FOREWORD

It is a great pleasure for me to write this Foreword, as I have known Don Barceloux professionally for many years and we have collaborated on various projects particularly for the American Academy of Clinical Toxicology. Dr. Barceloux first established himself as a distinguished and successful author with the publication in 1988 of the first edition of *Medical Toxicology: Diagnosis and Treatment of Human Poisoning*, which he co-authored with the late Matthew Ellenhorn.

Dr. Barceloux's reputation for producing systematic books of great quality was further enhanced in 2008 by the publication of the first volume (of four) of *Medical Toxicology*, which was entitled the *Medical Toxicology of Natural Substances: Foods, Fungi, Medicinal Herbs, Plants and Venomous Animals*; he wrote 171 of the 185 chapters. At the time of publication, this book had no rival, and that continues to be the case. I use it on a daily basis in my clinical practice.

While a substantial number of textbooks on clinical toxicology have been published in the last two decades, none has focused primarily on drug abuse. Equally, many books on drug abuse have been published over the same period, but none has been written from the perspective of the clinical/medical toxicologist.

For this reason I welcome, and indeed have been waiting eagerly for, the publication of the second volume in the *Medical Toxicology* series, which uses the same helpful format as volume 1. *Medical Toxicology of Drug Abuse*: *Synthesized Chemicals and Psychoactive Plants* provides in-depth up-to-date coverage of psychoactive agents that are abused, including newer designer drugs and psychoactive plants. Detailed information is provided on the pathophysiology, toxicokinetics, clinical effects (including the features associated with abstinence syndromes and reproductive abnormalities), treatment, and prevention of drug abuse. In addition, there are sections on epidemiology, on the chemical structure and physiochemical properties of the abused substances, on impurities introduced during synthesis, on the interpretation of the results of laboratory testing, and on the characteristics and geographical distribution of psychoactive plants. All but six of the 66 chapters in the present volume were authored by Dr. Barceloux himself; the remainder have been written by other acknowledged experts. After reading the book in proof I am confident its impact and usefulness will be similar to volume 1.

I commend this excellent book to the reader.

PREFACE

Medical Toxicology of Drug Abuse: *Synthesized Chemicals and Psychoactive Plants* is the second book in the Medical Toxicology Series that divides Medical Toxicology into the four following areas: Natural Substances, Drugs of Abuse, Occupational and Environmental Exposures, and Pharmaceutical Overdose. The book series is designed to provide in-depth, evidence-based coverage of the most important toxins affecting humans. This book covers a variety of older psychoactive drugs and newer designer drugs of abuse including recently popularized drug (e.g., methcathinone, mephedrone, *Salvia divinorum*, kratom). Information on a particular substance is discussed in the book commonly associated with the subject. Consequently, the most important psychoactive plants are discussed in the Drug Abuse book rather than the Natural Substances book, so the reader interested in information on drug abuse will not have to search two books. Pharmaceutical drugs (e.g., hydrocodone, morphine, oxycodone) used primarily for therapeutic purposes will be covered in the book on Pharmaceutical Overdose. Conversions for length and temperature in metric and imperial systems are provided to ease the use of this book by an international readership, whereas the metric system for mass and concentrations are retained to limit any confusion about doses in the United States. This book is designed as a convenient reference for answers to questions regarding exposure, pathophysiology, clinical effect, detection, and treatment of toxicity associated with drugs of abuse.

The format of this book follows the first book in the Medical Toxicology Series, *Medical Toxicology of Natural Substances: Foods, Fungi, Medicinal Herbs, Plants, and Venomous Animals*. When the reader is familiar with the templates used in the book series, the consistency of the organization allows the reader to easily locate the appropriate information necessary for decisions regarding the sources, effect, regulation, and management of toxic exposures. The following list provides organizational details on the material under the headings for each drug:

History includes facts about the discovery, past abuse, and earlier complications of drug abuse.

Botanical Description helps the reader identify the characteristics and geographic distribution of psychoactive plants.

Identifying Characteristics includes the chemical structure, physiochemical properties, and the terminology associated with the specific drug of abuse.

Exposure discusses the epidemiology, trends, sources, production processes, impurities added during synthesis of the drug, profiling of confiscated drugs, and common methods of misuse.

Dose Effect covers clinical data on the drug doses associated with overdose and fatalities in humans. The book emphasizes dose-related effects rather than adverse or idiosyncratic reactions.

Toxicokinetics discusses the disposition of the drug in the body including the absorption, distribution, biotransformation, and elimination along with maternal and fetal kinetics, tolerance, and drug interactions.

Histopathology and Pathophysiology presents information on the mechanisms of action and toxicity, autopsies, and postmortem changes associated with drug abuse.

Clinical Response provides data on the clinical features of toxicity following the illicit use of the drug including the onset, duration, and type of clinical effects (behavioral abnormalities, mental disorders, medical complications). Additionally, this section discusses reproductive abnormalities, fatalities, and any

symptoms associated with an abstinence syndrome following cessation of use.

Diagnostic Testing presents information important to the interpretation of the clinical significance of laboratory testing. This section includes current analytic methods to identify and quantitate the drug in biologic and confiscated material, effects of storage on analytic results, biomarkers of exposure in blood, urine, and postmortem material, abnormalities detected by imaging studies and ancillary tests, and driving impairment associated with use of the drug.

Treatment includes current information on the management of toxic effects associated with drug misuse and abuse including recommendations for first responders, life-threatening problems associated with overdose, the use of antidotes, and supportive care.

Medical Toxicology of Drug Abuse: Synthesized Chemicals and Psychoactive Plants focuses on scientifically confirmed facts about specific drugs of abuse based on the medical literature and clinical experience. References are documented to validate the information and to provide sources for further inquiry. My hope is that this interdisciplinary, evidence-based approach will increase communication between traditional clinical settings and fields aligned with Medical Toxicology including those in analytic laboratories, universities, regulatory agencies, and coroner's offices . . . and thus, encourage more inquiry into the pathophysiology, clinical effects, biomarkers, treatment, and prevention of drug abuse.

PART 1

SYNTHETIC and SEMISYNTHETIC CHEMICALS

Chapter 1

AMPHETAMINE and METHAMPHETAMINE

AMPHETAMINE

HISTORY

Amphetamine is a prototypical, noncatecholamine, sympathomimetic drug; the chemical structures of amphetamine, catecholamine-type neurohumoral transmitters (i.e., epinephrine, norepinephrine, dopamine), and the naturally occurring ephedrine are similar. Although some Chinese herbal folk remedies contained sympathomimetic drugs 5,000 years ago, Nagai did not isolate ephedrine from ma huang (*Ephedra vulgaris*) until 1887. Lazar Edeleano synthesized amphetamine in the same year.[1] Chen and Schmidt introduced ephedrine into Western medicine in the 1920s following their experience with the traditional Chinese herb, ma huang.[2]

Early US medical research on the pharmacologic effects of amphetamine began in the late 1920s during attempts to find an synthetic alternative for the use of ephedrine to treat asthma.[3,4] In the late 1920s, Alles and Prinzmetal introduced the use of racemic β-phenylisopropylamine (*d,l*-amphetamine sulfate) as a decongestant and bronchodilator.[5] Beginning in 1932, the Smith Kline & French Company marketed Benzedrine® (racemic β-phenylisopropylamine) as an inhaler for the treatment of nasal congestion and as an analeptic for the treatment of fatigue. Over the next decade, the medical applications for amphetamine were extended beyond its use as a decongestant and general stimulant to include appetite suppression, and as a treatment for narcolepsy and hyperactivity syndrome in chil-

dren.[6,7] However, in 1937, recognition of the abuse potential of amphetamine and its related compounds resulted in the restriction of the sale of amphetamine as a prescription drug in the United States.[8] Nevertheless, both the Axis and the Allies extensively used amphetamines to counter battle fatigue and to maintain alertness in their troops during World War II; amphetamines were issued in survival kits. After the war, widespread parenteral abuse of amphetamines occurred in Japan. Similar problems with amphetamine abuse occurred in Sweden during the 1950s and early 1960s.

The first major epidemic of amphetamine abuse in the United States occurred from the 1940s to the 1960s.[9] Case reports and articles from the American lay press documented the intravenous (IV) and oral abuse of amphetamine extracts from Benzedrine inhalers during the 1940s and 1950s.[10] Methods of abuse included the ingestion of folded paper strips containing amphetamine from the inhalers and the ingestion of amphetamine-moistened strips that were wrapped in cigarette paper and then dipped in coffee. Abuse of amphetamine from these papers occurred despite the addition of emetine and picric acid by the manufacturers. As a method to reduce the abuse Benzedrine® inhalers, manufacturers replaced the synthetic racemic amphetamine base (β-phenylisopropylamine) with the congener propylhexedrine. Marketing of this new product (Benzedrex®, B.F. Ascher & Co., Lenexa, KS) began in 1949. In 1959, the US Food and Drug Administration (FDA) restricted the use of these inhalers as a prescription drug because of the IV and oral abuse.

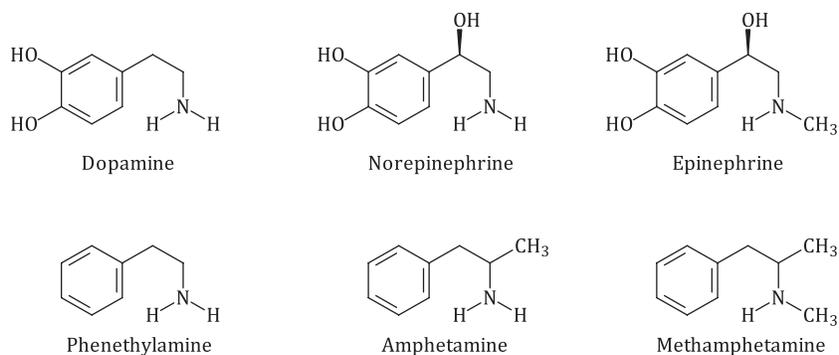
In the United States, IV amphetamine use with inhalant extracts was widespread during the 1950s and 1970s.


FIGURE 1.1. Chemical structures of dopamine, epinephrine, norepinephrine, phenethylamine, amphetamine, and methamphetamine.

Rampant IV drug use with methylphenidate and illicit amphetamines also occurred in the San Francisco drug culture during the 1960s. Possibly promoted by the use of amphetamine compounds commonly prescribed for the treatment of obesity and depression, the illicit use of amphetamine during this time primarily involved the diversion of drugs from pharmaceutical stocks. Initially, amphetamine and the *d*-isomer of amphetamine (dextroamphetamine) were listed as schedule III drugs; however, in 1971, these compounds were added to the list of schedule II drugs (i.e., drugs that have medical use, but significant abuse potential) in an attempt to limit the diversion of these drugs to illicit markets. Widespread IV amphetamine abuse among heroin addicts occurred in Washington, DC, as a result of the disruption of heroin supplies in the early 1970s; amphetamine control measures abruptly ended the substitution of amphetamine for heroin.[11] Until the mid-1970s, medical indications for amphetamine compounds included several common conditions (depression, fatigue, weight reduction). Subsequently, the FDA restricted the legal use of amphetamines to narcolepsy, hyperkinetic behavior in children, and short-term weight reduction. The use of amphetamine compounds for weight reduction is highly controversial; the Canadian government banned the use of amphetamine compounds for weight reduction in 1971. Case reports of amphetamine toxicity were relatively uncommon during the 1980s with use occurring primarily in deserts in the Southwestern United States.[12]

IDENTIFYING CHARACTERISTICS

Structure

Amphetamine (CAS No.300-62-9) is racemic β-phenylisopropylamine consisting of a phenyl ring substituted with an isopropylamino side chain. Amphetamine and the parent compound of sympathomimetic amines (β-phenethylamine) are structurally similar. Addition of hydroxyl substitutions on 3′-(*meta*-) and 4′-(*para*-) positions of the phenyl ring of phenethylamine produces the basic building block of the catecholamine neurotransmitters (epinephrine, norepinephrine, dopamine). Amphetamine compounds are not catecholamines because of the absence of aromatic hydroxyl moieties. Figure 1.1 compares the chemical structure of amphetamine, methamphetamine, and catecholamine neurotransmitters.

The phenylisopropylamines have a chiral center at the α-carbon, which allows enantiomers of differing biologic potencies. The dextrorotatory (*d*-) isomer of amphetamine is commercially available as dextroamphetamine (CAS:51-64-9, Dexedrine®). Alteration of the phenyl ring (e.g., chlorphentermine, fenfluramine) and the ethylamine side chain (e.g., propylhexedrine, diethylpropion, phendimetrazine, phenmetrazine) produces amphetamine derivatives with fewer side effects compared with amphetamine and methamphetamine as demonstrated in Figure 1.2.

Detailed pharmacologic investigations of phenethylamine derivatives demonstrate some basic rules for the structure–activity relationships in this class of compounds. The following 4-position on the phenethylamine nucleus can be substituted resulting in alterations of pharmacologic effect: 1) the amine nitrogen; 2) the carbon atom on the ethyl bridge, which is α to the nitrogen; 3) the carbon atom on the ethyl bridge, which is β to the nitrogen; and 4) the phenyl ring. Addition of a single aliphatic substituent to the nitrogen results in a somewhat prolonged duration of action and increased penetration of the central nervous system (CNS) relative to the nonsubstituted analogue, whereas disubstitution of the nitrogen abolishes nearly all stimulant

activity. Increasing anorectic effects result from the addition of a small aliphatic group to the α-carbon. Substitution of the β-carbon with a hydrogen bonding entity (e.g., hydroxyl moiety as in ephedrine or pseudo-ephedrine) produces strong stereochemical preferences with the (*R*) absolute configuration at this stereo-center having substantially greater adrenergic activity than the (*S*) configuration. Addition of alkoxy substitu-ents to the phenyl ring (e.g., methylenedioxymetham-phetamine [MDMA], mescaline) increases serotonergic activity and imparts hallucinogenic properties to the compound.

Physiochemical Properties

Amphetamine compounds are lipophilic, weak bases with pK_a values ranging from 8.8–10.4. The pK_a of amphetamine is 10.13. The drug base often is combined with HCl to form the hydrochloride salt, which has a melting point of 170–175°C.

5

Terminology

Although amphetamine refers specifically to racemic β-phenylisopropylamine, the term *amphetamine* frequently refers to several structurally related compounds (e.g., methamphetamine, fenfluramine, phentermine, synthetic amphetamine analogues) that share similar pharmacologic and toxicologic properties with amphetamine.[13] Amphetamine is a contraction of the older description of the prototypical compound, α-methylphenethylamine. Old trade names for amphetamine compounds include the following: Benzedrine (*d,l*-amphetamine), Biphetamine (*d,l*-amphetamine), Dexedrine (*d*-amphetamine), and Dexampex (*d*-amphetamine). Street names for amphetamine include Amp, Bennies, Black Beauties, Browns, Cranks, Fives, Goey, Hearts, Louee, Speed, Uppers, and Whiz.[14]

EXPOSURE

Epidemiology

The frequent inclusion of methamphetamine and other structurally similar amphetamine compounds (phenmetrazine, methylphenidate, diethylpropion, propylhexedrine) with racemic and *d*-amphetamine complicates the interpretation of epidemiologic data on the latter. Most studies on the misuse of prescription stimulants do not separate amphetamine from methylphenidate. Smaller studies with face-to-face interviews reported higher misuse rates, whereas larger, multisite studies reported lower rates. In a study of a convenience sample of 1,811 undergraduates at a large-public US research university, the reported lifetime rate of the illegal use of prescription stimulants (*d*-amphetamine, methylphenidate) was 34%.[15] A multisite study of 10,904 US college students reported a lifetime misuse and past year misuse of prescription stimulants (*d*-amphetamine, methylphenidate) of 6.9% and 4.1%, respectively.[16]

Sources

Approved indications for *d*-amphetamine in the United States are narcolepsy and attention deficient hyperactivity disorder (ADHD); off-label uses include the treatment of fatigue in cancer patients and the treatment of dysphoria/depression in combination with antidepressants.[17] Indications for this drug do not include the treatment of obesity, drug dependence, anxiety, or malaise.

Illicit manufacture of amphetamine remains uncommon, partly because the illicit synthesis of amphetamine is more complicated than the illicit synthesis of methamphetamine. Synthesis of amphetamine from benzylmethylketone (phenylacetone, CAS RN:103-79-7) is a reported method of illicit amphetamine production as displayed in Figure 1.3.[18] The addition of formamide or ammonium formate to benzylmethylketone produces the intermediate, *N*-formyl amphetamine. Refluxing *N*-formyl amphetamine with hydrochloric acid produces crude amphetamine that can be refined by extraction, steam distillation, or vacuum distillation. An alternate method for the clandestine synthesis of amphetamine is a 1-step reduction of phenylpropanolamine that directly yields amphetamine base. The production of amphetamine in clandestine laboratories increases the Leuckart-specific impurities (*N*-formyl amphetamine, 4-methyl-5-phenyl-pyrimidine) and yield of amphetamine compared with legally manufactured amphetamine.[19,20]

The source of some illicit racemic or *d*-amphetamine is the diversion of this drug from persons with legitimate prescriptions. Most studies on the use and misuse of prescription stimulants do not separate amphetamine from methylphenidate. In a retrospective review of published studies, the misuse and diversion of prescription stimulants for ADHD ranged from 5–35% among older adolescents and college-age populations.[21] Lifetime diversion rates of stimulant prescriptions from students with legitimate prescriptions ranged from 16–29%, when they were asked to trade, sell, or give the medication to another person.

Methods of Abuse

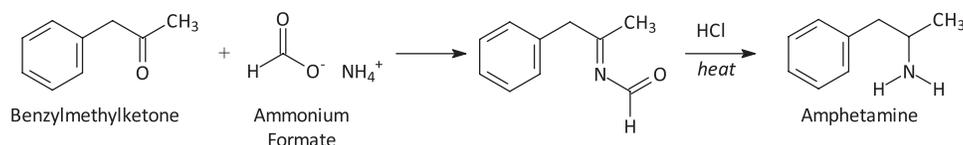
The effects of amphetamine appeal to individuals who interact poorly in social settings and have difficulty internalizing new experiences. Amphetamine use reduces the need for external stimuli by increasing internal arousal mechanisms. In contrast to antisocial,


FIGURE 1.3. Synthetic preparation of amphetamine from benzylmethylketone.

schizoid personalities who tend to *abuse* amphetamines (i.e., the drug interferes with their social, economic, or medical welfare), *misuse* of amphetamines (i.e., using these drugs for illicit purposes) occurs frequently in individuals trying to enhance performance or endurance. Long-term amphetamine use causes psychologic dependence and tolerance, although physical withdrawal symptoms are typically milder following chronic amphetamine use than chronic opiate or barbiturate use.

INTERMITTENT USE

The strong CNS effects of amphetamine persist longer than most other stimulants (e.g., cocaine). Because the use of amphetamine increases physical and mental alertness, these compounds are popular among college students studying for exams, athletes, and truck drivers who require prolonged vigilance or short periods of high energy.[22] Some individuals occasionally ingest 5–20 mg of amphetamine compounds to allay fatigue, elevate mood, or prolong wakefulness. Some professional football players consume amphetamine or other stimulants to induce rage, increase endurance, improve speed, and reduce weight.[23] Amphetamine may improve the performance of tired individuals on repetitive tasks, unless jitteriness or impaired judgment adversely affects performance. The degree of improved athletic performance is relatively small, but this effect may be significant in elite sports.[24] Most sporadic users do not develop a habitual craving for amphetamine. In addition, amphetamine may increase energy expenditures, resulting in excessive fatigue. Drug-induced impairment of judgment may reduce the recognition of the hazardous consequences of fatigue and the subsequent reduction in physical performance. Amphetamine is listed as a prohibited substance by the World Anti-Doping Agency (WADA).[25]

CHRONIC ORAL ABUSE

Following the chronic daily consumption of 20–40 mg amphetamine, a reduction in amphetamine dose may cause lethargy and depression. Although some initial improvement in alertness may occur, chronic amphetamine use eventually reduces mental and physical performance without awareness by the user. Daily amphetamine doses may increase to 50–150 mg as tolerance reduces the euphoric effects of amphetamine.[26] Polydrug abuse is a common comorbidity in amphetamine abusers, in part, because of the adverse effects of chronic amphetamine abuse including insomnia and agitation.

INTRAVENOUS ABUSE

Intravenous amphetamine users usually begin with abuse of oral amphetamines; then, they progress to IV injections to experience a more intense feeling of pleasure. Other pleasurable feelings that follow the IV administration of amphetamine include a sense of extreme mental and physical power, hyperactivity, hyperexcitability, euphoria, and heightened sexual awareness. As tolerance develops, the dose and frequency of the injections increase substantially. During "runs," injection of amphetamine occurs every 2 hours throughout the day for 3–6 days until exhaustion causes the user to fall asleep (i.e., "fall out"). Sleep lasts 12–18 hours or longer with more prolonged runs. With the escalation of the amphetamine dose, frightening perceptive experiences occur including hyperacousia, hallucination, illusions, and paranoia.[27] Complications of this form of abuse include violent and bizarre behavior, slovenly dress, emaciated appearance, and major medical complications.

DOSE EFFECT

Oral doses in habitual amphetamine users often range from 50–150 mg daily. Anecdotal reports suggest that the IV use of amphetamine begins with the injection of 20- to 40-mg doses, but the dose increases substantially as tolerance develops. Experienced IV amphetamine abusers typically inject from 100–300 mg amphetamine per use; however, as tolerance increases the maximum dose during binges may exceed 1 g without the development of severe complications.[27] The presence of multiple confounding factors complicates the determination of dose-effect relationships following the use of amphetamine including underlying cardiovascular disease (e.g., coronary artery disease, angiitis), vascular abnormalities (berry aneurysms), use of other illicit drugs, smoking, reporting bias, duration of abuse, and tolerance. In a case series of 11 patients with neurologic abnormalities associated with amphetamine use, the amphetamine dose ranged from 20–200 mg.[28] However, the chronicity of amphetamine use was not well documented in this case series. In a summary of 9 case reports of myocardial infarction associated with amphetamine use, the route of abuse included chronic oral and nasal amphetamine abuse as well as IV drug use.[29] The limited data and the presence of multiple confounding factors listed above prevented the determination of dose-response relationships. The ingestion of 250 mg amphetamine following by strenuous exercise (i.e., running 1.5 miles) was associated with the development of myoglobinuria and acute renal failure.[30]

TOXICOKINETICS

Absorption

Volunteer studies indicate that peak plasma amphetamine concentrations occur within 1–2 hours following the ingestion of a pharmacologic dose of amphetamine (i.e., 10–25 mg).[31] Complete gastrointestinal (GI) absorption of therapeutic doses of standard-release amphetamine usually occurs by 4–6 hours. Absorption of amphetamine through mucosal surfaces is pH dependent. The illicit use of amphetamines before intercourse as an aphrodisiac by insertion into the vagina (i.e., "balling") suggests that absorption of amphetamine across mucosal membranes also occurs. In a volunteer study, absorption of about 50% and 80% of an amphetamine dose applied to the buccal mucosa occurred within 5 minutes at pH of 8.16 and 9.18, respectively.[32]

Sustained-release preparations are available as resin-bound rather than soluble salts. These compounds produce reduced peak blood concentrations compared with standard amphetamine preparations, but total bioavailability and time to peak concentrations are similar to standard-release preparations.[33] Although experimental studies indicate that amphetamine delays gastric emptying and decreases intestinal motility,[34] there are inadequate data to determine whether this property is clinically significant during amphetamine intoxication.

Distribution

Amphetamine distributes primarily into the kidney, lungs, and brain. The extent of plasma protein binding to amphetamine is relatively low (i.e., about 16–20%) in humans as measured by *in vitro* equilibrium dialysis.[35] Animal studies indicate that there is substantial interspecies variation in the binding of amphetamine. The protein binding of amphetamine in the plasma of mice is about 17% compared with approximately 40% in the rat.[36] The volume of distribution of amphetamine in therapeutic doses administered to humans ranges from about 3–5 L/kg. Following chronic amphetamine abuse, the volume of distribution increases slightly (up to 6 L/kg).[37] Plasma protein binding, rate of absorption, and volumes of distribution of amphetamine enantiomers are similar.[38]

Biotransformation

The biotransformation of amphetamine and methamphetamine is analogous. Figure 1.4 demonstrates the biotransformation pathways of amphetamine and methamphetamine. Metabolites of amphetamine include active compounds (e.g., *p*-hydroxyamphetamine, *o*-hydroxynorephedrine, norephedrine). The major metabolic pathway for amphetamine involves deamination (i.e., hydroxylation at the α-carbon) to phenylacetone; then, oxidation of phenylacetone to benzoic acid followed by the conjugation of benzoic acid with glucuronic acid or glycine.[39] The deamination of amphetamine to phenylacetone probably involves the CYP2C subfamily of cytochrome P450 isoenzymes.[40] Smaller amounts of amphetamine are converted to norephedrine by oxidation. β-Hydroxylation produces the active metabolite *o*-hydroxynorephedrine, which acts as a false neurotransmitter and may account for some drug effect in chronic users. The metabolism of amphetamine varies substantially between various animal species.

Elimination

Normally, the kidneys excrete about 30% of a therapeutic dose of amphetamine over 24 hours, but the actual amount of urinary excretion is highly pH dependent. In an experimental study involving 4 participants, the urinary excretion of unchanged amphetamine was about four times greater than the excretion of deaminated metabolites (hippuric and benzoic acids), when the urinary pH was acidic (pH 5.5–6.0).[41] However, the urinary excretion of deaminated metabolites and unchanged amphetamine was similar during alkaline conditions (urinary pH 7.5–8.0). In a study of 7 volunteers ingesting 10–15 mg amphetamine sulfate, unchanged amphetamine in the urine during the first 16 hours after ingestion accounted for 2.2–4.2% of the administered dose when the urine pH ranged from 7.8–8.1. However, reducing the urine pH to 4.8–5.1 resulted in urinary excretion of 48–73% of the administered amphetamine dose as unchanged amphetamine during the first 16 hours after ingestion.[42]

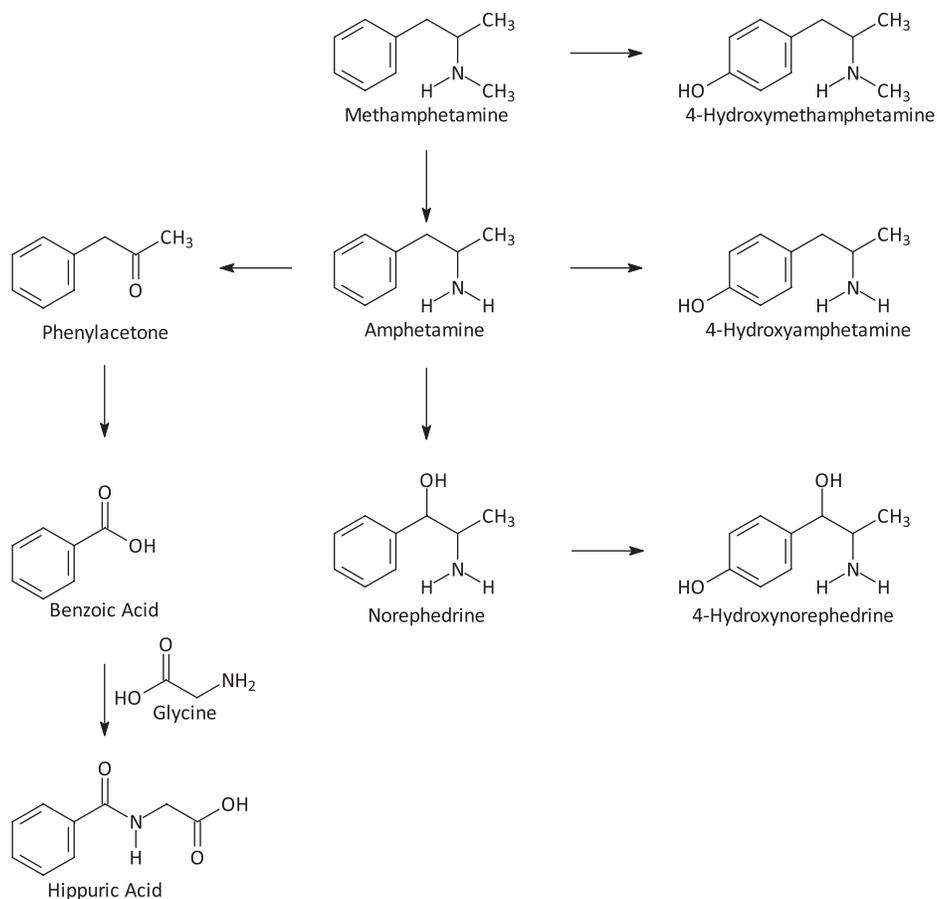
Consequently, the plasma elimination half-life of amphetamine is also urine pH dependent. The plasma half-life of amphetamine following a therapeutic dose is approximately 12 hours under normal urinary pH; however, experimental studies demonstrate that the plasma-elimination half-life ranges from 8–10.5 hours following urinary acidification compared with 16–31 hours following urinary alkalinization.[41] Furthermore, the *d*(+)-amphetamine enantiomer is more rapidly metabolized than the *l*(−)-enantiomer; under alkaline conditions, the mean plasma elimination half-life of the *d*(+)-amphetamine enantiomer was 12.7 hours compared with 17.0 for the *l*(−)-enantiomer.[38] Under acidic urine conditions, renal excretion of unchanged amphetamine is the major route of elimination, and


FIGURE 1.4. Pathways of amphetamine and methamphetamine biotransformation.

the plasma elimination half-life of the enantiomers is similar.

Tolerance

Acute tolerance develops to some of the subjective effects of amphetamine. In a study of healthy volunteers receiving a single 20-mg dose of *d*-amphetamine orally, the initial effects of amphetamine on mood dissipate before peak plasma amphetamine concentrations.[43] The maximum subjective ratings of "feel high" occurred between 1.5–2 hours after ingestion, whereas peak plasma amphetamine concentrations occurred about 4 hours after ingestion. In a study of 16 healthy volunteers, the administration of a second 20 mg dose of *d*-amphetamine 48 hours after the first 20 mg dose produced a slight reduction in the ratings for self-reported "feel drug," but all other mood, behavioral, and physiologic effects of *d*-amphetamine were unchanged.[44] Rapid development of tolerance to some of the side effects of amphetamine derivatives occurs during both chronic oral and IV use.

Maternal and Fetal Kinetics

Amphetamine crosses the placenta.[45] Volunteer studies indicate that *d*-amphetamine readily transfers into breast milk of lactating mothers. In a study of a lactating mother receiving 20 mg racemic amphetamine daily (5 mg every 2 h beginning at 10 AM), the milk/plasma ratio ranged from 2.8–7.5 during the days 10–42 after birth.[46] The corresponding amphetamine concentrations in milk ranged from 55–138 µg/L. In a case series of 4 mothers receiving a median daily *d*-amphetamine dose of 18 mg (range, 15–45 mg), the median milk/plasma ratio was 3.3 (range, 2.2–4.8) with the absolute infant dose of 21 µg/kg daily (range, 11–39 µg/kg/d).[47] Two of the 3 infants tested had detectable concentrations (2 µg/L, 18 µg/L) of *d*-amphetamine in their urine.

Drug Interactions

In general, the coadministration of amphetamine and monamine oxidase inhibitors is contraindicated because of the potential development of severe hypertension, hyperthermia, and altered consciousness. A case report associated the development of hyperthermia (43°C/109.4°F), agitation, seizures, opisthotonus, and coma in a 41-year-old woman following the administration of *d*-amphetamine, amobarbital, and tranylcypromine.[48] She recovered with intensive supportive measures. *d*-Amphetamine is a substrate for CYP2D6 isoenzymes; therefore, potential drug interactions may occur following the concomitant ingestion of fluoxetine, paroxetine, and, to a lesser extent, sertraline. However, there are inadequate *in vivo* human data to indicate that these potential interactions are clinically significant.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

Amphetamine exhibits a wide range of profound physiologic and behavioral effects in animals as well as humans including alteration of sleep, motor activity, appetite, attention, aggression, sexual behavior, learning, classical conditioning, and operant behavior. At high doses, increased hyperadrenergic effects result from excessive norepinephrine-mediated activity. Amphetamine is structurally similar to the neurotransmitters, dopamine and norepinephrine. The physiologic effects of amphetamine result from the enzymatic inactivation, release, and uptake of catecholamine neurotransmitters (dopamine, norepinephrine), and to a lesser extent, the indoleamine, 5-hydroxytryptamine (serotonin) neurotransmitter.[49] Consequently, amphetamine is a potent indirect agonist at the various monoaminergic receptors.

The mechanism of action of amphetamine is similar to other amphetamine compounds and pharmaceutic derivatives; however, the peripheral and central α- and β-adrenergic effects of these compounds vary. Amphetamine crosses the neuronal membrane predominantly via the neuronal monamine reuptake transporters. Direct drug-monoamine competition for the reuptake transporters by amphetamine inhibits the cellular uptake of catecholamines. By inhibiting intracellular vesicular monamine transporter 2, amphetamine reduces vesicular monoamine storage while increasing extracellular monoamines (dopamine, norepinephrine, serotonin).[50] This inhibition of carrier-mediated active uptake process involving catecholamine uptake transporters mediates the cardiovascular and anorexic effects of amphetamine.

CARDIOVASCULAR SYSTEM

Therapeutic doses of amphetamine raise systolic and diastolic blood pressure and initially slow heart rate. High doses of amphetamine cause tachycardia, palpitations, and dysrhythmias. *l*-Amphetamine is a slightly stronger cardiovascular stimulant than *d*-amphetamine.

CENTRAL NERVOUS SYSTEM

BEHAVIOR.   In animal and human studies, low doses of amphetamine are general stimulants that induce alertness, euphoria, increased confidence, gregariousness, enhanced mental and physical activity, and improved self-esteem.[51] Amphetamine increases wakefulness and delays the onset and duration of rapid eye movement (REM) sleep. Withdrawal following chronic use produces the opposite pattern, at least during the first several months after cessation of use. The analgesic effects of amphetamine are minimal with no clinical significance.

Amphetamine increases the concentration of norepinephrine in the periphery and dopamine in the CNS via effects on plasmalemmal and vesicular monoamine transporters (e.g., neuronal dopamine transporter, vesicular monoamine transporter-2).[50] This compound facilitates the release of these neurotransmitters and blocks their reuptake in the presynaptic nerve terminal. The primary site of action in the CNS is the dopamine transporter. The dopamine transporter translocates *d*-amphetamine into the interior of the presynaptic terminal; subsequently, the efflux of dopamine to the synaptic cleft occurs as a result of the release of dopamine from the vesicles in the cytosol. Additionally, *d*-amphetamine inhibits the clearance of dopamine from the synapse by competitively inhibiting the reuptake of dopamine by the dopamine transporter. Cocaine is a much stronger binder of this protein in the synapse than amphetamine.[52]

Amphetamine along with other drugs of abuse (e.g., alcohol, cocaine, heroin, methamphetamine) enhance the release of the neurotransmitter dopamine in the striatum (caudate, putamen, nucleus accumbens) as a result of their effects on the dopamine transporter.[53] Animal studies suggest that brain norepinephrine is responsible for amphetamine-induced locomotor stimulation, whereas dopamine mediates stereotyped behavior similar to amphetamine psychosis in humans as well as craving and addictive behavior.[54]

Children with ADHD (old term: syndrome of minimal brain dysfunction) are characterized by hyperactivity and aggressive behavior. About 75% of these children display improvement in hyperactivity, impulsivity, distractibility, and short-attention span following the administration of amphetamine compounds or analogues. These hyperactive children excrete lower levels of 3-methoxy-4-hydroxyphenylglycol (MHPG), the main metabolite of CNS norepinephrine. Studies of children with and without attention deficit hyperactivity disorder (ADHD) suggest subtle differences in psychoeducational test performance in relation to urinary homovanillic acid and MHPG concentrations.[55] The administration of *d*-amphetamine increases the urinary excretion of MHPG in clinical drug responders, but not in nonresponders.[56]

ANORECTIC PROPERTIES. Although amphetamine compounds do not alter metabolic rates at normal therapeutic doses, the use of these drugs ameliorates some of the effects of hunger and fatigue depending on personality type.[57] Weight loss from therapeutic doses of most anorexiant drugs results almost entirely from reduced food consumption, but increased physical activity contributes somewhat to initial weight reduction. At usual doses, tolerance abolishes anorectic properties after several months. Patients often regain lost weight after tolerance develops or drug administration ceases. Racemic amphetamine (*d*-, *l*-amphetamine) was the first drug used for appetite suppression. However, the dextrorotatory stereoisomer (dexamphetamine) is the active anorectic constituent of the racemic mixture of *d*-, *l*-amphetamine. Consequently, the use of dexamphetamine replaced the administration of racemic amphetamine for the treatment of obesity.

