band necrosis. In the case of a 17-year-old body stuffer, who died suddenly after ingesting a large dose of cocaine (postmortem blood cocaine = 98 mg/L), histologic examination of the heart revealed contraction band necrosis characterized by rhexis of the myofibrillar apparatus and anomalous, hypereosinophilic cross bands.[207] Segments of hypercontracted sarcomeres with extremely thickened Z lines formed these cross bands. Eosinophilic and lymphocytic infiltrates are consistent with subacute injury.[208] However, neither contraction band necrosis nor lymphocytic infiltration is a specific sign of cocaine abuse.[209] In a case-control study of 30 cocaine-associated deaths, contraction band necrosis was present in 93% of the cases compared with 45% of cases dying of sedative-hypnotic intoxication.[210] A postmortem study of 40 cocaine-associated deaths and 27 victims of sudden traumatic death did not detect a statistically significant difference in the presence of contraction band necrosis between the 2 groups (25% and 41%, respectively).[211] There was a statistically significant ($P \le .05$) difference in the presence of myocarditis (mononuclear infiltrate) between these 2 groups (20% vs. 3.7%, respectively).

Interpretation of lesions in the cardiac conduction system is somewhat controversial, and these abnormalities may be incidental to the cause of death. Potentially lethal histologic changes in the cardiac conduction system that may be present in cases of sudden death associated with cocaine use include severe thickening of the atrioventricular node artery, intranodal and perinodal fibrosis, and microscopic foci of chronic inflammatory infiltration.[212] Postmortem examinations of patients dying after cocaine use usually demonstrate either significant coronary artery disease[213] or myocardial hypertrophy with or without microfocal fibrosis.[4,214]

However, postmortem examinations indicate that pathologic evidence of a MI is absent in most cases of sudden death in cocaine abusers.[209] Typically, heart weights are about 10–15% greater than predicted from nomograms on normal heart size.[215] A case report associated chronic intimal proliferation, severe coronary artery stenosis, acute platelet thrombosis, and lymphocytic myocarditis in a 21-year-old with chronic IV cocaine abuse.[216]

Autopsies of body packers dying from cocaine intoxication reveal ruptured cots, foil, and bags as well as the usual signs of asphyxial death (e.g., pulmonary edema).[217] Severe local vascular engorgement suggesting acute ischemic necrosis is occasionally seen in areas where high, localized concentrations of cocaine exist.[361]

CLINICAL RESPONSE

Illicit Use

Altered sensation during the recreational use of cocaine typically involves visual ("snow light") and tactile (i.e., "coke bugs," formication) sensations. Olfactory and auditory illusions are much less common occurrences during cocaine use.[218] Visual misperceptions most commonly involve flashing lights in the peripheral vision ("snow lights"). Cardiovascular, CNS, and pulmonary effects are the primary complications associated with cocaine abuse. In a retrospective study of 137 patients presenting to an urban emergency department with cocaine intoxication, the most common complaints included the following: altered mental status (40%), chest pain (21%), syncope (19%), suicide attempt (13%), palpitations (12%), and seizures (12%).[219] The clinical effects of cocaine develop rapidly (<30–60 min) by all routes of exposure except ingestion, and the effects usually resolve within 2 hours after the use of a single dose of cocaine. Because of the rapid elimination half-life (<1 h) of cocaine, resolution of major symptoms occurs within 1–3 hours, unless secondary damage (e.g., hypoxic encephalopathy) or complications of hyperthermia supervene.

Complications of cocaine abuse depend somewhat on the route of exposure. Epidemiologic data indicate that the medical complications of cocaine abuse have changed with the shift from IV use to smoking and insufflation.[220] Medical effects of chronic cocaine abuse include anorexia, weight loss, malnutrition, water-soluble vitamin deficiencies, dehydration, pallor, tremor, headaches, and isolated convulsions. The complications of IV drug use include localized cellulitis or abscess, bacteremia with septic arthritis, endocarditis, hepatitis, autoimmune deficiency syndrome (AIDS), malaria,

osteomyelitis, pneumonia, and metastatic abscesses as well as necrotizing fasciitis[221] and wound botulism.[222]

Behavioral Abnormalities

Cocaine produces alertness, a sense of pleasure, a reduction of social inhibitions and anxiety, and a heightened sense of energy, self-esteem, and sexuality.[223] The euphoric effects begin within minutes and last approximately 20–45 minutes. Although cocaine enhances the feeling of pleasure, the use of this drug does not usually distort reality or produce hallucinations. After the elation subsides, restlessness, hyperactivity, irritability, and depression emerge; the development of these feeling reinforce continual cocaine use. In contrast to the feelings of sadness during the sober state, memories of drug-induced euphoria promote the continued use of cocaine. Binges or runs may last several days until either physical, financial, or drug resources are exhausted. The absence of daily use does not exclude addiction to cocaine.[223] Often, cocaine addiction involves multiple drugs of abuse including the use of sedative-hypnotics, ethanol, or heroin in an effort to counteract the rebound dysphoria ("crash") associated with cocaine use. Most casual users do not become addicted to cocaine, but some users discover that higher doses intensify the pharmacologic euphoria and they focus on internal sensations to the detriment of personal relationships and career goals. Controlled use may shift to compulsive use as the dose of cocaine increases or the user switches to more potent methods of administration (IV, smoking).

Complications from cocaine use are uncommon among low-dose users, but adverse behavioral effects are common in high-dose abusers.[223] Psychologic complications from chronic cocaine use include impaired judgment, impulsiveness, compulsive behavior, psychomotor activation, and grandiosity that may result in falls, traffic accidents, homicides, suicides, atypical sexual behavior, or criminal activity.[224,225]

Adverse neuropsychiatric effects of chronic cocaine use include insomnia, irritability, agitation, paranoia, delirium, anxiety, depression, chronic fatigue, impaired memory/concentration, and panic attacks.[59] Depending on dose, chronicity, personality, genetic predisposition, and expectations, cocaine produces a continuum of psychiatric syndromes ranging from euphoria and dysphoria to a schizophreniform psychosis similar to amphetamine-induced psychosis.[53] In a series of 996 emergency department visits and 279 hospital admissions for complications of cocaine abuse, the most common psychiatric complications were dysphoria, agitation, aggressive behavior, paranoia, psychosis, and hallucinations.[285]

High-doses of cocaine or habitual cocaine use produce profound mood changes characterized by paranoid thinking, agitation, irritability, restlessness, and impulsivity. Chronic users often become depressed, suspicious, irritable, and impotent, which reinforces continual cocaine use. Distorted thought processes can cause aggressive suicidal and homicidal behavior, impaired judgment, poor job performance, and depletion of personal finances. Attentional deficits increase the chance of accidental trauma. Recreational doses of cocaine suppress rapid eye movement (REM) sleep during the cocaine binge, and volunteer studies indicate that the REM sleep patterns do not return to normal until 3 nights after the cessation of cocaine use.[226] After cocaine use, depressive symptoms (cocaine blues, crash) and occasionally suicidal ideations appear, which the user may try to alleviate by continual drug use. Such symptoms are usually transient and resolve after resumption of normal sleep patterns. Following several days of bingeing, cocaine addicts may present with a depressed level of consciousness ranging from lethargy and hypersomnolence to lighter stages of coma (washed out syndrome).[227,228] These patients typically do not have neurologic or metabolic abnormalities on testing; within 18 hours, they usually return to their baseline mental state.

Mental Disorders

Chronic stimulant use can produce a paranoid psychosis that is similar to acute paranoid schizophrenia and methamphetamine-induced psychosis. High-dose, chronic use of cocaine is associated with dysphoria and an acute paranoid psychosis marked by delusions of persecution and paranoia as well as hallucinations, particularly auditory.[229] The paranoia typically focuses on illicit activities related to drug abuse during the cocaine binge, and the paranoia resolves by the early hypersomnolent phase of abstinence.[230,231] Consequently, the paranoid ideations last hours after the pleasurable effects of cocaine cease. Following chronic cocaine abuse, the paranoia becomes more intense and occurs earlier in the cocaine binge. In a study of 55 cocaine addicts admitted for inpatient therapy, 48% of the cocaine addicts reported the development of paranoia whenever they used cocaine.[232]

Typically, the acute psychosis associated with cocaine addicts resolves after several days of abstinence, and the patient's personality returns to baseline within approximately 5 days. In addition to the schizophrenic form psychosis, a confused toxic psychosis may develop that includes disorientation, short-term memory impairment, and organic brain dysfunction. Persistence of psychiatric symptoms beyond 5–7 days suggests an

underlying psychiatric disorder; however, case reports suggest that the psychotic symptoms associated with substance-induced psychosis may persist over 1 month in a small subset of chronic abusers.[233] Over 50% of individuals with a history of schizophrenia have a coexisting substance abuse disorder.[234] Furthermore, many individuals with substance abuse disorder have comorbid psychiatric disorders, particularly phobias, major depression, and antisocial personalities. In a study of 243 unrelated, recruited, cocaine-dependent adults, 90% of these individuals met the criteria for substance use disorders other than cocaine dependence.[235] Common nonsubstance use disorders included antisocial personality disorder (77%), major depression (10%), and attention deficit-hyperactivity disorder (10%).

Medical Complications

Cocaine intoxication and chronic cocaine abuse produce a variety of medical complications primarily involving the cardiovascular, central nervous, and the pulmonary systems. Table 56.1 outlines potential medical complications associated with cocaine abuse exclusive of reproductive effects. Cocaine overdose frequently occurs in the setting of multiple-drug use, particularly ethanol, opioids, and marijuana.[236]

CARDIAC

MYOCARDIAL ISCHEMIA AND INFARCTION.   Illicit use of cocaine increases myocardial oxygen demand by increasing the pulse and blood pressure, while reducing coronary artery diameter and increasing coronary vascular resistance.[237] The imbalance between myocardial oxygen supply and demand may produce chest pain, myocardial ischemia, or MI, particularly in patients with underlying cardiovascular disease. The overall incidence of cocaine-associated MI in patients with documented cocaine use and chest pain varies between about 0.7% (Acute Cardiac Ischemia-Time Insensitive Predictive Instrument Study)[238] and 6% (Cocaine Associated Chest Pain Study),[239] depending on the study population and the criteria for MI. The latter prospective multicenter study involved only patients presenting to urban hospitals with chest pain, whereas the former study included rural hospitals and a variety of cardiovascular complaints. Most, but not all of these patients presented to the emergency department within 3 hours of the use of cocaine. In the Determinants of Myocardial Infarction Onset Study, 38 of 3946 acute MI patients admitted using cocaine within the last year and 9 patients used cocaine within 1 hour after developing their MI.[240] The risk of MI in cocaine users increased 24-fold in the first hour after use compared with nonus-

TABLE 56.1. Potential Medical Complications of Cocaine Abuse.[59]

Organ System	Complication	Clinical Effects
Cardiovascular		
	Ischemia	Angina, myocardial infarction, cardiogenic shock, renal dysfunction/infarction, intestinal infarction, limb ischemia/compartment syndrome
	Hypertension	Intracranial hemorrhage, aortic dissection
	Dysrhythmias	Sinus tachycardia, supraventricular tachycardia, ventricular tachyarrhythmias, hypotension, cardiac arrest
	Myocarditis	
Central Nervous System		
	Seizures	Trauma, hypoxia
	Stroke	Cerebral embolism/infarction, subarachnoid hemorrhage, intracranial hemorrhage
	Neurologic deficits	Transient focal neurologic effects, altered consciousness, encephalopathy, coma
Respiratory		
	Respiratory depression/arrest, pulmonary edema	Hypoxia
	Barotrauma	Pneumomediastinum, pneumothorax
Metabolic		
	Hyperthermia	Multisystem organ failure, shock
	Rhabdomyolysis	Renal dysfunction
Immune System		
	Intravenous drug use	HIV infection, hepatitis B/C, endocarditis, wound botulism, tetanus

Abbreviation: HIV = Human immunodeficiency virus.

ers; this risk decreased rapidly to 4-fold 2 hours after using cocaine.

About 31–67% of patients with cocaine-associated MIs have arteriosclerotic coronary artery disease.[241] Most of these patients present to the emergency department within 24 hours of the last cocaine use. Myocardial ischemia and infarction occur after cocaine use from all routes of exposure, and the cocaine-induced cardiovascular complications (Q-wave and non-Q-wave MIs, myocarditis, dysrhythmias, cardiomyopathy, aortic aneurysm) are not dose-related.[242,243,244] Although most patients who develop cardiac abnormalities after cocaine use have preexisting cardiac disease,[237,245] case reports indicate that acute MI may occur in patients without angiographic evidence of coronary artery disease including patients with cocaine-associated MI and coronary artery ectasia or aneurysms.[246] Inhalation of 0.25 g of cocaine immediately preceded the development of chest pain and elevated cardiac enzymes in a 21-year-old man with structurally normal coronary arteries and a prior history of angina.[247] After the inhalation of 1.5 g of cocaine over 5 hours, a 28-year-old woman developed anterior chest pain as well as ECG and enzymatic evidence substantiating an anterior MI.[248] There was no prior history suggestive of preexisting heart disease or documented cardiovascular risk factors, and coronary angiography demonstrated no fixed coronary artery disease or ergonovine-induced coronary spasm. These case histories suggest that cocaine may produce coronary artery vasospasm or alter thrombin formation even in the absence of underlying disease as documented by normal coronary angiography and normal stress ECGs.[249]

Chest Pain. Although chest pain is a common complaint following the use of cocaine, documentation of a MI in these patients is relatively rare even in the presence of ECG changes suggestive of ischemia. The rate of MIs in patients hospitalized for chest pain after cocaine use varies from 0–31% with most studies near 6%, depending on the institution, patient population, criteria for MI, and admission policies.[250,251,252] Retrospective clinical studies indicate that recent cocaine use may affect serum myoglobin concentrations and, to a much lesser extent, serum CK-MB concentrations.[253] Elevation of creatine kinase (CK) and creatine kinase-myocardial band (CK-MB) fractions may occur following cocaine use without acute myocardial ischemia. In a study of 8 cocaine users admitted to an urban hospital with elevated CK-MB fractions and chest pain in the emergency department, only 2 patients had persistent CK-MB enzyme elevations on serial testing.[254] Recent cocaine use does not affect the specificity of serum cardiac troponin I.[253] Most patients, who develop

chest pain and a MI after cocaine use, present to the emergency department with ECG evidence of a MI.[255] Myocardial perfusion imaging did not detect significant myocardial ischemia in a prospective study of 14 patients with chest pain for >15 minutes after cocaine use and no ECG evidence of myocardial ischemia.[256] Consequently, most patients with chest pain following the use of cocaine have a low risk of developing myocardial ischemia. In a study of 293 patients with cocaine-associated chest pain enrolled in a multicenter, prospective clinical trial, 10 had acute myocardial ischemia and 2 had a documented MI.[238] Furthermore, most patients presenting to the emergency department with chest pain after cocaine use have normal cardiac function (cardiac output, cardiac index, stroke volume).[257] A prospective consecutive cohort study of cocaine-associated chest pain with low to intermediate cardiac risk have a low risk (i.e., <1%) of developing an acute MI during the first year after completing a chest pain observation unit protocol.[258] Exclusion criteria during admission and observation included the development of ECG or serum cardiac markers suggestive of acute MI, history of acute MI or coronary artery bypass graft, hemodynamic instability, and unstable angina.

Dysrhythmias. Cocaine-induced dysrhythmias commonly include sinus tachycardia and premature ventricular beats. These dysrhythmias are usually transient. The presence of underlying heart disease or the administration of massive cocaine doses are not prerequisites for the development of cocaine-associated cardiovascular complications.[259] Case reports temporally associate the use of ethanol and the nasal insufflation of cocaine with supraventricular tachycardia and myocardial ischemia as well as ventricular fibrillation and *torsade de pointes*.[260,261,262] The use of cocaine may unmask electrophysiologically silent accessory pathways resulting in the onset of life-threatening cardiac dysrhythmias.[259] In addition, the use of cocaine may prolong the QT_c interval in some, but not all, patients using cocaine and consequently potentiate the risk of ventricular fibrillation in susceptible patients (e.g., idiopathic long QT syndrome).[263] In a study of 45 cocaine abusers hospitalized for cocaine toxicity, the mean QT_c interval of the cohort with chest pain was significantly longer than the QT_c interval of the cohort without chest pain (approximately 510 ± 84 msec vs. 459 ± 74 msec, respectively).[264] Three patients in the former group developed *torsade de pointes* requiring resuscitation, whereas none of the patients in the latter group required defibrillation. High doses of cocaine may produce sodium channel blockade and direct myocardial depression similar to type I antidysrhythmic drugs.[242] Brugada syndrome is a congenital electrical disorder characterized by the appearance of

distinctive QRST-T wave patterns in the right precordial leads (i.e., coved ST elevation V_1–V_3) and an increased risk of sudden death in young healthy adults. Cocaine is one of the drugs associated with the appearance of the Brugada syndrome.[265]

During severe cocaine intoxication (hyperthermia, multiple seizures, metabolic acidosis) a variety of serious arrhythmias may develop including ventricular tachycardia and unstable wide and narrow complex bradyarrhythmias.[266] However, sudden death associated with cocaine-induced excited (agitated) delirium is usually not associated with ventricular fibrillation or ventricular tachycardia, even when Tasers or pepper sprays are used during restraining procedures. In a series of 18 cases of sudden death associated with excited delirium and restraint by law enforcement personnel, paramedics determined the rhythm of 13 individuals immediately prior to cardiac arrest.[267] Ventricular dysrhythmias were the primary cardiac arrest rhythm in only 1 of 13 cases, while ventricular fibrillation was not found in any of these 13 cases. Cocaine or amphetamine was present in the postmortem blood from 10 of these 13 cases.

MYOCARDITIS.   In a study of the postmortem examination of 40 cocaine-associated and 27 sudden trauma-related deaths, there was a statistically significant increase ($P \leq .05$) in the presence of myocarditis (mononuclear infiltrate) between these 2 groups (20% vs. 3.7%, respectively).[211] Other case reports associated cocaine abuse with eosinophilic infiltration of the myocardium.

CARDIOMYOPATHY.   Long-term, high-dose cocaine use may enhance the development of cardiomyopathy in the absence of coronary artery disease based on experimental evidence in animal models.[268] Dilated cardiomyopathy is a rare complication of cocaine abuse. A few case reports and case series associate chronic cocaine use with dilated cardiomyopathy and left ventricular dysfunction in the absence of atherosclerotic coronary artery disease.[269,270] Case reports indicate that the cardiac effects of the dilated cardiomyopathy are at least partially reversible.[271,272] During 5 months of abstinence from freebase cocaine, the left ventricular ejection fraction of a cocaine addict improved from <20% to 45%.[273] A study of 40 chronic cocaine abusers enrolled in an inpatient drug rehabilitation program demonstrated a statistically significant increase in left ventricular mass index in the cocaine group compared with 30 age-matched and race-matched controls.[274] Although ECGs indicated that left ventricular cavity dimensions and wall motion were normal in all participants, more cocaine addicts than controls (13 vs. 4) had increased posterior wall thickness.

AORTIC DISSECTION.   Although acute aortic dissection is an infrequent complication of cocaine abuse, some studies indicate that crack cocaine-associated acute aortic dissections account for about one-third of the cases, particularly in an inner city population consisting of a large number of black men with untreated hypertension.[275] In a retrospective chart review of 164 cases of acute aortic dissection at an urban hospital, 16 patients (9.8%) used cocaine in the 24-hour period prior to the onset of symptoms.[276] The mean duration between cocaine use and the onset of aortic dissection was 12.8 hours (range, 4–24 h). The incidences of DeBakey dissection types I, II, IIIa, and IIIb were similar between the cocaine users and the noncocaine users, whereas the prevalence of Stanford Group B dissections was greater in cocaine users than nonusers in another case series of 46 consecutive admissions for aortic dissection to an urban hospital.[277] A previously healthy 45-year-old man with preexisting hypertension developed a fatal, acute ascending aortic dissection after smoking freebase for several hours.[278] A 45-year-old chronic cocaine abuser developed severe, sudden, crushing substernal chest pain after a 36-hour cocaine binge.[279] He underwent successful repair of a dissecting aneurysm of the ascending aorta that required replacement of the aortic valve. Although most of these case reports document the occurrence of dissecting thoracic aneurysms in patients with cardiac risk factors (i.e., hypertension),[280,281] a few of these patients did not have known cardiac risk factors for the development of aortic aneurysms.[282,283] Almost all cases of aortic dissection involve the thoracic rather than the abdominal aorta.[284]

NEUROLOGIC

Common neurologic complications of chronic cocaine abusers admitted to medical facilities include focal neurologic deficits, seizures, headaches, and transient loss of consciousness.[285] The focal neurologic abnormalities involve visual, sensory, and motor disturbances that may result from transient ischemic events or structural lesions (stroke, subarachnoid hemorrhage). With the exception of seizures during a massive overdose of cocaine, the risk of developing neurologic complications during cocaine use is not clearly related to the dose or the route of cocaine administration.[286] In the vast majority of patients with cocaine-associated neurologic complications, symptoms develop within 6 hours of the use of cocaine. In a series of 33 patients presenting to an urban hospital with neurovascular sequelae associated with cocaine use, the percentage of patients developing these complications during cocaine use and during the subsequent 6 hours was 54.5% and 33.3%, respectively.[287] Occasional case reports associate cocaine use

with movement disorders (i.e., vocal and motor ticks, generalized dystonia, acute dystonic reaction) either as an exacerbation of a preexisting movement disorder (e.g., Tourette's syndrome)[288] or *de novo* dyskinesias attributed to cocaine use.[289] A case series of 4 patients associated cocaine use with Tourette syndrome, idiopathic dystonia/essential-like tremor, and tardive dystonia.[290]

INTRACRANIAL LESIONS. All types of strokes complicate the chronic use of cocaine including subarachnoid hemorrhage, intracerebral hemorrhage, ischemic infarction, and vasculitis.[291] Additionally, these strokes occur at a younger age and in a variety of locations including unusual areas (e.g., anterior spinal artery, bilateral thalamic lesions). Hemorrhagic strokes develop after the use of cocaine hydrochloride both via insufflation and freebase cocaine, but ischemic strokes are more common following freebase cocaine use than following the use of cocaine hydrochloride.[292,293] Although most angiographic studies of cocaine-associated strokes demonstrate the presence of arteriovenous malformations or an aneurysm, cerebrovascular lesions are absent in a minority of these cases.[294] Although the clinical prognosis of cocaine users with intracranial bleeding is unclear, a case-control study of cocaine users with subarachnoid hemorrhage did not detect a difference in the score on the Glasgow Outcome Scale between cocaine users and controls.[295] Embolic strokes are a complication of cocaine users with dilated cardiomyopathies and valvular lesions. Case reports also associate cocaine use with cerebral vasculitis manifest by focal weakness, headache, dysarthria, drowsiness, and low-grade fever.[296] Clinical features of intracranial lesions include sudden onset of severe headache, nausea, vomiting, loss of consciousness, and lateralizing neurologic signs (aphasia, hemiplegia, paresthesia, dysarthria).[297]

Toxic leukoencephalopathy is a progressive, frequently fatal neurologic disease characterized by structural alteration of cerebral white matter, particularly myelin, and consciousness that results from a variety of causes including drug abuse (e.g., heroin). Although most cases of cocaine-induced neurologic disease involves intracranial hemorrhage or vasculitis, rare case reports associate toxic leukoencephalopathy with an IV cocaine overdose[298] and cocaine abuse.[299] A case report associated cocaine abuse with toxic leukoencephalopathy that was partially reversible. A 30-year-old male developed mutism, stupor, hyperreflexia, and increased muscle tone after he continue cocaine abuse after a prior episode of toxic leukoencephalopathy resolved.[300] The fluid-attenuated inversion recovery (FLAIR) images on his MRI demonstrated diffuse symmetric hyperintensity of the periventricular white matter; he

recovered after 6 months of rehabilitation with some residual cognitive deficits (impaired short-term memory, visuospatial functions).

SEIZURES. Cocaine-associated seizures occur in patients with and without preexisting seizure disorders and in patients with massive cocaine intoxication as an agonal event.[301] Seizures in cocaine abusers following cocaine use by all routes of administration are usually isolated, generalized tonic-clonic seizures that occur during or shortly after cocaine use, but occasionally seizures may be partial.[302] In adults, seizures following the insufflation of cocaine usually occur in patients with an underlying seizure disorder.[303] In series of adults presenting to the emergency department, most patients with cocaine-associated seizures have a known history of cocaine abuse.[304] Seizures in adult patients with normal neurologic examination after the seizure are usually not associated with intracranial lesions. In a retrospective study of 33 uncomplicated, cocaine-associated seizures in patients with normal neurologic examinations, diagnostic testing did not demonstrate any neurologic abnormalities.[305] The presence of seizures along with coma and hyperthermia is an ominous prognostic sign.[286] In children, focal or generalized seizures occur following accidental ingestion of cocaine.[306] The most common neurologic complications in a case series of 41 children (age 2 months to 18 years) presenting to an emergency department following exposure to cocaine were seizures followed by obtundations and delirium.[307] Seizures in these children usually, but not always, are self-limited, depending on the amount of cocaine ingested.

HEADACHES. The abrupt onset of diffuse, severe headache immediately after using cocaine suggests the possibility of a hemorrhagic or ischemic stroke. However, headache is a nonspecific sign of intracranial hemorrhage because vascular headache is the most common adverse neurologic sign present during cocaine intoxication and withdrawal.[308] Most patients presenting with the primary complaint of headache without focal neurologic signs have a benign clinical course.[285] The use of cocaine may precipitate or aggravate migraine headaches.[309]

PULMONARY

Most pulmonary complications associated with cocaine use involve the smoking of freebase cocaine.[310] Crack lung refers to an acute, inflammatory pulmonary syndrome associated with the inhalation of freebase cocaine, manifest by fever, hemoptysis, hypoxemia, diffuse alveolar infiltrates, and in rare cases, respiratory failure.[311] The etiology of most of these pulmonary

complications is not well defined; pathologic changes include both alveolar hemorrhage and interstitial edema.[312] Chronic cough and bronchitis productive of black or blood-tinged sputum frequently result from habitual freebase smoking. Case reports associate freebase cocaine with pneumomediastinum[313,314] and pneumothorax.[315] Symptoms include pleuritic chest pain and dyspnea; the clinical course of these complications is usually benign. Most patients become asymptomatic within approximately 24 hours. In a review of 42 cases of pneumomediastinum, 19% had associated pneumothorax; only 1 patient required a chest tube.[316] Pulmonary edema may develop after pure freebase cocaine use,[317] and case reports suggest that the etiology is noncardiogenic based on normal cardiac size, elevated protein levels, and increased capillary permeability detected by bronchoalveolar lavage.[318] A fatal case of pulmonary edema followed the IV injection of freebase cocaine.[319] Smoking cocaine may produce bronchospasm in cocaine abusers with[320] and without[321] a history of preexisting asthma. Other pulmonary abnormalities associated with smoking cocaine include pulmonary hemorrhage, bronchiectasis and interstitial desquamative pneumonia, bronchiolitis obliterans, and diffuse alveolar infiltrates with hemoptysis and chest pain (hemorrhagic alveolitis or crack lung).[310,322] Clinical effects associated with hemorrhagic alveolitis include dyspnea, hypoxemia, fever, hemoptysis, and cough. The effect of freebase cocaine smoking on lung function and gas exchange remains controversial.[312] Pulmonary complications from the chronic insufflation of cocaine include dyspnea on exertion, cough, pulmonary opacities, pulmonary embolism/thrombosis, and pulmonary granulomas.

HEAD AND NECK

Chronic insufflation of cocaine causes a reactive hyperemia of nasal mucosa, recurrent epistaxis, anosmia, and a persistent rhinitis.[323] Mucosal erosions and, less often, nasal perforation and sinusitis also complicate chronic cocaine insufflation.[324,325] The sinusitis associated with nasal insufflation of cocaine is not associated with eosinophils on nasal smear and fails to improve with antihistamines and nasal sprays.[326] Case reports associate cerebrospinal fluid rhinorrhea with chronic cocaine administration via the nasal route.[327] The hot vapor associated with freebasing or crack cocaine use may produce thermal injuries to the upper airway manifest by sore throat, dysphagia, odynophagia, cough, dysphonia, and stridor.[328] Additional complications documented by case reports include nasal papilloma,[329] keratitis, iritis, and maculopathy with impaired color vision after insufflation,[330,331] and crack cocaine-associated corneal ulcers.[332,333] Infection with the development of hypopyon commonly complicates the occurrence of corneal erosions, frequently by unusual organisms (e.g., *Brevibacterium casei*, *Capnocytophaga* spp., *Streptococcus mitis*, *Streptococcus sanguis*). Large central scars with neovascularization and permanent visual loss may result.

RENAL

Acute renal failure secondary to the development of rhabdomyolysis is the most common renal complication of cocaine use.[310] Risk factors for acute renal failure in patients with cocaine-induced rhabdomyolysis include hypotension, hyperthermia, and high serum creatine kinase concentrations. In a series of 39 patients with acute rhabdomyolysis secondary to cocaine use, renal failure developed in 33% of these patients.[186] Mean serum creatine kinase concentration in patients with and without renal failure were approximately 28,000 U/L and 8,000 U/L, respectively. The presence of renal failure, rhabdomyolysis, severe liver dysfunction, and disseminated intravascular coagulation in patients from this case series indicated a poor prognosis. Renal failure may occur following cocaine use in the absence of rhabdomyolysis.[334] Rare case reports associate recent cocaine use with the development of renal infarction with[335] and without acute renal failure.[336] There are inadequate data to determine the effect of chronic cocaine use on the development of acute interstitial nephritis or chronic renal disease.

GASTROINTESTINAL TRACT

Gastrointestinal complications associated with cocaine abuse include mesenteric thrombosis, perforation, and ischemia. Intestinal ischemia is a complication of cocaine abuse via all routes.[337] Clinical features of mesenteric ischemia include abdominal pain, nausea, vomiting, and bloody diarrhea. Cocaine-associated enterocolitis typically involves inflammatory or ischemic changes in the proximal colon that occur within 3 days of the last cocaine use.[338] Case reports associated gastroduodenal perforations[339] and pneumoperitoneum[340] with crack cocaine smoking. The use of cocaine is not directly related to liver dysfunction, although liver failure may occur during severe cocaine intoxications along with multiple end organ failure and severe hyperthermia.

MUSCLES

Rhabdomyolysis associated with cocaine abuse may result from a variety of etiologies; most patients with cocaine-induced rhabdomyolysis have recognizable causes of muscle toxicity, such as compartment syn-

drome, prolonged immobilization, hyperactivity, seizures, hyperthermia, or direct trauma during periods of altered behavior.[341] The presence of rhabdomyolysis following cocaine use is not usually associated with toxic effects unless severe; the clinical features of severe rhabdomyolysis include weakness, myalgias, nausea, vomiting, hypocalcemia, muscle swelling, and myalgias. In a prospective study of 34 patients presenting to a large urban hospital with complaints related to cocaine use, 24% (8 cases) of these patients had evidence of rhabdomyolysis as defined by a creatine kinase concentration 5 times normal values (>1000 U/L).[342] Muscle symptoms did not correlate to serum creatine kinase concentrations. Severe rhabdomyolysis occurs both with and without cocaine-induced excited delirium, but the nonfatal cases of severe rhabdomyolysis associated with cocaine use shares many similar risk factors with excited delirium.[343]

TEMPERATURE CONTROL

Clinically serious elevation of temperature can occur in cocaine users, particularly in association with delirium. The hyperthermia can develop along with multiorgan failure that includes renal failure, rhabdomyolysis, liver failure, and disseminated intravascular coagulation.[344] These clinical features occur following all routes of exposure including nasal insufflation,[345] IV injection,[346] and smoking freebase (crack).[347]

ANAPHYLAXIS

True anaphylactic reaction to pure cocaine is extremely rare, although street samples may contain more allergenic drugs (e.g., quinine). Severe immediate reactions to cocaine use more likely result from massive overdose or rapid IV injection. Following very large cocaine doses, cardiac collapse and respiratory arrest may occur without grand mal seizures.

SKIN

Following the probable use of levamisole-contaminated cocaine, case reports documented the development of an occlusive, necrotizing vasculitis including purpura of the face and ear, retiform purpura of the trunk,[348,349] and agranulocytosis.[350,351] A 52-year-old woman presented to an emergency department with purpura of the face, breasts, and extremities.[352] The skin biopsy demonstrated an antineutrophil cytoplasmic antibody-positive vasculitis with focal intravascular fibrin formation. Analysis of her urine 2 days after admission detected 0.92 mg levamisole/L.

Overdose

Although recreational use of cocaine may cause severe cocaine intoxication, massive cocaine intoxication usually results from body packing or, less often, body stuffing.[353] Individuals who smuggle cocaine within their bodies are called "body packers" or "mules," whereas individuals who ingest cocaine to avoid arrest are "body stuffers." Body stuffers, who ingest poorly wrapped bundles of rock (freebase) cocaine to avoid arrest, usually develop symptoms of cocaine intoxication within a few hours, whereas the appearance of symptoms in smugglers (body packers) may be delayed many hours depending on the durability of the cocaine bags during transit through their intestinal tract.[354] The amount of cocaine and the effectiveness of the wrapping in preventing leakage accounts for the different onset and severity of intoxication associated with these 2 syndromes. In the past, bags were composed of plastic bags, balloons, or condoms that easily leaked, but the process is more automated now with much stronger wrappings (i.e., latex sheath (condom, balloon) covered with several layers of latex and sealed with a hard wax coating).[355] The patient is typically a young, white man who has recently arrived from South America.[356] The clinical presentation includes hyperthermia, tachycardia, hypertension, mydriasis, nervous or agitated behavior, toxic psychosis, delirium, and seizures. Early signs of cocaine intoxication include tachycardia, hypertension, agitation, anxiety, talkativeness, and muscle hyperactivity. The presence of these signs in a body packer or a body stuffer indicates that more serious signs of cocaine toxicity may develop, although the clinical course of body stuffers is usually mild. In contrast to body packers, body stuffers who develop cocaine toxicity typically will be symptomatic on admission or shortly thereafter. In a study of 98 cocaine body stuffers brought to the emergency department by law enforcement personnel, all complications occurred within 3–4 hours of admission to the emergency department including seizures in 4 patients.[357] Rarely, delayed seizures occur in body stuffers ingesting very large amounts of freebase cocaine.[358] Terminal convulsions, ventricular dysrhythmias, or respiratory arrest usually develops within the first 30 minutes following massive cocaine exposure.[359] Abdominal x-rays may or may not demonstrate foreign bodies, and the absence of radiodense material does not exclude the presence of cocaine packets.[12] Symptoms of cocaine intoxication can recur several days after apparent recovery when remaining bags rupture,[360] leading to death over 1 week after ingestion.[361] Typically, violent seizures followed by respiratory arrest precede death secondary to massive cocaine overdose.[203]

Fatalities

Causes of cocaine-associated fatalities include sudden death, accidental trauma, accidental overdoses, suicides, and homicides. In a review of cohort studies of IV or treatment-seeking cocaine users, the standardized mortality ratios were ~4–8 times higher than age- and sex-matched peers in the general population.[362] Mortality from trauma and infection are particularly high in this population, suggesting the importance of socioeconomic factors as well as drug habits. There are few mortality data on individuals using cocaine by insufflation only.

ACCIDENTAL OVERDOSE

Deaths resulting from the pharmacologic effects of cocaine are usually sudden and occur within a few hours of cocaine use.[59] The use of cocaine can precipitate a MI, dysrhythmias, and sudden death in patients with or without cardiovascular disease. In a Spanish prospective, case-control study of 668 cases of sudden death, 3.1% of these cases were associated with cocaine use.[363] Causes of sudden death included cardiovascular (62%), cerebrovascular (14%), excited delirium (14%), respiratory complications (5%), and metabolic abnormalities (5%). Severe coronary artery disease and coronary artery thrombosis were present in 29% and 14% of the sudden death cases, respectively. Death in young cocaine abusers is frequently abrupt and idiosyncratic, presumably as a result of a lethal ventricular arrhythmia or an idiopathic response to cocaine. However, the actual documentation of life-threatening ventricular arrhythmias secondary to recreational cocaine use is uncommon, especially considering the frequency of cocaine abuse in the United States.[364] Although risk factors for ventricular dysthymias (e.g., coronary artery disease, hypertrophy, hypertension, myocarditis, ischemia) are often present in case series on cocaine-associated sudden death, MI is uncommon in postmortem examination of these patients.[365,366] In a case series of 24 autopsies that demonstrated cocaine or benzoylecgonine in postmortem samples, significant coronary arteriosclerosis (>70% occlusion) was present in over 60% of these cases.[214] Other causes of death soon after exposure to cocaine include status epilepticus, centrally mediated respiratory arrest, excited delirium, and intracerebral hemorrhage. Although respiratory collapse and death frequently occur immediately after cocaine injection, administration of cocaine by the nasal or oral routes may delay terminal seizures as long as 1 hour after exposure.[14] Retrospective studies of cardiac arrest in crack cocaine users with positive urine drug screens for cocaine suggest that these patients are younger and more likely to survive with total neurologic recovery, when compared with cardiac arrest in patients without cocaine use.[367] The exception to good neurologic outcome in these patients is the crack cocaine-using patient with excited delirium.

EXCITED DELIRIUM

Sudden death occurs in a small subset of chronic cocaine abusers following the development of agitation, bizarre behavior, and delirium during the use of cocaine. Wetli and Fishbain first described this syndrome of fatal excited delirium in 7 chronic cocaine hydrochloride abusers in 1985.[203] The inappropriate behavior includes formication, disturbed perceptions, impaired thinking, hallucinations, aggression, breaking objects, screaming, and hyperactivity. Symptoms begin with the acute onset of intense paranoia, followed by bizarre and often violent behavior that requires forcible restraint by police, health care providers, or bystanders. Cardiorespiratory arrest may develop immediately or soon after being restrained. Sudden cardiorespiratory arrest during the restraint procedures or shortly thereafter does not usually result from the restraints or from trauma associated with the restraint procedure.[368] In a retrospective study of 58 cases of cocaine-induced fatal excited delirium and 125 cases of accidental cocaine fatalities without excited delirium, the excited delirium cases were more likely to be black, male, younger, heavier, and hyperthermic compared with accidental overdoses.[369] Additionally, the excited delirium cases were more likely to die during summer months. Although the fatal excited delirium cases were more likely to occur in police custody than accidental overdoses, only about one-third of the fatal excited delirium cases died in police custody. The postmortem cocaine concentrations and heart weights were similar in both groups.

The mechanism of death in cocaine-induced excited delirium is not well defined. A case series of 18 cases of sudden death associated with excited (agitated) delirium documented ventricular dysrhythmias in only 1 of 13 cases when the primary cardiac arrest rhythm was available.[267] This case series also included 196 cases of individuals surviving excited delirium in hobble restraints without significant medical complications. Although many cases of sudden death associated with excited delirium involve restraint procedures and cocaine abuse, sudden death during excited delirium also occurs in agitated patients without the presence of stimulant drugs[370,371] and without restraint procedures.[372] Frequently, patients dying following cardiac arrest during restraint procedures are hyperthermic and profoundly acidotic. The severity of the clinical response does not correlate directly to the absorbed dose of cocaine, and postmortem blood samples from these

patients typically contain lower cocaine concentrations (e.g., <0.6–1 mg/L) than blood samples from fatalities resulting from large cocaine overdoses. Additionally, the former patients do not usually develop preterminal seizures in contrast to the typical severe cocaine overdose.

Abstinence Syndrome

Although the spectrum and time course of abstinence syndromes following chronic cocaine use remains somewhat controversial, the consensus indicates that there are 3 phases: crash, withdrawal, and extinction.[223] Typically, the clinical features of cocaine withdrawal are mild, primarily involving sleep disturbances, vivid dreams, agitation, excessive appetite, fatigue, and psychomotor retardation.[373]

CRASH

The crash is the immediate rebound that develops soon (i.e. <1 h) after the cessation of cocaine use, and this phase usually lasts a few hours to a few days. The crash represents the extreme exhaustion that occurs after a binge of cocaine use as the craving for sleep replaces cravings for stimulant use. During this period, the use of other drugs (benzodiazepines, ethanol, sedatives, opioids, marijuana) is common as a means to reduce the agitation, dysphoria, depression, insomnia, and anxiety associated with the binge use of cocaine. Prolonged hypersomnolence, irritability, and periods of hyperphagia precede the return of a more normal mood. In clinical practice, the resumption of a normal sleep pattern followed by 3 or more days of abstinence confirms the resolution of a crash.[374]

WITHDRAWAL

The severe withdrawal symptoms seen in opioid and ethanol dependence do not occur after cessation of cocaine use, but the extent of withdrawal symptoms following the habitual use of cocaine remains controversial. Intermittent cocaine users do not usually experience withdrawal symptoms. Patients, who are abstinent after heavy cocaine use, report decreased energy, listlessness, anxiety, anhedonia, and limited interest in their environment, but the symptoms fluctuate and lack the intensity associated with a major mood disorder.[223] A craving for cocaine persists through this period. Mild symptoms generally begin after the crash (i.e., 1–5 days after cessation of cocaine use) and these symptoms increase in intensity over the next 12–96 hours.[374] Symptoms may last 1–10 weeks. The dosage and chronicity of cocaine use required to produce withdrawal symptoms have not been adequately studied, but heavy users (e.g., freebase cocaine users) are at the highest risk.[101] In a study of 12

cocaine addicts, who used mostly IV methods, the mood-distress scores and cravings for cocaine were highest at admission and decreased gradually over the 28 days of the study.[375]

EXTINCTION

A third phase (i.e., extinction) ensues after abstinence is sustained throughout the first 2 phases. Brief, episodic craving recurs after withdrawal symptoms resolve and during the extinction phase, particularly when confronted with stimuli (e.g., friends, settings) that remind the cocaine addict of prior experiences with the drug. Although these cravings gradually diminish over months to years, certain conditions (white powders, pipes, syringes, people, locations, moods) associated with cocaine-induced euphoria may evoke intense cravings for cocaine.

Reproductive/Developmental Abnormalities

The effect of maternal cocaine use on reproductive abnormalities remains controversial because of recall bias, unreliable exposure data (e.g., measurement of cocaine use during pregnancy), publication bias, and multiple confounding factors (e.g., multiple drug use, poor prenatal care). The most common adverse fetal consequences of *in utero* exposure to cocaine are low birth weight (<2500 g), preterm birth, and intrauterine growth restriction.[376,377] Some longitudinal studies demonstrate reduction in growth parameters of children exposed to cocaine during the first trimester,[378] whereas other studies do not detect growth abnormalities in children exposure to cocaine prenatally.[379] Potential complications of cocaine use during pregnancy include an increased risk of *abruptio placentae*,[380] stillbirth,[381] and preterm labor.[382] Potential cocaine-associated neonatal complications include congenital malformations, decreased fetal growth, microcephaly, seizures, cerebral infarction and hemorrhage, auditory system deficits, sudden infant death syndrome, speech/language delays, and behavioral changes.[383,384] Other potential adverse consequences of cocaine use during pregnancy involve delay in cognitive development,[385] oppositional defiant disorder, aggression,[386] attention deficit–hyperactivity disorder,[387] delayed motor development (posture, tone, hand-eye coordination),[388] and poor language development.[389] Chronic use of cocaine during pregnancy probably reduces birth measurements, but longitudinal studies suggest that these cocaine-related reductions in weight, length, and head circumference disappear during early childhood development.[390,391] In a case control study of 50 cocaine-abusing mothers, reproductive abnormalities included reduced birth weight, increased

malformation rates, and higher incidences of abruptio placentae and stillbirths.[392] Another study involving 30 women admitting to the use of cocaine during the first trimester of pregnancy did not detect any adverse obstetrical or neonatal effects during the first 18 months of life.[393] Studies of children born to mothers using cocaine during pregnancy did not detect a strong association between prenatal cocaine exposure and adjustment or IQ at age 4 years, particularly in girls.[394] However, after adjustment for confounding variables, another longitudinal study of cocaine-exposed children followed to age 3 years found deficits in the scores of these children on the Bayley Mental and Psychomotor Developmental Indices when compared with controls.[390] A number of methodologic issues limit the interpretation of data on the reproductive effects of cocaine including cohorts unrepresentative of the general population, accurate quantification of cocaine use, polydrug use, and difficulty controlling confounding variables (e.g., parenting styles). These methodologic issues prevent a definitive conclusion regarding the causal relationship between cocaine and adverse fetal outcomes.[395] Studies on the teratogenicity of cocaine in animals are also conflicting.[396]

DIAGNOSTIC TESTING

Unit Conversion

Cocaine

$$1\ nmol = 3.30\ \mu g$$

$$1\ \mu g = 0.303\ nmol$$

Cocaethylene

$$1\ nmol = 3.15\ \mu g$$

$$1\ \mu g = nmol/3.15 = 0.317\ nmol$$

Analytic Methods

METHODS

SCREENING.   Most screening tests for the detection of cocaine use involve the analysis of the metabolite, benzoylecgonine, in the urine by immunoassay.[397] The rapid and extensive metabolism of cocaine in blood and the instability of cocaine produce high false-negative values, when plasma cocaine is the primary analyte for screening purposes. Most immunoassays are relatively specific for benzoylecgonine and the assays demonstrate little cross-reactivity between cocaine and benzoylecgonine.[398,399] Postmortem screening for benzoylecgonine using standard immunoassays may be negative (i.e., below the cutoff) in cases involving death soon after the ingestion of massive amounts of cocaine based on rare case reports.[400] In such cases, the heart blood (but not the femoral blood) contains very high concentrations of both cocaine and benzoylecgonine.

Extraction of benzoylecgonine from urine typically involves liquid or solid-phase extraction using an extraction column. Benzoylecgonine is a polar, amphoteric, and highly hydrophilic compound that resists extraction by styrene-divinylbenzene copolymers (e.g., XAD-2) and ion exchange resins, but is removed from the matrix by solid-phase extraction and a variety of solvents (chloroform/isopropanol,   methanol/acetonitrile).[401,402] Hydrolysis of urine samples is not necessary because benzoylecgonine in not conjugated in urine in any significant amount.

CONFIRMATION.   Most analytic procedures use solid-phase extraction and deuterated analogues as internal standards.[403] Maintaining excessively alkaline conditions (i.e., pH >9) during the extraction procedure may cause substantial hydrolysis of cocaine present in the sample to ecgonine methyl ester. Gas chromatographic techniques and capillary columns separate cocaine and metabolites from other compounds. Detection methods include nitrogen phosphorus and electron capture. The use of gas chromatographic techniques may require pre-analytic chemical derivatization for the detection of cocaine metabolites depending on the detection method (e.g., the use of nitrogen phosphorus detection allows the quantitation of cocaine without derivation, but the detection of cocaine metabolites requires derivation). The most specific technique for determining the identification of a compound (e.g., cocaine) is mass spectrometry, which records a unique "fingerprint" of mass fragments by bombarding the sample with high-energy electrons in a controlled magnetic field. Both radioimmunoassay and enzyme immunoassay are sensitive semiquantitative methods of detecting benzoylecgonine in the urine with a lower cutoff of about 0.05 mg/L.[403]

The lower limit of quantitation (LLOQ) for cocaine and benzoylecgonine in postmortem blood samples using gas chromatography/mass spectrometry (GC/MS) is ~0.05 mg/L.[404] High performance liquid chromatography is more sensitive than thin layer chromatography, but this method is less sensitive than GC/MS unless combined with tandem mass spectrometry.[405] Solid-phase extraction followed by liquid chromatography/ tandem mass spectrometry allows the detection of cocaine and benzoylecgonine in plasma at a LLOQ of 0.02 mg/L.[406] In general, liquid chromatography/tandem mass spectrometry is more sensitive than GC/MS;[407] however, liquid chromatography/tandem mass spectrometry has potentially greater variability in product ion formation using multiple reaction monitoring or

selected reaction monitoring as well as the potential for components of the sample matrix to either suppress or enhance the ionization of target analytes (matrix effect). Anhydroecgonine methyl ester is a byproduct of smoking crack cocaine, and the presence of this byproduct is a marker of freebase cocaine use.[408] The use of GC/MS limits the artifactual formation of this marker.[409] Cocaine *N*-oxide is a minor oxidative metabolite of cocaine that decomposes to cocaine at temperatures exceeding 100°C (212°F). Consequently, the analysis of cocaine samples by methods that use high-temperature injection ports may overestimate (i.e., 10–20%) the actual concentration of cocaine.[410]

STREET SAMPLE ANALYSIS

Illicit cocaine samples commonly contain a variety of impurities and contaminants including natural alkaloids present in the crude leaf extracts, products of cocaine decomposition, and byproducts of the chemical processing of illicit cocaine. Identification of these impurities may assist in the determination of the origin of cocaine street samples. Natural compounds present in the leaves of coca plants beside cocaine include *cis*- and *trans*-cinnamoylcocaine, cuscohygrine, hygrine, hydroxycocaine, tropacocaine, trimethoxycocaine, and truxilline compounds. The *cis*- and *trans*-cinnamoylcocaine are relatively stable compounds that are structurally similar to cocaine.[411] Consequently, these minor alkaloids are extracted together with cocaine during the processing of the coca plant. However, the concentration of these alkaloids in cocaine varies because the use of oxidizing agents (e.g., potassium permanganate) during the processing of cocaine may destroy some of the cinnamoylcocaine.[412] The truxilline compounds are stable alkaloids that vary substantially in concentration between coca plant varieties and chemical processing does not affect the content of these natural alkaloids.[413] Comparison of the relative ratios of tropacocaine, norcocaine, cinnamoylcocaine, and cocaine helps determine the origin of samples of illicit cocaine.[414] Furthermore, the coca plant produces only the levo-stereoisomer of cocaine, so that detection of any of the diastereoisomers of cocaine (e.g., pseudococaine, allococaine, pseudoallococaine) or its *d*-enantiomer indicates synthetic production. Manufacturing byproducts include oxidation products from permanganate bleaching (*N*-norcocaine, *N*-acetylnorcocaine, *N*-formylnorcocaine, *N*-benzoylnorecgonine methyl ester),[415] hydrolysis products (benzoylecgonine, ecgonine, ecgonine methyl ester, benzoic acid, cinnamic acids, truxinic and truxillic acids), and solvent residues (acetone, diethyl ether).[416] A variety of sophisticated profiling procedures are available to determine the origin of illicit cocaine samples. Special chromatographic and spectroscopic techniques including mass spectrometry and nuclear magnetic resonance may be necessary to determine the origin of street samples.[45] Chromatographic methods can separate cocaine from commonly encountered adulterants list under the Impurities and Profiling section.[417]

STORAGE

Both the spontaneous chemical hydrolysis of cocaine to benzoylecgonine and the conversion of cocaine to ecgonine methyl ester (EME) via acylcholine acylhydrolase (pseudocholinesterase, butyrylcholinesterase, plasma cholinesterase) occur in preserved and postmortem samples, particularly under alkaline and warm conditions.[418] In unpreserved blood, *in vitro* stability studies indicate that plasma butyrylcholinesterase hydrolyze cocaine almost exclusively to ecgonine methyl ester.[419] The loss of cocaine can be dramatic in unpreserved samples. In antemortem whole blood fortified with cocaine, the cocaine concentration decreased from 2 mg/L to 0.64 mg/L when stored at room temperature for 24 hours.[419] The addition of sodium fluoride inhibits the enzymatic hydrolysis of cocaine to ecgonine methyl ester, but not the spontaneous chemical hydrolysis of cocaine to benzoylecgonine. In unpreserved whole blood samples, benzoylecgonine is more stable than ecgonine methyl ester when stored at room temperature. Over a 35-day period, the loss of benzoylecgonine from unpreserved blood samples stored at room temperature was 25% compared with 50% for ecgonine methyl ester.[419]

Because of the spontaneous, postmortem hydrolysis of EME and benzoylecgonine to ecgonine, the molar sum of cocaine and EME approximates the *minimum* amount of cocaine present at the time of death.[420] However, unpredictable postmortem changes in cocaine concentrations after death, and the presence of ecgonine methyl ester in patients presenting with cocaine intoxication limit the usefulness of using stoichiometric relationships to interpret postmortem cocaine changes.

Cholinesterase inhibitors (e.g., physostigmine, diisopropyl fluorophosphate) and fluoride ion inhibit the conversion of cocaine to EME, but not the spontaneous hydrolysis of cocaine to benzoylecgonine. The use of 0.25% sodium fluoride in blood samples (i.e., standard gray-top Vacutainer® tubes) prevents the hydrolysis of cocaine during transport and short-term storage (<48 h), particularly when the blood sample is stored in a gray-top tube and refrigerated.[421] However, the use of 0.25% sodium fluoride does not prevent the degradation of cocaine in blood samples stored at room temperature over longer periods. In a long-term study of cocaine concentrations (<0.2 mg/L) stored in blood samples containing 100 mg sodium fluoride at ambient

temperatures, no cocaine was detectable after 3 months as measured by GC/MS.[422] During an *in vitro* study of whole blood preserved with 0.25% sodium fluoride and stored at 20°C (68°F) containing cocaine concentrations up to 1 mg/L, cocaine was not detectable after 10 days as measured by liquid chromatography/mass spectrometry.[423] A similar sample retained about 25% of the original concentration of cocaine after 14 days when stored at 4°C (39.2°F).

The average *decrease* of benzoylecgonine in these blood samples at 3 months, 6 months, and 1 year was 74%, 93%, and 99%, respectively. No benzoylecgonine was detectable after 2 years. Refrigeration retards, but does not stop, both of these degradation processes. In an experimental study cocaine samples refrigerated at16°C (60.8°F) lost 30% of the original concentration during 36 days of storage with the highest 1-day loss of 7%.[424] An *in vitro* study of cocaine in human serum incubated at body temperature demonstrate that 20% of the cocaine was metabolized during the first hour with deesterification of cocaine to ecgonine methyl ester accounting for about two-thirds of the hydrolyzed cocaine.[425] The ratio of benzoylecgonine and ecgonine to ecgonine methyl ester increased as the incubation time increased. Within 4 hours, about 67% of the cocaine was hydrolyzed with ecgonine methyl ester, benzoylecgonine, and ecgonine accounting for about 18%, 28%, and 18% of the hydrolyzed cocaine, respectively. Freezing blood samples and the use of fluoride ion significantly limits both of these degradation processes. Over a 21-day period, cocaine concentrations remain stable in refrigerated blood samples (4°C/39.2°F) maintained at pH 5 with 2% sodium fluoride.[419] Storage of blood samples at −20°C (−4°F) in 2% sodium fluoride was associated with an approximate 15% decrease in the concentration of cocaine and benzoylecgonine after about 4–5 months.[426] Cocaine concentrations may remain detectable in some decomposed bodies when tissue samples are analyzed by GC/MS.[427]

The kidney excretes very small amounts (<1–2%) of unchanged cocaine in the urine. Cholinesterases are not present in urine; therefore, conversion of cocaine to EME does not occur in urine samples. However, conversion of cocaine to benzoylecgonine and ecgonine may occur depending on temperature and pH. Optimum storage conditions for urine samples involve freezing (−15°C/5°F) the specimen at pH of 5 adjusted with ascorbic acid.[428] Under these conditions, cocaine and benzoylecgonine are stable for at least 3 months. The stability of benzoylecgonine decreases substantially in alkaline urine (>50% loss over 2–3 months with pH >8.0).[429] In contrast to the storage of blood or liver samples, the use of sodium fluoride to inhibit the effect of pseudocholinesterases on cocaine is not necessary for

urine samples that do not contain cholinesterases. Because the concentrations of EME do not increase in urine samples during storage, the presence of EME indicates the *in vivo* conversion of cocaine to EME; therefore, the use of cocaine while the individual was alive.[430] In buffered formalin (pH = 7.4), cocaine undergoes hydrolysis to benzoylecgonine with a half-life of about 1 week, whereas cocaine is relatively stable in unbuffered formalin over 30 days.[431] Within 15–30 days after preservation with formalin, the rapid extraction of cocaine into formalin and subsequent hydrolysis to benzoylecgonine limits the detection of cocaine in these tissues.

Biomarkers

Pharmacokinetic studies of volunteers and animals given radiolabeled cocaine indicate that the whole blood/plasma ratio of cocaine is approximately 1.[73,432] The most common biologic samples used for the analysis of cocaine involve the blood and urine.

BILE/LIVER

Bile may contain substantial concentrations of cocaine and cocaine metabolites as measured by high performance liquid chromatography with ultraviolet detection (235 nm) or gas chromatography with flame ionization detection; however, there are few data to interpret the significance of cocaine concentrations in bile other than to confirm exposure.[433,434] Typically, cocaine and benzoylecgonine concentrations are several fold higher in postmortem bile than in postmortem blood.[435] Case series suggest that the liver/blood ratio of cocaine does not correlate to the route of exposure.[436]

BLOOD

ANTEMORTEM.   Measurements of blood cocaine concentrations document exposure, but these values seldom are available to guide clinical management. In general, the use of cocaine via the intranasal and oral routes produces lower blood cocaine concentrations over a more prolonged time than cocaine smoking. The administration of cocaine via smoking or IV injection produces peak concentrations of cocaine that are several times higher in arterial blood than in venous blood during the first 30 minutes after use.[437] Because euphoric effects occur before peak plasma concentrations, the rate of change in plasma cocaine concentrations may be more important that the absolute plasma concentration.[3] As with lysergic acid diethylamide and ethanol, the psychologic effects of cocaine are more prominent on the upward limb of the plasma cocaine curve than the downward limb (Mellanby effect).[438] Hence, identi-

cal plasma concentrations induce different effects depending on whether the plasma cocaine concentration is rising or falling.

Typically, peak plasma concentrations following recreational doses (0.2–2 mg/kg) of cocaine average about 0.2–0.6 mg/L depending on the route of administration, whereas the peak cocaine concentrations in plasma samples from intoxicated individuals range up to several mg/L.[59,73] The average peak cocaine concentration of 3 individuals smoking six 50-mg doses of cocaine over 90 minutes was 0.89 mg/L (range 0.69–1.20 mg/L).[439] Nasal application of cocaine doses of 2 mg/kg produced a mean peak plasma concentration of 0.161 mg/L 1 hour after administration. Equivalent oral doses caused higher peak plasma concentrations (0.21 mg/L) at 1 hour after ingestion.[69] In a study of 25 habitual coca chewers, the mean plasma cocaine concentration after a 45-minute chewing ritual was approximately 0.098 mg/L (range, 0.028–0.289 mg/L).[440] In a patient with acute cocaine toxicity after ingestion of cocaine-filled condoms, the serum cocaine concentration was 2 mg/L when the patient's mental status ranged from extreme agitation to nonresponsiveness.[360] Similarly, a 48-year-old body packer developed severe cocaine intoxication 4 days after being apprehended.[441] One hour after he sustained a cardiac arrest with asystole, his plasma cocaine concentration was 1.66 mg/L.

Acute and chronic tolerance may limit the clinical effects of cocaine. In a study of plasma cocaine concentrations from patients presenting to an urban emergency departments with cocaine intoxication, a patient was minimally intoxicated with a plasma cocaine concentration of 3.9 mg/L.[442] After an observation period, the patient was released to police custody. Participants in experimental studies have attained plasma cocaine concentrations of 3.0 mg/L during cocaine infusions without significant adverse clinical effects.[94] Plasma cocaine concentrations must be interpreted cautiously because of the previously discussed degradation of cocaine during storage as well as tolerance.

POSTMORTEM. The time of cocaine administration is difficult to determine from postmortem samples unless a single dose of cocaine was administered by one route of exposure. Furthermore, the position of a single analytic result on the drug concentration versus time curve is unknown. Consequently, extrapolating antemortem kinetics to a single postmortem analytic result is not valid. Factors to consider in determining the time of ingestion and the clinical effects of the cocaine dose include storage techniques, sampling site, route of administration, tolerance, previous history of cocaine use, individual susceptibility (e.g., cardiovascular disease, pseudocholinesterase deficiencies), concomitant drug use, role of adulterants, postmortem interval, and the time between administration and death.

In general, postmortem changes in cocaine blood concentrations are inconsistent; therefore, the determination of the cause of death should be based on a careful analysis of the factors listed above.[444] Cocaine is relatively stable in the corpse when stored at 20–37°C (68°–98.6°F) during the first 24 hours, particularly when the pH of the blood specimen falls.[443] However, changes in cocaine concentrations during the postmortem interval between death and analysis are highly site-specific and variable, and there is no consistent pattern in the magnitude and direction of changes in cocaine and metabolites during the postmortem interval.[444] The postmortem changes involve a dynamic process, which depends on the balance between postmortem degradation of cocaine and the postmortem redistribution of cocaine, particularly in the left ventricle of the heart. In a case series of blood samples drawn at the scene of death and at autopsy, the cocaine concentration increased in samples from the heart and femoral vein, but the cocaine concentration decreased in samples from the subclavian vein.[445]

Postmortem cocaine blood concentrations in cocaine-associated deaths are highly variable with concentrations ranging up to 100–200 mg/L in individuals, who die after ingesting cocaine bags.[446,447] Average cocaine concentrations in postmortem samples from fatalities resulting from the recreational use of only cocaine are approximately 5–6 mg/L.[448] Postmortem cocaine concentrations are frequently found in combination with other drugs, particularly ethanol, opioid medications, and heroin. In a Texas study of 461 cocaine-related deaths from 1993–2005, ~31% resulted from the use of cocaine alone compared with 42% ethanol plus cocaine and 29% cocaine plus opioid medication.[449] Heroin was present in 13% of the case series, whereas antipsychotic/antidepressants medications were present in 12%. Table 56.2 lists the median postmortem blood cocaine and benzoylecgonine concentrations for cocaine only and cocaine plus 1 additional drug in this study.