Mechanism of Toxicity

An amphetamine is an indirectly acting sympathomimetic drug that increases the effects of epinephrine in the peripheral sympathetic nervous system and the effects of dopamine, norepinephrine, and serotonin in the CNS. The acute toxicity of amphetamine primarily involves an exacerbation of pharmacologic effects of this drug (i.e., hyperadrenergic state). The psychoactive effects of amphetamine also result from indirect agonist action. Amphetamine displaces catecholamines from binding sites in the storage vesicles after diffusion of these compounds into the cytoplasm. Anxiety, dysphoria, confusion, depression, nausea, vomiting, headache, sweating, apprehension, tremulousness, confusion, and fatigue limit the use of increasing doses of amphetamine despite the development of tolerance.

CARDIOVASCULAR SYSTEM

Excessive sympathetic nervous system activity and vasoconstriction produced by amphetamine causes tachycardia, hypertension, and in susceptible patients, myocardial ischemia and cardiac arrhythmias. Intravenous amphetamine abusers develop the same serious complications (e.g., opportunistic infections) as other IV drug abusers with acquired immunodeficiency syndrome (AIDS).[58]

CENTRAL NERVOUS SYSTEM

Excessive doses of amphetamine cause stereotyped movements, hyperreactivity, dystonic and dyskinetic postures, and convulsions. The administration of high doses of amphetamine to animals causes long-term depression of both dopamine and serotonin synthesis in various regions of the brain. The long-term functional and pathologic consequences of chronic depletion of dopamine and serotonin for humans are unclear.[59] *d*-Amphetamine is a positive reinforcer under controlled laboratory condition in both animals and humans.[60,61]

The etiology of the intracerebral and subarachnoid hemorrhages associated with amphetamine use is probably multifactorial. Inflammation and necrosis of small cerebral arteries (i.e., vasculitis) secondary to particulate foreign bodies or bacterial endocarditis can develop after IV drug use.[62] Subsequently, the hypertension resulting from amphetamine abuse may cause vessel rupture and hemorrhage in the weakened areas of the vessels. However, vasculitis has occurred during oral acute dextroamphetamine intoxication,[63] amphetamine withdrawal, and therapeutic use of amphetamine as an anorectic drug.[28] The presence of vasculitis after exposure by different routes suggests an immunopathologic mechanism.

Postmortem Examination

In animal studies, the IV administration of lethal doses of amphetamine produces pathologic changes resembling experimental hyperthermia.[64] Postmortem examination of dogs administered a lethal IV dose of amphetamine sulfate without anesthesia demonstrate nonspecific findings of renal, vascular, pulmonary, and hepatic congestion as well as hemorrhage in the lungs and GI tract.[65] Cardiac changes include subendocardial hemorrhage, necrosis of myocardial fibers, and hemorrhage in the cardiac valve leaflets. There are no specific postmortem findings that separate amphetamine toxicity from other causes of death. Postmortem examination of the hearts from amphetamine abusers may or may not demonstrate structural abnormalities; cerebral

embolism does not usually occur in amphetamine-related fatalities.

CLINICAL RESPONSE

Illicit Use

Acute intoxication with amphetamine, methamphetamine, or cocaine produces similar clinical effects, manifesting primarily as an accentuation of pharmacologic effects on the cardiovascular and central nervous systems. A major distinguishing feature is the prolonged effect of amphetamine compared with cocaine; many case series report the clinical effects of methamphetamine and amphetamine without distinguishing the 2 drugs. Altered mental status was the most common complaint of 127 patients presenting to the emergency department following exposure to amphetamine or methamphetamine.[66] Thin-layer chromatography indicated that 37% of these patients used either methamphetamine or amphetamine alone and 26% tested positive for both substances; analysis of urine from the remainder of the patients demonstrated other drugs of abuse. Reported CNS symptoms included agitation, anxiety, confusion, delusions, hallucination, and suicidal ideation. Convulsions occurred in 4 of 127 cases.

Following the ingestion of large doses of amphetamine, CNS symptoms begin within 30–60 minutes and persist for 4–6 hours. Large overdoses, sustained-release preparations, and alkalinization of the urine prolong the clinical features of amphetamine toxicity. Table 1.1 outlines the common clinical features of mild to severe amphetamine (or methamphetamine) intoxication. Case reports associate amphetamine abuse with a variety of organ dysfunction including rhabdomyolysis

TABLE 1.1. Categorization of Symptoms of Amphetamine Toxicity by Severity.

Severity	Signs and Symptoms
Mild	Restlessness, talkativeness, irritability, insomnia, tremor, hyperreflexia, mydriasis, flushing, diaphoresis, combativeness, dry mucous membranes, nausea, vomiting, pallor
Moderate	Hyperactivity, confusion, hypertension, tachypnea, tachycardia, premature ventricular contractions, chest discomfort, vomiting, abdominal pain, profuse diaphoresis, mild temperature elevation, impulsivity, repetitive behavior, hallucinations, panic reaction
Severe	Delirium, marked hypertension or tachycardia, hyperpyrexia (over 40°C), convulsions, focal neurologic signs, hypotension, coma, ventricular dysrhythmias

with myoglobinuria, hyperpyrexia (up to 42.8°C/109°F) with hepatorenal dysfunction and rhabdomyolysis,[67] and disseminated intravascular coagulation (DIC) with end organ failure.[68]

BEHAVIORAL ABNORMALITIES

Small doses of amphetamines produce an elevation of mood and a sense of well-being. Larger doses cause apprehension, volatility, excitement, impulsiveness, aggressiveness, and poor judgment.[26] The effects of amphetamine on aggressive behaviors are complex and the changes in behavior depend on several factors including the drug dosage, the environment, and the individual drug user.[69] Behavior abnormalities during amphetamine intoxication include belligerency, moaning, aggression, hyperactivity, anxiety, frank psychosis, and screaming.[66] Although coma may develop suddenly following IV amphetamine use, the loss of consciousness in a patient with a history of amphetamine exposure should initiate a search for other drugs or complications (cerebral hemorrhage, hyperthermia, end organ failure, DIC).

MENTAL DISORDERS

The development of acute psychosis is a common occurrence after chronic, high-dose amphetamine abuse and rarely after a single large dose of amphetamine.[70] Classically, amphetamine-induced psychoses are paranoid psychoses with delusions of persecution and hallucinations under clear consciousness.[71] In a case series of 146 IV amphetamine abusers attending an outpatient psychiatric clinic, about 35% (50 patients) reported 1 or more psychotic episodes characterized by paranoid delusions, stereotyped behavior, visual and/or auditory hallucinations, and delusions of reference.[72] Psychotic reactions may occur in amphetamine abusers with or without a prior history of a psychiatric disorder, but premorbid schizoid/schizotypal personality and early, heavy amphetamine abuse predispose users to psychosis.[73] Case reports associate hallucinations and stereotyped compulsive behavior with the therapeutic use of amphetamine in patients with compensated schizophrenic personalities.[74]

The typical presentation of amphetamine-induced psychosis involves a patient with appropriate affect, paranoid ideations, delusions of persecution, auditory illusions or hallucinations, labile mood, increased sexual drive, delusions of reference, and a sensation of being watched or followed in the presence of a clear consciousness.[75] Thought disorders are uncommon in patients with amphetamine-induced psychoses. Common behavior changes include volatility, suspi-

ciousness, hyperactivity, aggression, hostility, and anxiety. Tactile hallucinations are distinctive features of amphetamine or cocaine abuse. These alterations of thinking cause formication (delusions of parasitosis) and destructive excoriation of the skin. Feelings of suspiciousness and anxiety may become overwhelming in the psychotic patient. Curiosity and a pleasurable suspiciousness become dysphoria and fixed delusions upon which the chronic user may act violently. Stereotyped, compulsive behavior invariably is associated with amphetamine psychosis. This ritualized conduct involves fixed behavioral sequences such as cleaning, sorting, grooming, counting, pacing, and rearranging. Amphetamine-intoxicated patients usually act appropriately given their intense conviction that their paranoid and delusional state is real. Psychotic symptoms usually disappear within several days, but delusions may remain for days to months, particularly if the psychosis developed following chronic use of high doses of IV amphetamine.

MEDICAL COMPLICATIONS

NEUROLOGIC

Acute. Both ischemic and hemorrhagic strokes are well recognized, but relatively rare complications of all routes of amphetamine abuse. Frequently, patients with these complications have a structural abnormality (aneurysm, arteriovenous malformation).[76,77] In a case-control study of 414 individuals with stroke admitted to an urban hospital, 73 patients (34%) were drug abusers (cocaine, amphetamines, heroin).[78] Almost three-quarters of the strokes in this study were hemorrhagic strokes located primarily in the periphery (e.g., subcortical white matter of cerebral hemispheres). The use of amphetamine is also a strong risk factor for hemorrhagic stroke in more social and economically heterogeneous, urban populations.[79] Most of these patients were chronic drugs users; the typical presentation involved the onset of severe headache with or without nausea within a few hours of amphetamine exposure.[80] Few of these patients lost consciousness, but confusion and disorientation occurred frequently. Depending on the location of the intracranial hemorrhage, other unilateral motor or sensory deficits may develop. The admission blood pressure is usually normal, although some patients present with marked hypertension. Seizures often are not part of the initial presentation, but convulsions may complicate convalescence. Intracerebral hematomas may cause brainstem herniation and death. The average mortality of patents with amphetamine-associated intracranial hemorrhage is approximately 30%, and most survivors have mild residual deficits.

Chronic. Habitual use or massive single doses of amphetamine may produce a toxic psychosis characterized by paranoia, delusions, hallucinations, or bizarre violent behavior. The amphetamine user presents as a restless, tremulous individual who is garrulous, suspicious, and anxious. Some individuals become hostile and aggressive. Although memory, orientation, and insight are usually preserved, high or prolonged amphetamine doses may cause the individual to act upon his or her delusions, leading to suicidal or homicidal actions.

CARDIOPULMONARY. Common cardiovascular symptoms and signs during amphetamine intoxication include hypertension, chest pain, palpitations, and dyspnea. Although chest pain frequently occurs following the use of amphetamines, electrocardiographic changes other than sinus tachycardia are uncommon. A few case reports associate the development of an acute myocardial infarction with both recent use of IV amphetamine[81,82] or chronic oral amphetamine abuse.[83] Angiographic studies do not often demonstrate significant coronary artery disease in these relatively young patients. The IV administration of amphetamine has been associated with the development of myocardial injury and pulmonary edema without the presence of significant coronary artery disease. Chest pain occurs in most, but not all, patients presenting to the emergency department with myocardial injury after the use of amphetamine.[29] An acute cardiomyopathy with elevated myocardial band fraction of creatine kinase (CK-MB), mitral valve prolapse, elevated mean capillary wedge pressures, and reduced cardiac output developed 10 hours after IV use of amphetamine.[84] Three hours after the IV administration of 20–60 mg amphetamine, a 24-year-old man presented at an emergency department with pulmonary edema.[85] Coronary angiograms demonstrated patent coronary arteries and a reduced ejection fraction (32%) that normalized after 12 days. The serum creatine kinase concentration peaked at 703 IU on the fourth day.

Case studies of cardiomyopathies following the abuse of amphetamine are rare, and the contribution of drug impurities and predisposing factors to the development of these cardiomyopathies remains unclear. The chronic oral abuse of dextroamphetamine (100 mg/d intermittently for 5 years, continuously for 7 years) was associated with the development of a fatal congestive cardiomyopathy; clinical deterioration occurred during dextroamphetamine withdrawal.[86] The postmortem examination demonstrated normal coronary arteries and a focal myocarditis similar to the myocardial changes associated with pheochromocytomas. Intravenous amphetamine abusers are subject to the same complications (e.g., endocarditis, pulmonary granulomas) as heroin abusers.

Fatalities

Death from the use of amphetamine is relatively rare except following intentional ingestion of massive amounts of amphetamine or secondary to trauma during amphetamine-induced psychosis; these situations usually involve novice amphetamine users. Nontraumatic deaths related to amphetamine typically involve suicide or the intentional ingestion of amphetamine to avoid criminal prosecution. Mechanisms of nontraumatic deaths associated with the misuse or abuse of amphetamine include the following causes: cardiovascular (acute left ventricular failure, ventricular fibrillation), cerebrovascular (subarachnoid or intraparenchymal hemorrhage, cerebral edema), and hyperthermia (seizures, rhabdomyolysis, DIC, cardiovascular collapse). Predisposing factors for the development of fatal reactions to amphetamine use includes the coadministration of other stimulant or arrhythmogenic drugs, hypokalemia, or preexisting cardiovascular disease.[87] IV drug abusers are subject to the potentially fatal complications of illicit IV drug administration including septicemia, fulminant hepatitis, subacute bacterial endocarditis, cor pulmonale resulting from foreign-body granulomas, necrotizing angiitis, and AIDS.[66]

Abstinence Syndrome

A withdrawal syndrome may occur in heavy users during the first week following cessation of use. The abstinence syndrome that follows cessation of chronic amphetamine use is relatively mild compared with CNS depressants (e.g., heroin, sedative-hypnotic drugs). Chronic amphetamine and cocaine use produces a similar abstinence syndrome, but there are no common physical symptoms that characterize stimulant withdrawal.[88] Abrupt discontinuance of amphetamine does not produce seizures or life-threatening symptoms, even in those patients who habitually consume large quantities of amphetamine. The symptoms associated with abstinence syndrome following chronic amphetamine use include a dysphoric mood (depression, irritability, anxiety) and psychomotor agitation along with fatigue, insomnia, hypersomnia, poor concentration, paranoia, akathisia, and drug craving.[89] Myalgias, abdominal pain, voracious appetite, and a profound depression with suicidal tendencies may complicate the immediate postwithdrawal period; the intensity of these symptoms usually peaks 2–3 days after cessation of amphetamine use.

Reproductive Abnormalities

Available evidence suggests that the therapeutic use of *d*-amphetamine during pregnancy does not increase the risk of adverse pregnancy outcomes including teratogenicity.[90,91] The abuse of *d*-amphetamine is associated with prematurity, low birth weight, impaired neurobehavioral development, and increased maternal–fetal morbidity; however, multiple sociologic and economic variables as well as polydrug use complicate the interpretation of the effect of methamphetamine on fetal outcomes.[92]

DIAGNOSTIC TESTING

Analytic Techniques

SCREENING

The most common screening methods for amphetamine in urine involve the detection of the parent compound by immunoassay [Abbott fluorescence polarization immunoassay (FPIA; Abbott Laboratories, Abbott Park, IL); Syva EMIT® (enzyme multiplied immunoassay technique; Siemens Healthcare Diagnostics, Deerfield, IL], radioimmunoassay (RIA; Roche Diagnostic Products Corp., Indianapolis, IN), or thin-layer chromatography (TLC). Colorimetric methods, ultraviolet spectrophotometric procedures, and fluorescence methods are now superseded by immunoassays.[93] The Toxi-Lab TLC® (Varian, Inc., Palo Alto, CA) method can detect amphetamine concentrations ranging from 0.5–3.0 mg/L, but in general the use of TLC methods is less sensitive than the use of immunoassays.[94]

Immunoassays are sensitive methods for screening urine samples for the presence of amphetamine, but these techniques lack specificity. Occasionally, large ingestions of some amphetamine-like compounds may produce false-positive results including over-the-counter inhalers (*l*-isomer of methamphetamine), diet medications (phentermine), or cold preparations (phenylpropanolamine, ephedrine, pseudoephedrine) depending on the urine drug concentration and the type of immunoassay.[95] Relatively high concentrations of illicit amphetamine analogs (methylenedioxyamphetamine [MDA], methylenedioxyethylamphetamine [MDEA], methylenedioxymethamphetamine [MDMA], 3-methoxy-4,5-methylenedioxyamphetamine [MMDA]) also cross-react with some of these screening tests to produce false-positive results, but the cross-reactivity varies between different screening procedures and the concentrations of the substance in the urine sample.[96,97] Metabolism of the antiparkinson drug, selegiline produces *l*- methamphetamine and *l*-amphetamine; however, the ratio of methamphetamine/amphetamine following the biotransformation of selegiline is approximately 2.5 compared with about 10 following the metabolism of methamphetamine.[98]

TABLE 1.2. Cross-Reactivity of Amphetamine Immunoassays.[93]

Drug	RIA	FPIA (TDx®)	EMIT d.a.u.® Polyclonal	EMIT d.a.u.® Monoclonal	EMIT II®
d-Amphetamine	100	90	100	250	100
d,l-Amphetamine	50	100	100	100	67
d-Methamphetamine	2.2	57	30	100	100

Phenylpropanolamine	2	0	30	1.3	0.4
Pseudoephedrine	0	0	30	1	0.3

Abbreviations: RIA = radioimmunoassay; FPIA = fluorescence polarization immunoassay.
*Significant cross-reactivity with urinary metabolites.

Rapid screening methods with gas chromatography/ mass spectrometry separate various sympathomimetic amine compounds, but these confirmation techniques are too technician- and time-intensive for routine use in most hospital laboratories.[99] Phencyclidine, cocaine, caffeine, and barbiturates do not cross-react with reagents in the immunoassays at concentrations up to 1 mg/mL.[100] Table 1.2 lists the cross-reactivity of various immunoassays. The radioimmunoassay (Roche RIA) is relatively specific for d-amphetamine. Cross-reactivity occurs primarily with its major metabolite, p-hydroxyamphetamine, and the illicit hallucinogenic drug, p-methoxyamphetamine. Phenylpropanolamine and β-phenylethylamine produce slight cross-reactivity with radioimmunoassays, but the concentrations of these drugs in urine usually are too low to produce false-positive results except following a severe overdose of these compounds.[101] The excretion of amphetamine is highly pH dependent, and amphetamine abusers may alkalinize their urine to reduce the concentration of amphetamines present in the urine or they may acidify their urine to increase amphetamine elimination.

CONFIRMATORY

Gas chromatography, high performance liquid chromatography, and gas chromatography/mass spectrometry are the most common methods to confirm and to quantify positive results of screening tests for amphetamine.[102,103] The US National Institute on Drug Abuse (NIDA) guideline requires that positive urine samples contain amphetamine concentration exceeding 200 ng/mL. Positive screening tests for amphetamine require confirmation by more specific methods (e.g., gas chromatography/mass spectrometry, high performance liquid chromatography), which separate amphetamine from methamphetamine and other structurally similar compounds. In contrast to gas chromatography/mass spectrometry, liquid chromatography/tandem mass spectrometry does not require sample derivation or hydrolysis. The interassay, interday variability (coefficient of variation) of liquid chromatography/tandem mass spectrometry for amphetamine was approximately 10–12%.[104] Detection limits for amphetamine in serum samples using a solid-phase microextraction method combined with liquid chromatography/electrospray ionization/tandem mass spectrometry was 0.3 µg/L.[105] The use of gas chromatography/mass spectrometry does not necessarily differentiate the illicit use of methamphetamine or amphetamine from the use of prescription drugs that contain these compounds or are metabolized to amphetamine and/or methamphetamine.[106] Interpretation of drug-testing results that include the alleged use of amphetamine/methamphetamine precursor drugs requires analysis of the following factors: detection of parent drug or unique metabolite, ratio of d- and l-enantiomers of methamphetamine and amphetamine, and methamphetamine and/or amphetamine concentrations relative to the history of prescription drug use (see Confirmatory Methods under Methamphetamine).

In addition to the presence of impurities from the clandestine synthesis of amphetamine compounds, drug samples contain many adulterants. Analysis of street samples suggests wide variation in the potency of samples including the absence of amphetamine derivatives in up to 40% of purported samples. These illicit drugs contain varying amounts of phencyclidine, lysergic acid diethylamide (LSD), 2,5-dimethoxy-4-methylamphetamine (STP), cocaine, atropine, mescaline, and strychnine, as well as additives (e.g., cornstarch, maltose, lactose, magnesium silicate, quinine, fibrous material).

STORAGE

Animal studies and examination of exhumed material indicate that amphetamine is fairly stable in the blood and bone marrow over several years of burial.[107] *In vitro* studies indicate that amphetamine is stable in urine samples stored at −20°C in 1% sodium fluoride for 2 years.[108] In a study of amphetamine concentrations in gray-top Vacutainer® (Becton, Dickinson, & Co., Franklin Lakes, NJ) tubes containing 100 mg sodium fluoride and 20 mg potassium oxalate, the mean decrease of the amphetamine concentration at 6 months and 1 year was 31% and 77%, respectively.[109] Amphetamine was less stable than methamphetamine. *N*-ethylbenzamide (CAS RN: 614-17-5) is a thermal decomposition product of the vulcanizing agent zinc ethylphenyldithiocarbamate (CAS RN: 3037-20-2) used in rubber production. The presence of this compound in glass containers sealed with a natural rubber septum may cause false-positive results for amphetamine as measured by gas chromatography,[110] but gas chromatography/mass spectrometry accurately identifies the contaminant.

Biomarkers

BLOOD

ANTEMORTEM. Toxicologic analyses of blood and urine confirm amphetamine ingestion, but these assays are not usually available to guide clinical management; extrapolation of these amphetamine concentrations to expected clinical effects must be done cautiously.

Paranoid delusions, disorganization of thoughts, hallucinations, and poor concentration occurred in a group of 18 patients evaluated for amphetamine psychosis.[111] The peak amphetamine concentration in plasma samples drawn from 15 of these psychotic patients within 24 hours of admission ranged from 0.08–0.64 mg/L. Although these patients received ammonia chloride for urine acidification (pH 5.1–6.1), the timing of the urine acidification in relation to the plasma sample was not reported. There was no correlation between psychiatric symptoms and plasma amphetamine concentrations. The mean peak plasma amphetamine concentration in plasma samples from 8 of the 18 chronic amphetamine abusers administered 200 mg amphetamine sulfate IV followed by urinary acidification (urine pH 5.1–5.4) was approximately 0.4 mg/L (range, 0.36–0.45 mg/L) compared with 0.43 mg/L (range, 0.31–0.60 mg/L) for 10 addicts receiving 160 mg amphetamine IV (urinary pH 5.2–6.4), as measured by gas chromatography/flame ionization detection. No psychotic symptoms occurred in these patients following the administration of these 2 amphetamine doses. The ingestion of approximately 1 g amphetamine chronically by tolerant users produces whole blood concentrations in the range of 2–3 mg/L with little obvious acute signs of intoxication.[112] In a study of amphetamine abusers hospitalized for psychotic behavior, the plasma amphetamine concentration ranged from 0.161–0.530 mg/L in admission peripheral blood samples.[111]

POSTMORTEM. There are limited data on postmortem blood concentrations of amphetamine; therefore, the interpretation of the significance of a specific postmortem concentration of amphetamine requires careful analysis of the circumstances surrounding the death, the behavior of the user, the autopsy, prescription medications, anatomic site of postmortem sample collection, and the reliability of the sample integrity. In particular, the lower ranges of amphetamine concentrations must be interpreted with caution because of tolerance and the subjectivity associated with the determination of the contribution of amphetamine to the cause of death.[113] Consequently, the postmortem amphetamine concentration should not be used alone to determine the cause of death. Postmortem *d*-amphetamine blood concentrations in a case series of amphetamine-related fatalities ranged from 0.5–41 mg/L with an average of 8.6 mg/L.[114] Separation of the enantiomers by chiral derivatization may assist in the determination of the timing of ingestion (i.e., late vs. early) because of the more rapid metabolism of the (*S*)-enantiomer of amphetamine. A (*S*)-/(*R*)-enantiomer ratio of approximately 1 suggests the recent ingestion of amphetamine.[115] The use of some prescription medications (selegiline) may produce small, but detectable amounts of amphetamine and methamphetamine in postmortem blood samples.

URINE

Urine amphetamine immunoassays detect the presence of these compounds following occasional use for

approximately 1–3 days depending on several factors including the dose, duration of use, urine pH, hydration (i.e., urine creatinine, specific gravity), analytic method (sensitivity, specificity, cutoff), and individual metabolic and excretion rates.[93] Because of structural similarities, phenylpropanolamine may cross-react with some amphetamine reagents. The potential for cross-reactivity depends on a variety of factors including the assay, the drug concentration, the extraction procedure (e.g., sodium periodate), and the metabolic products of the drug. At therapeutic concentrations, the cross-reactivity of these drugs to most immunoassays are relatively low, and false-positive results are unusual.[95] Drugs that produce amphetamine as a metabolite include amphetaminil, benzphetamine, clobenzorex, dimethamphetamine, N-ethylamphetamine, fenethylline, fenproporex, and mefenorex. High concentrations of other drugs that cause potential false-positive results on amphetamine immunoassays include the following: deprenyl, famprofazone, fencamine, furfenorex, mesocarb, phenothiazines (trifluoperazine, chlorpromazine, thioridazine),[116] prenylamine, trazodone,[117] bupropion,[118] and quinolones.[119]

Abnormalities

Acute renal failure may develop secondary to acute tubular necrosis (as a result of hypotension), rhabdomyolysis, intravascular coagulation, hypovolemia, or hyperpyrexia. Hypoxemia may result from seizures, noncardiac pulmonary edema, or acute cardiac failure. Pulmonary function tests, except the carbon dioxide diffusing capacity, usually remain normal during chronic amphetamine use. Leukocytosis occurs frequently after amphetamine use; a leukemoid reaction may occur. Case reports associate microangiopathic hemolytic anemia with IV polydrug use including the abuse of amphetamine.[120] In patients with amphetamine-induced intracranial hemorrhages, computed tomography (CT) may reveal intracerebral hematomas, hemorrhage of the thalamus, cerebral edema, or transtentorial herniation. Intracranial hemorrhages are usually located in the cerebral white matter rather than abnormalities in the sites (i.e., basal ganglia, pons, cerebellum) commonly associated with chronic hypertension.

Driving

The primary benefit of low doses of amphetamines is the variable reduction of fatigue.[121] The administration of 5–15 mg of dextroamphetamine to healthy, alert (i.e., nonfatigued) adults does not produce substantial improvement of fatigue[122] or psychomotor skills.[123,124] In a study of 30 student volunteers given 15 mg d-amphet-

amine, objective measures of reaction times increased about 10% above pretreatment values.[125] However, the report did not include the actual data or any statistical analysis. Improvement occurs in some selected tasks that require rapid responses or increased alertness (vigilance, simple reaction time, motor coordination, physical endurance), particularly in restoring baseline performance by fatigued volunteers.[126,127] Enhancement of performance is most likely to occur under conditions of boredom and low intellectual demand, and the positive effects of amphetamines decrease as the complexity of the task increases.[128] Saccadic eye movements are rapid conjugate shifts of gaze that allow changes in visual fixation from 1 object (e.g., pedestrian) to another (e.g., stoplight). Smooth pursuit eye movements stabilize visual images on the retina to optimize visual acuity. Studies in volunteers indicate that 15 mg d-amphetamine orally does not alter saccadic or smooth-pursuit eye movements, whereas the IV administration of the same dose abolishes the effect of fatigue on saccadic movements and reduces saccadic reaction time.[129]

Amphetamine users frequently abuse other drugs including ethanol. The interaction of d-amphetamine and ethanol on psychomotor tasks is complex with volunteer studies demonstrating contradictory results.[130,131] The Simulator Evaluation of Drug Impairment (SEDI) task is a measure of the skills (attention, memory, recognition, decision making, reaction time) required to operate machinery with precision. Although the administration of 10 mg d-amphetamine to 12 healthy volunteers did not alter their scores on the SEDI, this dose of d-amphetamine did attenuate the decrement produced by ethanol on accuracy and reaction time performance.[132] The mean peak ethanol concentration in these volunteers was approximately 100 mg/dL.

A driving stimulation study of healthy volunteers 2 hours after receiving 0.42 mg d-amphetamine/kg body weight indicated some impairment during daytime driving, but not during nighttime driving.[133] The mean dexamphetamine blood concentration was 83 ng/mL immediately prior to testing. The behaviors primarily contributing to this impairment included "failing to stop at a red traffic light," "slow reaction times," and "incorrect signaling." However, there were a large number of the control drivers judged impaired, and there was decreased visual acuity of the left (but not the right) eye of the volunteers receiving the d-amphetamine. There is some evidence that moderate doses (up to 30 mg) of amphetamines increase self-confidence and the acceptance of greater risk. However, these effects are neither strong nor consistent among different individuals.[134] In a study of 36 healthy volunteers, the administration of 10–20 mg d-amphetamine reduced scores on several psychologic measures of impulsivity,[135] whereas

other studies suggested increased impulsivity after *d*-amphetamine administration.[136] The use of *d*-amphetamine doses up to 25 mg is difficult to detect by standardized sobriety tests of motor coordination and observation of behavior.[137] Standard field sobriety tests (horizontal gaze nystagmus, walk and turn test, one leg stand test) are not sensitive measures of the effect of dexamphetamine as measured in adult volunteers receiving 0.42 mg/kg *d,l*-dexamphetamine or placebo.[138]

Impairment of driving skills also may develop during the withdrawal phase from chronic amphetamine abuse because of the presence of exhaustion, fatigue, depression, or agitation. Neuropsychologic testing of paid volunteers did not detect rebound effects following the administration of pharmacologic doses of *d*-amphetamine.[139] Consequently, impairment may occur even at low blood amphetamine concentrations. A study of 11 amphetamine abusers suggested that their accident rate was about 3–4 times higher than the rate expected based on age, sex, and driving exposure.[140] In a retrospective study of Norwegian drivers apprehended on the suspicion of driving under the influence, medical evaluation after the arrest indicated that 73% of the drivers with blood amphetamine concentrations exceeding 0.27 mg/L (2.0 μ*M*) were severely impaired.[141] American pilots selectively used dextroamphetamine during long flights (about 17 h and 35 h) during Operation Iraqi Freedom without obvious side-effects as evaluated by retrospective interviews within 4 weeks of the 94 sorties.[142]

There are few data on the blood amphetamine concentrations associated with driving impairment. Similar to the interpretation of postmortem amphetamine concentrations in blood samples, interpretation of the significance of specific amphetamine concentrations requires careful consideration of surrounding circumstances, behavior, tolerance, and the time of the sample. In a study of 6,094 drivers suspected of driving under the influence (moving traffic violations, sobriety checkpoints, traffic accidents), the mean blood amphetamine concentration was 1.01 mg/L (median 0.80 mg/L) with a range up to 11.9 mg/L.[143] There were no other drugs detected by gas chromatography/mass spectrometry in these blood samples.

TREATMENT

The treatment of amphetamine, methamphetamine, and cocaine intoxication is similar; there are fewer clinical data on the specific treatment of amphetamine or methamphetamine intoxication than cocaine intoxication. There are no unique features of amphetamine intoxication that require treatment different than methamphetamine intoxication (see Treatment under Methamphetamine). Because amphetamine is a weak base, urinary acidification increases the excretion of unchanged drug and causes a decrease of the plasma half-life. However, the clinical efficacy of this therapeutic maneuver on clinical outcome remains doubtful, especially because cardiovascular and renal complications may develop during the use of this procedure during amphetamine intoxication. The treatment of the hallucinations and paranoia associated with amphetamine-induced psychosis typically involves the administration of dopamine agonists (e.g., haloperidol, chlorpromazine). Newer generation antipsychotic medications (e.g., olanzapine) also reduce the symptoms associated with amphetamine-induced psychosis and these medications may be better tolerated than the older antipsychotics (e.g., haloperidol).[144]

METHAMPHETAMINE

HISTORY

While attempting to synthesize ephedrine in Japan, Ogata synthesized methamphetamine in 1919.[145] Later, he sold the license for this process to Burroughs Wellcome Company, which sold methamphetamine in the United States as Methedrine® until this drug was withdrawn from the US market in 1968. During World War II, the Japanese government widely distributed amphetamine compounds in the form of over-the-counter stimulants (philopon, shabu) to their civilian workers as a method to increase worker productivity. After the war, the distribution of large legal stockpiles of methamphetamine ampules contributed to widespread parenteral abuse of methamphetamines in Japan. Between 1945 and 1955, the epidemic of methamphetamine (wake-amine) addiction involved over 2 million Japanese citizens, beginning with writers, musicians, and artists. Later, the abuse of methamphetamine extended to the Korean minorities in Japan.[146] Tight production controls of methamphetamine in Japan began with the Stimulants Control Law of 1951. A massive education program and strict penalties in Japan sharply reduced the abuse of methamphetamine by the mid-1950s. Although drug addiction in the Japanese culture was rare prior to the methamphetamine epidemic, other forms of drug abuse (heroin, methaqualone, 1,2-diphenyl-1-dimethylaminoethane [SPA]) appeared after the initial methamphetamine epidemic.

During the 1960s, one of the treatments of heroin addiction was a liquid form of methamphetamine. Although abuse of methamphetamine initially involved

the diversion of pharmaceutic products, illicit production of methamphetamine began in the early 1960s in San Francisco, a process largely controlled by motorcycle gangs in the California Bay area. Illicit production spread along the Pacific Coast of the United States during the 1960s.[147] Initially, oral methamphetamine was listed as schedule III drugs; however, in 1971, methamphetamine was added the list of schedule II drugs (i.e., drugs that have medical use but significant abuse potential) in an attempt to limit the diversion of methamphetamine to illicit markets. During the 1950s and 1960s, methamphetamine was a common prescription medication for the treatment of depression and obesity with a peak of 31 million prescriptions in the United States during 1967.[147] Parenteral methamphetamine was always listed as a schedule II drug.

During the 1980s, illicit production of a smokable form of (+)-methamphetamine hydrochloride (Ice) began in Japan and Korea. Abuse of Ice spread to Taiwan, the Philippine Islands, Hawaii, and to the mainland United States by the late 1980s. Although the abuse of Ice never reached epidemic proportions similar to freebase cocaine, illicit use and manufacture of methamphetamine spread from California to the Midwest.[147] A third epidemic of methamphetamine abuse via IV and pulmonary routes occurred in Japan during the 1990s following the importation of illicit methamphetamine from China and North Korea.[148] Since the 1980s, clandestinely manufactured methamphetamine replaced legal supplies as the primary source of methamphetamine; Mexican-based distributors and so-called superlabs in California and the southwestern United States replaced local manufacture of methamphetamine. More recently, exports from large Mexican methamphetamine laboratories replaced regional sources as the main supplier of methamphetamine in the United States.[149] Recent data from the US Substance Abuse and Mental Health Services Administration suggest that the current methamphetamine epidemic may have peaked around 2004–2005 with the use of methamphetamine reaching a plateau.

IDENTIFYING CHARACTERISTICS

Structure

Methamphetamine (CAS RN:537-46-2) is the common name for N,α-dimethylphenethylamine (desoxyephedrine, methylamphetamine, phenylisopropylmethylamine). The structures of methamphetamine ($C_{10}H_{15}N$) and amphetamine are similar, but the amino nitrogen in methamphetamine has a methyl group as demonstrated in Figure 1.1. The configuration at the chiral center of methamphetamine results in a dextrorotatory isomer [d-methamphetamine, S-(+)-methamphetamine] and

a levorotatory isomer (l-methamphetamine, R-(–)-methamphetamine] with respect to plane-polarized light.[150] The [α]D25 (specific notation) of pure d-methamphetamine is +14–20°. Metabolism of the antiparkinson drug, selegiline, produces the l-(–) enantiomer of methamphetamine. Dimethylamphetamine is a pyrolysis product of methamphetamine and an illicit stimulant sold in Japan with no medical applications.[151] Although dimethylamphetamine has abuse potential, animal models suggest that this tertiary amino compound is substantially less potent than methamphetamine.[152]

The 2 enantiomers of methamphetamine demonstrate some differences in biologic effects. In volunteer studies of methamphetamine abusers administered IV methamphetamine doses of 0.5 mg/kg, the psychodynamic effects produced by l-methamphetamine and d-methamphetamine are similar; however, the effects of the former are shorter and less desirable as reported by the participants.[153] The abuse liabilities of racemic methamphetamine and d-methamphetamine are similar. Therapeutic doses of methamphetamine produce more prominent central than peripheral effects compared with similar doses of amphetamine as a result of the increased lipophilicity and enhanced CNS penetration of methamphetamine resulting from the N-methyl substitution.

Physiochemical Properties

The addition of a methyl group to amphetamine increases lipid solubility and transport of methamphetamine across the blood–brain barrier. The molecular weight of methamphetamine (freebase) is 149.24 g/mol. Freebase methamphetamine is a lipophilic weak base with a pK_a of 9.87 that is a dark liquid at room temperature; however, methamphetamine hydrochloride (molecular weight 185.74 g/mol) is a white to translucent crystalline solid at room temperature (melting point 170–175°C/338–347°F). Unlike most methamphetamine salts, the vapor pressure of methamphetamine hydrochloride is sufficiently high to allow the efficient smoking of this salt, regardless of the size of the crystals.[154] This hydrochloride salt of methamphetamine is soluble in water, chloroform, and ethanol, but not soluble in ether; extraction of methamphetamine from biologic samples occurs easily following the use of organic solvents at alkaline pH. Both methamphetamine and methamphetamine hydrochloride easily volatilize with heat; consequently, methamphetamine may volatilize during the dry-down or evaporation phase of extraction. Unlike cocaine hydrochloride, methamphetamine hydrochloride volatilizes at 300–305°C (572–581°F) without pyrolysis. Therefore, methamphetamine hydrochloride can be smoked in the salt form, whereas the smoking of cocaine

hydrochloride requires the complicated conversion of this salt to the freebase.

Because of the presence of protonated nitrogen and a chloride nucleophile, the hydrochloride salt of methamphetamine undergoes *N*-demethylation to amphetamine more easily than the methamphetamine base decomposes to amphetamine. The heating of methamphetamine hydrochloride salt to 400°C (752°F) and to 600°C (1,112°F) converts about 5% and 10%, respectively, of the methamphetamine dose to amphetamine.[155] Experimental studies indicate that demethylation and methylation reactions are the major pyrolysis processes at temperatures below 358°C (676°F).[156] At temperatures above 315°C (599°F), amphetamine and dimethylamphetamine form from demethylation and methylation reactions, respectively. Benzyl ethyl trimethylammonium is also a pyrolysis product, and the thermal degradation of this compound produces allylbenzene, *cis*-β-methylstyrene, and *trans*-β-methylstyrene. Above 445°C (833°F), the *l*-isomers of amphetamine and methamphetamine form from the respective *d*-isomer.[156]

Smoking methamphetamine in a tobacco mixture substantially reduces the recovery of methamphetamine compared with the recovery of methamphetamine using a smoking apparatus. In a study of the pyrolysis products from smoking methamphetamine mixed with tobacco in a smoking apparatus, the amount of methamphetamine transferred to tar ranged from 6% to 17%.[154] Major pyrolysis products of a 10- or 20-mg dose of methamphetamine present in mainstream smoke included methamphetamine, amphetamine, phenylacetone, dimethylamphetamine, and *N*-formyl, *N*-acetyl-, *N*-propionyl, and *N*-cyanomethyl methamphetamine compounds. Other minor pyrolysis products include *N*-acetylmethamphetamine, phenyl ester of propanoic acid, and furfuryl methamphetamine (*d,l*-furfenorex).[157] Mainstream smoke from the smoking apparatus contained 14.5% of the initial dose of 50 μg methamphetamine as measured by gas chromatography/mass spectrometry.[158] Other major products of pyrolysis present in the mainstream smoke included phenylacetone (3.1%), *N*-cyanomethylmethamphetamine (1.9%), *trans*-β-methylstyrene (1.7%), and *N*-formyl methamphetamine (1.5%).

Terminology

The street names Speed and Crank typically refer to forms of methamphetamine hydrochloride that contain either pure *d*-methamphetamine or a racemic mixture of *d*- and *l*- methamphetamine enantiomers depending on the process used to produce the illicit methamphetamine.[159] Other names for the solid form of methamphetamine include Base, Fast, Meth, P, Point, Pure, Rabbit, Tail, Wax, and Whiz.[14] Trade names for methamphetamine compounds include Desoxyn® (Ovation Pharmaceuticals, Inc., Deerfield, IL) and the discontinued product, Methampex®. Based on the appearance of methamphetamine crystals, this form of methamphetamine hydrochloride is known as Batu (Hawaii), Crystal Meth, Crystal, Ice, Glass, and Shabu.

EXPOSURE

Epidemiology

Methamphetamine is the second most popular illicit drug (i.e., after cannabis) worldwide with annual global prevalence of about 0.4%; amphetamine is relatively more common than methamphetamine in Europe compared with Asia, Oceania, and North America.[160] Crystalline methamphetamine is one of the most prevalent illicit drugs in the United States; use began in the western United States in the early 1990s and subsequently spread across the United States. The prevalence of methamphetamine use has stabilized since 2000 with a decrease in new methamphetamine users aged 12 years and older beginning around 2005.[161] Based on weighted Internet surveys, the overall prevalence of current nonmedical methamphetamine use in 2005 was 0.27% among 18- to 49-year-olds; the estimated lifetime (i.e., at least once) was 8.9%.[162] The use of methamphetamine is also common in Taiwan and other parts of Asia. Southeast and East Asia are major global sources for methamphetamine production and trafficking, particularly Cambodia, Indonesia, Malaysia, Philippines, and the Mekong region of Vietnam.[163] In a retrospective study of autopsy cases performed in Taiwan between 1991 and 1996, methamphetamine-*related* deaths as defined by a postmortem blood methamphetamine concentration exceeding 0.1 mg/L accounted for 3.4–12.1% of the total autopsy cases.[164] Reviews of drug use in Australia indicate an increase in both importation and local manufacture of methamphetamine.[165] National household surveys of drug use in New Zealand indicate the increased use of crystal methamphetamine between 2003 and 2006 as a result of fewer respondents stopping the use of methamphetamine and more respondents reporting the increased frequency methamphetamine use.[166] The use of methamphetamine in North America varies with geographical location, type of methamphetamine, route of administration, and type of user. Furthermore, the form of methamphetamine changed from nonmedical use to the use of powder methamphetamine, and now to the use of the more potent crystal methamphetamine (Ice) with high purity.[167] The prevalence of methamphetamine use among young adults in

San Francisco has traditionally been high, particularly among homosexual males and IV drug users. In a cross-sectional study of young (median age 22 years) IV drug users in San Francisco, about 50% reported IV drug use within the last 30 days. The IV use of methamphetamine was higher in homosexual males with 60% of homosexual male, IV drug users reporting recent injection of methamphetamine compared with 47% of heterosexual male, IV drug users.[168]

Sources

Therapeutic uses of methamphetamine include the treatment of attention deficit disorder (ADD) and narcolepsy. *d*-Methamphetamine is a prescription drug (Desoxyn®, Abbott Laboratories, Abbott Park, IL) available in the United States as a schedule II drug.

ORIGIN

In contrast to the synthesis of *d*-amphetamine, the production of methamphetamine is relatively simple. Methamphetamine synthesis involves the following general steps: 1) collection and storage of chemicals, 2) isolation of precursors and catalysts from commercial products, 3) cooking (mixing, heating, filtering), 4) extraction of methamphetamine base into organic solvent, and 5) salting (precipitation and drying of water-soluble salt).

METHAMPHETAMINE POWDER. The most common methods of the illicit manufacturing of methamphetamine are phenylacetone (P2P or phenyl-2-propanone), red phosphorus/hydrogen iodide (hydroiodic or hydriodic acid) reduction (Yankee Dope, Red P, or Red, White, and Blue), and ammonia/alkali metal reduction (Nazi Dope). Methamphetamine was originally synthesized in illicit laboratories primarily by reductive amination using the Leuckart reaction, which involved the condensation of phenylacetone (phenyl-2-propanone, P2P) with methylamine in the presence of formic acid and an aluminum amalgam catalyst. This forms an intermediate imine. As the geometry of the imine is flat, the reduction of the imine to methamphetamine proceeds without stereochemical preference. Therefore, the end-product of this synthetic approach is the racemic mixture of *d,l*-methamphetamine, which frequently contains the nonreacted starting material (phenylacetone). The legal restriction placed on phenylacetone in the early 1980s and substantial differences in the pharmacologic activity of the 2 methamphetamine enantiomers resulted in a search for alternative methods of methamphetamine synthesis.

Currently, the most popular methods of illicit methamphetamine synthesis involve the reduction of *l*-ephedrine or *d*-pseudoephedrine either with red phosphorus and hydriodic acid (the "red, white, and blue" method) or with sodium or lithium metal in condensed liquid ammonia (the Birch reduction or the "Nazi" method). The latter method is more common in rural areas. Both these methods produce *d*-methamphetamine with the former process yielding 54–82% of this enantiomer.[150] The substitution of phenylpropanolamine as the precursor in either synthetic process yields amphetamine.

The advantages of the synthetic approach to illicit methamphetamine production include the following: 1) the stereochemistry of the α-carbon is fixed in the starting material, so the reduction yields a pure product containing only the more desirable *d*-methamphetamine, and 2) the reagents and precursors are inexpensive, easily purchased on the commercial and retail level. The legitimate medical and commercial uses of these methamphetamine precursors severely limit attempts to restrict access to these chemicals; *smurfing* is the process whereby criminal individuals and groups attempt to circumvent state and federal pseudoephedrine sales restriction by purchasing small quantities of pseudoephedrine at multiple retail outlets. Alternatives for drug trafficking cartels are importation of ephedrine and pseudoephedrine from Southeast Asia and South America. Figure 1.5 displays both the Leuckart reaction and the reduction of ephedrine to yield methamphetamine. Although extremely uncommon, other synthetic processes for methamphetamine include "dry reduction" using hydriodic acid/red phosphorus with small amounts of water and the reduction of phenylacetone (phenyl-2-propanone) by the mercury-aluminum amalgam reduction.[169]

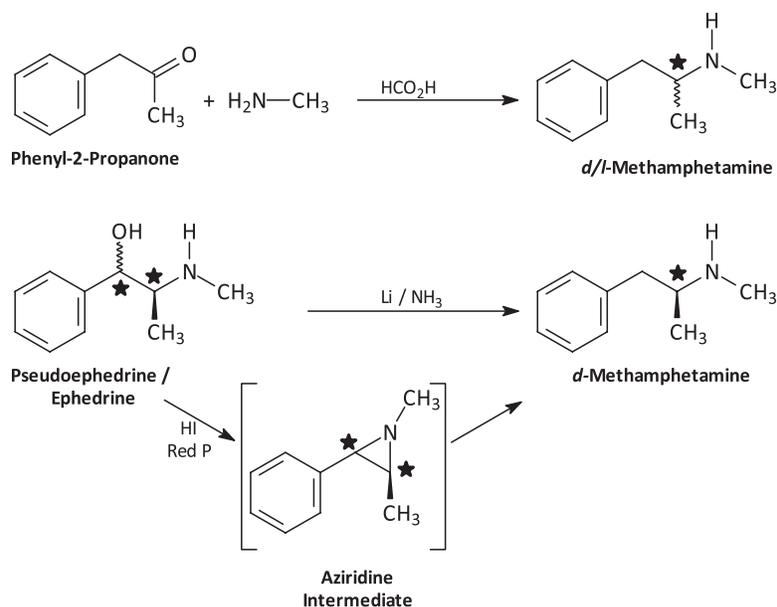
CRYSTAL METHAMPHETAMINE HYDROCHLORIDE (ICE). The slow cooling of hot solutions of saturated solutions of methamphetamine hydrochloride in certain organic solvents produces large, glass-like crystals. In contrast to freebase cocaine, crystal methamphetamine is not the freebase form of methamphetamine. The smokable form of methamphetamine contains relatively pure *d*-methamphetamine in contrast to the racemic mixture of methamphetamine produced by the condensation of phenylacetone and methylamine.[170] The terms Ice, Batu (Hawaii), or Crystal refer to the relatively pure, smokable form of *d*-methamphetamine hydrochloride because this synthetic product appears as transparent, sheet-like crystals.[159] Typically, the production of Ice involves the crystallization of methamphetamine hydrochloride from a saturated solvent solution using the ephedrine- or pseudoephedrine-reduction method. This


FIGURE 1.5. Synthetic routes to methamphetamine. The top scheme is the Leuckart reaction using phenyl-2-propanone (P2P) as a starting material. Reduction of the planar imine intermediate (not shown) results in a racemic mixture of *d*- and *l*-methamphetamine. The lower scheme depicts the reduction of ephedrine or pseudoephedrine (dictated by the stereochemistry of the benzylic hydroxyl) to form methamphetamine directly. Any one of a number of reductive techniques may be used for the reduction of ephedrine or pseudoephedrine to methamphetamine. However, the stereochemistry at the carbon alpha to the amine is maintained with these reductions yielding only the *d*-methamphetamine product.

process crystallizes sheets of *d*-methamphetamine hydrochloride crystals from the cooling of supersaturated, heated solutions of relatively pure *d*-methamphetamine as a result of the separation of the *d*- and *l*-isomers of ephedrine during the reduction process. Using ephedrine or pseudoephedrine as the starting material for Ice generates a more potent mixture that contains pure *d*-enantiomer rather than a racemic 50-50 mixture. The *d*-enantiomer of methamphetamine is several times more active pharmacologically than the *l*- enantiomer.[171]

METHAMPHETAMINE LABORATORIES

Retrospective, cross-sectional studies based on self-administered questionnaires suggest that symptoms experienced by law-enforcement personnel during investigations of clandestine methamphetamine laboratories include headache, sore throat, respiratory tract and mucous membrane irritation, nausea/vomiting, skin irritation, and various CNS symptoms.[172,173] Dermal burns are usually limited to persons directly involved in the production of illicit methamphetamine.[174] These injuries develop following spills, uncontrolled reactions, and/or fires during the manufacturing of methamphetamine. Phosphine gas is a by-product of the red phosphorous method (Red P) method for the clandestine

manufacturing of methamphetamine along with hydrochloric acid and iodine. In a study of a simulated red phosphorous cook, the airborne hydrogen chloride concentration during a 4-hour cooking period was 0.27 ppm; however, peak concentrations during the salting phase of the cook may substantially exceed this concentration.[175] The respirable methamphetamine concentration in this area during the cook was 720 μg/m^3. The anhydrous ammonia method generates ammonia and hydrochloric acid. Fatal concentrations of phosphine gas may form during the use of these types of manufacturing processes.[176] The increased popularity of methamphetamine and the proliferation of clandestine methamphetamine laboratories has caused an increasing incidence of burn injuries associated with laboratory accidents.[177] In a retrospective case-control study of 660 patients aged ≥16 years of age admitted to a burn center in the Midwestern United States, 10% of the 410 patients tested for drugs of abuse were positive for methamphetamine.[178] Burn injuries associated with the volatile process of methamphetamine synthesis are frequently more severe than other burn center patients including a higher incidence of third-degree burns, large burn areas, and inhalation injury.[178,179]

Children are often found during raids on homes with methamphetamine laboratories. The majority of the children display no overt clinical symptoms; however,

clinical features may range from respiratory irritation to agitation, seizures, and fatal sulfuric acid ingestion.[180] These children usually lack supervision and frequently have issues with school performance, criminal behavior, and social isolation. Protocols for the evaluation of these children include the following: 1) decontamination if external contamination is present, otherwise a bath/shower; 2) complete history, mental health, and physical examination within 48–72 hours, unless the presence of symptoms necessitates a medical evaluation earlier; 3) methamphetamine testing for legal purposes (urine drug screen with confirmation, hair samples), and placement in a safe environment.[181]

Methods of Abuse

The pattern of methamphetamine abuse is more frequent and more continuous during the daytime than cocaine abuse, which usually involves episodic use during the evening.[182] Because of the easy synthesis and available supplies of methamphetamine, users typically spend substantially less (i.e., 25%) money than cocaine users.[183] Methamphetamine is listed as a prohibited substance by WADA.[25]

Chronic Oral Abuse

"Parachuting" describes an oral method of methamphetamine abuse involving the swallowing of a methamphetamine-containing, sealed plastic bag with a hole cut on one end to dispense the amphetamine slowly during transit along the GI tract. Alternately, crushed methamphetamine tablets are rolled in a paper wrapper and swallowed. Severe, delayed (i.e., up to at least 42 h) methamphetamine toxicity can occur when the delayed release of large amounts of methamphetamine occurs during transit through the intestines.[184]

Intravenous Abuse

Intravenous methamphetamine abusers represent a subgroup of long-term, chronic drug abusers with a high prevalence of high-risk sexual and antisocial behaviors, comorbid psychiatric disorders, and multiple drug use.[185,186] A "speed freak" is a compulsive methamphetamine abuser, who uses the drug continuously for days during a "run." During this phase, the intense methamphetamine use substantially reduces food consumption, sleep, and personal hygiene. High methamphetamine doses produce extreme suspiciousness, hyperactivity, poor impulse control, or an overt paranoid psychosis that can be associated with unpredictable violent behavior.[187] Stereotyped behavior during these runs includes skin picking, bead stringing, pacing, repetitive actions,

and interminable chattering. Repeated IV injections (1–10 per day) prolong the run until exhaustion, disorganization, paranoia, severe anxiety, confusion, irritability, insomnia, or loss of drug supply terminates use, usually within several days to 1 week.

During the initial phase following cessation of methamphetamine use, exhaustion develops with the methamphetamine abuser sleeping deeply for 24–48 hours and then eating ravenously. Severe depression often occurs after the methamphetamine abuser becomes satiated. The methamphetamine abuser may resume IV drug use to relieve the depression, beginning another run.[188] To relieve anxiety, some methamphetamine abusers combine other IV drugs (e.g., heroin) with IV methamphetamine ("speedballing"). Particularly in the Pacific Northwest, methylphenidate (Ritalin®, Novartis, Basel, Switzerland) is a substitute for methamphetamine.

Occasionally, the rapid escalation of IV methamphetamine doses produces a condition called "overamped." During this situation, elevated blood pressure, temperature, and pulse, along with chest discomfort develop. Additionally, altered consciousness occurs, manifest by the inability to speak or move despite apparent awareness of the environment. Death from overdose is infrequent in tolerant individuals. In fact, habitual high-dose users commonly exhibit no apparent physical signs of dependence other than the obvious signs of economic, social, and emotional deterioration. The chronic abuser becomes unreliable, irritable, paranoid, and unstable, resulting in physical, social, and economic problems. Suicide may occur from either loss of impulse control or severe depression during the exhaustion phase. Adverse psychologic reactions from chronic methamphetamine abuse include anxiety reactions, psychosis, withdrawal reactions (e.g., exhaustion syndrome, biogenic amine depletion syndrome or [BADS]), prolonged depression, and persistent hallucinations.[189]

Smoking

The smoking of methamphetamine hydrochloride does not require conversion to the freebase in contrast to cocaine hydrochloride because of the relatively high volatility of methamphetamine hydrochloride. Typically, the methamphetamine hydrochloride crystals are heated in the base of a glass pipe and the vapors are inhaled ("chasing the white dragon"), *without* drawing the vapors through a coolant liquid that is common during the freebasing of cocaine.

Figure 1.6 displays a methamphetamine pipe. The crystallization of methamphetamine to the hydrochloride salt (Ice) is necessary because the lipid soluble, pure base form of methamphetamine evaporates easily

FIGURE 1.6. Methamphetamine pipe. (Photo courtesy of the US Drug Enforcement Agency).

at room temperatures. All crystals of methamphetamine are "smokable" regardless of the size of the crystal. In a pharmacokinetic study of chronic methamphetamine smokers, the average dose inhaled was approximately 22 mg.[190] Animal and human studies suggest that the pharmacologic effects of methamphetamine by inhalation and by IV route are similar.[191,192]

DOSE EFFECT

Illicit Use

The response to methamphetamine depends on a variety of factors including the percentage of active isomers, the setting, tolerance, and expectations. In a study of volunteers familiar with the effects of methamphetamine, the inhalation of 20–25 mg methamphetamine produced minimal subjective and cardiovascular effects, whereas a 30-mg dose of methamphetamine caused more pronounced and sustained effects.[193] The use of 40 mg methamphetamine produced extreme subjective effects characterized by feelings of omnipotence as well as decreased appetite, difficulty concentrating, insomnia, memory lapses, and intense craving for further doses. Anecdotal reports suggest that the IV use of methamphetamine begins with the injection of 20- to 40-mg doses, but as tolerance develops the dose increases substantially. The typical daily methamphetamine abuser smokes or insufflates 0.5–1 g during a 24-hour period beginning in the morning and continuing every 2–4 hours until sleep ensues. In a case series of 65 current methamphetamine abusers, the estimated mean daily dose of methamphetamine was 720 mg with a range up to 3.5 g.[194] A binge involves the use of methamphet-

amine every few hours until the user can no longer stay awake (i.e., usually 3–4 d). After the binge, the user sleeps for a prolonged period (e.g., 24–48 h) and may resume daily methamphetamine use or start on another binge. Experienced IV methamphetamine users typically inject from 100–300 mg per use with maximum doses exceeding 1 g during binges.[27] As much as 1 g may be injected every 2–3 hours by a speed freak during a binge up to a daily dose of 5–8 g for several days until exhaustion, psychosis, or loss of drug access terminates the "speed run."

Pharmaceutic Use

Medical use of methamphetamine includes the administration of daily doses up to 15 mg for obesity, up to 20–25 mg for ADD, and up to 60 mg for narcolepsy. Most methamphetamine analogues have been voluntarily removed from over-the-counter inhalants. However, the Vicks® inhaler (Procter & Gamble, Cincinnati, OH) is a nasal decongestant containing 50 mg of (*l*-methamphetamine (*l*-desoxyephedrine), menthol, camphor, methyl salicylate, and bornyl acetate. *l*-Methamphetamine has approximately 10% of the central nervous system potency of *d*-methamphetamine.[195]

Fatalities

Determination of a fatal human dose is complicated by interindividual variation including tolerance and variations in purity of illicit drugs.[196] Death from methamphetamine overdose is relatively rare compared with the prevalence of methamphetamine abuse. The minimal lethal methamphetamine dose varies with age and animal species.

ANIMAL

Experimental studies indicate that the IV LD_{50} of methamphetamine in adult, nontolerant monkeys maintained in primate chairs was approximately 15–20 mg/kg.[197] Young monkeys ($LD_{50} = 5$ mg/kg) and adult monkeys in open cages ($LD_{50} = 2$–3 mg/kg) were more vulnerable, particularly when hyperactivity and elevated body heat occur. Chronic administration of escalating doses of IV methamphetamine does not produce toxicity in some animal models. Methamphetamine is twice as toxic in animal models as amphetamine.

HUMAN

A 22-year-old man died 5 days after the ingestion of 140 mg methamphetamine hydrochloride.[198] He developed hyperthermia, hypotension, renal failure, and

hyperkalemia. Chronic methamphetamine users tolerate high doses of methamphetamine. Methamphetamine addicts can inject 1–5 g IV methamphetamine without developing severe complications as a result of the development of tolerance. A 27-year-old man survived after the injection of 75 mg methamphetamine with intensive supportive care after developing DIC, hypocalcemia, and rhabdomyolysis with myoglobinuria.[199] The estimated leakage of 20 g methamphetamine in a body packer caused his death (postmortem cardiac blood, 63.5 mg methamphetamine/L; admission blood, 8.6 mg methamphetamine/L), whereas a fellow body packer survived the estimated leakage of 18 g methamphetamine (admission blood, 7.6 mg methamphetamine/L) following intensive support for severe intoxication.[200]

TOXICOKINETICS

Absorption

ORAL

The pattern of methamphetamine absorption is similar to amphetamine, including absorption from mucosal surfaces.[32] Studies in volunteers indicate that the bioavailability of methamphetamine following ingestion is approximately 60–70%.[190] The average time between ingestion and peak plasma methamphetamine concentration was approximately 2–2.5 hours.[201] Ingestion of an 18-mg dose of methamphetamine hydrochloride by volunteers produced peak plasma concentrations of 0.035–0.038 mg/L with an average lag time from ingestion of about half an hour.[155]

INSUFFLATION

Methamphetamine easily crosses the alveolar and nasal membranes after smoking and insufflation. In a study of 11 methamphetamine abusers receiving up to 50 mg/70 kg body weight intranasally, peak cardiovascular and subjective effects occurred within 15 minutes of administration.[202] However, peak plasma methamphetamine concentrations occur about 4 hours after insufflation. Volunteer studies indicate that the bioavailability of intranasal doses of methamphetamine is near 80%.[203]

SMOKING

Absorption of methamphetamine hydrochloride (Ice) by the lungs is rapid with peak effects occurring within 15–20 minutes of the initiation of smoking.[190] Studies in volunteers indicate that the plasma methamphetamine concentration rises rapidly and then increases slowly over the next 4 hours before declining. Following the smoking of approximately 22 mg methamphetamine hydrochloride by 6 volunteers familiar with the effects of methamphetamine, the peak plasma methamphetamine concentration (0.047 ± 0.0056 mg/L) occurred at 2.5 ± 0.5 hours after initiation of smoking.[193] The peak plasma *amphetamine* (i.e., active metabolite) concentration of 0.003–0.006 mg/L in these volunteers occurred 10–24 hours after smoking began.[193] In a study of 8 experienced methamphetamine users, the mean bioavailability of the delivered doses of methamphetamine via intranasal administration and smoking were similar (i.e., 79% and 67%, respectively), depending on technique.[203] However, the absolute bioavailability of methamphetamine after smoking was substantially less (mean, 37%) than intranasal administration, primarily as a result of the amount of drug retained in the smoking apparatus.

Smoking of methamphetamine in a pipe reduces the bioavailability of the drug both by deposition of active compound in the pipe apparatus and through thermal decomposition. Following insertion of a pipe in an aluminum block heated to about 300°C, approximately 25% of the dose remained in the pipe after the completion of the smoking of a 30-mg dose of methamphetamine hydrochloride by healthy volunteers.[155] During this *in vitro* study, the recovery of intact methamphetamine base from pipes at temperatures of 400°C (752°F), 600°C (1,112°F), and 800°C (1,472°F) was approximately 98%, 88%, and 62%, respectively. The amount of amphetamine formed as a result of the complete pyrolysis methamphetamine was about 1%. The recovery of intact methamphetamine hydrochloride was slightly less than methamphetamine base with the recovery being 81%, 62%, and 38% for these temperatures, respectively.

MUCOSAL SURFACES

Case reports suggest that serious methamphetamine intoxication can develop following the concealment of methamphetamine-containing bags in the vagina. After inserting a bag of methamphetamine that leaked in her vagina, a 20-year-old woman developed seizures and apnea.[204] She recovered after intubation without obvious sequelae; however, her clinical course was complicated by aspiration pneumonia and mild rhabdomyolysis without renal dysfunction.

Distribution

Methamphetamine distributes widely to most parts of the body. The volume of distribution (V_d) of methamphetamine is approximately 3–4 L/kg, which is smaller than the V_d of phencyclidine, but higher than the V_d of cocaine. In a study of volunteers given an average

inhaled dose of 22 mg d-(+)-methamphetamine and an IV dose of 15.5 mg d-(+)-methamphetamine, the volume of distribution in the elimination phase was 3.24 ± 0.36 L/kg and 3.73 ± 0.59 L/kg, respectively.[190] Animal studies suggest that methamphetamine accumulates in the brain following distribution from the plasma. There are substantial differences in the protein binding of methamphetamine between most animal species and humans. The range of protein binding in a study of various animal species (bovine, rat, rabbit, guinea pig, horse, mouse, chicken) ranged from about 61–98%. Therefore, the pharmacokinetics of methamphetamine in animal studies must be extrapolated with caution to humans.[205]

Biotransformation

The metabolism of methamphetamine involves aromatic hydroxylation of the benzene ring at the 4-position, aliphatic hydroxylation of the β-carbon position (minor), N-demethylation to amphetamine, oxidative deamination, N-oxidation, and conjugation of nitrogen.[206,207] The 2 primary metabolites of methamphetamine biotransformation are 4-hydroxymethamphetamine and amphetamine. Amphetamine is both a minor metabolite of methamphetamine and a product of the pyrolysis of methamphetamine. Figure 1.4 demonstrates the biotransformation pathways of methamphetamine. Other minor oxidative metabolites in the urine include norephedrine, 4-hydroxynorephedrine, benzoic acid, and benzyl methyl ketoxime.[37] The metabolism of N-dimethylamphetamine also produces the active metabolite, amphetamine. Aromatic hydroxylation (4-hydroxylation) and N-demethylation of methamphetamine probably involves the cytochrome P450 isoenzyme, CYP2D6.[208] Additionally, other cytochrome P450 subfamilies (CYP2C, CYP3A) also catalyze the demethylation of methamphetamine along with cytochrome P450-independent pathways.[209] Hydroxyclobenzorex is a metabolite of illicit amphetamine that does not occur following the ingestion of therapeutic doses of amphetamines; consequently, the presence of this metabolite indicates illicit drug use.[210] The biotransformation methamphetamine varies substantially between animal species; humans metabolize a relatively smaller portion of methamphetamine and excrete a relatively larger portion of unchanged methamphetamine compared with rats and guinea pigs.[211]

Elimination

Methamphetamine is a highly basic drug with primarily renal elimination; therefore, the renal excretion of methamphetamine is dependent on urine pH, urine flow, and dose.[212] The plasma methamphetamine concentration rises rapidly after smoking and then reaches a plateau after several hours. The geometric mean plasma methamphetamine half-life in volunteers administered methamphetamine by smoking (30 mg in pipe bowl, 21.8 ± 0.3 mg estimated delivered dose) and IV injection (15.5 mg) was approximately 11 hours and 12 hours, respectively, with a range of about 8–18 hours.[190] The plasma elimination half-life of d-methamphetamine is longer than the corresponding l-enantiomer. In a study of 12 methamphetamine abusers administered IV doses of 0.5 mg/kg or 0.25 mg/kg, the plasma elimination half-life for l-methamphetamine ranged from 13.3–15.0 hours compared with 10.2–10.7 hours for d-methamphetamine.[153] The difference between the half-life of the 2 isomers was statistically significant at $P < .0001$. Metabolism of these 2 methamphetamine doses accounted for 58% and 55%, respectively, of the total clearance.

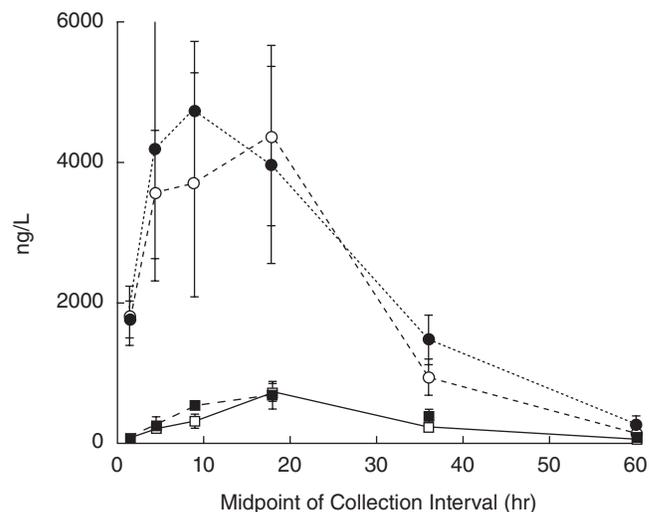
The renal excretion of amphetamine represented about 3–8% of the total methamphetamine clearance, whereas the renal excretion of unchanged methamphetamine accounted for most of the remaining clearance (i.e., about 40% of the total). Figure 1.7 displays the average urinary concentration of methamphetamine and amphetamine during the 60 hours after the administra-


FIGURE 1.7. Urinary concentrations of amphetamine and methamphetamine after smoking 30 mg methamphetamine and the intravenous administration of 15.5 mg methamphetamine.[190] Solid circle = urine methamphetamine concentration after smoking; solid box = urine amphetamine concentration after smoking; open circle = urinary methamphetamine concentration after IV administration; open box = urinary amphetamine concentration after IV administration. (Reprinted with permission from CE Cook, AR Jeffcoat, JM Hill, DE Pugh, PK Patetta, BM Sadler, WR White, M Perez-Reyes, Pharmacokinetics of methamphetamine self-administered to human subjects by smoking S-(+)-methamphetamine hydrochloride, Drug Metabolism and Disposition, Vol. 21, p. 717, copyright 1993.)

tion of methamphetamine via smoking (30 mg in a pipe) and IV (15.5 mg) injection. Under normal conditions (urine pH 6–8), the kidney excretes about 37–54% of an absorbed methamphetamine dose as unchanged methamphetamine within the first 24 hours, 15% as *p*-hydroxymethamphetamine, and 4–7% as amphetamine. In very acidic urine (pH ≤ 5.0) the percentage of unchanged methamphetamine excreted in the urine increases up to 76%, whereas this percentage decreases in very alkaline urine (pH ≥ 8.0) to as little as 2% of the absorbed dose. In a study of 8 volunteers receiving 4 daily 10 mg (low dose) or 4 daily 20 mg (high dose) doses of *sustained-release* (*d*)-methamphetamine, the urinary terminal elimination half-life was approximately 24 ± 7 hours compared with 21 ± 7 hours for amphetamine.[213] Urinary pH was not controlled in this study and about 12% of the urine samples had a pH in excess of 8.0. Analysis of the urine data indicated that more biotransformation and less excretion of unchanged methamphetamine occurred following the high dose than the low dose. Within the first 24 hours after the *first* methamphetamine doses, the mean peak urinary excretion rate for methamphetamine was about 300 ± 200 μg/h (range, 141–600 μg/h) at about 9 ± 8 h after the last dose. In comparison, the mean peak urinary excretion rate for the low methamphetamine dose was 674 ± 571 μg/h (range, 107–1,379 μg/h) at about 10 ± 7 hours after the last dose. Consequently, the fraction of methamphetamine excreted in the urine decreases with increasing doses of methamphetamine, and the amount of urinary methamphetamine is not proportional to the absorbed dose of methamphetamine. During the course of the study from the initial administration of the 4 daily methamphetamine doses to 8 days after the last methamphetamine dose, the peak urinary methamphetamine concentrations for the low-dose and high-dose regimens were approximately 6.14 ± 2.40 μg/mL (range, 3.1–10.9) and 11.3 ± 5.1 μg/mL (range, 5.1–18.5 μg/mL), respectively. Although low amphetamine/methamphetamine ratios (<5%) suggest recent use (i.e., <3–6 h), high intra- and interindividual variability limits the use of this ratio *alone* to determine the time of methamphetamine use.

Tolerance

The progressive decline in subjective and cardiovascular effects despite the presence of high and sustained methamphetamine plasma concentrations indicates the development of tolerance.[193] This tolerance is pharmacodynamic rather than related to changes in the methamphetamine metabolism.[214] Experimental studies indicate that the administration of low doses (10 mg) of methamphetamine for 2 weeks does not alter the pharmacokinetics of methamphetamine.[215] In a 15-day residential

study, healthy volunteers received oral methamphetamine 5 or 10 mg twice daily on days 4–6 and 10–12; the volunteers received placebo on the other days.[216] Compared with baseline placebo effects, positive subjective effects of methamphetamine occurred only on day 4; however, adverse effects persisted through day 12.

Interactions

Case reports suggest that the ingestion of ethanol can potentiate the side effects of methamphetamine.[217] In volunteer studies of methamphetamine addicts, the pattern of alcohol use altered the metabolism of methamphetamine. Simultaneous ingestion of ethanol inhibited the *p*-hydroxylation and *N*-demethylation of methamphetamine.[218] However, in a double-blind, double-placebo, within-subject study of methamphetamine addicts, the administration of ethanol (1 g/kg) did not alter the subjective effects following the IV administration of 30 mg methamphetamine.[219] Case reports associate fatal serotonin syndrome with the use of methamphetamine and moclobemide.[220]

Maternal/Fetal Kinetics

Methamphetamine crosses the placenta following use by the mother during pregnancy. An infant weighing approximately 2.5 pounds died 4 hours after birth via a cesarean section for partial abruption of a low lying placenta.[221] The mother ingested methamphetamine as a diet pill during the entire pregnancy. The postmortem concentration of methamphetamine in the blood, liver, and lungs of the neonate was 0.355 μg/g, 0.246 μg/g, and 0.857 μg/g, respectively. A postmortem case series included positive methamphetamine samples from two 1-month old infants and 5 fetuses dying between the fifth and eighth month of pregnancy.[222] The postmortem fetal blood concentrations of methamphetamine and amphetamine ranged from 0.18–1.2 mg/L and from 0–0.08 mg/L, respectively. In a study of pregnant sheep, methamphetamine crossed the placenta within 30 seconds of IV administration; fetal blood pressure increased 20–37% above baseline along with a drop in fetal oxyhemoglobin saturation and arterial pH.[223] Because of the longer elimination half-life of methamphetamine in the fetal circulation, the fetal methamphetamine concentration eventually exceeded the maternal methamphetamine concentration. Pharmacokinetic studies indicate that methamphetamine diffuses into breast milk following the recreational use of methamphetamine by lactating mothers. The absolute daily infant dose of methamphetamine and amphetamine in methamphetamine equivalents in 2 infants of lactating mothers using methamphetamine was

17.5 µg/kg and 44.7 µg/kg.[224] The mothers self-administered a single IV dose of methamphetamine from their usual source (purity/dose unknown). The authors recommended withholding breast feeding 48 hours after a recreational dose of methamphetamine.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

Methamphetamine stimulates the release of catecholamines from sympathetic nerve terminals, particularly dopamine in the mesocortical, mesolimbic, and nigrostriatal pathways; these structures influence emotions, motivation, reward systems, and motor output.[225] Methamphetamine enters the cytosol via passive diffusion and the membrane-bound catecholamine-uptake transporters, disrupting the pH gradient and facilitating the redistribution of monoamines in the cytosol. This process reverses the normal reuptake mechanism of the catecholamine transporters, resulting in increased movement of catecholamines into the synapses and the central and peripheral α- and β-adrenergic postsynaptic receptors.[1] Both the physiologic effects and mechanisms of action of methamphetamine and amphetamine are similar. The physiologic effects of methamphetamine result from the enzymatic inactivation, release, and uptake of catecholamine neurotransmitters (dopamine, norepinephrine), and to a lesser extent, the indoleamine, 5-hydroxytryptamine (serotonin) neurotransmitters. *In vitro* studies indicate that release of norepinephrine by methamphetamine is about twice as great as dopamine release and about 60-fold greater than serotonin release.[226] The effects of methamphetamine on the brain are complex and include dopaminergic, serotonergic, and GABAergic activity. Animal models suggest that methamphetamine stimulates the release of dopamine via several mechanisms including inhibition of monoamine oxidase and increased efflux of methamphetamine by displacement of storage vesicles. The dopamine transporter (DAT) is the primary site of action of methamphetamine as reflected by the absence of methamphetamine-induced effects in experiments with DAT knockout mice that lack the dopamine transporter.[227] Effects at monoaminergic synapses include the following: inhibition of monamine oxidase (MAO), blockade of uptake, and promotion of neurotransmitter release into the synaptic cleft. The prolonged action of methamphetamine at the synapse depletes available neurotransmitters and results in acute tolerance or tachyphylaxis. In part, this acute tolerance explains the use of escalating doses of methamphetamine during methamphetamine runs or binges.