Sudden death may occur in cocaine users with lower postmortem cocaine concentrations (<0.6–1 mg/L) when associated with hyperthermia and excited (agitated) delirium. In a retrospective review of the records from the Medical Examiner's Office in San Francisco, the presence of cocaine was considered incidental to death in 51 trauma victims.[215] The mean cocaine concentration in the postmortem blood samples was 0.487 ± 0.75 mg/L (range, 0–4.7 mg/L). The mean cocaine concentration in postmortem blood samples from 6 cases of sudden death associated with cocaine-induced excited delirium was 0.4 ± 0.3 mg/L, whereas the mean postmortem benzoylecgonine concentration

TABLE 56.2. Postmortem Blood Cocaine and Benzoylecgonine Concentrations Cocaine-Related Deaths in Bexar County, Texas 1993–2005.[449]

Cocaine Plus 1 Additional Drug (Cases)	Median Cocaine Concentration (Range)*	Median Benzoylecgonine Concentration (Range)*
Cocaine alone (143)	0.89 (0.01–78)	4.0 (0.02–90)
Ethanol (72)	0.35 (0.01–82)	1.5 (0.02–24)
Opioid medications (42)	0.08 (0.01–3.7)	1.4 (0.03–6.2)
Heroin (8)	0.12 (0.01–0.83)	1.0 (0.02–3.7)
Antipsychotics/ antidepressants (10)	0.17 (0.03–4.1)	1.1 (0.29–7.9)
Antihistamines (7)	0.33 (0.03–0.99)	2.4 (0.61–3.8)
Anxiolytics (3)	0.06 (0.01–0.11)	1.5 (0.23–2.8)

*mg/L; sampling site not reported.

was 5 ± 5 mg/L.[450] These concentrations were similar (i.e., 0.4 ± 0.4 mg/L and 2.4 ± 1.6 mg/L, respectively) to cocaine and benzoylecgonine concentrations in a case series of 21 individuals dying of inflicted trauma with cocaine in their postmortem blood. Cocaine-induced fatalities can occur at low cocaine concentrations as a result of prolonged postmortem interval, inadequate storage of postmortem blood samples, chronic cocaine-related myocardial abnormalities (myocardial hypertrophy, diffuse myocardial fibrosis, microangiopathy), coronary artery disease, and long QT syndrome.[451]

BRAIN

Cocaine diffuses easily into brain tissue, but the postmortem cocaine concentration in brain tissue varies substantially depending on the location of the sample.[452] In contrast to cocaine, the metabolite benzoylecgonine diffuses poorly into brain tissue. Fatal overdoses display a mean brain/blood benzoylecgonine ratio of 0.36, which suggests cocaine exposure within the proceeding 1–3 hours. Average ratios of brain/blood benzoylecgonine exceeding 1–1.5 suggest either chronic accumulation from prolonged use or exposure more than 8 hours previously. The cocaine concentrations in the brain are relatively stable compared with other sites. A case series suggested that the brain/blood ratios of cocaine and benzoylecgonine may help identify the time of death. A cocaine brain/blood ratio exceeding 10 commonly occurs following fatal cocaine overdoses when death occurs soon after exposure. For deaths that occurred within 1–3 hours after exposure, the average ratios were 9.6 and 0.36 for cocaine and benzoylecgonine, respectively.[453]

FREEBASE COCAINE

The major product of cocaine pyrolysis is methylecgonidine.[88] The presence of methylecgonidine (anhydroecgonine methyl ester) in urine, blood or hair samples is a biomarker of the inhalation of heated cocaine (e.g., freebase cocaine) rather than exposure via other routes.[454,455,456] Animal studies indicate that the elimination half-life of methylecgonidine is relatively short (15–20 min); therefore, the metabolite (ecgonidine) formed via esterase activity is probably a more useful biomarker because of the longer (i.e., 90–140 min) elimination half-life in blood.[457] Although both methyl ecgonidine and ecgonidine may be artifacts of GC/MS analysis,[458] the presence of these compounds in liver and urine samples suggest the use of freebase cocaine prior to death. The use of appropriate analytic techniques minimizes or avoids the formation of these artifacts. In a study of 15 fatalities associated with crack cocaine use, the median concentrations of methyl ecgonidine and ecgonidine in urine samples were 0.062 mg/L (range, 0–2.03 mg/L) and 0.456 mg/L (range, 0.109–7.452 mg/L), respectively.[459] Methyl ecgonidine was not frequently detected in postmortem liver samples, whereas ecgonidine was detectable in all liver samples (range, 0.090–3.274 μg/g).

HAIR

The use of hair analysis for cocaine has the theoretical advantage of detecting long-term cocaine use compared with urine drug screens based on the average hair growth rate of about 1 cm/month in adults, particularly when other samples are not available for analysis.[460] However, issues of external contamination,[461] variability in laboratory decontamination techniques,[462] decomposition of cocaine in alkaline media, and the variable deposition of cocaine in different types of hair complicate the analysis of hair samples as a means to document long-term cocaine use.[463,464] Consequently, the presence of cocaine and/or benzoylecgonine during hair analysis is not unambiguous proof of the use of cocaine, particularly in persons in close contact with cocaine. The studies of cocaine deposition in hair indicate that cocaine binds to the dark brown pigment (eumelanin), but not to the reddish-brown pigment (pheomelanin). There are few data on the deposition of cocaine and cocaine metabolites in hair or on the sensitivity of hair analysis for the detection of long-term cocaine use. The use of gas chromatography/tandem mass spectrometry using ion-trap detector in positive chemical ionization mode allows the simultaneous determination of cocaine, anhydroecgonine methyl ester (pyrolysis product), ecgonine methyl ester (metabolite), and cocaethylene (trans-esterification product with ethanol) in hair

samples with a LLOQ ranging from 0.005 µg/g (cocaine) to 0.05 µg/g (anhydroecgonine methyl ester).[465]

A case report suggested that at least 3 months of abstinence from cocaine use is necessary before cocaine is undetectable in hair samples as measured by GC/MS, whereas peak hair cocaine concentrations occur within 3 weeks following repeated use.[466] Extensive washing procedures (15-min isopropanol wash, followed by four 30-min phosphate buffer washes and two 60-min washes) are necessary to prevent external contamination.[467] Volunteer studies indicate that many decontamination measures do not separate external contamination from cocaine use.[468] Consequently, the occurrence of cocaine positive hair samples should be confirmed with testing other samples (e.g., urine).

Experimental studies in rodents suggest that the deposition of cocaine metabolites (e.g., benzoylecgonine, ecgonine methyl ester) in hair is low compared with the deposition of cocaine in hair.[469] Concentrations of cocaine in the hair of South American Coca chewers were much higher than concentrations of benzoylecgonine or ecgonine methyl ester (i.e., 5 and 12 times, respectively).[470] The presence of unique cocaine metabolites (norcocaine, cocaethylene) in hair samples supports the past use of cocaine.[471] A number of factors affect the sensitivity of hair analysis including sample preparation and alkaline personal hair products.

SALIVA

The passive diffusion of cocaine into saliva depends on lipid solubility, log P values, plasma protein binding, and salivary pH (cocaine is a weak base).[472] The passive diffusion of the metabolites, benzoylecgonine and ecgonine methyl ester into saliva is significantly less than cocaine. Experimental studies in human volunteers indicate that the cocaine saliva/plasma ratios generally are >1, but the screening potential of salivary cocaine in experimental studies on healthy adults is limited because the terminal half-life is shorter in saliva than in plasma.[473] However, salivary cocaine half-life is variable between individuals, in part because of differences in salivary pH, method of delivery, and duration of cocaine use. In a study of 20 chronic cocaine smokers, the mean terminal cocaine plasma half-life was 3.8 hours compared with 7.9 in saliva, whereas the mean terminal half-life of benzoylecgonine in plasma and saliva was similar (6.6 h and 9.2 h, respectively).[474] Both cocaine and benzoylecgonine were detectable in fewer participants in saliva than in plasma. All 20 participants had detectable benzoylecgonine in plasma compared with 11 positive saliva samples in the 20 participants. Contamination of saliva with cocaine occurs during exposure to intranasal or to freebase cocaine. In a volunteer study involving 2 men,

the IV administration of cocaine produced saliva/plasma concentration ratios of 0.5–2.96 during the 6 hours of sample collection after cocaine administration.[475]

URINE

Analysis of urine samples for benzoylecgonine documents exposure to cocaine, but urinary measurements of cocaine or benzoylecgonine are not clinically useful for the treatment of cocaine-intoxicated patients or for the determination of impairment.[476] Urinary drug screens are more sensitive tests for previous cocaine use than blood tests because cocaine metabolites persist longer in urine samples than in blood samples. The urine drug screen is a less sensitive test for cocaine in neonates than adults because of the reduced ability of the neonate to concentrate urine and subsequent wide fluctuations in urine osmolality. Urine concentrating ability of infants approaches adult values by 2 years of age. The cross-reactivity of immunoassays for benzoylecgonine to cocaine, ecgonine, and ecgonine methyl ester is low (i.e., <1%).[477] Several structurally similar compounds (i.e., *m*-hydroxybenzoylecgonine, *p*-hydroxybenzoylecgonine) present in meconium after maternal cocaine use produce high cross-reactivity with immunoassays for benzoylecgonine. Maximum urinary excretion of unchanged cocaine after a 1.5-mg/kg intranasal dose occurs within 2 hours and cocaine is usually detectable in the urine for 8 hours (maximum 12) after intranasal administration.[67] The urinary elimination half-life of the 2 main metabolites, benzoylecgonine and ecgonine methyl ester, substantially exceeds the elimination half-life of cocaine in the urine. Consequently, detection of cocaine use depends on the renal excretion of cocaine metabolites rather than unchanged cocaine.

The ingestion of coca leaf tea (mate de coca, Health Inca tea)[478] and the use of topical anesthetic solutions containing cocaine[479] can produce positive results in some immunoassay screens for benzoylecgonine within 24–36 hours after use. The addition of sodium chloride to urine samples may produce false-negative cocaine results on drug screening.[480] The ingestion of excessive fluid (<20 mg creatinine/dL, specific gravity <1.003) produces false-negative urine drug tests, but the urine drug tests rapidly revert to positive when the effects of dilution disappear. Consequently, the use of diuretics or herbal products for "flushing" does not change the sensitivity of the urine drug screen beyond the effect of dilution.[481]

Urinary benzoylecgonine excretion peaks from 4–6 hours postinsufflation and diminishes slowly over several days. Benzoylecgonine remains detectable in urine by chromatographic techniques or immunoassay (EMIT) for up to 48–72 hours following single doses of

cocaine depending on a variety of factors including the sensitivity of the specific assay,[482,483] whereas more sensitive (i.e., detection limits of 25 ng/mL) radioimmunoassays identify cocaine metabolites for 90–144 hours.[67] On October 1, 2010, the US Department of Health and Human Services Substance Abuse and Mental Health Services Administration (SAMHSA) issued a Final Notice of Revisions to the Mandatory Guidelines for Federal Workplace Drug Testing Programs that reduced the detection cutoff for illicit use of cocaine to ≥150 ng benzoylecgonine/mL urine and ≥100 ng benzoylecgonine/mL urine for confirmation using GC/MS.[484] In a study of 22 adults undergoing rhinologic procedures using intranasal 4% cocaine pledgets, the percentage of positive urine drug screens at 24, 48, and 72 hours after the procedures were 95%, 50%, and 5%, respectively.[485] The cutoff for a positive test in this study was 150 ng/mL. Studies of cocaine users admitted to medical facilities indicate that the urine drug screens for cocaine remains positive for 1–8 days after heavy cocaine use ceases.[486,487,488] During this period, urine samples from these heavy cocaine users may become positive after earlier samples contained benzoylecgonine concentrations below the established cutoff.[488] The normalization of the creatinine with a cutoff of 300 ng benzoylecgonine equivalents/mg creatinine increases detection time.[486] Case studies suggest that excretion of benzoylecgonine into the urine may continue for 1–3 weeks following heavy abuse (>8–10 g/d) of cocaine.[489] A negative urine drug screen usually indicates the absence of cocaine use within the last 2–3 days depending on the factors listed above.[93] Despite numerous references on the Internet linking false-positive urine tests for cocaine metabolites with amoxicillin use, clinical data indicate that amoxicillin is unlikely to cause false-positive immunoassays for cocaine metabolites.[490]

Determination of the time or amount of drug usage based on the urinary concentrations of cocaine or cocaine metabolites is not feasible from a single sample because of the large number of variables that affect urine concentrations of these compounds. These variables include frequency of use, dose, contaminants, route of administration, variable excretion rates, interindividual differences in cocaine kinetics, formation of condensation products (e.g., cocaethylene), drug interactions, and variation in physiologic parameters (blood flow, creatinine clearance, urine pH).[491]

Passive exposure of medical and security personnel to cocaine does not usually cause positive urine drug screen results for cocaine.[492] Some absorption of cocaine via passive inhalation may occur depending on the duration of exposure and the vaporization temperatures, but the quantity absorbed is not usually sufficient to produce a positive drug screen at the cutoff of 300 ng/mL. In a study of 6 healthy male volunteers exposed to the vapors from the smoking of 100- to 200-mg freebase cocaine in an unventilated room (12,600 L) for 1 hour, the peak benzoylecgonine concentration ranged from 0.022–0.123 mg/L and the amount of cocaine inhaled averaged 0.25 mg.[493] The minimum amount of absorbed cocaine necessary to produce a positive drug screen at the current cutoff is about 1 mg.

VITREOUS HUMOR

There are few data on postmortem changes in cocaine concentrations from samples of vitreous humor.[494] Experimental studies in animals indicate that the postmortem cocaine concentration in vitreous humor varies substantially with cocaine concentrations in antemortem blood and postmortem femoral blood.[495] In contrast to cocaine, the antemortem diffusion of benzoylecgonine into vitreous humor is limited. Because of postmortem changes including continuing metabolism, there is substantial variation between the ratio of cocaine concentrations in postmortem blood and vitreous humor samples, particularly following the use of both cocaine and ethanol. Often, the cocaine concentration is substantially higher in postmortem vitreous humor than in postmortem blood samples, and postmortem changes occur in vitreous humor as well as whole blood.[494]

Abnormalities

ILLICIT USE

PULMONARY. Pulmonary abnormalities present on chest x-ray secondary to cocaine use include pneumothorax, pneumomediastinum, pneumopericardium, hemothorax, atelectasis, and pulmonary edema.[496] Computed tomography (CT) with contrast may be necessary to detect hemorrhagic alveolitis and interstitial pneumonitis associated with crack lung as plain chest films may not demonstrate abnormalities in the presence of significant pulmonary symptoms. Abnormalities on imaging studies associated with crack lung include diffuse interstitial and alveolar opacities in the parenchyma that involve the parahilar regions.[178] Small pleural effusions may also occur. Severe cocaine intoxication may cause hypoxemia and hypercarbia as a result of respiratory depression and/or protracted seizures. Hypoxemia and reduced cardiac output contribute to the development of acid-base abnormalities. A noncardiogenic pulmonary edema may develop after IV administration of freebase cocaine and, in rare cases, contribute to hypoxemia. In severe cases, adult respiratory distress syndrome and end-stage respiratory failure results from interstitial pneumonitis and bronchiolitis obliterans with organizing pneumonia.

In a case series of 19 chronic freebase cocaine users, reduced carbon monoxide diffusing capacity (DL$_{co}$) occurred in 10 habitual users.[497] However, lung volumes, exercise testing, and forced expiratory volumes (FEV$_1$) were normal, indicating the absence of restrictive and obstructive pulmonary disease. A cross-sectional study of a convenience sample of habitual smokers of crack cocaine compared carbon monoxide diffusing capacity with matched control nonsmokers, ex-smokers, and smokers of tobacco only.[498] In contrast to tobacco smoking, neither habitual cocaine smoking nor the short-term administration of inhaled alkaloidal cocaine significantly affected DL$_{co}$.

CARDIOVASCULAR. Sinus tachycardia is the most frequent ECG change during cocaine intoxication. The initial ECG and other clinical factors are less predictive of myocardial ischemia in patients with cocaine-associated chest pain compared with patients with chest pain and no cocaine use. Additionally, there is a relatively high incidence of ECG abnormalities (e.g., left ventricular hypertrophy, early repolarization, ST elevation without ischemia) in patients with cocaine-associated chest pain, even in the absence of clinically significant coronary artery disease.[499] The sensitivity of detecting myocardial necrosis in patients with cocaine-associated chest pain is similar for serum troponin I and assays that directly measure the CK-MB protein concentration.[500] However, a study using the electrophoretic method for measuring CK-MB suggested that this method was less sensitive for detecting myocardial necrosis in these patients compared with the serum troponin I concentration.[238] The use of the relative index of CK-MB and CK increases the sensitivity of diagnosing myocardial necrosis with cardiac enzymes.[501] Myoglobin is a less-specific marker of acute myocardial infarction (AMI) than CK-MB or troponin I in patients with recent cocaine use. In a prospective study of 97 patients presenting with chest pain consistent with AMI, 20% had documented cocaine use.[253] Comparing the 2 groups, cocaine use altered the mean serum myoglobin concentration (179 vs. 74 ng/mL), but not the mean serum CK-MB or troponin I concentrations. The incidence of AMI in the two groups was comparable (cocaine use, 11%; no cocaine use, 12%).

BLOOD. Common abnormalities in blood chemistries following large cocaine doses include mild hyperglycemia and leukocytosis. Thrombocytopenia may occur following the IV use of cocaine, but the contribution of other substances (e.g., contaminates, drugs of abuse) cannot be excluded.[502] Agranulocytosis (i.e., absolute neutrophil count <0.5 × 10^9/L) may occur in chronic users of levamisole-contaminated cocaine. Morphologic features of cocaine users with agranulocytosis include plasmacytoid lymphocytes (i.e., mature lymphocyte with eccentric location of nucleus and basophilic tent to cytoplasm), bone marrow plasmacytosis, and megakaryocytic hyperplasia.[503] These patients are often HLA-B27 positive and have antineutrophil antibodies. More severe laboratory abnormalities occur in serious cocaine intoxication including profound metabolic acidosis, both with and without physical exertion. This metabolic acidosis is usually a hyperlactatemia, which is more severe and prolonged than expected from seizure activity or physical exertion. A 28-year-old woman developed coma, apnea, and generalized seizures following the unwitnessed ingestion of cocaine.[504] Her initial arterial pH was 6.39, and her rhythm deteriorated from a wide complex tachycardia to a slow idioventricular before responding to resuscitative measures. The initial arterial pH in a case series of 5 patients with cocaine-induced excited (agitated) delirium requiring restraint ranged from 6.25–6.81.[505] Two of these 5 patients survived after receiving advance cardiac life support. This severe metabolic acidosis (i.e., pH <7.0) can occur following cocaine use and exertion without physical restraint.[506] A 32-year-old chronic cocaine abuser received multiple, superficial shotgun wounds after running several blocks.[507] His oral temperature was 95°F (35°C), and his initial arterial pH was 6.91. He recovered rapidly with IV fluids. Experimental studies in healthy volunteers indicate that restraint procedures in the prone position do not contribute significantly to the profound metabolic acidosis associated with excited delirium and restraint by law enforcement personnel.[508,509,510] In patients with severe hypothermia, laboratory abnormalities include persistent hyperkalemia, transient hemoglobinuria, myoglobinuria without renal failure, elevated serum hepatic transaminases, and markedly increased serum creatine kinase concentrations.[303]

CENTRAL NERVOUS SYSTEM. The interpretation of neuropsychologic test results in chronic cocaine users is complicated by difficulty controlling confounding variables including time since last cocaine use. In a inpatient study of 8 long-term cocaine addicts without drug use for 6 months, single-photon emission computed tomography demonstrate cerebral hypoperfusion and neuropsychological testing detected deficits in attention concentration, memory, learning, word production, and visuomotor tasks based on published, age-matched normative data.[511] A meta-analysis of 15 studies on the effect of chronic cocaine use and neuropsychologic testing suggested that chronic cocaine use adversely affected attention, visual memory, design reproduction, and working memory, when compared with healthy,

normal controls.[512] Most tests of motor performance demonstrated minimal effects and the effect of cocaine use on executive functioning (planning, working memory, set-shifting) was inconsistent. However, there was substantial variability between different studies, and the effect of recent cocaine use on the neuropsychologic tests could not be excluded.

A case-control study of 62 male crack cocaine users with cerebrovascular accidents detected an increased incidence of cerebral white matter lesions on magnetic resonance imaging (MRI) when compared with age-matched controls.[513] The lesions were hyperintense on T2-weighted MR images, and they occurred primarily in areas of the middle cerebral artery with limited anastomoses. There were no lesions in the subcortical gray matter (basal ganglia, thalamus). Deficits in cerebral perfusion may occur in chronic cocaine users without evidence of cerebrovascular accidents.

BODY PACKING

Supine abdominal radiographs usually demonstrate professionally wrapped cocaine packets in the GI tract with sensitivities in case series ranging up to approximately 70–90%.[356,514,515] Radiographic signs of cocaine bags in the GI tract include multiple radiodense foreign bodies, "double-condom" or "halo" sign (air trapped between layers of condoms), and rosettes (air trapped in a knot tied on a condom).[516] The presence of thin air layers (i.e., halo sign) in the cocaine packages may result from the production process, and the occurrence of this radiographic sign does not necessarily imply rupture of the cocaine packet.[517] Contrast-enhanced plain abdominal radiography, barium enema, or an abdominal CT scan with contrast are optional imaging studies when plain abdominal radiographs do not detect cocaine packets in the GI tract of individuals suspected of body-packing.[518] There are limited clinical data on the sensitivity and specificity of ultrasound for the detection of cocaine packets in the GI tract, but a small case series suggested that ultrasound does demonstrate the presence of these packets.[519] Although urine drug of abuse screens provide adjunctive evidence for the ingestion of cocaine packets,[520] the sensitivity of these immunoassays is highly variable and the lack of a positive drug screen does not exclude the ingestion of cocaine packets.[521]

Driving

There are limited data on the effect of acute or chronic cocaine use on driving skills. Although the duration of action of cocaine is short, cocaine users frequently abuse other illicit drugs and ethanol concurrently with cocaine.

Furthermore, recreational use of freebase cocaine occurs in larger doses than administered in medical and experimental settings. Case reports associate cocaine use with serious driving impairment, but the rapid deterioration of cocaine in stored specimens limits direct correlation between cocaine concentrations and driving impairment.[522]

A number of recognized complications of cocaine use theoretically reduce the driving skills of cocaine users both during the acute phase of cocaine intoxication and the during the withdrawal phase. These potential adverse effects include light sensitivity, blurred vision with reduced glare recovery, irritability, poor judgment, anxiety with rapid steering or braking responses, ataxia, attentional deficits, risk taking, aggression, poor concentration, and fatigue.[523] In a Swedish case series of 61 drivers apprehended for suspected impaired driving with only cocaine in their blood, the mean and median cocaine concentrations in venous blood samples (time between blood draw and apprehension not reported) were 0.95 mg/L and 0.07 mg/L, respectively, compared with 1.01 mg/L and 0.70 mg/L for benzoylecgonine.[524] The maximum cocaine and benzoylecgonine concentrations were 0.5 mg/L and 3.1 mg/L, respectively; the mean benzoylecgonine/cocaine ratio was 13.8. Frequently mentioned clinical findings included conjunctival erythema, agitation, restlessness, mydriasis, unsteady gait, incoherent speech and rapid pulse.

In volunteer studies, the administration of cocaine in relatively low doses is not associated with significant deterioration of psychomotor performance. In a study of 7 volunteers, the inhalation of cocaine doses ranging from 10–40 mg did not cause statistically significant changes in responses to the digit symbol substitution test or to reaction times.[525]

Studies of postmortem blood from automobile accident victims indicate the detectable concentrations of cocaine occurs in <4–6% of the blood samples from Canadian,[526] European,[527] and Australian studies.[528] In postmortem blood from 370 fatally injured drivers in Washington State, 13 cases (3.5%) and 18 cases (4.9%) had detectable cocaine and benzoylecgonine, respectively.[529] The cocaine concentration ranged from <0.01–0.23 mg/L with a median of 0.11 mg/L. About two-thirds of these drivers also had detectable concentrations of ethanol. Difficulty determining culpability in these studies result from several variables including the deterioration of cocaine in storage, associating specific cocaine and cocaine metabolite concentrations with the phase of intoxication (i.e., acute intoxication vs. "crash"), and the frequent presence of other drugs. When cocaine is present in blood from fatal accident victims, ethanol concentrations usually indicate serious impairment.[530]

Standard field sobriety tests do not reliably detect the presence of recent cocaine use (i.e., based on positive urine drug screen) in drivers arrested for reckless driving.[531]

TREATMENT

Stabilization

Intractable seizures, respiratory arrest, hyperthermia, and dysrhythmias represent the most serious immediate risks to life. With the exception of delayed intestinal rupture of cocaine bags, major symptoms usually present within the first hour following cocaine exposure. The ingestion of cocaine base ("rock") may delay serious symptoms for several hours. Most victims of fatal cocaine intoxication die within minutes of exposure. Patients, who arrive at the hospital with vital signs, usually survive unless hyperthermia and multiorgan failure develop. The first priority is the assessment of ventilation and the establishment of an adequate airway. Nondepolarizing neuromuscular blockers (e.g., vecuronium, rocuronium, pancuronium) are preferable to depolarizing agents (e.g., succinylcholine) for rapid sequence intubation because of the theoretical potentiation of cocaine effects because plasma cholinesterase metabolize both cocaine and succinylcholine. Intravenous access should be established along with cardiac monitoring and pulse oximetry for all patients with signs of intoxication. A chest x-ray and arterial blood gas should be obtained for patients with altered consciousness or respiratory distress.[532] Invasive or non-invasive hemodynamic monitoring (echocardiography, bioimpedance techniques, Swan-Ganz catheter) may assist the clinician to maximize hemodynamic variables in patients with pulmonary edema. Naloxone (0.4–2 mg IV) in lethargic or comatose patients should be administered if the presence of heroin is suspected, beginning with low doses titrated to effect to prevent the development of opioid withdrawal.

Dysrhythmias

Sinus tachycardia is the most common dysrhythmia during cocaine intoxication, and treatment usually involves sedation with benzodiazepines (5 mg diazepam IV or 1–2 mg midazolam IV bolus repeated every 3–5 minutes as needed, titrated to effect). Sodium bicarbonate and lidocaine are the main therapeutic options for the treatment of most ventricular dysrhythmias including cocaine-induced ventricular tachycardia. Although lidocaine is a potential adulterant of cocaine, adverse reactions from the use of lidocaine during cocaine toxicity are not well documented. The administration of lido-caine in a case series of 29 patients with cocaine-associated MI was not associated with significant cardiovascular or CNS toxicity.[533] The majority of these patients received lidocaine more than 5 hours after cocaine use when the effects of cocaine would be minimal.

The use of IV sodium bicarbonate is an important option to the administration of lidocaine as a treatment for ventricular dysrhythmias, particularly when QRS prolongation (wide-complex tachyarrhythmia) occurs during obvious cocaine intoxication. Theoretically, the use of a sodium bicarbonate infusion to alkalinize the serum to a pH of 7.45–7.5 would be most beneficial for patients with a wide complex tachydysrhythmia and QRS prolongation.[169,534] However, there are few clinical data to document of the effectiveness of sodium bicarbonate therapy in this setting or to separate the effects of reversal of acidosis and hypertonic saline. Accelerated ventricular rhythm usually requires no treatment. The use of β-adrenergic antagonists, type 1A or 1C antiarrhythmic agents, and mixed α- and β-adrenergic antagonists are contraindicated in patients with cocaine intoxication.[535] There are few human data on the safety and efficacy of amiodarone for the treatment of cocaine-induce ventricular dysrhythmias. Therefore, the administration of amiodarone is not generally recommended for the treatment of cocaine-induced ventricular dysrhythmia pending further clinical data on the effect of amiodarone on QT prolongation during cocaine intoxication, particularly the interaction of amiodarone and cocaine on blockade of HERG channel currents.

Myocardial Infarction and Chest Pain

Patients with chest pain and ECG evidence of myocardial ischemia after cocaine use should be treated with the standard doses of nitrates (0.3–0.4 mg sublingual times every 5 minutes up to 3 times until relief, followed by nitroglycerin drip starting at 10–20 µg/min titrated 5–10 µg/min every 5–10 minutes to effect and blood pressure if sublingual nitroglycerin or nitroglycerine spray is ineffective), morphine (2 mg IV every 5 minutes titrated to pain relief and sedation), oxygen, aspirin (81 mg orally), and heparin. Clinical reports indicate that sublingual nitroglycerin abolishes cocaine-induced vasoconstriction both in atherosclerotic and in nonatherosclerotic segments of the coronary arteries.[536,537] Benzodiazepines (e.g., lorazepam) are safe medications for the treatment of patients with cocaine-associated chest pain,[538] and the early use of IV benzodiazepines may improve cardiac hemodynamics and relieve chest pain.[539,540] In patients with cocaine-associated chest pain and ischemic ECG changes, 20 mg diltiazem IV is a therapeutic option when the patient does not respond to benzodiazepines, nitrates, morphine, and oxygen.[541]

Intravenous phentolamine (1 mg IV every 5 minutes) titrated to relief of chest pain or hypotension also is an option for patients with chest pain unresponsive to standard treatments.[542] The elimination half-life of phentolamine is about 18 minutes. The use of β-adrenergic blockade is relatively contraindicated in the treatment of cocaine-associated chest pain because of the potentiation of cocaine-induced coronary vasoconstriction.[160] Although the early use of β-blockers in AMI is well accepted and a retrospective study suggests that the use of β-blockers reduces the risk of MI in cocaine users,[543] there are inadequate data to recommend the use of β-blockers in the treatment of patients with cardiovascular complications secondary to cocaine use. Furthermore, adverse reactions to β-blockers in this setting are variable and unpredictable; case reports and observational studies suggest that the use of β-blockers in cocaine associated MI increases the risk of myocardial necrosis and may cause catastrophic deterioration.[544,545]

Immediate coronary arteriography and angioplasty are indicated for patients with chest pain and documented ST elevation. Thrombolytic therapy should be used with caution because of the potential complication of aortic dissection and subarachnoid hemorrhage, as well as the lack of documented efficacy and poor correlation of the ECG to cocaine-associated MI.[546] When available, the use of coronary angioplasty is a safer modality than thrombolysis to determine the multifactorial etiologies of ischemic chest pain in cocaine users. However, there are few human data to guide management of cocaine-induced MI.

Hypotension

Often, fluids do not reverse the hypotension seen in the late depressive phase of cocaine intoxication. Frequently, the administration of dopamine and/or norepinephrine (Levophed) is needed to stabilize the blood pressure. Invasive or noninvasive hemodynamic monitoring may help optimize fluid resuscitation and the use of inotropic agents when pulmonary edema is present.

Hypertension

The stimulant phase of cocaine is usually short, and the treatment of hypertension and tachycardia is usually unnecessary. For cocaine-intoxicated patients requiring treatment for severe hypertension not responding to sedation, sodium nitroprusside infusion (initial rate 0.1 μg/kg/min titrated to desired end point, average therapeutic dose ranges from 0.5–8 μg/kg/min) and IV phentolamine (1–2.5 mg IV bolus, repeated in 5 minutes if no response) are the antihypertensive drugs of choice. The reduction in blood pressure must be done cautiously in patients with chronic hypertensive disease or acute cerebrovascular events with careful hemodynamic monitoring. The use of β-blockers for hypertension during cocaine intoxication is contraindicated because β-blocker drugs potentially increase cocaine-induced coronary vasoconstriction by blocking the β-receptors and by allowing unopposed α-receptor stimulation of coronary arteries.[547] A case report associated the use of IV propranolol during cocaine-induced hyperadrenergic state with a reduction in heart rate, diaphoresis, anxiety , and a significant increase in blood pressure requiring the use of sodium nitroprusside.[548] The use of calcium channel blockers offers no clear benefits in managing the hemodynamic effects of cocaine intoxication other than the second line management of cocaine-induced coronary artery vasospasm and associated myocardial ischemia.

Hyperthermia

Hyperthermia is an immediate, life-threatening complication of cocaine use. Core temperatures should be measured in all agitated patients. As measured by rectal thermocouple, a core temperature exceeding 40.5°C (105°F) indicates the need to cool the patient (e.g., ice water bath, evaporative cooling) and to monitor of vital signs every 10–15 minutes after stabilization. Ice packs and the use of hypothermic blankets are alternative measures when an ice bath is not available. The patient should be removed from ice water baths and internal cooling measures when the core rectal temperature drops to 39°C (102°F). Less-severe temperature elevations (<38–40°C/100.4–104°F) can be treated by placement in a cool room, removal of clothes, minimization of physical activity (sedation), tepid sponging, or evaporative methods (cool mist spray, fans). These patients should receive aggressive fluid resuscitation to maintain adequate urine output and to minimize the effects of rhabdomyolysis. These patients require sedation (e.g., benzodiazepines, continuous propofol infusion) and if necessary, paralysis with paralytic drugs.

Seizures

Lorazepam (2–4 mg IV in adults) and diazepam (0.1–0.3 mg/kg up to an adult dose of 10 mg) are the drugs of choice for cocaine-associated seizures. Phenobarbital (20 mg/kg loading dose with maximum infusion rate 50–100 mg/min) and propofol (3–5 mg/kg loading dose, 30–100 μg/kg/min maintenance infusion) are second-line drugs that are not well-tested in the clinical setting of cocaine-induced status epilepticus. Persistent seizures indicate the need for aggressive treatment of the hyperthermia and metabolic acidosis as well as consideration of pentobarbital-induced coma.

EXCITED DELIRIUM

There are few data to guide the treatment of excited delirium associated with cocaine intoxication. Cardiac arrest in these patients is typically associated with asystole as a terminal event (multisystem failure, rhabdomyolysis) rather than ventricular fibrillation; the prognosis of cardiac arrest in this situation is extremely poor. Hence, treatment is directed toward early recognition, sedation, detection/treatment of rhabdomyolysis, and restoration of homeostasis (hyperthermia, acidosis, fluid/electrolyte balance) prior to catastrophic events. Accurate assessment of central body temperature is essential to adequately treat patients with excited delirium.

Gut Decontamination

Because most recreational cocaine users do not ingest cocaine, gut decontamination procedures are usually unnecessary. Gut decontamination may be considered when the history suggests cocaine ingestions exceed 3 mg/kg within 1 hour of cocaine exposure. Activated charcoal is the decontamination measure of choice because of the rapid onset of action of cocaine. *In vitro* studies indicate that standard doses of activated charcoal adsorb cocaine well both in alkaline and in acidic conditions.[549] Although *in vitro* models suggest that alkalinization increases the hydrolysis of cocaine,[70] activated charcoal binds cocaine well in acidic conditions and there is little evidence that gastric alkalinization improves clinical outcome. An IV line should be started, vital signs and cardiac rhythm should be closely monitored, and medications (diazepam, lorazepam) should be immediately available for treatment.

BODY STUFFER

All cooperative body stuffers should receive 50 g activated charcoal if they present within 1–2 hours after ingestion. The administration of activated charcoal to uncooperative patients depends on clinical judgment of the risks and benefits based on the dose and on the time since ingestion. Cocaine is poorly visualized on plain abdominal radiographs. Abdominal radiographs are not necessary in body stuffers unless a large ingestion of professionally wrapped cocaine is suspected. Cocaine is radiolucent and the radiographic appearance of cocaine packages depends on the consistency of the wrapping material and the presence of air inside and outside the wrapping. CT imaging may reveal the distinctive straight line of rock cocaine surrounded by air trapped in a wrapping.[550] In a retrospective study of 98 cocaine body stuffers, none of the 17 abdominal radiographs were positive.[357]

BODY PACKER

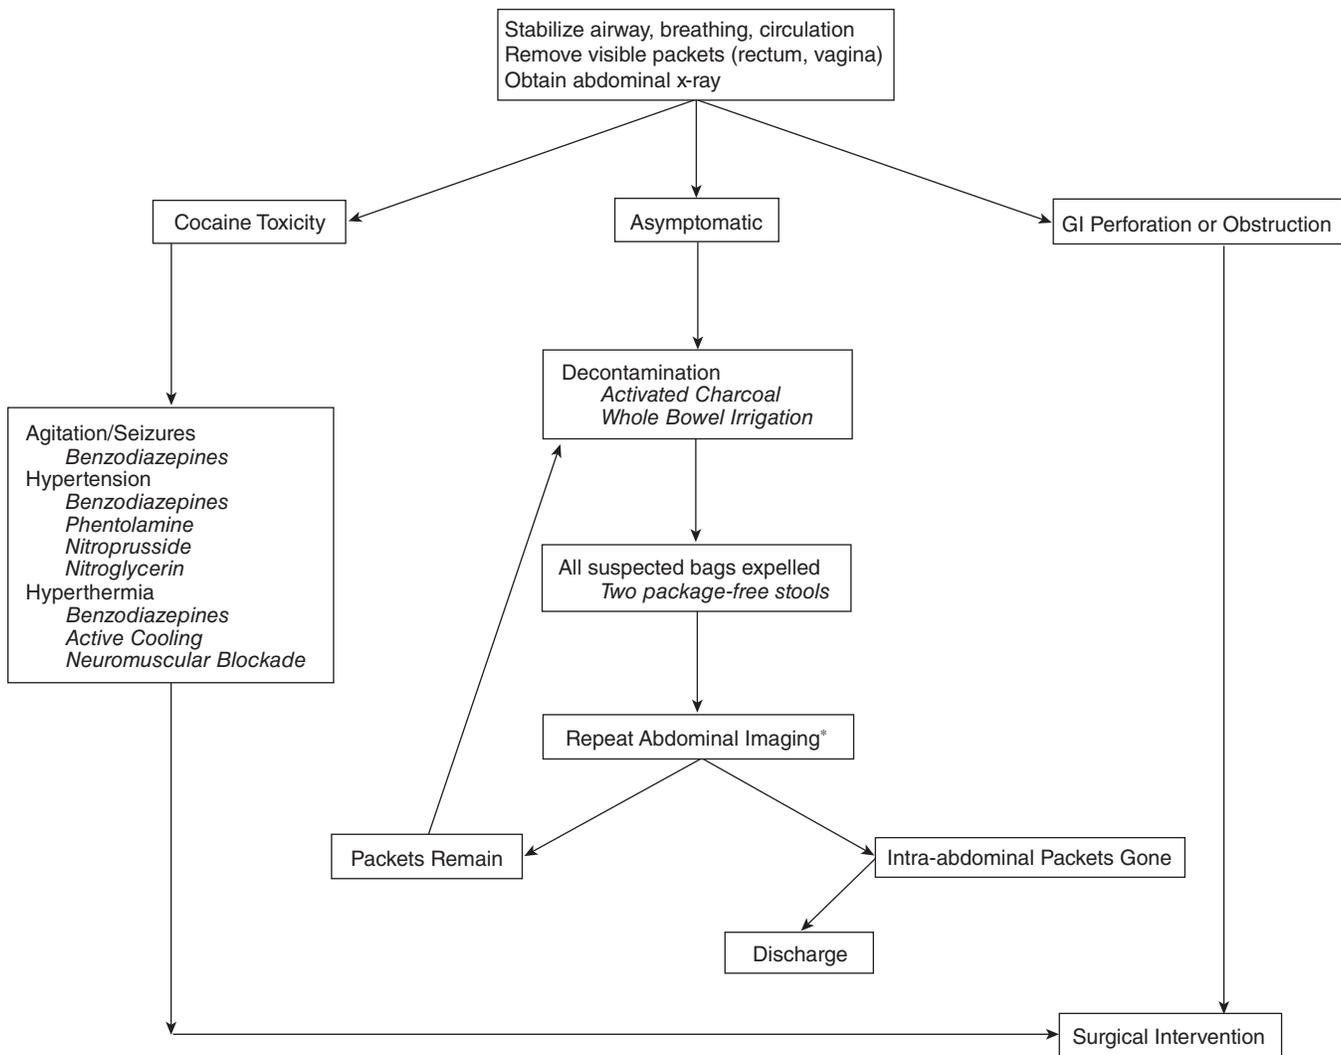
All body packers should receive activated charcoal, 1 g/kg, mild cathartics, and a stool softener (psyllium hydrophilic mucilloid in 3- to 4-g doses several hours after cathartic) to decrease the transit time of the packets. Serial activated charcoal (25–30 g every 2–4 h until the stool is charcoal-laden) is an option for these patients, but there are few data to indicate that the administration of serial activated charcoal improves clinical outcome. The management of these patients depends on the type of bag (i.e., propensity for breakage), the location, and the presence of symptoms.[356] The presence of well-wrapped cocaine packets (McCarron type 2 or 3) indicates a good prognosis.[551] Whole bowel irrigation (polyethylene glycol electrolyte solution 1–2 L/h) is an option for these patients, particularly following large (>10 g) ingestions of cocaine. The administration of standard doses of activated charcoal should precede the use of whole bowel irrigation by 30–60 minutes because *in vitro* studies indicated that desorption of cocaine from activated charcoal occurs following the addition of polyethylene glycol electrolyte lavage solution to activated charcoal, particularly at the acidic pH present in the stomach.[552] Although there are inadequate clinical data to confirm the efficacy of metoclopramide during WBI, the administration of metoclopramide has theoretical advantages during WBI. Metoclopramide (10 mg IV) accelerates gastric emptying and enhances smooth muscle activity from the esophagus through the small bowel. The endpoint of whole bowel irrigation is the presence of clear rectal effluent and the clearance of radiopaque packets. The removal of all bags must be done cautiously because attempted removal (including endoscopy) may puncture the packet and release cocaine. The primary indication for endoscopy is the removal of cocaine packets that did not pass through the pylorus. Oil-based laxatives are not recommended because of the potential of these laxatives to reduce the tensile strength of the packets. Surgical consultation should be obtained early (i.e., during first signs of cocaine intoxication), before the development of serious complications. Confirmation of the elimination of packets by contrast-enhanced CT should be done after decontamination measures and following the passage of 3 stools without packets. Figure 56.10 displays the algorithm for the treatment of body packers based on clinical presentation; complications of cocaine toxicity are treated with standard doses of the medications as listed under Stabilization.


FIGURE 56.10. Algorithm for the treatment of cocaine body packers.[355] *Contrast-enhanced abdominal computed tomography or contrast-enhanced radiography

Elimination Enhancement

The short biologic half-life of cocaine, the limited urinary excretion of unchanged cocaine, and the relatively large volume of distribution of cocaine limit the effectiveness of measures to enhance cocaine elimination. Consequently, no measures to enhance the elimination of cocaine are recommended other than the use of serial doses of activated charcoal in body packers.

Antidotes

There are no antidotes for cocaine intoxication. Specifically, β-blocking drugs are not antidotes for the hyperadrenergic state induced by cocaine intoxication. Experimental antidotes for cocaine intoxication include the use of mutant human butylcholinesterase to metabolize excessive cocaine doses.[553]

Supplemental Care

CHEST PAIN

Although the risk of AMI is substantially elevated in patients using cocaine, the incidence of myocardial ischemia in patients with cocaine-associated chest pain is relatively low. Elevation of cardiac enzymes (e.g., myoglobin) without baseline ECG abnormalities may occur in the absence of cocaine-associated AMI; alternately, some patients with cocaine-associated AMI may present to the emergency department without ischemic ECG changes.[554] High-risk patients should be admitted for

exclusion of AMI. Criteria for high-risk of AMI include ischemic ECG changes (ST elevation or ST depression ≥1 mm, ischemic T-wave inversion), elevated serum troponin I or CK-MB, hemodynamic instability or ventricular dysrhythmias, or recurrent ischemic symptoms with a history of coronary artery disease. Patients with low- or intermediate-risk of MI may be observed for 12 hours in an observation area. Stress testing helps identify ischemia in patients with underlying coronary artery disease. In a study of 256 cocaine-associated chest pain patients with low-to-intermediate risk of cardiovascular disease, 4 patients developed non-fatal MIs within 30 days of discharge from the observation unit.[555] All 4 of these patients continued to use cocaine.

MILD ACUTE INTOXICATION

Sedative doses of diazepam (2.5–5 mg IV) of lorazepam (1–2 mg IV) may be administered to patients with agitation. Acceptance, reduction of stimuli (i.e., rest, quiet, cool environment), and sincere reassurance are potentially useful therapeutic interventions. When the psychosis clears, each patient should be evaluated for suicidal and homicidal ideations. Besides potential self-harm, reasons for psychiatric hospitalization include chronic freebase use or IV injection, concurrent dependence, severe psychiatric or medical problems, severe psychosocial impairment, lack of social or family support, repeated outpatient failure, and poor motivation.[101] Patients who develop serious complications of ingesting cocaine packets usually present with signs of serious intoxication (seizures, dysrhythmias).

RHABDOMYOLYSIS

The development of rhabdomyolysis is unlikely in patients with mild acute cocaine intoxication or in patients with serum creatine kinase concentrations <1000 U/L.[556] Seizures, hyperactivity, hypokalemia or hyperkalemia, severe muscle spasm, and hyperthermia contribute to the development of rhabdomyolysis, and measures to resolve these clinical features are important to prevent worsening rhabdomyolysis. The early use of high doses of benzodiazepines helps limit the progression of rhabdomyolysis and renal failure. Kidney function should be monitored daily for several days in patients with evidence of significant muscle damage (i.e., serum creatine kinase >1,000–2,000 IU/L) if they are symptomatic or if the serum CK concentrations are rising. The treatment of rhabdomyolysis includes generous fluid replacement to maintain urinary output. The efficacy of alkalinization of the urine for the treatment of rhabdomyolysis is controversial. Hemodialysis is reserved for patients with renal failure, and there is no role for the prophylactic use of hemodialysis during rhabdomyolysis. Asymptomatic patients with serum CK <1,000–2,000 IU/L should be hydrated; these stable patients may be followed closely as outpatients to confirm declining levels.

BODY STUFFING/BODY PACKING

The integrity of the cocaine packets determines the onset and likelihood of cocaine toxicity following ingestion of these packets.[557] Body stuffers usually, but not always, swallow small amounts of loosely wrapped drugs to avoid arrest by police. Although most body stuffers develop no or only mild clinical features of cocaine intoxication,[558] occasionally body stuffers develop serious or fatal cocaine toxicity.[559] Body stuffers may be discharged if the vital signs remain normal and the patient remains asymptomatic 6–8 hours after ingestion as long as the cocaine was loosely wrapped (paper, single cellophane wrapping).[357,560] Body stuffers ingesting more securely wrapped cocaine packets may require longer observation periods (12–24 h). In contrast to body stuffers, body packers (swallowers, couriers, mules, internal carriers), can carry large quantities of cocaine, and these patients may develop delayed signs of serious cocaine intoxication if the cocaine packets leak. In a retrospective study of 4,660 cocaine body packers, 64 body packers (1.4%) developed signs of serious cocaine toxicity.[561] Typically, body packers carry about 1 kg of illicit drugs divided into 50–100 packets of about 10 g each.[562] Although previous packets were loosely wrapped, current smuggling techniques probably involves an automated process that densely packs the drug into a latex sheath (condom, balloon) covered with several layers of latex and a hard wax coating.[563] These processes also use aluminum foil, carbon paper, plastic food wrap, or other material to alter the radiodensity of the packet. Frequently, the body packers ingest constipating agents (loperamide, diphenoxylate) prior to transport with unaided passage of the packets being delayed 1–2 days to 2–3 weeks.[564] Oil-based laxatives should be avoided because of the potential for these agents to reduce the tensile strength of the wrappers and increase the risk of rupture.

The decision to surgically remove cocaine packets from the GI tract requires careful consideration of the potential risks and benefits. Indications for surgical intervention include signs of esophageal or intestinal obstruction (abdominal pain, vomiting), failure of the cocaine packets to progress through the stomach and small intestine, and evidence deterioration or leakage of the cocaine packets. The halo sign by itself is not an indication for surgical intervention because some air may be introduced into the cocaine packet during

production. The presence of cocaine in the urine may result from conditions other than deterioration of the cocaine packets (e.g., contamination of the packets, the use of semipermeable membranes, the simultaneous use of cocaine by the body packer).[565] Plain abdominal radiography has a high sensitivity (i.e., about 75–90%) for the detection of cocaine packets *in* body packers.[355] However, contrast-enhanced abdominal computed tomography is more sensitive, and this imaging technique is the procedure of choice when contrast is needed to improve sensitivity. Ultrasound and MRI are not sensitive techniques for the detection of cocaine packets in the GI tract.[566]

ACUTE PSYCHOSIS

Haloperidol (2–5 mg intramuscularly) may be useful in the treatment of psychotic reactions in the absence of excited delirium; there are few human data on the effect or safety of atypical antipsychotic medications (e.g., olanzapine) on acute psychosis associated with cocaine intoxication. The course of the acute psychotic episode usually is short (24–30 h) and hospitalization is usually necessary.

ADDICTION

The treatment of cocaine addiction is multifaceted combining psychotherapy, behavior therapy, and involvement in the 12-step programs similar to the treatment of other addictions. Current studies indicate that a combination of pharmacologic and behavioral or cognitive therapies provide the best approach to treatment, but most pharmacologic agents are either poorly tolerated or the onset of action is too long.[144,567] Strategies for the use of pharmaceutic agents include reducing withdrawal, ameliorating craving, blocking euphoria, and enhancing prefrontal cortical function (i.e., modulation of glutamate, dopamine, GABA receptors).[568] However, there is no single pharmacologic agent presently that has been found to consistently reduce cocaine use or cocaine cravings in multiple clinical trials; there are also no drugs for the treatment of cocaine addiction approved by the US Food and Drug Administration (FDA). Treatment of withdrawal symptoms is supportive and symptom-directed.[569,570]

Addiction is a chronic disorder with exacerbations and remissions, and the goal of outpatient therapy is to break the cycles of recurrent bingeing. Treatment of addiction generally involves the following 3 approaches: 1) behavioral methods to help the abuser recognize the destructive effects of cocaine and the need to stop, 2) supportive environment including self-help groups and family members to disassociate the abuser from cocaine sources and situations, and 3) psychodynamic interventions to help the abuser understand the reasons for cocaine use and the methods to fulfill this need without drugs.[163] Pharmacologic therapies provide adjunctive care to minimize the discomfort of cocaine withdrawal and reduce craving for cocaine. There are limited data supporting the clinical use of carbamazepine, dopamine agonists, disulfiram, phenytoin, and lithium in the treatment of cocaine dependence.[571] Pharmacologic adjuncts to the treatment of cocaine addiction include antidepressants, bromocriptine, carbamazepine, and fluoxetine.[59] Antidepressants are frequently prescribed to cocaine addicts to relieve some of the mood swings associated with the cessation of chronic cocaine use. Tricyclic antidepressants block catecholamine uptake and stabilize adrenergic and dopaminergic receptors as well as treating the anhedonia, depression, and dysphoria associated with cocaine withdrawal. The pharmacotherapy of cocaine addiction is experimental with no one superior protocol.[572] Bromocriptine and amantadine modify the depletion of dopamine associated with cocaine craving and withdrawal. Carbamazepine potentially alters the rekindling seizures associated with the desire to use cocaine. Neuroleptic drugs potentially block the euphoria associated with cocaine use. Other experimental medications include modafinil (a mild stimulant that blocks the euphoric effects of cocaine) to initiate abstinence and vigabatrin (an irreversible inhibitor of GABA transaminase that elevates brain GABA concentrations) to prevent relapse.[573] Cocaine vaccines (e.g., succinylnorcocaine linked to recombinant cholera toxin B-subunit protein) are experimental approaches to the treatment of cocaine addiction.[574]

Chapter 57

IBOGAINE (*Tabernanthe iboga* Baill.)

HISTORY

Ibogaine is one of the psychoactive indole alkaloids found in the West Central African shrub, *Tabernanthe iboga* that has been part of tribal culture in west-central Africa (Cameroon, Gabon, Republic of the Congo) for many centuries. In the Western culture, French and Belgian explorers first described the stimulant and aphrodisiac properties of the iboga root during the 1800s.[1] Professor Henri Baillon provided the first botanical description of the iboga plant before the Linnaean Society in Paris in 1889.[2] In the first part of the 20th century, French pharmacologists isolated a crystalline compound ("ibogaine" or "ibogine") from the root of the iboga plant that displayed stimulant properties in animal studies.[3,4] The popularity of ibogaine as a stimulant was limited. Dybowski and Landrin isolated ibogaine from *Tabernathe iboga* in 1901[3]; independently in the same year, Haller and Heckel also isolated ibogaine.[5] Lambarene® was an extract of the roots from a related species in the genus *Tabernanthe* (*Tabernanthe manii*) that was marketed in France between 1939 and 1970 as a stimulant. This extract contained 8 mg ibogaine for the treatment of depression, fatigue, asthenia, and convalescence from infectious diseases.[1] The chemical structure of ibogaine was not established until 1957.[6]

The hallucinogenic effects of ibogaine were widely publicized in the United States during the 1960s, and ibogaine was used to facilitate psychotherapy. During this time, anecdotal reports suggested that the abuse of ibogaine reduced cravings for heroin and cocaine. In 1970, the US Food and Drug Administration classified ibogaine along with lysergic acid diethylamide (LSD) and mescaline as a schedule I substance with use limited only to research. The status of ibogaine was similarly restricted in Belgium, Denmark, and Switzerland. France added ibogaine to their list of controlled substances in 2007. The International Olympic Committee also banned the use of ibogaine in athletes as a potential doping agent. There was little interest in ibogaine from pharmaceutic companies, in part, because the structure of a natural substance cannot be patented. However, Howard Lotsof received a US patent for the use of ibogaine in opioid withdrawal in 1985. During the late 1980s and the 1990s, ibogaine was introduced as an unapproved, rapid treatment of addiction, primarily in alternative settings.[7] Ibogaine is administered through a variety of self-help networks in private clinics in Mexico, the Caribbean (St. Kitts), and Panama.

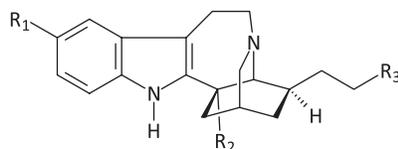
BOTANICAL DESCRIPTION

Common Name: Iboga

Scientific Name: *Tabernanthe iboga* Baill.

Botanical Family: Apocynaceae

Physical Description: This shrub reaches 6 feet (~1.8 m) in height with small green leaves and yellowish to pink flowers. The elongated oval fruit is orange and does not contain indole alkaloids.

Distribution and Ecology: The iboga plant is a rainforest shrub, which inhabits the undergrowth of tropical forests in central-west Africa, particularly Cameroon, Congo, and Gabon.


Alkaloid	R_1	R_2	R_3
Ibogaine	OCH_3	H	H
Noribogaine	OH	H	H
(±)-18-Methoxycoronaridine	H	CO_2CH_3	OCH_3

FIGURE 57.1. Chemical structures of ibogaine, noribogaine, and 18-methoxycoronaridine.

IDENTIFYING CHARACTERISTICS

Ibogaine (RN: 83-74-9, 12-methoxyibogamine) is one of several complex indole alkaloids present in root bark of the iboga plant along with tabernanthine (CAS RN: 83-94-3), ibogamine (CAS RN: 481-87-8), and ibogaline (CAS RN: 482-18-8). 18-Methoxycoronardine is a congener of ibogaine that demonstrates similar effects on drug craving in animal studies with less potential neurotoxicity.[8] Figure 57.1 displays the structure of ibogaine, noribogaine (CAS RN: 481-88-9), and 18-methoxycoronardine.

Ibogaine has a molecular weight of 310.44 g/mol and a molecular formula of $C_{20}H_{26}N_2O$. The free base is soluble in ethanol, methanol, and acetone, but insoluble in water; the hydrochloride salt is water soluble and decomposes at 299°C (~570°F). Ibogaine oxidizes spontaneously in solution, producing iboluteine and ibochine. The melting point of ibogaine is 153°C (~307°F). The pK_a of ibogaine in 80% methylcellulose is 8.1; this highly lipophilic drug has a heptane/water partition coefficient of 28.[9] In sunlight at 20°C (68°F), both ibogaine and noribogaine undergo degradation with a half-life of ~81 minutes and 11 minutes, respectively.[10]

EXPOSURE

Origin

Ibogaine is a psychoactive indole alkaloid isolated from the root bark of the tropical shrub, *Tabernanthe iboga*. Extraction of ibogaine from these roots is a complex process involving the use of alcohols and haloalkanes followed by chromatography for purification. However, the extraction of ibogaine from *T. iboga* is simpler than synthesis of ibogaine from nicotinamide. Ibogaine is also produced semisynthetically from voacangine, a component of root bark from the African tree *Voacanga africana* Stapf (Apocynaceae).[11]

Composition

Ibogaine is the most abundant alkaloid in extracts of the root bark of the iboga plant. The total alkaloid content of the dried root bark is ~5–6%.[1] The extract of *T. iboga* root extract is a complex mixture with the alkaloids in a dilute vinegar and ammonia extract of the bark divided approximately as follows: ibogaine, 80%; ibogaline, 15%; and ibogamine, up to 5%.[11] Other sources of ibogaine include *Voacanga thouarsii* var. *obtusa*,[12] *Tabernaemontana orientalis* R. Br.,[13] and *Tabernaemontana australis* (Mueell. Arg) Miers.[14]

Methods of Use

Ibogaine has a long tradition of use in West Africa as a stimulant and hallucinogen. Indigenous peoples in western Africa used extracts of the root from the iboga plant to improve endurance on hunting trips and to combat fatigue, thirst, and hunger. In higher doses, ibogaine is part of the initiation ceremonies of the Bwiti cult of Gabon, where practitioners believe that the use of ibogaine from the root of the iboga plant allows contact with ancestors in the spirit world.[15] This initiation ritual is similarly reported as near-death experiences with out-of-body feelings and a sense of floating over various landscape, encounters with deceased people, contact with divine entities, and arrival at the point of no return with subsequent return to reality.[16] To obtain psychoactive effects, the pulverized root bark of the iboga plant is swallowed with water. During these rituals, effects associated with the use of the root extract include excitation, inebriation, dramatic visual illusions, sensory synesthesias, euphoria, dysphoria, confusion, disorientation, and hallucination.[17] However, the root extract contains indole alkaloids in addition to ibogaine; therefore, the effect of ibogaine cannot be separated from other indole alkaloids in the extract.

DOSE EFFECT

Animals

In some animal studies, a single injection 100 mg ibogaine/kg to rats produces loss of Purkinje cells in the cerebellum, whereas the no observable adverse effect level (NOAEL) for neurologic damage following injection was 25 mg/kg in female rats.[18] At the higher ibo-

gaine dose, degeneration of Purkinje cells occurred as detected by the Fink-Heimer stain II and increased glial turnover detected by glial fibrillary acidic protein (astrocyte-specific protein).[19] Cerebellar degeneration appears primarily in areas 5 and 6 associated with the head and upper extremities. Clinical signs of neurologic abnormalities in rats administered doses exceeding 25 mg ibogaine/kg include ataxia, hyperexcitability, and abnormal posturing of the extremities.[20] However, there is substantial interspecies variation in the neurologic effects of ibogaine with monkeys and mice much less sensitive than rats.[21] In a study of white laboratory mice, the median lethal doses of ibogaine and noribogaine were 263 mg/kg and 630 mg/kg, respectively, with the ibogaine/noribogaine ratio being ~2.4.[22] At these higher doses, ibogaine depressed heart rate.

Humans

Based on anecdotal reports, the estimated threshold adult dose for hallucinations following ingestion of ibogaine is about 300 mg.[23] The typical dose for facilitating psychotherapeutic or spiritual insights is about 8–12 mg/kg.[7] Following oral doses of 4–25 mg/kg, open, non-blinded case reports suggested that the use of ibogaine was a rapid, easy means of suppressing the drug craving associated with heroin, cocaine, and amphetamine abuse.[24,25] The recommended oral dose for the treatment of drug addiction is 5–30 mg/kg.[8] In an open-label case series of heroin addicts receiving ibogaine for the treatment of withdrawal, the average ibogaine dose was approximately 20 mg/kg.[26] Case reports document the use of single ibogaine doses up to 1,800 mg for the treatment of heroin addiction.[27] There are inadequate data to determine the safety or efficacy of this dose for treating drug addiction.

TOXICOKINETICS

There are few toxicokinetic data on ibogaine in humans. Animal studies suggest that the oral bioavailability of ibogaine is gender- and dose-dependent. After oral administration of 5 mg/kg to rats, the bioavailability of ibogaine in male and female rats was 7% and 16%, respectively; following 50 mg/kg, the bioavailability was 43% and 71%, respectively.[28] These rodent studies also indicate that ibogaine undergoes substantial first-pass metabolism as well as large accumulation in adipose tissue as a result of the high lipophilicity.[29] The large fat reservoirs of ibogaine provide a mechanism for sustained release and prolonged action. The volume of distribution of ibogaine is large (i.e., 13 L/kg uncorrected for bioavailability).[21] Animal studies indicate that both ibogaine and noribogaine cross the blood–brain barrier.

Noribogaine (*O*-desmethylibogaine, 12-hydroxyibogamine) is the major metabolite of ibogaine, produced by CYP2D6-mediated *O*-demethylation.[30] *In vitro* studies using human liver microsomes indicate that CYP2C19 is the primary isoform involved with the biotransformation of the ibogaine analog, 18-methoxycaronaridine to its major metabolite, 18-hydroxycoronaridine.[31] In laboratory animals and volunteers, the plasma elimination half-life of ibogaine is short (i.e., 1–3 h) with >90% of the dose eliminated within 24 hours; however, pharmaceutic studies suggest that the terminal plasma half-life of ibogaine in humans (i.e., extensive CYP2D6 metabolizers) may be substantially longer (i.e., 5–8 h).[21] In rats, the gastrointestinal tract and kidneys eliminate about 60–70% of the administered dose of ibogaine; both ibogaine and noribogaine distribute into bile.[28] Limited human data suggests that the elimination half-life of noribogaine from blood is substantially longer than ibogaine.[32]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

The mechanism of action of ibogaine is complex and not well-defined. At pharmacologic doses, *in vitro* studies indicate that the actions of ibogaine result from the binding of ibogaine to a variety of central nervous system (CNS) receptors and channels including the κ- and μ-opioid receptors, σ_2 receptor,[33,34] and the serotonin transporter; additionally, ibogaine is a noncompetitive blocker of the *N*-methyl-*D*-aspartate (NMDA) receptor channel.[35] Other potential sites of ibogaine and noribogaine binding include $5HT_2$ and $5HT_3$, muscarinic (M_1, M_2), and nicotinic acetylcholine receptors as well as monoamine uptake sites.[9] The active metabolite, noribogaine, displays higher affinity for serotonin transporters and opioid receptor subtypes (i.e., moderate κ- and weak μ-opioid receptor agonist) compared with ibogaine as demonstrated in Table 57.1.

TABLE 57.1. Affinity of Ibogaine and Noribogaine for Central Nervous System Receptors. [30]

Receptor	Site	Ibogaine IC_{50} (μM)	Noribogaine IC_{50} (μM)
Serotonin			
Transporter	RTI-55 DAT	00.59	0.04
Opioid Mu	DAMGO	11.00	0.16
Opioid Kappa 1	U69593	25.00	4.20
Opioid Kappa 2	IOXY	23.80	92.30
Glutamine			
NMDA	MK-801	5.2	31.40

Noribogaine has little affinity for σ_2 receptors in contrast to ibogaine,[36] whereas noribogaine is approximately 10–15 times more potent than ibogaine in binding the serotonin transporter and inhibiting serotonin reuptake.

In vitro studies indicate that ibogaine noncompetitively blocks sodium influx through ganglionic-type nicotinic receptor channels.[37] Ibogaine has moderate affinity for the σ_2 receptor, which increases intracellular calcium and induces apoptosis. This compound has low affinity for σ_1 receptors, which modulate NMDA-type glutamatergic, dopaminergic, and cholinergic receptors. Additionally, *in vitro* studies indicate that ibogaine has low affinity (i.e., K_i >100 μM) for benzodiazepine, γ-aminobutyric acid ($GABA_A$), cannabinoid, dopaminergic, metabotropic glutamatergic, and serotonergic receptors.[33] Although ibogaine is structurally similar to serotonin and harmaline as a result of the shared indole ring, ibogaine does not display significant affinity for serotonin receptors at standard pharmacologic doses. However, noribogaine and to a lesser extent, ibogaine inhibit serotonin uptake by binding to serotonin transporter sites, resulting in increased extracellular concentrations of serotonin, particularly in the nucleus accumbens.[36] Both ibogaine and noribogaine also transiently decrease tissue dopamine concentrations by stimulating dopamine metabolism.

Animal studies suggest the possibility of neurotoxicity and possibly cardiotoxicity following the administration of ibogaine. In high doses (i.e., 100 mg/kg), some animal studies indicate that ibogaine produces loss of Purkinje neurons in the cerebellar vermis, particularly lobules 5 and 6, as detected by histochemical markers including astrocytosis, microgliosis, argyrophilic degeneration, and loss of calbindin immunoreactivity.[38] Observed effects in these animals include ataxia and tremor. The cause of this damage (e.g., excessive glutamate release) is not well-defined.[39]

CLINICAL RESPONSE

Because of the illicit status of ibogaine, there are limited human data in the peer-reviewed medical literature on the clinical effects of the drug. When administered in nonhospital settings for the amelioration of opioid withdrawal, common adverse effects include vomiting, myalgias, tremor, ataxia, loss of balance, and rarely, transient hypotension.[8] The onset of action is about 1–3 hours with initial effects of a dreamlike, waking state (floating, passage along a long path) persisting 4–8 hours. This dream-like state develops with visions of transcendent beings and a "panoramic readout of long-term memory."[8] Subsequently, a reflective period begins about 4–8 hours after ingestion with attention focused on inner subjec-

tive experiences rather than external cues. This phase lasts 8–24 hours. A third phase of stimulation starts 12–24 hours after ingestion and persists 24–72 hours. During this phase, volunteers regain normal attention to the environment and experience arousal and alertness.[9] Some patients report reduced need for sleep. Deaths associated with ibogaine are not well-reported, but high doses of ibogaine may produce coma and respiratory depression.[40]

DIAGNOSTIC TESTING

Analytic Methods

Techniques for the quantification of ibogaine include thin layer chromatography with UV spectrophotometry,[41] gas chromatography with flame ionization detection,[42] gas chromatography/mass spectrometry after organic extraction and derivatization with trifluoroacetic anhydride,[43] gas chromatography/electron impact/mass spectrometry in full scan mode,[44] high performance liquid chromatography (HPLC) with fluorometry,[10] liquid chromatography/electrospray ionization/mass spectrometry,[45] and liquid chromatography/tandem mass spectrometry.[46] The limit of detection (LOD) for HPLC with fluorometry is about 20 ng/mL with a coefficient of variation of 8–12%. The lower limit of quantitation (LLOQ) for both ibogaine and noribogaine using liquid chromatography/tandem mass spectrometry is 50 ng/mL with precision of 7.8% and 7.4%, respectively, and accuracy of 89.6% and 86.2%, respectively. The LOD for this method is 1 ng/mL. The LLOQ for ibogaine and noribogaine using liquid chromatography/electrospray ionization/mass spectrometry is 0.89 ng/mL and 1 ng/mL, respectively, in plasma with precision <14% and accuracy 9–10%. HPLC also allows LLOQ of ibogaine and noribogaine in the range of 1 ng/mL with precision ≤ 17%.[10] The use of solid-phase extraction along with gas chromatography/methane positive-ion/mass spectrometry allows the detection of ibogaine in plasma samples at LLOQ near 0.5 ng/mL.[47] Analysis by solid-phase extraction and HPLC with photodiode array detection allows the determination of ibogaine along with 12 other plant alkaloids (e.g., aconitine, anabasine, atropine, brucine, colchicine, cotinine, cystine, harmine, nicotine, scopolamine, strychnine, yohimbine).[48] The LLOQ of ibogaine using this screening method for analysis of serum and urine samples is 6.0 ng/mL and 3.2 ng/mL, respectively, both with coefficients of variation <5%. Aqueous solutions of ibogaine are relatively stable under refrigerated conditions. During refrigerated storage, the loss of ibogaine from a 10 mg/mL solution over 7 months was <10%.[43] There was no statistically significant difference

in ibogaine or noribogaine concentrations in plasma samples stored at $4°C$ (~$39°F$) and $-20°C$ ($-4°F$) for 1 year.[45]

Biomarkers

There are limited pharmacokinetic data on ibogaine. In heroin addicts receiving 500–800 mg ibogaine for the treatment of withdrawal, peak plasma ibogaine concentrations range between 30–1,250 ng/mL within 2–5 hours after ingestion. Plasma ibogaine concentrations decline rapidly to <10 ng/mL 24 hours after ingestion. Plasma noribogaine concentrations remain elevated substantially longer than ibogaine with peak concentrations between 700–1,200 ng/mL decreasing to 300–800 ng/mL 24 hours after the ingestion of ibogaine.[30,30] These studies indicate that there are substantial differences in the plasma ibogaine and noribogaine concentrations between poor and rapid CYP2D6 metabolizers. After the ingestion of ibogaine, poor metabolizers have much lower concentrations of noribogaine and higher concentrations of ibogaine than rapid metabolizers. A 37-year-old man was found dead on a beach after drowning.[46] The postmortem femoral blood contained 3,300 ng ibogaine/mL and 4,600 ng noribogaine/mL. The ratios of heart/femoral blood for ibogaine and noribogaine were 0.73 and 0.61, respectively. Subclavian blood drawn at the death scene from a 48-year-old drug addict found dead after ingesting the bark from *T. iboga* contained average ibogaine and noribogaine concentrations of 10,800 ± 400 ng/mL and 20,800 ± 3,000 ng/mL, respectively.[49] At autopsy 48 hours later, the femoral blood contained average ibogaine and noribogaine concentrations of 5,400 ± 1,400 ng/mL and 5,600 ± 900 ng/mL, respectively, probably as a result of oxidation.

TREATMENT

There are few clinical data on the treatment of toxicity associated with ibogaine. Treatment of adverse effects associated with ibogaine is supportive (e.g., antiemetics, rest). The hallucinogenic potential of ibogaine suggests that patients should be placed in a quiet environment with familiar friends and limited external stimuli. Although there are few clinical data, benzodiazepines are a therapeutic option for the treatment of anxiety associated with the behavioral effects of ibogaine.

Chapter 58

KHAT (*Catha edulis* (Vahl) Forsskal Ex Endl.) and CATHINONE

HISTORY

The habit of chewing Khat for stimulant properties has a long history in eastern Africa and southern Arabia, where the plant (*Catha edulis*) is indigenous. The Arabian physician, Najeeb Al-Deen Al-Samargandi recommended the use of khat for the treatment of depressive illness in an Arabic medical book written in the 13th century.[1] Khat probably originated in Ethiopia; the use of khat as a stimulant spread to Yemen during the 13th century.[2] Swedish botanist, Peter Forskal first described the khat tree during an expedition to Egypt and Yemen in the middle 18th century. The English adventurer-writer, Sir Richard Francis Burton (1821–1890) and the French Poet, Jean Arthur Rimbaud (1854–1891) wrote about chewing khat in Harer, Ethiopia during the 19th century.[3] Until recently, the use of khat remained localized to the areas where the plant is native because the active ingredient in khat leaves decays rapidly.[4] The habit has now spread to distant ethnic communities (e.g., Somali communities in South Wales and London).

BOTANICAL DESCRIPTION

Common Name: Khat, qat (Yemen), gat, mairungi (Uganda), miraa (Kenya), muhulo (Tanzania), muraa, musitate, jaad/qaad (Somalia), tchat (Ethiopia), African salad, bushman's tea

Scientific Name: *Catha edulis* (Vahl) Forsskal ex Endl.

Botanical Family: Celastraceae (bittersweet family)

Physical Description: This leafy evergreen shrub reaches up to 6 m (~20 ft) in height with opposite or alternate leaves about 1–4 cm (~0.5–1.5 in) wide and 5–10 cm (~2–4 in) long.[5] The glossy, brownish-green, leathery, elliptical to lanceolate leaves have serrated edges that resemble withered basil; as the leaves deteriorate, they become yellow-green and leathery. The odor is slightly aromatic and the taste is slightly sweet and astringent. There are no unique anatomic features that separate khat from other similar plant species; the identification of khat requires laboratory confirmation.

Distribution and Ecology: Khat grows on moist slopes at elevations of 3,000–8,000 ft (~1,000–2,500 m) in Yemen, Ethiopia, Kenya, and east Africa. Severe frosts in winter destroy the aerial parts of the plant and limit the height of the plant. Frequently, khat is grown among other commercial crops (coffee, legumes, papayas, peaches). In Yemen, khat is not cultivated in the hot, coastal cities (e.g., Aden, Hodieda, Mokalla).

IDENTIFYING CHARACTERISTICS

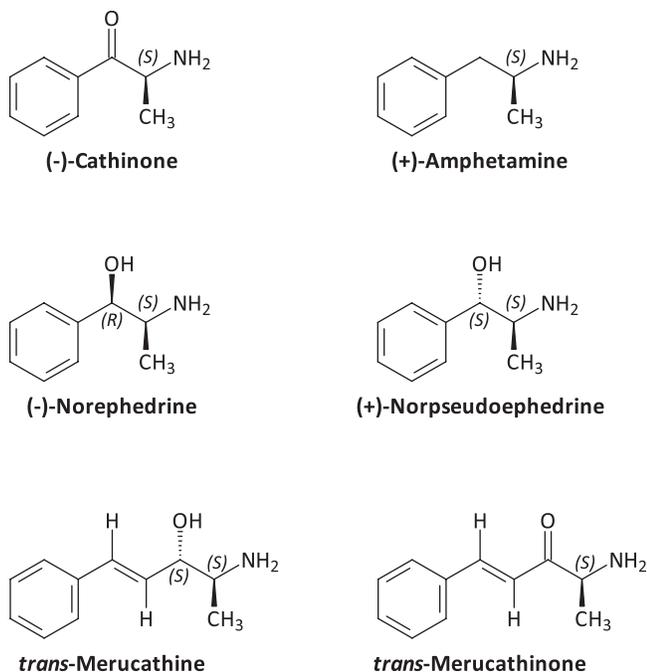
Fresh khat leaves contain up to 60 different catheduline compounds (polyesters of euonyminol) and several sympathomimetic phenylalkylamine compounds including cathinone [(−)-α-aminopropiophenone, 2-aminopropiophenone, CAS RN: 71031-15-7], cathine


FIGURE 58.1. Chemical structure of major chemical ingredients in khat, with (*R*) and (*S*) absolute configuration indicated at the stereocenters..

[(+)-norpseudoephedrine, CAS RN: 492-39-7], and (+/−)-norephedrine [phenylpropanolamine, CAS RN: 14838-15-4]. The only structural difference between amphetamine and cathinone is the presence of a carbonyl on the α-carbon of the amphetamine side chain as displayed in Figure 58.1. The World Health Organization (WHO) includes *S*-(−)-cathinone in schedule I (i.e., most controlled substance category as a result of high abuse potential) of the United Nations Convention on Psychotropic Substances. Khat also contains phenylpentenylamine alkaloids (merucathinone, merucathine, pseudomerucathine) and catheduline compounds. Other compounds in khat include tannins, terpenoids, flavonoids, ethereal oil, sterols, amino acids (alanine, glycine, glutamic acid, tryptophan), minerals (calcium, copper, iron, zinc), vitamins (ascorbic acid, carotene, niacin, riboflavine, thiamine), and glycosides.[6,7]

Although animal studies suggest that the sympathomimetic effects of (−)-cathinone (MW: 149.2) and (+)-norpseudoephedrine (cathine) are similar, *S*-(−)-cathinone is probably the active psychoactive ingredient in khat.[8,9] Cathinone is an intermediate in the synthesis of cathine that accumulates in young, but not in adult leaves. During the wilting of khat, the reduction of cathinone to cathine occurs.[13] The sympathomimetic effects of standardized khat leaves and pure cathinone are similar in experimental studies.[10]

S-(−)-Cathinone is the ketone congener of phenylpropanolamine (norephedrine).

EXPOSURE

Epidemiology

Chewing fresh khat leaves is a habit that is endemic in regions of east Africa (Djibouti, Ethiopia, Kenya, Madagascar, Somalia, Sudan, Tanzania, Uganda) and the southwestern Arabian Peninsula, particularly in Yemen. The use of khat is also common in immigrant communities (Yemen, Ethiopia, Somalia) in the United States, United Kingdom, and Australia.[11] Commercial sources of fresh khat include Kenya, Ethiopia, and Somalia. The first khat harvest occurs about 3–5 years after planting.[12] Only the fresh leaves produce the desired stimulatory effects.[13] However, the advent of air transportation allows the rapid distribution of fresh khat leaves before the deterioration of the active ingredients. The use of khat is prohibited in Australia, Denmark, Finland, France, Germany, New Zealand, Norway, Switzerland, and the United States; possession of the unprepared plant form is legal in the United Kingdom and the Netherlands. The World Health Organization classifies khat as a drug of abuse that can produce mild to moderate psychologic dependence. Hagigat is a capsule containing 200 mg cathinone that is marketed in Israel as an natural aphrodisiac and stimulant.[14] This product is a substitute for khat. The US Drug Enforcement Agency classifies cathinone as a schedule I drug (i.e., most restrictive), whereas cathine is a schedule IV drug.

Composition

The cathinone content of khat leaves depends primarily on the growing environment; therefore, the cathinone content varies substantially between khat specimens from different regions of Yemen.[2] Young, fresh leaves contain the highest concentration of cathinone.[15] These leaves lack the (+) isomer of cathinone; consequently, the (−) isomer of cathinone is the only natural enantiomer in *Catha edulis*.[16] Mature khat leaves usually contain more (+)-norpseudoephedrine than (−)-cathinone as a result of the conversion of cathinone to cathine [(+)-norpseudoephedrine] and (−)-norephedrine during maturation.[4] (+)-Norpseudoephedrine occurs in all parts of the khat plant, whereas cathinone occurs almost exclusively in the young leaves, shoots, and branchlets.[17]

The content of specific phenylalkylamine compounds in khat leaves varies substantially both as an absolute amount and as a percentage of total phenylalkylamine

content, depending on the origin and the age of the leaves. In a study of 22 samples of fresh khat leaves from Kenya, Ethiopia, Yemen, and Madagascar, the specific phenylalkylamine content as an approximate percentage of total phenylpropyl and phenylpentenyl content ranged between the following: cathinone, 5–59%; cathine [*S*,*S*-(+)-norpseudoephedrine], 30–79%; and phenylpropanol-amine [*R*,*S* -(−)-norephedrine], 4–19%.[18] Approximate phenylalkylamine content per gram fresh khat leaves typically ranges between the following: cathinone, 0.36–1.14 mg; cathine, 0.83–1.20 mg; and norephedrine, 0.08–0.47 mg.[19] Analysis of fresh khat leaves confiscated by Swiss custom officers demonstrate the following phenylalkylamine compounds in mg/g fresh weight: (−)-cathinone, 1.02 ± 0.11; *S*,*S*-(+)-norpseudoephedrine 0.86 ± 0.06; and *R*,*S*-(−)-norephedrine, 0.47 ± 0.05.[10] In a study of khat leaves confiscated at the Frankfurt airport and stored at −20°C (−4°F), the cathinone, cathine, and norephedrine content in the leaves were 1.14 mg/g, 0.83 mg/g, and 0.44 mg/g, respectively.[20] *S*-(−)-Cathinone is relatively unstable; this active compound decomposes rapidly into (+)-norpseudoephedrine and norephedrine within a few days of harvest. The fluoride content of khat is negligible based on analyses of khat leaves and saliva from khat chewers; high fluoride content in drinking water from rural areas of khat growing countries may account for the presence of fluorosis of the tooth enamel in some khat chewers.[21]

Methods of Use

Typically, the harvest of khat begins in the early morning to reach the market by late morning as bundles of twigs, stems, and leaves wrapped in banana leaves to preserve freshness as shown in Figure 58.2.[19]

Figure 58.3 displays dried khat leaves. Khat is a euphoriant that is an integral part of the Yemeni and Somali culture, where urban khat sessions are a common social gathering after lunch in dedicated rooms (i.e.,

muffraj).[22,23] Desirable effects include the initial onset of elation, increased alertness, enhanced sociability, loquacity, and heightened self-confidence. Later in the session, irritability, emotional lability, and depressive symptoms may develop. Khat is also used during work as a means to reduce physical fatigue.[24]

DOSE EFFECT

Prediction of a dose response to khat is complicated by the variation in the alkaloids and potency of khat leaves, tolerance, and large interindividual variations in cathinone absorption from the leaves. In volunteer studies, the ingestion of 0.5 mg cathinone/kg produces stimulatory effects similar to the chewing of high-grade Kenyan khat.[10] An average khat session over 3–4 hours involves the use of 100–200 g khat leaves that contain approximately 0.5–1 mg cathinone/kg.[18] In a case series of 34

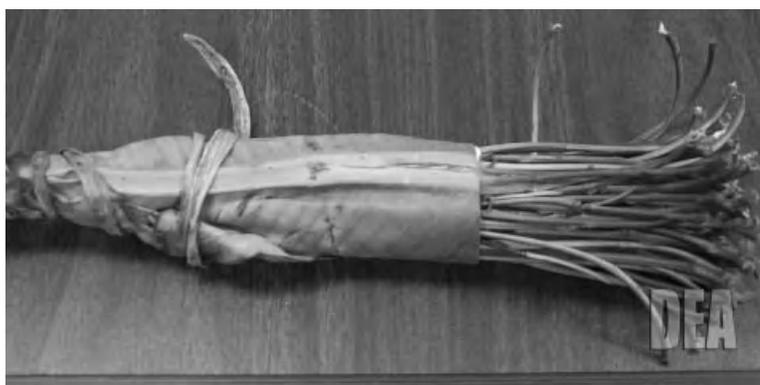
FIGURE 58.3. Dried khat leaves. (Photo courtesy of the US Drug Enforcement Agency)


FIGURE 58.2. Bundle of khat leaves, twigs, and stems wrapped in banana leaves. (Photo courtesy of the US Drug Enforcement Agency)

calls to the Israeli Poison Information Center regarding exposure to one-half to 6 capsules of Hagigat (cathinone), the main clinical features were headache, vomiting, hypertension, nausea, tachycardia, dyspnea, chest pain, and myalgias. Clinical symptoms did not correlate to the amount of Hagigat ingested.

TOXICOKINETICS

During a khat session, absorption of cathinone occurs primarily across the mucous membranes of the mouth. In a study of 4 adults chewing 600 mg khat leaves/kg body weight (i.e., about 25% of the usual dose in a khat session), the estimated absorption of cathinone in the mouth was $59 \pm 21\%$ with a mean volume of distribution of 2.7 ± 1.6 L/kg.[25] The time to maximal cathinone concentration (t_{max}) was 2.31 ± 0.65 hours. Cathinone undergoes ketone reduction to R,R-(−)-norpseudoephedrine (cathine) and R,S-(−)-norephedrine (phenylpropanolamine).[9,26] Volunteer studies indicate that norephedrine is the major metabolite of cathinone in humans; whereas cathine is the major decomposition product of cathinone in storage. In a study of 3 volunteers, R,R-(−)-norpseudoephedrine (cathine) and R,S-(−)-norephedrine (phenylpropanolamine) accounted for 2.5–5.2% and 20.1–34.9%, respectively, of the administered dose of 24 mg S-(−)-cathinone.[27] Cathine is much less active than cathinone. During volunteer studies, mean peak S-(−)-cathinone concentrations occurred about 2 ± 1 hours after the beginning of khat chewing, and the mean elimination half-life of S(−)-cathinone was approximately 4 ± 2 hours.[10] The S(−)-cathinone content in the khat leaves used during the study were similar to the S(−)-cathinone in high-grade Kenyan khat. Although cathinone shares similar pharmacologic effects with amphetamine, the duration of action for cathinone is shorter than that of amphetamine.[13] The stimulatory effects of khat usually last about 4 hours after chewing begins. Following the chewing of one-quarter of the normal dose of khat leaves, the mean plasma elimination half-life of cathinone and cathine were 1.5 ± 0.8 hours and 5.2 ± 3.4 hours, respectively.[25] Only about 2% of the absorbed dose of cathinone appears in the urine unchanged.[27] Cathinone and methcathinone are not metabolites of phenylpropanolamine or any other over-the-counter medications. Cathinone is a minor metabolite of the anorexic agent, diethylpropion.[28] There are limited data on the development of tolerance following chronic use of khat. In animal models, repeat administration of cathinone produces tolerance to the effects of cathinone eaten with food; these animals also demonstrate cross-tolerance to d-amphetamine.[29]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Cathinone is a naturally occurring β-keto-α-methyl-phenethylamine analog of amphetamine. Cathinone produces stimulatory effects similar to amphetamine as a result of the release of neurotransmitters (dopamine, serotonin, epinephrine) from presynaptic storage sites.[13] This compound is an indirect dopamine agonist that inhibits the reuptake of dopamine as well as functioning as a presynaptic releaser of dopamine in *in vitro* models (e.g., rat synaptosomes).[30] (−)-Cathinone also releases serotonin from striatal stores similar to d-amphetamine; however, the dopaminergic and serotonergic properties of cathinone are substantially weaker (i.e., 2–10 times) than d-amphetamine.[31] In volunteer studies, the administration of cathinone increases blood pressure and heart rate as well as causing CNS stimulation and euphoria.[32] Cathine is also an active constituent of khat that has dopaminergic properties similar to cathinone; however, the potency of cathine is much lower than cathinone.[33]

CLINICAL RESPONSE

Recreational Use

The ingestion of the active ingredients in khat initially produces stimulation of the CNS. The chewing of khat in a social setting causes mild euphoria, alertness, and hyperactivity followed by loquacity and increased social interaction within about 1 hour after the onset of chewing. Like other sympathomimetic drugs, khat can produce mydriasis, transient hypertension and tachycardia, hyperthermia, anorexia, headache, dry mouth, blurred vision, garrulousness, mood elevation, and arousal. Social and medical problems associated with the recreational use of khat include depression, malnutrition, insomnia, irritability, malaise, emotional lability, gastritis, constipation, impotence, and spontaneous sperm secretion. A case series associated the chronic use of khat with the development of severe, acute hepatotoxicity in patients without other obvious causes of hepatitis.[34]

Mental Disorders

Case reports associate a toxic psychosis with khat chewing, manifest by hyperactivity, pressured speech, anorexia, insomnia, and paranoid ideations in patients both with and without a personal and/or family history of psychiatric illness.[35] These symptoms disappeared 1 week after beginning thioridazine therapy (300 mg daily) and the cessation of khat use.[36] Two reported

types of psychosis include manic psychosis with grandiose delusions and a paranoid schizophrenic-like psychosis with persecutory delusions, auditory hallucinations, fear, and anxiety; however, the contribution of khat use to the development of persistent psychosis without pre-existing psychiatric disease remains unproven.[6]

Medical Complications

In Yemen, a hospital-based case-control study of 100 cases of acute myocardial infarctions (AMI) and 100 age- and sex-matched outpatient controls compared the 2 groups based on questionnaires covering personal history of khat chewing, smoking, hypertension, diabetes, and family history.[37] The odds ratio for AMI among khat chewers was 5.0 (95% CI: 1.9–13.1) with a substantially increased risk for heavy khat users. In a prospective, multicenter study of 8,176 consecutive patients from 6 adjacent Middle Eastern countries presenting with acute coronary syndrome, 11.4% were khat chewers, mainly of Yemen origin.[38] After adjustment for covariates (age, diabetes mellitus, dyslipidemia, hypertension, sex, smoking, thrombolytic therapy), khat use was an independent risk factor for in-hospital mortality (OR, 1.9; 95% CI: 1.3–2.7; P <.001) and stroke (OR, 2.7; 95% CK: 1.3–5.9; P =.01). There was a significant delay in the presentation of khat users; 59% of the khat users presented >12 hours after onset of symptoms compared with 21.1% of nonkhat users ($P < .001$). Several case reports associate hepatotoxicity with khat chewing by Middle Eastern immigrants to European countries.[39,40] Some of these patients developed liver failure and encephalopathy. Although common etiologies of hepatotoxicity were excluded, the cause of the liver toxicity remains unclear as a proven association between liver toxicity; khat chewing has not been established as a cause of hepatotoxicity in countries where khat use is common.

There are few data on the oral carcinogenicity of khat chewing, particularly data that controls for the strong risk factors of tobacco and alcohol use.[41] There is an increased prevalence of oral mucosal keratosis (i.e., a precancerous lesion) among khat chewers; however, there is currently insufficient evidence to associate chronic khat chewing with an increased incidence of oral cancers.[42] Chronic chewing of khat can cause green discoloration of the tongue and brownish discoloration of the teeth.[43]

Abstinence Syndrome

Prolonged khat use does not produce a well-defined abstinence syndrome, although a mild depressive reaction (irritability, anorexia, insomnia, nightmares) may occur during the time immediately after the cessation of khat use.[44]

DIAGNOSTIC TESTING

Analytic Methods

Analytic techniques for the quantitation of cathinone and other phenylalkylamine compounds are similar to the methods used for the detection of amphetamine. Several methods are available to detect cathinone in biologic samples including gas chromatography/ flame ionization detection, high performance liquid chromatography with photodiode array detection,[45] cation-exchange liquid chromatography,[46] and liquid chromatography/atmospheric pressure chemical ionization/mass spectrometry.[47] The lower limit of quantitation (LLOQ) of cathinone and methcathinone in urine samples following analysis by gas chromatography/ mass spectrometry (GC/MS) ranges between 12.5– 25 ng/mL,[48] whereas the LLOQ for cathinone and cathine in khat samples following cation-exchange liquid chromatography is 1.3 ng/mg fresh weight and 5.1 ng/mg fresh weight, respectively.[46] Detection of cathinone by immunoassay urine screens is highly variable depending on the specific reagent used and the amount of cross-reactivity between phenylpropanol-amine and cathinone. In a study of 4 volunteers chewing 0.6 g khat leaves/kg body weight, the Abbott fluorescence polarization immunoassay of subsequent urine samples did not detect the presence of amphetamine compounds.[20] Analysis of these samples by GC/MS demonstrated the presence of cathinone during the first 26 hours; the presence of cathine and norephedrine was detectable in all the samples collected during the duration of the study (i.e., 80 h). Although cathinone and methcathinone are stable for 3 days in refrigerated samples (2–4°C/~36–39°F) and in frozen samples (−18°C/~0°F) for 2 months, urine samples stored at 2–4°C for 3 months lost 79% of these compounds.[48]

Driving

Driving under the influence of khat is a suspected cause of the high road crash fatality rate in countries (e.g., Ethiopia) where khat is legal;[49] however, data and technology are not currently available in these countries to determine the effect of khat and other drugs on driving impairment and culpability for fatal crashes. In a case series of 19 individuals arrested for driving under the influence after reportedly chewing khat, the serum cathine concentration ranged from 16.5–314.7 ng/mL with a median of 128.9 ng/mL, whereas 16 serum samples had cathinone concentrations ranging from

9.2–73 ng/mL with a median of 33.2 ng/mL.[50] The serum cathinone concentration did not correlate well to impairment as detected by police observations; the driver with the worst driving performance had the lowest serum cathinone and cathine concentrations. Significant amounts of other drugs of abuse were not detected in this case series.

TREATMENT

As the intoxication that results from khat use is generally mild, patients rarely present for medical care of khat intoxication. There are no well-documented reports of severe toxicity following khat use. Treatment is supportive, similar to the treatment of amphetamine intoxication. Options for the treatment of agitation in a khat user include benzodiazepines or antipsychotic medications. Patients with hypertensive emergencies should be treated with sedation and vasodilators; patients with agitation and severe hyperthermia may require neuromuscular blockade with subsequent intubation and mechanical ventilation along with sedation and aggressive cooling.

Chapter 59

KRATOM
[*Mitragyna speciosa* (Korth.) Havil.]

HISTORY

Traditionally, manual laborers in Thailand and Malaysia used the leaves of kratom as a mild narcotic to increase productivity and reduce boredom. Reported kratom use by Malaysian laborers as an opium substitute dates back to at least 1836 as described by Low.[1] In 1895, Holmes identified *Mitragyna speciosa* as the source of the kratom used by workers when opium was unavailable.[2] Ellen Field named mitragynine, when she isolated this compound from kratom in 1921.[3] Joshi et al determined the chemical structure of the main alkaloid in kratom in 1963; two years later, Zacharias et al confirmed the structure with X-ray crystallography.[4] In a search for nonopiate analgesics in the 1960s and 1970s, over 20 alkaloids were identified in kratom.[5]

Studies by Grewal in 1932 at the University of Cambridge indicated that this substance was a central nervous system stimulant similar to cocaine based on his observation of the clinical effects of the administration of kratom to 5 men.[6] In 1943, Thailand banned the use of this substance (Kratom Act 2486). Macko et al investigated the use of mitragynine in animal experiments as a substitute for the analgesic and cough suppressant activities of codeine.[7] Reported in 1972, their studies suggested that the active ingredient was a metabolite of mitragynine rather than the parent drug because the subcutaneous route was substantially less effective than oral administration. The Thailand Narcotics Act B.E. 2522 placed kratom along with marijuana in Category 5 of a five-category classification of narcotics in 1979. The use of kratom in Australia became illegal in 2005. Kratom remains a popular drug in these areas.[2]

BOTANICAL DESCRIPTION

Common Name: kratom, kakuam, ithang, or thom (Thailand); baik-biak or ketum (Malaysia); herbal speedball, krypton (mixture *O*-demethyltramadol and kratom)

Scientific Name: *Mitragyna speciosa* (Korth.) Havil.

Botanical Family: Rubiaceae (coffee)

Physical Description: This large arboreal tree grows up to 30 m (~100 ft) in height; characteristic globular flowering head contain up to 120 florets.[8] Woody shoots have 10–12 leaves in opposite and crossing (decussate) pairs; the stems of the leaves vary from light green to red. Figure 59.1 displays a young kratom tree with leaves containing reddish stems and veins. The simple inflorescence (cluster of flowers on a stem) has two secondary axes (dichasial cyme) that form the characteristic globular flowering heads. The fruiting capsule contains numerous small flat seeds. The name of the plant derives from the shape of the stigmas (i.e., the area which receives the pollen) that resembles the mitre of a bishop.

Distribution and Ecology: This tropical tree is indigenous to Thailand, Malaysia, Myanmar and other areas of Southeast Asia, primarily in swampy areas. There are 9 species from the genus, *Mitragyna* species inhabit swamp-lands in West Africa, East Africa, and India as well as Southeast Asia.

IDENTIFYING CHARACTERISITCS

Kratom contains over 25 alkaloids, primarily indole (mitragynine, paynantheine) and oxindole (mitraphylline, speciophylline, speciofoline, isospeciofoline) alkaloids.[9,10] Speciogynine and speciociliatine are diastereomers of mitragynine. Mitragynine (CAS RN: 4098-40-2, 9-methoxy-corynantheidine) is the major indole alkaloid in kratom, accounting for up to 66% of the crude base depending on location, season, growing conditions, and variety.[11] Minor alkaloids include ajmalicine (CAS RN: 483-04-5), corynantheidine (CAS RN: 23407-35-4), isocorynantheidine, 7-hydroxymitragynine, mitraversine, mitraphylline, isomitraphylline, paynantheine (CAS RN: 1346-36-7), rhynchophylline (CAS RN: 76-66-4), and stipulatine.[12,13] Mitragynine and paynantheine are unique to *M. speciosa*. Figure 59.2 displays the chemical structure of mitragynine and some minor alkaloids in kratom. Other components of kratom include flavonoids, triterpenoid saponins, monoaryl glycosides, cyclohexanone glycosides, and secoiridoid glycosides.

Kratom is both a sedative and a stimulant that is structurally similar to yohimbine. *In vitro*, mitragynine (9-methoxy-corynantheidine) displays agonist activity at the μ– and δ–opioid receptors subtypes,[14] whereas corynantheidine is an opioid receptor antagonist.[15] The μ-opioid receptor is the primary receptor responsible for mediation of opioid-related respiratory depression, euphoria, and analgesia. The minor alkaloid, 7-hydroxymitragynine also demonstrates μ-opioid activity. Other alkaloids in kratom include the antinociceptive substance, 7-hydroxymitragynine, which is a minor alkaloid that is a more potent analgesic than mitragynine.[16] An oxidized derivative of mitragynine, mitragynine pseudoindoxyl, is also more potent than the parent compound.[17] Desmethyl mitragynine is a partial agonist for the μ-opioid receptor. Mitragynine is sparingly soluble in aqueous solutions at pH 4.0–5.7.[7] Table 59.1 displays some physical properties of mitragynine.

EXPOSURE

Sources

In traditional Southeast Asian medicine, kratom is used as a wound poultice, antipyretic, antidiarrheal agent, and opiate substitute during withdrawal. Natives also use the leaves of the kratom plant in cooking. Justifications for the use of kratom by rural workers in Thailand include increased endurance in the hot sun and relief of fatigue from overwork.[18] In this setting, kratom use occurs primarily among adults and the elderly. Kratom is not listed on the schedule of drugs from the US Drug Enforcement Agency, but this agency lists kratom as a drug of concern; kratom is illegal in Bhutan, Finland, Denmark, Poland, Lithuania, Thailand, Australia, Malaysia, and Myanmar (Burma). Kratom is widely available over the Internet, particularly as a dietary supplement for the amelioration of opioid withdrawal. Analysis of commercial samples of kratom indicated that the leaves of *Mitragyna speciosa* or closely related species are the source of these commercial products based on internal transcribed spacer sequence analysis of rDNA; the use of polymerase chain reaction-restriction fragment length polymorphism allows the separation of kratom from other psychoactive plants.[19] Kratom formulations include the leaf, powder, and a resin extract made from fresh kratom leaves.

The total alkaloid content and the oxindole alkaloids vary substantially between different geographic origins and seasons; however, the content of the major indole alkaloids (mitragynine, speciogynine, paynantheine) remains relatively stable in the leaves with some variation depending on season, strain, and other factors.[20] Alkaloid content also varies with the age of the plant with young plants containing higher concentrations of the mitragynine diastereomer, speciociliatine, and the paynantheine diastereomer, isopaynantheine, than older leaves. On average, green kratom leaves contain 0.2% mitragynine with the average green and dry leaf weighing ~1.7 g and~ 0.43 g, respectively.[21] Herbal mixtures of kratom may be adulterated by other substances. Krypton is the popular name of an herbal preparation containing powdered kratom leaves mixed with the synthetic opioid-receptor agonist, *O*-desmethyltramadol, which is the active metabolite of the analgesic, tramadol.[22]

Methods of Abuse

Figure 59.3 displays a man climbing a mature kratom tree to harvest the leaves for his personal use. These trees are hidden from public view to prevent theft; the wood surrounding the tree restricts others from climbing the tree to steal the leaves. The bitter leaves of kratom are chewed, smoked, or brewed as a tea; typically about 10 leaves are used daily. A popular, illicit drink for teenagers in Thailand is a kratom cocktail

FIGURE 59.3. A man climbing his mature kratom tree to harvest the leaves for his personal use. (Photo courtesy of Darika Sai-ngam, MA, and Sawitri Assanangkornchai, MD, PhD, Epidemiology Unit, Faculty of Medicine, Prince of Songkla University, Hat Yai, Songkhla, Thailand)

called 4×100 for the combination of the following 4 ingredients: cola drink, cough syrup, benzodiazepines, and kratom juice obtained by boiling kratom leaves for 1 hour. In a study of Thai kratom users, almost all were men and 90% of these users either chewed fresh leaves, ate the ground dried leaf, or drank an infusion of the dried leaves.[21] The drinking of a warm liquid (water, coffee) usually follows kratom use. Kratom users chew kratom about 3–10 times daily. In Thailand, natives sometimes combine the leaves from *Mitragyna parvifolia* (Roxb.) Korth. and the leaves of *Mitragyna speciosa*.

DOSE EFFECT

In animal models, the toxicity of mitragynine is relative low. The oral administration of 46–230 mg mitragynine/kg to rodents produced some decreased motor activity, analgesia, depressed respiratory rate, and reduced body temperature; oral mitragynine doses up to 920 mg/kg did not cause tremors, convulsions, or death in these animals.[7]

In studies of dogs, the oral administration of up to 80 mg mitragynine/kg did not produce observable effects. The subcutaneous administration of up to 69 mg mitragynine/kg to monkeys did not alter the activity of the animals. Recommended recreational doses of kratom leaves range from 2–10 g.

TOXICOKINETICS

Available data suggests that the biotransformation of mitragynine is complex. Animal studies indicate that mitragynine undergoes hydrolysis of the methylester on C16 and *O*-demethylation of the 9-methoxy and 17-methoxy groups followed by oxidation to carboxylic acids via intermediate aldehydes, reduction to alcohols, or some combination of oxidation and reduction.[23] Phase II metabolites in human urine include both glucuronide and sulfate conjugates. Following ingestion of kratom, urine compounds include mitragynine, paynantheine, and the diastereomers of mitragynine (speciogynine, speciociliatine) along with their metabolites.[24]

CLINICAL RESPONSE

The clinical effects of kratom begin soon (i.e., 5–10 min) after inhalation or mastication, and these effects typically persist for ~1 hour. The clinical effects of kratom are dose-dependent, although the dose-response curve is not well-defined. At low doses, kratom demonstrates stimulant properties, whereas at higher doses, the opioid properties of kratom predominate.[25] Desirable effects associated with the use of kratom include feelings of elation, sociability, alertness, and tranquility. Adverse effects associated with the recreational use of kratom include dry mouth, nausea, vomiting, diarrhea, nystagmus, diaphoresis, pruritus, tremor, and seizure. Complications associated with the chronic kratom use include anorexia, weight loss, hyperpigmentation of mucosal surfaces, and psychosis. In a study of 149 long-term kratom users (daily >5 years) and 168 occasional users (i.e., no more often than once weekly), the percentages of users believing they were dependent on kratom were 61% and 12%, respectively.[18] Adverse effects reported in this group of kratom users were constipation, tremulousness, headaches, fatigue, insomnia, poor concentration, impaired memory, and social withdrawal. Anecdotally, withdrawal symptoms (hostility, aggression, rhinitis, tearing, lethargy, myalgia, arthralgias, muscle jerks) associated the cessation of kratom use are usually modest.[21,26] Several case reports associate the ingestion of kratom and other drugs (modafinil during opiate withdrawal, *Datura stramonium* tea) with seizure activity, but the contribution of kratom to the development of seizures is unclear.[26,27]

DIAGNOSTIC TESTING

Analytic Methods

Techniques for the quantitation of mitragynine in serum include high pressure liquid chromatography with UV detection (225 nm), high pressure liquid chromatography/electrospray/tandem mass spectrometry using positive-ion detection and multiple reactions monitoring,[28] liquid chromatography/linear ion trap/mass spectrometry,[23] liquid chromatography/mass spectrometry,[29] and liquid chromatography/tandem mass spectrometry with amitriptyline as the internal standard.[30] The limit of detection (LOD) and lower limit of quantitation (LLOQ) for high pressure liquid chromatography with UV detection were 0.03 mg/L and 0.1 mg/L, respectively, compared with a LLOQ of 0.0002 mg/L for liquid chromatography/tandem mass spectrometry. Analysis of urine samples with high pressure liquid chromatography/electrospray/tandem mass spectrometry using ajmalicine as the internal standard and methyl-*t*-butyl ether extraction allows the detection of mitragynine above 0.00002 mg/L.[28] The intraday precision using ajmalicine as the internal standard at 0.001 mg/L and 0.005 mg/L is 12% and 16%, respectively. After enzymatic cleavage of conjugates, solid-phase extraction, and trimethylsilylation, the use of gas chromatography/mass spectrometry allows the detection of *O*-desmethyltramadol, mitragynine, and mitragynine metabolites in urine samples following the use of krypton.[31] The limit of detection of

O-desmethyltramadol and mitragynine was 0.1 mg/L and 0.05 mg/L, respectively.

Biomarkers

In a case series of 9 fatalities involving polydrug users with detectable amounts of *O*-desmethyltramadol in their postmortem blood and nonspecific postmortem findings (lung and brain congestion), the *O*-desmethyltramadol concentrations ranged from 0.4–4.3 mg/L (µg/g).[32] The mitragynine concentrations ranged from 0.02–0.18 mg/L (µg/g). The absence of detectable tramadol and *N*-desmethyltramadol in the postmortem blood samples indicates that these individuals consumed the herbal blend, krypton. All were found in asystole, and all except one individual were found dead in their homes. All analyzed postmortem samples except one were femoral. In Thailand, the prevalence of kratom use in randomly selected drivers was similar (0.9%) to the use of marijuana (1.1%); however, there are few data on the effects of kratom on driving skills.[33]

TREATMENT

There are few clinical data on the treatment of toxicity associated with the use kratom. Potentially, naloxone is an antidote for the opioid effects of kratom, but there are few data on the efficacy of this antidote for the reversal of toxicity associated with the use of kratom.

Chapter 60

MARIJUANA (*Cannabis sativa* L.) and Synthetic Cannabinoids

HISTORY

The hemp plant (*Cannabis sativa* L.) is the source of the flowers, dried leaves, and extracts (i.e., collectively called marijuana) that is a popular psychotropic drug worldwide. Cannabis was well known to the Assyrians, Egyptians, and Chinese many centuries before the beginning of Christianity;[1] however, the Old Testament does not clearly mention the use of the hemp plant (*Cannabis sativa* L.) despite prolonged trade between the Jews and Assyrians.[2] The ancient Chinese and Greeks used the plant stems in the production of rope and clothing fiber, whereas the Romans wove the cannabis fibers into rope during construction of their ships. The psychotropic and medicinal use of cannabis occurred in early India before the end of the 2nd millennium BC. The *Athara Veda* mentions cannabis as one of the five sacred plants used for "freedom from distress."[3] The medicinal use of the hemp plant dates back almost 5,000 years to the Chinese Emperor Shen-Nung, who recommended the use of this plant for several medical disorders in 2,737 BC.[4] These disorders included malaria, constipation, arthralgias, and female complaints. Between 2,000 BC and 1,400 BC, Indian physicians discovered the euphoric properties of *Cannabis sativa*; they recommended the hemp plant for sleep disorders, fever, appetite stimulant, headaches, rheumatism, and venereal diseases.[5]

Settlers at Jamestown, Virginia also cultivated this plant as a fiber source. In the mid-19th century, the Irish physician, WB O'Shaughnessy introduced the use of this plant into Western medicine as an analgesic, anticonvulsant, anxiolytic, and antiemetic.[6] During the 19th century, popular medicinal uses for the hemp plant in Western Europe included the treatment of asthma, pain, seizures, anxiety, muscle spasm, and anorexia. By the late 19th century, medicinal cannabis was being marketed by drug companies; however, more effective analgesic and sedative-hypnotic drugs replaced medicinal cannabis by 1900. Then, the Harrison Act of 1914 classified cannabis as a narcotic with cocaine and heroin, which resulted in a significant decline in the marketing and use of cannabis. The Marijuana Tax Act of 1937 banned the use of this plant in the United States.

Although the chemical structure of psychoactive cannabinoids in this plant was investigated in the 1930s and 1940s, the chemical structure of the active ingredient (Δ^9-tetrahydrocannabinaol, Δ^9-THC) was not isolated until 1964.[7] In 1985, the US Food & Drug Administration (FDA) approved the use of synthetic Δ^9-THC (dronabinol) as an antiemetic; the Belgian company, Solvay Pharmaceuticals began marketing dronabinol in the United States under the trademark, Marinol®. The existence of G-protein-coupled cannabinoid receptors was not discovered until 1988, when Devane and colleagues characterized the central CB1 receptor in rat brain.[8] In 1993, Munro and colleagues cloned the peripheral CB2 receptor from macrophages derived from the marginal zone of the spleen.[9]

BOTANICAL DESCRIPTION

There are several subspecies and varieties of *C. sativa* including *Cannabis sativa* subsp. *indica* (Lam.) E. Small & Cronq. (Oceania), *Cannabis sativa* subsp. *sativa* L. (Caribbean, North America), *Cannabis sativa* var.

sativa L., and *Cannabis sativa* var. *spontanea* Vavilov (North America).

Common Name: Hemp, marijuana, Indian hemp, Mary Jane, hashish, pot, grass, cannabis, weed

Scientific Name: *Cannabis sativa* L.

Botanical Family: Cannabaceae (Hemp)

Physical Description: *Cannabis sativa* L. is an aromatic, slightly branched, annual herb with variable numbers of palmate leaves that reach 3–10 feet (1–3 m) in height. Figure 60.1 displays a cultivated marijuana plant. The lower leaves typically are opposite and single with the leaves in the upper portion of the plant being alternate and containing 5–9 sharply serrate, smooth, dark green leaflets on long thin petioles. Usually, the small flowers are imperfect with an individual plant having either staminate (male) or pistillate (female) structures; however, some plants may contain both male and female flowers. The staminate flowers develop in loose, multibranched indeterminate inflorescence (panicle) along the erect, fibrous stems, whereas pistillate flowers appear in racemes. The male flowers have 5, almost separate, pale yellow segments, whereas the female flowers have a single, glandular, hairy, 5-veined leaf covering the ovary. The small, smooth, light brown-gray fruit contains the seed.

Distribution and Ecology: The hemp plant is a native species of Central Asia including Northeastern Iran, Afghanistan, Northern India, Southern

FIGURE 60.1. Cultivated marijuana plant. (Photo courtesy of the US Drug Enforcement Agency)

Siberia, and parts of China. However, this plant adapts well to northern temperate climates including parts of the United States and Europe; cultivation of this plant is now worldwide.

IDENTIFYING CHARACTERISTICS

Structures/Nomenclature

C. sativa contains over 400 chemicals (e.g., alcohols, steroids, sugars, fatty acids, phenols, terpenes) that include over 60 cannabinoids.[10] The main active ingredient, Δ^9-THC is a nonnitrogenous compound ($C_{21}H_{30}O_2$) that contains 2 chiral centers in *trans*-configuration. The term cannabinoids applies to the natural C_{21}-substituted monoterpenes and their carboxylic acid metabolites in marijuana, a large number of synthetic cannabinoid analogues, and the endogenous ligands of the cannabinoid receptors. Two numbering systems exist for cannabinoids that involve the monoterpenoid and dibenzopyran numbering as demonstrated in Figure 60.2.[11] In the latter numbering system for pyran compounds, the main active ingredient, tetrahydrocannabinol, is numbered Δ^9-THC. However, not all cannabinoids are pyran compounds; hence, a second nomenclature using a biogenetic basis exists. In this monoterpenoid numbering system, Δ^9-THC is Δ^1-THC. Although the biogenic numbering system has the advantages that all cannabinoids can be named and a carbon atom retains the same number in most chemical transformations, the formal dibenzopyran numbering system is more common.

There are several subclasses of cannabinoids with variable cannabinoid receptor agonist activity including cannabidiol, cannabigerol, cannabichromene, Δ^9-THC, Δ^8-THC, cannabinol, cannabicyclol, cannabielsoin, cannabinodiol, and cannabitriol compounds. Bicyclic, aminoalkylindole, and anandamide compounds are also cannabinoid receptor agonists. Quantitatively, the major cannabinoids in marijuana are cannabinoid acids of Δ^9-THC, cannabidiol, cannabichromene, and cannabigerol as demonstrated in Figure 60.3. There are 9 cannabinoids in the Δ^9-THC group consisting of compounds with 1,3,4, or 5 carbon side chains. Natural Δ^9-THC has two chiral centers at the C_{6a} and C_{10a} carbons; the term THC applies to the naturally occurring (-)-*trans*-isomer of Δ^9-THC.

Physiochemical Properties

Δ^9-THC (Dronabinol, CAS RN: 1972-08-3) is a volatile, viscous oil that is highly lipophilic and poorly water

soluble.[12] The odor probably results from the volatilization of α- and β-pinene, limonene, and myrcene from the plant material.[13] Δ^9-THC readily binds to glass and plastic.[14] Most metabolites of Δ^9-THC have similar solubility. Table 60.1 lists some physiochemical properties of Δ^9-THC. Air, heat, and light degrade Δ^9-THC to cannabidiol (CBD, CAS RN: 13956-29-1),[15] and the potency of cannabis products decreases as a result of the oxidation of the major active component (Δ^9-THC) to cannabinol (CBN, CAS RN: 521-35-7), particularly in acid media.[16] Drying of the plant material does not alter the qualitative composition of the oil or the odor associated with marijuana.[17]

In experimental studies, the naturally occurring (−)-enantiomer of *trans*-Δ^9-THC is more potent (i.e., 5–100 times) than the (+)-enantiomer.[18] Δ^8-THC is a less potent, positional isomer of Δ^9-THC. The cannabinoid acids do not produce psychotropic effects; the decarboxylation of these compounds to corresponding phenols during the smoking of marijuana results in psychotropic effects.[19] The decarboxylation of cannabinoid acids of Δ^9-THC during pyrolysis of marijuana produces the main psychotomimetic compound, Δ^9-THC; however, the decarboxylation of other naturally occurring cannabinoid acids (e.g., cannabinol, cannabidiol, cannabigerol, cannabichromene, cannabidiolic acid) probably does not produce psychoactive metabolites.[20,21] Smoking does not significantly alter the ratio of cannabinoid acid isomers.[22] An isomer of Δ^9-THC [Δ^8-THC ($\Delta^{1(6)}$-THC)] and the propyl homologue of Δ^9-THC (Δ^9-tetrahydrocannabivarin, CAS RN: 28172-17-0) possess some psychoactive properties, but these compounds probably do not contribute significantly to the psychomimetic effects present during

the smoking of marijuana.[23] Dronabinol degrades rapidly in acidic solutions.

Terminology

Marijuana (marihuana) refers to plant material from the hemp plant that produces psychotomimetic or therapeutic effects, primarily the flowering tops and dried leaves. Cannabis refers to any psychoactive part or preparation of the hemp plant (*C. sativa*) including loose marijuana plant material, buds, sinsemilla, Thai sticks, Mexican kilobricks, hashish, and hash oil; cannabis is also a collective term for psychoactive compounds derived from the marijuana plant. Terms used for marijuana include Pot, Mary Jane, MJ, Weed, Grass, Puff, Hagga, and Maconha. Ganja is the resinous portion of the small leaves and tops of cultivated plants. Bhang is a beverage consisting of an extract of the dried mature leaves and flower stems along with milk and nuts. Typically, bhang contains smaller concentrations of cannabinoids compared with hashish and ganja. Hashish (charas) is the concentrated, dried resin collected from flower tops that contains substantially higher (i.e., up to 10%) concentrations of Δ^9-THC compared with ganja and bhang. This form of marijuana is particularly common in the Middle East and North Africa. Hash oil is a dark green to amber, viscous alcohol or gasoline extract of marijuana. *Sinsemilla* (without seeds) refers to unpollinated female parts of *Cannabis sativa* that mature and produce seedless flowers without contact with male plants. The seedless portion of the female cannabis plant has a relatively high concentration (i.e., 5%) of Δ^9-THC. Dronabinol is the generic name for the main psychoactive cannabinoid (Δ^9-*trans*-tetrahydrocannabinol, Δ^9-THC). Marinol™ (Unimed Pharmaceuticals, Inc., Marietta, GA) is a commercial product that contains synthetic dronabinol in doses of 2.5 mg, 5 mg, and 10 mg dissolved in sesame oil. Terms used for marijuana soaked in embalming fluid include fry, dust, wet, leak leak, tecal, dip, hemey, and illy. Spice usually refers to smokable herbal products, which contain synthetic cannabinoid receptor agonists and are purchased relatively inexpensively over the Internet. Frequently, these products contain adulterants.

Form

Preparations and extracts of marijuana occur in a variety of forms including loose marijuana, kilobricks, sinsemilla, buds, Thai sticks, hashish, and hash oil. Usually, the plant is dried, cut, and then rolled into paper used for tobacco cigarettes.

EXPOSURE

Epidemiology

Consumption of marijuana as an illicit drug is widespread throughout the world including the United States and Europe. Epidemiologic research indicates that cannabis use among individuals aged 15–64 years is greatest in developed countries, particularly the United States, Australia, and New Zealand followed by most countries in Europe.[24] The use of marijuana is particularly high among young adults. The overall prevalence of marijuana use, abuse, and dependence depends on the population studied and criteria for use. Peak prevalence of marijuana use occurred during the late 1970s and early 1980s, when approximately 20–25% of the US population used marijuana at least once, and almost one-half of high school seniors used marijuana at least once in the preceding 12 months.[25] Frequent use among US high school students declined from 1979 to 1992 with data revealing daily use in high school seniors dropping from 11% to 2% during the latter part of that period.[26]

The prevalence of marijuana use among the younger populations remains high. During the mid and late 1990s, the use of marijuana among the younger population increased as a result of a decline in the social disapproval of marijuana and a reduction in the perceived risk of using this substance. A UK questionnaire study of marijuana use by a cross-faculty sample of 3,075 second-year university students from 10 universities demonstrated that about 60% of the students had used cannabis at least once.[27] Approximately 20% of the students used cannabis at least weekly. Approximately one-third of Americans have used marijuana at least once in their lifetimes, and about 8% of the US population used marijuana within the last year based on the 2000 National Household Survey on Drug Abuse.[28] In this study, the lifetime prevalence rates of marijuana dependence was the highest (approximately 4%) of all illicit drugs. Based on an analysis of the 1991–1992 National Longitudinal Alcohol Epidemiologic Survey and the 2001–2002 National Epidemiologic Survey on Alcohol and Related Conditions, the prevalence of marijuana use in the preceding year remained stable at approximately 4% during the 1990s in the United States.[29] However, the prevalence of marijuana abuse and dependency increased to approximately 1.1% and 0.4%, respectively, during this period as defined by *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (DSM-IV) criteria. Based on the annual US National Surveys on Drug Use and Health by the Substance Abuse & Mental Health Services Administration, past month marijuana use among

adolescents (i.e., 12–17 years) decreased from 2002 (8.2%) to 2005 (6.8%).[30] The prevalence of past marijuana use among this group remained constant between 2005 and 2007.

Sources

ORIGIN/COMPOSITION

The hemp plant originated in Central Asia and easily adapts to temperate and tropical environments. All parts of both female and male plants contain the major psychoactive substance, Δ^9-THC, particularly the resin secreted by the female plant. The highest Δ^9-THC concentrations occur in the flowering tops (bracts), the flowers, and leaves. The stems and roots contain relatively small concentrations of Δ^9-THC, whereas the seeds contain few cannabinoids. The content of natural cannabinoids in marijuana including the relative concentration of cannabinoid acids, and the cannabinoid acid/phenol ratios varies substantially because of environmental and genetic factors (rainfall, sunshine, temperature, strain and origin of the plant, altitude, soil fertility, cultivation practices, time since harvest).[31] Marijuana and tobacco smoke are qualitatively similar with the exception of the presence of nicotine in tobacco and cannabinoids in marijuana.[32] However, cannabis-smoking techniques (breath-holding, puff duration) that maximized the delivery of Δ^9-THC may increase the delivery of carbon monoxide and tar compared with tobacco smoking.

Marijuana plants grown in the United States traditionally contain low levels of Δ^9-THC ranging from ~1–5%. Hence, an average 500-mg marijuana cigarette contains between 5 and 25 mg of Δ^9-THC. The actual Δ^9-THC varies with the type of marijuana preparation (e.g., plant part, extract) and the source. Additionally, Δ^9-THC (Δ^1-THC) concentrations in marijuana increased substantially over the last several decades.[33] During the late 1960s, the average Δ^9-THC concentration was 1.5% compared with 3.0–3.5% in the 1980s. The analysis of 35,312 marijuana preparations confiscated in the United States over 18 years indicated that the average Δ^9-THC concentration increased from 1.5% in 1980 and 3.3% in 1983 to 4.2% in 1997.[34] The range of Δ^9-THC concentrations in 16 samples of *C. sativa* confiscated in Greece was 0.08–4.41%.[35] In samples confiscated in New Zealand, the Δ^9-THC concentration of marijuana leaf averaged about 1% compared with 3.5% Δ^9-THC, in samples of the female flowering heads.[36] The Δ^9-THC concentration of marijuana leaf imported into countries (e.g., England) varies substantially, but often the Δ^9-THC concentration

exceeds 5%.[37] Analysis of 46,211 confiscated cannabis preparations by the National Institute on Drug Abuse (NIDA) Potency Monitoring program at the University of Mississippi indicates that the mean Δ^9-THC concentration of confiscated cannabis preparations increased from 3.4% in 1993 to 8.8% in 2008.[38] The increased potency resulted primarily from the confiscation of more high potency (>9% Δ^9-THC) marijuana and sinsemilla samples from nondomestic sources. Analyses of high-potency cannabis samples (>10% Δ^9-THC) reveal new cannabinoid metabolites not previously identified in older, less-potent cannabis samples.[39,40] In addition, analyses of marijuana seizures near the California–Mexico border suggest that cannabidiol concentrations are decreasing as the Δ^9-THC concentration increases. Between 1996 and 2008 in this area, the Δ^9-THC/cannabidiol ratio increased in marijuana seizures from ~26 to 188.[41]

Analysis of seeds from *C. sativa* indicates that the Δ^9-THC content is highly variable depending on the type of seed. Cannabidiol (CBD) is the major cannabinoid in fiber-type cultivars of *C. sativa* called ditchweed. Hemp (fiber) seeds from these cultivars are a common constituent of birdseed mix that contains <1% Δ^9-THC and relative high concentrations of CBD (i.e., CBD > Δ^9-THC). In contrast, the seeds from plants cultivated for marijuana use have Δ^9-THC concentrations exceeding CBD concentrations. In a study of marijuana seeds using gas chromatography/mass spectrometry (GC/MS), the Δ^9-THC content of drug-type seeds ranged from 35.6–124 μg/g compared with 0–12 μg/g for hemp seeds.[42]

Based on voluntary analysis of street drugs, few misrepresentations occur with marijuana. In marijuana samples confiscated by US authorities from 1980–1997, the Δ^9-THC concentration in sinsemilla averaged from approximately 6–11%, whereas average concentration of Δ^9-THC in hashish and hash oil ranged from about 3–20%.[34] In data from the NIDA Potency Monitoring program, the Δ^9-THC concentration in hashish was variable (16.8 ± 16.3%), but did not increase significantly between 1993 and 2008.[38] Hashish resin Δ^9-THC concentrations range from approximately 4–15%.