Cardiovascular

Methamphetamine produces cardiovascular effects only in large doses, but it displays more prominent CNS effects at low doses when compared with amphetamine. A study of 2 champion cyclists demonstrated that the ingestion of 10 mg methamphetamine did not increase the capacity for aerobic exercise as measured by heart rate, minute ventilation, blood lactic acid concentration, and maximum oxygen consumption.[228] However, the administration of 10 mg methamphetamine increased their endurance of anaerobic metabolism and resulted in the ability to maintain higher levels of exercise for longer periods compared with placebo.

Central Nervous System

Experimental data indicate that at least some of the CNS effects of methamphetamine result from the alteration of pre- and postsynaptic dopamine activity in the brain. Animal data suggest an adaptive upregulation of nucleus accumbens dopamine D_1 receptor function during chronic methamphetamine administration.[229] G proteins are the intracellular messengers that link dopamine receptors to the effector enzyme, adenylyl cyclase. Dopamine receptor types are classified based on the ability to stimulate (D_1 receptors, also D_5) or inhibit (D_2 receptors, also D_3 and D_4) adenylyl cyclase through the mediation of the stimulatory or inhibitory G proteins. Although methamphetamine is usually considered more addictive than amphetamine, there are few data on the neurobiologic differences between these 2 structurally similar drugs. In a locomotor activity study of rats, methamphetamine and amphetamine similarly increased dopamine concentrations in the nucleus accumbens and the prefrontal cortex, but the dopamine concentrations in the prefrontal cortex were lower following methamphetamine than amphetamine administration.[230] The administration of amphetamine increased glutamine concentrations in the nucleus accumbens, whereas methamphetamine did not.

Mechanism of Toxicity

Cardiovascular System

Similar to amphetamine, methamphetamine causes excessive sympathetic nervous system activity and vasoconstriction, resulting in tachycardia and potentially, in susceptible patients, myocardial ischemia and cardiac arrhythmias. Dilated cardiomyopathy and congestive heart failure develops in some methamphetamine abusers, but the exact role of methamphetamine and the route of exposure require further clarification.[231] Experimental studies in animals indicate that chronic

methamphetamine administration causes myocyte atrophy, hypertrophy, cellular edema, eosinophilic degeneration, fibrosis, contraction bands, and vacuolization.[232] Ultrastructural changes include myofibrillar hypercontraction, loss of myofilaments, and mitochondrial degeneration.[233]

CENTRAL NERVOUS SYSTEM

The administration of high doses of methamphetamine to animals causes long-term depression of both dopamine and serotonin synthesis in various regions of the brain.[234,235,236] In studies of rodents, the chronic parenteral administration of methamphetamine produces marked alteration of nigrostriatal dopaminergic neurons at doses lower than those required to produce damage by 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP).[237] A study of gerbils administered 2 subcutaneous doses of methamphetamine at 35 mg/kg demonstrated morphologic alteration of mesocortical dopamine nerve fibers and their postsynaptic structure in the frontal cortex 1 week after administration.[238] *d*-Methamphetamine is a positive reinforcer under controlled laboratory condition in both animals and humans.[239,240]

In humans, chronic abuse of high doses of methamphetamine can produce a psychosis that simulates schizophrenia. Following termination of methamphetamine administration, recurrence of the psychotic symptoms may occur after the single use of amphetamine compounds or other drugs (e.g., ethanol).[241] Although the increased release of dopamine at the synaptic vesicles and the blockade of uptake are part of the effect of methamphetamine,[242] the exact mechanism of this neurotoxic effect is unclear. Postmortem examination of chronic methamphetamine users suggests that partial desensitization of dopamine stimulation of adenylyl cyclase activity occurs in the stratum following chronic methamphetamine use (caudate, putamen, nucleus accumbens);[243] however, autopsies of brains from chronic methamphetamine users do not indicate that methamphetamine distributes preferentially to dopamine-rich areas in the brain.[244]

In a study of methamphetamine abusers, positron emission tomography (PET) scanning detected moderate reduction of dopamine transporter concentrations in the caudate and putamen averaging 27.8% and 21.1%, respectively, when compared with controls.[245] A study of former methamphetamine abusers demonstrated a reduction in the density of dopamine transporter in the nucleus accumbens and caudate/putamen, but there was no difference in the density of striatal dopamine D_2 receptors as measured by PET scanning.[246] The long-term functional and pathologic consequences of chronic depletion of dopamine and serotonin (i.e., neuroadaptation) requires further clarification to understand the effects of age, genetics, and duration of use on catecholamine reuptake transporters and presynaptic receptors.[247]

HYPERTHERMIA

Animal models indicate that intrabrain heat production is the primary cause of functional brain hyperthermia; the cerebral circulation dissipates potentially dangerous heat from brain tissue by bringing relatively cooler blood and subsequently removing warmed blood.[248] Although physiologic and behavioral activation is a transient phenomenon, brain temperature may exceed physiologic limits under severe conditions. Methamphetamine stimulates brain metabolism in a dose-dependent pattern while strongly diminishing heat dissipation as a result of peripheral vasoconstriction. The combination of neural activation in the setting of strenuous physical exercise in a hot, humid environment may cause serious elevation of brain temperatures and fatal hyperthermia.

Postmortem Examination

The most common postmortem findings include pulmonary edema, intense visceral congestion, petechial hemorrhages, relatively increased core body temperature, and increased heart weight.[249] Edema and/or congestion typically occurs in multiple organs, particularly the lung and brain.[250] Mechanisms of sudden death include ruptured berry aneurysms and aortic dissection with cardiac tamponade.[251] Hyperpyrexia with subsequent rhabdomyolysis and hepatorenal failure commonly occurs during fatal methamphetamine intoxication.[252]

HEART

Postmortem examination of hearts from methamphetamine abusers may or may not demonstrate structural abnormalities. A 31-year-old woman, who smoked methamphetamine regularly, developed diffuse systemic vasospasm, an acute myocardial infarction and fatal cardiogenic shock.[253] Postmortem examination revealed diffuse transmural myocardial ischemia with patchy interstitial fibrosis and focal acute infarction of the posterior left ventricle and lateral papillary muscle. There was no histologic evidence of an active myocarditis. Histologic examination of methamphetamine addicts, who died suddenly, reveal hemorrhage and congestion of the lungs with either no changes[254] or relatively minor cardiac abnormalities.[255,256] These cardiac abnormalities included both hypertrophy and atrophy

of myocytes, disarray of myofibrils, endocardial hemorrhage, eosinophilic changes, small round cell infiltration, and degeneration of myofibrils including myolysis and contraction band necrosis.[257] Histologic examination of cardiac tissue may reveal varying degrees of coronary arteriosclerosis, but pathologic changes of a myocardial infarction are rare.[258]

CENTRAL NERVOUS SYSTEM

Intracranial abnormalities on postmortem examination of methamphetamine abusers include intracerebral hematoma with cerebral edema and uncal herniation,[259] subarachnoid hemorrhage with or without cerebral aneurysm, and necrotizing angitis.[62] Intraventricular hemorrhage following methamphetamine use is relatively rare compared with intracerebral or subarachnoid hemorrhage.[260] The pathologic changes of the cerebral vasculitis associated with methamphetamine abuse are similar to the changes of polyarteritis nodosa, but these changes involve primarily the large arteries in contrast to the vascular changes associated with typical hypersensitivity angiitis.[261] Postmortem examination of the brains of methamphetamine users indicates that methamphetamine is distributed relatively evenly throughout the brain rather than concentrating in dopamine-rich areas.[262]

CLINICAL RESPONSE

Illicit Use

Methamphetamine, amphetamine, and cocaine produce similar clinical effects with the major distinguishing feature being the prolonged effect of methamphetamine or amphetamine compared with cocaine. Agitation and sinus tachycardia were the most common effects in a retrospective review of 47 methamphetamine exposures in children under the age of 6 years as reported to the California Poison Control System.[263] Seizures occurred in 2 cases (9%). Following the ingestion of large doses of methamphetamine, CNS symptoms begin within 30–60 minutes and persist for 4–6 hours. The onset of symptoms following the inhalation of methamphetamine is much more rapid than ingestion. Unusual complications associated with methamphetamine toxicity include decreased visual acuity secondary to retinal vasculitis[264] or hemorrhage.[265] Methamphetamine abuse is a common cause of rhabdomyolysis. In a retrospective study of 367 emergency department patients with rhabdomyolysis (serum creatine kinase ≥1000 U/L), 43% of the patients had positive urine drug screens for methamphetamine.[266] Case reports document rhabdomyolysis with myoglobinuria, hyperpyrexia, leukemoid

reaction, disseminated intravascular coagulation, and acute renal failure following IV administration of phenmetrazine and methamphetamine.[199] Headache, myalgias, lightheadedness, paresthesias, weakness, and delirium can occur along with hyperthermia.

Suggestive signs of chronic methamphetamine abuse include involuntary repetitive movements (rocking, fidgeting), multiple crusts on the skin (skin picking), extensive dental caries at base of anterior maxillary teeth, cachexia, fatigue, forgetfulness, agitation, and irritability. Case reports associate chronic amphetamine abuse with choreoathetoid movements that typically resolves with 12–24 hours.[267] Rampant dental caries often occur following the chronic abuse of methamphetamine.[268] The characteristic pattern of tooth decay involves the buccal smooth surface of the posterior teeth and the interproximal of the anterior teeth.[269] These caries often progress to complete destruction of the coronal portion of the tooth. The etiology of this pattern is unclear, but contributing factors include xerostomia, bruxism, and lack of oral hygiene.[270] Rare case reports associate methamphetamine abuse with transient visual loss, retinal vasculitis, and retinal hemorrhage.[271,272]

BEHAVIORAL ABNORMALITIES

Most methamphetamine users do not display overt signs of methamphetamine use. An acute anxiety reaction characterized by dysphoria, agitation, and muscle tremors was the most common acute psychiatric complaint of patients presenting to the Haight-Ashbury Clinic (San Francisco, CA) during the epidemic of methamphetamine use during the 1960s.[188]

MENTAL DISORDERS

The prevalence of psychotic symptoms is substantially higher in methamphetamine users than the general population, particularly in dependent methamphetamine abusers. In a cohort of 309 recruited individuals using methamphetamine at least monthly, 13% of the participants screened positive for psychosis with 23% experiencing at least 1 clinically significant symptom of suspiciousness, unusual thought content, or hallucinations in the previous year.[273] Psychotic reactions occur in methamphetamine abusers with or without a prior history of a psychiatric disorder, but premorbid schizoid/schizotypal personality and early, heavy methamphetamine abuse predispose users to methamphetamine-related psychosis.[274] Separating the effects of drug abuse and comorbid psychiatric disorder is difficult because over 50% of individuals with a history of schizophrenia have a coexisting substance

abuse disorder.[275] Furthermore, about 50% of individuals with methamphetamine dependence have comorbid psychiatric disorders other than substance abuse, particular anxiety disorders (e.g., phobias, social/generalized anxiety), mood disorders (major depression), and antisocial personalities.[276] Experimental studies indicate that a single dose of methamphetamine can cause brief (i.e., few hours) increases in psychotic features in schizophrenic patients.[277] In a experimental study of 14 psychotic patients with a history of methamphetamine abuse, the IV administration of methamphetamine in doses up to 640 mg over 1 hour produced psychotic symptoms that persisted up to 5–6 days in 2 patients.[278] The persistence of psychotic symptoms longer than a week in 1 patient was associated with recurrent methamphetamine use.

The clinical presentation of methamphetamine-induced and amphetamine-induced psychoses is similar. In a select population of 31 incarcerated, chronic IV methamphetamine abusers with psychosis, common symptoms included auditory and visual hallucinations, delusions of persecution and reference, thought broadcasting, depression, and suicidal ideations.[279] Orientation, memory, and sensorium usually remain clear, but transient, fluctuating disturbances of consciousness may occur during periods of florid psychosis after heavy methamphetamine use.[280]

Although the acute psychosis induced by methamphetamine resembles paranoid schizophrenia, several characteristics other than the clearing of psychotic symptoms with abstinence separate drug-induced psychoses from paranoid schizophrenia.[281] For example, paranoid schizophrenics typically manifest more clouding of consciousness, auditory hallucinations, thought disorders, flat affect along with less sexual stimulation and stereotyped repetitive behavior than patients with methamphetamine-induced psychoses.[282] About 29% of 31 incarcerated, chronic IV methamphetamine abusers with psychosis suffered from recurrent episodes of psychosis (flashbacks).[279] In this population of methamphetamine users, psychologic stress, cessation of antipsychotic medication, or recurrent drug use precipitated these flashbacks.[283,284] Cocaine- and methamphetamine-induced psychoses are too similar to distinguish based on presenting signs and symptoms. Other drugs associated with psychoses include bromide, alcohol, hallucinogenic drugs, L-dopa, monoamine oxidase inhibitors, and tricyclic antidepressants.

In contrast to the psychosis associated with schizophrenia, the methamphetamine-induced psychosis typically resolves shortly after cessation of drug use; occasionally, the psychotic symptoms are persistent and refractory to pharmacologic treatment despite abstinence. Most patients with methamphetamine-induced psychosis improve within hours to a week of abstinence, but the psychosis may persist over 3–6 months in some patients, particularly after prolonged methamphetamine abuse.[285,286] Spontaneous recurrence of methamphetamine-induced psychoses occasionally develop in patients with a previous history of drug-induced psychosis, particularly during periods of psychologic stress that involve fear of other people.[287,288] The acute relapse into psychosis may occur after an extended asymptomatic period during abstinence from methamphetamine use. The relapse is similar to the previous psychotic episode with typical clinical features including bizarre delusions, auditory hallucinations, delusions with jealous or persecutory content, and incoherence or loosening of association.[289] Ethanol or small doses of methamphetamine (i.e., 50 mg over 5 days) may reactivate the extreme paranoia along with negativistic and suspicious attitudes.[290] Case reports suggest that the use of stimulant drugs can exacerbate the presence of chronic fluctuating somatic and vocal tics (e.g., eye blinking, jaw jerks, hip turning, humming, panting, muscle jerks).[291] Parkinsonism is not a prominent clinical feature of methamphetamine use despite the reduction of dopamine concentrations in the caudate of chronic methamphetamine users.[292]

MEDICAL COMPLICATIONS

CENTRAL NERVOUS SYSTEM.   Cerebrovascular complications associated with methamphetamine abuse include ischemic stroke, intracerebral hemorrhage, and subarachnoid hemorrhage, particularly in the anterior circulation.[293] Frequently, these patients have underlying vascular pathology including atherosclerosis, stenosis, and/or aneurysms. Case reports associate the IV use of methamphetamine with the development of necrotizing angiitis and both ischemic and hemorrhagic stroke including fatal pontine hemorrhage.[294] Cerebral embolism may result from endocarditis complicating IV methamphetamine abuse. Fatal spontaneous intracranial hemorrhage and subarachnoid hemorrhages can occur without evidence of vasculitis or structural abnormalities.[295] Occasional intracerebral hemorrhages occur in the basal ganglia following methamphetamine inhalation.[28,296] Although an ischemic stroke is less common than a hemorrhagic stroke following drug abuse, ischemic strokes do occur after methamphetamine abuse by oral, IV, or pulmonary routes.[297] The cause of these strokes is multifactorial.[298] Although most of the patients with subarachnoid hemorrhages had cerebral aneurysms,[299] most of the cases of thrombosis and intracerebral hemorrhage were not associated with documented vasculitis, vascular malformations, or vasospasm.[78]

CARDIOPULMONARY SYSTEM.   A few case reports associate acute myocardial infarction with the inhalation of methamphetamine.[300] Although these patients frequently have coronary artery disease, some reports associate the inhalation of methamphetamine with the development of myocardial injury and pulmonary edema without the presence of significant coronary artery disease.[253] Epidemiologic data suggests that methamphetamine use modestly increases the risk of acute myocardial infarction. In a study of 11,011 acute myocardial infarctions identified in a quality indicators database from Texas, the adjusted odds ratio for acute myocardial infarction in methamphetamine users was 1.61 (95% CI: 1.24–2.04, $P = 0.0004$).[301] The adjusted confounders included cocaine, alcohol, and tobacco use, hypertension, diabetes mellitus, lipid disorders, obesity, congenital defects, and coagulation abnormalities. Noncardiogenic pulmonary edema following methamphetamine use is very rare. A case report associated the development of pulmonary edema following methamphetamine inhalation with normal pulmonary artery pressures.[302] No cardiac catheterization was performed. Case reports associate the development of acute aortic dissection with hypertensive crises following the use of methamphetamine. In a case series of 109 patients presenting to an urban hospital with aortic dissection, patients with methamphetamine abuse accounted for 5.5% of patients of all ages and 20% of the patients in this series under 50 years of age.[303]

Case studies of cardiomyopathies following the abuse of methamphetamine are rare; the contribution of drug impurities and predisposing factors to the development of these cardiomyopathies remains unclear. Case reports suggest that a cardiomyopathy may develop following the chronic ingestion of methamphetamine without evidence of myocardial necrosis, and the cardiomyopathy typically resolves with cessation of methamphetamine use.[304] A retrospective review of patients ≤45 years of age hospitalized for congestive heart failure suggested that a history of methamphetamine use was associated with a more severe cardiomyopathy.[305] The reduction in left ventricular ejection fraction was statistically significant at $P = 0.004$. However, there was no documentation of a dose response.

PERIPHERAL VASCULAR. Perivascular infiltration of methamphetamine can produce local necrosis, cellulitis, granulomas, and abscess formation. Intra-arterial injection causes intense vasospasm with distal cyanosis, ecchymosis, petechiae, edema, paresthesias, pain, weakness, necrosis, and decreased capillary filling. Immediate intense vasospasm is obvious after intra-arterial injections. Rarely, case reports associate ischemic colitis with methamphetamine use via exposure routes other than IV (e.g., smoking, oral).[306,307]

Fatalities

Death from methamphetamine use alone without underlying cardiac and/or vascular pathology is relatively rare except following intentional ingestion of massive amounts of methamphetamine. In one case series of postmortem examinations with detectable quantities of methamphetamine, two-thirds of fatalities involved with methamphetamine use resulted from violence, including accidents, suicide, and, less often, homicide.[254] The most common nontraumatic, nonoverdose causes of death associated with methamphetamine use include cerebrovascular hemorrhage and heart disease.[308] Rarely, hallucinations and sudden death occur during strenuous exercise in warm environments, particularly in chronic, heavy methamphetamine abusers. Persistent seizures, hyperthermia (>39–40°C/102.2–104°F), coma, severe tachycardia (>160–170 beats/minute), shock, renal failure, severe rhabdomyolysis, and focal weakness are poor prognostic signs.[309,310] Sudden death may occur during restraint of an agitated, chronic methamphetamine abuser in the same manner as the chronic use of high doses of cocaine causes excited delirium with hyperthermia, severe lactic acidosis, and sudden death during restraint occurring in both the hospital setting and police custody.[311,312]

Abstinence Syndrome

As a binge progresses, unpleasant side effects ("tweaking") replace the pleasurable effects of using methamphetamine including dysphoria, depression, fatigue, paranoia, akathisia, anxiety, irritability, confusion, insomnia, and drug craving.[313] The intensity of these symptoms usually peaks 1–3 days after cessation of methamphetamine use. The acute phase of amphetamine withdrawal initially involves increased sleeping ("nod off") and eating followed by anhedonia, irritability, poor concentration, anxiety, and craving-during the depressive phase ("crash"). Typically, these symptoms are mild and most symptoms resolve within several days to 1 week.[314] Although some symptoms may last several weeks, the persistence of severe symptoms beyond 1 week suggests an underlying disease process.[315]

Reproductive Abnormalities

Based on animal studies and limited human data, potential adverse effects of methamphetamine abuse during pregnancy include low birth weight,[316] prematurity, and malformations (cleft palate, cardiac anomalies);[317]

however, multiple sociologic and economic variables as well as polydrug use complicate the interpretation of the effect of methamphetamine on fetal outcomes.[92,318] In general, studies of mothers using illicit drugs (i.e., methamphetamine) demonstrate higher rates of prematurity and intrauterine growth retardation (reduced body weight and length, smaller head circumference) in the drug-exposed group compared with groups of mothers without a history of illicit drug use.[319,320] Case reports also associated methamphetamine use by pregnant women with fetal death and maternal complications (eclampsia, HELLP syndrome, amnionic emboli, death).[321] Follow-up studies of children from mothers using methamphetamine during pregnancy indicate a high rate of behavioral problems (aggressive behavior, problems with peers) and poor school performance (delayed development in math and language achievement), but the psychosocial effects associated with maternal drug use are difficult to separate from the effects of methamphetamine use during the prenatal period.[322] Many of these studies suffer from small sample size, inadequate control groups, poor exposure data, and confounding with other prenatal drug use.

DIAGNOSTIC TESTING

Analytic Methods

Screening

Immunoassays are sensitive methods for screening urine samples for the presence of methamphetamine, but these techniques lack specificity. Newer immunoassays (e.g., EMIT II®) are more specific than older assays (e.g., EMIT d.a.u.®), but some assays cross-react with high concentrations of phenmetrazine, phentermine, benzphetamine, illicit hallucinogenic derivatives (MDA, MDEA, MDMA), antidepressants (bupropion),[323] and some phenothiazine compounds (chlorpromazine, promethazine).[324,325] Gas chromatography is a popular method for screening methamphetamine because of the lack of native fluorescence, significant oxidative electrochemical properties at low voltage, and good ultraviolet absorption characteristics. Methamphetamine elutes early in underivatized samples; some methamphetamine may be lost during the time the detector is turned off for the elution of the solvent front.[150] High concentrations of ephedrine or pseudoephedrine may result in the formation of methamphetamine at the injector port of the gas chromatograph.[326]

Confirmatory

Illicit Use.   The NIDA guideline requires that positive urine samples contain amphetamine and methamphet-

amine concentrations exceeding 200 ng/mL and 500 ng/mL, respectively. Positive screening tests for methamphetamine require confirmation by more specific methods (e.g., gas chromatography/mass spectrometry), which provide structure-specific information. Human studies suggest that the requirement for the presence of >200 ng amphetamine/mL may result in substantial numbers of false-negative samples because of the relatively small amount of amphetamine excreted after the use of methamphetamine as a result of variations in dose and dosing frequency of methamphetamine. The pharmaceutic preparation of methamphetamine in the United States is the *d*-enantiomer; therefore, the presence of both *d*- and *l*-enantiomers suggests the use of illicit methamphetamine unless the individual ingested prescription drugs (e.g., ethylamphetamine, famprofazone, fencamine, fenproporex, prenylamine) that are metabolized to methamphetamine and contain both enantiomers.[327] Separation of these 2 enantiomers requires special chiral columns or derivatizing reagents. High performance liquid chromatography retention time data are not compound-specific like the data obtained by gas chromatography/mass spectrometry methods; therefore, more interference occurs during high performance liquid chromatography procedures compared with gas chromatography/mass spectrometry.[93] In contrast to gas chromatography/mass spectrometry, liquid chromatography/tandem mass spectrometry does not require sample derivation or hydrolysis. The interassay variability (coefficient of variation) of liquid chromatography/tandem mass spectrometry between days for methamphetamine was approximately 10–12%.[328] Detection limits for methamphetamine in serum samples using a solid phase microextraction method combined with liquid chromatography/electrospray ionization/tandem mass spectrometry was 0.04 ng/mL.[105] Enhanced polymer column extraction with gas chromatography/mass spectrometry in scan mode is a simple, reliable method to determine the presence of structurally related amphetamine compounds (e.g., MDMA, MDA, PMA) that cross-react with the methamphetamine immunoassays.[329] The lower limits of detection of these compounds ranges between 5–50 ng/mL. Excessively high temperatures in the injector can cause a confirmed positive for methamphetamine when ephedrine is present in the sample and heat-catalyzed reduction of the ephedrine to methamphetamine occurs. However, the sample should not contain the required 200 ng/mL amphetamine. Phentermine is a structural isomer of methamphetamine; consequently, the similar mass spectrum for these 2 structurally similar drugs requires careful analysis of the retention times and mass spectra for consistency. Derivatization resolves the lack of specificity of methamphetamine mass spectrum.

MEDICINAL USE.   The use of gas chromatography/mass spectrometry does not necessarily differentiate the illicit use of methamphetamine or amphetamine from the use of prescription drugs that contain these compounds or compounds that are metabolized to amphetamine and/or methamphetamine.[106] The interpretation of drug testing results involving the alleged use of amphetamine/methamphetamine precursor drugs requires analysis of the following factors: 1) detection of parent drug or unique metabolite, 2) ratio of *d*-/*l*-enantiomers of methamphetamine and amphetamine, and 3) methamphetamine and/or amphetamine concentrations relative to the history of prescription drug use. In a study of urine samples from 10 volunteers collected during the 12-hour period following the administration of 30 mg *d*-methamphetamine, about 90% of the methamphetamine-positive samples did not contain amphetamine concentrations above the 200 ng/mL standard.[330] Some biologic samples with high concentrations of methamphetamine may not contain detectable concentrations (>50 ng/mL) of *d*-amphetamine.[331] Gas chromatography/mass spectrometry with electro impact or chemical ionization separates amphetamine and methamphetamine from related amines including ephedrine, phenylpropanolamine, phentermine, and synthetic amphetamine analogues (e.g., methylenedioxymethamphetamine).[332]

Medicinal drugs that produce amphetamine or methamphetamine as metabolites include the following: amphetaminil, benzphetamine, clobenzorex, deprenyl, dimethylamphetamine, ethylamphetamine, famprofazone, fencamine, fenethylline, fenproporex, furfenorex, mefenorex, mesocarb, prenylamine, and selegiline. Medications with unique metabolites include 4-hydroxyclobenzorex (clobenzorex), famprofazone (3-hydroxymethylpyrazolone, *p*-hydroxydesmethylfamprofazone), fenethylline (7-carboxymethyltheophylline), fenproporex (dihydroxyfenproporex, hydroxyfenproporex), furfenorex (1-phenyl-2-[*N*-methyl-*N*-γ-valerolactonylamino]-propane), mefenorex (hydroxymethoxymefenorex, hydroxymefenorex), and prenylamine (diphenylpropylamine).[327] The Vicks® inhaler contains 50 mg of *l*-methamphetamine (desoxyephedrine). Therapeutic use of these inhalers does not usually produce positive results on currently available immunoassays, but excessive use of these inhalers potentially may produce false-positive results.[333] Although the Vicks® inhaler sold in the United States contains 50 mg *l*-methamphetamine, Vicks® inhalers from other countries may contain different concentrations of enantiomers.[334] Enantiomeric separation using chiral chromatography or derivatization techniques (e.g., chiral gas chromatography/mass spectrometry or high performance liquid chromatography) differentiate the use of Vicks® inhaler from the use of racemic methamphetamine.[335] Currently, the common reduction process for methamphetamine production yields enantiomerically pure *d*-methamphetamine. Consequently, the detection of essentially pure *l*-enantiomers of methamphetamine and amphetamine indicates the use of these inhalers. Metabolism of prescription drugs that produce only the *d*- and/or *l*-enantiomer include benzphetamine (*d*-enantiomer), deprenyl (*l*-enantiomer), dimethylamphetamine (*d*-enantiomer), ethylamphetamine (*d*- and *l*-enantiomer), famprofazone (*d*- and *l*-enantiomer), fencamine (*d*- and *l*-enantiomer), fenproporex (*d*- and *l*-enantiomer), prenylamine (*d*- and *l*-enantiomer).[327]

HAIR.   Methods for the quantitation of methamphetamine in hair samples include liquid chromatography/mass spectrometry and gas chromatography/mass spectrometry (gas chromatography/mass spectrometry). Liquid chromatography/mass spectrometry is highly sensitive and reproducible, whereas capillary gas chromatography produces a sharp peak and electron ionization produces highly reproducible mass spectra. Gas chromatography/mass spectrometry coupled with micropulverized extraction, aqueous acetylation and microextraction by packed sorbent allows the determination of methamphetamine in a 1 mg hair specimen with <20% deviation from the lower limit of quantitation (0.2 ng/mg).[336]

STREET SAMPLE ANALYSIS

Impurities appear during the illicit manufacture of methamphetamine as a result of incomplete reactions and inadequate purification of intermediate and final products. Methamphetamine may contain additives (e.g., methylsulfonylmethane or dimethyl sulfone) or adulterants (e.g., other stimulants) as a result of additions to the methamphetamine after the synthetic process. There are several routes of methamphetamine synthesis, and each route produces unique organic impurities. Methods for profiling impurities in illicit methamphetamine include gas chromatography with flame ionization detector,[337] high performance liquid chromatography using column switching,[20] and gas chromatography/mass spectrometry after liquid/liquid extraction with organic solvents,[338] headspace solid phase microextraction,[339] or thermal desorption.[340] Analysis of illicit samples with these methods provides useful information regarding drug sources and trafficking routes.[341]

The presence of nonreacted phenylacetone or the presence of a racemate in an illicit drug sample of methamphetamine suggests the use of the Leuckart

method of methamphetamine synthesis. α-Benzyl-phenethylamine derivatives are the most common contaminates of the reductive amination of phenylacetone using the Leuckart procedure to produce amphetamine and methamphetamine.[342] Side reactions and incomplete conversions during the Leuckart process result in a variety of impurities and intermediate products, including benzyl methyl ketone, dibenzyl ketone, formamide, di(1-phenylisopropyl) formamide, formic acid, methylamine, N,N-dimethyl amphetamine, N-formyl amphetamine, di(1-phenylisopropyl)amine, benzylamine, and several pyrimidine and pyridine compounds.[343,344] Benzaldehyde is a common contaminant of methamphetamine produced when phenylacetone (P2P) is synthesized from the reaction of benzaldehyde with nitroethane followed by hydrogenation with iron and hydrochloric acid. However, the presence of benzaldehyde is not specific for this type of reaction.

Impurities from the clandestine synthesis of methamphetamine from ephedrine or pseudoephedrine via hydriodic acid include 1-benzyl-3-methylnaphthalene and 1,3-dimethyl-2-phenylnaphthalene.[345] An aziridine is a potentially toxic intermediate of the reduction of ephedrine, probably through the intermediate formation of iodoephedrine with the Red P/HI method. The Birch reduction of ephedrine or pseudoephedrine to form methamphetamine involves treatment of the starting material with an alkali metal (e.g., lithium or sodium in liquid ammonia). During this process, an over-reduction causes the partial reduction of the aromatic ring along with the production of small amounts of the cyclohexadienyl analogue of methamphetamine. Several of these impurities (e.g., α-benzyl-N-methyl-phenethylamine or BNMPA) are pharmacologically active, but the toxic effects of these impurities remains relatively unreported.[346,347] Rarely, lead contaminates illicit methamphetamine.[348] Although postproduction adulteration is the most likely cause of lead contamination in illicit methamphetamine, potentially lead can contaminate the methamphetamine syntheses when lead acetate and phenyl acetic acid are used to produce phenylacetone (phenyl-2-propanone).

STORAGE

Methamphetamine is relatively stable in properly stored and frozen postmortem samples. Animal studies and examination of exhumed material indicate that methamphetamine is fairly stable in the blood and bone marrow over several years.[349] *In vitro* studies indicate that methamphetamine is stable in urine samples stored at −20°C in 1% sodium fluoride for 2 years.[108] In a study of methamphetamine concentrations in samples stored at ambient temperature in gray-top Vacutainer® (Becton

Dickinson, Franklin Lakes, NJ) tubes containing 100 mg sodium fluoride and 20 mg potassium oxalate, the mean decrease in methamphetamine concentrations at 6 months and 3 years was 9.31% and 38.1%, respectively.[109]

Biomarkers

The time course of the deposition of methamphetamine and amphetamine in oral fluids and plasma is similar, but the concentrations of these drugs are higher and the detection time shorter compared with urine. In a study of 5 volunteers receiving 10 mg or 20 mg methamphetamine daily for 4 days, the mean detection times were 0.02 and 4.8 hours, respectively, using the recommended cutoff (5 ng methamphetamine/mL, >2.5 ng amphetamine/mL).[350] The mean times to last positive specimen at this cutoff were 4.0 hours and 20.6 hours, respectively. Analysis of urine samples had higher detection times and rates compared with oral fluids.

BLOOD

THERAPEUTIC USE.   Following the ingestion of a liquid dose of 12.5 mg methamphetamine, the mean peak plasma concentration of methamphetamine was about 0.02 mg/L as measured by gas chromatography with flame-ionization detection.[201] Volunteer studies indicate that the central (arousal) and peripheral sympathomimetic effects (i.e., elevated heart rate and blood pressure) begin at plasma methamphetamine concentrations near 0.005 mg/L and 0.02 mg/L, respectively.[351] Doses of methamphetamine in clinical studies do not usually exceed 60 mg, which corresponds to a maximum blood methamphetamine concentration of approximately 0.1–0.2 mg/L.[352] The actual physical effects of methamphetamine are somewhat variable depending on the duration of drug use, psychiatric state, and the situation as well as the methamphetamine concentration. Moderate subjective effects, as defined by a mean score of 38% of the maximum "high" ever achieved, occurred in 6 experienced methamphetamine users following the smoking of 30 mg (inhaled dose of about 22 mg) methamphetamine hydrochloride.[193] The mean peak plasma concentration of methamphetamine was approximately 0.047 mg/L.

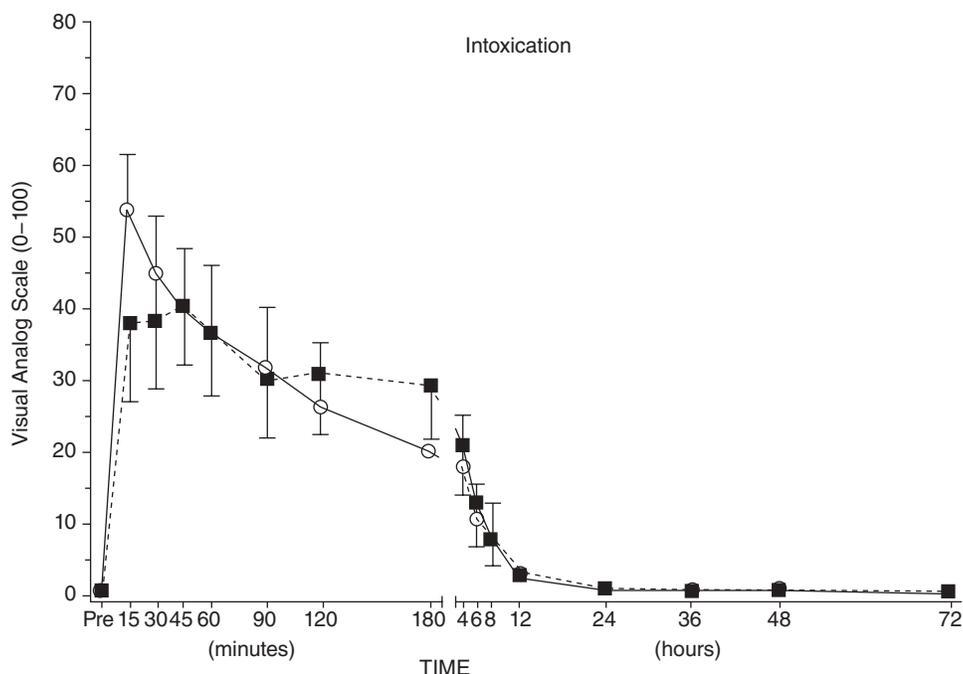
The clinical effects of methamphetamine decline more rapidly than the concentration of methamphetamine in the plasma as a result of acute tolerance to the effects of methamphetamine. Consequently, the acute subjective and cardiovascular effects of methamphetamine subside despite the presence of methamphetamine in the plasma. In a study of 8 experienced methamphetamine users, each volunteer received either a 50 mg intranasal dose of methamphetamine along with 10 mg deuterium-labeled methamphetamine


FIGURE 1.8. Subjective effects of intranasal (squares) and smoked (circles) methamphetamine based on Visual Analog Scale (0–100) over 72 hours.[203] Each participant also received 10 mg intravenous deuterium-labeled methamphetamine with the intranasal or smoked dose of methamphetamine. (Reprinted by permission from Macmillan Publishers Ltd: Clinical Pharmacology & Therapeutics, Vol. 74, DE Harris, H Boxenbaum, ET Everhart, G Sequeira, JE Mendelson et al., The bioavailability of intranasal and smoked methamphetamine, p. 484, 2003.)

intravenously or 40 mg of smoked methamphetamine along with 10 mg deuterium-labeled methamphetamine IV.[203] Subjective effects of methamphetamine were measured by a visual analog scale from 0–100 with zero being no effect and 100 being "most ever." Figure 1.8 displays the time course of the visual analog scale for intoxication following the administration of methamphetamine via smoking and intranasal administration.