PRODUCTION PROCESSES

Clandestine laboratories can synthesize a number of psychotomimetic tetrahydrocannabinol compounds including Δ^{10a}-THC (Δ^3-THC), Δ^9-*cis*-tetrahydrocannabinol (Δ^9-*cis*-THC), and Δ^9-*trans*-tetrahydrocannabinol (Δ^9-*trans*-THC).[43] Modification of the dimethylheptyl side chain markedly increases the potency of tetrahydrocannabinol compounds. Marinol™ (Unimed

Pharmaceuticals, Inc., Marietta, GA) is synthetic Δ^9-THC that is structurally identical to natural Δ^9-THC.

IMPURITIES AND PROFILING

Fungal species frequently contaminate marijuana cigarettes including *Aspergillus fumigatus*, *Aspergillus flavus*, *Aspergillus niger*, *Penicillium* spp., *Mucor* ssp., *Thermoactinomyces candidus*, and *Thermoactinomyces vulgaris*.[44] Therefore, marijuana smoking is a potential source for exposure to fungal antigens. The presence of Δ^9-tetrahydrocannabivarin, the C3 homologue of Δ^9-THC, and the carboxylic acid metabolite, Δ^9-tetrahydrocannabivarin carboxylic acid, are markers for the ingestion of natural marijuana.[45]

MEDICINAL USES

There is renewed interest in the medicinal use of cannabinoids. The two current indications for the use of the synthetic cannabinoid (dronabinol, Marinol™) are chemotherapy-induced nausea and vomiting and AIDS-related anorexia.[46] Dronabinol is an oral medication approved as a schedule II drug in the United States for the treatment of nausea and vomiting in chemotherapy patients and a stimulant for appetite in AIDS patients. Other potential uses of dronabinol in cancer patients include analgesia, mood elevation, muscle relaxation, and relief of insomnia.[47] Current areas of research for use of synthetic Δ^9-THC include bronchodilation for asthma; antiemetic for chemotherapy; reduction of intraocular pressure in glaucoma; and use as an anticonvulsant, anxiolytic, analgesic, or antiinflammatory agent. Unfortunately, unwanted side effects limit the medicinal use of Δ^9-THC, particularly in the elderly; however, investigation of synthetic derivatives of Δ^9-THC may reduce adverse reactions. Randomized, double-blind, placebo-controlled studies have not supported the use of Δ^9-THC for postoperative pain in doses of 5 mg.[48] Although cannabinoids may regulate some of the processes involved with neurodegeneration, limited clinical data currently do not support the use of cannabinoids in the treatment of neurodegenerative diseases (e.g., Alzheimer disease) or the symptoms associated with dementia.[49] Currently, over 10 US states have medical cannabis programs. These medical cannabis laws rely on postmarketing surveillance studies rather than the usual FDA approval process (i.e., small and large animal testing, human toxicity studies, dose response data, adverse effect studies). Evidence-based guidelines for the use of medical cannabis have not been formulated at the present time, and there are inadequate data to determine the efficacy and safety profile of medical cannabis.[50]

Methods of Abuse

The most common route of exposure to marijuana is inhalation by a variety of sources including cigarettes, pipes, bongs, or "buckets" (i.e., inhaling the fumes from a mass of plant or resin ignited in a plastic bottle).

Figure 60.4 displays a bong and Figure 60.5 shows a variety of pipes used to smoke cannabis. Occasionally, marijuana users add other ingredients to the marijuana (e.g., phencyclidine, embalming fluid).[51] The use of embalming fluid involves the freezing of marijuana leaves saturated with embalming fluid and the crushing of the dried leaves into a dust. This dust is then added to cigars or marijuana cigarettes. Other patterns of use include the addition of embalming fluid to mint leaves or tobacco without the concomitant use of marijuana or phencyclidine.[52] The smoking of marijuana is associated with mild euphoria, a sense of well-being, and relaxation. Among long-term marijuana users, the use and dependence on marijuana is fairly stable; some of these users fulfill the criteria for drug-seeking behavior.[53]

FIGURE 60.5. Assorted pipes used to smoke cannabis. (Photo courtesy of the US Drug Enforcement Agency)

Animal studies indicate that marijuana is an atypical drug of abuse that exhibits reinforcing/rewarding properties under experimental conditions different than other drugs of abuse (e.g., cocaine, heroin, alcohol, nicotine).[54]

Marijuana smokers typically inhale deeply while holding their breath to maximize absorption. The subjective effects depend on a number of factors including smoking efficiency, potency of the cannabis, pyrolysis of active ingredients, loss of Δ^9-THC in sidestream smoke, and amount of Δ^9-THC trapped in the upper respiratory tract.[55] Compared with tobacco smokers, marijuana smokers typically use fewer cigarettes, but they retain the smoke longer because of deep inhalation and breath holding during the smoking process.[56] Volunteer studies suggest that the respiratory deposition of tar and the absorption of carbon monoxide are substantially greater following the smoking of marijuana than cigarettes as a result of the differences in smoking techniques.[57] The rapid absorption of Δ^9-THC and quick onset of action after the initiation of smoking allows titration of the desired effect by adjusting the pulmonary dose of Δ^9-THC, whereas absorption of Δ^9-THC following ingestion is much slower and less predictable. Consequently, marijuana use via ingestion occurs less often, primarily as a bakery product (cookie, cake) or as an extract. Because of the limited water solubility of Δ^9-THC, water extracts of marijuana are not suitable for intravenous

(IV) administration. Although there has been a modest increase in the potency of various forms of marijuana, the major recent change in prevalence is the use of more potent forms of marijuana by young adults at an earlier age.[58]

Personality variables associated with marijuana use include heightened levels of stress, poor self-esteem, tension, guilt-prone, emotional instability, rebelliousness, impulsivity, and lack of control.[59] The issue of progression from marijuana use to other street drugs remains controversial. A cross-sectional survey of young Australian adults suggests that the early (i.e., <17 years old) use of marijuana is a significant risk factor for the later use of other drugs of abuse and the development of drug-related problems after controlling for genetic and social factors.[60] This study suggests that peers and social context affect the risks associated with early-onset cannabis use in addition to genetic and other environmental factors.

DOSE EFFECT

The individual response to recreational doses of marijuana depends on the absorbed dose, the personality, the expectation of the user, and the setting. Initial effects range from euphoria, perceptual alterations, and relaxation at low dose to depersonalization, pressured speech, paranoia, and manic psychosis at high dose. The usual form of recreational marijuana use involves the smoking of a 0.5- to 1-g cigarette. Typical low-dose marijuana cigarettes in volunteer studies contain about 16-mg Δ^9-THC, whereas high-dose cigarettes contain approximately 34-mg Δ^9-THC. The inhaled dose of Δ^9-THC associated with pharmacologic effects ranges from about 2–22 mg, depending on the variables listed above.[61] Given the bioavailable Δ^9-THC in smoke, the estimated internal dose of Δ^9-THC associated with pharmacologic effects is approximately 0.2–4.4 mg. In volunteers, the IV administration of up to 5-mg Δ^9-THC produces a variety of transient effects including euphoria, anxiety, deficits in verbal recall, altered body perception, paranoia, conceptual disorganization, illusions, depersonalization, derealization, extreme slowing of time, blunted affect, and emotional withdrawal.[62]

The use of marijuana by most adults produces mild intoxication with the exception of multisystemic failure following the IV administration of crude marijuana extract. Despite the substantially lower bioavailability of Δ^9-THC following ingestion compared with smoking, case reports indicate that children develop adverse reactions after accidental ingestion of marijuana-containing substances.[63] In experimental studies on healthy adults, the behavioral profile after smoking a marijuana cigarette (3.1% Δ^9-THC) was similar to the

effects of ingesting 20-mg Δ^9-THC with the exception of some mild abstinence symptoms (irritability, feeling miserable) after the psychotomimetic effects of smoking marijuana resolved.[64]

TOXICOKINETICS

Absorption

SMOKING

During the smoking of marijuana, the spontaneous decarboxylation of THC carboxylic acids produces the active compound, Δ^9-THC. The absorption of Δ^9-THC following inhalation is rapid. The bioavailability of Δ^9-THC via inhalation is relatively low (i.e., 10–35%) as a result of pyrolysis and the off-gassing of Δ^9-THC in sidestream smoke; consequently, the bioavailability depends on a variety of factors including the efficiency of the smoking process, puff duration, depth of inhalation, and duration of breath-holding.[65] The use of a pipe that limits sidestream smoke substantially increases (i.e., to about 45%) the bioavailability of Δ^9-THC.[22] In a small group of volunteers, the systemic bioavailability of Δ^9-THC via inhalation averaged about 27 ± 10% for the heavy users and approximately 14 ± 1% for the light users.[66] The average systemic availability of Δ^9-THC following the inhalation of a standard dose of marijuana by a group of 11 volunteers was 18 ± 6% (range, 10–50%) compared with 6 ± 3% for the ingestion of a similar dose of Δ^9-THC.[67] Plasma concentrations of Δ^9-THC increase rapidly after the initiation of smoking and peak concentrations occur about 7–8 minutes after initiation of smoking.[68] Subsequently, plasma Δ^9-THC plasma concentrations decline rapidly, and this decline in plasma Δ^9-THC occurs before maximum psychotropic effects. Subjective feelings of euphoria and maximal heart rate acceleration develop about 20–30 minutes after peak plasma Δ^9-THC concentrations; the subjective effects resolve within 3–4 hours after inhalation ceases.[69]

INGESTION

After oral administration, absorption of Δ^9-THC is slow and somewhat erratic with peak plasma Δ^9-THC concentrations occurring about 60–120 minutes after ingestion. These concentrations remain relatively constant for 4–6 hours. Following the oral administration of 5 mg and 10 mg of Δ^9-THC as Dronabinol®, peak plasma Δ^9-THC concentrations occurred about 1½ to 2 hours after administration with mean peak concentrations of approximately 1 ± 0.2 ng/mL and 3.6 ± 0.6 ng/mL, respectively.[70] A large first-pass effect reduces the

amount of Δ^9-THC entering the systemic circulation. Therefore, equivalent clinical effects following exposure to Δ^9-THC require higher oral doses compared with the pulmonary route.[67] The mean systemic bioavailability (i.e., 6% ± 3%) of Δ^9-THC after marijuana ingestion is approximately one-third of the bioavailability of Δ^9-THC after smoking.[71] Subjectively, the effects of an oral Δ^9-THC dose of 120 µg/kg are similar to those of inhalation of 50 µg/kg.[72] There are minimal differences in the absorption, distribution, and biotransformation of Δ^9-THC between sexes.[71]

Distribution

The distribution of Δ^9-THC is very rapid compared with the metabolism of Δ^9-THC. After cessation of smoking, plasma Δ^9-THC concentrations quickly decline as Δ^9-THC distributes into tissue; subsequently, a slow, terminal elimination phase begins. Δ^9-THC is highly lipid soluble, and this compound crosses the blood—brain barrier relatively easily along with the active 11-OH metabolite. Because of the extremely high lipid solubility of cannabinoids, these chemicals accumulate in fatty tissues with peak tissue concentrations of these compounds occurring about 4–5 days after exposure. Subsequently, these tissue stores release the cannabinoids slowly into the blood for elimination. As a result of the rapid disappearance of Δ^9-THC from the blood following the cessation of smoking, peripheral blood concentrations do not reflect the concentration of Δ^9-THC at the receptor sites in the brain.

The average steady state volume of distribution of Δ^9-THC after IV administration is large (i.e., approximately 9–10 L/kg body weight) compared with the relatively small, initial volume of distribution (about 0.04 L/kg) as a result of high protein binding that limits the initial disposition of Δ^9-THC.[73,74] Plasma Δ^9-THC is about 95–99% protein bound with the distribution between lipoproteins and albumin being approximately 6:4.[75] Both 11-nor-Δ^9-carboxy tetrahydrocannabinol and the glucuronide metabolite are also highly (i.e., about 97%) protein bound.

Biotransformation

Δ^9-THC

Cytochrome P450 isoenzymes metabolize almost all Δ^9-THC via microsomal hydroxylation and catalytic oxidation to a large variety of metabolites. The major metabolites of Δ^9-THC are mono-hydroxylated compounds, but the pattern of hydroxylation varies considerably between animal species as a result of the variable expression of cytochrome P450 isoenzymes.[76] Allylic

893

hydroxylation at C_8 or C_{11} converts the parent drug to hydroxylated metabolites; then, further biotransformation occurs via oxidation at the pentyl side chain. This pathway probably involves the formation of an intermediate aldehyde, followed by oxidation and the subsequent glucuronidation of the carboxy group. The conversion of Δ^9-THC to hydroxylated metabolites requires NADPH and molecular oxygen. In humans, the biotransformation of Δ^9-THC occurs primarily by hydroxylation via the CYP2C subfamily (primarily CYP2C9) and, to a lesser extent, CYP3A4. In mouse hepatic microsomes, the major isozyme responsible for the hydroxylation of cannabinoids at the 11α- and 8α-positions of Δ^9-THC was CYP2C29.[77] CYP2C9 polymorphism accounts for some variation in Δ^9-THC biotransformation. In a study of 43 healthy volunteers, median areas under the curve (AUC) of Δ^9-THC and 11-nor-9-carboxy-9-tetrahydrocannabinol were three-fold higher and 70% lower, respectively, in CYP2C9*3/*3 homozygotes than in CYP2C9*1/*1 homozygotes.[78] Figure 60.6 demonstrates the structure of the major metabolites of tetrahydrocannabinol.

The principal active metabolite, 11-OH-Δ^9-THC, appears in the plasma within 10 minutes of the IV administration of Δ^9-THC.[90] The amount of cannabinoid metabolites in the plasma depends on the route of administration, but the amount of 11-OH-Δ^9-THC is substantially less (i.e., <10%) than the concentration of Δ^9-THC after smoking or IV administration of Δ^9-THC.[71] Although the administration of 11-OH-Δ^9-THC produces psychologic symptoms in human volunteers within 3–5 minutes of administration,[79] the speed and duration of drug hydroxylation does not correlate to the clinical effects of Δ^9-THC based on evidence from volunteer studies of slow and fast drug hydroxylators.[80] Although 11-OH-Δ^9-THC contributes to the effect of marijuana after oral doses, this metabolite does not account for all actions of the drug, especially after inhalation.[23] The active metabolite undergoes further metabolism to the inactive, polar compound 8,11-dihydroxy-Δ^9-THC, which appears in the urine and feces. The primary alcohol at C-11 is metabolized to the corresponding 11-nor-acid (THC-COOH) or to the more polar acidic cannabinoids by aliphatic alcohol dehydrogenase enzymes. Ketones, aldehydes, and carboxylic acids are the end products of Δ^9-THC metabolism.[81]

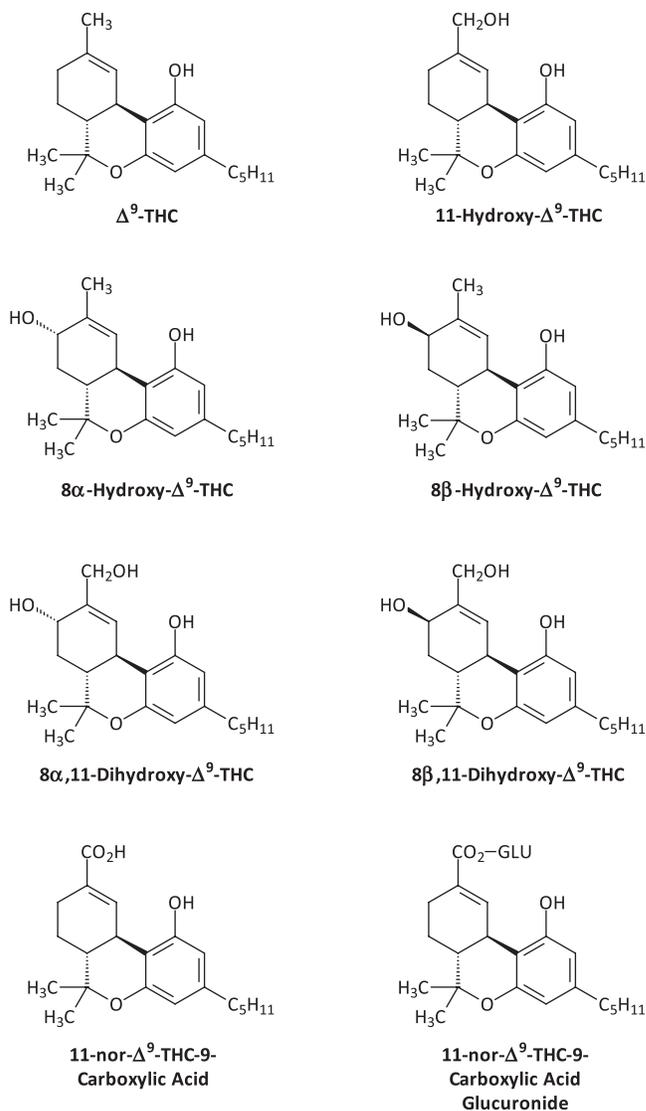
Urinary excretion of acidic Δ^9-THC metabolites accounts for about 20–30% of the elimination of Δ^9-THC with a majority (about 13–16%) of the parent compound appearing in the urine within 3 days.[71] Most of the cannabinoid metabolites in urine appear in the form of acidic glucuronide conjugates.[82] Biliary excretion via the feces is the major route of elimination of


FIGURE 60.6. Major metabolites of Δ^9-tetrahydrocannabinol (Δ^9-THC) as identified in human fluids. Δ^9-THC and 11-OH-Δ^9-THC are active compounds, whereas 8β-OH-Δ^9-THC is less active and 8α-OH-Δ^9-THC is much less active. 11-nor-Δ^9-THC-9-COOH is inactive.[82]

unconjugated cannabinoid metabolites with about 30% of an IV dose and 50% of an oral dose excreted in the feces within 3 days after administration.[71] Enterohepatic recirculation contributes to prolonged excretion of metabolites.

OTHER CANNABINOIDS

Extracts of marijuana contain over 60 cannabinoids including cannabinol (CBN) and cannabidiol (CBD). These later two cannabinoids do not possess clinically significant psychoactive properties.[83,84] The metabolism

of CBD, which is a precursor of Δ^9-THC, is similar to the biotransformation of Δ^9-THC with urinary excretion of metabolites accounting for about 16% of the dose during the first 72 hours.[11] However, unchanged CBD appears in the feces in larger amounts compared with unchanged Δ^9-THC. The major route of CBD metabolism is hydroxylation and oxidation at C_7 followed by hydroxylation in the pentyl and propenyl groups to form hydroxylated derivatives of CBD-7-oic acid. At least 33 metabolites appeared in the urine of a dystonic patient treated with CBD including acids formed by β-oxidation and biotransformation of the pentyl side-chain.[85]

Elimination

Δ^9-THC

Biotransformation accounts for almost all of the elimination of Δ^9-THC with renal excretion of unchanged Δ^9-THC accounting for <1% of the absorbed dose. The time course of plasma Δ^9-THC concentrations following inhalation and IV administration is similar, and the plasma Δ^9-THC concentrations rapidly decline following the development of peak concentrations soon after the cessation of smoking. In a study of 6 volunteers smoking a single 1.75% (15.8 mg) Δ^9-THC or 3.55% (33.8 mg) cigarette, the plasma Δ^9-THC concentrations (ng/mL) at specific times after smoking began were as follows: 0.5 hour, 8–50; 1 hour, 3–20; 2 hours, 1–8; 4 hours, 0–2.5.[86] These ranges depend on the dose of marijuana (puff volume, puff number, duration and spacing of puffs, hold time, percentage active ingredient). Following the smoking of 2 marijuana cigarettes (0.15 mg/kg), the ranges of Δ^9-THC plasma concentrations at 0.5 hour and at 1 hour were 36–177 ng/mL and 14–69 ng/mL, respectively.[87] Other factors that affect these ranges in addition to Δ^9-THC dose include the route (i.e., ingestion vs. inhalation) and chronic usage (>3 times/week). Although there is substantial individual variation in plasma and serum Δ^9-THC concentrations following inhalation of cannabis, pharmacokinetic studies indicate that the dose response is relatively linear after smoking cannabis cigarettes containing up to 70 mg Δ^9-THC.[88] The ingestion of Δ^9-THC produces delayed peak plasma times and lower peak plasma concentrations compared with smoking and IV administration of Δ^9-THC. Additionally, the ingestion of Δ^9-THC produces relatively higher concentrations of 11-OH-THC compared with smoking.[71]

The mean terminal plasma elimination half-life of Δ^9-THC is relatively long because of the slow diffusion of the highly lipophilic Δ^9-THC from tissue, particularly in habitual marijuana users. The true elimination half-life is difficult to calculate because of the slow equilibrium between tissue and plasma at the low concentrations of Δ^9-THC present in the terminal phase. Earlier studies of chronic users by less-sensitive assays indicated that the terminal plasma half-life of Δ^9-THC ranged from 20–56 hours after IV administration.[89] In comparison, the mean plasma elimination half-life in naïve users was approximately 28 hours.[90] A study of 3 chronic user smoking 4 marijuana cigarettes (15 mg Δ^9-THC/cigarette) over 2 days demonstrated a plasma elimination half-life of about 4 days with a range of approximately 3–5 days.[91]

Metabolites

Excretion of Δ^9-THC metabolites after exposure to marijuana occurs over days depending on the chronicity of cannabis use as a result of the extensive enterohepatic recirculation of metabolites and the redistribution of Δ^9-THC from fatty tissues. Because of the enterohepatic recirculation and extensive protein binding of cannabinoids, excretion of these metabolites occurs predominately in the feces rather than the urine. The actual percentage of the dose excreted into the feces and urine depends of the route of exposure. Following oral administration of Δ^9-THC, excretion of acid metabolites in the feces accounts for approximately 65–80% of the dose, whereas urinary excretion accounts for about 20–35% of the dose.[71] About 5% of the dose appeared in the feces as unchanged Δ^9-THC. During the first 3 days after IV administration of Δ^9-THC to male volunteers in this same study, cumulative cannabinoid excretion was 15% ± 4% in the urine and 35% ± 11% in feces.

Blood.   The plasma elimination half-life of Δ^9-THC metabolites is substantially longer than the parent Δ^9-THC. The two most important oxidative metabolites are the active metabolite, 11-hydroxy-Δ^9-tetrahydrocannabinol (11-OH-THC) and the inactive metabolite 11-nor-9-carboxy-Δ^9-tetrahydrocannabinol (THC-COOH). The mean peak plasma Δ^9-THC is approximately 3 times greater than the mean peak plasma THC-COOH concentration and 20 times greater than the mean 11-OH-THC concentration. Peak plasma 11-OH-THC concentrations occur immediately after the cessation of smoking. In a study of 6 healthy male volunteers smoking a single low-dose (1.75%) and high-dose (3.55%) marijuana cigarette, the mean peak plasma 11-OH-THC concentrations were 6.7 and 7.5 ng/mL, respectively.[86] Using GC/MS (limit of detection, 0.5 ng/mL), the detection times were approximately 4.5 and 11 hours, respectively. In most, but not all individuals, the

plasma Δ^9-THC concentration remained detectable longer than the plasma 11-OH-THC concentration. After about 2–3 hours after initiation of smoking, the ratio of Δ^9-THC/11-OH-THC is approximately 2:1 as demonstrated in Figure 60.7.

The mean peak plasma THC-COOH concentration occurs about 2 hours after smoking begins. Equal amounts of Δ^9-THC and THC-COOH were present in the plasma approximately 0.5 hour (range, 0.3–0.8 hour) after smoking began. A study of frequent and infrequent marijuana users administered 5 mg Δ^9-THC IV demonstrated that the ratio of Δ^9-THC/THC-COOH remained above 1 only within 45 minutes of IV administration.[92] The plasma elimination half-life of THC-COOH for frequent and infrequent cannabis users following injection of 5 mg Δ^9-THC was 5.2 ± 0.8 days and 6.2 ± 6.7 days, respectively. There were few differences in physiologic, psychologic, and pharmacokinetic data between frequent and infrequent marijuana users. Following oral administration of 15 mg Δ^9-THC plasma concentrations of Δ^9-THC are relatively low (i.e., approximately 3–6 ng/mL) compared with plasma Δ^9-THC concentrations after the inhalation of similar doses of Δ^9-THC.[93] However, the 11-OH-THC plasma concentrations are much higher compared with inhalation of similar doses of Δ^9-THC as demonstrated in Figure 60.8.

URINE. The main urinary metabolite of Δ^9-THC biotransformation is the acid glucuronide of THC-COOH. The kidneys excrete only small amounts of free THC-COOH in the urine. As a result of the high protein binding of cannabinoids and extensive enterohepatic recirculation, most of the absorbed dose of Δ^9-THC appears in the feces. Following ingestion, fecal and renal excretion accounted for about 65–80% and 20–35% of the elimination of Δ^9-THC, respectively. The terminal elimination of THC-COOH is relatively long, depending on several factors including the dose, chronicity of use, analytic method, and the duration of monitoring. In a study of 6 healthy volunteers, the urinary excretion half-life of THC-COOH ranged from 25–35 hours during a 7-day monitoring period and 44–60 hours during a 14-day monitoring period.[94] The urine from 13 heavy marijuana users was analyzed by high-performance liquid chromatography (limit of detection, 7 ng/mL) after they smoked 4 marijuana cigarettes (15 mg Δ^9-THC/cigarette) over 2 days.[95] The elimination half-life of THC-COOH ranged from about 1–10 days with a mean of approximately 3 ± 2 days. The urine of frequent marijuana users may contain small amounts of unconjugated THC-COOH for several days following the administration of Δ^9-THC; however, the urine of infrequent users usually contains only conjugated THC-COOH.

FIGURE 60.7. Mean plasma concentrations of Δ^9-Tetrahydrocannabinol (THC), 11-hydroxy-THC (11-OH-THC), and 11-nor-9-carboxy-THC (THC-COOH) based on 6 study participants smoking 34 mg Δ^9-THC. TOLERANCE

Tolerance to sleep, mood, behavioral, cardiovascular, and autonomic changes associated with marijuana use develops and resolves rapidly. Tolerance to the cardiovascular and psychologic effects developed in 6 study participants following oral administration of 30 mg of Δ^9-THC every 4 hours for 10–12 days.[73] In a study of experienced marijuana users at least 5 days of steady intoxication (i.e., 20–30 mg every 3–4 hours) was necessary to produce minimal withdrawal symptoms; the degree of withdrawal was related to the dose of Δ^9-THC.[96] Tolerance to tachycardia and psychotropic effects develops after volunteers smoke marijuana cigarettes containing 40 mg Δ^9-THC (four 500-mg, 2% Δ^9-THC marijuana cigarettes) over 14–21 days.[97] Smoking lower doses of Δ^9-THC may not produce tolerance. In a study of 6 healthy volunteers smoking 1 marijuana cigarette containing about 9-mg Δ^9-THC daily for 13 days, the only significant change in the response to Δ^9-THC was a mild reduction in the tachycardia associated with smoking cannabis.[98]

The basis of tolerance associated with cannabis use probably involves pharmacodynamic events (receptor downregulation, receptor conformational changes, receptor internalization) rather than alteration of the pharmacokinetics of Δ^9-THC.[4] Tolerance to the tachycardia and psychotropic effects follows similar temporal patterns.

MATERNAL AND FETAL KINETICS

Δ^9-THC rapidly crosses the placenta in most animal species; however, animal studies suggest that the peak Δ^9-THC concentration after IV administration is substantially lower in the fetus than in the mother.[99] About 3 hours after IV administration, the Δ^9-THC concentrations in the mother and fetus are similar. The 11-OH-THC and 11-nor-9-carboxy-Δ^9-THC metabolites cross the placenta much less efficiently than Δ^9-THC.[100] Excretion of Δ^9-THC in breast milk occurs following maternal exposure, particularly following habitual marijuana use. Analysis of breast milk in a chronic heavy marijuana user demonstrated Δ^9-THC concentrations in breast milk 8.4 times higher (i.e., low ng/mL range) than maternal plasma Δ^9-THC concentrations.[101] Consequently, a nursing infant potential may ingestion daily doses of 0.01–0.1 mg Δ^9-THC from a nursing mother consuming 1–2 cannabis cigarettes daily.

DRUG INTERACTIONS

Exposure to marijuana frequently occurs along with other drugs (e.g., tobacco, ethanol, other psychoactive drugs). Potential interactions result from the presence of common metabolic pathways, competition for binding sites on plasma proteins, and functional adaption of various neural systems. In a study of 8 healthy volunteers, blood ethanol elimination rates decreased approximately 12–13% in 7 of 8 volunteers receiving 60–180 mg Δ^9-THC/day in divided doses for 14 days.[102] However, volunteer studies suggest that the effect of the simultaneous administration of ethanol and cannabis is additive pharmacodynamically with regard to subjective intoxication and behavioral impairment.[103] The administration of cannabidiol in daily oral doses of 600 mg for 5–12 days inhibited hexobarbital metabolism in 10 volunteers.[104] Chronic or concurrent use of marijuana alters the behavioral and physiologic effects of barbiturates, nicotine, ethanol, amphetamines, cocaine, and other psychoactive drugs (e.g., phencyclidine, opiates).[105] A case report associated the combined use of marijuana (i.e., CYP3A4 inhibitor) and Viagra® (Pfizer Pharmaceuticals, New York, NY) with the development of a myocardial infarction.[106]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

The behavioral effects of cannabis are unique; these complex behavioral actions probably result from the interaction of psychoactive cannabinoids with specific, G-protein-coupled cannabinoid receptors and other neurochemical systems. These G-proteins cause inhibition of adenylate cyclase and reduction in the conversion of AMP to cyclic AMP. Other G protein-coupled receptors include corticotropin and melanotropin receptors. CB_1 receptors are also coupled to ion channels, negatively to N-type and P/Q type calcium channels as well as M-type potassium channels and positively to A-type potassium channels.[11] There are at least 3 (CB_1, CB_2, CB_3) and perhaps other cannabinoid receptor subtypes.[107] The CB_1 receptors mediate psychoactive properties. The CB_2 cannabinoid receptors appear in the periphery (e.g., spleen, thymus, tonsils) primarily in immune cells (e.g., B-cell lymphocytes, natural killer cells).[108] Activation of CB_1 receptors produces psychomimetic effects, whereas activation of CB_2 receptors does not. These cannabinoid receptors affect several neurotransmitters including acetylcholine, dopamine, γ-aminobutyric acid, histamine, 5-hydroxytryptamine, norepinephrine, opioid peptides, and prostaglandins.[4] Anandamide is a fatty-acid derivative of arachidonic acid (arachidonylethanolamide) that possesses pharmacologic actions similar to Δ^9-THC. This prostaglandin-like substance is an endogenous ligand for the central and peripheral cannabinoid receptors that acts through

intracellular G-proteins and the modulation of ion transport.[4] However, anandamide has a shorter half-life and is a less potent agonist of the CB_1 and CB_2 receptors than Δ^9-THC.[109]

Central Nervous System

The CB_1 receptor is the most common cannabinoid receptor in the brain; these receptors occur in the hippocampus, basal ganglia (substantia nigra, pars reticulata, globus pallidus, entopeduncular nucleus, lateral caudate, putamen), and the molecular layer of the cerebellum. Purkinje cells and pyramidal neurons synthesize and release endocannabinoids that stimulate nearby CB_1 receptors, which directly target both GABAergic (inhibitory) and glutamatergic (excitatory) terminals. The hippocampus codes sensory information and newly acquired memory as well as influencing changes in mood and behavior. The cerebellum is involved with coordination of motor movement and motor learning, whereas the basal ganglia are involved with movement. Endogenous ligands for these cannabinoid receptors include anandamide, 2-arachidonoyl glycerol, 2-arachidonoyl glyceryl ether (noladine ether), *O*-arachidonoyl ethanolamine (virodhamine), and *N*-arachidonoyl-dopamine (NADA). These endogenous cannabinoids bind and stimulate the cannabinoid and vanilloid receptors; reuptake processes and rapid enzymatic inactivation regulate the action of these compounds. These endocannabinoids (e.g., anandamide, noladine ether, virodhamine) along with bicyclic and tricyclic analogues of Δ^9-THC are agonists, whereas 1,5-biarylpyrazoles are cannabinoid receptor antagonists.[54]

Activation of the CB_1 and CB_2 receptors inhibits adenylyl cyclase activity and reduces the intracellular concentration of cAMP, resulting in the phosphorylation and stimulation of the mitogen-activated protein kinases, extracellular signal-regulated kinase 1 (ERK1) and ERK2.[110] The CB_1 receptor is an inhibitory, G protein-coupled receptor that responds more to psychoactive cannabinoids (i.e., Δ^9-THC) than to nonpsychoactive cannabinoids. CB_1 receptors undergo downregulation and desensitization following chronic administration of THC or synthetic cannabinoid agonists.[111] Both the CB_1 and CB_2 receptors regulate the release of several central neurotransmitters including glutamate, γ-aminobutyric acid, dopamine, noradrenaline, serotonin, and acetylcholine.[112] CB_2 receptors are more prominent in the immune system than the brain. Some experimental evidence suggests the presence of non-CB_1, non-CB_2, and G protein-coupled cannabinoid receptors.[113] Synthetic CB_2 agonists are *potential* analgesics for inflammation-

based pain based on the effect of the CB_2 receptor on immune function.[114]

Several animal studies suggest that chronic exposure to Δ^9-THC alters the structure and function of the rat hippocampus, which is the portion of the brain associated with learning and memory, particularly in immature animals.[115,116] Both age and duration of exposure (i.e., >10% of the lifespan) are important variables in the responses during these animals studies.[117] Functional imaging studies of chronic cannabis users suggest the presence of subtle increases in activity within the frontal, limbic, and cerebellar regions following continued marijuana use.[118] However, the clinical significance and reversibility of these changes are unclear.

Cardiovascular System

The cardiovascular actions of cannabinoids are complex, characterized by vasodilation, increased cardiac output, and tachycardia. The CB_1 receptor agonists have complex cardiovascular actions including the inhibition of distinct voltage-gated calcium channels and activate inwardly rectifying potassium channels.[119] The vascular responses to cannabinoids potentially results from a variety of actions including stimulation of the cannabinoid, vanilloid, and novel endothelial cannabinoid receptors, the release of nitric oxide and endothelium-derived hyperpolarizing factor (EDHF), metabolism of endocannabinoids to vasoactive molecules, and interaction of the sympathetic nervous system.[120] The effect of smoking a cannabis cigarette on exercise performance is a modest reduction in maximal exercise performance with premature achievement of maximal oxygen uptake.[121] Plasma norepinephrine rises about 30 minutes after exposure and remains elevated for about 2 hours.[122] Tachycardia following cannabis use is dose-related with the typical increases averaging 20–50 beats per minute. High doses of Δ^9-THC can produce heart rates of 140 beats/minute with mild elevation of systolic blood pressure.

Pulmonary System

The inhalation or the ingestion of Δ^9-THC produces mild, dose-dependent bronchodilation in both healthy and asthmatic volunteers that persists at least 1 hour without central respiratory depressant effects,[123] however, marijuana smoke is a bronchial irritant. In some asthmatic individuals, cough and bronchoconstriction develop after inhalation of marijuana smoke or aerosolized Δ^9-THC.[124] Although studies of chronic marijuana users indicate that the chronic use of marijuana is not associated with nonspecific airway hyperresponsiveness,[125,126] the chronic smoking of cannabis

does not protect individuals smoking both marijuana and tobacco from developing increased airway hyper-reactivity.[127] Oral cannabinoids other than Δ^9-THC (e.g., cannabinol, cannabidiol) are probably not effective bronchodilators.[128]

Habitual marijuana use produces epithelial injury to the large airways similar to cigarette smoke despite the inhalation of much lower quantities of smoke. Bronchial biopsies of heavy marijuana smokers demonstrate his-tologic evidence of chronic inflammation (erythema, nonciliated basal cell hyperplasia), increased secretions (mucus-secreting goblet cell hyperplasia), and dysregu-lated growth of the bronchial epithelium.[129] A study of habitual cannabis smokers did not detect increases in alveolar epithelial permeability based on the clearance of technetium (^{99m}Tc)-labeled diethylenetriamine penta-acetate (DTPA).[130] Histologic examination of postmor-tem lung samples from heavy marijuana smokers dem-onstrated focal infiltrates of heavily pigmented macrophages surrounding bronchioles, focal ulceration of the columnar epithelium, focal early fibrosis with lymphocytic infiltration, and light to moderate infiltra-tion of pigmented monocytes within the alveoli.[131] Hyperplasia of the mucus-secreting surface epithelial (goblet) cells and replacement of normal ciliated cells by nonciliated basal cells probably accounts for the high frequency of symptoms consistent with chronic bronchi-tis.[132] Bronchoscopy of marijuana smokers indicate that pathologic bronchial mucosal changes associated with smoking tobacco and marijuana together are greater than the mucosal alterations associated with smoking either substance alone.[133]

Eye

Ophthalmic effects of exposure to Δ^9-THC include marked congestion of conjunctival vessels, slight pupil-lary constriction with preservation of the light reflex, mild reduction of tearing, and a dose-related reduction of intraocular pressure. Although the administration of Δ^9-THC can reduce intraocular pressure for several hours, the development of tolerance and significant sys-temic toxicity limits the medical application of this drug for glaucoma.[134]

Endocrine System

Animal models indicate that cannabinoid administra-tion acutely alters multiple hormonal systems, including the suppression of the gonadal steroids, growth hormone, prolactin, and thyroid hormone.[135] These effects result from the binding of the endogenous cannabinoid recep-tor to areas in the hypothalamus. Cannabinoids also activate the hypothalamic–pituitary–adrenal axis. The

human health effects of chronic cannabis use on the endocrine system remain unclear.

Immune System

Δ^9-THC is an immune modulator with predominately immunosuppressive effects on various immune cells in *in vitro* and animal testing.[136] *In vitro* studies indicate that cannabinoids modulate the immune response, pri-marily by immunosuppressive actions on various immune cells including macrophages, T-lymphocytes, and natural killer cells.[137] These studies also suggest that cannabinoids may modulate host resistance, especially the secondary immune response as well as altering the function of immune cytokines and the activity of network cells (macrophages; T helper cells, T_h1 and T_h2). Leukocytes contain cannabinoid receptors (e.g., CB_2); stimulation of these receptors causes complex actions on the release of immunostimulatory T_h1 cytokines (e.g., interleukin-2, interferon-γ) and immuno-inhibitory T_h2 cytokines (interleukin-10, interleukin-4).[138] The mecha-nisms of these actions are both cannabinoid receptor-dependent and cannabinoid receptor-independent with modulation of sensitive targets of cannabinoids (e.g., interleukin-2) being variable, depending on experimen-tal conditions.[139] Despite these *in vitro* changes, there are insufficient data to conclude that habitual use of marijuana increases the prevalence of infections or malignancies.

CLINICAL RESPONSE

Illicit Use

The individual's response to marijuana depends on the premorbid personality, existing scene, prior experience, and amount of Δ^9-THC absorbed. The subjective effects of cannabis classically involve a state of euphoria fol-lowed by drowsiness, sedation, and occasionally depres-sion that resolve within a few hours. Categories of psychologic effects after recreational marijuana use include affective (euphoria, garrulousness), somatic (feeling of floating), sensory (increased perception of external stimuli, vivid visual imagery), and cognitive (decreased short-term memory, distortion of time per-ception, reduced concentration/attention).[11] None of the clinical features of marijuana use are specific to the absorption of the active ingredient, Δ^9-THC. Group smoking of cannabis promotes social interaction, friend-liness, and laughter.

Following inhalation of Δ^9-THC, subjective effects begin within a few minutes, reach a maximum in 15–30 minutes, and resolve over 2–3 hours, whereas

psychotropic effects begin 30–90 minutes after the ingestion of cannabis, reach a maximum in about 2–3 hours, and resolve over 4–12 hours.[11] Most studies of the after-effects of smoking typical recreational doses of cannabis do not demonstrate evidence of clinically significant hangover effects common after ethanol or long-acting sedative-hypnotic drug use.[140] In a study of 12 regular marijuana smokers receiving 40 standardized puffs of marijuana smoke over 5 separate smoking periods in the late afternoon and evening, questionnaires on mood, sleep, and temporal perception were administered to determine the potential after-effects of the typical week-end use of marijuana.[141] Evaluation of performance included behavioral tasks ranging from simple reaction time to more complex tasks of psychomotor and cognitive functions. This study did not detect evidence of clinically significant, residual subjective intoxication the morning after use; most behavioral tests and mood scales returned to normal ranges the following day. Fine motor coordination and special perceptions were not tested. Case series associate blepharospasm, photophobia, and decreased accommodation with habitual marijuana use.[142] Conjunctival erythema is a more reliable sign of exposure to Δ^9-THC than tachycardia.[67]

BEHAVIORAL TOXICITY

During the late 1960s and the early 1970s, an amotivational syndrome was associated with chronic marijuana use among adolescents and young adults characterized by apathy, loss of effectiveness at completing complex tasks, easy frustration, poor concentration, diminished goal-directed behavior, and poor job performance.[143,144] The clinical features of this syndrome are similar to the clinical features associated with chronic intoxication with any sedative-type drug. In most cases, memory, alertness, concentrations, and cognitive skills return to normal within 1 month, and the contribution of the pharmacologic effects of chronic marijuana use remain unclear. Current data have not demonstrated a definite causal relationship between chronic marijuana use and psychosocial harm. Alternate explanations for the association between marijuana use and the psychosocial problems remain plausible including reverse causation (i.e., drug use is a consequence rather than a cause of psychosocial problems), bias, and confounding.[145]

The frequency of marijuana use in problem adolescent ethanol abuse and the similarity of psychosocial patterns between problem drinking and habitual marijuana use suggest that marijuana use is part of adolescent problem behavior. Such adolescents often express lower expectations of academic achievement, less compatibility with friends and parents, less religious behavior, more independence, less involvement with conventional institutions, more problem role models, greater tolerance of deviate behavior, and more involvement in problem acts (e.g., public drunkenness) compared with adolescents without drinking or cannabis problems.[146]

MENTAL DISORDERS

Rarely, a self-limited, acute psychosis develops following marijuana use with either clear consciousness or an acute confusional state.[147] When present, the acute confusional state is transient and self-limited, involving apprehension, suspiciousness, memory impairment, depersonalization, and derealization. Predisposing factors to the development of the acute confusional state include first-time use, high doses of marijuana, and possibly a predisposition to the development of psychosis.[148] The acute psychosis may present with mania-like features (e.g., grandiosity, excitement, hostility, lack of cooperation).[149] Although an acute psychosis with clear consciousness can develop following marijuana use, clinical data suggest that these clinical features usually represent the exacerbation of schizophrenia or a relapse in vulnerable patients (i.e., previously psychotic patients).[150,151] Although cannabis produces some anxiolytic effects, the heavy use of cannabis by schizophrenic patients may exacerbate some of their psychotic and manic symptoms.[152] The prevalence of cannabis abuse and dependence is relatively high among individuals with high risk of developing schizophrenia, particularly young adolescents with the early onset of dependency. In a study of 68 individuals with high risk factors for schizophrenia, 32% had a history of cannabis abuse or dependence.[153] Some population-based cohort studies suggest that the early and continued heavy cannabis use in adolescence increases the incidence of psychotic symptoms, and may increase the risk of persistent psychotic symptoms by enhancing the normal transitory developmental expression of psychotic experiences during adolescence.[154,155] These studies demonstrate a dose-dependent effect of cannabis use on the incidence of psychotic symptoms based on self-reported symptoms.

The clinical features of an acute psychosis during intoxication are not specific enough to warrant the classification of unique marijuana-related psychosis. In a study comparing heavy marijuana users and other patients admitted to psychiatric hospitals for acute psychosis, the marijuana users demonstrated more hypomania and agitation compared with the nonmarijuana group.[156] These symptoms improved substantially over 1 week. The nonmarijuana users demonstrated more affective flattening, auditory hallucinations, incoherence of speech, and hysteria compared with the marijuana

group. The etiology of the acute psychosis after chronic marijuana use remains controversial because of unresolved issues about premorbid personalities and multiple-drug use. Prospective studies suggest that continued marijuana use exacerbates psychotic symptoms and increases the risk of relapse.[157] Flashbacks are the relapse of symptoms experienced during intoxication. Although rare, flashbacks can occur during the first 3 months after cessation of cannabis use.[158]

Although cannabis intoxication can produce an acute transient psychotic episode in some individuals as well as short-term exacerbation of preexisting psychotic symptoms, controversy remains regarding the ability of chronic marijuana use to cause schizophrenia or other chronic functional psychotic states. Longitudinal studies suggest an increased risk (median odds ratio [OR], 2.3; range, 1.77–10.9) of psychosis or psychotic symptoms following the chronic use of cannabis, but concerns about reverse causality and the control of confounding variables limits definitive conclusions.[159] A review of existing medical literature indicated that marijuana use is neither a sufficient nor necessary cause for psychosis; the use of marijuana is part of a complex constellation of factors leading to psychosis.[160] However, a meta-analysis of 11 case-control and cohort studies on cannabis use and psychosis suggested a threefold increased risk of developing schizophrenia or a schizophrenia-like psychosis, particularly in individuals using cannabis during early adolescence.[161] This meta-analysis did not detect evidence of publication bias or heterogeneity.

MEDICAL COMPLICATIONS

The most common adverse effect of smoking marijuana is an unpleasant feeling of anxiety that may progress to panic. Clinical features of acute anxiety reactions include restlessness, depersonalization, fear of dying, panic, feeling of loss of control, and paranoia. High cannabis doses also produce transient mood disturbances and dysphoric reactions that include anxiety, fear, paranoia, depression, disorientation, confusion, and delusions. Lethargy occurs following the absorption of high doses of Δ^9-THC, especially several hours after cessation of smoking cannabis. Hallucinations are rare, occurring primarily at high doses. During the early 1980s, an outbreak of *Salmonella muenchen* gastroenteritis was associated with the consumption of contaminated marijuana in Ohio, Michigan, Georgia, and Alabama.[162] A case report associated jogging on a warm day after smoking a marijuana cigarette with the classic features of hyperthermia (rectal temperature 41.7°C/107.1°F, delirium, hot, dry skin).[163] Although a substantial portion of atopic individual are sensitive to marijuana pollen,[164] only rare

case reports associate marijuana exposure with the clinical manifestation of allergic symptoms.[165]

Rare case reports associate daily cannabis use (e.g., 2–4 joints) with a cyclical vomiting illness that resolves with cessation of cannabis use and recurs following resumption of cannabis use.[166,167] These patients also develop weight loss, abdominal pain, sweating, flushing, thirst, and alteration in body temperature that recur with reinstitution of cannabis use. Although periodontal disease is associated with tobacco smoking, the smoking of cannabis does not increase the risk of periodontal disease.[168] Gynecomastia is a relatively common physical finding in men as a result of the ingestion of a wide variety of drugs including calcium-channel blockers, cancer chemotherapeutic agents, ketoconazole, spironolactone, and histamine$_2$-receptor blockers. The evidence for the ability of marijuana to produce gynecomastia is contradictory.[169,170] Rare case reports associate heavy marijuana use with pancreatitis.[171]

CARDIOVASCULAR SYSTEM. In volunteer studies, elevated heart rate is a consistent finding during the acute phase of intoxication with marijuana.[172] The cardiovascular effects of Δ^9-THC do not usually cause serious health problems for most young, healthy users. However, cannabis smoking by patients with cardiovascular disease poses some health risks because of the consequences resulting from increased cardiac work, tachycardia, increased catecholamine levels, carboxyhemoglobin, and postural hypotension. Potential complications include myocardial infarction and stroke. Several case reports temporally associated the smoking of marijuana cigarettes with the development of myocardial infarctions. Elevated serum creatinine kinase concentrations without fractionation, electrocardiographic changes consistent with a subendocardial myocardial infarction, and pulmonary edema occurred in a 25-year-old man soon after smoking marijuana.[173] Subsequent coronary angiography revealed no significant occlusion of his coronary arteries and normal left ventricular dysfunction. A study of 3,882 patients with recent myocardial infarction suggested that smoking marijuana may be a rare trigger of acute myocardial infarction because of the mildly elevated risk of an acute myocardial infarction within the first hour after the initiation of smoking.[174] However, the study was based on interviews without documentation of drug use; therefore, misclassification of exposure and the presence of confounding variables complicate the interpretation of this study.

RESPIRATORY SYSTEM. Although marijuana smoke is a pulmonary irritant that contains increased concentrations of polyaromatic hydrocarbons, tars, sterols, and

terpenes compared with tobacco smoke,[175] smoking of marijuana does not usually produce clinically significant *acute* effects on the respiratory system.[132] However, important respiratory abnormalities result from the habitual use of marijuana compared with the use of tobacco alone. Controlled, population-based studies indicate that the habitual use of marijuana increases the prevalence of chronic respiratory symptoms of bronchitis including wheezing, cough, and exertional dyspnea.[176] However, not all studies of chronic marijuana users demonstrate an increased prevalence of symptoms of chronic bronchitis. A study comparing chronic marijuana use, tobacco smokers, and nonsmokers did not detect a difference in the prevalence of chronic cough, sputum production, or wheeze between marijuana and tobacco smokers.[177] Additionally, there was no was additive adverse effects of chronic marijuana use on tobacco smokers.

Studies of lung function in cannabis smokers associate cumulative cannabis use with higher lung volumes (increased forced vital capacity, functional residual capacity, residual volume, total lung capacity), suggesting hyperinflation and increased large airways resistance rather than airflow obstruction (chronic obstructive pulmonary disease) or impairment of gas transfer (emphysema).[178] Although some studies suggest an accelerated increase in airway obstruction in nontobacco smoking cannabis smokers,[179] most studies of habitual marijuana users do not support a strong association between regular marijuana smoking and chronic obstructive pulmonary disease. Evaluation of habitual marijuana smokers (daily or thrice weekly smoking for 2–5 years) suggested mild impairment of large-airway conductance, but sensitive indicators of peripheral-airway disease (e.g., midexpiratory flow rates) did not decline.[180] An 8-year longitudinal study of more than 900 young adults revealed a dose-dependent relationship between cumulative marijuana consumption and decline in FEV_1/VC. However, adjusting for confounding variables (age, weight, tobacco use) reduced the negative effect of habitual marijuana use on the FEV_1/VC to marginal significance ($p < 0.09$).[181] A study of 15 asymptomatic, healthy cannabis smokers did not detect a statistically significant reduction of the single-breath carbon monoxide diffusing capacity when compared with the nonsmoking control group.[182] This test is a sensitive physiologic indicator of emphysema; a significant reduction of this test occurred in the group of combined marijuana and tobacco smokers. Although paraquat may contaminate marijuana products from some foreign countries (e.g., Mexico), the high combustion temperatures in marijuana cigarettes destroys paraquat; therefore, there is no significant risk of paraquat-induced pulmonary fibrosis from cannabis smoking. Although the chronic histopathologic effects of inhaling cannabis smoke and tobacco smoke are similar, there are few data to clarify the carcinogenic potential of cannabis smoke on the respiratory tract.[183] Case reports suggest that multiple large bullae can occur in the lungs of marijuana smokers, particularly in the upper lobes;[184] however, macroscopic evidence of emphysema is usually absent.[185]

INTRAVENOUS USE.   In volunteer studies, the IV administration of up to 5-mg Δ^9-THC causes a variety of transient symptoms including altered perceptions, increased anxiety, euphoria, disruption of verbal recall, reduced attention, and increased distractibility.[62] General orientation is usually not impaired at these Δ^9-THC doses. Intravenous injection of boiled aqueous extract of cannabis seeds ("pot tea") produces severe, acute, multisystem illness manifest by gastrointestinal (GI) distress, fever, myalgias, rhabdomyolysis, acute renal failure, hypotension, pulmonary edema, and coagulopathy.[186,187] Severe headache, blurred vision, diaphoresis, chills, dizziness, and dyspnea begin soon after injection followed in several hours by fever, GI distress, diffuse myalgias, rhabdomyolysis, hypotension, and renal insufficiency.[188] These patients recovered within about 1 week with supportive care.

Accidental Exposure

Following accidental ingestion of marijuana cookies, case reports document the occurrence of tachycardia, conjunctival hyperemia, pallor, ataxic gait, labile affect, vertical and horizontal nystagmus, fine tremor, and altered consciousness.[63] Symptoms usually develop within a few hours of ingestion and typically resolve by 6 hours after ingestion. Alteration of systemic blood pressure is uncommon. Ingestion of marijuana-filled balloons has been associated with intestinal obstruction and GI distress.[189] Systemic symptoms other than GI complaints and lethargy are uncommon, even following rupture of the balloons.[190]

Fatalities

Few reports of marijuana-associated fatalities appear in the medical literature; the etiology of these fatalities is not well documented.[191] Although a case report of a 25-year-old man associated his death with the ingestion of bhang over the 24 hours preceding his death,[192] the contribution of Δ^9-THC to his death is unclear because of his complicated cardiac history (rheumatic heart disease, open heart surgery).

Abstinence Syndrome

Chronic marijuana use may cause psychologic dependency and a mild withdrawal reaction, but the risk of physical dependence is low compared with opioids and benzodiazepines.[193] A mild withdrawal syndrome following abstinence from chronic marijuana consumption may occur in some heavy marijuana users, particularly affective and behavioral symptoms.[194] There are few robust associations between demographic characteristics and cannabis withdrawal based on responses to questionnaires from a convenience sample of 104 nontreatment-seeking, adult cannabis smokers.[195] In contrast to opioid and alcohol withdrawal, clinically significant physical symptoms of withdrawal do not usually occur following cessation of chronic marijuana use. Withdrawal symptoms following cessation of regular cannabis use include aggression, anger, anxiety, jitteriness, irritability, restlessness, sleep disturbances, anorexia, nausea, abdominal pain, weight loss, sweating, salivation, and increased body temperature, particularly during the first 10 days after the cessation of marijuana use. In study of participants in the US National Epidemiologic Survey on Alcohol and Related Conditions, the association of withdrawal symptoms to other dependence criteria for ethanol and marijuana was similar.[196] About 44% of frequent marijuana users (≥3 times weekly) reported ≥2 withdrawal symptoms; whereas about 34% reported ≥3 withdrawal symptoms. In these structured interviews, marijuana users described 2 types of withdrawal patterns: 1) weakness, hypersomnia, and psychomotor retardation; and 2) anxiety, restlessness, depression, and insomnia.

Typically, withdrawal symptoms begin 1–3 days after cessation of regular cannabis use and reach maximum effects about 2–6 days after cessation with resolution occurring in 4–14 days.[197,198] Craving for marijuana is not usually a predominant part of the withdrawal syndrome. A 21-day inpatient study of marijuana smokers demonstrated decreased food intake and increased rating of anxiety, irritability, and abdominal pain after 4 days of smoking marijuana placebo cigarettes.[199] Not all chronic marijuana users experience withdrawal symptoms following cessation of cannabis use. In a study of current and former chronic marijuana users, 40% of the participants did not experience clinically significant symptoms following cessation of use, and the lack of craving for marijuana suggested that the physical signs in the other 60% were not as strong as other drugs of abuse.[200]

Reproductive Abnormalities

There are few data on the teratogenic and developmental issues associated with marijuana use during pregnancy. Some anecdotal evidence suggests that heavy marijuana use during pregnancy produces a fetal alcohol syndrome-like clinical presentation characterized by tremulousness, intrauterine growth retardation, and facial dysmorphogenesis.[201] Comparison of the daily use of marijuana and the absence of marijuana use during pregnancy suggests that chronic marijuana use during pregnancy reduces birth weights and increases prevalence of facial dysmorphogenesis.[202] However, the large number of confounders in women drug users limits conclusions about the teratogenic potential of marijuana.

Carcinogenesis

Cannabis and Δ^9-THC are not recognized carcinogens by the International Agency for Research on Cancer or the US National Toxicology Program. There is no definitive epidemiologic evidence that regular cannabis smoking causes cancer of the lung or lower respiratory tract similar to cigarette smoking. To date, the epidemiologic evidence is conflicting. A case series reported 34 young patients with squamous cell carcinomas that were chronic marijuana smokers,[203] and a case-control study of head and neck cancer suggested a possible causal link between chronic marijuana smoking and squamous cell cancer of the head and neck.[204] In the latter study of 173 previously untreated cases with pathologically confirmed squamous cell carcinoma of the head and neck and 176 cancer-free controls, the odds ratio (OR) for head and neck cancer among individuals who ever smoked marijuana was 2.6 (95% CI: 1.1–6.6) and 3.1 (95% CI: 1.0–9.7) for marijuana smokers under the age of 55 years. However, there are no well-controlled prospective studies of chronic marijuana users to support this evidence, and most case control studies do not report an increased risk of head and neck cancer among marijuana users.[205] In a population-based, case-control study of 407 patients with oral squamous cell carcinoma, the OR for ever-use of marijuana was 0.9 (95% CI: 0.6–1.3).[206] There were no trends in increased risk of oral cancer with increasing duration or frequency of marijuana use. There was no overall excess of cancer or of tobacco-related cancers in a study of marijuana smokers in approximately 65,000 Kaiser Permanente Medical Care Program enrollees aged 15 through 49 years based on self-administered research questionnaires.[207] However, current cannabis smokers did have an elevated risk of prostate cancer (RR = 4.7, 95% CI: 1.4–15.5). Although there is a relative increased risk of death among heavy, chronic marijuana users, most of the excess risk results from social background variables.[208] In pooled data from 4,029 head and neck cancer cases and 5,015 controls in 5 case-control studies within the INHANCE Consortium, the risk of head and neck

cancer was not elevated by ever-smoking marijuana (OR = 0.88; 95% CI: 0.67–1.16).[209] There was no increased risk associated with increasing frequency, duration, or cumulative consumption of marijuana smoking. Self-reported interview data provided the basis for the classification of marijuana smoking and known risk factors.

DIAGNOSTIC TESTING

Analytic Methods

SCREENING

Thin layer chromatography (TLC), enzyme immunoassays (EIA), cloned enzyme donor immunoassays (CEDIA), and fluorescence polarization immunoassay (FPIA) are the most common analytic techniques available for the screening of urine for the presence of marijuana metabolites.[210] Radioimmunoassay (RIA) and kinetic interaction of microparticles in solution assays (KIMS) are obsolete screen techniques that have been superseded by the above methods. Immunoassays cross-react with many cannabinoids and their metabolites; hence, these methods do not determine which cannabinoids are present in the sample. The EMIT cannabinoid assay is a reliable semiquantitative urine screening test (20–50 ng/mL THC-COOH equivalent sensitivity level) based on competitive protein binding with the inactive Δ^9-THC metabolite, 11-nor-Δ^9-tetrahydrocannabinol-9-carboxylic acid (THC-COOH). The antiserum cross-reacts with most 9-substituted metabolites including the glucuronide conjugates; therefore, the results are expressed as THC-COOH equivalents. In contrast to the EMIT antigen, the Roche Abuscreen® (Roche Pharmaceuticals, Nutley, NJ) radioimmunoassay antigen was conjugated to the phenolic hydroxyl group of cannabinoids via a carboxymethyl derivative; thus, the Roche assay produces a different set of cross-reactivities compared with the EMIT assay. The Abbott TDx® (Abbott Laboratories, Abbott Park, IL) assay (i.e., fluorescence polarization immunoassay) binds equally to THC-COOH, its glucuronide and the corresponding isomer.[211] In general, reduced binding to the antiserum occurs in the presence of hydroxylated derivatives of Δ^9-THC; the binding to noncannabinoid constituents is small.

The accuracy, sensitivity, and specificity of immunoassays are unique to the specific product and these parameters may vary over time.[212] Depending on sensitivity, one urine sample may be positive by one immunoassay but negative by another assay. The incidence of false-positive rates from immunoassays [e.g., EMIT d.a.u. (Syva Corp., Palo Alto, CA), Roche Abuscreen ONLINE™ (Roche Diagnostics, Indianapolis, IN), Abbott TDx analyzer] is approximately 4%.[213] Typically, cross-reactivity of THC-COOH glucuronide by these immunoassays and the relatively high concentration of THC-COOH provides sufficient sensitivity to eliminate the need for hydrolysis during the screening of urine samples (GC/MS confirmation usually measures total THC-COOH after enzymatic or alkaline hydrolysis). Thin layer chromatographic procedures (e.g., TOXI-LAB, Varian, Inc., Palo Alto, CA) are sensitive compared with the EMIT-d.a.u., but the former procedure produces more false-positives near the cutoff concentration of 20 ng THC-COOH/mL.[214] With alkaline hydrolysis and Fast Blue BB staining, the limit of detection for THC-COOH in urine samples is about 5–10 ng/mL.[215] Urine specimens should be checked for pH and specific gravity whenever an unanticipated false-negative result occurs. The use of creatinine-corrected THC-COOH concentrations adjusts the effect of urinary dilution.[216]

The addition of adulterants may destroy Δ^9-THC-COOH in urine samples, depending on the pH, storage time, and urine temperature. Adding bleach to urine samples causes false-positive results in radioimmunoassay.[217] This adulterant also causes false-negative results in enzyme immunoassays and fluorescence polarization immunoassays as a result of the effect of the bleach on immunoassay reagents.[218] Many oxidizing agents can destroy Δ^9-THC-COOH in urine samples, particularly under acidic conditions. Under experimental conditions chromate, nitrite, Oxone® (potassium peroxymonosulfate), Fenton's reagent (hydrogen peroxide/ferrous ammonium sulfate), permanganate, periodate, peroxidase, and extracts from red radish, black mustard seeds, and horseradish destroyed most of the Δ^9-THC-COOH in urine samples within 48 hours of exposure.[219]

CONFIRMATION

Analytic methods for the confirmation and quantitation of Δ^9-THC and metabolites in biologic specimens include gas chromatography, high performance liquid chromatography, liquid chromatography/mass spectrometry, liquid chromatography/tandem mass spectrometry, capillary electrophoresis/mass spectrometry, and gas chromatography/mass spectrometry.[220] Gas chromatography[221] and HPLC with electrochemical detection[222] provide greater specificity compared with immunoassays, but these methods do furnish sufficient structural information. Gas chromatography/mass spectrometry provides the sensitivity and specificity necessary for the confirmation of positive results from immunoassays and for the quantitation of specific cannabinoids.[223,224] The detection limits for Δ^9-THC and the

major metabolites using GC/MS range from approximately 1–2 ng/mL. For quantitation of Δ^9-THC and metabolites in blood samples, GC/MS with electron impact ionization is a common analytic method. The use of gas chromatography/tandem mass spectrometry with negative-ion chemical ionization is a more rapid alternative to gas chromatography/electron impact/mass spectrometry and gas chromatography/positive-ion electron impact/mass spectrometry with the following lower limits of quantitation (LLOQ): Δ^9-THC, 0.5 ng/mL; 11-OH-THC, 0.5 ng/mL, and THC-COOH, 2.5 ng/mL.[225] Liquid chromatography/tandem mass spectrometry has similar LLOQ of Δ^9-THC and the major metabolites with the advantage that derivation of THC-COOH is unnecessary in contrast to GC/MS.[226,227] GC/MS methods are available for the detection of cannabinoids in hair samples with a LLOQ in the range of 0.04–0.08 ng/mg and coefficients of variation in the range of 8%.[228] High performance liquid chromatography with electrospray ionization mass spectrometry provides a limit of detection and LLOQ for Δ^9-THC of approximately 1 ng/mL and 2 ng/mL, respectively.[229] The conjugation of glucuronic acid with Δ^9-THC and its metabolites facilitates the urinary excretion of Δ^9-THC and THC-COOH.[230] During preparation of the sample, cleavage of the glucuronide bond occurs either enzymatically with β-glucuronidase or chemically with alkaline solutions. The extent of the hydrolysis of cannabinoid conjugates depends on the method and the glucuronidase activity of the particular species used.[231] Incomplete hydrolysis of the sample and diffusion of cannabinoids into glass or plastic containers can reduce the recovery of Δ^9-THC and/or metabolites in biologic samples.