Illicit Use. The clinical effects of methamphetamine depend, in part, on the presence of tolerance. In a case series of 7 chronic methamphetamine abusers exhibiting signs of violence and irrational behavior, the blood methamphetamine concentrations ranged from 0.15–0.56 mg/L as measured by gas chromatography with hydrogen-flame ionization detector.[353] Of 1,265 blood samples submitted for analysis from individuals involved in criminal activity (driving under the influence, rape, homicide, under influence of a controlled substance), about 12% (157 samples) tested positive for methamphetamine.[354] The methamphetamine concentrations ranged from 0.025–2.03 mg/L with a mean concentration of 0.308 mg/L.

Overdose. A review of animal and postmortem data suggested that mild, moderate, and serious intoxications occur at blood methamphetamine concentrations near

0.3 mg/L, 0.4–0.5 mg/L, and 3 mg/L, respectively.[355,356] Following a methamphetamine overdose, blood methamphetamine concentrations in the range of 1–2 mg/L are associated with severe methamphetamine intoxication (hyperthermia, DIC, renal failure, rhabdomyolysis) and death. A 33-year-old male was arrested for driving erratically, and his initial whole blood methamphetamine concentration was 0.23 mg/L.[357] About 3–4 hours after ingesting an unknown amount of methamphetamine, he developed confusion, agitation, and diaphoresis, followed by seizures, hyperthermia, and a marked sinus tachycardia. The serum methamphetamine concentration was 1.94 mg/L. He later developed hyperthermia and fatal DIC. Following a methamphetamine overdose, the plasma methamphetamine concentration 1 hour prior to death from hyperthermia and multiorgan failure was 6.74 μmol/dL (approximately 10 mg/L) with a blood ethanol concentration near 50 mg/dL.[358] A 41-year-old man presented to the emergency department with agitation, diaphoresis, marked sinus tachycardia (160 beats/min), hallucinations, and a temperature of 41.6°C (106.9°F).[359] The serum methamphetamine and amphetamine concentrations on admission 6 hours after the injection of methamphetamine were 0.3 mg/L and 0.04 mg/L, respectively. He recovered after a prolonged course of rhabdomyolysis and hepatorenal

failure. Rarely, survival occurs when the blood methamphetamine concentration exceeds 3–4 mg/L. A driver ingested a bag of methamphetamine following a routine traffic stop, and his serum methamphetamine concentration 1 hour later on arrival to the hospital was 9.46 mg/L.[360] He developed dysrhythmias and seizures, but he survived with supportive care. Details of his medical care were not reported. There are few data on the ratio of whole blood methamphetamine/plasma methamphetamine concentrations.

POSTMORTEM.   There are limited data on postmortem blood concentrations of methamphetamine; therefore, the interpretation of the significance of a specific postmortem concentration of methamphetamine requires careful analysis of the circumstances surrounding the death, the behavior of the individual, the autopsy, prescription medications, anatomic site of postmortem sample collection, and the reliability of the sample integrity. In particular, the lower ranges of methamphetamine concentrations must be interpreted with caution because of tolerance and the subjectivity associated with the determination of the contribution of methamphetamine to the cause of death.[164,361]

A study of 413 autopsy reports of cases with detectable methamphetamine in postmortem blood did not find a statistically significant difference ($P = 0.65$) in the mean methamphetamine concentration (2.08 mg/L) between deaths related to the medical effects of methamphetamine and the mean methamphetamine concentration (1.78 mg/L) in deaths not related to the medical effects of methamphetamine.[249] The use of some prescription medications may produce small, but detectable amounts of amphetamine and methamphetamine in postmortem blood samples. The concentration of methamphetamine and amphetamine in postmortem heart blood samples from a 72-year-old woman, who was found dead with a suicide note, was 0.28 mg/L and 0.08 mg/L, respectively.[362] Her list of prescribed medications included selegiline, desipramine, trazodone, and bromocriptine. The source of the methamphetamine and amphetamine was probably the metabolism of selegiline. Consequently, the postmortem methamphetamine concentration should not be used alone to determine the cause of death.

Concentrations.   Most deaths related to methamphetamines are associated with postmortem methamphetamine concentrations exceeding 0.5–1 mg/L. In a series of 13 autopsies in which methamphetamine was the only drug present in toxicologically significant quantities, the methamphetamine concentration in postmortem blood samples (site not reported) ranged from 0.09–18 mg/L with a median of 0.96 mg/L.[363] There is a wide range of

methamphetamine concentrations in blood samples from methamphetamine-related deaths, and the range of methamphetamine concentrations in blood samples from homicides and accidental overdoses usually overlap.[364] In a case series of 23 homicides and 9 accidental overdoses involving only methamphetamine use, the mean (± standard deviation) methamphetamine concentrations in postmortem blood from the 23 homicides and 9 accidental overdoses was 0.66 (±1) mg/L and 0.980 (±1) mg/L, respectively.[365] Amphetamine is a metabolite of methamphetamine, and case reports indicate that the amphetamine concentrations in postmortem blood from fatal cases of methamphetamine overdose are approximately 4–5% of the blood methamphetamine concentration.[366]

Redistribution.   Some postmortem redistribution of methamphetamine likely occurs because of the basic pK_a and the diffusion of methamphetamine from the sites in the pulmonary veins to the left side of the heart.[367] Additionally, failure to ligate the femoral vein during aspiration of postmortem blood may cause an increase in redistribution of methamphetamine from central to peripheral blood in cases involving the ingestion of large amounts of methamphetamine.[311] In postmortem samples from 4 methamphetamine abusers, blood samples from the left heart were 1.9–2.6 times higher than blood samples from the right heart.[368] The methamphetamine concentrations in samples from the femoral veins were closer to the concentrations in the right heart than to the left heart. In a case series of 3 fatalities, the left/right heart blood ratio was 1.0, 1.59, and 2.06 with the highest ratio occurring in autopsy blood containing the highest concentration of methamphetamine.[367] In a case series of 20 autopsies, the heart/femoral blood ratios of methamphetamine averaged 2.1 with a range of 1.2–5.0.[369] The presence of large amounts of methamphetamine in the stomach may result in the postmortem diffusion of significant amounts of methamphetamine to cardiac blood.[200] Stomach fluid and saliva may contain small amounts of amphetamine (i.e., about 0.1% of the blood methamphetamine concentration) as a result of the diffusion of amphetamine from surrounding blood vessels.[252]

URINE

The absorption of methamphetamine is rapid with the appearance of the parent compounds in the urine beginning about 20 minutes after ingestion. The concentration of methamphetamine depends on a number of variables including dose, duration of use, urine pH, urinary excretion rates, and individual pharmacokinetics. Figure 1.7 demonstrates urine methamphetamine

and amphetamine concentrations in urine samples from volunteers receiving 15.5 mg methamphetamine intravenously or 30 mg methamphetamine via a glass pipe. The mean methamphetamine concentration in urine samples from 30 outpatients presenting for treatment of methamphetamine abuse was 18.1 ± 26.2 mg/L (range, 0–101.5 mg/L).[370] In 16 urine samples from methamphetamine addicts sent to a Japanese criminal science laboratory, the median urine methamphetamine concentration was about 21 mg/L (range, 0.7–157.5 mg/L).[371] The median methamphetamine concentration in 30 forensic urine samples from Japanese users arrested for methamphetamine use was about 6.7 mg/L (range, 0.77–154.2 mg/L).[372]

Urine amphetamine immunoassays detect the presence of these compounds following occasional use for approximately 1–3 days depending on several factors including the dose, duration of use, urine pH, hydration (i.e., urine creatinine, specific gravity), analytic method (sensitivity, specificity, cutoff), and individual metabolic and excretion rates.[373] The normal urinary pH range is about 4.5–8.0 with urine creatinine concentration below 20 mg/dL and specific gravity <1.003 suggesting dilution of the urine specimen. The US DOT Regulations (49 Code of Federal Regulations Part 40) defines a substituted urine specimen as containing ≤5 mg creatinine/dL *and* a specific gravity of ≤1.001 or ≥1.020. Other criteria for an adulterated specimen include nitrite ≥500 µg/mL, urine pH ≤3 or ≥11 or the presence of substances (e.g., glutaraldehyde, chlorochromate, hydrogen peroxide, bleach, anionic surfactant, hydrochloric acid) normally absent in human urine. Studies of volunteer methamphetamine users indicate that under extreme circumstances the urine drug screen for amphetamine/methamphetamine may remain positive for approximately 1 week.[374] Current US workplace drug testing for methamphetamine requires the presence of urinary methamphetamine and urinary amphetamine concentrations above 500 ng/mL and 200 ng/mL, respectively. Because of interindividual variation and low urinary concentrations of amphetamine, the detection rate for urine specimens collected within 12 hours of ingestion and analyzed using these cutoffs is relatively low. In a volunteer study of 8 volunteers ingesting daily doses of 10 mg methamphetamine for 4 days, about 16% of the urine specimens collected within 12 hours of the dose of amphetamine were positive based on the current cutoff.[375] Final detection times after the 4 doses averaged 55.0 ± 18.7 hours with a range of 31–92 hours. Reducing the methamphetamine cutoff to 250 ng/mL extends the detection time to approximately 24 hours. In a study of 5 healthy volunteers receiving 10 mg or 20 mg methamphetamine daily for 4 days, the mean detection times for methamphetamine in urine samples based on current cutoffs were 43.6 and 66.9 hours, respectively.[350] Lowering the cutoff to 250 ng methamphetamine/mL and 100 ng amphetamine/mL increased the mean detection times to 59.5 and 79.7 hours, respectively. Although detectable concentrations of *d*-amphetamine (i.e., >50 ng/mL) are usually present in urine samples containing methamphetamine, the absence of detectable concentrations of *d*-amphetamine does not necessarily confirm the lack of methamphetamine abuse.[376]

α-Benzyl-*N*-methylphenethylamine (BNMPA) is an impurity that contaminates illicit methamphetamine produced by the Leuckart reaction using phenylacetone (phenyl-2-propanone) synthesized from phenylacetic acid. The presence of BNMPA or its major metabolite, *p*-OH-BNMPA, indicates the illicit use of methamphetamine.[377] Additionally, the presence of the (*d*)-enantiomer or a racemic mixture of methamphetamine enantiomers *suggests* the illicit use of methamphetamine in contrast to licit drugs, which contain only the (*l*)-enantiomer.[378,379] When calibrated at 0.3 mg *d*-amphetamine/L, excessive use (i.e., >twice recommended dose) of Vicks® nasal inhaler (*l*-methamphetamine) may produce false-positive results on some immunoassays, but false-positive results are unlikely during the use of a 1000 ng/mL cutoff.[380] The metabolism of the anti-parkinson drugs, selegiline and deprenyl produces *l*-amphetamine and *l*-methamphetamine, resulting in positive urine drug screens for methamphetamine. Detection of these metabolites requires chiral chromatography; routine gas chromatography/mass spectrometry does not separate the *d*- and *l*-enantiomers. Additionally, the ratio of methamphetamine/amphetamine is much lower (i.e., 2.5) following selegiline ingestion than following methamphetamine ingestion (i.e., about 10).[98] Because of structural similarities, ephedrine and pseudoephedrine may cross-react with some immunoassay screening reagents for methamphetamine.

HAIR

Sensitive methods for detecting amphetamine and methamphetamine in hair include gas chromatography/mass spectrometry[381,382] and liquid chromatography/tandem mass spectrometry liquid chromatography/tandem mass spectrometry.[383] Multiple factors complicate the interpretation of the results of hair analysis including hair growth rates, analytic techniques (washing, sample preparation), drug incorporation rates, sectional differences in drug concentrations, hair color and melanin content (increased incorporation in dark hair), life-style differences (shampooing, dyeing, bleaching), sunlight

exposure, and limited data on the correlation between chronic drug use and hair concentrations.[384] In general, the methamphetamine and amphetamine concentrations in axillary and pubic hair are somewhat higher than scalp hair. In a study of 5 methamphetamine users, the mean methamphetamine concentrations in scalp and axillary hair were 13.49 µg/g (range, 2.7–22.7 µg/g) and 18.68 µg/g (range, 2.9–53.35 µg/g), respectively.[385] There is substantial variation in the metabolite/parent drug ratio (amphetamine/methamphetamine) ratio in hair samples. The methamphetamine and amphetamine concentrations in 2,444 positive forensic samples submitted for methamphetamine abuse ranged from 0.51–193.75 µg/g and 0.13–13.39 µg/g, respectively, in head hair.[386] The amphetamine/methamphetamine ratio was 0.004–1.16. A 12-week study of 6 methamphetamine users admitted to a drug treatment program demonstrated peak methamphetamine concentrations in hair samples ranging from 1–7 cm from the root over the course of the study.[387] The incorporation of basic drugs into hair is relatively high compared with acidic and neutral drugs.[388] Consequently, the use of hair analysis to detect methamphetamine use requires further validation.

Abnormalities

RHABDOMYOLYSIS

Rhabdomyolysis may develop after the administration of large methamphetamine doses, particularly in association with hyperthermia.[389] Potential laboratory changes in patients with rhabdomyolysis include elevated serum muscle enzymes (creatine kinase, aldolase), myoglobinuria, hyperbilirubinemia, hyperuricemia, hypocalcemia, hyperkalemia, renal failure, hyperphosphatemia, and hypokalemia. Coagulopathies associated with hyperthermia and DIC may cause intramuscular hemorrhage, elevated compartment pressures, and rhabdomyolysis.

BLOOD

Leukocytosis occurs frequently after methamphetamine use. Disseminated intravascular coagulation (thrombocytopenia, hypofibrinogenemia, hypoprothrombinemia, reduced partial thromboplastin levels, elevated fibrin split products) can occur after IV or oral amphetamine use, especially in association with rhabdomyolysis and hyperthermia. Hypoglycemia is a rare complication of severe methamphetamine intoxication, probably as a result of the depletion of glycogen stores during prolonged hyperadrenergic state.[310] Elevated serum hepatic aminotransferases complicate the IV abuse of methamphetamine, but the frequency of direct drug hepatotoxicity is unclear in the absence of rhabdomyolysis and end organ failure.

CENTRAL NERVOUS SYSTEM

ACUTE. Intracranial hemorrhages in methamphetamine abusers are usually located in the cerebral white matter rather than the sites commonly associated with chronic hypertension (i.e., basal ganglia, pons, cerebellum). These intracranial hemorrhages may occur in association with aneurysms or arteriovenous malformations. Other pathologic findings associated with amphetamine use include subarachnoid hemorrhage, subdural hematoma, and drug-induced vasculitis.[390,391] Angiographic studies of involved vessels demonstrate beading of the anterior or middle cerebral arteries with partial or complete occlusion of small-caliber vessels (<1 mm).[392]

CHRONIC. Neuropsychologic testing suggests that high-dose methamphetamine/amphetamine abuse reduces scores on the Wechsler Memory Scale-Revised tests on attention/concentration, delayed recall indices, and verbal memory compared with controls who do not use illicit drugs.[393] There were no statistical differences in neuropsychologic scores between controls ($n = 9$) and low-dependence methamphetamine/amphetamine users as defined by the severity of dependence scale (i.e., intensity of use rather than cumulative dose). Total lifetime street-use of methamphetamine/amphetamine was not significantly different between the high-dose ($n = 11$) and low-dose methamphetamine/amphetamine ($n = 15$) groups. About 68% of the drug users used methamphetamine/amphetamines intravenously; the study did not separate amphetamine users from methamphetamine users. A study of cognitive function in chronic methamphetamine users demonstrated statistically significant differences in test scores on visual discrimination learning and shifting as well as smaller differences in visuospatial memory, when compared with age- and IQ-matched controls.[394] In a meta-analysis of 18 studies on neuropsychologic testing in chronic methamphetamine abusers, moderate to large deficits occurred in domains of learning ($d = -0.66$), executive functions ($d = -0.63$), and memory ($d = -0.59$).[395] These results suggest detrimental effects on the limbic and frontostriatal circuits. The most prominent effects on memory occurred in episodic memory, which is a multifactorial ability (e.g., encoding, consolidation, retrieval) dependent on multiple regions in the brain (e.g., frontal, temporal). Slightly smaller effects were observed in attention/working memory, language, and

visuoconstruction. The relationship between these deficits and characteristics of methamphetamine use (e.g., route, duration of use, abstinence) and confounders (e.g., premorbid psychologic conditions, comorbid diseases) are not well defined.

Although there are limited data, human studies suggests that chronic methamphetamine abuse produces permanent alteration of brain chemistry and function. PET scans detected a reduction in dopamine transporters in the caudate nucleus and putamen of 6 abstinent methamphetamine users.[396] However, none of these former methamphetamine abusers had clinical signs of parkinsonism. The reported mean period of abstinence for these former methamphetamine users was 3 years. A brain proton magnetic resonance spectroscopy (MRS) study of 26 abstinent methamphetamine abusers demonstrated an approximate 5% reduction in the concentration of the neuronal marker, *N*-acetylaspartate, in the basal ganglia and in frontal white matter.[397] The median time from the imaging study to the last reported use of methamphetamine was about 4 months.

Driving

There are limited data on the causal relationship between methamphetamine use and trauma, including traffic accidents. In general, the increasing prevalence of methamphetamine in postmortem samples from drivers in fatal accidents reflects the increasing abuse of this drug. A retrospective study of patients admitted to a California trauma center indicated that the percentage of urine samples positive for amphetamines (presumably mostly methamphetamine based on prevalence of use) and for cocaine was 13.2% versus 6.2%, respectively.[398] Studies of postmortem blood from fatal traffic accident victims demonstrated that the rate of methamphetamine use ranged from 1.8%–8.0%.[352,399,400] In a study of 17 drivers involved in fatal traffic accidents, the postmortem methamphetamine concentration ranged from 0.05–2.6 mg/L with a median of 0.35 mg/L.[363] Accident investigation of these fatal accidents indicated that 16 of the 17 drivers were responsible for the fatal accident. Drifting out of the lane of travel and reckless (high speed) driving were the most prominent causal factors. In a study of postmortem blood samples from 370 fatally injured drivers, detectable concentrations of methamphetamine occurred in 18 (4.9%). The methamphetamine concentrations ranged from <0.01–1.08 mg/L with mean and median concentrations of 0.73 mg/L and 0.26 mg/L, respectively.[401] Culpability for the accidents was not reported.

A study of 26 positive blood samples from drivers apprehended for driving under the influence of methamphetamine demonstrated a mean methamphet-amine concentration of 0.55 mg/L with a range up to 1.88 mg/L.[352] Two additional drivers developed irrational, agitated, violent behavior after ingesting methamphetamine during their apprehension. The methamphetamine concentrations were 2.58 mg/L and 9.46 mg/L. The latter driver developed seizures. Driving abnormalities associated with methamphetamine intoxication includes tailgating, rapid lane changes without signaling, and speeding.[402]

The effect of methamphetamine on driving is complex and dose-related. In general at low doses, methamphetamine is a stimulant, but psychomotor skills, reasoning, and cognition deteriorate as the dose and duration of use increases.[150] Furthermore, CNS depression during the withdrawal phase and psychotic symptoms from chronic abuse of high doses of methamphetamine may impair driving skills. The intensity of effects at a specific methamphetamine concentration depends in part on the amount of tolerance to amphetamines. Studies of volunteers given methamphetamine indicate that the effects of methamphetamine on the psychomotor skills required to operate machinery effectively are similar to the effects of *d*-amphetamine. The administration of 15–20 mg methamphetamine to healthy volunteers slightly improves performance on some simple tasks (reaction times, vigilance, attention), particularly in fatigued subjects. However, the positive effects of methamphetamine on psychomotor skills is neither consistent or without adverse effects. In study of 70 college-age volunteers receiving IV methamphetamine (0.2 mg/kg or 0.3 mg/kg) or placebo, methamphetamine alone produced subjective arousal and a small improvement in recall of recently learned words; however, the number of incorrect responses increased substantially.[403] In a study of 36 male college students receiving 15 mg methamphetamine/150 pounds intravenously, there was slightly improved speed on some repetitive motor tasks when compared with baseline.[404] However, there were no differences between methamphetamine and placebo on several tests of reaction time. Standard field sobriety tests (horizontal gaze nystagmus, walk and turn test, one leg stand test) are not sensitive measures of the effect of methamphetamine as measured in adult volunteers receiving 0.42 mg/kg *d,l*-methamphetamine or placebo.[138]

TREATMENT

Stabilization

The treatment of amphetamine, methamphetamine, and cocaine intoxications are similar; however, there are fewer clinical data on the specific treatment of methamphetamine intoxication compared with cocaine. The

major life-threatening complications of acute methamphetamine intoxication include hyperthermia, hypertension, seizures, cardiovascular instability, and trauma. Coma, shock, acute renal failure, severe hyperthermia (i.e., temperature >41°C/105.8°F), and seizures are poor prognostic indicators.[405] Severely intoxicated patients require IV access, cardiac monitoring, pulse oximetry, an electrocardiogram (ECG), and supplemental oxygen. Respiratory depression does not usually occur during mild to moderate methamphetamine intoxication, but pulmonary edema (cardiogenic shock, acute respiratory distress syndrome) can develop during severe methamphetamine poisoning. Most patients tolerate sinus tachycardia without pharmacologic intervention. Both hypertension and tachycardia often respond to IV benzodiazepines (adult: lorazepam 2 mg or diazepam 5 mg bolus titrated to effect). Core body temperatures should be measured in any agitated patient. Patients with suspected myocardial ischemia should be managed with nitrates, morphine, benzodiazepines, aspirin, and benzodiazepines. Hypotension may respond to fluid challenges, but often a vasopressor is needed. Shock is a poor prognostic sign that indicates the need for monitoring of cardiac output to determine the most efficacious combination of fluid and vasopressors.

HYPERTENSION

Elevated blood pressure during methamphetamine intoxication does not usually require treatment unless the hypertension contributes to myocardial ischemia. Benzodiazepines can be administered for agitation. Treatment for severe hypertension includes IV sodium nitroprusside (0.5–8 µg/kg/min) or phentolamine (2.5–5 mg initial IV bolus). Phenothiazine compounds reduce amphetamine-induced hypertension in animal models, but there are inadequate clinical data to determine the efficacy of these drugs during methamphetamine toxicity. Theoretical concerns about potential reduction in the seizure threshold have limited the administration of phenothiazine compounds in clinical practice. Beta blockers should be avoided because the blockade of β₂-mediated vasodilation can cause vasoconstriction and paradoxical worsening of the hypertension associated with the methamphetamine.

SEIZURES

Seizures usually respond to benzodiazepines (lorazepam, diazepam). Therapeutic options for the treatment of status epilepticus include phenobarbital and anesthetic agents (e.g., propofol). Hyperthermia, acidosis, hypoxemia, and rhabdomyolysis may complicate the clinical course during status epilepticus; these patients should be evaluated for the presence of these complications.

AGITATION

Diazepam (5–10 mg IV in adults or 0.1–0.3 mg/kg in children) or lorazepam (1–2 mg IV in adults) are the safest drugs for agitation; IV midazolam (initial starting dose, 0.03 mg/kg/h) titrated to effect is a short-acting alternative to IV lorazepam or diazepam, particularly in critical patients. Lorazepam is preferred to diazepam when IV access is unavailable.[66] Benzodiazepines should be titrated to the desired clinical effect. Intravenous droperidol (2.5–5 mg) is an alternative to diazepam or lorazepam for the treatment of acutely agitated methamphetamine-intoxicated patients. In a prospective clinical study of adult patients, the administration of IV droperidol (2.5–5 mg) produced more rapid and profound sedation compared with IV lorazepam (2–4 mg) in a group of 146 patients with methamphetamine intoxication.[406] More repeat doses of lorazepam were administered during the first hour of treatment than repeat doses of droperidol. A study of 18 pediatric patients with methamphetamine intoxication suggested that IV haloperidol is a safe adjunctive therapy with benzodiazepines for the treatment of acute methamphetamine intoxication in children.[407] The starting dose of haloperidol was 0.025–0.05 mg/kg, repeated every 15–30 minutes as necessary for the treatment of delirium. Hypotension, respiratory depression, and dystonic reactions are potential complications of butyrophenone use. A calm environment and familiar faces may also help alleviate agitation.

HYPERTHERMIA

Severe temperature elevation (i.e., >40–42°C/104–107.6°F) is a poor prognostic sign, and hyperthermia frequently occurs with evidence of end-organ failure (hypotension, hyperkalemia, metabolic acidosis, rhabdomyolysis, elevated serum creatinine kinase, coagulopathy).[309] Elevated core body temperature should be treated aggressively, especially when temperatures exceed 39–40°C (102.2–104°F). Cooling measures include removal of clothing, cool rooms, cool mist spray to the skin, liberal use of fans, ice baths, and sedation (benzodiazepines). Ice-bath immersion produces the most rapid response, but technical difficulties frequently limit the use of this modality. The use of hypothermic blankets or the application of ice packs often does not produce sufficient cooling for these patients. Neuromuscular paralysis, sedation (midazolam, continuous propofol infusion), and mechanical ventilation may be necessary to reduce the muscle rigidity and

hyperactivity associated with refractory hyperthermia.[408] Vital signs should be followed closely (i.e., every 15–20 minutes) and cooling measures continued until core temperatures are below 38.5–39°C (101.3–102°F). Less severe temperature elevations (<38–40°C/100.4–104°F) can be treated by placement in a cool room, removal of clothes, minimization of physical activity (sedation), tepid sponging, or evaporative methods (cool mist spray, fans).

Gut Decontamination

There are few data on the effect of decontamination procedures on the clinical outcome of methamphetamine intoxication. Most patients requiring treatment for ingesting methamphetamine are "body stuffers," who attempted to conceal evidence by swallowing variable quantities of methamphetamine. Animal studies indicate that the administration of activated charcoal within 1 minute after the oral administration of a lethal dose of methamphetamine reduces early mortality in mice, but mortality at 48 hours was similar between the treated and untreated groups of mice.[409] All animals demonstrated signs (piloerection, tremor, agitation) of methamphetamine toxicity within 9 minutes of oral administration of the methamphetamine. The administration of activated charcoal, sedation as needed, and supportive care are treatment options for body stuffers. More aggressive decontamination (polyethylene glycol electrolyte lavage solution) is necessary for body packers; however, the ingestion of methamphetamine by body packers is unusual compared with cocaine because of the ease of local clandestine manufacture of methamphetamine.

Elimination Enhancement

Currently, the use of forced diuresis with urinary acidification is not recommended. There are inadequate clinical data on the efficacy of hemodialysis, peritoneal dialysis, and hemoperfusion during amphetamine intoxication to recommend the use of these procedures. The large volume of distribution of methamphetamine suggests that these measures will not significantly increase the elimination rate of methamphetamine. Animal studies do not support the use of multiple-dose activated charcoal as a means of enhancing methamphetamine elimination.[410]

Antidotes

There are no specific antidotes for methamphetamine intoxication.

Supplemental Care

Most methamphetamine body stuffers with serious methamphetamine intoxication present to the emergency department with a pulse >120 bpm and/or body temperature ≥38.0°C (100.4°C).[411] Delayed symptoms may occur following the ingestion of well-wrapped baggies or rolled plastic baggies that simulate sustained release packaging ("parachuting methamphetamine"). Monitoring of these patients may be necessary up to 24 hours after ingestion.

ANCILLARY TESTS

Depending on clinical judgment and severity of poisoning, laboratory examination includes complete blood count, serum electrolytes, calcium, phosphorus, uric acid, creatine kinase, hepatic transaminases, creatinine, glucose, blood urea nitrogen (BUN), coagulation profile (platelet count, fibrin split products, fibrinogen, prothrombin time, partial thromboplastin time), urinalysis including myoglobin, arterial blood gases, chest x-ray, ECG, cardiac monitoring, and appropriate diagnostic neurologic testing (i.e., CT of the brain with or without angiography, lumbar puncture). The use of the urine dipstick is a convenient method to detect the presence of hemoglobin or myoglobin at concentrations above 5–10 mg/L.[412] After the cessation of the myoglobin formation, hepatic metabolism and renal excretion clear plasma myoglobin within 1–6 hours. The presence of myoglobinuria necessitates generous fluid replacement, but alkalinization of the urine is not routinely recommended because the excretion of amphetamine compounds decreases substantially in alkaline urine and there are inadequate data to support the efficacy of alkalinization in this setting.

METHAMPHETAMINE PSYCHOSIS

Fulminant psychosis in chronic methamphetamine abusers requires hospitalization to provide a protective environment, particularly when suicidal ideations are present. There are limited clinical data on the treatment of methamphetamine psychosis.[413] Empirical treatment includes the use of chlorpromazine at dosages of 50 mg orally or intramuscularly every 4 hours. Depending on adverse effects (sedation, orthostatic hypotension) and clinical response, the total daily dose varies up to 200–800 mg divided in 4–6 doses. The administration of oral or intramuscular doses (2–5 mg) of haloperidol every 6 hours is an alternative to chlorpromazine. Newer antipsychotic medications include olanzapine; limited clinical data suggest that olanzapine is as effective as

haloperidol for methamphetamine psychosis with lower risk of adverse effects.[414] Long-term management of the habitual methamphetamine user is difficult because of frequent relapses. Treatment of these patients involves group therapy and restructured lifestyles. Gradual withdrawal with methamphetamine is unnecessary. Heavy abusers become irritable and depressed during this period; antidepressants and suicide precautions are often required. In addition to behavioral group therapy, experimental pharmaceutic treatment of underlying methamphetamine abuse include the use of bupropion or risperidone.[415,416] Other experimental pharmacologic agents for the treatment of methamphetamine abuse include baclofen, mirtazapine, and topiramate.[417] The concomitant use of antipsychotic drugs does not necessarily prevent the exacerbation of psychotic symptoms in patients, who continue to use methamphetamine.

COMPLICATIONS

Severe methamphetamine intoxication may be complicated by a variety of problems, including acute renal failure, rhabdomyolysis, acute compartment syndrome, subarachnoid hemorrhage, intracerebral hemorrhage, cerebral edema with transtentorial herniation, DIC, and acute respiratory distress syndrome/acute lung injury. Laboratory examinations and repeat physical examinations are necessary to diagnose these conditions early. Management is primarily supportive, but surgery may be required for intracranial lesions or compartment syndrome.

Distal ischemia is usually an isolated problem resulting from inadvertent intra-arterial administration of methamphetamine compounds; there are few clinical data on outcomes to guide treatment of the distal ischemia. Therapeutic options for the treatment of ischemia include intra-arterial tolazoline (12–25 mg/limb), IV nitroprusside infusions (0.5–8 µg/kg/min), dextran 40 (80 mL/h), local nerve blocks, and axillary nerve block. Other therapeutic measures include the use of heparin, thrombolytics, and papaverine. Monitoring of intra-arterial pressure during these infusions is mandatory. Supportive care for compartment syndrome includes analgesics, elevation of extremities, and elimination of methamphetamine exposure. Fasciotomies are usually unnecessary unless there is clear evidence of high compartment pressures and associated distal ischemia.

Chapter 2

METHYLPHENIDATE

HISTORY

Methylphenidate was first synthesized in 1944 by Ciba-Geigy Pharmaceutical Company as an analeptic agent for the treatment of barbiturate overdose. Initial indications for the use of methylphenidate were lethargy, chronic fatigue, depression (with or without psychosis), senile behavior, and narcolepsy. Now methylphenidate is primarily prescribed in the United States for the treatment of attention deficit disorder (ADD) and attention deficit hyperactivity disorder (ADHD) in children and adolescents.[1] Narcolepsy-associated somnolence is also treated with methylphenidate. In 1960, a case report documented the daily ingestion of up to 125 tablets of methylphenidate in a 37-year-old woman, who required hospitalization for her addiction.[2] Sweden withdrew methylphenidate from their list of approved drugs in 1968. During the 1970s, the intravenous (IV) abuse of methylphenidate occurred, particularly on the West Coast of the United States.[3] Intravenous drug abusers used methylphenidate as a stimulant in combination with opiates (e.g., pentazocine); however, daily use of methylphenidate was low (i.e., <1–2%) compared with most other drugs of abuse.[4]

IDENTIFYING CHARACTERISTICS

Physiochemical Properties

Methylphenidate is a white, odorless, crystalline powder. Table 2.1 lists some physiochemical properties of methylphenidate.

Methylphenidate (CAS RN: 113-45-1) is a piperidine-substituted phenylisopropylamine that is structurally related to amphetamine. Figure 2.1 displays the chemical structure of methylphenidate. The molecular formula of methylphenidate is $C_{14}H_{19}NO_2$. Methylphenidate exists as 4 isomers as a result of the presence of 2 chiral centers; however, the pharmaceutical formulation of methylphenidate (Ritalin®, Novartis Pharmaceutical Corp., East Hanover, NJ) contain a racemic mixture of *threo*-(*S*,*S*)-(−)- and *threo*-(*R*,*R*)-(+)-isomers. The pharmacologic and toxic actions of methylphenidate result primarily from the *threo*-(+)-enantiomer, which selectively competes for the dopamine uptake binding site on the dopamine transporter in the basal ganglia.[5] The binding of the *threo*-(−)-enantiomer to the dopamine transporter is diffuse and nonspecific.[6]

Terminology

The IV use of crushed pentazocine (Talwin®, Sanofi-Aventis US, Bridgewater, NJ) and methylphenidate (Ritalin®) is called "Ts and blues," "poor man's heroin," or "Ts and Rs."[7] The name, "Ts and blues" also refers to the IV use of the combination of pentazocine (Talwin®) and the antihistamine tripelennamine (Pyribenzamine®, Novartis Pharmaceutical Corp., East Hanover, NJ). Street names for methylphenidate include Skippy, R-ball, and Vitamin R.

Form

Because of the technical difficulty associated with stereospecific synthesis, drug diversion is the primary source of illicit methylphenidate rather than clandestine synthesis. Consequently, illicit methylphenidate is usually pharmaceutic grade and impurities are usually not clinical significant following ingestion. The IV use of crushed Ritalin® tablets results in the injection of talc (magnesium silicate) particles.

TABLE 2.1. Physical Properties of Methylphenidate.

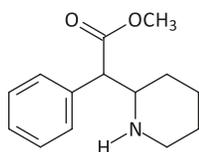
Physical Property	Value
Molecular Mass	
Methylphenidate	233.31 g/mol
Methylphenidate HCl	269.77 g/mol
pKa	8.77
log P (Octanol-Water)	0.2
Water Solubility	2.01E+05 mg/L (25°C)
Vapor Pressure (Free Base)	5.89E-05 mm Hg (25°C)
Henry's Law Constant	4.38E-09 atm-m^3/Mole (25°C)
Atmospheric OH Rate Constant	1.11E-10 cm^3/molecule-second (25°C)


FIGURE 2.1. Chemical structure of methylphenidate.

EXPOSURE

Epidemiology

The abuse of methylphenidate is significantly less common than other major stimulant drugs of abuse (e.g., methamphetamine, cocaine). However, a small percentage of adolescents and young adults use methylphenidate for nonmedical purposes. In a survey of US high school seniors (Monitoring the Future Study), the nonmedical use of Ritalin® among high school seniors increased over the last 2 decades with the approximate percentage ranging from about 2–3% in 2000.[8] In a study of substance-abusing adolescents with comorbid psychiatric conditions, methylphenidate misuse was 4 times higher than methylphenidate abuse with about 5% of the study population abusing methylphenidate on a regular basis.[9] The primary method of methylphenidate abuse was the insufflation of crushed Ritalin® tablets. Misuse of methylphenidate occurs on college campuses reportedly as a means to improving study skills.[10]

Most studies on the misuse of prescription stimulants do not separate amphetamine from methylphenidate. The rate of misuse is substantially higher than the rate of daily abuse, and methylphenidate abuse is probably much less common than most other substances of abuse. In a study of 450 adolescents referred for treatment in a Canadian substance abuse program, 23% reported the nonmedical use of methylphenidate or *d*-amphetamine and 6% abused one or both of these substances.[9] Smaller studies with face-to-face interviews reported higher misuse rates, whereas larger, multisite studies reported lower rates. In a study of a convenience sample of 1,811 undergraduates at a large-public US research university, the reported lifetime rate of the illegal use of prescription stimulants (*d*-amphetamine, methylphenidate) was 34%.[11] A multisite study of 10,904 US college students reported a lifetime misuse and past-year misuse of prescription stimulants (*d*-amphetamine, methylphenidate) of 6.9% and 4.1%, respectively.[12]

Sources

The US Controlled Substances Act lists methylphenidate (Ritalin®) as a schedule II substance (i.e., a medically prescribed drug with the highest abuse potential and dependence profile). Methylphenidate is a well-established treatment for ADHD in immediate-release tablets of 5 mg, 10 mg, and 20 mg. Off-label uses of methylphenidate include the adjunctive treatment of depression and the treatment of poststroke cognitive impairment. Extended-release tablets of methylphenidate in 18 mg-, 36 mg-, and 54 mg-formulations are available as Concerta® (ALZA Corporation, McNeil Consumer & Specialty Pharmaceuticals, Fort Washington, PA). These tablets are coated with immediate-release methylphenidate surrounding an osmotic pump resulting in continuous methylphenidate release over a 10-hour period. Although these preparations contain both *d*- and *l-threo*-methylphenidate, only the *d*-enantiomer has significant pharmacologic activity. Most reports in the medical literature regarding methylphenidate involve adults injecting pharmaceutic-grade methylphenidate or the diversion of pharmaceutic products by adolescents or young adults.[13]

Methods of Abuse

Volunteer studies indicate that oral methylphenidate has some abuse potential; however, high doses (supratherapeutic) are necessary to produce stimulant-like subjective effects. The use of up to 48 mg methylphenidate did not increase the desire to take the drug again in a volunteer study.[14] This study suggested that the use of methylphenidate was associated with significant dysphoric effects that would reduce the abuse potential of the drug. A small percentage of adolescents and young adults treated for ADD will use methylphenidate for nonmedical purposes.[15] Methylphenidate is a drug of abuse on college campuses where the insufflation or ingestion of this drug is used to increase concentration, improve alertness, or for recreational purposes (i.e., getting high, experimenting).[16] In a retrospective review

of published studies, the misuse and diversion of prescription stimulants for ADHD ranged from 5–35% among older adolescents and college-age populations.[13] Lifetime diversion rates of stimulant prescriptions from students with legitimate prescription was 16–29%, when asked to trade, sell, or give the medication to another person. Case series indicate that the abuse pattern and toxicity of IV methylphenidate and cocaine/amphetamine sulfate abuse are similar, characterized by cyclical binging and crashing.[17]

DOSE EFFECT

Medical uses for methylphenidate include the treatment of narcolepsy in adults and ADD in children. The usual daily oral dose of immediate-release methylphenidate for ADD is 10–60 mg. In healthy individuals, the administration of methylphenidate increases activity, arousal, sociability, and mood; however, in volunteer studies, there is substantial variation in the response of healthy volunteers despite receiving the same IV dose of 20 mg methylphenidate.[18] Clinical effects in this study ranged from euphoria to dysphoria, anxiety, and malaise. In a retrospective study of 113 exposures to methylphenidate reported to poison control centers, adverse effects in pediatric patients were not associated with methylphenidate ingestions of ≤1 mg/kg.[19] Side effects of methylphenidate are dose-related with the incidence of these effects substantially increasing at doses above 2 mg/kg.[20] In animal studies, the administration of methylphenidate in doses of 10 times the maximum therapeutic dose increases systolic blood pressure, but there are no electrocardiographic or conduction abnormalities.[21] Common adverse effects include headache, anxiety, irritability, abdominal pain, anorexia, palpitations, and tachycardia. Case reports indicate that abuse of prescription methylphenidate by adolescents occurs at daily doses of 200 mg via insufflation[22] and ingestion.[23] Habitual IV methylphenidate abusers can tolerate substantially higher daily doses.

TOXICOKINETICS

Absorption

Methylphenidate is available in immediate-release and long-acting formulations. The gastrointestinal tract rapidly absorbs pharmaceutic doses of immediate-release methylphenidate with peak plasma concentrations (C_{max}) occurring within 1–3 hours of ingestion.[24] The absorption of long-acting preparations is bimodal with the second peak occurring about 3–4 hours after the peak associated with immediate-release preparations. Substantial presystemic elimination of *d-threo-*

methylphenidate occurs following the ingestion of therapeutic doses, resulting in relatively low absolute bioavailability (i.e., 0.11–0.53).[25] As a result of the wide variation in the bioavailability between individuals, the plasma methylphenidate concentrations vary substantially between individuals receiving the same dose of methylphenidate.[1] In a study of healthy adults, the mean maximal concentration (C_{max}) of methylphenidate in plasma following the ingestion of 0.15 mg/kg and 0.3 mg/kg was 3.5 ± 0.4 ng/mL and 7.8 ± 0.8 ng/mL, respectively.[26]

The time to reach peak concentrations in the brain is similar for both cocaine and methylphenidate. In a positron emission tomography (PET) study of healthy volunteers receiving 0.5 mg methylphenidate/kg intravenously, the time between administration and peak uptake in the brain for cocaine and methylphenidate was 2–8 minutes and 4–10 minutes, respectively.[5]

The pharmacokinetics of the *threo*-(*R*,*R*)-(+)-isomer and the racemic mixture are similar with the exception of first-pass metabolism. The extensive presystemic clearance and the relatively rapid clearance of the less active *threo*-(*S*,*S*)-(–)-isomer results in very low plasma concentrations compared with the active (+)-enantiomer following ingestion of pharmaceutic doses of methylphenidate. In a randomized, single-dose, cross-over study of 21 healthy volunteers receiving 40 mg racemic methylphenidate orally, the peak concentration of the *threo*-(*S*,*S*)-(–)-isomer was approximately 18- to 22-fold lower than active *threo*-(*R*,*R*)-(+)-isomer.[27] The IV administration of the racemic mixture bypasses the presystemic clearance of the (–)-enantiomer; consequently, the plasma concentrations of the 2 enantiomers are similar after IV administration. Methylphenidate is a basic compound that accumulates in the acidic environment of the stomach as a result of ion trapping, even following IV administration.

Distribution

Methylphenidate has a large volume of distribution ranging from about 10–50 L/kg in children receiving chronic daily oral doses of methylphenidate up to 1.3 mg/kg.[28] In a study of 8 boys with ADHD, the mean volume of distribution was 39.28 ± 7.67 L/kg with a range of 27.19–47.93 L/kg.[29] In a study of 8 children, the mean protein-bound methylphenidate was 15.2% ± 5.2%.[28] The binding of methylphenidate to plasma proteins is relatively low (i.e., 10–33%).[30] The relatively low protein binding and high lipid solubility of methylphenidate results in the large volume of distribution and high tissue binding, particularly in the brain where methylphenidate concentrations typically exceed plasma methylphenidate concentrations.

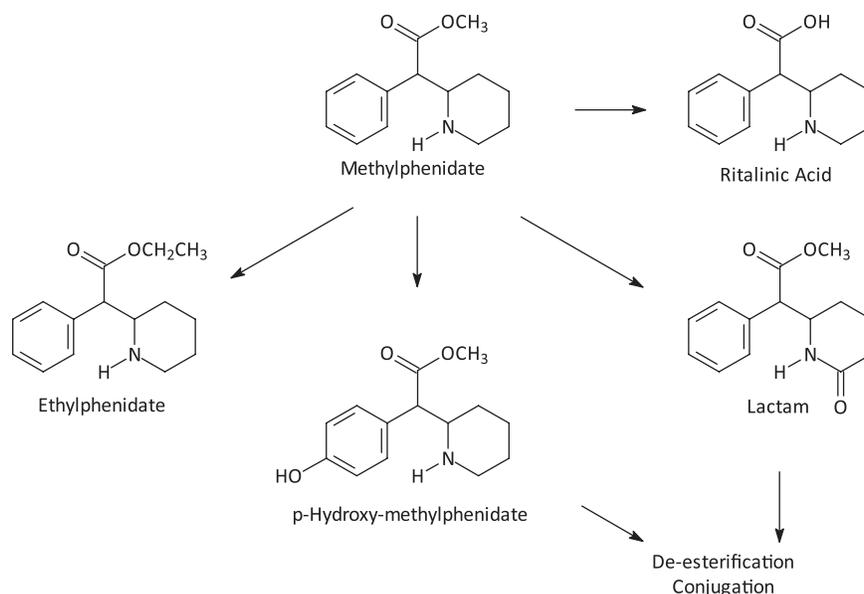
59


FIGURE 2.2. Biotransformation of methylphenidate.

Biotransformation

The main metabolic pathway in humans is the rapid de-esterification of methylphenidate to an inactive metabolite, ritalinic acid (CAS RN: 19395-41-6, α-phenyl-2-piperidineacetic acid) via hydrolytic esterase found throughout the body. During the biotransformation of methylphenidate, the hydrolysis of the methyl ester linkage with the subsequent formation of ritalinic acid accounts for over 80% of the absorbed methylphenidate dose.[31] Figure 2.2 demonstrates the biotransformation of methylphenidate. The *p*-hydroxylation of methylphenidate to *p*-hydroxymethylphenidate and the microsomal oxidation to 6-oxomethylphenidate (lactam) and 5-hydroxy-6-oxomethylphenidate are minor pathways in humans. Ritalinic acid appears in the urine unchanged or as 6-oxoritalinic acid. Ethylphenidate is a metabolite formed in the presence of ethanol via a carboxylesterase-dependent transesterification, similar to the formation of cocaethylene;[32] however, volunteer studies indicate that the formation of ethylphenidate is limited in the presence of moderate ethanol doses.[33] The metabolism of methylphenidate is stereoselective with a gradual increase in the *threo*-(+)/(−) ratio beginning about 1.5 hours after ingestion.[30] There is no evidence of interconversion between enantiomers of methylphenidate.

Elimination

The kidney eliminates less than 1% of an oral dose of 20 mg methylphenidate dose unchanged, although acid-ification will somewhat enhance excretion; fecal elimination is minimal.[34] The plasma elimination of methylphenidate is relatively rapid with a mean elimination half-life of about 3 hours (range, 2–8 h) after the ingestion of pharmaceutic doses of methylphenidate. In a study of 8 boys with ADHD, the mean plasma elimination half-life was 3.33 ± 0.65 hours with a range of 2.24–4.31 hours.[29] In healthy volunteer studies, the clearance of the inactive *threo*-(*S*,*S*)-(−)-isomer is approximately 2½ times greater than the active *threo*-(*R*,*R*)-(+)-isomer. The plasma half-life of ritalinic acid is approximately 3–5 hours with the mean plasma elimination half-life being slightly longer following IV administration (4.8 ± 0.5 h) than ingestion on an empty stomach (3.4 ± 0.4 hours).[25] Renal excretion of ritalinic acid accounts for approximately 60–80% of the methylphenidate dose.[31] In PET studies of the brains of healthy volunteers after the IV administration of methylphenidate, the clearance of methylphenidate from the striatum was significantly longer (90 minutes) than the clearance of cocaine (20 minutes).[5] Unchanged methylphenidate accounts for about 1% of the methylphenidate dose.

Maternal and Fetal Kinetics

There are limited data on the distribution of methylphenidate during pregnancy or lactation as a result of the use of this drug primarily in children and adolescents. Limited data suggests that substantial amounts of methylphenidate are not excreted in breast milk. Evaluation of breast milk from a 31-year-old woman receiving

methylphenidate doses of 5 mg in the morning and 10 mg at noon indicated that the infant dose was approximately 0.16% of the maternal dose.[35] Breastfeeding in the morning prior to the first dose of methylphenidate probably does not transfer methylphenidate to the infant because of the short elimination half-life of methylphenidate. In a study of a 26-year-old lactating mother on 40 mg methylphenidate twice daily, the milk/plasma ratio of methylphenidate was 2.7 with a relative infant dose of 0.2% of the weight-adjusted maternal dose.[36]

Tolerance

Children treated for ADD do not usually experience the mood elevation or euphoria commonly present in adult IV methylphenidate abusers, even at the beginning of therapy. The development of acute tolerance during the slow onset of action following the ingestion of methylphenidate mitigates the reinforcing effects and abuse potential of methylphenidate.[37] The injection of large doses of methylphenidate produces a rapid increase in synaptic dopamine concentrations that is not modulated by acute tolerance, and the short interval between administration and perceived effects enhances the addictive potential of the drug.

Drug Interactions

In pharmacokinetic studies, the administration of ethanol 30 minutes before or after racemic methylphenidate increases the peak plasma concentration and the area under the concentration-time curve (AUC) by approximately 40% and 25%, respectively.[38] The *threo*-(*S*,*S*)-(−)-isomer and high doses of methylphenidate inhibit the action of monoamine oxidase. As a result, the concomitant use of methylphenidate and monoamine oxidase inhibitors potentially can cause a hypertensive emergency.[39] In general, stimulants may exacerbate symptoms of schizophrenia. Even in the absence of psychotic disorders, the administration of methylphenidate may antagonize the central dopaminergic effects of haloperidol or similar antipsychotic medications.[40] A case report associated the coadministration of disulfiram and methylphenidate with the onset of psychotic episode that resolved within 1 day.[41]

There are few data on drug interactions associated with chronic methylphenidate use. Potential interactions include the inhibition of the metabolism of the coumarin, ethyl biscoumacetate, anticonvulsants (diphenylhydantoin, primidone, phenobarbital), and tricyclic antidepressants.[42] However, there are inadequate *in vivo* human data to indicate that these potential interactions are clinically significant. Rare case reports suggest the possibility that the administration of methylphenidate with a selective serotonin reuptake inhibitor (SSRI) may increase the risk of serotonin syndrome.[43] In a study of cocaine-dependent volunteers, the coadministration of methylphenidate and cocaine reduced some of the desired effects of cocaine (e.g., "good effects," "desire for cocaine"); however, the administration of methylphenidate did not alter the pharmacokinetics of cocaine.[44]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

Methylphenidate is a noncatecholamine sympathomimetic drug with both direct and indirect adrenergic agonist activity. Modification of the side chain of the basic-phenylamine moiety into a heterocyclic structure (e.g., methylphenidate) attenuates the anorectic and cardiovascular effects of amphetamine, but this structural change maintains the central nervous system (CNS) stimulant properties. The dopamine transporter (DAT) recycles extracellular dopamine from perisynaptic regions to the interior of the neuron. Methylphenidate binds to presynaptic dopamine transporters, resulting in the reversible inhibition of dopamine reuptake and increased synaptic dopamine concentrations.[45] The affinity of cocaine and methylphenidate for dopamine transporters in rat striatum is similar (i.e., 640 nmol/L and 390 nmol/L, respectively).[46] The result is prolonged postsynaptic and presynaptic dopamine receptor interactions. Depending on ionic conditions, the dopamine transporter functions as a mediator of inward-directed dopamine transport (i.e., reuptake) and/or outward directed dopamine transport (i.e., release). Methylphenidate impedes the clearance of dopamine from the synapse by competing with dopamine for the uptake-binding site. In contrast to amphetamine, methylphenidate is probably not a substrate for entry into the cytoplasm by the dopamine transporter; therefore, little presynaptic dopamine release occurs following the administration of methylphenidate.[47] Of the 2 enantiomers (*d*- and *l-threo*-methylphenidate) of methylphenidate, only the *d-threo*-methylphenidate binds significantly to the dopamine transporters.

The distribution of methylphenidate and cocaine in the brain is similar. Although both cocaine and methylphenidate occupy similar sites in the striatum and compete directly for these sites, the clearance of these 2 drugs from these sites differs significantly.[48] The clearance of cocaine from the dopamine transporter is much more rapid than methylphenidate, and the abuse potential for methylphenidate is substantially less

than cocaine. Therapeutic oral doses produce peak methylphenidate concentrations in the brain within 60–90 minutes, and these concentrations result in the inhibition of >50% of the dopamine transporters.[5] To a lesser extent, methylphenidate also binds to norepinephrine transporters, resulting in increased synaptic concentrations of norepinephrine. The serotonin transporter probably is not affected by methylphenidate.[1] Some increase in cortical acetylcholine may occur as a result of the indirect stimulation of cortical D_1 receptors.[49] In rodent studies, *d*-methylphenidate is a relatively weak substrate for the polymorphic efflux transporter P-glycoprotein in the brain.[50]

Mechanism of Toxicity

The IV administration or insufflation of methylphenidate produces rapid increases in brain methylphenidate concentrations with associated euphoria. However, the ingestion of therapeutic doses of methylphenidate results in slower uptake of methylphenidate in the brain with significantly reduced euphoric effects compared with the IV and nasal routes of methylphenidate administration. The ability of most drugs of abuse to raise dopamine concentrations in the nucleus accumbens correlates to the self-administration (i.e., reinforcing properties) of the drug. Psychostimulant drugs (e.g., methylphenidate) raise extracellular dopamine concentrations by inhibiting the dopamine transporter.[51] Oral therapeutic doses (0.25–1 mg/kg) of methylphenidate block about 50–75% of the dopamine transporters, but the abuse potential of oral methylphenidate is substantially less than IV methylphenidate.[52] Based on PET studies of the human brain, IV administration produces peak brain methylphenidate concentrations 8–15 minutes after use compared with 60–90 minutes following the oral administration of methylphenidate.[5] Although IV methylphenidate produces rapid increases of extracellular dopamine in the brain, the slow elimination of methylphenidate from the brain reduces the reinforcing effects that lead to repeated use, especially compared with the rapid elimination and high abuse potential of cocaine.[53] This slower egress of methylphenidate from the brain may decrease drug craving compared with cocaine. The highest density of methylphenidate uptake occurs in the striatum with lesser amounts in the prefrontal cortex and limbic regions.[1] The behavioral and cardiovascular effects of methylphenidate may involve more than 1 neurotransmitter.[51]

Postmortem Examination

The IV injection of dissolved tablets produces tiny particles of talc that migrate to the pulmonary vessels and pulmonary interstitium, particularly in intravascular or perivascular locations. A foreign body reaction develops manifest by birefringent talc crystals under polarized light. These particles produce granulomas that can cause widespread pulmonary vascular obstruction, pulmonary hypertension, biventricular enlargement, and cor pulmonale.[54] The α-adrenergic properties of methylphenidate may enhance the effects of the pulmonary granulomas on the intima and muscular layers of the pulmonary vessels, resulting in pulmonary hypertension and right ventricular hypertrophy.[55] A case series of postmortem examination of 7 young, IV Ritalin® abusers associated IV administration of dissolved Ritalin® tablets with the development of a symmetric, panlobular emphysema, particularly in the lower lobes.[56] Panlobular emphysema is an uncommon complication of IV abuse of other drugs. Microscopic examination of the lungs demonstrated variable amounts of talc granulomas, inflammatory infiltrates, and occlusive vascular lesions. There was minimal interstitial fibrosis. Talc (magnesium silicate) is a filler and lubricant in the Ritalin® tablet. These pathologic findings are similar to the histologic features of emphysema associated with α_1-antitrypsin deficiency rather than the micronodularity, pleural abnormalities, and progressive massive fibrosis associated with other types of IV drug abuse.[57] Furthermore, obstructive lung disease is an uncommon complication of more common forms of IV drug abuse (e.g., heroin).[58] Pleural abnormalities and progressive massive fibrosis do not usually occur following chronic IV methylphenidate use. The postmortem examination of heart from a 19-year-old demonstrated microscopic foci of necrosis in myocardial fibers surrounded by degenerating polymorphonuclear leukocytic and histocytic cells, similar to the cardiac lesions associated with catecholamine cardiomyopathy; however, contraction band necrosis was absent.[59] He had a cardiac arrest shortly after insufflating methylphenidate and died 16 hours later after sustaining severe hypoxic brain damage and global myocardial ischemia. Traditional anatomic findings of IV drug abuse were absent as was a history of IV drug use.

CLINICAL RESPONSE

The toxic effects of methylphenidate are an extension of pharmacologic effects that include agitation, hallucination, psychosis, seizures, lethargy, tachydysrhythmia, hypertension, weight loss, and hyperthermia. Similar to other stimulant drugs (e.g., cocaine, methamphetamine, pemoline), the use of methylphenidate may exacerbate the tics associated with Tourette syndrome.[60] Rare case reports associate orofacial and extremity dyskinesias with the ingestion of methylphenidate.[61] These dyskinetic movements begin soon after the ingestion of methylphenidate and resolve the same day.

Medical Use

Adverse effects associated with the therapeutic use of methylphenidate include headache, irritability, insomnia, anorexia, abdominal pain, weight loss, irritability, jitteriness, motor tics, anxiety, palpitations, tachycardia, and visual hallucinations.[62] Dose-related increases in blood pressure and heart rate may occur depending on tolerance.[63] In clinical studies, the therapeutic use of methylphenidate is associated with small, but clinically insignificant increases in the mean heart rate and blood pressure without changes in the electrocardiogram; minor elevations in the mean systolic blood pressure (<5 mm Hg) also may persist at least 6 months.[64] Rare case reports and reports from the US Food and Drug Administration Adverse Event Reporting System document sudden death in adolescents on therapeutic doses of methylphenidate; however, the number of sudden deaths in the stimulant-treated children was similar to the general pediatric population.[65,66] In a matched case-control study of 564 cases of sudden death occurring in children aged 7–19 years from 1985–1996, there was a statistically significant incidence of methylphenidate use in the cases of sudden death when compared with a control group of deaths from motor vehicle accidents matched within 3 years of age.[67] There was no analytic confirmation of methylphenidate use; therefore, potential reporting bias limits conclusions regarding causation.

Illicit Use

Following IV injection of crushed methamphetamine tablets, adverse effects include agitation, anxiety, sense of doom, hypoesthesias, chest pain, hypertension, dyspnea, tachycardia, mydriasis, elevated body temperature, and rhabdomyolysis. In addition to the typical complications of IV drug use (e.g., endocarditis, HIV), case reports indicate that long-term, intravenous Ritalin® abusers can develop severe panlobar emphysema, particularly in the lower lobes.[68] These drug abusers develop profound obstructive lung disease characterized by severe hypoxia, decreased diffusing capacities, and radiologic evidence of hyperinflation. These severe pulmonary deficits develop at a relatively young age (4th and 5th decade) similar to α_1-antitripsinase deficiency. However, case series of these patients have not detected this enzyme defect.[56] Multiorgan failure developed in a 32-year-old Ritalin® abuser, who increased her IV dose from 30 mg to 110 mg over 5 months.[69] Two hours after the last dose of 110 mg Ritalin® (methylphenidate) dissolved in tap water, she developed nausea, vomiting, increasing dyspnea, lethargy, and paresthesias. Over the next 24 hours these symptoms progressed to marked tachypnea, metabolic acidosis, hypoxia, hypotension, and multiorgan failure including disseminated intravascular coagulation (DIC). She survived with intensive cardiorespiratory support.

An acute cardiomyopathy (global hypokinesis with left ventricular ejection fraction of 30–35%) and diffuse ST elevations in inferolateral leads developed in a 17-year-old adolescent after the ingestion of 1 methylphenidate tablet at a party.[70] No cardiac coronary artery catheterization was performed. He also smoked marijuana and drank alcohol at this party as confirmed on a urine drug screen that detected no other drugs. A case report associated the chronic ingestion of 60 mg methylphenidate daily for 6 months with the development of a cerebral lacunar infarction manifested by left-sided weakness without loss of consciousness.[71] A computed tomography (CT) scan of the brain demonstrated a lacunar infarction involving the head of the right caudate nucleus and adjacent anterior limb of the internal capsule; the cerebral angiography was normal.

Overdose

The symptoms of methylphenidate intoxication are similar to the clinical features associated with an overdose of other sympathomimetic drugs. Symptoms reported to poison control centers following excessive exposure to methylphenidate include agitation/anxiety, mydriasis, abdominal pains, vomiting, palpitations, tachycardia, and lethargy.[72,73] Severe symptoms are unusual in these case series; typically, the level of conscious and vital signs are normal. Methylphenidate overdose can produce a variety of CNS and cardiovascular effects. Neurologic effects associated with methylphenidate intoxication in addition to the symptoms listed above include restlessness, tremors, muscle twitching, hyperreflexia, lightheadedness, euphoria, hallucination, delusions, paranoia, psychosis, and seizures.[17,20] Cardiac effects include tachycardia, dysrhythmias, hypertension, and chest pain. A 28-year-old woman developed chest pain, ST and T wave depression in her inferolateral leads, and global ventricular hypokinesia (ejection fraction, 30%) after an overdose of methylphenidate.[74] Although the troponin I was elevated, the serum creatine kinase and coronary angiogram were normal. She recovered without sequelae. Syncope may occur, primarily immediately after injection. Fever, diaphoresis, tachypnea, mydriasis, vomiting, and abdominal pain also complicate methylphenidate overdose. Case reports associate the insufflation of crushed methylphenidate tablets with sudden loss of consciousness and cardiopulmonary arrest.[59] The differential diagnosis of methylphenidate intoxication includes toxicity from the use of cocaine, methamphetamine,

3,4-methylenedioxymethamphetamine (MDMA), mescaline, psilocybin, lysergic acid diethylamide (LSD), phencyclidine, anticholinergic agents, pseudoephedrine, ephedrine, phenylpropanolamine, and caffeine.

Abstinence Syndrome

There are few clinical data on the symptoms associated with withdrawal from chronic abuse of methylphenidate. Withdrawal symptoms are probably similar to the abstinence syndrome associated with amphetamine compounds including apathy, lethargy, depression, and paranoia.[22]

Reproductive Abnormalities

There is insufficient data on the developmental toxicity of chronic methylphenidate use in humans. Although some evidence suggests that the maternal abuse of methylphenidate during pregnancy reduces growth and increases prematurity, the lack of adequately controlled studies limits conclusions regarding the causal relationship between methylphenidate and retarded growth. Therapeutic doses of methylphenidate do not increase the incidence of tics or movement disorders in children or increase the incidence of malformations in surveillance studies.[75] A case series of IV pentazocine and methylphenidate-abusing mothers suggested that the IV abuse of these drugs does not produce unique teratogenic abnormalities, but the neonates of these mothers have a relatively high rate of prematurity and growth retardation similar to neonates of other drug-abusing mothers.[76] Adverse pregnancy outcomes in this series included low intelligence, neonatal withdrawal, and malformations; however, the lack of a control group and multiple confounders (e.g., polydrug abuse, smoking, maternal health) limit conclusions regarding the etiology of these abnormalities.

DIAGNOSTIC TESTING

Analytic Methods

Techniques used to detect methylphenidate include enzyme immunoassay (ELISA), gas chromatography, and gas chromatography/mass spectrometric detection of the *O*-trimethylsilyl, *N*-trifluoroacetyl derivatives.[77] ELISA testing results in a relatively high number (i.e., 10%) of false-positive assays. Liquid chromatography/ tandem mass spectrometry is a more rapid, specific method with a limit of quantitation for methylphenidate and ritalinic acid of 23 μg/L (100 nM) and 117 μg/L (500 nM), respectively.[78] Analysis of urine by chiral derivatization gas chromatographic/mass spectrometry with detection by electron impact ionization/selected ion monitoring allows the determination of methylphenidate isomers.[79] Methods for the quantitation of methylphenidate in hair include liquid chromatography/ positive electrospray ionization/ mass spectrometry in selected ion monitoring acquisition mode[80] and gas chromatography/mass spectrometry with *N*-methyl-bisheptafluorobutyric amide derivatization and analysis of the perfluorobutyryl derivatives in SIM.[81] Using the former method, the methylphenidate concentrations ranged from 0.15–4.17 ng/mg in hair, with decreasing drug concentration in distal hair segments. The limit of detection was 0.02 ng/mg in hair. The methylphenidate concentrations following analysis by the latter method ranged from 0.073–1.1 ng/mg in hair, but the methylphenidate concentration did not correlate closely to the methylphenidate dose based on dividing samples from 17 children into low- (10–15 mg daily), medium- (20 mg daily), and high-dose (40–54 mg daily) groups.

Biomarkers

Blood

There is substantial individual variation in plasma methylphenidate concentrations in individuals given the same dose. In a study of 4 children receiving oral methylphenidate doses of 10–15 mg, the plasma methylphenidate and ritalinic acid concentrations ranged from 4–25 μg/L and 80–250 μg/L, respectively, 3–6 hours after ingestion.[28] A fatality occurred about 1 hour after the IV injection of an estimated 40 mg methylphenidate. The methylphenidate postmortem blood level was 2,800 μg/L and the stomach contents (140 mL) contained 1.6 mg methylphenidate.[82] The presence of small amounts of methylphenidate in the stomach does not imply the ingestion of methylphenidate because this drug is basic and accumulates in the acidic environment of the stomach. There are few data on the blood/plasma ratio of methylphenidate. In a study of a single patient, the whole blood/plasma ratio of methylphenidate was about 0.7–0.8.[34]

Urine

Routine urine immunoassay drug screens are relatively insensitive to the presence of methylphenidate. Liquid chromatography/electrospray ionization/tandem mass spectrometry is a rapid, sensitive, and highly specific method for the detection of methylphenidate and the metabolite, ritalinic acid in urine samples.[78]

Abnormalities

Emphysema can complicate the IV abuse of methylphenidate. Plain radiographs demonstrate a symmetrical distribution, primarily involving the lung bases, while CT scans demonstrate low attenuation in the basilar areas.[57] Right ventricular hypertrophy may develop as a result of pulmonary hypertension. Electrocardiographic abnormalities (e.g., QT_c prolongation, QRS widening, dysrhythmias) are unusual in case series of methylphenidate overdoses reported to poison centers.[72] Pulmonary function tests typically reveal a variety of defects as a result of polydrug use including obstructive defects, restrictive patterns, and decreased diffusing capacity as well as hypoxia.[17]

Driving

The blood sample from a person arrested for erratic driving contained approximately 500 µg methylphenidate/L as measured by gas chromatography with flame ionization detection.[83] This individual performed poorly on balance tests, and he reported that he ingested an indeterminate number of methylphenidate tablets 12 hours prior to his apprehension. Individual variability and tolerance to methylphenidate complicates the correlation of plasma methylphenidate concentrations to effects. An increased frequency of vehicular crashes, traffic citations, driving performance deficits, and driving-related cognitive impairments occur in adolescents and adults with ADHD. Methylphenidate treatment of individuals with ADHD improves driving performance. In a study of high-risk ADHD patients, methylphenidate treatment resulted in improvements in information processing (e.g., visuomotor coordination under high-stress conditions), visual orientation, and sustained visual attention compared with baseline and an untreated ADHD control group.[84] In a virtual driving simulator study of 53 adults with ADHD, two 20-mg doses of methylphenidate reduced impulsiveness, variability of steering in the standard driving course, and driving speed during the obstacle course.[85]

TREATMENT

There are few data on the treatment of serious methylphenidate intoxication; however, the treatment of serious methylphenidate intoxication is similar to the treatment of methamphetamine and amphetamine toxicity. (See Amphetamine/Methamphetamine Treatment section). Most agitated patients intoxicated with methylphenidate respond to reassurance, a quiet environment, and IV benzodiazepines (lorazepam, diazepam).

Haloperidol is an option for the treatment of agitation, delirium, or hallucination associated with methylphenidate intoxication, when optimal benzodiazepine therapy does not control these abnormalities. Similar to methamphetamine, the major life-threatening complications of acute methylphenidate intoxication include hyperthermia, hypertension, seizures, cardiovascular instability, and trauma. Coma, shock, acute renal failure, severe hyperthermia (i.e., temperature >41°C/105.8°F), and seizures are poor prognostic indicators. Severely intoxicated patients require IV access, cardiac monitoring, pulse oximetry, 12-lead ECG, and supplemental oxygen. Respiratory depression does not usually occur during mild to moderate methylphenidate intoxication, but pulmonary edema (cardiogenic or due to acute lung injury) can develop during severe methylphenidate poisoning. Underlying pulmonary hypertension occurs in habitual IV methylphenidate users that may intensify during acute methylphenidate intoxication.

Most patients tolerate sinus tachycardia without pharmacologic intervention. Both hypertension and tachycardia often respond to IV benzodiazepines (adults: lorazepam 2 mg or diazepam 5 mg IV bolus titrated to effect). Core temperatures should be measured in any agitated patient. Patients with suspected myocardial ischemia as a result of underlying cardiac disease should be managed with nitrates, morphine, benzodiazepines, and aspirin. Hypotension may respond to fluid challenges, but a vasopressor is often needed. Shock is a poor prognostic sign that indicates the need for monitoring of cardiac output to determine the most efficacious combination of fluid and vasopressors. There are no specific antidotes for methylphenidate intoxication, and there are no clinical data to support the use of methods to enhance the elimination of methylphenidate.

Chapter 3

PROLINTANE

HISTORY

Prolintane hydrochloride is a central nervous system (CNS) stimulant that has been marketed in Europe since the 1960s as an antidepressant (i.e., antifatigue), analeptic, and vasopressor (i.e., orthostatic hypotension) agent. The first reports of prolintane abuse appeared in Europe during the early 2000s when prolintane was identified in tablets distributed at a rave party (i.e., all-night dancing with electronically synthesized music).[1] Later reports documented the recreational use of prolintane in the United States.[2]

IDENTIFYING CHARACTERISTICS

Prolintane (CAS RN: 493-92-5, $C_{15}H_{23}N$) is a synthetic sympathomimetic amine with pharmacologic properties similar to d-amphetamine. The molecular weight (MW) of prolintane is 217.35 g/mol, whereas the MW of the hydrochloride salt (CAS RN: 1211-28-5) is 253.8 g/mol. Prolintane hydrochloride is a water-soluble compound that is a white powder with a melting point of approximately 133ºC. Figure 3.1 demonstrates the chemical structure of prolintane [(R,S)-1-(α-propylphenethyl)-pyrrolidine].

EXPOSURE

Therapeutic uses of prolintane in Africa, Europe, and Australia include the treatment of narcolepsy, attention deficit hyperactivity disorder (ADHD), fatigue, and orthostatic hypotension. Prolintane is formulated with multivitamins including ascorbic acid and sold as an orange tablet (e.g., "kitovit") or a tonic. Proprietary preparations include Villescon® (Boehringer Ingelheim, Berkshire, UK), Promotil® (Boehringer Ingelheim, Paris, France), and Catovit® (Boehringer Ingelheim, New South Wales, Australia). This drug is not approved for pharmaceutic use in the United States. Prolintane is a popular rave drug in Europe, but the documented use of prolintane in this setting in the United States is rare.[1] Additionally, prolintane has been implicated as a doping agent in athletics (e.g., cycling);[3] this compound is now banned by the US National Collegiate Athletic Association and the World Anti-Doping Agency (WADA).[4]

DOSE EFFECT

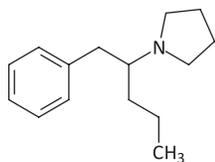
Typical adult therapeutic doses of prolintane are 10–40 mg daily. In therapeutic trials, 20 mg prolintane is a mild stimulant equivalent to approximately 100 mg caffeine.[5] The use of therapeutic doses of prolintane is associated with a subjective feeling of improved concentration and decreased fatigue, but there are minimal changes in objective measures of fatigue and mental activity.[6] The stimulant properties of prolintane are substantially less than d-amphetamine. In a study of fatigued volunteers, the administration of 20 mg or 40 mg prolintane produced similar, but less intense effects than 20 mg d-amphetamine.[7] These clinical effects included stimulation, euphoria, anorexia, and mild elevation of systolic blood pressure. In experimental studies of healthy volunteers, prolintane has little cardiovascular activity following the administration of a single dose of 20 mg.[8] This dose slightly improves some mental tasks (e.g., sign


FIGURE 3.1. Chemical structure of prolintane.

recordings), but not others (e.g., digit span). The clinical significance of these results on memory, learning, and concentration is unclear. In volunteer studies, the administration of prolintane (20–40 mg) increases wakefulness and improves performance on some perceptual and arithmetic tasks in fatigued individuals.[7,9]

TOXICOKINETICS

The first-pass effect of prolintane is large. Prolintane undergoes extensive oxidation and *N*-dealkylation in the body with the formation of at least 18 metabolites. The metabolism of prolintane primarily involves biotransformation. The major metabolic pathways are aromatic hydroxylation (*para*- and *meta*-positions), lactam formation, γ-amino acid formation, heterocyclic hydroxylation (3- and 4-positions), and propyl hydroxylation at ω-, (ω-1)-positions.[10] Oxidation of the α-carbon of the pyrrolidine ring forms the major metabolite, oxoprolintane. In a study of 5 healthy volunteers receiving 0.15 mg prolintane/kg intravenously, the mean plasma elimination half-life was approximately 4.5 hours.[11] The urine pH of these volunteers was within the normal range. The kidney excretes minimal amounts (i.e., <1–2%) of prolintane unchanged.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Prolintane is a CNS stimulant with many pharmacologic properties similar to *d*-amphetamine. However, rodent studies indicate that prolintane enhances brain dopamine turnover produced by dopamine receptor antagonists similar to methylphenidate and cocaine, whereas amphetamine and methamphetamine do not cause similar effects.[12]

CLINICAL RESPONSE

Prolintane is a sympathomimetic amine that has psychostimulant properties similar to *d*-amphetamine and phentermine. Adverse effects of therapeutic doses include nausea, vomiting, anxiety, irritability, insomnia, lightheadedness, headache, euphoria, palpitations, diaphoresis, confusion, agitation, disorientation, and acute

psychosis.[13] Clinical effects associated with the abuse of prolintane include lightheadedness, insomnia, irritability, and nervousness. Excessive use of prolintane may also cause hypertension, tachycardia, hyperreflexia, mydriasis, hyperthermia, agitation, confusion, disorientation, hallucinations, and psychosis.