STORAGE

BLOOD. The stability of Δ^9-THC and metabolites [11-hydroxy-Δ^9-tetrahydrocannabinol(11-OH-THC),11-nor-9-carboxy-Δ^9-tetrahydrocannabinol(THC-COOH)] varies with temperature, storage container, and compound. Short-term storage of Δ^9-THC in glass vials at room temperature for 4 days followed by freezing (–20°C/–4°F) for 4 weeks did not produce significant reductions in whole-blood concentrations of Δ^9-THC, but analysis of Δ^9-THC in samples stored in polystyrene containers demonstrated substantial losses.[232] Some degradation of cannabinoids occurs during prolonged storage (>1 month) at room temperature, particularly the decarboxylation of cannabinoid acids to neutral cannabinoids. After storage of blood samples 6 months at room temperature, the concentrations of Δ^9-THC and 11-OH-THC decreased by 90% and by 44%, respectively.[233] The concentration of THC-COOH was not significantly different from the control. This study detected

no statistically significant changes in the concentrations of Δ^9-THC or the two metabolites (11-OH-THC, THC-COOH) in blood samples stored at 4°C (39.2°F) or –10°C (14°F) for 4 months. During a 10-day storage period at 4°C and 20°C, the amount of 11-nor-Δ^9-carboxy THC glucuronide (THC-COOH-glucuronide) converted to 11-nor-Δ^9-carboxy THC averaged about 20% and 70%, respectively.[234] 1-Nor-Δ^9-carboxy THC glucuronide was stable at freezing temperature (–20°C/–4°F).

URINE.   In addition to the degradation of cannabinoids from the solution via oxidation, loss also occurs during the handling and storage of samples, primarily during the first few hours of storage.[235] Adsorption to material surfaces (borosilicates) probably accounts for a substantial portion of the loss of cannabinoids from solution.[236] Factors determining the loss of cannabinoids include the solvent type, the amount of exposed surface area, temperature, the type of container, sample pH, and analytic variation.[237] A study of THC-COOH losses indicated that storage losses occur both by adsorption to material surfaces and losses during pipetting and storage handling.[238] High-density polyethylene containers produced the greatest losses and untreated glass (e.g., amber sialylated glassware) caused the smallest losses. Loss of THC-COOH during storage is less from frozen urine samples than urine samples stored at room temperature. Storage of urine samples at room temperature for 10 days resulted in an average THC-COOH loss of about 22%.[239] The mean loss of this metabolite in frozen urine specimens analyzed after 40 days, 1 year, and 3 years was 8.0 ± 10.6%, 15.8 ± 4.2%, and 19.6 ± 6.7%, respectively. Storage of urine samples in plastic tubes at –16°C (3.2°F) to –18°C (–0.4°F) over 45 days resulted in a mean loss of 11% (range, 0–34%) of the THC-COOH present in the original sample.[240]

Biomarkers

11-Nor-9-carboxy-Δ^9-THC (THC-COOH) is highly lipophilic and poorly water soluble. Consequently, the highest concentrations of THC-COOH following absorption of Δ^9-THC occur in the bile and very small concentrations occur in the vitreous humor. Postmortem examination of 50 vitreous humor samples by immunoassay (cutoff 50 ng/mL) yielded no positive results for cannabinoids, whereas 30 postmortem blood specimens from the same cases tested positive for THC-COOH ranging from 4–104 ng/mL as measured by GC/MS in select ion monitoring (SIM) mode.[241] In a study of 50 traffic fatalities with positive urine drug screens for THC-COOH, the mean THC-COOH concentration in bile was 12,900 ng/mL (range, 1,030–43,700 ng/mL) compared with 81 ng/mL (range, 16–330 ng/mL) in

heart blood and 314 ng/mL (range, 44–2,330 ng/mL) in urine samples.[242] The THC-COOH concentration in 10 of the 50 samples of vitreous humor was nondetectable (<1 ng/mL), and the concentration in the rest of the vitreous samples was <10 ng/mL. Consequently, vitreous humor is a poor sampling media for the detection of marijuana use, whereas bile is a good sampling media for the detection of low postmortem concentrations of THC-COOH.

Blood

Δ^9-THC resides mostly in plasma with almost 90% of Δ^9-THC in whole blood distributed in the plasma and the remainder in the erythrocytes. Therefore, the plasma/whole blood ratio of Δ^9-THC is similar to the inverse of the hematocrit, and the whole blood concentration of Δ^9-THC is about one-half the corresponding plasma concentration.[243] In a study of 7 volunteers, the mean plasma/whole blood ratio of Δ^9-THC was 1.54 (range, 1.4–1.9).[244] The distributions of THC-COOH and 11-OH-THC in plasma and whole blood are similar to the distribution of Δ^9-THC. The mean plasma/whole blood ratio of 11-OH-THC was 1.7 (range, 1.4–2.2). In an experimental study, the mean plasma/whole blood ratios of 11-nor-Δ^9-carboxy THC (THC-COOH) and the corresponding glucuronide at a concentration of 100 ng/mL were 1.54 and 1.61, respectively.[234] At a concentration of 500 ng/mL, the mean plasma/whole ratios of both compounds were 1.47. Examination of postmortem "serum" and whole blood samples for Δ^9-THC and metabolites suggests that postmortem changes (e.g., hemolysis, protein aggregation/degradation) alter the plasma/whole blood ratio of Δ^9-THC and metabolites. In a study of 6 postmortem blood samples, the mean "serum"/whole blood ratios of Δ^9-THC and 11-OH-Δ^9-THC were 2.2 (range, 1.5–2.8) and 2.3 (range, 1.5–3.9), respectively.[244] These values demonstrated wider ranges for the ratios compared with the ratios in live humans. The postmortem variability in this ratio limits the estimation of the time of last cannabis use based on the ratio of Δ^9-THC and metabolites. Most analytic methods for the determination of Δ^9-THC and metabolites in blood measure free cannabinoids rather than conjugated or total cannabinoids.

CONCENTRATION.   Plasma concentrations of Δ^9-THC do not correlate well to physiologic and psychotropic effects based on volunteer studies; the determination of impairment requires the presence of very high concentrations of Δ^9-THC. The subjective "high" and the physiologic tachycardia following cannabis smoking lags 20–30 minutes behind peak plasma levels (i.e., ~7–8

minutes after initiation of smoking) and then declines slowly to baseline over 4 hours.[245] Effects are dose- and interval-related, and smoking higher-potency cigarettes prolongs psychotomimetic effects. Modeling of Δ^9-THC kinetics indicates that smoking one 9-mg marijuana cigarette per hour maintains the psychotropic effects of marijuana; these effects last about 2 hours after the cessation of smoking.[246] Initial peak plasma concentrations sampled 15 minutes after the initiation of smoking marijuana cigarettes (19 mg Δ^9-THC content) were between 50–70 ng/mL.[67] An average "high" (rated 4 on a scale of 10) occurred when the Δ^9-THC plasma concentration was about 9 ng/mL. Conjunctival injection consistently occurred with plasma Δ^9-THC concentrations exceeding 5 ng/mL and this sign was more reliable than tachycardia in predicting clinical effect. Maximum clinical effects do not occur at peak plasma Δ^9-THC concentrations, and substantial individual variability occurs both in the magnitude of clinical effect and in peak concentrations.[69] There are inadequate data to correlate whole blood Δ^9-THC levels below 5 ng/mL and serum or plasma concentrations <10 ng/mL to physical impairment because of the variability of individual pharmacokinetics, tolerance, and the lack of a direct relationship between blood Δ^9-THC concentrations and neuropsychologic responses. Although there is substantial interindividual variation in peak plasma Δ^9-THC concentrations following the inhalation of similar Δ^9-THC doses, pharmacokinetic studies indicate linear kinetics in Δ^9-THC doses up to at least 70 mg. In a study of 24 male occasional cannabis users, the mean maximum serum Δ^9-THC concentrations following the inhalation of marijuana cigarettes containing 49 mg and 69 mg were approximately 203 ng/mL and 231 ng/mL, respectively.[247]

The presence of THC-COOH supports the validity of Δ^9-THC measurements. Plasma Δ^9-THC concentrations do not reliably detect the smoking of 1 marijuana cigarette per day by an infrequent user, when tested in the morning following inhalation.[248] Case reports document the presence of detectable concentrations of THC in postmortem samples from patients, who die suddenly.[249,250] However, the contribution of THC to these deaths is unclear, in part because of the lack of serious cardiovascular effects in patients with acute THC intoxication.

TIME OF EXPOSURE.   Predicting the time elapsed since the initiation of smoking is complicated by factors that affect the plasma Δ^9-THC, including the chronic use of marijuana (i.e., residual plasma Δ^9-THC concentrations), the efficiency of the smoking process, and the potency of the marijuana. Peak plasma concentrations of Δ^9-THC occur within approximately 7–10 minutes

after exposure. The presence of plasma Δ^9-THC concentrations exceeding 20 ng/mL indicates smoking within the last hour and plasma concentrations >50 ng/mL indicates that smoking began within the last 20 minutes. By 1 hour after smoking, plasma Δ^9-THC concentrations are usually below 5–10 ng/mL. Plasma Δ^9-THC concentrations decline rapidly within the first hour after smoking ceases, and these concentrations are relatively low (2–3 ng/mL) within 6 hours after cessation of marijuana smoking by casual user.[87] For example, the inhalation of 1.75% and 3.55% marijuana cigarettes produced peak concentrations of 50–129 ng Δ^9-THC/mL and 76–267 ng Δ^9-THC/mL, respectively.[86] Within 2 hours of smoking these cigarettes, the plasma Δ^9-THC concentration dropped below 5 ng/mL. Chronic use of large quantities of cannabis may result in more persistent elevations of plasma Δ^9-THC and THC-COOH concentrations than occur in casual cannabis users. In a study of 18 chronic, high-dose cannabis users monitored on an inpatient research unit for 7 days, 9 (50%) of the chronic users had plasma Δ^9-THC concentrations exceeding 1 ng/mL (range, 1.2–5.5 ng/mL) on the 7th day of abstinence as measured by two-dimensional GC/MS.[251] The plasma THC-COOH concentrations in the 18 volunteers on day 7 ranged from 2.8–45.6 ng/mL. All participants had at least one daily blood specimen that contained a plasma Δ^9-THC concentration higher than the previous day.

Volunteer studies indicate that the peak concentrations of the major metabolite, THC-COOH, occur about 30 minutes after the commencement of smoking.[69] The peak effect of marijuana apparently occurs near the time after exposure when Δ^9-THC and THC-COOH are present in equivalent concentrations. Measurement of the relative amounts of these 2 compounds in whole blood or plasma helps determine when peak effects develop.[23] A THC-COOH/Δ^9-THC ratio greater than 4 suggests that pharmacologic effects are no longer present (i.e., >3–4 hours after smoking).[252] However, a study of 298 forensic blood specimens positive for cannabinoids revealed that Δ^9-THC blood concentrations >10 ng/mL were required before 70% of the samples had blood THC-COOH/Δ^9-THC ratios <4. Part of the variance probably results from the fact that chronic users reach higher blood THC-COOH concentrations more rapidly compared with infrequent users.[253] Because of interindividual variation in the pharmacokinetics of Δ^9-THC, estimation of the blood Δ^9-THC concentrations based *only* on cannabinoid metabolite concentrations is unreliable.

The pharmacokinetics of marijuana after IV administration is similar to the pharmacokinetics following smoking, but the ingestion of marijuana produces lower, delayed peak levels. After ingestion of Δ^9-THC, the onset of clinical effects develops slower and lasts longer compared with IV or pulmonary administration, but subjective effects occur at much lower plasma concentrations than after injection or inhalation. In a study of 11 healthy volunteers, the same degree of intoxication in volunteers occurred at plasma Δ^9-THC levels of 2–4 ng/mL after ingestion compared with plasma Δ^9-THC of 9 ng/mL following inhalation.[67] A small study of 4 volunteers without prior marijuana use indicated that a total plasma metabolite/Δ^9-THC ratio below 20 was consistent with recent oral cannabis consumption, but the administration of multiple Δ^9-THC doses in chronic users produced substantially higher ratios (i.e., >30) as measured by radioimmunoassay.[254]

POSTMORTEM. Most postmortem analytic tests involve whole blood samples. The concentration of Δ^9-THC in plasma is about 1.5–2 times the concentration of Δ^9-THC in whole blood because Δ^9-THC is highly bound to plasma proteins. Despite the widespread use of cannabis, there are few case reports documenting the presence of Δ^9-THC in the postmortem examination of individuals dying without an obvious cause of death.[255] During the autopsy of a suspected marijuana-induced death, the tissue concentrations of Δ^9-THC were as follows (mg/100g): kidney, 3.75; liver, 4.2; spleen, 1.2; stomach, 0.8; and intestine, 0.2.[65] Unusually high postmortem blood Δ^9-THC concentrations and low blood THC-COOH concentrations may occur in decomposed bodies, particularly when reductive anaerobic processes (e.g., during submersion) convert the metabolite to the parent compound.[256] Although case series document the presence of Δ^9-THC in the blood concentrations <5–10 ng/mL in postmortem samples from patients dying with cardiovascular disease,[250] the contribution of Δ^9-THC to the death of these patients is unclear. Despite the high lipid solubility of Δ^9-THC and the large volume of distribution, postmortem redistribution of Δ^9-THC is relatively modest (e.g., heart/femoral blood ratios ranging from 0.3–3.0); additionally, there is some variability in the distribution of THC between whole blood and serum during the postmortem period.[244]

URINE

Urine drug screens for the detection of marijuana use are particularly susceptible to false-negative results after adulteration of the urine sample (e.g., addition of bleach, glutaraldehyde, oxidants, pyridinium chlorochromate, or nitrites). Additionally, the use of nonsteroidal antiinflammatory analgesics can interfere with the derivatization of THC-COOH during GC/MS procedures, causing false-negative results for

THC-COOH.[257] Typically, urine samples are clear to pale yellow with concentrated urine in early morning samples providing the most reliable results. The temperature of urine samples recorded within 4 minutes of collection should be between 32–38ºC (89.6–100.4ºF); the pH usually ranges from 4.5–8.0. Urine creatinine concentrations from healthy individuals typically exceed 20 mg/dL. Factors suggesting alteration of the urine sample include pH <3 or >11, specific gravity <1.002 or >1.020, nitrites >500 μg/mL, and urine creatinine <5 mg/dL.[258]

DETECTION TIMES. Urinary detection times vary substantially as a result of differences in assays (limits of detection, cross-reactivity, cutoff), individuals (body mass, pharmacogenetics, chronicity of drug use), dose, urine parameters (pH, specific gravity), route of administration, and the efficacy of hydrolytic methods. The amount of cannabinoids in the urine depends on a variety of factors including the amount of drug absorbed, the time since consumption, the metabolic rate, fluid intake, individual variability, and the chronicity of use. Metabolites are detectable in plasma within minutes of the initiation of smoking and these metabolites persist after the disappearance of Δ^9-THC. Positive urine tests document the prior use of marijuana, but these urine assays do not correlate to psychomotor impairment. There is no direct correlation between blood Δ^9-THC concentrations and urine concentrations of THC-COOH.[253] Typically, the urine drug screen for cannabinoids remains positive for 1–4 days after occasional marijuana use and approximately 7–10 days following heavy cannabis abuse, depending on the factors listed above.[259]

Occasional Use. The urine cannabinoid concentration does not accurately predict the amount of Δ^9-THC absorbed because a small concentration may result either from a large dose taken a long time previously or from a small dose administered recently. The presence of total (conjugated and unconjugated) Δ^9-THC concentrations in the urine samples exceeding 2 ng/mL suggests recent use (<5–6 hours) of marijuana as measured by GC/MS following enzymatic hydrolysis.[260] In 1994, the US Department of Health and Human Services (DHHS) changed the official requirement for the immunoassay screening cutoff concentration of marijuana metabolites from 100 ng/mL to 50 ng/mL.[261] Mean detection times vary directly with the cutoff concentration of a particular assay, and there is substantial variation in detection times of various immunoassays. For a cutoff of 50 ng/mL, the mean detection times in a group of 6 healthy volunteers smoking a single low dose (1.75% Δ^9-THC) cigarette was <1 day whereas the inha-

lation of a single high-dose cigarette (3.55% Δ^9-THC) produced a positive immunoassay for <2 days (range, 57–122.3 hours).[262] The detection times using GC/MS with a 15 ng/mL cutoff were approximately twice as long as the mean detection times using an immunoassay with a 50 ng/mL cutoff. The mean detection times ranged from 1–5 days (mean, 33.7 ± 9.2 hours) after the low-dose cigarette and from 3–6 days (mean, 88.6 ± 23.2 hours) after the high-dose cigarette. Following the ingestion of marijuana brownies containing the equivalent plant material of one or two marijuana cigarettes (2.8% Δ^9-THC), the mean times to the first negative EMIT® d.a.u. Cannabinoid 20 Assay (20 ng/mL cutoff) were ~58 ± 14 hours and 82 ± 23 hours, respectively; the mean times to the last positive were 122 ± 28 hours and 143 ± 23 hours, respectively.[263] Cannabis seed oil contains Δ^9-THC concentrations ranging from 3–1,500 μg/g oil; the ingestion of the potent forms of this oil may produce positive immunoassays for cannabinoid metabolites up to about 6 days after ingestion.[264]

Chronic Use. Because Δ^9-THC can accumulate in body fat, detectable urine THC metabolites may appear several weeks after cessation of chronic marijuana use, depending on the sensitivity of the assay.[265] In patients testing positive for Δ^9-THC-COOH after previously negative urine samples collected >48 hours before the positive sample, serial evaluation of the Δ^9-THC-COOH/creatinine ratio by quantitative immunoassay results may help detect new marijuana use. A urine THC-COOH/creatinine ratio of 2 specimens collected at least 24–96 hours apart (i.e., dividing the THC-COOH/creatinine ratio of specimen 2 by the ratio in specimen 1) exceeding 0.5 suggests recent marijuana use based on the analysis by fluorescence-polarization immunoassay.[266,267] The use of a ratio of total cannabinoids/creatinine in the second specimen exceeding 150% of the first specimen as measured by EMIT®d.a.u. immunoassay is a more specific method of detecting recent marijuana use, but this method lacks the sensitivity of using the THC-COOH/creatinine ratio of 0.5.[268] However, the use of a single 0.5 ratio may generate unrealistically high reuse rates when the urine specimen contains a low THC-COOH/creatinine ratio (<50 ng/mg) and an unrealistically low rate when the urine specimen contains a high THC-COOH/creatinine ratio (200–400 ng/mg). A model development study suggests that a mono-exponential model of an initial THC-COOH/creatinine ratio and time between specimens based on the Marquardt-Levenberg algorithm provides a better data fit than the use of a single 0.5 ratio.[269]

Positive results for THC-COOH should be confirmed by GC/MS because of potential false-positive values. In a study of 148 urine specimens, the sensitivity

and specificity of the fluorescence-polarization immunoassay for detecting recent drug use was 95.3% and 44.4%, respectively, when compared with GC/MS analysis of THC-COOH.[270] These values indicate that this assay cross-reacts with cannabinoid metabolites other than THC-COOH. Marijuana research during the 1970s and 1980s used less-sensitive and less-specific assay methods compared with current immunoassays with GC/MS confirmation.[262] The excretion times of studies conducted during this period were associated with much longer excretion times compared with current analytic methods. For example, The EMIT® d.a.u. (sensitivity, 20 ng/mL) detected urine cannabinoids for an average of 27 consecutive days with an upper range of 46 consecutive days after cessation by chronic marijuana users.[271] Over 2 months may be necessary for urine cannabinoid concentrations to remain below the cutoff value for 10 consecutive days. Current methods indicate that urine samples from occasional marijuana users remain positive for cannabinoids up to ~1–4 days compared with up to 7–10 days for chronic marijuana users.

CROSS-REACTIVITY.   The major metabolic pathway of Δ^9-THC involves allylic hydroxylation at the C_{11} position and, to a lesser extent, at the C_8 position. The initial metabolite is 11-hydroxy-Δ^9-THC (11-OH-THC), which is oxidized to the major metabolite found in the blood and urine, 11-nor-9-carboxy-Δ^9-THC (THC-COOH). The glucuronidation of hydroxylated and carboxylated metabolites facilitates the excretion of these metabolites in the urine. The chief limitation of immunoassay procedures is the inherent cross-reactivity of the assay with other nonpsychoactive cannabinoids. Marijuana contains more than 400 compounds; urine immunoassays cross-react with dihydroxy-THC, polar acids, and perhaps other compounds. High concentrations of ibuprofen interfered with the methylation of THC-COOH leading to false-negative results on earlier EMIT® d.a.u. cannabinoid 100-ng assays, but later reagents were reformulated to reduce this cross-reactivity with the exception of tolmetin.[257,272] Additionally, the ingestion of the nonnucleoside reverse transcriptase inhibitor, efavirenz, may cause false-positive results for THC in some urine drug screens.[273]

PASSIVE INHALATION.   Although low concentrations of cannabinoids can occur in urine samples shortly after exposure to passive marijuana smoke in public or private settings,[274] positive cannabinoid urine immunoassays (i.e., >50 ng/mL cutoff) following passive inhalation of marijuana smoke is unlikely, except following very high, prolonged exposure (e.g., the equivalent of 16 marijuana cigarettes in a small room for 1 hour on 6 consecutive days).[275,276] In a study of naïve marijuana users sitting in a small, closed car (1,650 L air), marijuana smoking by others in the car produced urine cannabinoid concentrations near 20 ng/mL in urine samples from the nonsmoking volunteers as measured by immunoassays. These nonsmoking study participants did not develop psychotomimetic symptoms despite the presence of maximum levels of tolerable smoke.[277] Even when urine samples were collected for 24 hours after exposure in the enclosed environment, only 3 of 80 urine samples from nonsmokers were positive at the 20 ng/mL level and none were positive at the 50 ng/mL level.[278] A 1-hour exposure of 3 study participants to 4 marijuana cigarettes in a room $10 \times 10 \times 8$ feet (21,600 L air) with ventilation did not produce urine concentrations >6 ng THC-COOH/mL when tested 24 hours later by RIA.[279]

PASSIVE INGESTION.   Low concentrations (<1%) of Δ^9-THC and other cannabinoids contaminate hemp seed oil as a result of the extraction process. The Δ^9-THC content in these products depends upon the type of seed (i.e., fiber from hemp <hemp seed oil/capsules) and the presence of leaf debris. Recently, the hemp seed industry introduced new washing steps before pressing and the shelling of seeds to reduce the concentration of Δ^9-THC in hemp products. Hemp seed oil is available as a diet supplement for essential fatty acids. Given current cutoffs, the possibility of a positive urine drug screen within 48 hours after ingestion of manufacturer-recommended doses of low-Δ^9-THC containing hemp products is unlikely. However, positive drug screens for marijuana may occur rarely depending on the concentration of the product and the time since ingestion. The ingestion of large amounts (e.g., 135 mL over 4½ days) of older hemp seed oil may produce positive immunoassays (50 ng/mL cannabinoid metabolites by immunoassay screening, 15 ng/mL of THC-COOH by GC/MS confirmation) up to 2 days after ingestion.[280] However, volunteer studies indicate that hemp oil contains sufficiently low concentrations of Δ^9-THC to prevent the occurrence of confirmed false-positive drug of abuse screens after the ingestion of usual quantities of hemp oil. The daily ingestion of 0.6 mg Δ^9-THC for 10 days did not produce urine THC-COOH concentrations above the federal confirmation cutoff (i.e., 15 ng/mL).[281] This dose is equivalent to the consumption of approximately 125 mL of hemp oil containing Δ^9-THC concentrations of 5 µg/g or 300 g of hulled seeds containing 2 µg THC/g. Although the ingestion of several cookies and candy bars containing hemp seed oil may produce positive immunoassays at the 50 ng/mL and the 20 ng/mL cutoff levels, the urinary THC-COOH concentrations do not usually exceed the criteria for GC/MS of 15 ng

THC-COOH/mL).[282] Trace amounts of THC-COOH also may be present in the urine of individuals ingesting hemp seed tea, but these trace concentrations do not usually exceed GC/MS confirmatory concentrations (15 ng/mL).[283] The ingestion of Marinol® in daily doses of 7.5–14.8 mg commonly produces positive cannabinoid immunoassays for marijuana use within 4 days after ingestion based on volunteer studies.[284] Δ^9-tetrahydrocannabivarin is a C3 homologue of Δ^9-THC that occurs in urine specimens following exposure to Δ^9-THC, but not following exposure to Marinol®. Consequently, the presence of Δ^9-tetrahydrocannabivarin-9-carboxylic acid in the urine indicates the use of marijuana rather than Marinol®,[45] but detection of this metabolite is not readily available from commercial sources. Validation of claims of positive urine tests resulting from the ingestion of hemp products requires analysis of the ingested products for Δ^9-THC content and evaluation of urine Δ^9-THC metabolites for consistency with the dose ingested.

HAIR

The incorporation of Δ^9- THC and THC-COOH into hair is very low compared with cocaine. The latter drug of abuse has the highest incorporation rate in hair with a cocaine/THC-COOH incorporation ratio of 3,600.[285] The recent use of marijuana is difficult to detect by analysis of hair samples for marijuana metabolites, but several analytic methods are available to screen hair for the presence of cannabinoids as a result of chronic cannabis use including GC/MS with headspace solid-phase microextraction[286] and gas chromatography/negative ion chemical ionization/mass spectrometry.[287,288] Major problems include the potential contamination of hair by external sources of marijuana, the difficulty detecting the low concentrations of THC-COOH present in the hair after exposure to cannabis, and the photodegradation of Δ^9-THC by sunlight.[289,290] Basic drugs (amphetamines, cocaine, opiates) are incorporated into hair in preference to acidic drugs (e.g., THC-COOH). In contrast to these basic drugs, THC-COOH has a low affinity for melanin; therefore, hair color is not an important determinant of the THC-COOH content in hair.[291] In a study of 12 regular marijuana users and 10 controls (no marijuana use), the concentration of Δ^9-THC in hair was not significantly related to self-reports of amount of marijuana use.[292] However, the sum of major cannabinoids (THC, CBD, CBN) in the hair of regular users did correlate to the amount of marijuana use. Gas chromatography/mass spectrometry is the analytic method of choice for the quantitation of cannabinoids in hair because of the low concentration of these substances in the hair of marijuana users. Studies on the long-term stability of Δ^9-THC and its metabolites in hair are necessary before the significance of cannabinoids in hair can be determined.

SWEAT

Passive diffusion of an unbound drug across a concentration gradient and through lipid membranes results in the transfer of the drug from plasma to sweat. Basic drugs accumulate more easily in sweat than acidic drugs because the mean pH of sweat is relatively acidic (i.e., pH = 6.3). Patches applied to the skin allow oxygen, carbon dioxide, and water vapor to escape while the drug remains adsorbed in the patch. Δ^9- THC is a relatively neutral drug and the accumulation of Δ^9- THC in sweat is lower (low ng/patch) compared with basic drugs (cocaine, amphetamines, opiates). Δ^9-THC also adheres to glass and plastic surfaces as well as constituents of the patch. The principal acidic urinary metabolite of Δ^9-THC (11-nor-9-carboxy-Δ^9-THC) is not usually detected in sweat patches.[293] The US Substance Abuse and Mental Health Services Administration (SAMHSA) established a cutoff of 1.5 ng Δ^9-THC/2.5 mL of eluate with a confirmatory cutoff of 0.5 ng Δ^9-THC/2.5 mL of eluate. Analytic methods (e.g., gas chromatography/ negative ion chemical ionization/mass spectrometry) are available to measure Δ^9-THC concentrations in this range.[294] The potential advantage of sweat patch testing is the use of one patch during a week. However, issues that complicate the interpretation of Δ^9-THC in sweat include the inability of washing procedures to remove all drug deposited on the skin and resorption/volatilization of Δ^9-THC from the patches.

SALIVA

The smoking of marijuana exposes the oral mucosa to high concentrations of Δ^9-THC, resulting in direct deposition of Δ^9-THC into oral fluid; only minor amounts of Δ^9-THC and metabolites diffuse into saliva from the blood. Advantages of testing saliva for cannabis use include ease of collection, direct supervision of samples, and closer correlation between cannabis exposure and testing; limitations compared with urine testing include the relatively smaller sample size and the lower concentration of Δ^9-THC and metabolites in saliva. In general, detection time for cannabis is shorter in saliva than urine.

In a study of 22 injured drivers with detectable THC-COOH in their urine samples as measured by GC/MS, 14 saliva samples collected with Sarstedt Salivettes (Etten Leur, Netherlands) were positive for cannabis use.[295] In a study of 10 current cannabis users smoking a single marijuana cigarette with an average Δ^9-THC

content of 20–25 mg, oral fluid specimens collected with the Intercept™ DOA Oral Specimen Collection Device (OraSure Technologies, Inc., Bethlehem, PA) was consistently positive for cannabis over a mean time of 13 ± 2 hours (range, 1–24 hours) after smoking as measured by GC/MS/MS (15 ng/mL cutoff), whereas the average time to the last positive oral specimen was 34 ± 11 hours (range, 1–72 hours).[296] The urine samples tested positive consecutively for cannabis for an average of 33 ± 10 hours (range, 4–72 hours); the average time to the last positive urine specimen was 58 ± 6 hours (range, 16–72 hours) using the same method.

Abnormalities

BLOOD

Laboratory abnormalities during marijuana intoxication typically are minor. However, following the IV administration of boiled marijuana extract, blood abnormalities include transient leukocytosis and thrombocytopenia, mild increase in serum hepatic aminotransferases, moderate rhabdomyolysis (increased serum creatine kinase, myoglobinuria), mild to moderate renal dysfunction (increased serum creatinine), and electrolyte imbalance.[297,298]

CARDIOVASCULAR

Rare case reports temporally associate marijuana smoking with the development of asymptomatic second-degree (Mobitz type I) heart block,[299] right bundle-branch-type ventricular tachycardia with near syncope,[300] and atrial fibrillation.[301] A case report associated the use of high doses of marijuana with the development of syncope and the Brugada syndrome.[302]

NEUROLOGIC

IMAGING STUDIES.   There is no conclusive evidence that the chronic use of marijuana causes structural abnormalities in the brain. Two cross-sectional studies of long-term marijuana users did not detect structural differences in the brains of long-term marijuana users and controls.[303,304] In particular, these imaging studies do not demonstrate significant changes in tissue volumes of the gray and white matter, cerebrospinal fluid or the hippocampus.[305] There was no direct evidence of cerebral atrophy or abnormalities of the ventricles in the brain computerized axial tomography images of 19 habitual marijuana users.[306] A functional MRI study of nine chronic cannabis smokers demonstrated decreased activation of cortical areas (Brodmann areas 6, 24, and 26) associated with complex information processing and

attention related to motor function during the first 4–36 hours after cessation of marijuana use.[307] These changes are consistent with deficits in attention during the early withdrawal phase.

NEUROPSYCHOLOGIC TESTING

Acute.   During the state of intoxication, alteration of motor control (e.g., body sway, sustained attention), and sensory function (e.g., overestimation of time) occurs. Long-term memory, reaction times, and hand–eye coordination are relatively resistant to the acute effects of typical recreational marijuana doses. After controlling for premorbid intelligence in a group of college students, almost daily marijuana use was associated with significantly greater impairment in attentional and executive functions when compared with monthly marijuana smokers.[308] This study did not attempt to determine neuropsychologic function during a period of abstinence. Selective attentional deficits[309] and short-term memory impairment[310] may persist during the first month of abstinence, but most neuropsychologic test scores return to normal within one month of the beginning of abstinence despite a history of heavy cannabis use.[311]

The acute smoking of marijuana may impair acquisition and working (i.e., short-term) memory, but not the retrieval processes during the period of intoxication.[4] Some researchers report impairment of multiple cognitive domains (short-term memory,[312] verbal episodic memory,[313] sustained attention, risk taking,[314] executive function[315]) during acute cannabis intoxication, whereas other studies did not detect impairment of cognitive flexibility,[316] mental calculation, reasoning, risk taking,[315] and executive function.[317] In general, acute cannabis intoxication slows responses during task performance, while overall performance accuracy is less affected. The performance effects of frequent cannabis users appear more subtle than occasional users.[313]

Chronic.   There is limited evidence that chronic marijuana use causes permanent gross cognitive impairment other than the effects of acute drug use, particularly following abstinence of 1–3 months.[318] The areas of concern following chronic marijuana use involve mild deficits in executive cognitive functioning, working memory, abstract reasoning, processing speed, overall IQ, and selective attention. The issue of the chronic effects of heavy marijuana use on the central nervous system remains unresolved, partly because of the difficulty determining the effect of confounders (e.g., anxiety disorders, major depression), establishing control groups with similar baseline psychologic testing scores, and evaluating the persistence of Δ^9-THC beyond the testing period. Experimental studies suggest that

some neurocognitive deficits remain in heavy cannabis users within 7 days after exposure ceases, but there are limited data to suggest that heavy cannabis use causes permanent reduction in neuropsychologic test scores.[319] In a study of college students abstinent for 1 day, heavy marijuana users (i.e., marijuana use 29 days in last month) displayed significantly greater impairment on attention/executive functions, as evidenced by greater perseverations on card sorting and reduced learning of word lists, compared with light marijuana users (i.e., marijuana use 1 day within the last month).[320] In a study of adolescent marijuana users, verbal working memory improved after 3 weeks of abstinence, but some attention deficits remained when compared with testing at the time of last cannabis use.[321]

A prospective, longitudinal study of 113 young adults assessed since infancy separated the cohort into light (<5 joints) and heavy (>5 joints/week) current users, former users (i.e., at least 3 months of abstinence from marijuana use), and nonusers.[322] After controlling for confounding factors and predrug performance on baseline neuropsychologic testing, the current regular heavy users did significantly worse than nonusers in scores on overall IQ, immediate and delayed memory, and processing speed. The adjusted scores on sustained attention and abstract reasoning were not statistically different between these two groups. Former marijuana smokers did not demonstrate any significant cognitive impairment, and the impairment of current heavy users resolved after 3 months of abstinence. A small case series of 10 volunteers using ganja chronically for religious purposes did not detect neuropsychologic abnormalities as measured by standardized neuropsychologic testing.[323]

Some studies suggest that the effects of heavy marijuana use may extend beyond the short-term period of intoxication. A retrospective, cross-sectional neuropsychologic study of nearly daily, long-term marijuana use indicate that heavy marijuana users scored significantly lower on tests of memory and attention compared with shorter-term (i.e., 10 year) marijuana use and nonuser controls.[324] A battery of neurocognitive tests administered to heavy marijuana users after a 28-day period of abstinence demonstrated persistent decrements in tests measuring memory, executive function, psychomotor speed, and manual dexterity when compared to a light marijuana user group.[325] However, the sample size was small, and there was a statistically significant difference in education level between the two groups. Additionally, the decrements in performance were not clinically abnormal, except for a few tests. Comparison of neuropsychologic test scores from current heavy marijuana users (>5,000 times during lifetime), former heavy users <50 times last 3 months), and controls (<50 times during lifetime) demonstrated no significant differences among

the group test scores nor any correlation between cumulative marijuana use and test scores after 7 days of abstinence.[326] There were significant differences between current chronic marijuana users and test scores on the recall of word lists for the first 7days of abstinence, but after that time the test scores between the groups were similar. Areas tested included general intellectual function, abstraction ability, sustained attention, verbal fluency, and ability to learn and recall new verbal and visuospatial information.

Driving

Although laboratory data including driving simulator studies indicate that smoking cannabis impairs some psychomotor skills and cognition (e.g., free recall of previously learned items) in a dose-dependent relationship, current culpability and case-control data is inconsistent with regard to the association of smoking typical doses of cannabis with either serious driving impairment or increased risk of traffic accidents.[327,328] Epidemiology data indicate that cannabis is the most common *illicit* drug detected in impaired drivers and motor vehicle injury accidents; however, interpretation of current epidemiology studies is limited by the lack of adequate control data (e.g., similar of risky behavior between 2 groups) and the rapid decline of Δ^9-THC between the incident and blood sampling. In general, the effect of marijuana on the learning of new tasks appears greater compared with the execution of well-trained tasks; however, the effect of Δ^9-THC is greater on highly automated tasks (e.g., road tracking control) compared with cognitive driving tasks requiring conscious control.[329] The greatest performance impairment from cannabis occurs during the first 20–40 minutes after smoking cannabis with impairment declining to baseline 2.5–4 hours after cannabis use.[330] Culpability analysis of 44 accidents involving injured drivers using only Δ^9-THC and no other drugs did not detect an increased risk of accidents involving only Δ^9-THC, but there was insufficient power in the study to determine an increased risk for whole blood Δ^9-THC concentrations exceeding 2 ng/mL.[331] Often, the use of cannabis occurs with other drugs, particularly ethanol; existing data suggest that the use of ethanol and cannabis together increases the risk of injury in motor vehicle accidents.[329]

Sensory, Motor, and Cognitive Tasks

Although laboratory studies suggest that Δ^9-THC impairs some psychomotor and cognitive functions including tracking, coordination, vigilance, divided attention, memory information processing, and perception, these decrements in performance affect primarily

highly automatic driving function rather than more complex tasks that require conscious control. In contrast, ethanol affects complex driving tasks more than highly automated driving tasks.[329] The issue of whether these decrements in driving performance are sufficiently large to increase the risk of accidents is inconclusive, in part because cannabis users tend to overestimate their impairment and may employ compensatory strategies depending on the degree of impairment.[336] The effect of Δ^9-THC on cognitive and psychomotor tasks associated with driving varies between individuals during the first few hours after inhalation, depending on the Δ^9-THC dose (smoking technique), tolerance, and the subject's ability to compensate for impaired skills and perception.[332] Furthermore, most subjective measures of cannabis exposure are more sensitive to Δ^9-THC effects than performance measures following doses that produce peak plasma Δ^9-THC concentrations below 170 ng/mL.[333] Overall, the impairment of driving skills is substantially less following the smoking of typical doses of marijuana than during the period of time associated with blood ethanol concentrations of 80–100 mg/dL.[334] In experimental studies, behavioral and physiologic effects begin concurrently or within minutes after the appearance of Δ^9-THC in the blood despite the substantial time delay between peak plasma Δ^9-THC concentrations and drug-induced effects.[335]

Modest impairment of human performance primarily involves divided attention, vigilance, perceptual speed, and complex tracking tasks (e.g., increased lateral position variability, headway control or distance between driver's vehicle and vehicle in front, critical tracking). The peak effects of Δ^9-THC on memory and divided attention occur approximately 15–30 minutes after smoking stops.[336,337] Testing of sensory functions in the laboratory setting is usually less affected by cannabis use than perceptual performance. Static visual acuity and visual search behavior are not significantly altered directly by the use of marijuana under either low or high contrast conditions based on volunteer studies using typical recreational marijuana doses. [338,339] Reported alterations of color vision associated with marijuana use include dyschromatopsia, yellow vision, increased color perception, and colored, flashing lights.[340] For at least 2 hours after ingesting Δ^9-THC, a dose-related decrease in glare recovery occurs as a result of alterations in light adaptation.[341] In a study of 10 cannabis users smoking cigarettes containing low dose (1.77% Δ^9-THC) and high dose (3.95% Δ^9-THC), the high dose increased body sway and marginally increased brake latency compared with placebo.[342] There was no significant difference between scores after placebo, low dose, or high dose on choice reaction time, critical flicker fusion, or a rapid judgment task. There are minimal effects on simple reaction times following smoking typical doses (peak plasma Δ^9-THC concentrations 63–188 ng/mL) of marijuana based on volunteer studies.[334] Experimental studies suggest tolerance to the impairment of some driving skills occurs in regular cannabis smokers. In a study of chronic cannabis users and nonusers, cannabis users were less impaired in peripheral signal detection than nonusers.[343]

The concurrent consumption of ethanol and marijuana may produce additive effects on some, but not all psychomotor functions associated with driving. In a controlled study of human volunteers ingesting 320 µg Δ^9-THC/kg, modest decrements in cognition, standing steadiness, psychomotor coordination, and reaction speed occurred. The addition of 0.54 g ethanol/kg (i.e., average peak ethanol concentration = 80 mg/dL) resulted in additional decrements in standing steadiness and psychomotor coordination, but no reduction in scores on cognition or simple reaction times.[344] Potentially, some cross-tolerance may occur in chronic marijuana users between Δ^9-THC and ethanol based on the attenuation of ethanol-induced impairment on computerized tracking skills of chronic marijuana users (i.e., daily for at least 3 years) compared with infrequent marijuana users.[345]

DRIVING COURSES AND SIMULATORS

The degree of impairment associated with cannabis use in driving simulators and driving courses is somewhat inconsistent and relatively minor. Although laboratory studies demonstrate some impairment of individual psychomotor skills immediately following Δ^9-THC exposure, there is minimal to modest impairment of overall performance in city and highway driving tests, in part because of the adjustment of drivers to their perception of impairment.[346,347] For example, the tendency to increase the distance between their car and the car in front of them as well as slower driving in these studies compensate for impairment of lane control and other driving skills. In some driving studies, experienced cannabis smokers demonstrate minimal impairment while driving a closed course under the influence of cannabis, except when combined with ethanol.[348] A high school driver education instructor, safety manager (American Automobile Association) and off-duty patrol officer evaluated performance on the closed-driving course based on their interpretation of impairment. A study of performance on a closed-course driving after cannabis use did not detect significant impairment. Volunteer studies using driving simulators suggest that drivers tested within 1 hour of smoking a marijuana cigarette (13 mg, 17 mg) drive slower than under control conditions.[349] In contrast, the average driving speed during a simulated driving test of the same drivers after ingesting

ethanol (estimated ethanol concentration = 0.05%) was higher compared with control conditions.

In general, driving impairment as evaluated by roadside sobriety tests does not correlate well with Δ^9-THC concentrations during the first 2 hours after exposure, especially compared with the dose-related impairment associated with ethanol consumption.[350] Scores on most psychomotor and cognitive tasks including simulated car-driving were normal the morning after marijuana use, despite the presence of subjective and behavioral effects the previous evening.[351] An uncontrolled study of 9 pilots using flight simulators suggested that some impairment of very complex human performance (i.e., flying skills) may occur up to 24 hours after the use of recreational doses (e.g., 20 mg Δ^9-THC) of marijuana.[352]

CULPABILITY AND CASE-CONTROL STUDIES

The results of culpability and case control studies that compare the actual risk of causing an accident between a sober driver and a driver under the influence of cannabis are inconsistent. Some,[353] but not all,[354] culpability studies of drivers involved in accidents while using illicit drugs suggest that the use of marijuana can increase the risk of an accident, particularly when the whole blood Δ^9-THC concentration exceeds 5 ng/mL. A review of culpability studies suggested that the presence of Δ^9-THC in the blood of crash victims increases the risk of culpability, particularly at higher doses as compared with drivers without recent drugs or alcohol use.[355] The concomitant use of Δ^9-THC and alcohol sharply increases the crash risk in epidemiologic analyses compared with either drug alone, even at relatively low concentrations. Although smoking marijuana does impair some driving skills, the drivers are usually aware of the impairment and compensate by focusing their attention on the perceived task.[327] However, they may not adequately compensate for unexpected events or for those tasks that require continuous attention.[356] Part of the difficultly in interpreting the effect of marijuana in some studies is the use of markers of recent exposure (11-hydroxy-Δ^9-THC) rather than Δ^9-THC concentrations as well as the high prevalence of concomitant ethanol and marijuana use. The rapid biotransformation of the active ingredient (Δ^9-THC) in marijuana complicates the use of blood as a biomarker of driving impairment because of the typical delay (i.e., 30–90 minutes) between apprehension and withdrawal of the blood sample. A 10-year Swedish study of individuals apprehended for suspected driving under the influence of drugs included 1,276 individuals with only Δ^9-THC in their blood samples.[357] The mean and median Δ^9-THC whole blood concentrations were 3.6 ng/mL and 2.0 ng/mL, respectively, with a range up

to 10 ng/mL. The study did not report the time between the initial stop for suspected driving under the influence and the sampling of venous blood. Over 85% of the 8,794 individuals arrested with Δ^9-THC in their blood also used other drugs.

BLOOD Δ^9-THC CONCENTRATIONS

There are limited data on the impairment associated with specific Δ^9-THC concentrations in plasma/serum and whole blood; consequently, there are difficulties deriving a risk-based *per se* limit for driving under the influence of cannabis, particularly given the rapid decline of Δ^9-THC concentrations between the time of the incident and sampling. Interpretation of the effect of a blood Δ^9-THC requires analysis of a variety of factors including the driving scenario (type of crash, road conditions, vehicle defects, cause of crash, appropriateness of driving response, compensatory actions, fatigue), magnitude of Δ^9-THC concentration, time interval between incident and withdrawal of the blood sample, concomitant presence of other drugs, and the time of the incident in relation to the last use of cannabis. In a study of 440 drivers apprehended for suspected driving under the influence of drugs, 53% of these drivers tested positive for Δ^9-THC with a median plasma concentration of 3 ng/mL (range, 1–35 ng/mL).[358] However, the study did not separate drivers with multiple drugs from drivers with only Δ^9-THC in their blood samples. Although the degree of impairment increases with increasing plasma/serum Δ^9-THC, the magnitude of the impairment is not linearly correlated to low plasma/serum Δ^9-THC concentrations as a result of individual sensitivities. Experimental studies suggest that the plasma/serum Δ^9-THC correlates better to the proportion of observations indicative of significant impairment rather than the magnitude of the impairment. In a study using critical tracking task (measure of on-the-road tracking performance), stop signal task (motor impulsivity), and Tower of London task (executive function/planning), significant impairment of all tasks in all 20 recreational cannabis users occurred at serum Δ^9-THC concentrations exceeding 30 ng/mL.[359] Limited epidemiology data suggest that serum Δ^9-THC concentrations of 12–16 ng/mL correlate to the odds ratio (i.e., 1.5–2) of an accident associated with a BAC of 50 mg/dL.[360]

TREATMENT

Stabilization

The most common presentation to the emergency department following marijuana exposure involves anxiety or dysphoria. These patients usually respond to

reassurance, reduction of external stimuli, and rest. They usually require no laboratory studies to aid management other than urine drug screens to confirm cannabis use and other tests as needed to exclude concurrent illnesses. Mild tranquilizers (e.g., lorazepam, 1–2 mg IV or intramuscularly [IM]) may be necessary if supportive measures do not calm the patient. Patients who do not respond rapidly to supportive care should be carefully evaluated for trauma and concurrent illnesses including rapid evaluation for hypoglycemia. Although the cardiovascular effects of Δ^9-THC do not usually cause serious health problems for most young, healthy users, rarely patients with significant cardiovascular disease may develop angina, dysrhythmias, myocardial infarction, or pulmonary edema. These patients should receive an IV line, cardiac monitoring, an electrocardiogram, cardiac enzymes, and other measures (aspirin, beta blockers, anticoagulants, antiplatelet drugs, coronary angiography) as dictated by the extent of coronary artery occlusion and myocardial damage.

Serious alterations of vital signs after cannabis use is extremely rare, except following the IV administration of marijuana extract. Hypovolemia from severe GI fluid loss may require the administration of fluids. These patients require hospitalization because of the potential development of multisystem failure including adult respiratory distress syndrome and acute renal failure within several days after injection. Consequently, careful management of both fluid and electrolyte balance is necessary. Laboratory analysis includes complete blood count, electrolytes, calcium, serum glucose, creatinine, blood urea nitrogen (BUN), hepatic aminotransferase, and muscle enzymes, complete coagulation profiles, electrocardiogram, chest x-ray, and urinalysis for myoglobin and protein.

Gut Decontamination

Decontamination measures are usually unnecessary following exposure to marijuana. Theoretically, the administration of activated charcoal to children, who present to the emergency department within 1 hour after ingesting ≥1 whole marijuana cigarette or cookie, is appropriate, but there are few data to guide management. Consumption of <1 whole marijuana cigarette does not require decontamination measures. Whenever patients ingest other substances (e.g., phencyclidine [PCP]) with the marijuana cigarette, decontamination measures are determined by treatment for that substance.

Acute Psychosis

Most psychotic symptoms that develop after marijuana use resolve within 6 hours, but rarely the acute psychosis may persist up to 1 week following heavy, habitual marijuana use. Most patients respond to reduction of stimuli in a normally lit room with a few familiar people and reassurance by medical personnel. Diazepam (5 mg IV) or lorazepam (1–2 mg IV) may be necessary to sedate these patients. Continued aggressive behavior despite the use of these measures may necessitate the use of physical restraints and neuroleptic drugs (e.g., haloperidol 5 mg IM).

Withdrawal/Dependence

Withdrawal symptoms may develop within 1–2 days after the cessation of heavy, chronic marijuana use (i.e., repeated daily smoking) manifest by GI distress, anorexia, anxiety, insomnia, irritability, and aggression.[199] Typically, these symptoms resolve within about 10–14 days. There are few data on the pharmacologic treatment of these withdrawal symptoms; potential therapies beside cognitive and behavioral therapies include oral tetrahydrocannabinol, mirtazapine, rimonabant, and buspirone.[361] Compared with placebo, nefazodone maintenance therapy (i.e., 450 mg/day) decreases some (anxiety, muscle pain), but not all (e.g., irritability, insomnia, malaise) withdrawal symptoms.[362] In 2 placebo-controlled, within-subject studies, the mood stabilizer, divalproex (500 mg/day increased every 2 days until a maintenance dose of 1,500 mg/day), reduced the craving for marijuana, but this dosage increased ratings of anxiety, irritability, and malaise while decreasing performance on psychomotor tasks.[363] Oral Δ^9-THC reduced both marijuana craving and withdrawal symptoms at a dose (10 mg/daily) that did not produce subjective effects. Withdrawal symptoms (marijuana craving, decreased appetite, sleep disturbances) during abstinence phases may contribute to cannabis dependence.[364] Treatment of cannabis dependence involves referral of the patient to sources for cognitive behavioral, motivation enhancement, and contingency management therapies.[28] Oral Δ^9-THC therapy typically is short-term in contrast to the use of methadone for opiate dependence.

SYNTHETIC CANNABINOIDS

HISTORY

In the late 1970s and the 1980s, chemists at Pfizer, Inc. investigated the analgesic properties of synthetic

FIGURE 60.9. Packages of spice. (Photo courtesy of the *Drug Identification Bible*)

nonclassical CP series of cannabinoids (e.g., CP-47,497); these compounds lacked the classical dibenzopyran structure of Δ^9-THC.[365,366] This investigation included the synthesis of the potent cannabinoid analog, cannabicyclohexanol. Research into the pharmacologic properties of synthetic nonclassical cannabinoids expanded in the 1990s and early 2000s with the investigations of JW Huffman and colleagues into the structure-activity relationships of indene-, indole-, and pyrrole-derived cannabinoids (JWH series).[367] Research at the Hebrew University of Jerusalem produced the HU series of cannabinoid receptor agonists (e.g., HU-210). In 2006, hits appeared in the World Wide Web promoting the smoking of herbal incense ("spice") that contained legal synthetic cannabinoids. These compounds were derivatives of aminoalkylindole class of ligands that bind and activate the CB_1 receptors. These commercial herbal products were distributed widely in brightly colored packages throughout Europe, Japan, and the United States by 2008.

Figure 60.9 displays some brightly colored packages of spice. In January 2009, the German Health Authorities banned the use of herbal incense containing CP-47,497-C8 and JWH-018; however, other synthetic cannabinoids (e.g., JWH-073, JWH-250, JWH-398) soon appeared on the market as suppliers responded to prohibitions and the prosecution of sellers.[368,369] The US

Drug Enforcement Agency (DEA) added JWH-018, JWH-073, JWH-200, CP-47,497, and cannabicyclohexanol to the list of schedule I substances in late 2010.

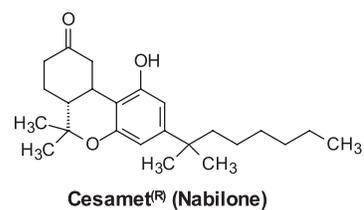
IDENTIFYING CHARACTERISTICS

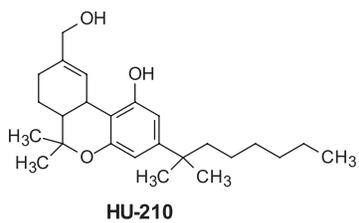
Synthetic cannabinoids are a diverse group of compounds that are derived from indole, indene, and pyrrole structures and bind to one or both cannabinoid receptors with different affinities. Most synthetic cannabinoids (e.g., HU-210, CP-55,950) are potent cannabinoid receptor agonists, whereas Δ^9-THC is a weak partial agonist at both cannabinoid receptors. There are the following 4 structural classes of synthetic cannabinoids: 1) classical cannabinoids, 2) nonclassical cannabinoids, 3) aminoalkylindoles, and 4) eicosanoids as displayed in Figure 60.10.[370] Classical cannabinoids are dibenzopyran compounds that include Δ^9-THC, other plant cannabinoids (cannabinol, cannabidiol), and the synthetic compound, HU-210. The nonclassical cannabinoids lack a pyran ring structure and include the cyclohexylphenols, CP-47,497 and cannabicyclohexanol. The aminoalkylindoles include the well-studied naphthoylindole compounds in the JWH series (see Figure 60.10 and Figure 60.11). Most synthetic cannabinoids in spice (K2) belong to the JWH series that primarily activate CB_1 receptors (e.g., JWH-018) rather than CB_2 receptors (e.g., JWH-015). The eicosanoid group includes natural endocannabinoids (e.g., anandamide), synthetic derivatives, and noladine ether.

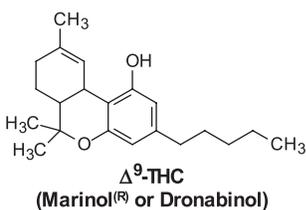
In vitro testing (i.e., cannabinoid receptor binding studies) indicates that the synthetic cannabinoids in herbal incense products are more potent than Δ^9-THC.[371] For example, JWH-018 has an approximately 4-fold higher affinity to the CB_1 receptor and about a 10-fold higher affinity for the CB_2 receptor than Δ^9-THC.[367] The affinity of the synthetic cannabinoid compounds for the cannabinoid receptors varies. CP-47,497-C8, and JWH-073 have higher affinity for the CB_1 receptor compared with the CB_2 receptor,[365] whereas JWH-018 and JWH-250 have similar affinity for both cannabinoid receptors. JWH-015 binds primarily to CB_2 receptors.[372] Street names for synthetic cannabinoids include Spice, Spice Gold, K2, Dream, Aroma, Scence, Skunk, Smoke, and Yucatan Fire.

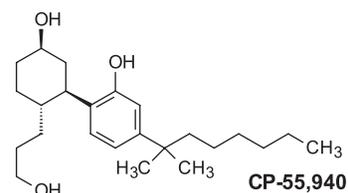
EXPOSURE

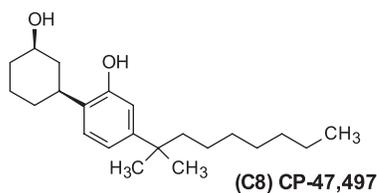
Spice refers to herbal products that are marketed as incense and legal alternatives to cannabis; often these products contain synthetic cannabinoids. In a study of herbal products sold in Japan for cannabis-like effects, the concentrations of detected synthetic cannabinoids

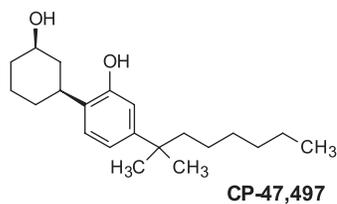
Classical Cannabinoids


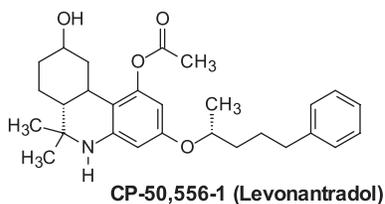


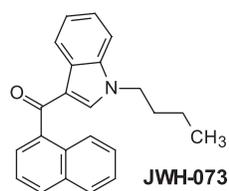


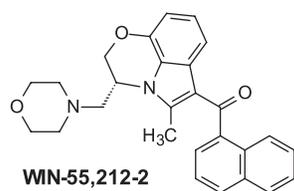
Non-Classical Cannabinoids


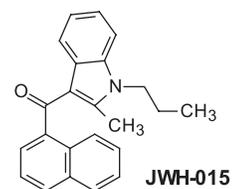


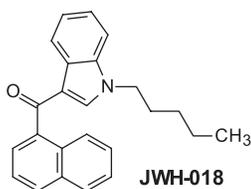


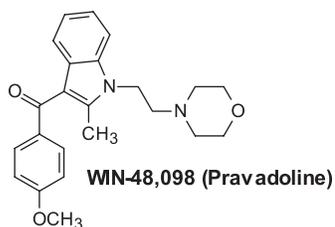


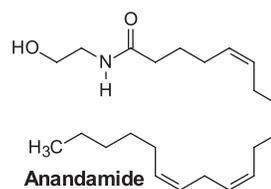
Aminoalkylindoles










Eicosanoids


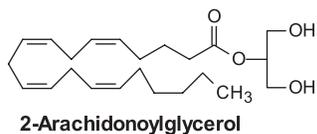


FIGURE 60.10. Classification of synthetic cannabinoids based on the four structural types of cannabinoid ligands that bind to cannabinoid receptors.[370]

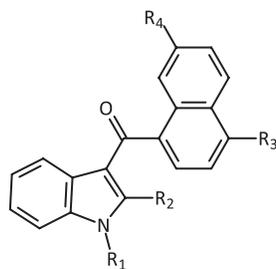
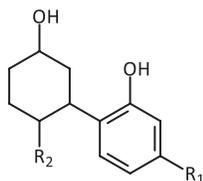
Naphthoylindoles (R = H, unless otherwise specified)


JWH-018 (342.1852)	R_1 = pentyl
JWH-073 (328.1696)	R_1 = butyl
JWH-398 (376.1463)	R_1 = pentyl, R_3 = Cl
JWH-081 (372.1958)	R_1 = pentyl, R_3 = OCH_3
JWH-007 (356.2009)	R_1 = pentyl, R2 = CH_3
JWH-019 (356.2009)	R_1 = hexyl
JWH-047 (356.2009)	R_1 = butyl, R2 = CH_3, R4 = CH_3
JWH-122 (356.2009)	R_1 = pentyl, R_3 = CH_3
JWH-180 (356.2009)	R_1 = propyl, R_3 = propyl
JWH-049 (384.2322)	R_1 = hexyl, R_2 = CH_3, R_4 = CH_3
JWH-182 (384.2322)	R_1 = pentyl, R_3 = propyl
JWH-213 (384.2322)	R_1 = pentyl, R_2 = CH_3, R_3 = ethyl

Cyclohexylphenols (R = H, unless otherwise specified)


CP-47,497 (319.2632)	R_1 = 1,1-dimethylheptyl
Analog V (305.2475)	R_1 = 1,1-dimethylhexyl
Analog VII (333.2788)	R_1 = 1,1-dimethyloctyl
Analog VIII (347.2945)	R_1 = 1,1-dimethylnonyl

FIGURE 60.11. Chemical structures of some naphthoylindole (JWH) and cyclohexylphenol (CP) type synthetic cannabinoid compounds. Specific compounds are listed by identification number followed by isotopic mass in parentheses. Adapted from Reference 381.

was as follows: cannabicyclohexanol, 1.1–16.9 mg/g; JWH-018, 2.0–35.9 mg/g, and oleamide, 7.6–210.9 mg/g.[373]

TOXICOKINETICS

There are few human data on the kinetics of synthetic cannabinoids; similar to Δ^9-THC, the biotransformation of JWH-018 is complex. *In vitro* studies indicate that JWH-018 metabolites include a variety of phase I metabolites including monohydroxylated, dihydroxylated, trihydroxylated, *N*-dealkylated, carboxylated, and dehydrated compounds, as well as metabolites containing a dihydrodiol structure.[374] Limited data in humans suggests that the kidney excretes little JWH-018 unchanged in the urine with hydroxylation of the indole ring and the *N*-alkyl chain forming most metabolites that are conjugated with glucuronic acid.[375,376]

CLINICAL RESPONSE

There are few data on the adverse effects associated with smoking herbal products containing synthetic cannabinoids. Potential toxic effects include nausea, vomiting, blurred vision, tremors, ataxia, altered consciousness, confusion, irritability, paranoia, hallucinations, mydriasis, hypertension, and tachycardia. Typically, patients admitted to the emergency department after smoking products containing synthetic cannabinoid compounds complain of anxiety, disorientation, agitation, and palpitations; abnormal physical findings include conjunctival erythema, lateral gaze nystagmus, tachycardia, and altered mood (e.g., inappropriate laughter).[377,378] The clinical features usually resolve soon after admission to the emergency department. Several case reports associate the sudden reemergence of florid psychosis in previously stable patients with histories of prior psychotic episodes precipitated by cannabis.[379] Manifestations of these episodes involve primarily agitation and disorganization with grandiose and paranoid delusions. Case reports associate the chronic use with the development of withdrawal symptoms. A 20-year-old man with a history of using spice gold daily for 8 months developed withdrawal symptoms 3 days after cessation of use.[380] Clinical features of the withdrawal syndrome included drug craving, anxiety, nightmares, diaphoresis nausea, headache, tremor, hypertension, and sinus tachycardia. The symptoms resolved by the 7th day of hospitalization.