DIAGNOSTIC TESTING

Analytic methods for the detection of prolintane include thin-layer chromatography,[14] gas chromatography with nitrogen-selective detection,[11] high performance liquid chromatography with ultraviolet detection (252 nm, 258 nm, 264 nm),[2] gas chromatography/mass spectrometry,[15] and capillary zone electrophoresis with β-cyclodextrin-modified micellar electrokinetic chromatography.[16] The limit of detection (LOD) and lower limit of quantitation (LLOQ) for the latter method were 300 ± 100 ng/mL and $1,000 \pm 100$ ng/mL, respectively. Prolintane is 1 of 14 tertiary amine stimulants detected by screening and confirmation with gas chromatography/mass spectrometry and liquid chromatography/tandem mass spectrometry.[17] The LOD in urine samples using this method is 10 ng/mL; this method meets WADA's requirements for sensitivity. Following the intravenous (IV) injection of 0.15 mg prolintane/kg to 5 healthy volunteers, the mean peak plasma prolintane concentration was approximately 60 ng/mL.[11] Prolintane use is not usually detectable by routine urine immunoassay drug screens.

TREATMENT

Treatment is supportive, similar to the treatment of *d*-amphetamine intoxication.

Chapter 4

PROPYLHEXEDRINE

HISTORY

The Smith, Kline, and French Company introduced Benzedrine® inhalers during the early 1930s as racemic amphetamine. One Benzedrine® inhaler contained the equivalent of 250 mg of racemic amphetamine. These inhalers remained available as over-the-counter products until 1949, when Smith Kline & French voluntarily removed amphetamine inhalers from the market in response to reports of abuse and sudden death.[1,2] The Benzedrine® inhaler was replaced by the Benzedrex® inhaler (B.F. Ascher & Co., Lenexa, KS), which contained 250 mg of propylhexedrine (i.e., no amphetamine) in a combination with 12.5 mg methanol and various aromatics hydrocarbons. Some airlines (e.g., Pan American) distributed Benzedrex® inhalers in the 1950s as decongestants to reduce discomfort resulting from changes in cabin pressures. The usual method of Benzedrine® and Benzedrex® abuse involved the chewing and swallowing of the amphetamine-containing cotton pledget, preferably with chewing gum to reduce the irritant properties of the base. Occasionally, the strips were soaked in beverages (i.e., coffee, alcohol) or swallowed whole. One study of an incarcerated population in the 1940s revealed that 25% of the inmate population used the inhalant material for recreational purposes.[3] By the mid-1970s, the medical literature contained reports of both oral and intravenous (IV) abuse of the propylhexedrine inhalers. The abuse of propylhexedrine was sporadic throughout North America with cases reported from Dallas, Toronto, and San Francisco during the 1980s;[4] however, there are little current data on propylhexedrine abuse because most national US databases on drug abuse do not include propylhexedrine.

IDENTIFYING CHARACTERISTICS

Propylhexedrine (CAS RN: 101-40-6, MW = 155.3 g/mol) is an α-adrenergic agonist with a molecular formula of $C_{21}H_{10}N$. This slightly water-soluble compound is a clear, colorless liquid that vaporizes slowly at room temperature. The hydrochloride salt of propylhexedrine (MW = 191.7 g/mol) is a crystalline solid with a melting point of approximately 127°C/260.6°F. Table 4.1 displays some physical properties of propylhexedrine.

This drug is an alicyclic aliphatic sympathomimetic amine structurally similar to methamphetamine. Figure 4.1 displays the structural similarity between propylhexedrine and other common aromatic sympathomimetic compounds including methamphetamine and the neurotransmitter, epinephrine.

EXPOSURE

The primary medicinal use of propylhexedrine is the symptomatic relief of nasal congestion without rebound. Propylhexedrine is a potent α-adrenergic sympathomimetic agent, which is a "stimulant of last resort" for abusers when more desirable stimulants are unavailable. However, the abuse potential of propylhexedrine is low compared with methamphetamine, phenmetrazine, or methylphenidate.[5] Most drug users prefer cocaine and methamphetamine to propylhexedrine, and propylhexedrine abuse is typically brief as the users rapidly lose interest in the drug.[3] The street names for

TABLE 4.1. Physical Properties of Propylhexedrine.

Physical Property	Value
Boiling Point	205°C/401°F
log P (Octanol-Water)	3.500

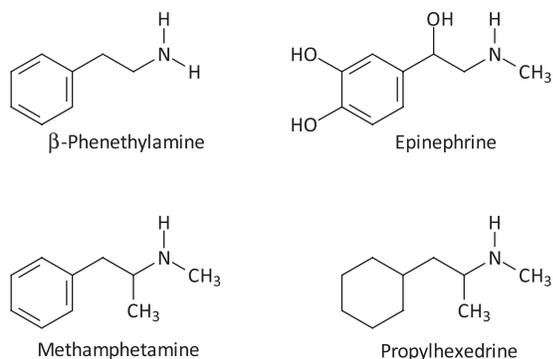

FIGURE 4.1. Structural similarities of methamphetamine, β-phenylethylamine, epinephrine, and propylhexedrine.

the propylhexedrine extract include Bathtub Crystal, Crystal, and Bathtub Crank. Abuse of propylhexedrine nasal inhalers involves habitual inhalation, ingestion or chewing of the propylhexedrine-containing cotton plug, or injection of an acidic solution prepared from the dismantled inhaler. Nasal abuse of propylhexedrine is uncommon.

Habitual use of these inhalers involves the daily use of the contents of 2 to 11 inhalers. Following the disassembly of the inhaler, the cotton pledget is soaked in muriatic (hydrochloric) acid to remove the propylhexedrine.[4] Heating of this extract produces a brown residue that subsequently is redissolved in water and injected. Depending on the purity of the process, the resultant solution contains a variety of impurities including polymeric material, fine fibers, methanol, and lavender oil. Some patients with previous amphetamine experience consider the euphoria induced by the IV injection of Benzedrex® extracts, 15 mg of methamphetamine, and 75 mg of phenmetrazine similar.[6] Benzedrex® abuse is commonly associated with polydrug abuse and homosexual activities.[7] Euphoria apparently does not result from inhalation.

DOSE EFFECT

The ingestion of a hot water extract of a cotton pledget containing 250 mg propylhexedrine produced anxiety, agitation, tremors, nausea, and diaphoresis that resolved without sequelae 4 hours after ingestion.[8] Ingestion of an estimated 375 mg propylhexedrine by a 3-year-old caused tremor, muscle spasticity, tachycardia, and insomnia that resolved without sequelae.[9]

TOXICOKINETICS

Propylhexedrine penetrates the blood–brain barrier rapidly. In rodent studies, this drug has a large volume of distribution ($V_d = 19.3$ L/kg) after IV administration.[10] Biotransformation of propylhexedrine involves N-demethylation, N-oxidation, and 4″-hydroxylation with urinary metabolites including norpropylhexedrine, cyclohexylacetoxime, and 4-hydroxypropylhexedrine.[11] The approximate elimination half-life of propylhexedrine after IV administration to rodents is about 2.5 hours.[8]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

Propylhexedrine is a potent local vasoconstrictor with substantially less (i.e., <10%) CNS stimulating effect compared with dextroamphetamine sulfate. The acute toxicity of propylhexedrine is an exacerbation of pharmacologic effects of this drug. The psychoactive effects of these compounds result from indirect agonist actions that cause the displacement of catecholamines from binding sites in the storage vesicles.

At least in part, the central effects of propylhexedrine result from alterations in the neurotransmitters, dopamine and norepinephrine, because of the close structural resemblance of amphetamine compounds to these neurotransmitters. Increasing the synaptic concentration of these neurotransmitters either by direct release from storage vesicles or by inhibition of reuptake is the most likely mechanism of toxicity.

Postmortem Examination

Autopsies of individuals with a history of IV propylhexedrine abuse usually demonstrate foreign body granulomas in the pulmonary parenchyma containing birefringent crystalline material along with variable amounts of pulmonary hypertension and right ventricular hypertrophy.[12] Histologic examination reveals diffuse interstitial alveolar fibrosis, pulmonary edema with focal intra-alveolar hemorrhage, intimal and medial proliferation with luminal obstruction, medial hypertrophy of the muscular arteries, and focal myocardial fibrosis (usually without clinically significant coronary artery stenosis).[13]

CLINICAL RESPONSE

Illicit Use

Propylhexedrine is a potent local vasoconstrictor with mild to moderate CNS stimulant effects. Although propylhexedrine seems structurally similar to methamphetamine, the substitution of a cyclohexyl ring for the phenyl moiety substantially reduces the desirable CNS effects of propylhexedrine. Mild intoxication causes restlessness, irritability, anxiety, mydriasis, diaphoresis, nausea, and tachycardia. More severe effects associated with serious propylhexedrine intoxication include hypertension, tachypnea, cardiac dysrhythmias, hyperpyrexia, seizures, psychosis, and coma.

MENTAL DISORDERS

A case report associated the development of an acute paranoid psychosis with the daily chewing of 10–12 propylhexedrine inhalers by 2 amphetamine abusers.[14] The psychosis in both of these patients resolved after the cessation of drug use. Initially, the propylhexedrine abuser can experience headache, nausea, and double vision followed by euphoria that lasts several hours.[4] Case reports associate deterioration of chronic paranoid schizophrenia with the chewing of propylhexedrine decongestant inhalants as manifest by the onset of acute delusional mood and paranoid delusions.[15] Other factors (sleep deprivation, predrug personality, idiosyncratic reactions) contribute to the development of the toxic psychosis. Homicidal and suicidal ideations may occur during drug-induced psychosis.[5]

MEDICAL COMPLICATIONS

Peripheral vascular complications of IV propylhexedrine abuse include local ischemia with necrosis of the digits requiring amputation,[16] cellulitis, sterile abscess, and a fatal abscess in the neck after an attempted central venous injection of an aqueous extract of propylhexedrine-containing inhalers.[17] Incidental injection of the propylhexedrine extract into a peripheral artery caused local vasoconstriction, inflammation, infection, and necrosis manifest by intense pain, marked edema, blanching of the extremity, and loss of distal arterial pulses.[18] A case report of a 22-year-old man associated the development of pulmonary edema, hypotension, anterior myocardial infarction on electrocardiogram (ECG), accelerated junctional rhythm, and pericardial effusion with the ingestion of 250 mg of propylhexedrine obtained from a Benzedrex® inhaler several hours prior to the onset of symptoms.[19] The patient recovered after intensive cardiorespiratory support. There was no cardiac angiography or echocardiography. Pulmonary edema is a common finding among habitual IV propylhexedrine abusers presenting to emergency departments with dyspnea and cardiovascular instability; cor pulmonale can develop in these patients.[11] Case reports associated the IV use of propylhexedrine extracts with the development of brainstem dysfunction including transient diplopia, right-internuclear ophthalmoplegia, and focal paralysis of the tongue.[7]

Fatalities

Several case reports associated cardiac arrest with the chronic IV administration of propylhexedrine, particularly during extreme exertion (e.g., resisting arrest, fleeing from an assailant or a crime scene)[20] or working outside.[21] These patients are frequently severely acidotic, hypotensive, and unresponsive to the standard techniques of advanced cardiac life support. Right ventricular hypertrophy and pulmonary hypertension is often present. A 29-year-old man was transported to a hospital with abdominal pain, nausea, vomiting, and chest pain.[11] Shortly after arrival, he developed a seizure, severe metabolic acidosis, hypotension, and cardiopulmonary arrest. He had no evidence of ischemia on the ECG, and the chest x-ray demonstrated right ventricular cardiomegaly and pulmonary edema.

DIAGNOSTIC TESTING

Analytic Methods

Analysis of biologic samples for propylhexedrine is similar to the methods used to detect methamphetamine and amphetamine; typically these methods involve gas chromatographic separation with detection by flame ionization (FID), mass spectrometry (MS), or nitrogen–phosphorus detection (NPD). Challenges associated with inadequate chromatographic resolution or co-elution of propylhexedrine with methamphetamine can be resolved by the use of selective ion monitoring (SIM) mode in the mass spectrometer. Preanalytical derivatization with heptafluorobutyric anhydride or 4-carbethoxyhexafluorobutyryl chloride following chromatographic separation and MS detection in SIM mode also effectively distinguishes methamphetamine from propylhexedrine. Mass spectral fragmentation of methamphetamine includes the tropylium ion (m/z 91) from phenyl ring expansion and benzyl carbon incorporation; the lack of a phenyl ring in propylhexedrine eliminates this ion from its mass spectrum. Additionally, the mass spectrum of propylhexedrine includes a prominent occurrence at m/z 182, which is

absent in the mass spectrum of methamphetamine.[22] High performance liquid chromatography/atmospheric pressure chemical ionization/mass spectrometry does not require preanalytical derivatization necessary for gas chromatographic analysis. This method allows the separation of sympathomimetic amines including propylhexedrine with limits of detection in the range of 0.001–0.005 mg/L.[23]

Biomarkers

The blood propylhexedrine concentration in blood samples drawn 30 minutes after the insufflation of 15 puffs from a Benzedrex® inhaler by a healthy volunteer was 0.1 mg/L. The typical dose of Benzedrex® inhaler is 2 puffs in each nostril. A 30-year-old man was found dead in his residence with multiple cotton pledgets from disassembled Benzedrex® inhalers.[24] The postmortem blood propylhexedrine concentration was 30 mg/L. Typically, the postmortem blood samples of IV abusers found dead after propylhexedrine injection ranges from approximately 1.0–2.5 mg/L. The postmortem propylhexedrine concentration in blood samples from 2 IV propylhexedrine abusers found dead was 0.3 mg/dL and 2.0 mg/L compared with 1.6 mg/L in postmortem blood from an IV propylhexedrine abuser who died 3 hours after admission to the emergency department with pulseless electrical activity.[10] The propylhexedrine concentrations in postmortem blood samples from patients dying from causes other than propylhexedrine intoxication can overlap with the concentrations associated with fatal IV propylhexedrine intoxication. The propylhexedrine concentrations in postmortem blood from a 23-year-old hanging victim, a 25-year-old with fatal head wounds, and a 27-year-old man with fatal gunshot wounds to the chest were 2.5 mg/L, 1.1 mg/L, and 0.8 mg/L, respectively.[11]

Abnormalities

With the exception of the carbon monoxide diffusing capacity, pulmonary function tests are often normal in IV propylhexedrine abusers.[5] Pulmonary fibrosis, right ventricular hypertrophy, and pulmonary hypertension are frequent findings in chronic IV propylhexedrine abusers.

TREATMENT

Stabilization

The treatment of propylhexedrine intoxication is similar to the treatment of methamphetamine and amphetamine toxicity. Most agitated patients intoxicated with propylhexedrine respond to reassurance, a quiet environment, and IV benzodiazepines (lorazepam, diazepam). Similar to methamphetamine, the major life-threatening complications of acute propylhexedrine intoxication include hyperthermia, hypertension, seizures, cardiovascular instability, and trauma. Coma, shock, acute renal failure, severe hyperthermia (i.e., temperature >41ºC/105.8ºF), and seizures are poor prognostic indicators. Severely intoxicated patients require IV access, cardiac monitoring, pulse oximetry, an ECG, and supplemental oxygen. Respiratory depression does not usually occur during mild to moderate propylhexedrine intoxication, but pulmonary edema (i.e., cardiogenic, acute lung injury) can develop during severe propylhexedrine poisoning. Underlying pulmonary hypertension can occur in habitual IV propylhexedrine users.

Most patients tolerate sinus tachycardia without pharmacologic intervention unless the tachycardia results from right-sided heart failure. Both hypertension and tachycardia often respond to IV benzodiazepines (Adult: lorazepam 2 mg or diazepam 5 mg IV bolus titrated to effect). Core temperatures should be measured in any agitated patient. Patients with suspected myocardial ischemia should be managed according to the usual guidelines for myocardial ischemia including aspirin, antiplatelet agents, thrombolytics, primary percutaneous coronary intervention, and blood pressure control as needed. Hypotension may respond to fluid challenges, but often a vasopressor is needed. Shock is a poor prognostic sign that indicates the need for monitoring of cardiac output to determine the most efficacious combination of fluid and vasopressors. There are no specific antidotes for propylhexedrine intoxication or efficacious methods to enhance the elimination of propylhexedrine.

Supportive Care

Treatment for local tissue damage resulting from the IV administration of extracts containing propylhexedrine includes antibiotics, vasodilators, debridement, and local wound care. The presentation of serious deep infections in the setting of distal ischemia may be subtle; therefore, suspected areas of infection should be imaged with ultrasound or magnetic resonance imaging (MRI) and early drainage. Distal ischemia is usually an isolated problem resulting from inadvertent intra-arterial administration of propylhexedrine; there are few clinical data on outcomes to guide treatment of the distal ischemia. Therapeutic options for the treatment of ischemia include intra-arterial tolazoline (12–25 mg/limb), IV nitroprusside infusions (0.5–8 μg/kg/min), Dextran 40 (80 mL/h), local nerve blocks, and axillary nerve block.

If a compartment syndrome is suspected, compartment pressures should be measured to help guide the need for fasciotomy. Criteria for fasciotomy include <30 mm Hg difference between compartment and diastolic blood pressures or obvious clinical symptoms of compartment syndrome (severe pain unrelieved by splinting, severe pain with passive stretching unrelated to injury).[25] Supportive care for compartment syndrome includes analgesics, elevation of extremities, and consideration of the use of anticoagulant or antiplatelet drugs.[26] Although the use of prostanoids (e.g., iloprost) is an option for the treatment of critical distal ischemia, there is no conclusive evidence of the long-term effectiveness and safety of different prostanoids including iloprost.[27]

Chapter 5

FLUNITRAZEPAM

HISTORY

In 1975, Hoffmann-La Roche (Roche) Pharmaceuticals (Basel, Switzerland) introduced flunitrazepam (Rohypnol®) into European markets as a more potent hypnotic drug than diazepam. Case reports of flunitrazepam abuse appeared in the United States in the early 1990s despite the lack of approval of this drug for medical use. The first US confiscation of illicit flunitrazepam occurred in 1989; in 1996, the importation of flunitrazepam across the US border was banned.[1] In 1995, the World Health Organization (WHO) recommended the change of flunitrazepam from a schedule IV classification (small, but significant risk of abuse) to a schedule III (a substantial risk to public health) of the Convention on Psychotropic Substances based on the widespread abuse of flunitrazepam by opiate abusers. In an attempt to reduce the abuse of flunitrazepam in the late 1990s, Roche Pharmaceuticals reduced the number of Mexican distributors, discontinued the sale of the 2-mg tablet, halted direct sale of flunitrazepam to pharmacies, and added blue dye to the tablets.

IDENTIFYING CHARACTERISTICS

Flunitrazepam (2H-1,4-benzodiazepin-2-one,1,3-dihydro-5-(2-fluorophenyl)-1-methyl-7-nitro-) has a molecular formula of $C_{16}H_{12}FN_3O_3$. Figure 5.1 displays the chemical structure of flunitrazepam (CAS RN: 1622-62-4), which is similar to the chemical structure of diazepam. The pKa of flunitrazepam is 1.82; at 37°C, the water solubility decreases as the pH increases resulting in a decrease in solubility as the drug moves from the acidic environment of the stomach to the more alkaline environs of the small intestines. At body temperature, the water solubility of this compound is 850 µg/mL (pH 1), whereas the water solubility decreases to 6 µg/mL at pH 7.4. Flunitrazepam is tasteless, colorless, and soluble in ethanol. However, reformulation of flunitrazepam tablets in the late 1990s resulted in the slow dissolution of the tablets and a cloudy, blue-tinged solution. Flunitrazepam is highly lipid soluble, with rapid penetration of the blood–brain barrier and fast onset of central nervous system (CNS) action compared with most other benzodiazepines. Table 5.1 lists some physiochemical properties of flunitrazepam.

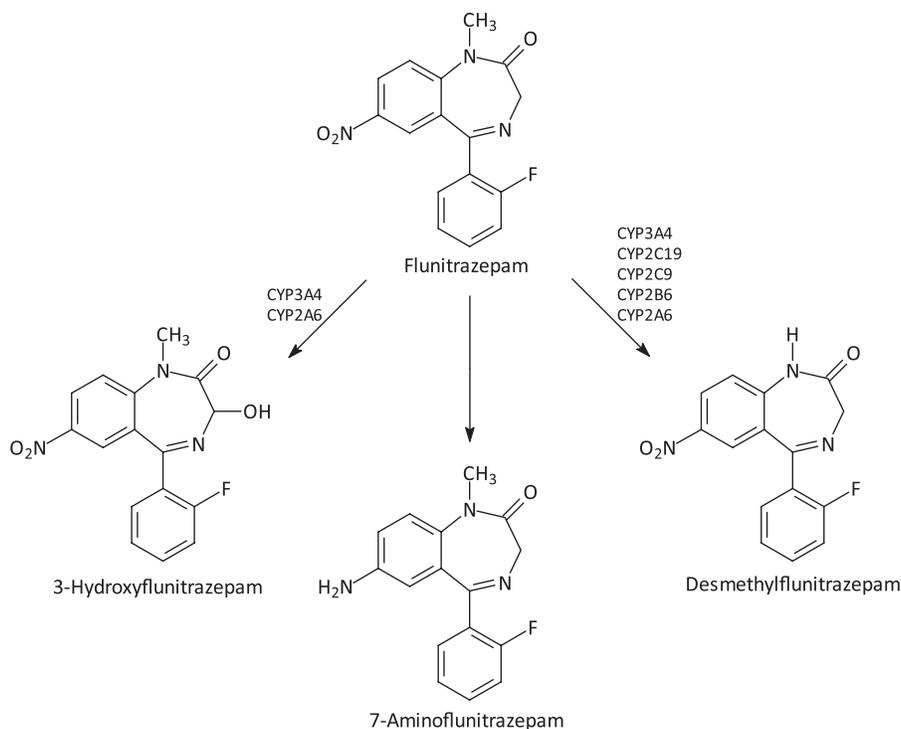
Street names for Rohypnol® include Roofies, Rophies, Ropies, Ruffiew, Ribs, Ropes, Ropers, Roches, Rochas, Rochas Dos (2-mg tablet), Rophs, R-25, R05-4200, Roach-2s, Rubies, Forget Pills, Mexican Valium, Circles, Darkene, La Roche, Mind Erasers, Papas, Peanuts, Trip and Fall, Remember All, Wolfies, and the Date Rape Drug. A variety of pharmaceutic companies market flunitrazepam in some countries throughout the world as tablets and solutions under different trade names including Darkene® (Bayer Schering Pharma, Berlin, Germany), Ilman® (Demo S.A., Athens, Greece), Insom® (Aspen Pharmacare, Johannesburg, South Africa), Hipnosedon® (Roche), Hypnodorm® (Alphapharm, New South Wales, Australia; Teva, Petach Tikva, Israel), Nilium® (HELP S.A. Pharmaceutical Co., Athens, Greece), Roipnol® (Roche), Valsera® (Polifarma, Rome, Italy), and Vulbegal® (Coup Pharmaceutical Products S.A., Athens, Greece).[2] The tablets are crushed by flunitrazepam addicts for insufflation or injection. Flunitrazepam is a pharmaceutic preparation that is


FIGURE 5.1. Biotransformation of flunitrazepam.

TABLE 5.1. Some Physiochemical Properties of Flunitrazepam.

Physical Property	Value
Melting Point	166–167°C (~331–333°F)
log P (Octanol-Water)	2.06
Water Solubility	72.8 mg/L (25°C)
Vapor Pressure	2.54E-09 mm Hg (25°C)
Henry's Law Constant	2.26E-11 atm-m³/mole (25°C)
Atmospheric OH Rate Constant	6.05E-12 cm³/molecule-second (25°C)

relatively pure. However, surreptitious substitution of other benzodiazepines (e.g., lorazepam, diazepam, clonazepam, bromazepam) for flunitrazepam may occur.

EXPOSURE

Epidemiology

Although flunitrazepam has never been approved for medical use in the United States, this compound is a frequently prescribed hypnotic drug in many countries, particularly in Scandinavia. The US National

Institute on Drug Abuse lists flunitrazepam as a "club drug" along with methamphetamine, 3,4-methylenedioxymethamphetamine (ecstasy, MDMA), LSD (*d*-lysergic acid diethylamide), ketamine, and GHB (γ-hydroxybutyrate). The use of ketamine and flunitrazepam among American youth is the least prevalent drug among these club drugs with a lifetime use of 0.4% for US youth aged 16–23 years based on the annual National Survey on Drug Use and Health.[3] With the exception of use of this drug during sexual assault, the abuse of flunitrazepam occurs primarily among multidrug users of club drugs, particularly women.

Sources

Flunitrazepam is a sedative-hypnotic drug available in many countries in Europe, Asia, Australia, and South America. This drug has not been approved for therapeutic use in the United States or Canada. Medical uses outside the United States include the treatment of insomnia, preanesthetic anxiety, and agitation. Flunitrazepam is marketed as 0.5-mg and 1-mg tablets as well as an injectable form. The United States banned the importation of flunitrazepam in 1996, but Mexico and some Latin American countries remain sources for smuggling flunitrazepam into the United States. An epi-

demic of anticholinergic poisoning (i.e., mydriasis, visual hallucinations, plucking behavior, agitation, coma) occurred when scopolamine was sold as illicit Rohypnol®.[4]

Methods of Abuse

Flunitrazepam produces a sense of relaxation and disinhibition similar to ethanol. Certain individuals use flunitrazepam to enhance the effects of ethanol or marijuana. The primary route of flunitrazepam abuse is ingestion, particularly in combination with the abuse of other drugs by polydrug abusers.[5,6] The abuse of flunitrazepam alone is uncommon. Other routes of flunitrazepam abuse include the injection or insufflation of crushed flunitrazepam tablets.[7,8] Flunitrazepam is a common drug of abuse among benzodiazepine-using heroin addicts.[9] Volunteer studies in methadone-maintained patients suggest that high doses of flunitrazepam (4 mg) produce euphoria in these patients.[10] Similar to other benzodiazepines, medicinal use of flunitrazepam frequently involves the chronic administration of this drug. In this setting, there is no definite evidence that the abuse of flunitrazepam is greater than other potent benzodiazepines.[11]

Flunitrazepam is one of numerous drugs used to chemically subdue victims in a sexual assault or robbery.[12,13] The victim's suggestibility and passivity after flunitrazepam ingestion provide the opportunity for assault with little or no recollection by the victim. Anecdotal reports suggest that the victim may develop drowsiness after the ingestion of a drink laced with the drug, and then loss of memory; subsequently, the victim remembers awakening in a place different than the original location.[14] Despite widespread media attention, flunitrazepam is an uncommon agent of suspected rapists based on the analysis of urine specimens from cases reported to rape treatment centers.[15,16] Ethanol remains the most common drug detected in samples collected from cases of suspected drug-facilitated sexual assault. In a prospective case series of 78 inner-city emergency department patients alleging the ingestion of a spiked drink, unexplained sedative drugs were detected in only 2 patients.[17] The mean time between alleged exposure and biologic sampling was 5.9 hours (range, 1–12 h). Sixty percent of the participants in the study had serum ethanol concentrations exceeding 150 mg/dL. Analysis of 2,003 urine samples of suspected chemical assault victims referred from a US rape treatment center demonstrated that alcohol and marijuana metabolites were present in 63% and 30% of these samples, respectively.[14] Flunitrazepam was detected in <0.5% of these urine samples, usually in combination with other drugs.

DOSE EFFECT

Illicit Use

Interviews with flunitrazepam abusers suggest that flunitrazepam use is occasional in most of the polydrug users, but some chronic abusers ingest up to 7–15 tablets at one time, usually with alcohol.[7] Drug-facilitated sexual assault case reports indicate that the ingestion of flunitrazepam doses as low as 1 mg can cause antero-grade amnesia, drowsiness, and confusion within the immediate period after consumption of an adulterated drink.[18] Despite these effects, case reports suggest that some automated tasks (e.g., driving) can be accomplished during the period of amnesia with some impairment of psychomotor skills.

Medical Use

The usual therapeutic dose of flunitrazepam for the treatment of insomnia is 1–2 mg at bedtime. Similar to other benzodiazepines, volunteer studies indicate that flunitrazepam doses between 1–4 mg produce dose-dependent effects on psychomotor performance (e.g., reaction time, balance, hand-eye coordination), vigilance, attention, and short-term memory, particularly explicit memory (recall/recognition of recent events and personal interactions).[19,20] Flunitrazepam induces memory loss during the time of peak effect of the drug. This inability to recall information occurs at the same doses used to promote sleep. Higher doses produce longer periods of memory loss, but the limited data to date do not indicate that the amnesic action of flunitrazepam is significantly greater than other potent benzodiazepines.[21]

Toxicity

Based on French poison center data, the ingestion of 0.25–0.29 mg flunitrazepam/kg was a potentially toxic dose of flunitrazepam that required medical supervision.[22] A review of the toxicity associated with the ingestion of excessive doses of flunitrazepam suggested that the ingestion of single doses of 10–30 mg by adults produces coma, whereas the ingestion of 40–50 mg causes respiratory depression.[21] The ingestion of 40 mg flunitrazepam by a 21-month-old boy was associated with coma, respiratory depression, hypotonia, bradycardia, and hypotension.[23] Tolerance to the effects of flunitrazepam is not well defined. The suicidal ingestion of 100 mg flunitrazepam by a 24-year-old woman was associated with sedation and hypoventilation, requiring the continuous infusion of the antidote, flumazenil.[24]

TOXICOKINETICS

Absorption

The oral bioavailability of flunitrazepam is approximately 80–90%.[25] Volunteer studies indicate that the peak plasma concentration of flunitrazepam occurs about 2 hours after ingestion of 2 mg flunitrazepam with initial peak flunitrazepam concentrations ranging from about 10–15 ng/mL.[26,27]

Distribution

Following the intravenous (IV) administration of flunitrazepam to patients prior to anesthesia, the average volume of distribution at steady state is about 2.5–3.5 L/kg.[28,29] Plasma protein binding is approximately 80%.[30] Distribution kinetics rather than elimination kinetics are the primary determinate of the duration of action of flunitrazepam with an open 3-compartment model best describing the disappearance of flunitrazepam from the blood.

Biotransformation

Flunitrazepam is structurally similar to diazepam, and the oxidative pathways of these 2 benzodiazepines are similar. The biotransformation of flunitrazepam produces many metabolites including the major metabolites *N*-desmethylflunitrazepam, 3-hydroxyflunitrazepam, and 7-aminoflunitrazepam. Existing data suggests that metabolites account for minor, if any effects of flunitrazepam. Receptor binding studies suggest that the binding of desmethylflunitrazepam is similar to flunitrazepam, whereas the binding of 7-aminoflunitrazepam is an order of magnitude less than flunitrazepam.[31] There are inadequate human studies to determine if any of these metabolites are present in sufficient concentrations to produce clinical or toxic effects; the main hypnotic effects of flunitrazepam probably result from the parent compound. *In vitro* studies suggest that CYP3A4 is the major CYP isoform involved with the oxidation of flunitrazepam to *N*-desmethyl-flunitrazepam and 3-hydroxy-flunitrazepam as displayed in Figure 5.1.[32] Although *in vitro* studies suggest the involvement of CYP2C19 in the oxidation of flunitrazepam,[33] *in vivo* studies indicate that the role of CYP2C19 in the formation of *N*-desmethylflunitrazepam and 3-hydroxyflunitrazepam is minor.[34]

Elimination

Flunitrazepam is almost completely metabolized with only small amounts of this drug appearing in the urine unchanged. The plasma elimination half-life of flunitrazepam is about 24–48 hours. Following IV administration of a mean flunitrazepam dose of 21 μg/kg (range, 14–33 μg/kg) to 12 patients undergoing anesthesia, the mean serum elimination half-life of flunitrazepam was about 25 hours (range, 15–66 h).[28] In a study of 8 patients ingesting 2 mg flunitrazepam daily for 28 days, the terminal plasma elimination half-life was 20–36 hours.[26] Another study of healthy adults receiving single and multiple doses of flunitrazepam, the terminal elimination half-life averaged about 13 hours and 19 hours, respectively.[29] The plasma elimination half-life of flunitrazepam substantially exceeds the duration of action as a result of the rapid distribution of flunitrazepam into the tissues.

Maternal and Fetal Kinetics

Flunitrazepam crosses the placenta. The fetus is considered part of the deep (3rd) compartment. In a study of pregnant women near term receiving intramuscular flunitrazepam, there was no statistically significant difference between maternal and fetal venous plasma concentrations of flunitrazepam.[30] Although flunitrazepam appears in the milk of breast-feeding mothers ingesting flunitrazepam, clinical effects in the breast-feed infant are not expected unless high doses of flunitrazepam are ingested.[35]

Tolerance

Although tolerance to benzodiazepines develops during chronic administration, there are few data on tolerance in flunitrazepam users.

Drug Interactions

Flunitrazepam potentially enhances the effect of other sedative-hypnotic drugs, ethanol, and buprenorphine. In volunteer studies, the combination of a morning dose of ethanol (0.5 g/kg body weight) and prior-evening dose of flunitrazepam (2 mg) significantly impaired standing steadiness, tracking, and reaction times when compared with flunitrazepam and ethanol alone.[36]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

Commercially available benzodiazepines produce therapeutic effects by binding to benzodiazepine receptors within the γ-aminobutyric acid$_A$ (GABA$_A$)-complex. However, these drugs differ in their effects from phar-

macologic (i.e., duration and onset of action) and pharmacodynamic actions. Similar to other benzodiazepines, flunitrazepam is an indirect γ-aminobutyric-acid (GABA) agonist that enhances the binding of GABA to postsynaptic neuronal chloride channels. This action opens the chloride channel of post-synaptic neurons, resulting in an influx of chloride and hyperpolarization of the cell along with a reduction in cell excitability. The enhancement of inhibitory neurotransmission in the brain and spinal cord causes sedation and reduced anxiety. Benzodiazepines potentiate GABA-mediated inhibition in a more selective manner than barbiturates and ethanol by increasing the affinity of GABA for its receptor. The potency of a specific benzodiazepine compound depends on the drug concentrations at the receptor site as well as the degree of affinity for the corresponding receptor. Flunitrazepam is highly lipophilic, and this drug is one of the most potent benzodiazepine compounds. The affinity of flunitrazepam for benzodiazepine receptors is somewhat greater than some (e.g., alprazolam, diazepam, and oxazepam), but not all (e.g., triazolam, midazolam) commercial benzodiazepines.[37] The rapid onset of action and the high potency of this drug increase the abuse liability of flunitrazepam compared with other, less potent benzodiazepines.

Mechanism of Toxicity

The pharmacodynamic interaction of flunitrazepam with the GABA$_A$-benzodiazepine receptor complex throughout the central nervous system causes ataxia, sedation, drowsiness, sleep, reduced anxiety, anticonvulsant effects, and impairment of memory. The disturbance of memory is dose-dependent. This impairment of memory probably involves the process of the consolidation of information into memory storage rather than input or retrieval of information. The types of memory storage include short-term memory storage (primary memory), middle course memory storage (secondary memory), and long-term memory storage (tertiary memory). Short-term storage includes the information necessary for thought processes and understanding. The consolidation of short-term memory into long-term memory occurs both as explicit memory ("conscious") and implicit ("unconscious") memory. The former is semantic (facts, general information), episodic (events personally experienced) and autobiographic (e.g., recall of names) memory, whereas implicit memory is the unconscious memory for automated tasks (i.e., actions of the normal daily routine, such as driving a car). As with most hypnotic-sedative drugs, the loss of memory associated with flunitrazepam is primarily anterograde rather than retrograde amnesia (i.e., loss of early memories). Most cases of anterograde amnesia involve the inability to remember their normal daily routine (e.g., driving, talking to people, work activities). In contrast to the loss of memory associated with ethanol, individuals with anterograde amnesia following the use of flunitrazepam can perform complex tasks (e.g., driving a car). Volunteer studies suggest that 2-mg doses of flunitrazepam impair memory and prolong rapid eye movement (REM) latency without changing the percentage of REM sleep.[38] However, not all volunteers developed memory impairment at this dose. With intermediate doses (e.g., 2 mg) of flunitrazepam, impairment of explicit memory can occur without significant changes in psychomotor sedation (e.g., reduced simple choice reaction times), vigilance, or attention.[39] The anterograde amnesia probably results, at least in part, from impairment of memory consolidation secondary to REM sleep suppression. In very high doses, flunitrazepam can cause respiratory depression, usually before clinically significant reduction in blood pressure.

Postmortem Examination

There are no specific pathologic features associated with postmortem examination of flunitrazepam-induced fatalities.[40] Postmortem examination of individuals, who died after ingesting flunitrazepam, demonstrates typical findings associated with respiratory depression and anoxia (i.e., pulmonary and/or cerebral edema).

CLINICAL RESPONSE

The pharmacologic effects of flunitrazepam include sedation, reduced anxiety, muscle relaxation, and increased seizure threshold. The onset of action following ingestion is about 15–20 minutes and the duration of action of is approximately 4–8 hours. Adverse effects associated with the abuse of flunitrazepam include lethargy, lightheadedness, gastrointestinal distress, psychomotor retardation, poor coordination, slurred speech, confusion, tremors, nightmares, and low blood pressure.[41] Benzodiazepines (e.g., lorazepam, diazepam, flunitrazepam) produce dose-dependent amnesia. Anterograde amnesia is associated with the administration of flunitrazepam, particularly with doses exceeding 4 mg; loss of memory begins 5–60 minutes after ingestion of flunitrazepam, depending on the dose.[42] Retrograde amnesia (i.e., recalling objects prior to the administration of the drug) is usually preserved. Flunitrazepam is mostly a sedating drug. However, some individuals experience idiosyncratic, paradoxical reactions towards benzodiazepines including flunitrazepam. These unexpected reactions include talkativeness, agitation, confusion, loss of impulse control, aggression,

and violent behavior.[43,44] Individuals with increased risk of paradoxical reactions include elderly, children, alcoholics, and psychiatric patients with personality or psychotic disorders.