DIAGNOSTIC TESTING

Synthetic cannabinoids typically are not detected by urine drug screens. Methods for the quantitation of synthetic cannabinoids in confiscated samples include gas

chromatography/mass spectrometry in electron impact mode (70eV), liquid chromatography/high resolution accurate mass spectrometry,[381] and ultra high performance liquid chromatography/electrospray ionization/mass spectrometry.[373] Accuracy for the latter method ranged from −6.9–4.4%. Metabolites of synthetic cannabinoids are detectable with liquid chromatography/tandem mass spectrometry.[382] The lower limit of detection with this method is about 0.1 ng/mL. The use of spice products does not usually produce positive urine drug screens, and a negative urine drug of abuse screen does not exclude exposure to synthetic designer cannabinoid compounds. Laboratory abnormalities associated with the use of these drugs include leukocytosis, lactic acidosis, and elevated serum creatine kinase.[377]

TREATMENT

Treatment is supportive, similar to the treatment of cannabis.

Chapter 61

Mate Tea (*Ilex paraguariensis* A. St. Hil.)

HISTORY

Indigenous tribes (e.g., Guarani Indians) from South America traditionally used tea from the *Ilex paraguariensis* A. St. Hil. as a mild stimulant.[1] In the 16th century, cultivation of this plant began in Jesuit settlements in South America, leading to the designation of the beverage as Jesuitic tea. This tea was introduced into Europe by the Jesuits. Mate is a derivative of the Quechua word ("matí") for the cup or vessel used to drink the tea. In Brazil, the word for this vessel is *chimarrão*.

BOTANICAL DESCRIPTION

Ilex species are medium to large trees distributed in tropical and subtropical regions, mostly in South America and East Asia; many *Ilex* species appear similar to the mate tree. *I. brevicuspis* Reissek and *I. theezans* Reissek grow in similar habitats in northeastern Argentina, southern Brazil, and eastern Paraguay as *I. paraguariensis* A. St. Hil. *I. argentina* Lillo is a native tree in northwestern Argentina.

Common Name: Mate (tea), chimarrão (tea or vessel), yerba-buena (tea)

Scientific Name: *Ilex paraguariensis* A. St. Hil.

Botanical Family: Aquifoliaceae (holly)

Physical Description: The perennial, evergreen tree reaches 18 m (~60 feet) in height. The alternate, obovate leaves have a serrated margin and obtuse apex. The inflorescences are a close group of flat-topped flowers with the outer flowers opening first (corymboid fascicles). These small and simple flowers appear from October through November with a whitish corolla. The fruit has 4–5 single seeds that develop from March to June.

Distribution and Ecology: This subtropical species prefers climates with relatively even rainfall throughout the year and mean temperatures 21–22°C (~70°F); however, this tree does tolerate temperatures below freezing in the plateaus and mountain regions of southern Brazil. The mate tree is a native species of parts of southern Brazil, Uruguay, Paraguay, and Argentina.

IDENTIFYING CHARACTERISTICS

Mate tea contains caffeine (1,3,7-trimethylxanthine) and theobromine (3,7-dimethylxanthine, CAS RN: 83-67-0) in significantly higher concentrations than coffee. The tea does not contain significant amounts of theophylline (1,3-dimethylxanthine). Figure 61.1 displays the chemical structures of the major xanthines and caffeoyl derivatives in mate tea. The physiochemical properties of caffeine are discussed in the caffeine chapter. Table 61.1 displays some physiochemical properties of theobromine.

EXPOSURE

Epidemiology

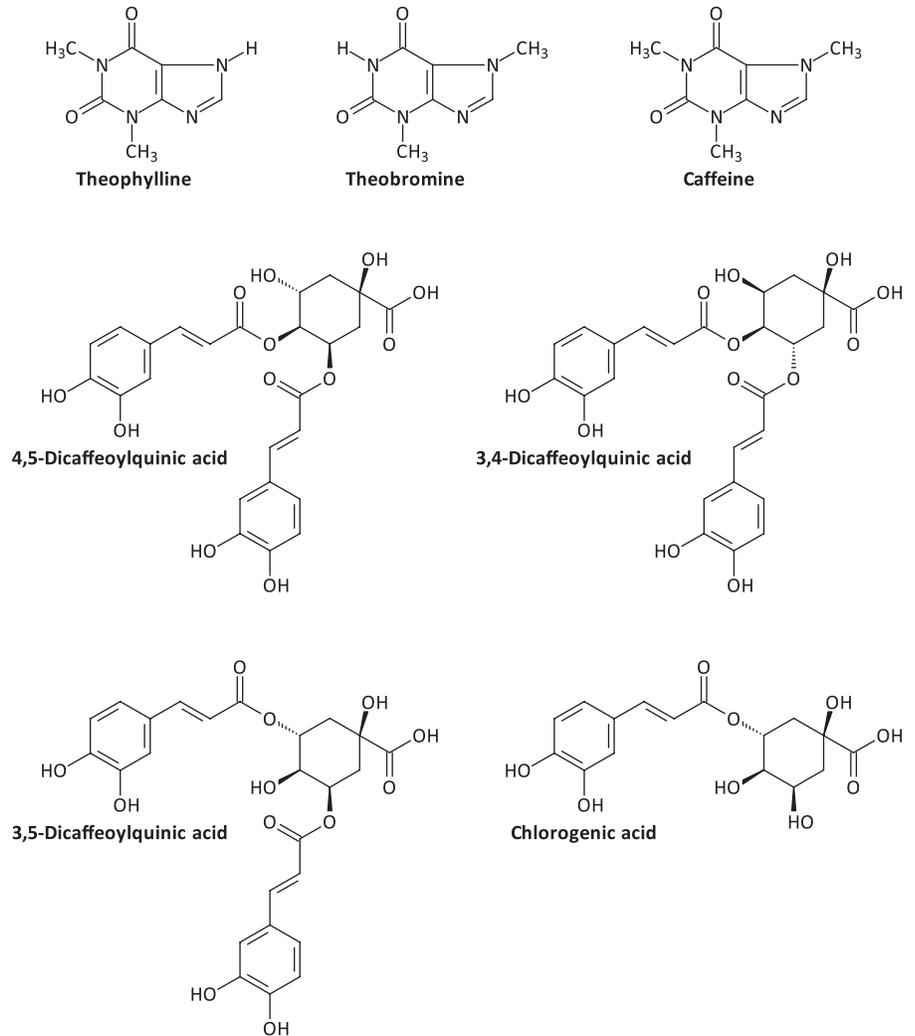
Mate tea is a popular drink in southern South America including Argentina, Bolivia, Brazil, Chile, Ecuador, Paraguay, and Uruguay. Argentina is the major mate tea producer, followed by Brazil and Paraguay.[4] In the


FIGURE 61.1. Chemical structures of major xanthines and caffeoyl derivatives in mate tea.

TABLE 61.1. Some Physiochemical Properties of Theobromine.

Physical Property	Value
Melting Point	357°C (~675°F)
pKa Dissociation Constant	9.9
log P (Octanol-Water)	−0.78
Water Solubility	330 mg/L (25°C/77°F)
Vapor Pressure	8.95E-10 mm Hg (25°C/77°F)

Middle East, the Druze of Lebanon, Syria, and the Golan Heights mate tea is also consumed. Currently, the gauchos of South America, primarily in Argentina, Southern Brazil, Paraguay, and Uruguay, consume mate tea as a traditional beverage. Guarani indigenous tribes from South America use an infusion (erva-maté, yerba maté) from the dried leaves and twigs of *Ilex paraguariensis* as a mildly stimulating beverage. In folk medicine, this tea is a central nervous system stimulant, diuretic,

and a treatment for rheumatoid arthritis. Other folk uses for yerba maté include the treatment of headaches, obesity, fatigue, hemorrhoids, constipation, hypertension, and hepatic disorders.[2]

Sources

ORIGIN

Mate tea is an aqueous infusion prepared from dried leaves of *Ilex paraguariensis*. Precursors for the biosynthesis of caffeine in *Ilex paraguariensis* are purine nucleotides (e.g., adenine, guanosine, hypoxanthine). This biosynthesis occurs primarily in young leaves via salvage enzymes during the early stages of development.[3]

COMPOSITION

Mate tea contains a variety of substances including xanthines (caffeine, theobromine), chlorogenic acids

933

(caffeoylquinic, dicaffeoylquinic, feruloylquinic, diferuloylquinic, *p*-coumaroylquinic, caffeoyl-*p*-coumaroylquinic, caffeoyl-feruloylquinic, caffeoyl-sinapoylquinic, tricaffeoylquinic, dicaffeoyl-feruloylquinic), shikimic acid derivatives (caffeoylshikimates, dicaffeoylshikimates, tricaffeoylshikimates, feruloylshikimates), flavonoids (kaempferol, quercetin, rutin), amino acids, minerals (calcium, iron, phosphorus), vitamins (B_1 B_2, C), and saponins (mate saponin 1–5), depending on brewing condition, the age of the leaves, and the *Ilex* species.[4,5] Caffeine is the most common purine alkaloid in mate leaves; theophylline is usually not found in significant amounts in mate leaves. Typical concentrations of caffeine and theobromine in these leaves are 1–2% and 0.3–0.9% dry weight, respectively. Older mate leaves contain less caffeine and theobromine than younger leaves. Analysis of leaves of different ages suggest that the concentration of these 2 compounds may decrease in older leaves up to approximately 50% and 20%, respectively.[6] The concentration of caffeine and theobromine is highest in *I. paraguariensis* compared with other *Ilex* species including *Ilex argentina* Lillo*, I. brevicuspis* Reissek, and *I. theezans* Reissek. In 14 samples of commercial mate tea prepared from leaves and stems of *I. paraguariensis*, the caffeine and theobromine content varied from 0.30–1.72% and 0.08–0.66%, respectively, as measured by high performance capillary electrophoresis.[7] The caffeine and theobromine content varied somewhat with temperature and filter size. Theophylline was not quantifiable in these species including *Ilex paraguariensis* with the exception of *I. pseudobuxus* (0.6 ± 0.2 mg/100 g dried herb). Caffeine and theobromine occur in the leaf epicuticular waxes of *Ilex paraguariensis* at average concentrations of about 0.5% dry leaf weight.[8]

The leaves from *Ilex paraguariensis* contain approximately 5–10% saponins along with caffeoyl derivatives (caffeic acid, chlorogenic acid, 3,4-dicaffeoylquinic acid, 3,5-dicaffeoylquinic acid, 4,5-dicaffeoylquinic acid) and flavonoids (kaempferol, quercetin, rutin).[9,10] This fraction contains at least 10 glycosides of ursolic or oleanolic acids including mate saponins 1-5, $J1_{a/b}$, $J2_{a/b}$, $J3_{a/b}$, and J4.[11]

PRODUCTION PROCESSES

Commercial production of mate tea involves both harvesting from rainforests and cultivation on mate plantations. Sun-exposed leaves of mate trees grown on plantations usually have higher polyphenol concentrations than leaves harvested from more-shaded areas in rainforests.[12] After harvest, blanching of the leaves inactivates degradation enzymes (e.g., polyphenol oxidase) and fermentation is halted by placing the leaves in a rotating cylinder (*sapeco*) near an open flame. In contrast to the flash heating of mate leaves over an open flame, green tea undergoes steaming or pan-frying. Black teas are not blanched before drying; thus, substantial fermentation occurs during the processing of black teas. Further drying of the mate leaves results from the use of continuous rotary/belt driers or the traditional discontinuous bed drier (*barbaqua*) with a wood fire. This wood-fired process is slow compared with the rapid, high-temperature air drying of green tea. As a result of the differences in processing procedures, mate tea contains high concentrations of the chlorogenic acid and caffeoyl derivatives compared with green and black teas.[13] Additionally, mate tea contains no catechin in contrast to the other two types of tea.

IMPURITIES

As analyzed by high performance liquid chromatography, other *Ilex* species contain nondetectable to minimal amounts of caffeine and theobromine including *I. argentina*, *I. brevicuspis*, *I. dumosa* Reissek var. *dumosa*, *I. microdonta* Reissek, *I. pseudobuxus* Reissek, and *I. theezans*.[14] These species may be substituted for purported *I. paraguariensis* as adulterants of mate tea include the addition *I. integerrima* (Vell.) Reissek and *I. taubertiana* Loes. These plants also contain triterpene saponins, flavonoids, phenolic acids, and xanthines, and the concentrations of these compounds vary compared with *Ilex paraguariensis*. Multivariate analysis of the metabolite fingerprints of plant material extracts by ^{1}H NMR spectroscopy allows the identification of various *Ilex* species.[15] Consumption of tea from *Ilex paraguariensis* contaminated with belladonna alkaloids (hyoscyamine, scopolamine) resulted in anticholinergic poisoning manifest by dry skin, tachycardia, mydriasis, dry skin, agitation, and hallucination.[16]

Methods of Use

Preparation of mate tea (chimarrão) involves placing dried, minced leaves inside a mate receptacle (i.e., dried porongo gourd) and pouring hot water over the leaves.[17] This method is a partial infusion as some of the mate leaves remain dry. The aqueous extract is usually imbibed through a metal straw (*bombilla*), which has a metal strainer on the lower end. Hot water may be added to the gourd several times during the day with some users drinking more than 1 L of the tea daily. An alternate method for drinking this tea (*terere*) involves the successive addition of cold water to the mate leaves or branches along with the addition of sugar, other plant species, and/or other flavorings. Some differences in the methylxanthine and phenolic content

result from different types of infusions with coarse-ground mate extracted by hot water (chimarrão) containing the highest methylxanthine content.[18] The vessel typically contains about 50 g mate. *Ilex paraguariensis* is the primary ingredient of the commercial product, yerba maté, and most mate teas. Commercial products often are distributed as individual tea bags (1–2 g). The addition of boiling water to the infusion results in the ingestion of very hot liquid in most locations with the exception of Paraguay and southwestern Brazil, where the beverage is consumed cold.

DOSE EFFECT

One cup (150 mL) of mate tea contains about 80 mg caffeine, which is a similar caffeine concentration as a cup of coffee; however, the ingestion of higher amounts (i.e., up to 500 mL) of mate tea results in higher total caffeine intake for the average individual. Analysis of Brazilian samples of commercial mate tea prepared by traditional gaucho methods indicates that a typical infusion of mate contains approximately 260 mg caffeine, 240 mg chlorogenic acids, and 170 mg caffeic acid.[19]

TOXICOKINETICS

There are few data on the toxicokinetics of caffeine in humans after the ingestion of mate tea; however, there are no data to indicate that the absorption and biotransformation of caffeine is significantly different following the ingestion of mate tea than after the ingestion of coffee.

CLINICAL RESPONSE

The International Agency for Research on Cancer (IARC) lists mate tea and hot mate tea as unclassified (Group 3) and probable (Group 2A) human carcinogens, respectively, based on limited case-control studies indicating an increased risk primarily of squamous cell esophageal cancer.[20] There are few animal data on the carcinogenicity of the active constituents of mate tea, and most epidemiologic data does not separate the drinking of hot and cold mate tea. Epidemiologic studies suggest that the chronic ingestion of hot mate tea is associated with a moderate risk of malignant neoplasms of the upper aerodigestive tract. The excess risk as determined by the relative risk (RR) of upper aerodigestive cancer in a case-control study of mate tea drinkers from southern Brazil was 1.6 (95% CI: 1.2–2.2) after adjustment for confounding factors (tobacco use, alcohol drinking).[21] Most of the increase risk involves oral cancer (RR = 1.9, 95% CI: 1.1–3.3) and laryngeal cancer (RR = 2.2, 95% CI 1.1–4.5). Limited *in vitro* studies suggest that mate tea contains genotoxic and mutagenic compounds as measured by lysogenic induction in *Escherichia coli* and the induction of mutagenesis in *Salmonella typhimurium* (Ames test).[22]

Limited studies on mate tea drinkers and esophageal cancer suggest the risk of esophageal cancer increases independently with both the amount of mate tea consumed (i.e., about ~3-fold for highest categories of use) and the temperature of the drink.[23] In a retrospective, hospital-based case-control study, the relative risk of esophageal cancer in mate tea drinkers was 2.84 (95% CI: 1.41–5.73).[24] After adjusting for cumulative mate tea consumption, the reported drinking of very hot mate tea almost doubled the risk of esophageal cancer when compared with the drinking of warm to hot mate tea, whereas patients with high cumulative mate tea exposure with little tobacco or alcohol use had a statistically insignificant increase (OR = 1.52, 95% CI: 0.88–2.62) in the occurrence of esophageal cancer. In a series of 5 case-control South American studies, the cumulative effects of mate amount and mate temperature were more than multiplicative.[25] The odds ratio of esophageal cancer in heavy drinkers (>1.50 L/d) of very hot mate tea was 4.14 (95% CI: 2.24–7.67) compared with light mate tea drinkers (<0.50 L/d) of cold/warm/hot mate tea. Other cancers of the aerodigestive tract associated with mate tea drinking include the larynx, tongue, and oropharynx.[26,27] These risks persist after adjustment for the strong risk factors of tobacco and alcohol use. A case-control study of 107 cases of laryngeal cancer and 290 controls without tobacco or alcohol use demonstrated an approximate 3-fold increase in the risk of laryngeal cancer, after controlling for the effects of age, tobacco and alcohol consumption.[28] The drinking of hot mate tea also increases the risk of chronic esophagitis.[29] A case-control study of mate tea drinking suggested a small increase (OR = 1.6, 95% CI: 1.1–2.4) in the risk of lung cancer in heavy mate tea drinkers (≥2 L/d) after adjustment for smoking, primarily for small cell lung cancer.[30] Pulmonary adenocarcinoma was not associated with mate tea drinking. The very high maternal consumption (1 L daily) of mate tea has been associated with a neonatal withdrawal syndrome (increased jitteriness, irritability, hypertonia, brisk tendon reflexes, and high-pitched cry).[31] Symptoms of withdrawal began about 17 hours after birth and resolved by 84 hours after birth. The estimated maternal intake of caffeine during pregnancy was 930 mg daily.

DIAGNOSTIC TESTING

Analytic methods for the identification and quantitation of phenolic compounds in mate tea include high performance liquid chromatography with photodiode array

detection,[12] conventional gas chromatography/mass spectrometry (GC/MS),[32,33] and solid-phase microextraction with 2-D GC/MS.[34] There are few data on caffeine or theobromine concentrations after the ingestion of mate tea. Abnormalities following the ingestion of mate tea and coffee probably are similar because caffeine is the main active ingredient.

TREATMENT

Mate tea contains substantial amounts of caffeine; the treatment of intoxication with this substance is identical to the treatment of caffeine toxicity (e.g., coffee). However, serious caffeine intoxication is unlikely because of the volume of mate tea necessary to produce blood caffeine concentrations similar to those reported in serious caffeine overdose.

Chapter 62

MORNING GLORY FAMILY (CONVOLVULACEAE)

HISTORY

In Mexico, native Indians have used seeds from *Ipomoea violacea* L. (*tlitliltzin*) and *Turbina corymbosa* (L.) Raf. (seeds = *ololiuqui*; plant = *coaxihuitl* or snake plant) in religious rites since the time of the Aztecs. Their use of ololiuqui for divinatory and medicinal purposes were well-guarded secrets from the Spanish Conquistadors that remained shrouded in mystery until a specimen *T. corymbosa* was discovered in a Zapotec indian garden in the Mexican state of Oaxaca.[1] Samuel Richardson, an officer of the Anglo-Mexican Mining Association, transported morning glory seeds from Mexico to England in the 1830s; now the morning glory in a common cultivar in England and North America.

During the 1950s and 1960s, Albert Hoffman and his associates investigated extracts of ololiuqui and *Ipomoea violacea* with the subsequent isolation of various ergot alkaloids including lysergic acid amides.[2] In 1960, Aldous Huxley identified the hallucinogen in ololiuqui as ergine (*d*-lysergic acid amide), which was structurally similar to ergot alkaloids in the fungus, *Claviceps purpurea*.[3] Further research indicated that the plant tissue in the embryo of the seed of *T. corymbosa* produced this ergot alkaloid rather than a fungal infection of the seed coat or seed membrane.[4] Following the discovery of ergine in ololiuqui, research with thin layer chromatography in the 1960s revealed ergot alkaloids in other members of the Convolvulaceae (morning glory) family including *Ipomoea violacea*.[5] In the 1960s, the publication of the hallucinogenic properties of these seeds in the popular press led to an upsurge of morning glory seed consumption among teenagers and young adults.

BOTANICAL DESCRIPTION

Common Name: Heavenly-blue morning glory, beach moonflower, badoh negro

Scientific Name: *Ipomoea violacea* L. [*Calonyction tuba* (Schlecht.) Colla, *Ipomoea macrantha* Roemer & J.A. Schultes, *Ipomoea tuba* (Schlecht.) G. Don]

Botanical Family: Convolvulaceae (morning glory)

Physical Description: This glabrous (hairless), perennial plant has smooth, twining, round, or angular stems. The ovate leaves narrow at the apex (acuminate or cuspidate) and are 5–16 cm long by 5–14 cm wide with petioles 3.5–6 cm long. The solitary flowers are narrowly funnel-shaped with the corolla opening at night. The flowers are hermaphrodite (both male and female) and they appear July through September. The fruit is obtuse at the apex with the capsule being globose and containing black seeds. Figure 62.1 displays the seeds of beach moonflower (*Ipomoea violacea* L.).

Distribution and Ecology: The distribution of this plant extends to North America, the Caribbean, and Oceania, particularly in tropical coastal regions (e.g., Texas, Florida, Hawaii, Puerto Rico). Cultivars of morning glory are common in North America and England. Popular cultivars of morning glories are Heavenly Blue (blue flowers) and Pearly Gates (white flowers), Wedding Bells (lavender flowers), Flying Saucers (variegated blue and white flowers), Summer Skies (pale blue flowers), and Blue Star (pale blue flowers).

FIGURE 62.1. Seeds (ololiuqui) of a beach moonflower (*Ipomoea violacea* L). (Photo courtesy of Steve Hurst and the USDA-NRCS PLANTS Database).

FIGURE 62.2. Leaves and flowers of the Christmas vine (*T. corymbosa*). (Richard A. Howard Image Collection. Photo courtesy of Smithsonian Institution).

Common Name: Christmas vine, Christmas wreath, aguinaldo blanco, corona de novia, badoh

Scientific Name: *Turbina corymbosa* (L.) Raf. [*Rivea corymbosa* (L.), *Ipomoea corymbosa* (L.) Roth ex Roemer & J.A. Schultes, *Convolvulus corymbosus* L.]

Botanical Family: Convolvulaceae (morning glory)

Physical Description: This woody vine reaches up to 5 m (~16 feet) laterally with gray stems up to 2.5 cm (1 inch) in diameter. The leaves have cordate blades 5–8 cm (~2–3 inches) long with elongated tips. The inflorescences are corymbose (flat-topped) cymes that arise from the leaf axils. The trumpet-shaped corolla is white with a red or purple throat and green or greenish gray radiating stripes. Each capsule contains one brown, pubescent seed. Seeds mature about 60 days after fertilization. Figure 62.2 displays the leaves and flowers of the Christmas vine.

Distribution and Ecology: The Christmas vine is indigenous to the West Indies, Mexico, Central America, and the tropical portion of South America. This plant has naturalized to areas in Florida, Hawaii and other Pacific Islands, Australia, and some some parts of Europe, Africa, and Asia. The Christmas vine grows as a single plant or a patch of vines on open sunny, undisturbed, well-drained areas of roadsides, pastures, streams, and secondary forests

Common Name: Elephant creeper, woodrose, baby woodrose, Hawaiian woodrose, Hawaiian baby woodrose

Scientific Name: *Argyreia nervosa* (Burm. f.) Bojer [*Rivea nervosa* (Burm. f.) Hallier f., *Argyreia speciosa* (L. f.) Sweet]

Botanical Family: Convolvulaceae (morning glory)

Physical Description: This woody, climbing tropical plant contains large, heart-shaped leaves with dense, white silky hairs protruding from the underside of the leaf. The shallow lobed, purple-pink pedals are about 6 cm (~2 ½ inches) long. The yellow-brown fruit is spherical and about 2 cm (~¾ inch) in diameter.

Distribution and Ecology: *Argyreia nervosa* grows in the subtropical environment of Hawaii, California, and Florida. This plant is native to India, but cultivation of this plant occurs throughout Southeast Asia and other tropical countries. The elephant creeper prefers brushland and margins of secondary forests up to 1500 m (~5,000 feet) altitude.

IDENTIFYING CHARACTERISTICS

The seeds of certain members of the morning glory family contain psychotomimetic indole alkaloids that are structurally related to lysergic acid diethylamide (LSD). The mind-altering compounds of the morning glory family are similar to the ergot alkaloids (ergoline) found in the ergot fungus (*Claviceps purpurea*), which was associated with epidemic outbreaks of St. Anthony's Fire (ergotism) during the Middle Ages. Ergoline (lysergic acid)-like alkaloids in the morning glory family (Convolvulaceae) include *d*-lysergic acid amide (ergine), isolysergic acid amide (isoergine), ergonovine (ergometrine), lysergol, ergometrinine, penniclavine,

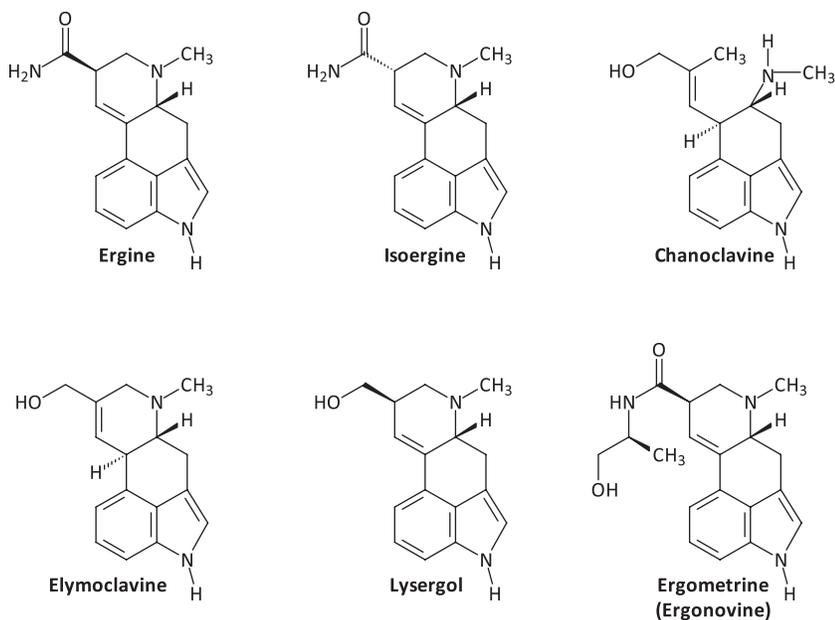
939


FIGURE 62.3. The chemical structures of ergoline alkaloids present in *Ipomoea violacea* L.

chanoclavine, elymoclavine, and lysergic acid α-hydroxyethylamide.[6,7] Ergoline alkaloids detected in the Hawaiian woodrose (*Argyreia nervosa*) include ergine, isoergine, and penniclavine.[8] Ergine (lysergamide, CAS RN: 478-94-4), isoergine (*d*-isolysergic acid amide, CAS RN: 2889-26-1), chanoclavine, and elymoclavine are the major constituents of morning glory seeds. The psychomimetic properties of ergine are substantially less (i.e., ~10%) than the psychomimetic potency of LSD,[3] whereas chanoclavine and elymoclavine demonstrate no psychomimetic properties.[9] Figure 62.3 displays the chemical structures of the ergoline alkaloids from *I. violacea*.

EXPOSURE

Composition

The indole alkaloids (ergine, isoergine) are the active constituents of morning glory seeds. Analytic data suggest that biosynthesis of the ergoline alkaloids also occurs in clavicipitaceous fungi; translocation then can transfer these substances to the infected plant.[10] Most varieties of morning glory plants contain seeds with similar indole alkaloid content.[11] These alkaloids represent up to about 0.1% of the dry weight of the seeds from *I. violacea* with the highest alkaloid content occurring during the early stages of seed development.[12,13] As measured by spectrophotofluorimetry, the total alkaloid content of a convenience sample of *I. violacea* leaves ranged from 0.027–0.04%.[14] The psychomimetically inactive compound, chanoclavine is the most abundant

alkaloid in the immature seed. Common varieties of morning glories without evidence of hallucinogenic alkaloids in the seeds include common morning glory [*I. purpurea* (L.) Roth], white edge morning glory [*I. nil* (L.) Roth], tropical white morning glory (*I. alba* L.), cardinal climber morning glory [*I. multifida* (Raf.) Shinners], cypress vine morning glory (*I. quamoclit* L.), and Mexican or red morning glory (*I. coccinea* L.).[11] The seeds from *Turbina corymbosa* contain about 40% of the isoergine concentration and <20% the ergine content of seeds from *I. violacea*. Ergine content of one seed from *A. nervosa* is similar to the ergine content of 75 to 100 *I. violacea* seeds.[15] Other genera (e.g., *Argyreia*) in the Convolvulaceae family also contain large amounts of these potentially mind-altering indole compounds. Typically, the ergoline alkaloid content in the seeds from the Hawaiian woodrose (elephant creeper, *Argyreia nervosa*) is higher than *I. violacea*. Analysis of seeds from the Hawaiian woodrose demonstrate total indole alkaloid content of 0.5–0.9% with ergine and isoergine accounting for the largest fraction (0.136% and 0.188%, respectively).[16]

Methods of Use

The abuse of morning glory seeds is limited by adverse effects and the relatively low potency of the hallucinogenic components of the seeds. Most of the case reports about the misuse of morning glory seeds were published in the 1960s after the publication of the ergoline alkaloid content of the Hawaiian woodrose by Hylin and Watson.[8] The black seeds of the baby woodrose

(*Argyreia nervosa*) are an inexpensive hallucinogen for Hawaiians, but adverse side effects (e.g., constipation, lethargy, nausea, blurred vision) and mild psychomimetic effects limit use.[17] The morning glory plant is a traditional Chinese medicine (QianNiuZi, *Ipomoea purpurea* (L.) Roth) used for the treatment of edema, ascites, obesity, induction of labor, and fever.[18]

DOSE EFFECT

Large numbers of well-pulverized seeds from *Ipomoea violacea* are necessary to produce psychomimetic effects.[11] The content of psychoactive compounds in these seeds varies with individual plants, time of harvest, environmental conditions, and cultural practices. Reportedly, Indian ololiuqui users would ingest 13 seeds; however, the ingestion of this amount of ololiuqui seeds did not produce effects other than apathy in self-experimenters.[19] In general, the ingestion of 20–50 seeds is a low dose that may produce increased or decreased social interaction, restlessness, and heightened awareness for several hours. Doses of 60–100 seeds were associated with irritable apathy, passivity, some increased awareness, and heightened visual perceptions.[19] The ingestion of 100–150 seeds causes similar effects to 75–150 µg LSD with spacial distortions, visual illusions, elation, and enhanced imagery lasting up to 4 hours. The ingestion of 200–500 seeds is a large dose that produces intense psychomimetic effects along with unpleasant adverse reactions (nausea, vomiting, abdominal pain, paresthesias, cold extremities, and lethargy).[20]

The ingestion of 15 seeds from the Hawaiian woodrose (*Argyreia nervosa*) along with other drugs (marijuana, ether, dextromethorphan) was associated with visual hallucinations, suicidal and homicidal ideations, sinus tachycardia, hypertension, and hyperreflexia in an 18-year-old male.[21] This patient was being treated for depression with paroxetine at the time of the ingestion. The ingestion of 12 Hawaiian woodrose seeds was associated with auditory hallucination, blurred vision, diaphoresis, lightheadedness, nausea, and vomiting.[22]

TOXICOKINETICS

The absorption of indole alkaloids from morning glory seeds requires the pulverization or thorough mastication of the seeds to produce psychomimetic effects. There are few data on the toxicokinetics of the active compounds, ergine and isoergine. In rodent studies, the plasma elimination of isoergine is rapid with an estimated plasma elimination half-life of 30 minutes.[23] Within about 30 minutes after intraperitoneal administration, the brain and plasma concentrations are similar.

CLINICAL RESPONSE

Clinical features of morning glory intoxication are somewhat similar to the effects caused by the sympathomimetic and hallucinogenic properties of LSD. Ingestion of seeds from *I. violacea* produces dilated pupils, hyperreflexia, facial erythema, a dissociative state, and emotional lability within 3 hours followed by irritability and anxiety.[24] Adverse effects include nausea, vomiting, diarrhea, polyuria, numbness, cool extremities, muscle stiffness, lethargy, and uterine stimulation. Hypotension occurred following the intravenous injection of the boiled extract of morning glory seeds.[25] Abnormalities of behavior and perceptions usually resolve in 24–36 hours. However, hallucinogen persisting perception disorder (flashbacks) and recurrent dissociative feelings may recur after symptoms initially resolve.[20] Like LSD, the ingestion of well-masticated morning glory seeds can cause panic reactions, marked paranoia, and violent behavior. Panic states, prolonged dissociative reactions, and psychotic behavior have been associated with trauma and suicide.[26] Memory, intellect, and orientation are less impaired than behavior. Case reports associate the ingestion of seeds from the Hawaiian woodrose (*Argyreia nervosa*) with hallucinations, disorientation, agitation, lightheadedness, blurred vision, nausea, and vomiting.[22,27] Physical signs included tachycardia, hypertension, nystagmus, and mydriasis. Flashbacks characterized by auditory hallucinations recurred at least 1 month after ingestion.[22] Case reports suggest that the clinical features of Hawaiian woodrose intoxication are more similar to the sedative effects and autonomic disturbances associated with scopolamine than the gastrointestinal and psychomimetic effects of LSD.[28]

DIAGNOSTIC TESTING

Chromatographic methods can distinguish the indole alkaloids present in morning glory seeds.[29] Methods for the detection of indole alkaloids from the morning glory family include spectrophotofluorimetry[14] and thin layer chromatography.[30] However, gas chromatography/mass spectrometry allows the confirmation and quantitation of ergine, isoergine, and other indole alkaloids from the morning glory family.[31] Alternate methods of quantitation include liquid chromatography/electrospray ionization/tandem mass spectrometry in positive selected reaction monitoring mode[32] and mixed-mode cation exchange solid-phase extraction followed by ultra performance liquid chromatography/time of flight/mass spectrometry (LLOQ: 1.3 ng/mL, blood; 5.0 ng/mL, urine).[33] Using the latter method, analysis of post-mortem blood from a 29-year-old man, who died 3

hours after ingesting Hawaiian baby woodrose seeds when he attempted to fly out of the 4th floor of a building, demonstrated ergine (lysergamide) concentrations in postmortem blood and urine of 4.9 ng/mL and 1,000 ng/mL, respectively. A surviving witness ingested 6 seeds at the same time; his blood ergine concentration 9 hours after ingestion was 1.8 ng/mL. The seeds were soaked for about 3 hours prior to ingestion, and both men smoked cannabis soon after ingesting the seeds. Leukocytosis may occur during intoxication with morning glory seeds.[34]

TREATMENT

The management of morning glory seed intoxication is supportive, similar to the treatment of LSD intoxication. Decontamination measures are usually unnecessary unless indicated by the concomitant ingestion of other substances. Management involves reassurance to calm the patient and a protective environment to prevent accidental trauma and intentional self-harm. Benzodiazepines (e.g., diazepam, lorazepam) are the sedatives of choice; the use of benzodiazepines may improve symptoms of muscle stiffness. Patients with severe muscle stiffness should be evaluated for rhabdomyolysis and renal dysfunction. Behavioral symptoms usually resolve within 8–12 hours. Persistence of symptoms necessitates thorough psychiatric evaluation.

Chapter 63

PEYOTE [*Lophophora williamsii* (Lem. Ex Salm-Dyck) Coult.] and MESCALINE

HISTORY

The use of peyote for hallucinogenic purposes dates back many centuries, particularly in the southwestern United States and Mexico. Peyote buttons containing psychoactive alkaloids (mescaline) were found in prehistoric Native American caves in Texas dating from 3,780–3,660 BC[1] and in Mexican burial caves dating back to 1,070–810 BC.[2] The Franciscan missionary, Bernardino de Sahagun documented the use of peyote by local native Indians during the Spanish conquest of Mexico.[3] The Mescalero Apaches of the Great Plains originated a peyote rite during the 19th century; the use of peyote spread to the Kiowa and Comanche tribes. They believed that God was the Great Spirit, who infused part of his being into peyote; Christ was the man who provided peyote to them when needed.[4] In 1888, the German toxicologist Lewin discovered the ritual use of the peyote cactus by Indian tribes in Mexico.[5] Heffter isolated mescaline from peyote buttons along with three other tetrahydroisoquinoline compounds by 1898,[6] and Spath synthesized mescaline in 1919.[7] During the end of the 19th century, interest in mescaline as a mind-altering drug increased briefly. In 1918, the Native American Church formed; part of the ritual of this church includes the legal use of peyote. Reports on the hallucinogenic effects of peyote appeared in the medical literature during the 1920s.[8] In 1964, the California Supreme Court ruled in People v. Woody that individuals could not be denied the sacramental use of peyote even though state law prohibits the use of the plant. Although federal statutes (American Indian Religious Freedom Act) exempt Native American Church members from federal prosecution of the sacramental use of peyote, litigation continues on issues of membership, equal protection, and due process.[9] Recent US Supreme Court decisions allow states to prohibit the use of peyote for religious purposes.

BOTANICAL DESCRIPTION

Common Name: Peyote, mescal button, mescal

Scientific Name: *Lophophora williamsii* (Lem. ex Salm-Dyck) Coult.

Botanical Family: Cactaceae (cactus)

Physical Description: This small spineless blue-green cactus has a diameter of about 3–10 cm (~1–4 inches) with well-defined ribs and furrows, pinkish white flowers, and a large, cylindrical perennial rootstock. In the center of the spherical portion of each button, tufts of light yellow hairs develop where the flowers later form. The small dome-shaped heads are removed and dried as mescal or peyote buttons. Figure 63.1 displays a specimen of *L. williamsii* with the flower.

Distribution and Ecology: Peyote is indigenous to the dry slopes and rocky cliffs of the Rio Grande Valley in Texas as well as the Mexican plateau in northern and central Mexico.

IDENTIFYING CHARACTERISTICS

The 2 major classes of psychedelic hallucinogens are phenethylamine compounds (e.g., mescaline) and indoleamine compounds (e.g., *d*-lysergic acid diethylamide or LSD). Mescaline (3,4,5-trimethoxy-β-

phenylethylamine, CAS RN: 54-04-6) shares the phenethylamine nucleus with LSD, whereas serotonin and psilocin share the indolethylamine nucleus with LSD as displayed in Figure 63.2.

Of the more than 60 alkaloids in peyote, mescaline is the major hallucinogenic compound. Other potentially active β-phenylethylamine and isoquinoline alkaloids in peyote include anhalamine, anhalidine, anhalinine, anhalonidine, anhalonine, *N*-methylmescaline, pellotine, and hordenine (anhaline).[4] However, these compounds do not share the hallucinogenic properties of mescaline. Mescaline shares hallucinogenic properties with other phenylethylamine compounds including methamphetamine designer drugs (e.g., 3,4-methylenedioxymethamphetamine, ecstasy). The intensely bitter, acrid taste of mescaline distinguishes peyote from the tasteless hallucinogen, LSD. Table 63.1 lists some physiochemical properties of mescaline. Mescaline is moderately soluble in water and soluble in alcohol and chloroform, but not in ether.

FIGURE 63.1. Flowering peyote cactus (*Lophophora williamsii*). (Richard A. Howard Image Collection. Photo courtesy of Smithsonian Institution.)

Form

Peyote buttons are round fleshy tops from the cactus that are sliced and dried for prolonged storage. The dried mescal buttons used in religious ceremonies are transverse slices of the crown of the cactus. Forms of peyote included peeled fresh buttons, dried or ground powder, steeped tea, and dried whole buttons. Crystalized mescaline is distributed illegally in the form of a capsule or pill.

EXPOSURE

Sources

ORIGIN

In addition to peyote, several South American cactus species contain mescaline including the large columnar San Pedro cactus of Andean slopes in Ecuador, Peru, northern Chile, and Bolivia [*Echinopsis pachanoi* (Britton & Rose) Friedrich & G. D. Rowley, formerly known as *Trichocereus pachanoi* Britton & Rose], Dona Ana or nipple beehive cactus [*Coryphantha macromeris* (Engelm.) Lem.], and the candelabra-like Peruvian cactus (*Trichocereus peruvianus* Britton & Rose, Peruvian torch). The false peyote (*Ariocarpus retusis* Scheidw.) of Mexico contains few or no hallucinogenic compounds.[10] Several other members of the cactus family contain structurally related phenylethylamine derivatives. Although the San Pedro cactus and

Vapor Pressure	3.22E-04 mm Hg (25°C/77°F)

FIGURE 63.2. Chemical structures of serotonin (5-HT), psilocin, *d*-lysergic acid diethylamide (LSD), and mescaline. The A, B, and C rings represent the ring structures in LSD that are shared at least in part by serotonin, mescaline, and psilocin. Mescaline shares the phenethylamine nucleus with LSD.[28]

peyote both contain mescaline, the latter contains other mescaline-like and tetrahydroisoquinoline alkaloids (anhalonidine, anhalonine, lophophine, lophophorine, 3,4-methylenedioxyphenethylamine or MDPEA, *N,N*-dimethyl-3,4-methylenedioxyphenethylamine or lobivine, pellotine).[11] Although some of these alkaloids (e.g., lophophine) may be psychoactive, the contribution of these minor alkaloids to psychomimetic effects is unclear because of their relatively low concentrations. The Dona Ana cactus also produces a variety of methylated catecholamine derivatives of which the phenylethylamine normacromerine (CAS RN: 5653-66-7, *N*-demethylmacromerine) is the most abundant. Other β-hydroxyphenethylamine compounds include macromerine (CAS RN: 2970-95-8, *N,N*-dimethyl-3,4-dimethoxy -β-hydroxyphenethylamine), *N*-formylnormacromerine, metanephrine, *N*-methylmetanephrine, synephrine, and *N*-methyltyramine.[12] Although animal studies suggest that some of these phenethylamine compounds are psychoactive, mescaline remains the most potent hallucinogen isolated from the cactus family to date.[13]

COMPOSITION

The estimated total alkaloid content of dried peyote buttons is about 3.7% compared with 0.41% for fresh peyote buttons with mescaline representing ~6% of the alkaloid fraction.[7] Each button contains ~50–100 mg of mescaline.[30] In a study of 13 mescaline-containing specimens of *L. williamsii*, the mescaline concentration ranged from 12.7–48.3 mg/g.[14] Other *Lophophora* specimens did not contain detectable concentrations of mescaline. Specimens of *E. pachanoi* usually contain higher concentrations of mescaline than other *Echinopsis* species. The mescaline content of 7 specimens of *E. pachanoi* ranged from 0.40–4.7% dry weight as measured by high performance liquid chromatography with mass-selective detection in electron ionization mode.[15] The mescaline content of 6 specimens of the San Pedro cactus (*Echinopsis pachanoi*) from Swiss flower shops, shopping centers, and private collections varied from 0.11–2.37% dry weight as measured by high performance liquid chromatography with photodiode array detection.[16]

IMPURITIES

Purported samples of peyote or mescaline may contain *d*-lysergic acid diethylamide (LSD) as a surreptitious additive. Analysis of 50 California samples reported to contain mescaline indicated that mescaline was present in only 17% of the samples.[17]

946

Methods of Use

The primary route of exposure to peyote and mescaline is oral, rarely mescaline powder is insufflated. In a 12-year retrospective review of the California Poison Control System data, 31 cases of peyote or mescaline exposure were retrieved with 97% oral and 3% nasal exposures.[18] The Native American Church (peyote religion) is a Navajo revitalization movement that uses peyote as a sacrament and medicinal herb to treat a variety of physical and psychologic conditions.[19] Consumption of peyote usually occurs during an all-night communal healing ritual called a peyote meeting. A celebrant (*Road Man*) typically leads the participants during these rituals that often involve personal or family crises. Beginning at nightfall, the participants consume peyote in the form of a powder or a tea. The ritual includes singing, playing of musical instruments, and praying until dawn. Addiction to peyote is unusual. Preliminary data from studies of illicit (i.e., nonceremonial) use of peyote suggests that illicit peyote use among American Indian adolescents with serious substance abuse disorders is uncommon.[20]

DOSE EFFECT

The clinical pattern following the administration of 5 mg mescaline/kg, 1 μg LSD, and 150 μg psilocybin/kg is similar, although the intensity and duration of the psychomimetic effects of mescaline is somewhat greater at these doses.[21] Mescaline has the lowest potency among orally active naturally occurring hallucinogens.[22] A typical adult mescaline dose is about 200 mg (5–7 mg/kg) with average doses ranging up to 500 mg. This dose correlates to about 3–8 peyote buttons and initially produces nausea, tremor, and diaphoresis followed in 1–2 hours by a dream-like state with kaleidoscopic visual illusions before sleep occurs.[4] In animal studies, mescaline doses exceeding 20–60 mg/kg produce hypotension, bradycardia, and respiratory depression.[23] In humans, fatalities usually result from trauma secondary to distorted sensory perception rather than intoxication.[24]

TOXICOKINETICS

There are limited data on mescaline toxicokinetics. The rapid onset of symptoms following the ingestion of peyote indicates that gastrointestinal absorption of mescaline begins soon after swallowing.[21] Following the oral administration of 5–6 mg mescaline/kg to adult volunteers, the biologic half-life of mescaline was about 6 hours with 87% of the dose of mescaline eliminated in the urine within 24 hours.[25,26] During this study, the

renal excretion of unchanged mescaline accounted for 55–60% of the administered dose, whereas the major metabolite (3,4,5-trimethoxyphenylacetic acid) accounted for about 27–30%. *N*-Acetyl-*β*-(3,4,dimethoxy-5-hydroxyphenyl) ethylamine and *N*-acetyl mescaline were minor metabolites. Unlike some other psychoactive amphetamine derivatives (e.g., *p*-methoxyamphetamine, PMA), mescaline does not interact significantly with CYP2D6.[27] Substrates for this isoenzyme include tricyclic antidepressants, lipophilic β-adrenoceptor blockers, and amphetamine.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mescaline belongs to the phenethylamine class of hallucinogens that includes the methamphetamine-related designer drugs. Along with the other major class of psychedelic hallucinogens (i.e., indoleamine compounds including LSD), mescaline shares an affinity for the 5-HT$_{2A}$ serotonin receptor subtype, where experimental studies in rats suggest that mescaline acts as a partial agonist.[28] Although these receptor subtypes occur in multiple regions of the brain (olfactory tubercle and bulb, facial nucleus, nucleus accumbens), most of these receptors reside in the cerebral cortex.[29] Stimulation of these receptor subtypes may alter glutamatergic excitatory postsynaptic potentials in the pyramidal cells of the cerebral cortex, but the exact mechanism of action remains undefined.

CLINICAL RESPONSE

The ingestion of peyote (mescaline) produces the rapid onset (<1 h) of mild gastrointestinal distress (nausea, rarely vomiting and diarrhea).[3] Autonomic signs (mydriasis, mild tachycardia, elevated blood pressure, diaphoresis, tremor) and alteration of perception, thought, and feeling follow the gastrointestinal phase.[18] The bitter, acrid taste of peyote is often associated with nausea and vomiting in the novice user, particularly with large doses.[30] Nystagmus, headache, ataxia, and hyperreflexia may also occur. After the gastrointestinal phase subsides, a sensory phase begins, manifested by vivid visual hallucinations that reach a peak about 3–4 hours after ingestion. Other stimulatory effects include euphoria, a general feeling of well-being, and feelings of physical power.[31] Auditory hallucinations are uncommon with mescaline intoxication. Although the sensorium remains clear, emotional lability, anxiety, agitation, and panic reactions predispose intoxicated patients to self-inflicted or accidental trauma. Rare complications associated with the use of peyote include the development of severe gastrointestinal bleeding from Mallory-Weiss

tear[32] and psychosis with sleep deprivation.[33] The latter effect was reported in a 54-year-old Native American man, who became convinced he was hunted by animal spirits within a few hours of ingesting peyote juice during a healing ceremony. These psychotic symptoms persisted for 2 weeks with complete sleep deprivation, but resolved following trazodone therapy and sleep.

Medically related fatalities secondary to the ingestion of peyote are rare; death during peyote intoxication usually results from trauma secondary to altered perceptions.[24] Symptoms of acute peyote intoxication typically resolve ~6–12 hours after ingestion. Peak psychologic effects occur about 1.5–2 hours after injection of mescaline, and most of the effects resolved within 9 hours. A case report associated development of botulism with the ingestion of peyote contaminated with botulism B toxin.[34] The ceremonial tea was prepared from dried alkaline-ground peyote buttons stored in a closed jar for 2 month under refrigeration.

There are limited data on the reproductive effects of chronic peyote use. A controlled study of members of the Navajo Native American Church, where peyote use is legal, did not detect residual psychologic or cognitive effects with long-term peyote use.[35] Controlled studies of habitual peyote users among Mexican Indians with a long cultural tradition of religious peyote consumption detected no increased incidence of chromosomal aberration in the peripheral blood lymphocytes.[36] Daily use of mescaline produces tolerance to the effects of mescaline as well as cross-tolerance to LSD.[3] However, the tolerance regresses rapidly and disappears about 3–4 days after cessation of use.

DIAGNOSTIC TESTING

Analytic Methods

Older immunoassays do not usually detect the presence of mescaline in urine drug of abuse screens.[37] Methods for the quantitation of mescaline in biologic samples include high performance liquid chromatography with photodiode array detection,[16] gas chromatography with nitrogen phosphorus detection after liquid-liquid extraction using butyl chloride,[38] liquid chromatography/tandem mass spectrometry,[39] cation-exchange liquid chromatography,[40] and gas chromatography/mass spectrometry in selected ion-monitoring (SIM) mode after solid phase extraction with C8 and cation exchange cartridges.[41] The precision (i.e., coefficient of variation) for the latter method in plasma was ≤20%. The limit of detection for mescaline in urine using liquid chromatography/tandem mass spectrometry was 3–5 ng/mL with an accuracy <3%. The use of gas chromatography/mass spectrometry in SIM mode allows the quantitation of

mescaline in hair in the range of 0.08 ng/mg with inter-day accuracy between -12.7% and 11.6%.[42]

Biomarkers

The mean concentration of mescaline in whole blood samples from 12 volunteers given 500 mg mescaline orally was 3,800 ng/mL at 2 hours and 1,500 ng/mL at 7 hours after dosing as measured by total radioactivity.[25] In a study of 11 volunteers receiving 5 mg mescaline/kg intravenously, the mean mescaline concentration in blood samples drawn during peak effects 2 hours after dosing was 2,100 ng/mL.[43] The postmortem mescaline concentration in blood samples from an individual who deliberately jumped from a 600 ft cliff while under the influence of mescaline was 9,700 ng/mL.[24] The mescaline concentration in a postmortem femoral blood sample from a 53-year-old man who was murdered while participating in a peyote ceremony was 2,950 ng/mL.[38]

Abnormalities

In a study of 12 healthy volunteers administered 0.5 g mescaline, functional brain imaging with 99mTc-HMPAO single photon emission computed tomography (SPECT) demonstrated increase regional blood flow in the anterior cerebrum, particularly in the right anterior cortical regions.[44] There was no increased blood flow in the subcortical (limbic) structures. In a study of long-term peyote users from the Navajo Native American Church, total lifetime peyote use did not correlate to neuropsychologic performance on tests of memory, attention, or executive functions.[35]

TREATMENT

Management of peyote intoxication is similar to the treatment for LSD intoxication. Placing the patient in a quiet, dark environment with calm reassurance provides the best setting. Because of the rapid absorption of mescaline, gastrointestinal decontamination is usually unnecessary unless indicated by the concomitant ingestion of another drug within 1 hour prior to presentation. Benzodiazepines (diazepam, lorazepam) are the treatment of choice if the patient does not respond to a calm, reassuring environment.

Chapter 64

PSILOCYBIN and HALLUCINOGENIC MUSHROOMS

HISTORY

The Aztecs and neighboring tribes used ceremonial mushrooms called teonanácatl (God's flesh) in religious rites before the arrival of the Spaniards in the New World;[1] medieval Spanish books from the 16th and 17th centuries mentioned the use of small gill fungi ("teonanácatl") by North American Indians for ritual and medicinal purposes.[2] Small stone statues of fungi from ancient Mayan ruins in Guatemala suggest the use of hallucinogenic mushrooms before the time of Christ.[3,4] The use of mushrooms by North American Indians to produce mystical revelations during religious ceremonies continued into the 20th century. In the late 1950s, Wasson rediscovered the mushroom cult in Southern Mexico. *Psilocybe mexicana* R. Heim was identified as the active component of teonanácatl;[5] subsequently, Heim et al provided botanical descriptions of several species of hallucinogenic *Psilocybe* fungi.[6] In 1958, Hofmann et al isolated 2 hallucinogenic components (i.e., psilocybin, psilocin) from mushrooms used in Mazatec Indian ceremonies in the state of Oaxaca, Mexico.[7] These indole compounds have LSD-like properties and produce alterations of autonomic function, motor reflexes, behavior, and perception. Hoffer and Osmond elucidated the chemical structures of psilocybin and psilocin in 1967. In the 1960s, recreational ingestion of psilocybin-containing mushrooms was popularized in the western United States by Aldous Huxley and Carlos Castaneda. Later, recreational use of these substances spread to Australia followed by the United Kingdom and then to the rest of Europe.[8] In the late 1990s, hallucinogen use (mescaline, psilocybin) increased significantly in high school students.[9]

BOTANICAL DESCRIPTION

The three most important genera of mushrooms containing psilocybin are *Psilocybe*, *Panaeolus*, and *Gymnopilus* as listed in Table 64.1.[10] The best-known European psychoactive fungi is *Psilocybe semilanceata* (Fries) Kummer, whereas the most common hallucinogenic mushroom in the United States is *Psilocybe cubensis* (Earle) Singer and, to a lesser extent, *Psilocybe stuntzii* Guzman and Ott and *Panaeolus subbalteatus* (Berkley et Broome) Sacc.[11] The principal hallucinogenic mushrooms in North America grow primarily in the Pacific Northwest, Hawaii, Texas, and Florida, usually on animal manure in pastures and grain fields. Psychoactive mushrooms in the Hawaiian Islands that contain psilocybin include *Copelandia anomala* (Murrill) Singer*, Copelandia bispora* (Malençon & Bertault) Singer & R.A. Weeks, *Copelandia cambodginiensis* (Ola'h & R. Heim) Singer & R.A. Weeks, *Copelandia cyanescens* (Berk. & Broome) Singer, *Copelandia tropicalis* (Ola'h) Singer & R.A. Weeks (*Panaeolus tropicalis*), and *Panaeolus subbalteatus* (Berkley et Broome) Sacc.[12] The use of fungi as a psychoactive agent is uncommon in South America and Asia. Wavy caps refers to *Psilocybe cyanescens* Wakef. (*Psilocybe subaeruginosa* Cleland) as displayed in Figure 64.1.

Common Name: Gold cap, cubes, blue legs, golden tops, common large psilocybe

Scientific Name: *Psilocybe cubensis* (Earle) Singer

Botanical Family: Strophariaceae

Physical Description: These white to pale yellow mushroom have broad (1.5-8 cm/~0.5–1.5 inches)

FIGURE 64.1. Wavy caps of the genus *Psilocybe*. (Photo courtesy of *Drug Identification Bible*)

TABLE 64.1. Major Psilocybin-Containing Mushrooms.

Genus	Species
Psilocybe	*argentipes, bohemica, cubensis, cyanescens, fimetaria, liniformans, mexicana, pelliculosa, pseudobullacea, semilanceata, serbica, strictipes, sylvatica, subcubensis*
Panaeolus	*ater, cyanescens, papilionaceus, semilanceatus, subbalteatus*
Panaeolina	*foenisecii*
Gymnopilus	*junonius (spectabilis)*
Pluteus	*nigroviridis, salicinus*
Inocybe	*aeruginascens, coelestium, corydalina, haemacta, tricolor*

convex caps and smooth stems measuring up to 1.5 cm (~0.5 inch) in height. The elliptical spores are dark purple brown to violet brown and about 8–10 μm × 11–17 μm in size. Characteristically, the flesh turns blue with handling.

Distribution and Ecology: The distribution of this mushroom occurs across Central and South America, India, Southeast Asia, Western Australia, and Oceania.

Common Name: Liberty cap

Scientific Name: *Psilocybe semilanceata* (Fries) Kummer

Botanical Family: Strophariaceae

Physical Description: This small, dark chestnut brown to pale yellow mushroom has a small (0.5–2.5 cm), broad cap with a sharply conical top and an indented (striate) margin. The relatively thin stem is smooth with slight thickening at the base.

The gills are violet-grey to deep purple-brown with elliptical spores (10–14 μm × 6–8 μm) and a dark purple-brown spore mass.

Distribution and Ecology: This popular recreational hallucinogenic mushroom appears in pastures, meadows, and occasionally in lawns in the US Pacific Northwest.[13,14] In Europe, *Psilocybe semilanceata* is the most widely distribute psilocybin-containing fungus growing areas in countries bordering the Atlantic Ocean. This fungus also grows in Central Europe in pastures and grassy fields that contain waste products.

Common Name: Blue-staining Panaeolus, blue meanies, gold caps, gold tops

Scientific Name: *Panaeolus cyanescens* (Berkley et Broome) Sacc.

Botanical Family: *Incertae sedis* (uncertain placement), Order: Agaricales

Physical Description: This widely distributed mushroom has a thin, whitish to dark brown stalk 50–70 mm × 2.5–5 mm and a smooth surface covered with white powder. The broad (1–4 cm) cap is convex with dark purple to black spores.

Distribution and Ecology: This mushroom is widely distributed in tropical and subtropical regions (e.g. Gulf coast, Hawaii, Mexico, India, Australia, Thailand, Philippines), particularly in or near dung in pastures.

Common Name: Belted Panaeolus

Scientific Name: *Panaeolus subbalteatus* (Berkley et Broome) Sacc.

Botanical Family: *Incertae sedis* (uncertain placement), Order: Agaricales

Physical Description: The brown to reddish brown pileus is 13–50 mm in length, and the stalk is rather stout measuring 35–90 mm × 3–8 mm. The gills are moderately broad and lanceolate. The bluing of flesh with trauma distinguishes *P. subbalteatus* from other species in this genus.[15]

Distribution and Ecology: *Panaeolus subbalteatus* grows throughout North and South America, Africa, and Europe, particularly in manure, compost, and fertilized lawns during warm weather.

Common Name: Giant Gymnopilus, big laughing mushroom

Scientific Name: *Gymnopilus junonius* (Fr.) P.D. Orton (*G. spectabilis*)

Botanical Family: Strophariaceae

Physical Description: The large, broad, convex cap reaches 40 cm with a smooth to silky, dry surface and small scales. The cap is bright yellow-orange initially, but changes to a rust-orange with age. The gills are notched to adnate. The stalk is thick and somewhat expanded in the middle. The veil is pale yellow to rusty in color and usually forms a superior ring on the stalk. The spores are elliptical and slightly wrinkled.

Distribution and Ecology: This mushroom appears around stumps and trees, particularly in conifer and hardwood forests in the fall, winter, and early spring. This mushroom is distributed worldwide over the United States, Europe, Japan, Australia, India, North Africa, and South America.

IDENTIFYING CHARACTERISTICS

Structure

The active constituents of hallucinogenic mushrooms are probably indole compounds belonging to a small, unique group of natural products that contain hydroxy or phosphate groups in position 4 of the indole ring and which are derived from tryptamine and the precursor, tryptophan.[11] Psilocybin (CAS RN: 520-52-5, 4-phosphoryloxy-*N*,*N*-dimethyltryptamine) and the active, dephosphorylated metabolite, psilocin (CAS RN: 520-53-6, 4-hydroxy-*N*,*N*-dimethyltryptamine) are the main active ingredients, but the exact role of these compounds and other constituents (phenylethylamine, baeocystin) is not well-defined. Psilocybin and psilocin are structurally similar to tryptamines (bufotenine, harmine, LSD). Figure 64.2 displays the chemical structures of psilocybin, psilocin, and the demethylated psilocybin compound, baeocystin. In addition to psilocybin and baeocystin, the hallucinogenic Central European mushroom, *Inocybe aeruginascens* contains a quaternary ammonium compound, *N,N, N*-trimethyl-4-phosphoryloxytryptamine (CAS RN: 114264-95-8, aeruginascin) that is structurally related to bufotenidine (CAS RN: 487-91-2).[16]

Physiochemical Properties

Psilocybin and psilocin are soluble in methanol and aqueous ethanol, but relatively insoluble in petroleum ether and chloroform. The rapid dephosphorylation of psilocybin to psilocin suggests that psilocybin may be a prodrug.[17] In equimolar amounts, psilocybin and psilocin produce similar hallucinogenic effects, but psilocin is approximately 1½ times more potent hallucinogen than psilocybin.[11] The demethylated psilocybin compounds (baeocystin, norbaeocystin) are serotonin analogues that occur in some *Psilocybe* species.

Psilocybin is colorless, and the incubation of this compound with ceruloplasmin does not cause the uptake of oxygen or the formation of a blue color. Psilocin lacks the stabilizing phosphate group. The oxidation of this compound or the addition of ceruloplasmin or copper oxidase from the gill plates of *Mytilus edulis* (blue mussel) produces strongly blue-colored products.[18]

EXPOSURE

Origin

Psilocybe baeocystis and *Psilocybe semilanceata* contain the demethylated psilocybin compounds, baeocystin and norbaeocystin. Specimens from other *Psilocybe* species [*P. cyanescens, P. cubensis, P. pelliculosa* (A.H. Sm.) Singer & A.H. Sm.*, P. sylvatica* (Peck) Singer & A.H. Sm.*, P. stuntzii)* and genera (*Conocybe smithii* Watling, *Panaeolus subbalteatus*] usually contain smaller concentrations of baeocystin.[19,20] Psilocybin-containing mushrooms are widely available from Internet sources.[21]

PSILOCYBE

In studies of the psilocybin content in mushroom samples from the genus *Psilocybe*, *P. aztecorum* var. bonetii (*P. bonetii* Guzmán), *P. zapotecorum* R. Heim (P. *candidipes*), and *P. stuntzii* (Guzmán and Ott) contained detectable concentrations of psilocybin whereas *P. bolivarii* did not.[22,23] Psilocin concentrations in these

Psilocybin   **Baeocystin**   **Psilocin**

TABLE 64.2. Indole Alkaloid Content (% dry weight) of Cultivated and Natural Mushrooms Following Extraction in Pure Methanol.[31]

Species	Psilocybin	Psilocin	Baeocystin
*Psilocybe semilanceata**	0.98	—	0.34
Psilocybe bohemica	0.85	0.02	0.04
*Psilocybe bohemica**	0.93	0.04	0.02
*Psilocybe cubensis**	0.63	0.11	0.02
*Gymnopilus purpuratus**	0.34	0.29	0.05
Inocybe aeruginascens	0.40	—	0.21
Panaeolus cyanescens	0.32	0.51	0.02

*Cultivated.

samples were not detectable. Other species that contain significant concentrations of psilocybin include *P. semilanceata* (Fries) Kummer, *P. bohemica* Sebek, *P. cubensis* (Earle) Singer, *Gymnopilus purpuratus* (Cooke et Messe) Sing., *Panaeolus cyanescens* (Berkley et Broome) Sacc., and *Inocybe aeruginascens* Babos.[11]

PANAEOLUS

In a study of the psilocybin content in mushroom samples from the genus *Panaeolus*, *P. cambodginiensis* and *P. subbalteatus* (Berkley et Broome) Sacc. contained detectable concentrations of psilocybin whereas *P. foenisecii* (Pers.) J. Schröt. (*Psathyrella foenisecii*) and *Panaeolus papilionaceus* (Bull.) Quél (*P. sphinctrinus*) did not.[22] Psilocin concentrations in these samples were not detectable.

GYMNOPILUS

Species from *Gymnopilus* that contain psilocybin include *G. luteus* (Peck) Hesler, *G. purpuratus*, *Gymnopilus junonius* (*G. spectabilis*), *G. subspectabilis*, *G. validipes* (Peck) Hesler, *G. aeruginosus* (Peck) Singer, and *G. viridans* Murrill.[24] The psilocybin content of some of the species (e.g., *G. junonius*) is highly variable and do not contain detectable amounts of psilocybin as analyzed by high performance liquid chromatography (HPLC; LOD not reported).[25]

Composition

The content of psilocybin and psilocin in hallucinogenic mushrooms depends on species, season, environmental conditions, storage, extraction method, and soil conditions (phosphorus, nitrogen). Experimental studies indicate that psilocybin appears in the initial fruiting phase (mycelium knots); the vegetative portion (mycelium) of the fungus does not contain psychoactive indole alkaloids.[26] Even under rigidly controlled growing conditions, the psilocybin content of individual samples of

Psilocybe cubensis varied by a factor of 4.[27] The alkaloid content of psilocybin-containing mushrooms averages about 1–2% dry weight (water content approximately 89 ± 2%), depending on the species, drying method, analytic procedure, and season.[27] In a study of 74 samples of *P. cubensis* obtained from retail sources, the mean percentage (dry weight) of psilocybin and psilocin were 1.151 ± 0.228 % and 0.126 ± 0.066 %, respectively, as measured by cation-exchange liquid chromatography.[28] The average highest alkaloid content by dry weight (3.00 ± 0.24 %) in this study of several psilocybin-containing mushrooms occurred in specimens of *Panaeolus cyanescens* Berkeley and Broome. In a study of 20 species of mushrooms from 7 genera in the Pacific Northwest United States, the total psilocybin and psilocin concentration by dry weight ranged from 0.1% to about 2% as measured by HPLC.[29]

Table 64.2 lists the indole alkaloid content of psilocybin, psilocin, and baeocystin in samples both from cultivated and naturally grown mushroom species. Generally, the content of psilocybin is substantially higher than psilocin; mushrooms from *Psilocybe semilanceata* and *Psilocybe bohemica* usually contain the highest concentrations of psilocybin.[30,31] The psilocybin and psilocin content in fresh and confiscated samples of *P. semilanceata* were approximately 1.8% and 0.2%, respectively.[32] The baeocystin content was about 0.85%. Typically, the psilocybin content of *Psilocybe cubensis* is about 10–12 mg/g dried mushroom.[33] The average psilocybin concentration in another study of samples of *Psilocybe cubensis* was about 7 mg/10 g fresh weight (7 mg/g dry weight).[34] In 2 series, the psilocybin and psilocin content of samples from *Psilocybe cubensis* varied from approximately 0.17–1.07% dry weight and 0.11–0.42% dry weight, respectively, as measured by HPLC and gas chromatography/mass spectrometry (GC/MS).[31,35] Analysis of specimens of *Psilocybe semilanceata* demonstrated the presence of phenylethylamine at lower concentrations than psilocybin,[36] but the role of phenylethylamine in producing the psychomimetic effects of hallucinogenic mushrooms remains unclear.

Production Processes

The chemical synthesis of psilocybin and psilocin is difficult compared with 5-hydroxy substituted indole derivatives (e.g., bufotenin, serotonin). A reported synthetic route to psilocybin requires 10 steps and has a relatively low yield.[37] Hence, most sources of psilocybin are natural.

Impurities and Profiling

In samples of hallucinogenic mushrooms confiscated by German authorities, the most common mushroom was *Psilocybe cubensis* followed by *Psilocybe semilanceata*, *Panaeolus cyanescens*, and *Psilocybe tampanensis* Guzmán & S.H. Pollock.[33] Table 64.3 outlines the psilocybin and psilocin content of the confiscated mushrooms. Psilocybin and psilocin are illegal drugs classified by the US Drug Enforcement Agency as schedule I (no recognized medical use with high abuse potential).

Psilocybe subcubensis is macroscopically similar to *Psilocybe cubensis*; analysis of a confiscated sample from *P. subcubensis* demonstrated psilocybin concentrations in the cap and stem of 0.86 mg/g dry weight and 0.80 mg/g dry weight, respectively.[38] The content of psilocin was relatively low (0.02 mg/g dry weight and 0.03 mg/g dry weight, respectively).

Methods of Use

Desirable effects of hallucinogenic (magic) mushroom use include feelings of a different perspective, hallucination, joviality, and a sense of being part of the natural surroundings. In a Swedish study of 103 suspected cases of intoxication from psychoactive plants, analysis of urine samples indicated that psilocin was the most frequently detected drug, accounting for 54% of the cases.[39] The source of psilocin for a majority of these individuals was the purchase of hallucinogenic mushrooms over the Internet. Use of these mushrooms is relatively infrequent, but the experience is often intense. In a self-selected convenience sample of hallucinogenic

Table 64.3. Psilocybin and Psilocin Content of Hallucinogenic Mushrooms Confiscated in Germany.[33]

Species	Psilocybin Range*	Psilocin Range*	Sample Size
Psilocybe cubensis	N.D.–1.07	0.01–0.23	18
Psilocybe semilanceata	0.01–0.91	0.01–0.90	9
Psilocybe tampanensis	N.D.–0.19	0.01–0.03	4
Panaeolus cyanescens	0.02–1.15	0.09–0.90	6

Abbreviation: N.D. = nondetectable.
*Reported as % dry weight

mushroom users in Edinburgh and Bristol, 47% of the users reported the ingestion of hallucinogenic mushrooms 4–12 times yearly.[40] Reasons for the infrequent use included the intensity of the experience, anxiety, and paranoia. This study was completed prior to the reclassification of hallucinogenic mushrooms to UK Class A drug (most harm, greatest penalty) in 2005. A cross-sectional survey of dance drug users in the UK prior to the reclassification of psilocybin indicated a lifetime (i.e., ever) and current use (i.e., within last month) prevalence of 48% and 13.7%, respectively.[41]

DOSE EFFECT

The typical recreational dose of psilocybin required to produce desired effects is approximately 5–15 mg with a threshold of about 0.040 mg psilocybin/kg body weight and a range up to approximately 50 mg or 3.5–5 g dry weight (35–50 g, wet weight), depending on the species and psilocybin content. [42,43] In volunteer studies, the ingestion of 0.25 mg psilocybin/kg produced euphoria, sense of grandiosity, visual illusions, difficulty thinking, and impaired functioning.[44] In an double-blind experimental study of 12 volunteers receiving up to 0.25 mg/kg psilocybin (high dose condition), reductions occurred in the speed of voluntary movements and working memory along with feelings of depersonalization and derealization.[45] In a clinical trial of the efficacy of psilocybin in the treatment of 9 patients with obsessive-compulsive disorder, psilocybin doses ranged up to 0.30 mg/kg.[46] Other than transient mild hypertension in one subject, no adverse effects were reported.

The ingestion of psilocybin causes wide variation in the clinical response of different individuals ingesting the same dose. Agitation and hallucination developed after the ingestion of 10 mushrooms by one patient, whereas the ingestion of 200 mushrooms by an unrelated patient produced only abdominal pain.[47] The low concentration of active ingredients in these species limits symptoms after the ingestion of 1–2 mushrooms; relatively large numbers of mushrooms (10–100) are necessary to produce psychomimetic effects depending on the mood, tolerance, setting, and personality of the patient. A case report associated the development of coma, convulsions, and hyperthermia with the ingestion of cooked mushrooms by young children, but there was no laboratory confirmation or quantitation of psilocybin;[48] the clinical course was poorly documented.

TOXICOKINETICS

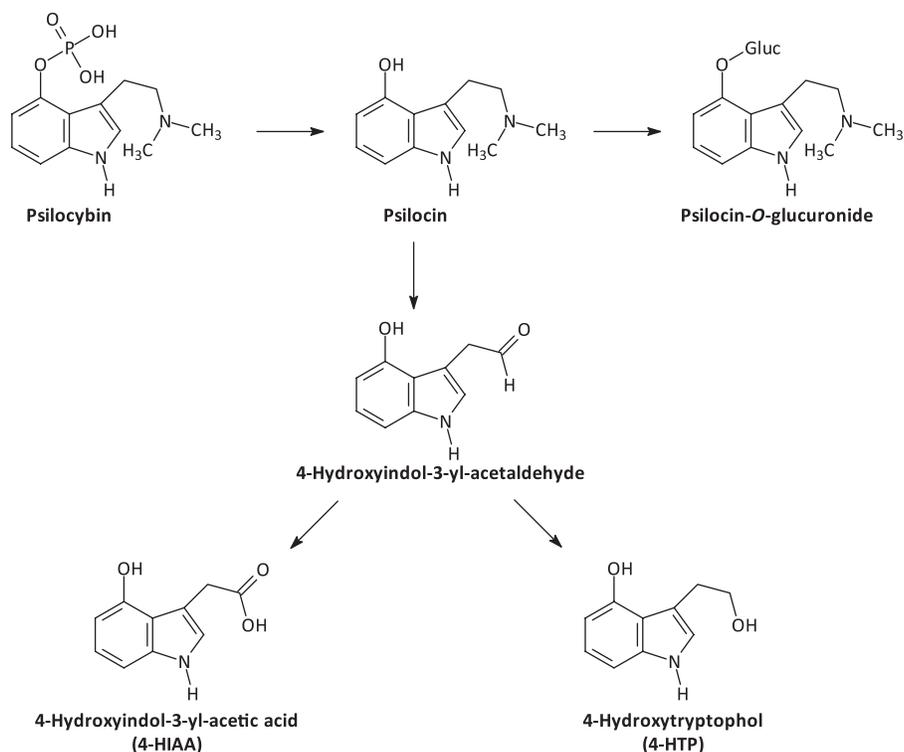
In a study of 3 fasted volunteers receiving 0.224 mg psilocybin/kg body weight (i.e., about 10–20 mg), the bioavailability of psilocybin was 52.7% ± 20%.[17]


FIGURE 64.3. Psilocybin metabolism.[50]

Psilocybin underwent rapid dephosphorylation to psilocin followed by glucuronidation and renal excretion as the glucuronide conjugate. In this study, peak plasma psilocin concentration occurred at a mean of ~105 ± 37 minutes after psilocybin ingestion. The plasma elimination half-life of psilocin following oral dosing was approximately 2.5 ± 1 hours. Figure 64.3 outlines the metabolism of psilocybin. An alternative metabolic pathway is inactivation of psilocin by monoamine oxidase to 4-hydroxy-tryptopole and 4-hydroxyindole-3-acetic acid. Excretion of psilocin in the urine occurs primarily by psilocybin glucuronidation, catalyzed by UGT1A10 in the small intestine and by UGT1A9 in the liver.[49] Within the first 24 hours after ingesting 0.212 ± 0.025 mg psilocybin/kg body weight, the average amount of unchanged psilocin excreted in urine samples from 8 volunteers was 3.4% ± 0.9% of the applied dose.[50] In a case report involving the ingestion of psilocybin-containing mushrooms, the free and total psilocin concentrations in a urine sample were 230 ng/mL and 1,760 ng/mL, respectively, when analyzed by GC/MS after enzymatic hydrolysis.[51]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Animal studies demonstrate that psilocybin produces mild sympathomimetic stimulation and relatively low toxicity with an intravenous LD_{50} about 2.5 times less than the phenethylamine hallucinogen, mescaline.[52,53] Because of the structural similarity to tryptamines, both psilocybin and psilocin demonstrate high affinity for serotonin receptors, particularly 5-HT$_{2A}$ and to a lesser extent 5-HT$_{1A}$ receptors. Receptor binding studies in rats demonstrate psilocin binds primarily to 5-HT$_{2A}$ receptors (K_i = 6 nM) with lower affinity for the 5-HT$_{1A}$ receptors (K_i = 190 nM).[54] In contrast to another indoleamine hallucinogen, LSD, psilocybin does not directly stimulate dopamine D_2 receptors and most, but not all of the hallucinogenic effects of psilocybin are mediated by the 5-HT$_{2A}$ receptor.[55] Administration of the 5-HT$_{2A}$ antagonist, ketanserin, blocks most of the subjective effects of psilocybin,[56] whereas the intravenous administration of the dopamine D_2 receptor antagonists produces little alteration of the hallucinogenic effects of psilocybin.[57]

Positron emission tomography (PET) studies indicate that psilocybin decreases receptor binding in the caudate nucleus and putamen consistent with an increase in endogenous dopamine concentrations in the striatum.[44] Hallucinations are illusions that the afflicted person believes are real, and these distorted perceptions cause changes in emotions and behavior. Unregulated agonist activity of neurons associated with the processing of visual and emotional information produces hallucination without alteration of state of consciousness.

Hallucinogenic drugs (e.g., psilocybin) induce states of consciousness similar to acute schizophrenic disorders along with deficits in sustained and spatial attention.[58] The sense of the passage of time is slowed, resulting in a subjective overestimation of time intervals.

CLINICAL RESPONSE

The ingestion of hallucinogenic mushrooms containing psilocybin produces clinical features qualitatively similar to LSD and mescaline, but the dose of psilocybin required to produce these symptoms is much higher.[59] Desired subjective effects include giddiness, laughter, euphoria, elation, and visual enhancement and alterations of perceptions (e.g., waves, moving surfaces). A short latent period of ~30–60 minutes precedes the onset of somatic symptoms (facial erythema, mydriasis, headache, tremor, diaphoresis, agitation, euphoria). The onset of clinical effects after the ingestion of water extracts (soup, tea) is more rapid compared with the whole mushroom (i.e., about 10 minutes vs. ~20–40 minutes, respectively). Common clinical features associated with the ingestion of hallucinogenic mushrooms include disturbances of affect, body image (depersonalization), and perception; mydriasis; blurred vision; hyperreflexia; and tachycardia. Clinical signs (e.g., tachycardia, hypertension, hyperreflexia) are usually mild.[60] Compared with LSD, the ingestion of psilocybin frequently produces less intensive depersonalization, milder somatic symptoms, and more intense spatial illusions.[11] Alterations of perception (i.e., distortion of shapes and colors) occur in most patients, but true visual hallucinations are uncommon. Auditory hallucinations occur very rarely, although a heightened awareness of sound and paresthesias do develop during psilocybin intoxication. Drowsiness and a dream-lacking sleep often follow the perceptual alterations. The potential for self-inflicted or accidental trauma during periods of altered behavior represents the greatest health hazard.[61]

Emergency department visits are uncommon after the ingestion of psilocybin-containing mushrooms. In those who do seek medical assistance, typical presentation occurs 2–4 hours after ingestion and includes symptoms of nausea, vomiting, headache, lightheadedness, weakness, anxiety, and confusion.[62] Other adverse clinical effects of hallucinogenic mushrooms include fever, mydriasis, tachycardia, lightheadedness, ataxia, anxiety, fear, apprehension, hallucinations, muscle weakness, compulsive movements, and stupor.[63,64] Adverse psychologic reactions during psilocybin intoxication include depersonalization, derealization, dysphoria, disorientation, agitation, delirium, and aggressive behavior. Most symptoms resolve within 4–6 hours with some sleep disturbances lasting up to 24 hours; the persistence of dysphoric symptoms beyond 12 hours is rare.[65] Adverse psychiatric symptoms do not usually persist, although some case series report the recurrence of flashbacks and panic attacks within the first 4 months after ingestion.[47,61]

Several case reports associated suspected intravenous administration of psilocybin extract with vomiting, myalgias, hyperpyrexia, hypoxemia, and mild methemoglobinemia; however, the case reports did not include the documentation of psilocybin in serum or urine samples.[66] Rare case reports associate recurrent perceptual distortions with the use of psilocybin-containing mushrooms.[67] These perceptual disturbances include abnormal colored images, intensified trailing colors, distorted geometrical forms, micropsia, and macropsia. Fatalities during intoxication from hallucinogenic mushrooms usually result from altered perception and trauma rather than intoxication, frequently in association with other drugs.[42]

DIAGNOSTIC TESTING

Analytic Methods

Analytic methods for the detection of psilocybin and the less stable metabolite, psilocin, include infrared spectroscopy,[68] ultraviolet spectrophotometry,[68] thin layer chromatography,[69] capillary electrophoresis, GC/MS,[35,70] liquid chromatography/tandem mass spectrometry,[71] and high performance liquid chromatography (HPLC).[72] Limitations of gas chromatographic methods result from the poor volatility of psilocybin and decomposition of psilocybin (i.e., heat-induced loss of phosphate group) during the injection phase; therefore, liquid chromatographic methods are preferred to separation by gas chromatography. The presence of a phosphate ester in psilocybin limits the detection of this compound, but not psilocin by GC/MS. HPLC is the most common analytic technique with detection modes including ultraviolet,[73] fluorescence,[74] electrochemical,[75] voltametric,[76] mass spectrometry, and chemiluminescence.[77] The limit of detection (LOD) for HPLC ranges from 1.2×10^{-8} mol/L (chemiluminescence) to 9.7×10^{-6} mol/L (fluorescence). Other tests for damaged or decomposed samples containing psilocybin include DNA-based testing using amplified fragment length polymorphism.[78] The one-step methanol extraction is a simple, efficient method for removing psilocybin and related compounds from a fungal mass.[30]

Enzymatic hydrolysis of glucuronide conjugates in urine samples and derivation with *N*-methyl-*N*-trimethylsilyl-trifluoroacetamide reduces the lower limit of quantitation for psilocin from 200 ng/mL to 10 ng/mL, as measured by GC/MS after solid phase

extraction.[79] Enzymatic hydrolysis of glucuronide conjugates increases the yield of psilocin when compared with acid and alkaline hydrolysis.[71] Psilocin is thermolabile, and degradation of psilocin occurs with storage. In a urine sample stored at 4ºC (~39ºF) for 26 days without preservatives, the psilocin concentration decreased ~44%.[80]

Biomarkers

About 5–6 hours after the ingestion of an estimated dose of 4–5 g hallucinogenic mushrooms, the serum-free and total psilocybin concentrations were 18 ng/mL and 52 ng/mL, respectively.[51] At the time the blood was drawn, the patient had ataxia, slurred speech, mydriasis, disorientation, and lethargy. In a study of 6 volunteers receiving 0.224 mg/ psilocybin/kg body weight, the mean peak plasma psilocin concentration about 1½ hours after ingestion was approximately 8 ± 3 ng/mL.[17] The active metabolite, psilocin is detectable in urine for about 24 hours after ingestion of a medium dose of psilocybin. Enzymatic hydrolysis of urine samples with β-glucuronidase extends the detection time of psilocin in the urine beyond 24 hours after ingestion.[50]

Although urine drugs of abuse screens do not specifically analyze specimens for psilocybin, occasionally urine drug tests are positive for amphetamine following the use of hallucinogenic mushrooms. Anecdotal reports suggest that some polyclonal antibody assay kits detect the consumption of some hallucinogenic mushrooms as positive for the presence of amphetamine. Analysis of urine from the false-positive tests for amphetamine suggested that the presence of phenethylamine account for the false-positive tests.[36] A urine fluorescence polarization immunoassay for amphetamine/methamphetamine was positive despite the presence of only psilocin; the calculated cross-reactivity with the immunoassay was 1.3% at 50,000 ng/mL.[80] Foods (chocolate, cheese, wine) are also endogenous sources for phenethylamine.

Abnormalities

Rare case reports document mild elevations of lactate dehydrogenase (LDH), serum aspartate aminotransferase, and alkaline phosphatase following the ingestion and intravenous administration of psilocybin-containing mushrooms, but liver function is usually normal.[81] Following the ingestion of psilocybin, cerebral metabolic patterns as determined by fluorodeoxyglucose-PET scanning demonstrated hypermetabolism in the prefrontal and inferior temporal regions of the right hemisphere (e.g., anterior cingulate) and relatively hypometabolism in the subcortical regions (e.g., thalamus) when compared with placebo.[82] These findings are similar to the hypermetabolism in the frontal regions associated with the ingestion of mescaline.[83]

TREATMENT

Most patients ingest psilocybin-containing mushrooms without developing symptoms requiring emergency medical care. Decontamination measures are usually unnecessary; the use of decontamination measures should be limited to cases where other toxic drugs or compounds have been ingested within 1–2 hours of presentation. There are no specific data on the efficacy of decontamination measures (e.g., activated charcoal) after the ingestion of hallucinogenic mushrooms. Rarely, the ingestion of hallucinogenic compounds is associated with hyperthermia that requires undressing the patient and rapid cooling measures.

Dysphoria is the major complaint for most patients presenting to the emergency department after ingesting hallucinogenic mushrooms; a quiet, supportive environment (darkened room with familiar faces) along with calm reassurance usually provides sufficient treatment for the dysphoria. The patient should be observed until the dysphoria resolves (i.e., usually within 4–6 h). The treatment room should contain minimal visual and auditory stimuli, and the presence of relatives or friends to give reassurance is helpful. Benzodiazepines (e.g., diazepam, lorazepam, midazolam) may be necessary for sedation if dysphoria persists. Antipsychotics (e.g., haloperidol) should be reserved for frank hallucinations. Severely agitated patients should be evaluated for rhabdomyolysis if the agitation persists, and the possibility of *Amanita phalloides* poisoning should be considered in patients presenting with the late onset (e.g., >6 h postingestion) of gastrointestinal symptoms.

Chapter 65

Salvia divinorum Epling & Jativa and Salvinorin A

HISTORY

For many centuries, Mazateca shamans from the Sierra Mazateca region of the Mexican state of Oaxaca used the psychotropic effects of the hallucinogenic mint, *Salvia divinorum*, as a substitute for psilocybin-containing mushrooms in ceremonial healing and divination rituals.[1] The shamans considered the hallucinogenic effects of *Salvia divinorum* weak; this plant was substituted for hallucinogenic mushrooms in ceremonies only when the supply of these mushrooms was inadequate. Jean Basset Johnston first described the use of *Salvia divinorum* in 1939 while studying the use of psilocybin mushrooms by the Mazateca people. This plant was not characterized botanically until 1962.[2] Ortega et al isolated and identified the main psychoactive ingredients, salvinorin A and B in 1982.[3] Traditionally, use of *Salvia divinorum* involved the ingestion of a water infusion or mastication of the leaves; however, as the use of this plant spread to other parts of North America and Europe, smoking the leaves became a more popular route of administration. Most countries do not regulate the distribution of *Salvia divinorum*; additionally, *Salvia divinorum* products are available over the Internet.[4]

BOTANICAL DESCRIPTION

Common Name: Diviner's sage, Mexican mint, leaves of Mary the Shepherdess, magic mint, Sally-D, Sage of the Seers, ska Pastora, ska Maria, hierba de Maria, hojas de la Pastora, hojas de Maria

Scientific Name: *Salvia divinorum* Epling & Jativa

Botanical Family: Lamiaceae (mint)

Physical Description: This perennial herb has large green leaves and hollow, square, flowering stems that reach over 1 meter in height. White flowers with purple calyces appear from May thorough September. This plant is primarily cultivated, and produces fertile seeds. One plant has sufficient cuttings to provide a user with a constant supply of the leaves.

Distribution and Ecology: *S. divinorum* is a native plant of a relatively small Sierra Mazateca region in the mountainous northeastern Mexican state of Oaxaca. *S. divinorum* grows in forested ravines and other humid areas of the Sierra Mazateca at altitudes between 750–1500 m (~2,500–5,000 ft).

IDENTIFYING CHARACTERISTICS

The main active ingredient in this plant is a water-insoluble, trans-neoclerodane diterpene called salvinorin A (CAS RN: 83729-01-5, $C_{23}H_{28}O_8$).[5] Closely related compounds present in lower concentrations include salvinorin B, salvinorin C, salvinorin D, salvinorin E, salvinorin F, divinatorin A, divinatorin B, divinatorin C, and (-)-hardwickiic acid. Other compounds in *S. divinorum* include alkanes, tocopherol, stigmasterol, fatty acids, and neophytadiene.[6] Salvinorin A is a structurally unique furanolactone neoclerodane diterpene that is distinct from other naturally occurring hallucinogens (e.g., psilocybin, mescaline, *N,N*-dimethyltryptamine), synthetic hallucinogens (e.g., LSD, 4-bromo-2,5-dimethoxyphylisopropylamine or DOB,

ketamine) and opiates; salvinorin A lacks the amino and phenolic moieties common to all opiate-based ligands. This compound is the first reported nonnitrogenous (non-alkaloidal) opioid receptor agonist and hallucinogen.[7] In contrast to most hallucinogens, salvinorin A has κ-opioid agonist activity (analgesia, dysphoria, perceptual distortions, sedation) rather than affinity for 5-HT$_{2A}$ receptors.[8] Figure 65.1 demonstrates the structurally related salvinorin compounds. Under normal conditions, drying the leaves does not affect potency.[9]

EXPOSURE

Sources

Indians from the Sierra Mazateca region of Mexico used this plant for divination. Mazateca shamans (curanderos or folk healers) utilize the dream-like states induced by this indigenous plant to venture into supernatural realms and contact divine entities to remedy the complaints of their clients. Additionally, this plant has been part of healing ceremonies of the Mazateca Indians of Oaxaca for headaches, anemia, diarrhea, and rheumatism.[1] In Western drug cultures, visionary illu-

sions are the desired effects from *S. divinorum*. Case reports describe the use of a quid of *Salvia divinorum* leaves as a treatment for depression,[10] but the lack of clinical trials limits any conclusions regarding the effectiveness of *Salvia divinorum* as an antidepressant.

The plant is available over the Internet and in smart shops (vendors specializing in natural psychoactive drugs) as dried plant material, fortified plant material, and liquid extracts.[11] Figure 65.2 displays confiscated salvia leaves, and Figure 65.3 displays the liquid extract of *S. divinorum*. Most countries do not regulate the use of this plant, except Australia, Belgium, Denmark, Estonia, Finland, Italy, South Korea, Spain, and Sweden. In Europe, *S. divinorum* is cultivated as a substitute for marijuana. *S. divinorum* is not listed as a controlled substance under the US Controlled Substances Act, but some individual states (Delaware, Louisiana, Maine, Missouri, North Dakota, Oklahoma, Tennessee) control the use of this plant. *Salvia divinorum* is commonly smoked in home environments, although a significant minority use *Salvia divinorum* in more social settings (parks, bars, parties).[12] Use of *Salvia divinorum* is particularly common among polydrug users (e.g., lysergic acid diethylamide, ecstasy, phencyclidine, cocaine, heroin).[13]

FIGURE 65.3. Liquid extract of *Salvia divinorum*. (Photo courtesy of *Drug Identification Bible*)

Composition

Extracts of *S. divinorum* contain at least 15 neoclerodane diterpene compounds (salvinorin A-I, divinatorin A-F, salvidivin A-D).[14] Salvinorin A and related compounds are components of a complex resin that accumulates in the subcuticular space of peltate glandular trichomes.[15] In a study of 20 dry leaf samples, the salvinorin A content ranged between 0.0895–0.37% dry

TABLE 65.1. Salvinorin Concentrations in Samples from Sierra Mazateca and Hawaii.[18]

Compound	Sierra Mazateca (% w/w)	Hawaii (% w/w)
Salvinorin A	0.76	0.78
Salvinorin B	0.42	1.04
Salvinorin C	0.59	0.62
Salvinorin D	0.05	0.05
Salvinorin E	0.02	0.03
Salvinorin F	0.16	0.15

weight with an average of about 0.245%.[16] The stems contain much smaller (e.g., 4%) salvinorin A concentrations compared with the dried leaves. In 3 samples of dried *S. divinorum* leaves obtained over the Internet in Japan, the salvinorin A and salvinorin B (deacetylated metabolite) content of the dried leaves ranged between 0.32–0.50% and 0.01–0.017%, respectively.[17] The concentrated extracts of *S. divinorum* from this study contained much higher concentrations of salvinorin A (0.41–3.89%) and salvinorin B (0.026–0.242%) than the dried leaves. Some geographic variation occurs in the content of salvinorin A and other salvinorin compounds. Table 65.1 lists the salvinorin content of *S. divinorum* leaves grown in Sierra Mazateca and in Hawaii. This analysis indicates that salvinorin A may not be the most abundant salvinorin compound in certain strains of *S. divinorum* leaves.[18]

The salvinorin A content in *Salvia divinorum* products available over the Internet and in drug paraphernalia shops is highly variable. Analysis of a convenience sample of 4 *S. divinorum* leaves and one *S. divinorum* extract marketed as herbal products (Internet, drug paraphernalia shops) suggested that these products contain much less (i.e., 1–16%) salvinorin A than the label claims.[19] The content of salvinorin A in the leaves ranged between 0.126–1.137 mg/g, whereas the extract contained 0.952 mg/g.

Salvinorin C and other salvinorin compounds are minor constituents of *S. divinorum* compared with salvinorin A, and the former compound has weaker affinity for the κ-opioid receptor than salvinorin A.[20] The ratio of salvinorin C/salvinorin A is greater in mature leaves and stems than in young leaves and bracts. Woody vascular tissue and the pith of the stems do not contain salvinorin compounds.

Methods of Abuse

Traditionally, leaves from *S. divinorum* are masticated as a quid or crushed and the extract ingested as a beverage. The main route of administration for the

963

recreational use of *S. divinorum* is smoking the dry leaves.[21] The large number of leaves required for hallucinogenic effects and bitterness of the prepared aqueous extracts of this plant limit abuse. The effects of salvinorin A appeal more to individual experimentalists seeking philosophical insights rather than to party-goers seeking pleasurable experiences. Preliminary data suggests that the chronic use of *S. divinorum* is not prevalent among college students.[11]

DOSE EFFECT

The potency of salvinorin A is similar to synthetic hallucinogens (e.g., lysergic acid diethylamide [LSD], 2,5-dimethoxy-4-bromoamphetamine [DOB]). The effective oral dose of salvinorin A in humans ranges from about 0.2–1 mg. In an experimental study of healthy, hallucinogen-experienced participants, the inhalation of salvinorin A doses up to 0.021 mg/kg bodyweight did not alter heart rate or blood pressure despite the presence of subjective effects.[22] Typically, dried leaves from *S. divinorum* contain 0.9–3.8 mg salvinorin A, and the inhalation of vapors from <500 mg of these leaves are required to produce a hallucinogenic experience.[23] By convention, counting of leaves is done in pairs rather than individual leaves. Traditionally, small doses (4–5 pairs of fresh or dried leaves) are used for a tonic, whereas large doses (20–60 pairs of leaves) produce vivid hallucinations. The chewing of less than 20 pair of leaves reportedly does not produce altered states of consciousness.[9]

TOXICOKINETICS

Salvinorin A is well-absorbed through the oral mucosa and the lungs; however, the gastrointestinal tract deactivates this compound. The administration of up to 4 mg salvinorin A sublingually for 5 minutes did not result in physiologic or subjective effects in 8 volunteers with experience using *S. divinorum*.[24] Consequently, use of this compound for hallucinogenic purposes typically involves smoking or prolonged mastication (>10 min) rather than ingestion.[25] The mean plasma elimination half-life of salvinorin A in primates following intravenous administration was 56.6 ± 24.8 minutes.[26] The C2 hydroxyl derivative, salvinorin B, is the major metabolite of salvinorin A as a result of the hydrolysis of the 2-acetoxy group of salvinorin A; salvinorin B is an inactive metabolite.[27,28] *In vitro* studies suggest the involvement of UGT2B7 and several cytochrome P450 isoenzymes in the biotransformation of salvinorin A including CYP2D6, CYP1A1, CYP2E1, and CYP2C18.[29] Other enzymes (e.g., lactonases, UGT2B7) may catalyze

the production of increasingly hydrophilic metabolites before excretion by the kidney.[7]

The distribution and elimination of salvinorin A in the brain is consistent with the rapid action and brief (i.e., 10 minutes) duration of action. In a positron emission tomography (PET) study of baboons using [^{11}C]-salvinorin A, 3.3% of the injected dose appeared in the brain within 40 seconds; the mean elimination half-life of this radiolabeled compound from the brain was approximately 8 minutes.[30] In a rodent study, the mean plasma elimination half-life was about 75 minutes.[29]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Salvinorin A is a potent κ-opioid receptor agonist that is structurally distinct from classical hallucinogens and opioid agonists.[27] *In vitro* studies indicate that salvinorin A binds to G protein-coupled κ-opioid receptors, but not to cloned μ-opioid or δ-opioid receptors.[31] Salvinorin A demonstrates no affinity for the 5-HT$_{2A}$ serotonin receptor, which is the principal molecular target of classical hallucinogens.[32] These *in vitro* studies indicate that salvinorin A has little affinity for norepinephrine, dopamine, glutamine, or GABA-transporters. Salvinorin B, salvinorin D, and salvinorin E are inactive at the κ-opioid receptor, but salvinorin C may possess weak κ-opioid agonist activity.[27]

CLINICAL RESPONSE

Depending on the dose and individual sensitivity, the clinical response ranges from subtle changes in perception to profound dream-like visions and bizarre feelings of depersonalization. Pulmonary absorption of high doses of salvinorin A from *S. divinorum* produces auditory and visual hallucinations, loss of body control, alterations in perception, sense of motion, perception of being in more than one location at a time, reliving childhood experiences, amnesia, hysterical laughter, and loss of consciousness.[25] Typically, the hallucinations involve synesthesias (i.e., hearing colors, smelling sounds) that are accompanied by a feeling of separation of the mind from the body (spatiotemporal dislocation).[33] The intensity of the hallucinogenic experience associated with smoking *S. divinorum* leaves varies substantially depending on the individual and the setting based on observations of videos of *S. divinorum* users.[34] The most frequently endorsed responses of recent *S. divinorum* users in an online survey were "unexpected effects" and "excessively intense experience"; these responses suggest that the hallucinogenic and dissociative effects of using this compound are greater than other hallucinogens (LSD, psilocybin) used by this group.[35] Some

users compare S. *divinorum* with ketamine except the effects of ketamine are more consistent and not associated with uncontrolled laughter.[36] Other interviews of *S. divinorum* users suggest the effects of smoking leaves from this plant are similar to LSD, cannabis, or represent an entirely unique experience.[37]

The onset of effects is rapid (i.e., 1 minute) following smoking of *S. divinorum* leaves with resolution of effects occurring within 10–20 minutes. The onset following the use of a quid (i.e., a portion suitable for chewing but not swallowing) is about 5–15 minutes with cessation of effects ~2 hours after swallowing the quid.[25] The effects of ingesting the extract lasts ~1 hour.[25] Shivering, exhaustion, and poor concentration may occur for several hours following disappearance of psychomimetic effects of *S. divinorum*. Other potential adverse reactions following the use of *S. divinorum* include panic attacks, terror, fear, diaphoresis, and psychosis, particularly in individuals unintentionally inhaling smoke from the leaves.[38] In a retrospective study of reports of *S. divinorum* use to the California Poison Control System, adverse effects associated with *S. divinorum* exposure included confusion, disorientation, hallucination, giddiness, dizziness, a flushed sensation, and tachycardia.[39] Of the individuals in this study with intentional exposure to only *S. divinorum*, 72% had psychotomimetic or neuromotor disturbances.

Although case reports associate persistent psychosis (paranoia, echolalia, flight of ideas, psychomotor agitation) with the use of *S. divinorum*,[40] the causal role of this plant in the etiology of psychosis is not well-defined. Case reports suggest that an increasing number of leaves are necessary to maintain the initial psychotropic effects from the ingestion of a quid.[23] Based on information from questionnaires reported by users of *Salvia divinorum*, some users experience a state of mental and physical malaise after use similar to a hangover from heavy ethanol ingestion.[41]

DIAGNOSTIC TESTING

Methods for the quantitation of salvinorin compounds in biologic samples include liquid chromatography/atmospheric pressure chemical ionization/mass spectrometry,[42] gas chromatography/mass spectrometry (GC/MS),[43] gas chromatography/mass spectrometry after acetyl-derivation,[6] and liquid chromatography/electrospray ionization/mass spectrometry in selected ion monitoring (SIM) mode.[44] The limits of detection (LOD) and lower limit of quantitation (LLOQ) for the latter method in biologic specimens are 2.5 ng/mL and 5.0 ng/mL, respectively, with a coefficient of variation <8.5%. For liquid chromatography/atmospheric pressure chemical ionization/mass spectrometry, the LLOQ

for salvinorin A in plasma is 2 ng/mL. For analysis of these compounds in plant material, analytical methods include liquid chromatography/electrospray ionization/multistage ion trap/mass spectrometry,[18] high performance liquid chromatography with UV detection,[16] and thin layer chromatography/gas chromatography/mass spectroscopy.[45] Routine urine drug screens do not usually detect the use of *S. divinorum*.[46] Following the smoking of 75 mg *Salvia divinorum* leaves, urine samples collected from 2 volunteers about 1.5 hours after smoking contained salvinorin A concentrations of 2.4 ng/mL and 10.9 ng/mL, as measured by GC/MS (LOD, 5 ng/mL).[43] Blood samples could not be collected from these 2 volunteers because they experienced intense hallucinations immediately after smoking began. Salvinorin A was not detectable in urine samples collected 9.5 hours after smoking began when measured by GC/MS (LLOQ, 15 ng/mL).

TREATMENT

Although agitation, delirium, or confusion may occur after the use of *Salvia divinorum*, the physiologic and psychologic effects of this hallucinogen typically are mild.[47] These patients usually respond to a quiet, supportive environment. Benzodiazepines are rarely required for sedation. The major risk following the use of *Salvia divinorum* is trauma secondary to altered sensorium. Naloxone is a potential antidote for the clinical effects of *Salvia divinorum* based theoretically on the opioid agonist activity of salvinorin A, but there are inadequate data to determine the effectiveness of naloxone on the reversal of clinical effects of this plant. In mice, treatment with the κ–opioid receptor antagonist, norbinaltorphimine (CAS RN: 105618-26-6) prior to the intravenous administration of salvinorin A completely prevents the analgesic effects of salvinorin A.[48]

Chapter 66

Tobacco, Nicotine, and Pituri

COMMON TOBACCO (*Nicotiana tabacum* L.)

HISTORY

The tobacco plant was a common commercial plant long before Christopher Columbus reached the Americas. The major active ingredient of tobacco, nicotine, was named after Jean Nicot, who popularized the use of tobacco in the 16th century as an analgesic for headaches.[1] The indigenous North American tobacco plant is *Nicotiana rustica*. Although the South American variety, *N. tabacum,* was cultivated in Virginia by European settlers for commercial purposes, Native Americans smoked *N. rustica* (Aztec tobacco) leaves for many centuries prior to the voyages of Columbus. On October 11, 1492, Christopher Columbus was given dried tobacco leaves at the House of the Arawaks. The Indians taught tobacco smoking to European sailors; subsequently, the tobacco plant was introduced along all major trade routes in Europe, Asia, Africa, and Australia. The tobacco plant (*N. tabacum*) first grown in France and Spain originated in Brazil and Mexico, whereas in Portugal and England, the tobacco plants (*N. rustica*) first originated in Virginia and Florida.[2] Nicotine was isolated from *Nicotiana* species in 1828, but the pharmacologic properties of nicotine were not identified until 1898.[1]

The modern history of tobacco smoking started with the design of the cigarette vending machine patented by James Bonsack in 1880, encouraged in part by concern over the spread of tuberculosis by the spitting of chewing tobacco. Since the 1920s, cigarettes accounted for most of the consumption of tobacco with cigars, chewing tobacco, and pipes declining to a relatively small portion of tobacco consumption.[2] Although the association between smoking and pulmonary diseases was first recognized in the 1870s, the association of smoking with various diseases was ignored until the 1950s. Several case-control studies during the early 1950s related smoking to the development of lung cancer; by the end of the 1950s, cohort studies suggested a causal relationship between smoking and lung cancer as well as other diseases.[3] The US Surgeon General first suggested a link between tobacco smoking, emphysema, and cancer in 1964.[4] By 1984, sufficient data accumulated that allowed the US Surgeon General to state that cigarette smoking was a major cause of chronic obstructive lung disease.[5] As a result of increased awareness and antitobacco sentiment in the United States, tobacco smoking rates decreased from 42% in 1965 to 25% in 1990. Since that time, US smoking rates have declined slowly with the US tobacco smoking rate being about 21.6% in 2003,[6] 20.9% in 2004,[7] and 19.8% in 2007.[8] Within the last 5 years, there has been little change in U.S. smoking rates with an estimated 20.6% of U.S. adults over 18 years of age being current cigarette smokers in 2009.[9]

BOTANICAL DESCRIPTION

The genus *Nicotiana* consists of about 60 plant species in North and South America, Australia, and the South Pacific.[1] *N. rustica* L. is native to Virginia, but the com-

IDENTIFYING CHARACTERISTICS

Nicotine [(*S*)-3-(1-methyl-2-pyrrolidinyl)pyridine, CAS RN: 54-11-5] is a tertiary amine consisting of a pyridine and a pyrrolidine ring (Figure 66.2). Tobacco products contain the citrate and malate salts of nicotine, whereas insecticides contain the free alkaline base or sulfate salt.[10] Minor alkaloids in tobacco leaves with nicotine-like pharmacologic activity include nornicotine (CAS RN: 494-97-3), metanicotine (CAS RN: 538-79-4), and anabasine (CAS RN: 494-52-0); however, these minor alkaloids are less potent pharmacologically than nicotine.[11] Nicotine is a water soluble, weak base with an alkaline pK_a of 8.0–8.5. At pH 8.9, about 90% of nicotine is unbound. Table 66.1 lists some of the physiochemical properties of nicotine.

EXPOSURE

Origin

Cultivation of tobacco occurs in over 100 countries with the top five producers in order (China, Brazil, India, United States, Malawi) accounting for two-thirds of the worldwide production. Nicotine is the major addictive constituent of tobacco products. Cigarettes are the most common method of smoking tobacco, both as manufactured and hand-rolled products. These products used fine-cut tobaccos wrapped in paper or maize leaves. Cigars contain cut tobacco surrounded by a binder leaf and a wrapper leaf rolled on the outside of the tobacco contents, whereas bidis contain shredded tobacco wrapped in nontobacco leaves (e.g., dried tendu leaves, *Diospyros melanoxylon* Roxb.). Table 66.2 describes the

FIGURE 66.1. Leaves and flowers of *Nicotiana tabacum* L. (common tobacco). (Photo courtesy of J. S. Peterson and USDA-NRCS PLANTS Database.)

mercial value of this plant is substantially less than the South American native, *N. tabacum*.

Common Name: Burley tobacco, common tobacco, cultivated tobacco

Scientific Name: *Nicotiana tabacum* L.

Botanical Family: Solanaceae (nightshade)

Physical Description: A stout annual herb with few leafy branches and a height of about 2–3 m (~6–10 feet). The long leaves are ovate or lanceolate, measuring up to 60 cm (~2 feet) in length. Pale, cream-colored to pink flowers are about 5 cm (2 inches) long and clustered at the ends of the branches. The globular seeds are brown and somewhat kidney-shaped. Figure 66.1 displays the leaves and flowers of the common tobacco plant.

Distribution and Ecology: This plant is a native species of South America that is now cultivated worldwide. Common tobacco prefers humid environments (80–85% humidity) and warm temperatures (20–30°C/68–86°F). This plant does not survive well in the wild.

TABLE 66.2. Common Types of Tobacco Smoking Products. Adapted from Reference 2.

Type	Description
Bidi	Hand-rolled Indian cigarettes that contain 0.2–0.3 g sun-dried tendu (temburni) leaf rolled into a conical shape together with flaked tobacco and secured with a thread
Chuttaa	Hand-rolled, home-made small cigar prepared by rolling local tobacco inside a sun-dried tobacco leaf. Reverse smoking (burning end inside mouth) of chuttaa is prevalent in women from rural India.
Cigar	Any roll of tobacco wrapped in leaf tobacco or in any other substance containing tobacco. Varieties include regular cigars, premium cigars, little cigars, and small cigars ("cigarillos") with filters and shaped like cigarettes. Regular cigars are up to 17 mm (2/3 inch) in diameter and 110–150 mm (4¼–6 inches) in length.
Cigarette	Any roll of tobacco wrapped in paper or other nontobacco material with or without filter. Dimensions: approximately 8 mm (1/3 inch) in diameter and 70–120 mm (2¾–4 ¾)in length
Hookah	Waterpipe using sweetened and flavored tobacco (maassel) along with charcoal to maintain combustion of the moist tobacco.
Kretek	Small cigar containing tobacco (approximately 60%), cloves, and cocoa. The burning blend gives a characteristic flavor and honey-like taste to the smoke.

common tobacco smoking products used in the world. Iqmik is a mixture of tobacco leaves and alkaline fungus ash (*Phellinus igniarius* L.) used by native peoples in Western Alaska as a recreational smokeless tobacco product.[12] The use of narghile waterpipes (hookah, shisha) is an increasing popular method of smoking tobacco.[13] The highly aromatic and flavored tobacco paste (maassel) is placed in the head of the waterpipe as demonstrated in Figure 66.3. The maassel may include a variety of flavorings (e.g., apple, cappuccino, mint). The prepackaged paste contains glycerol and ~25% w/w tobacco along with the flavoring.[14] Because of the high water content of maassel, the use of charcoal is necessary to maintain combustion of the maassel. A typical hookah session lasts about 1 hour. The prevalence of the use of waterpipes to smoke tobacco is increasing in the Middle East and worldwide including the United States, particularly among adolescents and young adults who use alcohol, tobacco, and cannabis.[15,16] In a cross-sectional survey of 689 high school students in southern California, ever-use and current use of hookah was ~26% and ~10%, respectively.[17]

Composition

TOBACCO PRODUCTS

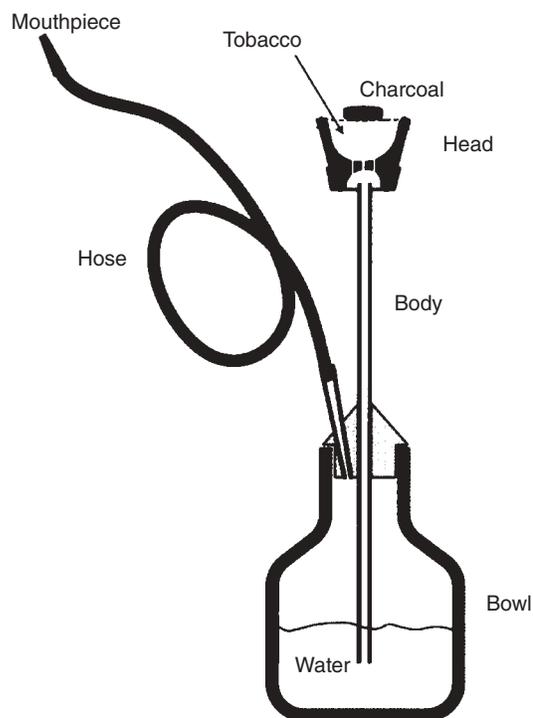
Nicotine is the major toxic alkaloid in *N. tabacum* (cultivated tobacco) leaves averaging between 0.2–4.75% in cured tobacco by weight, depending on growing conditions, maturity, use of fertilizers, position of leaf on the stalk, and plant genetics.[2] In a study of 15 popular US brands of cigarettes, the cigarette tobacco contained an average nicotine content of 1.57% ± 0.33% weight, and


FIGURE 66.3. Schematic representation of a narghile (hookah) waterpipe.[14] Sweetened tobacco (maassel) is placed in the head with burning charcoal on top of the tobacco to maintain combustion. Perforated aluminum foil separates the burning charcoal and maassel. Smoke exits the head when inhalation at the mouthpiece increases the temperature of the charcoal; the smoke then flows through the water and into the hose. Reprinted from Food and Toxicology, Vol. 48, Issue 11, E Sepetdjian, N Saliba, A Shihadeh, Carcinogenic PAH in waterpipe charcoal products, p. 3243, copyright 2010, with permission from Elsevier.

nicotine represents approximately 95% of the total alkaloid content.[18] The classification of tobacco is based primarily on curing methods and tobacco types. For example, US tobacco types used in cigarettes include flue-cured, fire-cured, light air-cured, and dark air-cured. These tobacco products are blended to achieve a specific pH, taste, nicotine content, and burning characteristics. The nicotine content of oral snuff and pipe tobacco are similar to cigarette tobacco, whereas cigars and chewing tobacco contain about half the nicotine content of cigarette tobacco.[19] In general, a typical commercial tobacco cigarette (rod) contains about 8–14 mg nicotine.[20] In a study of the nicotine content of Japanese cigarettes, mean percentage of nicotine in the tobacco in 32 filtered cigarettes was $1.77 \pm 0.30\%$.[21] The amount of tobacco in these cigarettes ranged between 800–1,000 mg and the nicotine content between 13–30 mg. The usual absorbed dose of nicotine from smoking a cigarette is about 1–1.5 mg with a range of 0.3–2 mg depending on nicotine content and smoking techniques. In a volunteer study, estimates of the absorbed nicotine dose from average exposure to tobacco products was as follows: cigarette, 1.8 mg; snuff, 3.6 mg; chewing tobacco, 4.5 mg; and gum, 1.9 mg.[22] The nicotine in tobacco is primarily the (S)-isomer with the (R)-isomer representing only about 0.1–0.6% of the total nicotine content. However, racemization during the combustion process increases the (R)-isomer content to about 10% of the nicotine content in smoke.[23] The most abundant minor alkaloids are nornicotine and anatabine (CAS RN: 581-49-7) followed by anabasine and metanicotine. Unburned tobacco contains fewer carcinogens than tobacco smoke. The most potent carcinogens in smokeless tobacco products are nitrosamines including 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone [NNK] and N'-nitrosonornicotine [NNN].[24] Ammonium hydroxide and diammonium phosphate are added to reconstituted tobacco leaf as a flavoring agent and binder. In rodent studies, the addition of these compounds up to 5% of tobacco leaf increases per cigarette yields of nicotine, tar, and total particulate matter; however, 90-day inhalation studies demonstrate a decrease in formaldehyde content in smoke and minimal histopathologic changes when compared with tobacco leaf without these 2 compounds.[25]

TOBACCO SMOKE

MAINSTREAM SMOKE. Mainstream smoke is the smoke released from the mouth-end of the tobacco smoking product during puffing that is an aerosol containing gases (i.e., primarily nitrogen, oxygen, carbon dioxide) and about 10^{10} particles/mL (tar). The distribution of chemicals between the two phases depends on environ-

mental characteristics and the physiochemical properties (e.g., volatility, stability) of the individual chemicals. Table 66.3 lists the yields from 40 chemicals in mainstream smoke from 26 US cigarette brands using the Massachusetts method of machine-smoking. Sidestream smoke is released from the burning end of the tobacco or through the surrounding material mostly between puffs, whereas secondhand (environmental) smoke is an

Constituent	Median Yield	Range
Tar	25.8 mg	6.1–48.7 mg
Carbon monoxide	22.5 mg	11.0–40.7 mg
Nicotine	1.70 mg	0.50–3.32 mg
Acetaldehyde	1618.1 µg	596.2–2133.4 µg
Isoprene	713.2 µg	288.1–1192.8 µg
Acetone	627.9 µg	258.5–828.9 µg
Nitric oxide	457.3 µg	202.8–607.1 µg
Hydrogen cyanide	380.8 µg	98.7–567.5 µg
Methyl ethyl ketone	170.3 µg	72.5–230.2 µg
Acrolein	162.9 µg	51.2–223.4 µg
Toluene	124.2 µg	48.3–173.7 µg
Propionaldehyde	110.2 µg	46.8–144.7 µg
Hydroquinone	103.9 µg	27.7–203.4 µg
Catechol	92.1 µg	28.1–222.8 µg
Benzene	75.9 µg	28.0–105.9 µg
1,3-Butadiene	75.2 µg	23.6–122.5 µg
Butyraldehyde	70.0 µg	28.8–95.6 µg
Formaldehyde	49.5 µg	12.2–105.8 µg
Crotonaldehyde	44.1 µg	11.6–66.2 µg
Ammonia	36.6 µg	9.8–87.7 µg
Phenol	25.1 µg	7.0–142.2 µg
Acrylonitrile	23.2 µg	7.8–39.1 µg
m-Cresol + p-cresol	19.4 µg	7.3–77.3 µg
Pyridine	14.9 µg	2.8–27.7 µg
Styrene	11.7 µg	4.5–19.3 µg
o-Cresol	8.0 µg	ND–33.9 ug
Quinoline	1.0 µg	0.3–2.7 µg
NNN	199.1 ng	99.9–317.3 ng
N-Acetyltransferase	186.3 ng	95.2–298.6 ng
NNK	147.3 ng	53.5–220.7 ng
Cadmium	131.8 ng	31.0–221.8 ng
Lead	52.1 ng	11.0–92.1 ng
1-Aminonaphthalene	30.7 ng	13.4–64.5 ng
N-Nitrosoanabasine	26.2 ng	14.2–45.3 ng
Benzo[a]pyrene	22.5 ng	5.6–41.5 ng
2-Aminonaphthalene	15.5 ng	5.7–28.6 ng
Arsenic	10.7 ng	1.6–24.9 ng
Mercury	4.8 ng	2.5–14.2 ng
4-Aminobiphenyl	4.5 ng	18.–7.8 ng
3-Aminobiphenyl	2.9 ng	1.3–4.8 ng

Abbreviations: NNN = N'-nitrosonornicotine; NNK = 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone

air-diluted mixture of sidestream smoke and exhaled mainstream smoke. About 15–25% of the nicotine in tobacco appears in mainstream smoke, while sidestream smoke contains about 75% of the nicotine in cigarette tobacco.[26]

The particulate phase of tobacco smoke contains at least 3,500 chemicals and over 60 carcinogens for which there is sufficient evidence of carcinogenicity in either laboratory animals or humans as evaluated by the International Agency for Research on Cancer (IARC). These carcinogens include polycyclic aromatic hydrocarbons (e.g., benzo[a]pyrene), nitrosamines, and aromatic amines), aromatic amines, benzene, N-nitrosamines, and low-molecular-weight organic compounds as well as other lung carcinogens, tumor promoters, and cocarcinogens.[27] Many of the compounds are carcinogenic in some, but not all, animal models with the exception of the tobacco-specific N-nitrosamine, 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK). This compound is a potent carcinogen in all three rodent models (hamster, mouse, rat) tested. In general, the concentrations of strong carcinogens (e.g., polycyclic aromatic hydrocarbons, nitrosamines, aromatic amines) occur in smaller amounts than weak carcinogens (e.g., acetaldehyde).[28] Cigarette smoke also contains metals including cadmium, lead, chromium, nickel, mercury, and arsenic. The carcinogenicity of metals in tobacco smoke is not well defined because of the lack of data on valence states and anions that strongly influence the carcinogenic properties of these metals. Table 66.4 lists the most important carcinogens in mainstream tobacco smoke. In addition to being a tumor promoter, cigarette smoke contains cocarcinogens (e.g., catechol, methylcatechol, pyrogallol, pyrene, benzo[e]pyrene, fluoranthene, decane, undecane).[27] Cigarette smoke contains free radicals in the particulate phase that can induce oxidative damage.[29]

Most of these carcinogens form during combustion; consequently tobacco smoke contains more carcinogens than tobacco leaves.[30] The chemical composition of tobacco smoke depends primarily on the type of tobacco and smoking method rather than stated tar yields. Newer curing technologies can reduce the concentrations of tobacco-specific nitrosamines (e.g., NNK). Other factors determining the composition of tobacco smoke include the presence of filters, type of additives, amount of ventilation, and the paper porosity. Almost three-quarters of the nicotine in a cigarette appears in the sidestream smoke, primarily in the gaseous or vapor phase. In most developed countries, the yield of tar, nicotine, and carbon monoxide in cigarette smoke has decreased over recent decades based on standard machine-smoking tests. The sales-weighted average yield of nicotine in US cigarette smoke in 1998 was

0.9 mg compared with 1.4 mg in 1968.[31] The tar yield, nicotine content, and carbon monoxide concentrations in tobacco smoke do not correlate directly to the amounts of various carcinogens present in tobacco smoke. Narghile waterpipe smoke (hookah, shisha) contains substantial amounts of nicotine and polycyclic aromatic hydrocarbons associated with cancer, at least in part as a result of the combustion of charcoal during the heating of tobacco; however, the exact composition of waterpipe smoke differs from cigarette smoke.[32,33]

SECONDHAND (ENVIRONMENTAL) SMOKE. Secondhand (environmental) tobacco smoke is a mixture of exhaled mainstream smoke and sidestream smoke from the tobacco smoking source that is diluted with ambient air. Secondhand tobacco smoke is qualitatively different than mainstream smoke, consisting of a gas phase and a particulate phase that change with time and distribution in the environment. Table 66.4 lists the ratio of the concentration of some carcinogens in sidestream smoke to the ratio of these compounds in mainstream smoke. There is substantial variability in the chemical composition of inhaled secondhand smoke depending on the smoking source and smoking patterns. Secondhand smoke contains nicotine as well as carcinogens and other toxins. The dilution of sidestream smoke in ambient air causes substantially less intake of carcinogens than mainstream smoke; therefore, the carcinogenic risk of lung cancer is proportionally reduced for passive smoking compared with active smoking.[34] The typical nicotine concentration in the ambient air from homes of tobacco smokers ranges from about 2–10 µg/m^3.

DOSE EFFECT

Tobacco Products

The average manufactured cigarette in the United States contains 8–14 mg of nicotine; during usual smoking conditions, the cigarette smoker absorbs approximately 1–2 mg nicotine/cigarette.[35,36] Nicotine extraction from 5–10 cigarettes in hot water and the subsequent administration of the fluid as an enema resulted in moderately severe poisoning.[37] Although most cases of cigarette ingestion by children result in no or mild symptoms, severe poisonings (depressed respiration, dysrhythmias, convulsions) occurred after the reported ingestion of 2 European cigarettes (nicotine content not reported) by 9- and 10-month-old infants.[38] A retrospective review of 700 US children below the age of 6 years indicated that serious toxicity is unlikely following the ingestion of <2 whole cigarettes or <6 cigarette butts.[39] This study also indicated that the inges-

TABLE 66.4. Recognized Pulmonary Carcinogens in Mainstream Tobacco Smoke. Adapted from Reference 27.

Carcinogen Class	Compound	Amount (ng/cigarette)*	Ratio†

*Mainstream smoke.

†Ratio of amount in sidestream smoke to amount in mainstream smoke. Although most of these ratios exceed 1, dilution with ambient air substantially reduces passive uptake of these carcinogens by nonsmokers.

tion of 7.5–15 g of smokeless tobacco by young children was associated with vomiting, agitation, and altered consciousness. Symptoms of nicotine toxicity may develop in patients following the ingestion of smaller quantities of tobacco products from other countries because these products may contain more nicotine than corresponding US tobacco products.

Overdose

Although the commonly quoted estimated lethal adult dose of nicotine is approximately 60 mg,[40] there are few data correlating serious nicotine toxicity to dose. A 17-year-old man developed vomiting and sudden cardiopulmonary arrest a few minutes after ingesting a solution containing an estimated dose of 5 g nicotine.[10]

Risk Assessment

Tobacco smoking causes an estimated 90% of male lung cancer deaths and 75–80% of female lung cancer deaths in the United States. Fewer than 20% of smokers will develop lung cancer, depending on the balance between the activation and detoxification of carcinogens in tobacco smoke and their smoking techniques. Smoking

cessation reduces the risk of developing lung cancer after 5 years of abstinence, but the relative risk of lung cancer in a smoker never returns to the lung cancer risks of lifelong nonsmokers.[27] Reduction of smoking by 50% in heavy smokers (≥15 cigarettes/d) also reduces the risk of lung cancer.[41]

TOXICOKINETICS

Absorption

Case reports of nicotine toxicity document the absorption of clinically significant amounts of nicotine from the skin,[42] lungs, rectum,[43] and gastrointestinal tract. [44] The absorption of nicotine is highly pH-dependent and the amount of nicotine dose absorbed depends on product pH, formulation, mastication, and nicotine content. The oral bioavailability of nicotine is approximately 20–45% as a result of a large first-pass effect.[45] As a result of the alkaline pK_a of nicotine, the acid pH of the buccal cavity and the stomach limit the absorption of nicotine from these locations. Nicotine absorption is much higher in the alkaline environment of the duodenum than in the acid milieu of the stomach. Nicotine chewing gum is formulated with a buffered ion

exchange resin base of pH 8.5 that releases nicotine slowly for absorption through the buccal mucosa and small intestine. Experimental studies demonstrated that absorption of nicotine from a solution buffered to a pH of 1, 7.4 and 9.8 was 3.3%, 8.2%, and 18.6%, respectively.[46] Case reports indicate that serious toxicity may result from the dermal absorption of nicotine. Dermal absorption of a 95% nicotine solution resulted in coma and respiratory failure.[47]

The absorption of nicotine in smoke delivered to the alveoli and small airways is rapid as a result of the easy diffusion of nicotine across pulmonary membranes in the physiological pH (i.e., 7.4) of the lungs. Peak plasma concentrations of nicotine during smoking occur about 10 minutes after inhalation.[48]

Distribution

Nicotine distributes extensively and rapidly into tissues with a volume of distribution (V_d) ranging from about 2.2–3.3L/kg.[49] The average V_d following the intravenous administration of a nicotine dose equivalent to that present in commercial cigarettes was approximately 1.7 L/kg.[50] The V_d of cotinine is smaller (i.e., about 0.7–0.9 L/kg) than nicotine. Although there is substantial interindividual variation, nicotine concentrations are generally higher in arterial blood than venous blood with a mean ratio of 2.3–2.8 (range up to 10) during active smoking.[51] Plasma concentrations of nicotine decline rapidly over 20 minutes following the cessation of smoking with a distribution half-life of ~8 minutes.[23]

Plasma protein binding of both nicotine and cotinine is low (i.e., <5%). Cotinine distributes into semen at concentrations similar to those in the blood.[52]

Biotransformation

The liver extensively metabolizes nicotine to at least 6 primary metabolites as displayed in Figure 66.4. Hepatic cytochrome P450 enzymes catalyze the metabolism of about 70–80% of administered dose of nicotine to inactive metabolites (e.g., cotinine, nicotine-1′-N-oxide) via C-oxidation. In vitro and in vivo studies indicate that CYP2A6 is the primary enzyme for the oxidation of nicotine and cotinine. CYP2A6 genetic variants contribute to the interindividual and interethnic variation in nicotine and cotinine metabolism.[53] Experimental studies of poor and extensive metabolizers of dextromethorphan (i.e., a probe for CYP2D6 activity) indicate that CYP2D6 is not the major isoenzyme for the metabolism of nicotine or cotinine.[54] CYP2B6 is the second most active cytochrome P450 isoenzyme in nicotine C-oxidation, and CYP2E1 has some activity in vitro at high nicotine concentrations.[55] Nornicotine is a minor metabolite of nicotine as well as a constituent of tobacco. Cotinine has 6 primary metabolites including 3′-hydroxycotinine, 5′-hydroxycotinine, cotinine N-oxide, cotinine methonium ion, cotinine glucuronide, and norcotinine.

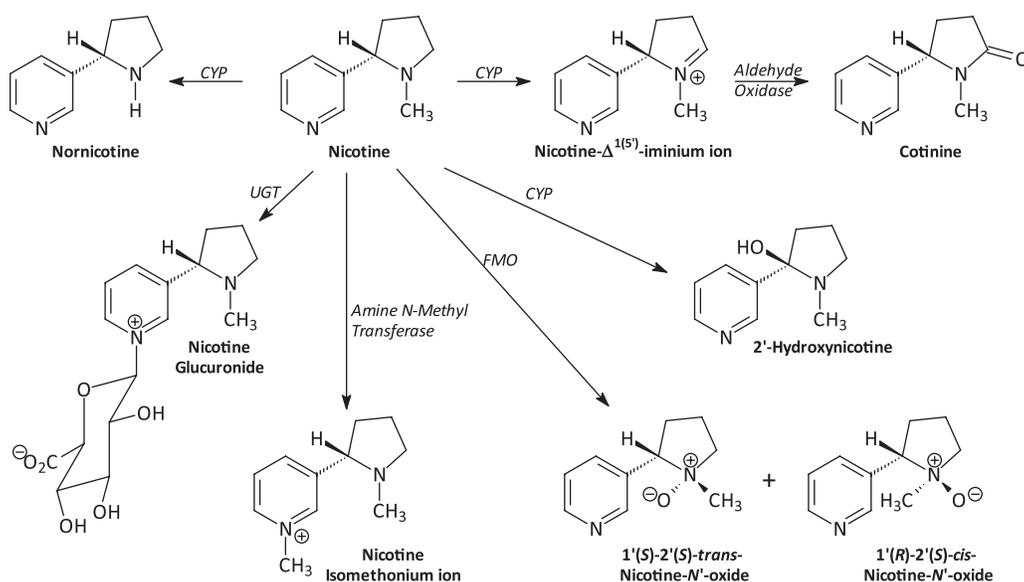
The initial step in the bioactivation of carcinogens in smoke involves the cytochrome P450 isoenzymes, whereas monoamine oxidases, lipoxygenases, cyclooxygenases, and myeloperoxidases are less commonly


FIGURE 66.4. Primary routes of nicotine metabolism.[23] CYP = cytochrome P450 isoenzymes; FMO = Flavin-containing monooxygenase 3; UGT = uridine diphosphate-glucuronosyl transferases.

involved with nicotine metabolism. Metabolic activation of the carcinogens typically results in electrophilic, oxygenated intermediates that covalently bind to DNA or other macromolecules to form adducts. Detoxification of these electrophilic intermediates involves further transformation catalyzed by glutathione *S*-transferases, epoxide hydrolase, *N*-acetyl transferases, uridine-5′-diphosphate-glucuronosyltransferases, sulfotransferases, and other enzymes. The metabolic activation of benzo[a]pyrene results in the formation of the highly electrophilic 7,8-diol-9,10-epoxide, which forms adducts with exocyclic N^2 of guanine. α-Hydroxylation is the major metabolic activation pathway for both NNK and the main metabolite [4-(*N*-methylnitrosamino)-1(3-pyridyl)-1-butanol, NNAL]. This pathway produces diazonium ions and the subsequent formation of methyl adducts (7-methylguanine, O^6-methylguanine) as well as pyridyloxobutyl adducts. *In vivo* studies indicate that tobacco smoke induces several phase I and phase II enzymes including CYP1A1, CYP1A2, CYP2E1, and some isoforms of uridine-5′-diphosphate-glucuronosyltransferase.[56]

Elimination

Although nicotine has high affinity for CYP2A6, the clearance of nicotine from the blood depends more on hepatic blood flow than intrinsic metabolic activity. The excretion of nicotine occurs by glomerular filtration and tubular secretion depending on urinary pH. In acidic urine, nicotine appears primarily in the ionized form and tubular reabsorption is minimal. The kidneys excrete nicotine metabolites as 3′-hydroxycotinine, unchanged compounds or glucuronide conjugates with 3′-hydroxycotinine being the main urinary metabolite of nicotine and cotinine in all mammalian species studied.[23,66] Figure 66.5 displays urinary nicotine and metabolites in humans as a percentage of an absorbed dose of nicotine. About 5–10% of the absorbed dose of nicotine from cigarette smoking appears in the urine as unchanged nicotine, depending on urinary pH.[57] The kidneys excrete about 10–15% of an absorbed dose of nicotine as unconjugated cotinine in the urine, whereas the remainder of this metabolite is converted to cotinine glucuronide, *trans*-3′-hydroxycotinine and *trans*-3′-hydroxycotinine glucuronide. The average plasma elimination half-life of nicotine following intravenous administration is about 2–3 hours, whereas the plasma half-life of the inactive metabolite cotinine is about 16–20 hours. Elimination of nicotine and cotinine is similar in smokers and nonsmokers, but there is substantial individual variation in the clearance rates of both of these compounds.[58] After 3–4 days, blood and urine cotinine concentrations decline to values associated with nonsmokers.[59] Table 66.5 lists the approximate urinary elimination half-life of tobacco alkaloids determined in a study of 34 habitual tobacco users.[60]

Maternal and Fetal Kinetics

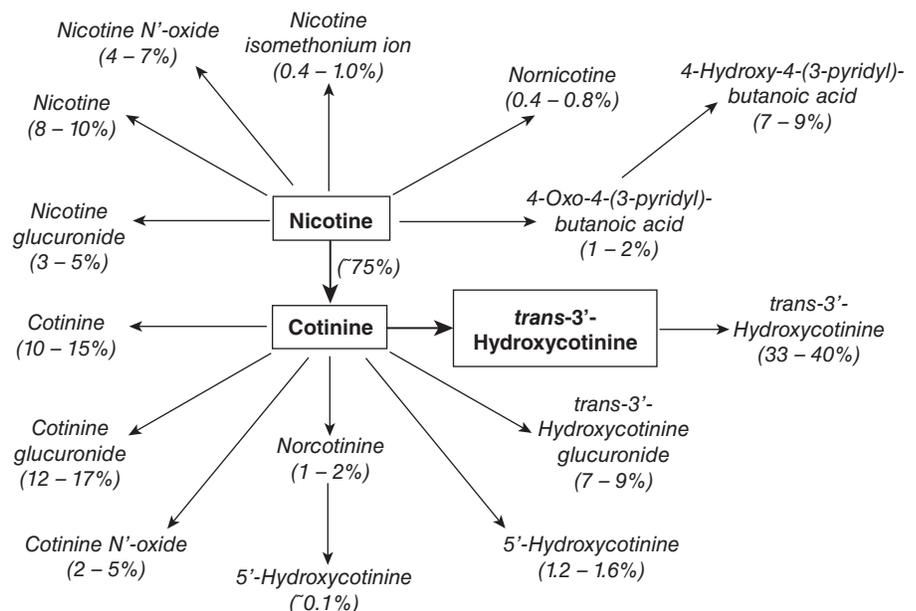
Nicotine crosses the placenta easily without evidence of biotransformation to cotinine by the placenta.[61]


FIGURE 66.5. Urinary elimination of an absorbed dose of nicotine.[23]

TABLE 66.5. Approximate Urinary Elimination Half-Life of Tobacco Alkaloids.[60]

Alkaloid	Mean Urinary t$_{1/2}$*	Range*
Anabasine	16	10–27
Anatabine	10	6–15
Nornicotine	12	6–27
Nicotine	11	4–31
Cotinine	19	10–37

*Rounded to nearest hour; t$_{1/2}$ = half-life in hours.

Potentially, the nicotine concentration is slightly higher in fetal serum than in maternal serum. Secretion of nicotine in breast milk also occurs with a milk/maternal plasma nicotine ratio of approximately 3.[23] In a study of 18 smoking (i.e., 2–20 cigarettes/d) and 2 snuff-taking mothers, the mean daily intake of nicotine by breast-feed infants was about 7 μg/kg.[62]

Drug Interactions

Potential drug interactions involved with the induction of cytochrome P450 isoenzymes involved with nicotine metabolism heparin, theophylline, caffeine, tacrine, imipramine, haloperidol, pentazocine, propranolol, flecainide, and estradiol; however, there are limited human data on the clinical relevance of these potential drug interactions.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Pathologic examinations of the bronchial mucosa in smokers reveal a variety of histologic changes including epithelial and goblet cell hyperplasia, submucosal glandular hypertrophy, subepithelial mononuclear cells (e.g., macrophages, CD8$^+$ T-cells), and ciliary denudation. Although these bronchial changes occur in the vast majority of smokers, these changes are not specific to tobacco smoking.[63] Characteristics of emphysema-type destruction of the distal bronchiole are almost universally present in heavy smokers (i.e., 2 packs/d).[64] Typically, centrilobular emphysema occurs in the upper lobes in tobacco smokers with chronic obstructive pulmonary disease (COPD).

Nicotine

Nicotine is the classic agonist for nicotinic cholinergic receptors. Nicotinic cholinergic receptors are ligand-gated ion channels consisting of 5 subunits; these receptors occur in the brain, autonomic ganglia, and the neuromuscular junction.[65] Although nicotinic receptors appear throughout the brain including the amygdala, septum, locus ceruleus, and brainstem motor nuclei, the highest concentrations of binding sites are located in the cortex, interpeduncular nucleus, and the thalamus.[66] Initially, nicotine stimulates the nicotinic cholinergic receptors stereoselectively in the sympathetic and parasympathetic ganglia of the autonomic nervous system as well as in the neuromuscular junction.[67] (S)-Nicotine is the active stereoisomer whereas (R)-nicotine is a weak agonist at the nicotinic cholinergic receptors. Depending on the dose of nicotine, the stimulatory phase may be transient with prolonged ganglionic blockade resulting from persistent membrane depolarization. Nicotine is not likely a direct carcinogen. Studies on the cocarcinogenicity and tumor promoting property via activation of protein kinase A/B are inconsistent.[28]

Tobacco Smoke

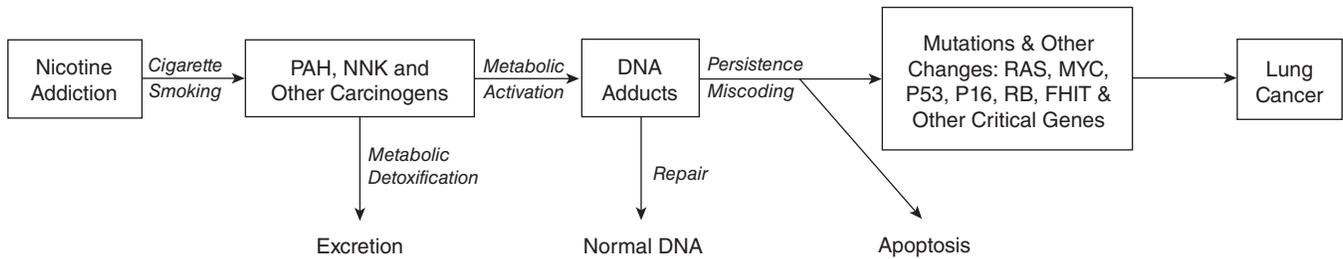
Tobacco smoke acts on multiple stages of carcinogenesis as well as causing chronic inflammation and disruption of natural protective barriers. In tobacco smoke, there are numerous carcinogens capable of initiating and promoting tumors in addition to acting as cocarcinogens. Figure 66.6 demonstrates the effect of carcinogens in tobacco smoke on multiple mutations and cellular processes in the development of lung cancer. Hallmarks of cancer include self-sufficiency in growth signals, insensitivity to antigrowth signals, sustained angiogenesis, tissue invasion and metastasis, evasion of apoptosis, and limitless replicative potential.[68] The stem cell and its early progenitor cell are the target cells for the initiation event during carcinogenesis.[69] Most carcinogens require metabolic activation, primarily by the cytochrome P450 isoenzymes. Cigarette smoking induces CYP1A1 and CYP2D6; the former helps metabolize polycyclic aromatic hydrocarbons in tobacco smoke, whereas the latter isoenzyme activates several nitrosamines including NNK.[70] The oxygenated intermediates formed by cytochrome P450 isoenzymes typically undergo further transformation by phase II enzymes (e.g., glutathione S-transferases, uridine-5′-diphosphate-glucuronosyltransferases, sulfotransferases). The GSTM1 gene codes for the mu class of glutathione S-transferases that acts upon various carcinogens including polycyclic aromatic hydrocarbon diol epoxide.[71] Biotransformation of carcinogens by the cytochrome P450 system detoxifies most of these compounds, but some of these electrophilic compounds form DNA adducts. Cellular repair mechanisms eliminate most DNA adducts before mutations occur by direct repair, base excision repair, and nucleotide excision repair. Apoptosis (i.e., programmed cell death) also removes cells with damaged DNA. Some DNA adducts


FIGURE 66.6. The effect of carcinogens in tobacco smoke on the multiple mutations and cellular processes in the development of lung cancer.[27]

evade normal repair mechanisms, leading to miscoding and permanent critical point mutations in oncogenes (e.g., Kirsten-ras) and tumor suppressor genes (e.g., p53). These mutations disrupt cell-cycle checkpoints and ultimately result in loss of normal growth control and the clinical appearance of a tumor.

Reinke's edema involves the swelling of the superficial lamina propria of the vocal cords, primarily in middle-aged female smokers.[72] The degree of edema and the associated voice abnormalities (hoarse, raspy) are directly related to the daily cigarette consumption and duration of exposure to smoke. These lesions are not precancerous.

CLINICAL RESPONSE

Acute Nicotine Poisoning

The onset of symptoms following the ingestion of toxic doses of nicotine is rapid (15–30 minutes) beginning with gastrointestinal distress (nausea, vomiting, abdominal pain, diarrhea, salivation). Case reports from the older medical literature indicate that death can occur within 5–10 minutes of the ingestion of liquid pesticide containing 40% nicotine.[73,74] Vomiting is almost always present following the ingestion of tobacco products, but the absence of vomiting does not necessarily exclude the development of potentially serious nicotine toxicity.[75] Symptoms in mild nicotine poisoning resolve in several hours. Severe nicotine poisoning involves a stimulatory phase followed by an inhibitory phase that occurs over 24 hours. Transiently, hypertension and tachycardia can develop followed by hypotension, bradycardia, decreased deep tendon reflexes, fasciculations, paralysis, and cardiovascular collapse. Neurologic symptoms include headache, diaphoresis, ataxia, lightheadedness, weakness, confusion, and in severe poisonings, convulsions, coma, and respiratory failure.[44] Nicotine acts unpredictably as an agonist of the muscarinic receptors; therefore, the presence of cholinergic symptoms (miosis, salivation, lacrimation, bronchorrhea, diarrhea, bradycardia) is variable.[76]

Green Tobacco Sickness

Case series associate the harvesting of green tobacco in a moist environment with an occupational disease called green tobacco sickness, particularly in nonsmokers.[77,78] This disease affects up to one-quarter of tobacco farm workers. Predisposing factors include working conditions and location,[79] lack of protective clothing (e.g., rain suits),[80] working with burley- or flue-cured tobacco,[81] working in humid environments with wet tobacco leaves, and workers with disruption of their skin integrity (e.g., superficial wounds, rash).[82,83] Cigarette smokers rarely display symptoms of green tobacco sickness, suggesting that a tolerance to nicotine can develop as a result of chronic tobacco smoking.[84] This self-limited illness is characterized by nonspecific effects including headache, pallor, nausea, vomiting, diarrhea, abdominal cramps, weakness, lightheadedness, diplopia, and difficulty breathing.[85] Symptoms typically begin during the afternoon or evening after a full day of work with moist, green tobacco. The disease typically resolves by the following day. Occasionally, hospitalization may be required for bradycardia, hypotension, and dehydration.[86]

Tobacco Smoking

Tobacco smoking increases overall morbidity and mortality as a result of the increased incidence of various cancers, chronic obstructive pulmonary disease, cardiovascular disease, cerebrovascular disease, and atherosclerotic peripheral vascular disease. These increased overall mortality ratios for smokers are approximately 2.2 and 2.4 for men smoking <1 pack cigarettes per day and >1 pack cigarettes per day, respectively, compared with nonsmokers. The mortality ratios for women

smoking similar amounts of cigarettes are about 1.6 and 2.1, respectively.[87]

Cancer

The International Agency for Research on Cancer lists tobacco smoking and tobacco smoke as human carcinogens (Group 1).[2] Although tobacco smoke is carcinogenic, there are few data supporting nicotine as a carcinogen. Tobacco smoke is the most extreme example of a systemic carcinogen with tobacco smoking identified as the cause of cancer at more organ sites than any other carcinogen. Smoking causes cancers of the lungs, oral cavity, pharynx, larynx, esophagus (squamous cell carcinoma), pancreas, bladder, and renal pelvis. The increased risks of developing these cancers in tobacco smokers range from a 3-fold increase in pancreatic cancer to a 20-fold increased risk of lung cancer. Additionally, there is a causal association between tobacco smoking and cancers of the nasal cavity and sinuses, adenocarcinoma of the esophagus, stomach, liver, renal cell cancer of the kidney, cervical cancer of the uterus, and myeloid leukemia. In general, there is an approximate 2- to 3-fold increased risk of developing these types of cancers in tobacco smokers when compared with nonsmokers. Although there is some evidence of an association between tobacco smoking and colorectal cancers, the difficulty controlling potential confounders in these studies limits conclusions regarding a causal link between tobacco smoking and colorectal cancer. Tobacco smoking probably does not cause an increased risk of developing endometrial, skin, ovary, central nervous system, thyroid, prostate, or female breast cancers.[88] There is also no clear association between tobacco smoking and multiple myeloma, lymphomas, lymphocytic leukemia, or soft tissue sarcoma. Tobacco smoke and in particular, the base/neutral fractions of cigarette smoke condensate are genotoxic in humans and in experimental animals, producing numerous mutagens in the urine.[89] In humans, tobacco smoking produces gene mutations and chromosomal abnormalities with lung tumors of smokers containing higher frequencies of *TP53* and *KRAS* mutations relative to nonsmokers.

Lung. Lung cancer is the most common cause of cancer death in the world; however, only about 20% of regular smokers develop lung cancer and the cause of this susceptibility is unclear.[90] Tobacco smoking accounts for up to 90% of lungs cancer deaths in populations with a high prevalence of tobacco smoking. The risk of lung cancer increases with the number of cigarettes smoked, the age of onset of tobacco smoking, and the duration of tobacco smoking with the latter risk

factor being the strongest determinant of lung cancer in these smokers. The use of filters and low tar cigarettes reduces mortality rates from tobacco smoking-induced lung cancer only slightly.[91] The risk of dying from lung cancer in a person smoking >2 packs cigarettes per day is up to 23-fold higher than that of nonsmokers.[92] Cessation of smoking eliminates the further increase in the risk of lung cancer. Tobacco smoking increases the risk of all histologic types of lung cancer, particularly squamous cell and small cell carcinoma.[93] In a meta-analysis of 48 studies from the last decades of the 20th century, the combined estimate of relative risk for heavy smokers (i.e., $\geq$ 30 cigarettes/d) ranged from 4.10 (95% CI: 3.16–5.31) for adenocarcinoma to 11.3 (95% CI: 8.10–15.9) for squamous cell carcinoma, and 18.3 (95% CI: 9.26–36.4) for small cell carcinoma.[94] There was a similar dose response curve for smoking duration with the highest risk for squamous cell and small cell carcinomas. Family history of lung cancer and concomitant exposure to radon or asbestos substantially increases the risk of lung cancer in tobacco smokers.[95]

Upper Aerodigestive Tract. Tobacco smoking is causally associated with cancers of the oral cavity (lip, tongue, mucosa), nasal cavity and paranasal sinuses, nasopharynx, oropharynx, hypopharynx, and larynx. The relative risk of cancers of the oral cavity and pharynx associated with smoking ranges from about 2- to 10-fold depending on associated risk factors.[88] The use of smokeless tobacco or ethanol in combination with tobacco smoking substantially increases the risk of cancer in the oral cavity and larynx. Smoking over 30 cigarettes daily and drinking 20 ounces of ethanol weekly increases the risk of developing upper airway cancer ~9-fold compared with nonsmokers.[96] Squamous cell carcinoma of nasal cavity and paranasal sinuses is more closely associated with tobacco smoking than adenocarcinomas in this area. Nasopharyngeal cancer is endemic in regions of Southeast Asia and North Africa as a result of Epstein-Barr virus infection. The relative risk of these cancers is about 2–5 times greater in smokers than nonsmokers.[97]

Upper Digestive Tract. In most epidemiologic studies, the risk of all types of esophageal cancers increases with the duration of smoking and numbers of cigarettes smoked daily, particularly with squamous cell carcinoma. Over 90% of esophageal cancers are either squamous cell carcinomas or adenocarcinomas. Tobacco smoking in combination with ethanol consumption greatly increases the risk of squamous cell cancer of the esophagus. There is a dose-related increase in pancreatic cancer related to the number of cigarettes smoked daily and the duration of smoking. Both cohort and

case-control studies of tobacco smoking and stomach cancer demonstrate a consistent increased risk associated with tobacco smoking in both men and women, even after control of confounders (e.g., ethanol consumption, dietary factors, *Helicobacter pylori* infection). A meta-analysis of 40 epidemiologic studies on the risk of stomach cancer in tobacco smokers indicated a relative risk of about 1.5–1.6 when compared with non-smokers.[98] There is sufficient evidence to associate a moderate increased risk of liver cancer in tobacco smokers after control for ethanol consumption and hepatitis B and hepatitis C infections. Most studies indicate that the risk of liver cancer increases with higher daily cigarette consumption and duration of tobacco smoking.

URINARY TRACT. Tobacco smoking is an important, dose-related risk factor in developing transitional cell carcinomas of the bladder, ureter, and renal pelvis. Several cohort and case-control studies indicate that tobacco smoking increases the risk of renal cell carcinoma in both men and women. A meta-analysis of 19 case-control studies and 5 cohort studies demonstrates a relative risk of renal cell carcinoma of 1.54 (95% CI: 1.42–1.68) and 1.22 (95% CI: 1.09–1.36) for male and female smokers, respectively.[99] There was a strong dose-dependent increase in the relative risk associated with intensity of smoking (i.e., daily cigarette consumption).

CERVIX. Several studies associate invasive cervical squamous cell carcinoma with tobacco smoking, even after adjustment for human papillomavirus infection. In a case-control study of 180 women with adenocarcinoma of the cervix, 391 women with squamous cell carcinoma of the cervix, and 923 population controls, long duration of smoking (≥20 years) was associated with a 2-fold increase in the risk of squamous cell carcinoma of the cervix.[100] Tobacco smoking was not associated with the risk of adenocarcinoma in the cervix. Limited studies of adenocarcinomas and adenosquamous carcinomas have not demonstrated a consistent relationship between tobacco smoking and these cervical cancers. In a meta-analysis of 6 case-control studies, current smoking was associated with a significantly increased risk of squamous cell carcinoma (summary odds ratio [OR] = 1.47, 95% CI: 1.15–1.88), but not with an increased risk of adenocarcinoma (summary OR = 0.82, 95% CI: 0.60–1.11).[101]

LEUKEMIA. There is a causal relationship between tobacco smoking and myeloid leukemia that increases with the amount of tobacco smoking. Two prospective studies demonstrated an approximately 50% increase in myeloid leukemia in tobacco smokers.[102] Other types of leukemia and lymphomas have not been directly linked to tobacco smoking.

CARDIOVASCULAR DISEASE

Prospective studies suggest that tobacco smoking increases the incidence of coronary artery disease 2- to 4-fold with a similar increased risk of sudden death as a result of the prothrombotic properties of tobacco smoke, after adjustment for dietary factors, blood pressure, and serum lipoproteins.[103,104] Tobacco smoking also increases the risk of coronary artery disease in individuals with other risk factors (e.g., hypercholesterolemia, diabetes mellitus). Cessation of smoking significantly reduces the increased relative risk of myocardial infarction in patients under the age of 55 years to near zero after 2 years.[105] Tobacco smoking accelerates aortic atherosclerosis and increases mortality from aortic aneurysm when compared with nonsmokers.[91] Cigarette smoking is a strong risk factor for peripheral arterial disease; smoking increases the risk of peripheral vascular disease severalfold in a dose-dependent manner.[103] Analysis of data from the Framingham Offspring Study indicated that the OR of peripheral vascular disease associated with smoking was 2.0 (95% CI: 1.1–3.4).[106] A hospital-based case-control study compared 291 smokers with newly diagnosed peripheral vascular disease and 828 age- and sex-matched smokers without peripheral vascular disease.[107] Smokers in the highest quartile had an increased risk of developing peripheral vascular disease compared with smokers in the lowest quartile The odds ratio of peripheral vascular disease for the highest quartile (>48 pack-years) of smokers was 1.63 (95% CI: 1.11–2.39; *P* = .011) compared with the lowest quartile (<31 pack-years). Epidemiologic studies indicate that exposure to secondhand tobacco smoke also increases the risk of coronary artery disease. Available meta-analyses suggest that involuntary smoking increases the risk of an acute coronary event by about 25–35%; however, studies on the risk of cardiovascular disease and the use of snuff are inconsistent. A Swedish case-control study compared the use of snuff in 1,760 men, age 45–70 years, with a history of myocardial infarction in 1992–1994 based on mailed questionnaires. After adjustment for age, hospital catchment area, and smoking, the relative risk of first acute myocardial infarction in former and current snuff users was 1.1 (95% CI: 0.8–1.5) and 1.0 (95% CI: 0.8–1.3), respectively. A Swedish mortality study of 6,297 smokeless tobacco users and 32,546 nontobacco users demonstrated an age-adjusted increased risk of death from all cardiovascular diseases (RR = 1.4, 95% CI: 1.2–1.6) during a 12-year follow-up.[108] There was no increased risk of cancer-related deaths in smokeless tobacco users.

However, a Swedish population-based cohort study of 16,754 women and 10,473 men over 10 years did not detect any statistically significant increased risk of myocardial infarction or stroke in men or women.[109] The relative risk (RR) of myocardial infarction in male snuff users compared with nontobacco users was 1.05 (95% CI: 0.8–1.4, $P = .74$) after adjustment for age and potential confounders.

PULMONARY DISEASE

Tobacco smoking is the most important risk factor for the development of COPD. Chronic obstructive pulmonary disease includes chronic bronchitis and emphysema; the smoking-attributable disease burden (mortality, morbidity, cost) is greater for COPD than for smoking-attributable disease associated with coronary artery disease or lung cancer.[110] Chronic bronchitis is defined by the presence of chronic productive cough for at least 3 months in 2 consecutive years after the exclusion of other causes of chronic cough. Emphysema is characterized by abnormal, permanent expansion of airspaces distal to the terminal bronchiole along with destruction of the walls and the absence of obvious fibrosis.

The unique inflammatory process associated with asthma separates this disease from COPD, although some airway hyperresponsiveness occurs in some cases of COPD. About 50% of tobacco smokers develop chronic bronchitis, manifest by inflammation of the large airways and chronic, productive cough. Approximately 30% of tobacco smokers do not develop chronic respiratory symptoms or clinically significant abnormalities of lung function despite the presence of pulmonary inflammation and subtle changes in lung function.[111] Objectively, COPD is manifest by irreversible decline of forced expiratory volume in one second (FEV_1) exceeding 50 mL/year, increasing dyspnea and other respiratory symptoms (cough, sputum production, wheezing), and progressive deterioration of health. Chronic obstructive pulmonary disease results in a reduction of the ratio of FEV_1 to forced vital capacity (FVC) below 88% of predicted in males and 89% of predicted in females.[112] The reversibility of tobacco-induced decline in FEV_1 differs between smokers with COPD, smokers with nonobstructive bronchitis, and smokers without chronic respiratory symptoms. Cessation of tobacco smoking reduces bronchial hyperresponsiveness and respiratory symptoms, and also prevents the excessive decline in lung function in all three of these groups. Cross-sectional studies indicate that FEV_1 is lowest in tobacco smokers, intermediate in ex-smokers, and highest in nonsmokers. The exception is the group of ex-smokers over the age of 70 years. The FEV_1 of these ex-smokers is similar to smokers of the same age, probably as a result of the cessation of smoking by symptomatic smokers (i.e., "healthy smoker effect").[113]

The initial diagnosis of COPD is usually established in individuals over the age of 45–50 years with a history of smoking for several decades. Tobacco smokers develop more respiratory symptoms (cough, sputum production, wheezing, dyspnea), increased respiratory infections, and an accelerated decline in the FEV_1 when compared with nonsmokers and former tobacco smokers.[114] The suboptimal development of lung function during childhood and early adolescence along with accelerated decline of FEV_1 as a result of smoking substantially increase the risk of clinically significant COPD in later years.[115] The development of COPD in tobacco smokers depends on genetic susceptibility as only 10–20% of tobacco smokers develop clinically significant airway obstruction, but to date only α-1-antitrypsin deficiency has been identified as a cause of the increased susceptibility.[116] Consequently, the dose-response of active tobacco smoking on the severity of airflow obstruction (i.e., FEV_1) is relatively weak. The impact of environmental smoke on adult lung function is relatively small compared with active tobacco smoking. Although studies indicate that exposure to environmental smoke causes a statistically significant accelerated decline in FEV_1, the magnitude of the decreases is relatively small (i.e., about 3–4 mL/y).[117]

Cigarette smoking is associated with several diffuse lung diseases that result from bronchiolar and interstitial lung inflammation secondary to chronic tobacco smoke inhalation. These diseases occur primarily in relatively young adult smokers. Smoking-related diffuse lung diseases include desquamative interstitial pneumonia, respiratory bronchiolitis-associated interstitial lung disease, pulmonary Langerhans cell histiocytosis, and acute eosinophilic pneumonia; smoking also increases the risk of developing fibrotic interstitial lung diseases (e.g., idiopathic pulmonary fibrosis).[118]

CEREBROVASCULAR DISEASE

After controlling for hypertension and coronary artery disease, the risk of stroke in tobacco smokers is about 2-fold greater than in nonsmokers.[103] In general, the relative risk of a tobacco smoker developing cerebrovascular disease is lower than coronary artery disease or aortic aneurysm. Pooled estimates using death as the endpoint in 9 epidemiologic studies indicated that the association of ever smoking with aortic aneurysm is 2.5 times (95% CI: 2.2–2.8) greater than the association of ever smoking with coronary artery disease and 3.5 times (95% CI: 2.4–5.3) greater than the association of ever smoking with cerebrovascular disease.[119]

Prenatal maternal smoking is associated with placental abruption, placenta previa, premature rupture of the membranes, fetal growth restriction, and preterm delivery.[120] Maternal smoking is also associated with an increased incidence of complications during pregnancy, particularly intrauterine growth retardation resulting in lower neonatal birth weights, when compared with nonsmokers.[121] There is a dose-related effect of maternal smoking on birthweight as a result of intrauterine growth retardation rather than preterm delivery.[122] The estimated effect is a 5% reduction in relative weight/ daily pack of cigarettes smoked by the mother.[123] Cessation of smoking by the 16th week of pregnancy results in normal neonatal birth weights, when compared with infants from nonsmoking mothers.[124] However, there is no definite evidence that maternal smoke causes long-term adverse effects on growth or cognitive function.[125] A large cross-section study suggested that maternal smoking causes a borderline increase (OR = 1.5, 95% Cl: 1.0–2.2) in the risk of abruptio placentae,[126] whereas the risk of placenta previa is mildly increased (OR = 1.9, 95% CI: 1.2–3.0) in maternal smokers.[127] In general, studies demonstrate that the risk of hypertensive disease during pregnancy including preeclampsia is reduced in maternal smokers when compared with nonsmokers.[128]

Abstinence Syndrome

Mild symptoms of withdrawal develop in some smokers following cessation of tobacco use. Symptoms include anxiety, depression, difficulty concentrating, irritability, anger, restlessness, and sleep difficulties.[129] Distinguishing features of nicotine withdrawal include mild slowing of heart rate and weight gain. Abstinence symptoms begin about 6–12 hours after the cessation of smoking and peak in 1–3 days. Resolution of symptoms occurs over 3–4 weeks.[130] With the exception of nicotine craving, these symptoms are not protracted. Neonatal withdrawal from maternal use of tobacco probably does not occur.[131]

Involuntary Smoking

The International Agency for Research on Cancer lists involuntary (passive) tobacco smoking as a human carcinogen (Group 1).[2] Similarly, the US Toxicology Program lists environmental tobacco smoke as a human carcinogen and the US EPA lists environmental smoke as a class A carcinogen. There is substantial evidence to document the genotoxicity of secondhand smoke.

Review of human biomarker studies of nonsmokers with involuntary exposure to tobacco smoke demonstrate the presence of DNA adducts, urinary mutagenicity, urinary metabolites of carcinogens, and sister chromatid exchanges (SCEs).[132] Meta-analysis of studies of lung cancer risks in nontobacco smokers with smoking partners demonstrate a dose-related increase in the risk of lung cancer in the nontobacco smoking partner compared with nonsmokers without a smoking partner. After controlling for confounders, these relative risks of lung cancer in the nonsmoker are ~20% in women and 30% in men.[133] The excess risk of lung cancer increases with increasing exposure to secondhand smoke. Meta-analyses of secondhand smoke in the workplace demonstrate smaller excess risk of lung cancer in nonsmokers in the range of 12–19%. Analysis of data from the Alcohol-Related Cancers and Genetic Susceptibility in Europe included 2,103 upper aerodigestive tract squamous cell carcinoma cases (oral cavity, oropharynx, hypolarynx, larynx) and 2,221 controls in the project.[134] Among never smokers, ever exposure to involuntary smoking was associated with an increased risk of these cancers (OR = 1.60; 95% CI: 1.04–2.46). The evidence of an increased risk of breast cancer or childhood cancers as a result of secondhand smoke is inconsistent. The absence of a strong dose-response relationship and the lack of a causal link between breast cancer and active smoking strongly argue against a causal association between breast cancer and secondhand smoke. Similarly, the association between exposure to environmental tobacco smoke (ETS) as a child and adult cancers is controversial. A study of 112,430 never smokers within the European Prospective Investigation into Cancer and Nutrition cohort did not detect a substantial risk of developing adult cancers after childhood exposure to ETS.[135] After stratifying by age, sex, and study center as well as adjusting for eduction, alcohol consumption, body mass index, physical activity, nutrition, and adult ETS exposure, there was no association between childhood ETS exposure in never smokers and overall cancer risks (hazard ratio = 0.97; 95% CI: 0.92–1.02) based on self-reports of childhood ETS. The only exception was pancreatic cancer; after adjustment for diabetes, the hazard ratio for pancreatic cancer in never smokers was 2.09 (95% CI: 1.14–3.84) as estimated by Cox proportional hazards models.

DIAGNOSTIC TESTING

Analytic Methods

Techniques for the determination of nicotine and cotinine concentrations in biologic samples include enzyme

immunoassay, chemiluminescent immunoassay, gas chromatography, high performance liquid chromatography, and gas or liquid chromatography/mass spectrometry. The limit of detection for the chemiluminescent immunoassay (Diagnostic Products Corp., Los Angeles, CA) was 2 ng/mL in 20 μL serum compared with 5 ng/mL in 50 μL urine for double antibody radioimmunoassay (Diagnostic Products Corp.).[136] The cross-reactivity of 3-hydroxycotinine for the chemiluminescent and cotinine enzyme immunoassay (Diagnostic Reagents, Sunnyvale, CA) was about 28% and 50%, respectively, with little cross-reactivity to other substances. Cotinine is stable in urine stored up to 30 hours at room temperature;[137] this compound is relatively stable in frozen urine samples stored at –20ºC (–4ºF) for at least several years.[138]

Biomarkers

Potential biomarkers for exposure to tobacco smoke include nicotine, cotinine, thiocyanate, carboxyhemoglobin, hydroxyproline, *N*-nitrosoproline, 1- and 2-naphthol, hydroxyphenanthrene compounds, phenanthrene dihydrodiols, 1-hydroxypyrene, benzene metabolites (*trans*, *trans*-muconic acid, *S*-phenylmercapturic acid), 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanol [NNAL] and glucuronides (NNAL-Gluc), tobacco-specific adducts (protein, DNA), 8-oxodeoxyguanosine, 3-ethyladenine, and aromatic amines.[139] Active smoking increases the concentration of benzene, volatile organic compounds, and carbon monoxide in exhaled air. The concentrations of urinary metabolites of known carcinogens, including benzene metabolites, in smoke are higher in the urine of tobacco smokers than nonsmokers.

The most widely used biomarker of exposure to active or passive tobacco smoke is cotinine, which is a highly specific internal dose marker of both mainstream smoke and environmental tobacco smoke. Cotinine concentrations reflect exposure to the particulate-phase constituents (tar), but there are no direct biomarkers for tar uptake. NNAL and NNAL-Gluc are useful biomarkers because these two compounds are metabolites of the tobacco-specific carcinogen, 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone. Other sensitive biomarkers for tobacco products include *trans*, *trans*-muconic acid, *S*-phenylmercapturic acid, naphthalene metabolites (1-, 2-napthol), 1-hydroxypyrene, 8-oxodeoxyguanosine, and 3-ethyladenine.[139] However, these biomarkers lack specificity as only NNAL and NNAL-Gluc are specific for exposure to tobacco products. Serum thiocyanate concentrations increase during moderate to heavy smoking, but determination of serum thiocyanate concentrations does not distinguish between nonsmokers, light smokers, or passive smokers.[2]

NICOTINE

The mean plasma nicotine concentration following smoking of one cigarette ranges from about 5–30 ng/mL as a result of the absorption of ~1 mg nicotine/cigarette smoked.[140] After smoking a cigarette, the average plasma nicotine concentration of regular smokers increases to ~10–11 ng/mL.[141] Typical plasma nicotine concentrations of smokers during the afternoon range from about 10–50 ng/mL.[142] The short plasma elimination half-life of nicotine limits the use of plasma nicotine as a biomarker of tobacco smoke exposure. In a study of volunteers undergoing treatment for nicotine addiction, the steady-state serum nicotine concentrations 2 weeks after the daily administration of 22 mg nicotine via transdermal patches ranged between 10–50 ng/mL.[143] Blood samples were drawn immediately before the daily nicotine patches were applied.

During occupational exposure to tobacco leaves at harvest time, the mean plasma nicotine concentrations from 10 healthy, nonsmoking women drawn during the morning work shift ranged between 0.79 ± 0.12 and 2.16 ± 0.84 ng/mL.[144] Peak serum nicotine concentrations exceeding 2,000 ng/mL indicate serious toxicity. A case report of a woman, who died of asphyxia from a plastic bag tied over her head following the placement of multiple nicotine patches on her body, suggests that some postmortem redistribution of nicotine may occur, although the distribution of the nicotine patches on the body may also alter the heart/femoral blood nicotine concentrations.[145]

COTININE

Cotinine is a sensitive, specific biomarker of exposure to tobacco smoke for up to about 2–3 days after exposure, depending on the intensity of tobacco smoking.[146] Estimates of serum and urine cotinine concentrations for children and adults are available based on pharmacokinetic equations using respiratory rate, duration of daily exposure, and concentration of nicotine in ambient air as displayed for adults in Equation 66.1 (for urine) and Equation 66.2 (for serum).[147]

$$U = 0.039\, \rho HN \qquad (66.1)$$

$$S = 0.006\, \rho HN \qquad (66.2)$$

where U = urine cotinine concentration in adults; ρ = respiration rate (sedentary = 0.5 m³/h, light activity = 1.0 m³/h); H = daily exposure duration (hours); and N = atmospheric nicotine concentration (μg/m³); and S = serum.

BLOOD. During occupational exposure to tobacco leaves at harvest time, the mean plasma cotinine concentrations from 10 healthy, nonsmoking women drawn during the morning work shift ranged between 8.74–20.54 ng/mL.[144] Typical plasma cotinine concentrations of smokers during the afternoon ranges from about 250–300 ng/mL.[142] The steady-state serum cotinine concentration in a group of active smokers ranged from 94–444 ng/mL.[143] In a study of volunteers undergoing treatment for nicotine addiction, the steady-state serum cotinine concentrations 2 weeks after the daily administration of 22 mg nicotine via transdermal patches ranged between 35–249 ng/mL.[143] In a study of 88 adult nonsmokers, light to moderate smokers (1–19 cigarettes daily), and heavy smokers (≥20 cigarettes daily), the median cotinine concentrations in blood were 0.8 ng/mL, 137 ng/mL, and 467 ng/mL, respectively, as measured by radioimmunoassay.[148] Serum cotinine concentrations below 10 ng/mL are highly suggestive of the lack of tobacco smoking in the last few days to a week.[136]

URINE. Although nicotine occurs in some foods (e.g., tomatoes, potatoes, bell pepper, cauliflower, black tea), the dose is relatively small compared with the nicotine in environmental tobacco smoke. The estimated average daily intake of nicotine from food sources was about 9 μg with range up to 100 μg, primarily as the result of ingesting black and instant teas.[149] The maximum daily urinary cotinine concentration in this study was approximately 6 ng/mL. Nicotine replacement therapy causes increased urinary cotinine concentrations; therefore, the analysis of minor alkaloids (e.g., anatabine, anabasine) from tobacco smoke is necessary to separate tobacco smoking from nicotine replacement therapy.[150]

Cotinine is a sensitive and specific biomarker for discriminating the source of tobacco smoke exposure. The concentration of cotinine in urine samples from smokers is about one magnitude greater than serum. In a study of 88 adult nonsmokers, light to moderate smokers (1–19 cigarettes daily), and heavy smokers (≥20 cigarettes daily), the median cotinine concentrations in urine samples from the 3 groups were 17 ng/mL, 3,416 ng/mL, and 7,179 ng/mL, respectively.[148] Urine cotinine concentrations below 200 ng/mL are highly suggestive of the lack of tobacco smoking in the last few days to a week.[136] In a study of involuntary and active smokers, receiver operating characteristics analysis determined an optimal urine cotinine cutoff of 31.5 ng/mL for the separation of these 2 groups with a sensitivity of 97.1 % and specificity of 93.9%.[151] Urine 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanol (NNAL) is also a sensitive and specific urinary marker of involuntary and active smoking that is present up to about 1 month after exposure.

DNA/PROTEIN ADDUCTS

DNA adducts directly measure the extent of carcinogen reactions with DNA. However, DNA and protein adducts are nonspecific markers of the early biologic effects of tobacco smoke. Protein adducts (hemoglobin, albumin) are surrogates for DNA adducts that are easier to obtain than DNA adducts. Covalent binding of carcinogens in tobacco smoke to blood proteins results in an increased incidence of these adducts in tobacco smokers compared with nonsmokers, primarily at guanine or adenine. These adducts result from a variety of chemicals in tobacco smoke including benzene, aromatic amines, polycyclic aromatic hydrocarbons, tobacco-specific nitrosamines [4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone], acrylonitrile, and acrylamide. Protein adducts reflect the integrated exposure to tobacco smoke over the preceding 4 months as a result of their long elimination half-life. For example, N-(2-hydroxyethyl)valine results from the reaction between ethylene oxide in tobacco smoke and N-terminal valine in hemoglobin. This protein adduct is a nonspecific biologic effective dose marker of exposure to tobacco smoke.[152]

Abnormalities

FEV_1

The classical functional deficits associated with COPD and emphysema include airflow obstruction (i.e., decreased FEV_1), increased lung compliance, reduced diffusion capacity, and progressive air trapping with hyperinflation. In healthy subjects, maximal lung function occurs near the age of 20–25 years followed by a slow decline beginning about 35 years of age. The decline in FEV_1 in cross-sectional studies averages about 20–30 mL/year in nonsmokers compared with 25–80 mL/year in current smokers. The largest declines in FEV_1 occur in the approximate 15% of the smoking population susceptible to developing COPD and results in annual rates of decline up to 150 mL.[153] After adjustment for age and height, tobacco smokers overall had an average accelerated decline in the FEV_1 of ~13–14 mL/year during longitudinal studies lasting 5–10 years.[154,155] In these longitudinal studies, declines in FVC are not as closely associated with tobacco smoking as FEV_1.[156] Most studies demonstrate that after about 2 years of smoking cessation, the annual decline in FEV_1 of ex-smokers is similar to nonsmokers, but the overall FEV_1 of ex-smokers is not similar to nonsmokers because of the persistence of previous lung damage in ex-smokers.[157] The improvement in FEV_1 depends on several factors including airway responsiveness to beta-agonist, baseline FEV_1, methacholine reactivity, age, sex,

race, and baseline smoking rate. In a 5-year, longitudinal study of ex-smokers and nonsmokers, the mean annual rate of decline in FEV_1 after the first year of the study among the participants with sustained cessation of smoking was half the rate among those continuing to smoke (i.e., 31 ± 48 mL and 62 ± 55 mL, respectively).[158] The severity of the decline in FEV_1 is strongly related to cumulative cigarette consumption and preexisting airway hyperresponsiveness. The impact of tar content and filters on the severity of airflow obstruction measured by FEV_1 is unclear because many smokers alter inhalation patterns as an adaption to the lower nicotine content. In a study of 1,492 smokers of plain cigarettes and 1,936 smokers of filter cigarettes, there was no significant difference in the decline of FEV_1 between smokers of filter and nonfiltered cigarettes over a 5-year period.[159] A meta-analysis of 6 cross-sectional studies comparing water-pipe smokers, cigarette smokers, and nonsmokers did not detect a statistically significant difference in the decline in FEV_1 between water-pipe smokers and cigarette smokers.[160] The pooled standardized mean difference for FEV_1 was –0.43 (95% CI: –0.58–0.29) for water-pipe smokers compared with nonsmokers. The difference was equivalent to a 4.04% reduction in FEV_1. There was low homogeneity between the studies, and none of the studies reported using a standardized exposure assessment tool.

CARBOXYHEMOGLOBIN

Tobacco smoking is a known source of carboxyhemoglobin in smokers. There is a moderate correlation between cigarette smoking and carboxyhemoglobin depending on a variety of factors related to smoking topography (i.e., frequency of cigarette consumption, duration of inhalation, cigarette puff volume, cigarette length, the time since last smoking) as well as respiratory rate, ambient ventilation, and ambient carbon monoxide concentrations.[161,162,163] Under normal atmospheric conditions, the terminal elimination half-life of carboxyhemoglobin is approximately 4–6 hours. Most non-smoking urban dwellers have carboxyhemoglobin concentrations below 3% compared with 3–8% for smokers. In a study of 14 adults smoking at least one pack per day, the venous carboxyhemoglobin concentration averaged 8.2% (range. 1.4–14.5%).[164] A study of 856 Italian smokers and nonsmokers detected mean arterial capillary (ear lobe) carboxyhemoglobin concentrations of $4.17\% \pm 2.19\%$ and $1.82\% \pm 0.75\%$, respectively.[165] Smokers were defined as smoking ≥5 cigarettes daily with the last cigarette within the preceding 48 hours, whereas nonsmokers were defined as responding

"no" to the question, "Have you ever smoked cigarettes daily?" Carboxyhemoglobin concentrations exceeding 3% are very unusual in nonsmokers without an external source of carbon monoxide; the presence of carboxyhemoglobin concentrations exceeding these values suggests recent tobacco smoking absent an external source of carbon monoxide.[166] Blood carboxyhemoglobin concentrations exceeding 10% in smokers suggests an external source of carbon monoxide, unless the exposure resulted from inhaled smoke from a waterpipe (narghile, hookah) in hookah cafes and bars;[167] typically patrons in these establishments have higher exhaled carbon monoxide concentrations than patrons of traditional bars.[168] The burning of charcoal during the use of a waterpipe may result in substantial elevations of carboxyhemoglobin (i.e., 25–30%) in the user.

TREATMENT

Stabilization

Respiratory failure represents the greatest risk to life following serious nicotine intoxication; therefore, patients should be evaluated carefully for evidence of respiratory insufficiency. Patients with altered sensorium should receive intravenous fluids, cardiac monitoring, pulse oximetry, and oxygen as needed in addition to rapid evaluation of blood glucose and intravenous naloxone if opiate intoxication is suspected. The initial hypertension and tachycardia associated with nicotine intoxication should not be aggressively treated unless there is evidence of end-organ failure because a depressive phase of bradycardia and hypotension often follows the initial period of stimulation.

Decontamination

Because nicotine stimulates the emetic center in the medulla oblongata, spontaneous vomiting occurs in most nicotine ingestions; therefore, most nicotine ingestions require no decontamination measures. Most children only taste tobacco products, and they do not usually develop symptoms. The administration of activated charcoal to alert children is usually unnecessary; there are no clinical data to confirm the clinical efficacy of activated charcoal following the ingestion of cigarettes or plant parts from *Nicotiana* species. Additionally, the rapid onset of changes in consciousness and the potential for seizures during serious tobacco intoxications increases the risk of using decontamination measures. All skin contaminated with nicotine solutions should be washed thoroughly with a nonalkaline soap and cool water.

Elimination Enhancement

Continuous nasogastric suction and serial activated charcoal are theoretically advantageous, but there are inadequate clinical data to recommend these procedures routinely. Acidification of the urine also has theoretical pharmacokinetic advantages, but the use of acid diuresis is discouraged because of the lack of data to support the efficacy of this method, the short duration of nicotine action, and complications (e.g., rhabdomyolysis) associated with acid diuresis.

Antidotes

Atropine may improve bradycardia and hypotension, but this drug does not reverse neuromuscular weakness during nicotine intoxication.

Supplemental Care

The treatment of nicotine poisoning is primarily supportive. Serious poisoning must be followed closely in an intensive care setting for the development of respiratory failure within the first 12 hours. Seizures can be treated with benzodiazepines (diazepam, lorazepam); the use of large benzodiazepine doses may impair the ability of the patient to protect their airway, requiring intubation.

CORKWOOD TREE and PITURI [*Duboisia hopwoodii* (F. MUELL.) F. MUELL.]

HISTORY

For many centuries in Central Australia, Aboriginal people habitually chewed wild nicotine-containing plants from the Solanaceae family, primarily *Nicotiana* spp. [e.g., *N. rosulata* subs. *ingulba* (J.M.Black) P.Horton] and *Duboisia hopwoodii* (F. Muell.) F. Muell. There are a variety of names for the substances extracted from these plants as a result of the many languages and dialects including bedgery, pedgery, pitchery, and most commonly pituri.[169] In the middle 1800s, European explorers on the eastern margin of Australia's central desert observed the use of the dried leaves and terminal stems of the desert plant, *Duboisia hopwoodii* as a stimulant and narcotic for long marches similar to cocoa leaves in Bolivia.[170,171] Tribal elders used the plant to induce a state of consciousness that allowed the inculcation of values, beliefs, and religious tenets of the tribe as well as the performance of painful initiation rites.[172] Plant species from specific locations in western Australia and the Mulligan-Georgina Rivers area were highly prized in the Australian Aboriginal culture as valuable trade item until the 1930s.[173] Experimental studies in the later 1800s indicate that nicotine was the main active ingredient.[174]

BOTANICAL DESCRIPTION

There are 3 species of *Duboisia* in Australia including *D. hopwoodii*, *D. myoporoides* R. Br., and *D. leichhardtii* (F. Muell.) F. Muell. *D. hopwoodii* is the only *Duboisia* species that contains substantial amounts of nicotine and the only *Duboisia* species used by Australian Aborigines to make pituri. *D. myoporoides* (corkwood) grows in eastern coastal Australia from Cooktown to Nowra and New Caledonia, whereas *D. leichhardtii* grows in the higher elevations of inland Queensland from Monto to Yarraman.[175]

Common Name: Corkwood tree
Scientific Name: *Duboisia hopwoodii* (F. Muell.) F. Muell.
Botanical Family: Solanaceae (nightshade)
Physical Description: An erect shrub 3–4 m (~10–13 feet) tall with attractive white flowers that produce black berries. The bark is light with the consistency of cork; the leaves are alternate, smooth, and narrowly elliptical.
Distribution and Ecology: This shrub is a native species of Australia including New South Wales, Northern Territory, Queensland, South Australia, and Western Australia. *D. hopwoodii* occurs primarily in the arid regions of central Australia. Figure 66.7 displays the flowers, leaves, and stems of this plant.

EXPOSURE

Origin

In contrast to other *Duboisia* species, *D. hopwoodii* contains primarily nicotine and nornicotine rather than tropane alkaloids present in *D. myoporoides* and *D. leichhardtii*. The latter two *Duboisia* species are

FIGURE 66.7. *Duboisia hopwoodii* (F. Muell.) F. Muell. (Photography by G. Byrne, C.P. Campbell, and G Cocktern. Image used with the permission of the Western Australian Herbarium, Department of Environment and Conservation; http://florabase.dec.wa.gov.au/)

commercial sources of hyoscine, scopolamine, and hyoscyamine (*l*-atropine); plantations of *D. myoporoides* in Queensland supply the bulk of the world's raw scopolamine.[176]

Composition

Analysis of leaves from *D. hopwoodii* demonstrated the presence of nicotine, nornicotine, myosmine [3-(1-pyrroline-2-yl)pyridine], *N*-formyl nornicotine, cotinine, N-acetyl nornicotine, anabasine, anatabine, anatalline, and bipyridyl.[173] Nicotine was the major alkaloid in the West Australian collection, whereas nornicotine was predominant in the Northern Territory sample. The amounts of nicotine and nornicotine in pituri range up to about 5% and 4%, respectively, with the highest nicotine content in the young shoots. In an analysis of 70 samples of pituri, the nicotine and nornicotine concentrations ranged between 0–5.3% and 0.1–4.1%, respectively.[177] Analytic data from the early 1900s suggest that the nicotine content of pituri was approximately 2.5%.[178]

Methods of Use

Aboriginal people of Australia traditionally chewed the leaves of nicotine-containing desert plants, *Duboisia hopwoodii* and other *Nicotiana* species, as a recreational and ritual drug called pituri. About 1 tablespoon of cured leaf and stem from specific strains of *D. hopwoodii* are ground with alkali plant ash to form a brownish-gray paste or pituri quid ready for mastication. The range of wood burned for ash included *Acacia* spp., *Eucalyptus* spp., and *Grevillea* spp.[169] The masticated leaves (quid) is retained in the lower lip or buccal mucosa to continuously extract the nicotine. Ceremonially, the quid was passed from mouth to mouth beginning with the head man. When not retained in the mouth, the quid may be stored behind the ear, under the breast, or held against the skin by a headband or armband. These people carried the leaves and stems in a specially woven bag containing approximately ~1.5 kg of material. Older men of the tribe kept the details of the drying process as part of the knowledge of the sacred ritual. The addition of alkali ash to the quid increases the release of the weakly basic nicotine from the plant material and facilitates the diffusion of nicotine across the oral mucosa. With the deterioration of traditional Aboriginal lifestyles, the plant material for pituri was sun dried by women; much of the knowledge of the use of psychoactive drugs was lost after European immigration into Australia.[172] Aborigines in Central Australia used *D. hopwoodii* primarily as a poison to capture fish and emu.[173]

DOSE EFFECT

There are few data on dose-related effects of pituri. The concentrations of nicotine and nornicotine in pituri are similar to common tobacco; hence, the dose-effect of these substances are expected to be similar.

CLINICAL RESPONSE

There are few data on the clinical effects of pituri. Nicotine is the main active ingredient in pituri; the clinical features of tobacco and pituri intoxication are expected to be similar as noted in the nicotine section. The onset of symptoms following the ingestion of toxic doses of nicotine is rapid (15–30 minutes) beginning with gastrointestinal distress (nausea, vomiting, abdominal pain, diarrhea, salivation). Other species of Duboisia (*D. myoporoides*, *D. leichhardtii*) produce an atropine-like, anticholinergic poisoning similar to henbane (*Hyoscyamus niger*) rather than nicotine poisoning.

TREATMENT

The treatment of pituri intoxication is supportive and similar to nicotine and common tobacco poisoning.