Illicit Use

In some criminals, the use of large doses of flunitrazepam is associated with feelings of power, enhanced self-esteem, omnipotence, loss of fear and episodic memory, and impulsive violence, particularly when ingested with alcohol.[45] However, the role of flunitrazepam in producing the impulsive behavior remains unclear. Rare case reports associate the abuse of flunitrazepam with a variety of inappropriate behavior including loss of impulse control, irritability, aggression, verbal hostility, physical assaults, and suicidal actions.[46] However, the causal role of flunitrazepam in these behaviors is difficult to determine, and there is no definite evidence that flunitrazepam is more often associated with these behaviors than other benzodiazepines.[47] A case report associated the IV administration of dissolved flunitrazepam tablets into the femoral artery with the development of distal peripheral ischemia that resolved following treatment with anticoagulation and intraarterial urokinase and prostaglandins.[48] Flunitrazepam is occasionally administered during drug-facilitated sexual assaults and robberies as a means to induce amnesia and disinhibition.[49]

Overdose

The clinical effects of an overdose of flunitrazepam are similar to the toxicity of other benzodiazepines. In a study of children ingesting flunitrazepam, common clinical features of a flunitrazepam overdose were related to alterations of consciousness, particularly drowsiness, agitation, and ataxia.[22] Less common effects of flunitrazepam overdose include bradycardia, hypotension, coma, and hypotonia.

Abstinence Syndrome

Abrupt termination of the chronic use of flunitrazepam causes withdrawal reactions including restlessness, agitation, irritability, headache, myalgias, paresthesias, and confusion. This abstinence syndrome is similar to other benzodiazepines. In a study of 28 addicts using up to 8–10 mg flunitrazepam daily, withdrawal symptoms (e.g., anxiety, fear, insomnia, confusion, shivering, tachycardia, involuntary movement, paresthesias, perceptual changes) began about 36 hours after cessation of flunitrazepam use.[50] Withdrawal seizures can occur up to about 1 week after the cessation of flunitrazepam use,

particularly in alcoholics. Other withdrawal effects include derealization (i.e., perception that external world is strange and dreamlike), depersonalization, delirium, and hallucinations. Rebound insomnia (i.e., a temporary worsening of sleep after discontinuation of hypnotic drugs) is a sensitive indicator of physiological dependence on benzodiazepine drugs (i.e., flunitrazepam).[21] In a study of 6 insomniacs receiving 2 mg flunitrazepam nightly for 4 weeks, sleep latency and total wake time were significantly increased above baseline for the first 3 nights after discontinuation of the drug.[51] These parameters returned to baseline within 2 weeks. The capacity of flunitrazepam to produce physiologic dependence or withdrawal symptoms after administration of an antagonist or discontinuation of treatment is similar to other potent benzodiazepines.[21]

Reproductive Abnormalities

There is no clear association between the use of flunitrazepam by pregnant women and the development of reproductive abnormalities, including delayed neurobehavioral development.[52]

DIAGNOSTIC TESTING

Analytic Methods

Screening

Benzodiazepine immunoassays (e.g., enzyme immunoassays, fluorescence polarization immunoassays, radioimmunoassays) are relatively specific, but the sensitivity of older immunoassay screening tests for the small flunitrazepam concentrations typically present in urine samples after either therapeutic use or abuse is relatively low. Furthermore, most benzodiazepine immunoassay reagents react poorly with flunitrazepam metabolites (e.g., 7-aminonitrazepam).[53] More recently developed immunoassays (e.g., Cozart ELISA, Cozart Bioscience, Oxfordshire, UK; Immunalysis ELISA, Immunalysis Corporation, Pomona, CA) are more sensitive (i.e., 30 ng/mL) for 7-aminoflunitrazepam than older immunoassays.[54] Significant cross-reactivity with this assay occurs only with diazepam.[55] Radioreceptor assays lower the limit of detection to pharmacologically active concentrations of flunitrazepam, but these techniques do not identify specific compounds.[56] Although gas chromatography with electron capture detection has high sensitivity, this technique lacks specificity and has poor sensitivity for flunitrazepam metabolites (e.g., 7-aminoflunitrazepam, 3-hydroxy-flunitrazepam). Rapid drug detector kits (e.g., Drink Detective®, SureScreen Diagnostics, London) are commercially

available for the detection of club drugs including fluni-trazepam, but the these products lack both sensitivity and specificity, particularly in drinks containing tonic water and fruit juices.[57] Other methods for the detection of flunitrazepam and other drugs of abuse in food and drink include lateral-flow immunoassay with confirmation by high-performance liquid chromatography coupled with quadrupole ion trap/time-of-flight tandem mass spectrometry.[58]

CONFIRMATORY

Methods to quantitate flunitrazepam and associated metabolites in biologic samples include gas chromatography, high performance liquid chromatography with ultraviolet detection (250 nm),[34] gas chromatography/mass spectrometry,[59] high performance liquid chromatography/tandem mass spectrometry,[60,61] ion trap gas chromatography/tandem mass spectrometry,[62] liquid chromatography/atmospheric pressure photoionization/mass spectrometry,[63] and micellar electrokinetic chromatography.[64] Gas chromatography/mass spectrometry with electron impact or negative chemical ionization detection are sensitive and specific confirmatory methods for the quantitation of flunitrazepam, but these methods do not detect polar metabolites without derivatization. In contrast to gas chromatography/electron impact/mass spectrometry and gas chromatography/negative chemical ionization/mass spectrometry, liquid chromatography/mass spectrometry methods using atmospheric pressure chemical ionization or electrospray ionization are sensitive, specific analytic methods that do not require derivatization. The lower limit of quantitation (LLOQ) for flunitrazepam using high performance liquid chromatography with ultraviolet detection is about 0.5 ng/mL, whereas the LLOQ for flunitrazepam and 7-aminoflunitrazepam using gas chromatography/mass spectrometry is 0.1 ng/mL and 0.01 ng/mL, respectively. The limit of detection (LOD) for high performance liquid chromatography/atmospheric pressure chemical ionization mass spectrometry is 0.2 ng/mL for flunitrazepam and 7-aminonitrazepam and 0.1 ng/mL for *N*-desmethylflunitrazepam and 3-hydroxyflunitrazepam.[65] Using liquid chromatography/electrospray ionization/mass spectrometry with solid-phase extraction, the LOD in biologic samples for these 4 compounds was 0.025 ng/mL, 0.25 ng/mL, 0.04 ng/mL, and 0.2 ng/mL, respectively.[66]

STORAGE

Flunitrazepam is relatively stable in sterile blood, but rapid conversion of this compound to 7-aminoflunitrazepam occurs in the presence of bacteria and elevated temperature. An experimental study of non-fluoridated postmortem blood contaminated with bacteria indicated that the conversion of flunitrazepam to 7-aminoflunitrazepam is almost complete within 8 hours at room temperature.[67] In a study of nonfluoridated blood samples spiked with 0.25 mg/L flunitrazepam, the flunitrazepam concentration over 3 months of storage decreased by 90%, 70%, and 15%, when stored at room temperature, 4°C, and –20°C, respectively.[68] Flunitrazepam is relative stable when stored in sodium fluoride at –20°C, but some loss of the 7-aminoflunitrazepam occurs. Although 7-aminoflunitrazepam is more resistant than flunitrazepam to bacteria and elevated temperature, degradation of this metabolite occurs during prolonged storage. After storage at –20°C (–4°F) for 2 months and 24 months with preservatives (1% sodium fluoride/potassium oxalate), the original concentration of 7-aminoflunitrazepam decreased 29% and 68%, respectively.[67] Consequently, analysis of these samples preferably should occur within 1 week.

Biomarkers

Using sensitive methods (e.g., gas chromatography/negative chemical ionization/mass spectrometry), volunteer studies indicate that 7-aminofluntrazepam is detectable in hair for at least 28 days after the ingestion of 2 mg flunitrazepam.[69] However, timing of the use of flunitrazepam is difficult to determine using hair analysis. Flunitrazepam is less basic than 7-aminoflunitrazepam; therefore, the flunitrazepam concentrations in hair are lower and more difficult to detect than 7-aminonitrazepam. Using tandem mass spectrometry, hair analysis complements rather than replaces the analysis of blood and urine for flunitrazepam and associated metabolites.[70] Flunitrazepam diffuses poorly into vitreous humor, and the postmortem vitreous concentrations of flunitrazepam are about one-third of the peripheral blood.[71]

BLOOD

The whole blood/plasma ratio of flunitrazepam is about 0.75 with a range of 0.65–0.80.[29]

THERAPEUTIC/ILLICIT USE. The elimination of flunitrazepam from the blood is rapid, and detection of flunitrazepam in blood samples requires sensitive analytic methods. Peak flunitrazepam concentrations occur about 2–4 hours after oral administration with peak concentrations reaching 10–15 ng/mL after single 2-mg IV doses and 15–20 ng/mL after 1 month of daily oral dosing of 2 mg flunitrazepam, respectively.[26,72] Flunitrazepam was detectable in whole blood samples,

but not in plasma samples up to 4 hours after the oral administration of 2 mg flunitrazepam, as measured by gas chromatography/mass spectrometry (LOD, 5 ng/mL).[73] Flunitrazepam concentrations in blood do not correlate to agitated or aggressive behavior. In a Norwegian study of drivers apprehended for suspected driving under the influence and suspects of violent crimes, agitation or aggressive behavior was not more common in the group with the highest blood flunitrazepam concentration, when compared with individuals with therapeutic concentrations of flunitrazepam.[80] Although the onset and duration of anterograde amnesia associated with the administration of flunitrazepam is dose-dependent, impairment of explicit memory (recall/recognition of recent events and personal interactions) can occur following ingestion of therapeutic concentrations of flunitrazepam.[39]

OVERDOSE.   In a study of 588 blood samples collected from patients presenting to a French emergency department, 7 serum samples were positive only for flunitrazepam, as measured by gas chromatography/mass spectrometry (LOD, ~4 ng/mL).[74] The mean serum flunitrazepam concentration was 284 ± 342 ng/mL with a range of 19–1,011 ng/mL. The clinical conditions of these patients were not described in this paper.

POSTMORTEM.   A study of antemortem and postmortem samples from 4 individuals suggests that postmortem diffusion of flunitrazepam and 7-aminoflunitrazepam into peripheral tissues (e.g., femoral blood) is probably too small to confound the interpretation of postmortem flunitrazepam concentrations; the study was too small to provide statistical analysis.[71] However, as a result of the postmortem conversion of flunitrazepam to 7-aminoflunitrazepam, postmortem blood concentrations of flunitrazepam alone may not accurately reflect antemortem flunitrazepam concentrations.[40] In such cases, the individuals typically have high concentrations (0.4–0.8 mg/L) of 7-aminoflunitrazepam because the total blood concentrations of nitrobenzodiazepine compounds are relatively stable during the initial postmortem interval.

URINE

The duration of positive urine samples after the use of flunitrazepam depends on the sensitivity of the analytic method, preparation techniques (e.g., enzymatic hydrolysis), route of exposure, interindividual variation, and the flunitrazepam dose. The major metabolite, 7-aminoflunitrazepam, was detectable in urine samples from volunteers for 3 days after the ingestion of 0.5 mg fluni-

trazepam, as measured by gas chromatography/mass spectrometry (LOD, 2 ng/mL).[75] Using liquid chromatography/tandem mass spectrometry with a cutoff of 0.5 ng/mL, 7-aminoflunitrazepam was detectable in hydrolyzed urine for 5 days in all 16 volunteers receiving 0.5 mg flunitrazepam, whereas the window of detection was extended to 10 days in 2 volunteers.[76] The ratio of 7-aminodesmethylflunitrazepam/7-aminoflunitrazepam increased with time independent of dose in this study; a ratio of 0.1 suggested ingestion within 4 hours compared with >72 hours for ratios exceeding 0.6. In a study of 10 healthy volunteers receiving 2 mg flunitrazepam, 7-aminoflunitrazepam was detectable for 14 days, 21 days, and 28 days in 6, 1, and 3 volunteers, respectively, as measured by gas chromatography/negative chemical ionization/mass spectrometry.[77] The LLOQ for 7-aminoflunitrazepam in hydrolyzed urine was 10 pg/mL (0.010 ng/mL). The flunitrazepam concentrations in these urine specimens were 2 orders of magnitude below the 7-aminoflunitrazepam concentrations. In the study using liquid chromatography/tandem mass spectrometry, 7 of the 16 volunteers receiving a single dose of 2 mg flunitrazepam had detectable 7-aminoflunitrazem concentrations in hydrolyzed urine for 10 days. The window of detection for 7-aminoflunitrazepam in urine is substantially shorter (48–96 h), when using liquid chromatography with diode array detection, gas chromatography/mass spectrometry, or liquid chromatography/mass spectrometry rather than gas chromatography/negative chemical ionization/mass spectrometry.[78] Following chronic abuse of flunitrazepam, high concentrations of 3-hydroxyflunitrazepam also occur in hydrolyzed urine samples from these individuals. Typically, the concentration of total 7-aminoflunitrazepam in urine samples is several fold higher than the concentration of free 7-aminoflunitrazepam.[79]

Driving

Volunteer studies indicate that the ingestion of flunitrazepam at night can produce some residual effects on psychomotor skills involved with driving during the following morning and perhaps some effect on driving skills in the following afternoon. In a study of 20 male volunteers, the ingestion of 2 mg flunitrazepam at night caused some detrimental effects on standing steadiness, tracking, choice reaction, and flicker recognition.[36] A study of 29 healthy volunteers suggested that an IV flunitrazepam dose of 0.03 mg/kg causes some impairment of reaction times and coordination 4 hours after administration.[72] The ingestion of ethanol at doses of 0.5 g/kg in the morning produced synergistic effects on psychomotor skills. Examination of individuals under

the influence of flunitrazepam demonstrate typical effects of a central nervous system depressant including poor coordination, slurred speech, and horizontal gaze nystagmus.[53] Flunitrazepam was the only drug detected in blood samples from 415 Norwegian drivers suspected of driving under the influence and 7 suspects of violent crime.[80] Only a relatively small subset (i.e., 6%) displayed restlessness or agitated behavior, and the number of individuals with this type of behavior was not more prevalent in the individuals with high flunitrazepam concentrations. Volunteer studies suggest that acute tolerance develops to some psychomotor skill (e.g., simple and choice reaction times) following the administration of medium to large doses (i.e., 1–2 mg) of flunitrazepam.[81]

TREATMENT

The treatment of flunitrazepam toxicity is usually supportive. Most patients ingesting excessive amounts of flunitrazepam develop only minor symptoms of drowsiness, ataxia, confusion, slurred speech, and anterograde amnesia. These effects usually resolve with observation for the development of toxicity from the coingestion of other drugs or the presence of accidental trauma. The primary life-threatening effects of a large overdose of flunitrazepam are increased risk of trauma, coma, respiratory depression, and aspiration. These patients should have IV access established along with monitoring of oxygenation (i.e., pulse oximetry, arterial blood gases) as needed. Gut decontamination (i.e., activated charcoal) is usually not necessary because of the mild toxicity associated with flunitrazepam unless indicated by the coingestion of a more toxic drug. Flumazenil is a specific antidote for benzodiazepine toxicity, but the use of this antidote is limited by the infrequent occurrence of serious toxicity during benzodiazepine toxicity and the potential development of withdrawal in benzodiazepine-dependent patients. Additionally, flumazenil increases the risk of seizures following the ingestion of proconvulsant drugs, particularly during tricyclic antidepressant toxicity.[82] The use of flumazenil during flunitrazepam toxicity requires an assessment of the potential benefits of reversing life-threatening cardiorespiratory depression related to flunitrazepam and the risk of precipitating adverse reactions (withdrawal, ventricular dysrhythmias, seizures). The onset of action of IV flumazenil is 1–2 minutes with peak effects 5–10 minutes after injection. The initial adult dose is 0.2 mg IV followed by 0.3 mg and 0.5 mg at 1- to 2-minute intervals up to 3 mg titrated to desired clinical effects. If the administration of a total of 3 mg produces a partial response, then additional doses up to 2 mg may be administered intravenously. Pure benzodiazepine over-

doses typically require about 0.5–1 mg. Failure to respond to a total of 5 mg flumazenil indicates that the altered consciousness probably is not related to benzodiazepine toxicity. The pediatric dose of flumazenil is not well established, but IV doses of 0.01–0.02 mg/kg (maximum dose, 0.2 mg) have been administered successfully without complications.[83] The plasma half-life of flunitrazepam far exceeds the half-life of flumazenil; therefore, patients responding to flumazenil must be observed for 24 hours to prevent recurrence of adverse effects.[23] Methods to enhance elimination (e.g., hemodialysis, hemofiltration, hemoperfusion) are not effective for highly lipophilic and widely distributed drugs, such as flunitrazepam.

Chapter 6

GAMMA HYDROXYBUTYRATE and RELATED DRUGS

γ-HYDROXYBUTYRATE (GHB)

HISTORY

Although Saytzeff isolated GHB in 1874,[1] the first synthesis of gamma hydroxybutyrate (GHB) occurred during the early 1960s, when Henry Laborit searched for an active, synthetic analogue of γ-aminobutyric acid (GABA) that readily crossed the blood–brain barrier and persisted longer than GABA.[2] Preliminary studies demonstrated the similar sedative effects of GHB and γ-butyrolactone; however, animal studies in the late 1960s revealed that the biologic and behavioral effects of γ-butyrolactone resulted from the rapid conversion of this compound to GHB by an active lactonase.[3] Early uses of GHB included anesthesia and sleep-induction. In 1962, Blumenfeld et al reported the first use of GHB for surgical anesthesia in humans.[4] Although GHB was an effective anesthetic with minimal cardiorespiratory depression, recognition of undesirable postoperative sequelae (nausea, vomiting, myoclonus, Cheyne-Stokes respirations), lack of muscle relaxation, and poor analgesia limited the use of GHB as an anesthetic.[5] In 1964, Helrich et al induced sleep in healthy volunteers following the intravenous (IV) administration of GHB at doses up to 9 g (100 mg/kg).[6] Before 1990, GHB was sold as a dietary supplement in the United States that was a replacement for L-tryptophan. In the United States, reports of enhanced growth hormone release and potential anabolic effects resulted in the misuse of GHB by body builders during the early 1990s[7]; however, the lack of scientific support for the anabolic effects of GHB resulted in the subsequent reduction of GHB use for anabolic purposes.[8] In the 1990s, the discovery of the euphoric, sedative, and short-term growth hormone-releasing properties of GHB in the club drug and body-building scenes resulted in the popularization of GHB as a substance of abuse.[9] However, case reports associated serious toxic effects (coma, seizures) with the recreational use of GHB.[10,11] The US Food and Drug Administration (FDA) issued a recall for GHB- and GBL-containing nutritional supplements in early 1999. The Hillory J. Farias and Samantha Reid Date-Rape Drug Prohibition Act of 2000 reclassified GHB as a schedule I controlled substance as a result of reports of physical dependence and withdrawal following chronic GHB and the use of GHB for sedation and anterograde amnesia during drug-facilitated sexual assaults.[12] GHB became a controlled substance in most European Union member states in 2001. Amendments to the US Controlled Substances Act allowed the clinical development of sodium oxybate (i.e., oral formulation of GHB) to proceed via a unique, bifurcated schedule. Subsequently, the FDA approved the use of sodium oxybate for the treatment of cataplexy in 2002 as a schedule II drug. To promote the safe use of this drug and to alleviate concerns over possible diversion and abuse following product approval, a proprietary restricted drug distribution system (Xyrem® Success Program) was established. Components of the program include a centralized distribution and dispensing system with tracking of prescription shipments, a physician and

patient registry, and compulsory educational materials for patients and physicians along with an initial post-marketing surveillance program.[13] In 2005, the FDA extended the therapeutic use of sodium oxybate (GHB) to include the treatment of excessive daytime sleepiness in patients with narcolepsy. The treatment of cataplexy in adult patients with narcolepsy was approved in the European Union in 2005.

IDENTIFYING CHARACTERISTICS

GHB (CAS RN: 591-81-1, $C_4H_8O_3$, MW: 104.10 g/mol) is an endogenous short-chain fatty acid that is an active metabolite of the inhibitory neurotransmitter, γ-aminobutyric acid (GABA).[14] Sodium oxybate (CAS RN: 502-85-2, MW: 127.09 g/mol) is the sodium salt of GHB that is the current oral form used to administer GHB therapeutically. One level teaspoon (i.e., 5 mL) of pure GHB weighs 4.4 g.[11] Common street names for GHB include Cherry Meth, Easy Lay, Everclear, G, George, Gina, Grievous Bodily Harm (GBH), Georgia Homeboy, Great Hormones at Bedtime, Goops, Growth Hormone Booster, Liquid Ecstasy, Liquid X, Organic or Nature's Quaalude, Oxy-Sleep, Poor Man's Heroin, Salty Water, Scoop, Soap, Vitamin G, Wolfies, and Zonked. GHB appears on the illicit market as a clear, odorless, oily liquid, a crystalline powder, or a gel (sodium salt). The liquid form has a slightly salty taste; occasionally, food dyes or cinnamon are added to improve palatability. The colorless, odorless, highly water soluble properties of the liquid allows the surreptitious use of GHB in the drinks of drug-facilitated sexual assault victims.

EXPOSURE

Epidemiology

Illicit GHB use in the United States declined dramatically following the scheduling of GHB as a schedule I controlled substance; GHB exposures reported to the California Poison Control System decreased 76% from 1999 ($n = 426$) to 2003 ($n = 101$).[15] Based on Drug Abuse Warning Network (DAWN) data, approximately 0.3–0.4% of drug-related emergency department (ED) visits in the United States are associated with GHB or GHB analogues.[16] Data from the 2004 National Drug Strategy Household Survey indicated that the prevalence of GHB use was relatively low in Australia.[17] About 0.5% of Australians aged 14 years or older reported the use of GHB at least once in their lifetime and 0.1% reported recent use. The prevalence of GHB use was highest among 20- to 29-year-olds. Although

detection issues complicate the interpretation of studies of GHB use during drug-facilitated sexual assault, existing studies suggest that GHB use in this setting is uncommon (<3%), similar to the use of flunitrazepam. In a systematic review of 11 studies on the involvement of GHB in reported sexual assaults, the range of detectable GHB concentrations in reported sexual assaults was 0.2–4.4%.[18] However, the short window of GHB detection limits conclusions regarding the prevalence of GHB use during drug-facilitated sexual assault.[19,20] Past and present medicinal uses of GHB include weight loss, sedation, the treatment of narcolepsy and alcohol or opiate withdrawal, and the induction of rapid eye movement sleep and general anesthesia. The use of GHB as an anesthetic has been discarded because of unpredictable anesthetic effects and adverse reactions.

Sources

The illicit manufacture of GHB involves the heating of a GBL mixture alkalinized with lye. After the addition of acetone, the mixture is dried. The ester hydrolysis of γ-butyrolactone produces clear solutions containing an amount of GHB equivalent to about 70% of the GBL weight. In a series of 418 samples seized at homosexual-oriented clubs in Australia, 225 samples were liquid with 85 (37.8%) containing GHB and 140 (62.2%) containing GBL.[21] None of the samples contained 1,4-butanediol (1,4-BD). In the United States, GHB is available as sodium oxybate (Xyrem®, Jazz Pharmaceuticals, Palo Alto, CA) for the treatment of cataplexy in patients with narcolepsy. GHB is available in Europe (Alcover®, CT Laboratorio Farmaceutico, SRL, San Remo, Italy) for use as an anesthetic or for the treatment of alcohol or opiate withdrawal.[22] Although randomized clinical trials indicate that GHB is superior to placebo for the treatment of alcohol withdrawal, the use of GHB for this indication is not clearly better than benzodiazepines or chlormethiazole in maintaining abstinence.[23]

Methods of Abuse

By the late 1990s and early 2000s, GHB was a popular club drug that was associated with drug-facilitated sexual assault.[24] The use of GHB at party settings appears more common among men than women, and the use of GHB frequently occurs in polydrug users (ethanol, ecstasy, methamphetamine, cocaine, ketamine).[25,26] Although GHB has a reputation as a club drug, an online survey of 189 individuals using GHB at least once in their lifetime suggested that private homes are a more common venue for GHB use than nightclubs.[27] Reports from GHB users describe the effects of

GHB as similar to sedative-hypnotic or alcohol intoxication, and chronic use may cause tolerance and dependence.[28] Desirable effects associated with the GHB use recreationally include euphoria, relaxation, loss of inhibitions, increased sociability, better mood, and enhanced sexual awareness. Although increased sexual desire, arousal, and activity are often related to GHB use, the use of GHB is also associated with decreased sexual performance and impaired memory of the sexual experience.[29] Visual or auditory hallucinations and involuntary limb movements are not typically associated with GHB use. Preclinical studies of GHB suggest that the abuse potential of GHB is relatively low; however, GHB abuse is a reported complication of the treatment of alcohol dependence/withdrawal with GHB.[30] In a double-blind study of 14 volunteers with histories of drug abuse, measures of likelihood of abuse (e.g., ratings of liking, reinforcing effects) indicate that the abuse likelihood of GHB is lower than pentobarbital and greater than triazolam.[31] Memory impairment was less with GHB compared with pentobarbital or triazolam, and GHB produced significantly greater adverse effects (e.g., nausea). A study of 12 healthy recreational users of GHB demonstrated that the ratings for euphoria and pleasurable effects following oral administration of 40–60 mg GHB/kg were slightly higher than 0.7 mg ethanol/kg or 1.25 mg flunitrazepam.[32]

DOSE EFFECT

For the treatment of narcolepsy, the standard dose of sodium oxybate is 4.5–9.0 g at bedtime. Single oral doses of 10 mg GHB/kg produce short-term amnesia and hypotonia, whereas the ingestion of 20–30 mg/kg causes drowsiness. In clinical trials, therapeutic doses of GHB for the induction of sleep typically range from 15–30 mg/kg with doses up to 30–50 mg/kg producing sleep that is reversible by external stimulation compared with 50–150 mg/kg for the treatment of alcoholics in withdrawal.[33,34] Euphoria may occur at GHB doses used to induce sleep. GHB doses above 60 mg/kg are associated with obtundation and coma.[35] Intravenous GHB doses of 60–70 mg/kg induce sleep within 5–15 minutes and coma lasting about 1–2 hours followed by rapid arousal.[36] Adverse effects at these doses include nausea, vomiting, hypotonia, bradycardia, respiratory depression, and Cheyne-Stokes respiration.[37]

The typical street dose of GHB is 2–6 g (25–75 mg/kg or approximately ½–1¼ teaspoon of pure GHB), but experienced users may ingest up to 30 g.[11] Withdrawal symptoms usually occur in high-dose, chronic GHB users, whereas the administration of 50 mg GHB/kg daily for 6 months to alcoholic patients was not associated with withdrawal following abrupt cessation of GHB therapy at the end of the study.[38] In a case series of 48 narcolepsy patients treated with 2.25–3 g GHB daily for up to 9 years, evidence of withdrawal did not occur.[39] The exact dose of GHB associated with withdrawal symptoms is difficult to estimate because the origin of the GHB often is a powder obtained over the Internet and the patients are frequently polydrug abusers. The escalating use of GHB up to an estimated 40 g daily was associated with withdrawal symptoms including anxiety, tremors, diaphoresis, hallucination, paranoia, nystagmus, impaired memory, hypertension, and tachycardia based on case reports.[40] Prevention of withdrawal symptoms may require frequent administration in the day and night. Typically, individuals ingest GHB doses every 2–4 hours during the night to prevent insomnia or anxiety.

TOXICOKINETICS

Absorption

Volunteer studies indicate that the absorption of GHB is rapid and capacity-limited with peak plasma GHB concentrations occurring <1 hour after ingestion.[41] Peak GHB plasma concentrations occur within about 20–45 minutes after the ingestion of 25–50 mg GHB/kg body weight by healthy volunteers.[42] In a study of alcoholic patients receiving 25 mg GHB/kg twice daily for 7 days, the mean maximum plasma GHB concentration was 55 ± 19 mg/L with a range from 32–85 mg/L.[43] The median time to peak plasma GHB concentration was 30 minutes (range, 20–45 min). Following the oral administration of single GHB (sodium oxybate) doses of 60 mg/kg and 72 mg/kg, the mean maximum plasma GHB concentrations were 113.5 ± 20.1 mg/L (range, 90.3–134.7 mg/L) and 130.1 ± 10.7 mg/L (range, 122.5–137.6 mg/L), respectively.[44] Figure 6.1 displays the time-concentration curves for GHB after the oral administration of a single dose of 12.5 mg/kg, 25 mg/kg, or 50 mg/kg to 8 healthy male volunteers. The absorption of sodium oxybate (Xyrem®, Orphan Medical, Minnetonka, MN) in solution is also rapid with peak GHB concentrations occurring within 30–60 minutes after administration.[45]

Distribution

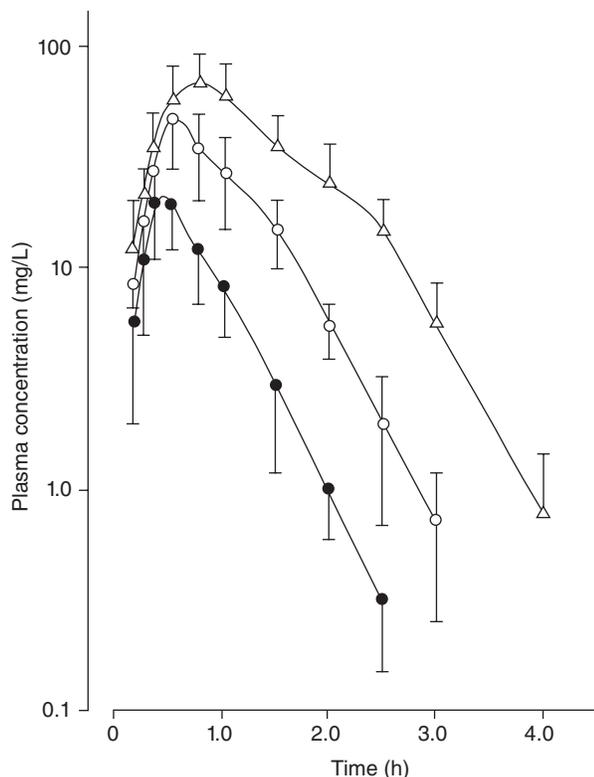
GHB is poorly protein bound, and the apparent volume of distribution is relatively small (0.4–0.6 L/kg). In a study of 8 healthy volunteers receiving a single GHB dose of 25 mg/kg, the mean volume of distribution was 52.7 ± 15.0 L (range, 19.1–155 L).[42]


FIGURE 6.1. Plasma concentrations of γ-hydroxybutyrate (GHB) following oral administration of 12.5 mg/kg (closed circle), 25 mg/kg (open circle), and 50 mg/kg (open triangle). (Reprinted with kind permission from Springer Science+Business Media: European Journal of Clinical Pharmacology, Dose-dependent absorption and elimination of gamma-hydroxybutyric acid in healthy volunteers, Vol. 45, 1993, p. 354, P. Palatini, Fig. 1A.)

Biotransformation

The metabolism of GHB primarily involves conversion to succinic semialdehyde and then succinate followed by the conversion of succinate to carbon dioxide and water via the tricarboxylic acid cycle (Krebs cycle). Several minor pathways of GHB metabolism also exist, including the reduction of GHB to succinic semialdehyde by the mitochondrial enzyme, GHB-oxoacid-transhydrogenase (D-2-hydroxyglutarate transhydrogenase), and β-oxidation as displayed in Figure 6.2.

Elimination

Elimination of GHB results primarily from biotransformation rather than renal excretion. The kidneys excrete <1–2% of a therapeutic GHB dose (25 mg/kg twice daily for 7 days) unchanged.[43] The elimination of GHB is rapid, but nonlinear as a result of capacity-limited kinetics following the administration of GHB doses

above 50 mg/kg. Following typical therapeutic or recreational doses of GHB, the plasma elimination half-life is approximately 20–30 minutes. In a study of alcoholic patients receiving 25 mg GHB/kg twice daily for 7 days, the median plasma elimination half-life was 27 ± 5 minutes with a range of 20–45 minutes.[43] In a study of 6 narcolepsy patients, the plasma elimination half-life of GHB was 53 ± 19 minutes following administration of two 3 g-doses at a 4-hour interval.[46] Plasma GHB concentrations were nondetectable within approximately 4–6 hours after ingestion as measured by gas chromatography with mass selective detection (lower limit of quantitation [LLOQ], ~7 mg/L). The elimination of GHB following the administration of therapeutic doses of sodium oxybate (Xyrem®) is also rapid with an average plasma elimination half-life of about 40 minutes.[45] Case reports of GHB overdoses suggest that zero-order or saturation (Michaelis-Menten) kinetics best describe the elimination of GHB following the ingestion of very large doses of GHB.[47]

Drug Interactions

The illicit use of GHB frequently occurs with the ingestion of other drugs, particularly ethanol; GHB and ethanol share similar sedative effects. In a double-blind, placebo-controlled, crossover study, 16 healthy adults received GHB (50 mg sodium oxybate/kg) and/or ethanol (0.6 g/kg, estimated blood ethanol concentration 50 mg/dL). The combination of GHB and ethanol produced more significant adverse effects (vomiting, decreased blood pressure, reduced oxygen saturation) compared with placebo or each drug alone.[48] However, there were minimal pharmacokinetic interactions (i.e., no statistically significant reduction in elimination half-life or maximal plasma GHB concentrations).

Case reports suggest that concomitant use of human immunodeficiency virus 1 (HIV-1) protease inhibitors with GHB may exacerbate the respiratory depression and bradycardia associated with GHB intoxication.[49] Valproate, phenobarbital, barbital, and chlorpromazine inhibit NADPH-dependent aldehyde reductase, which catalyze the formation of GHB from succinic semialdehyde;[50] however, the clinical relevance of this inhibition in regard to GHB concentrations and clinical effects is unclear.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

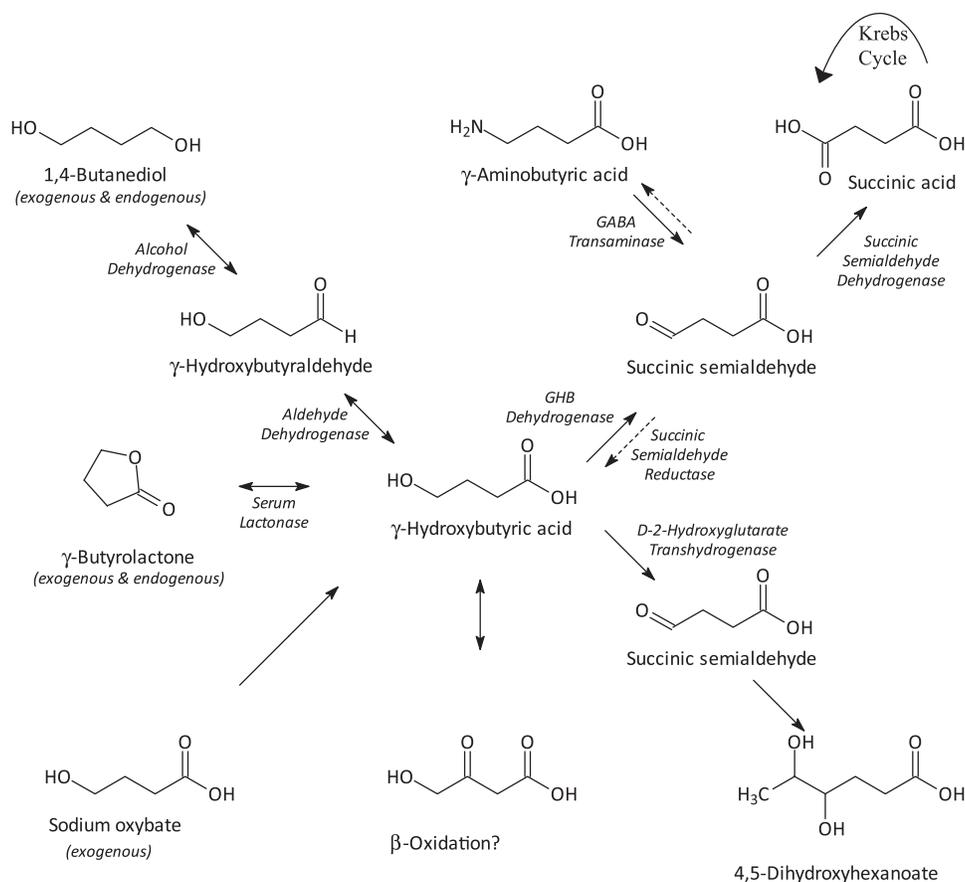
GHB is a natural constituent of the brain that is both a precursor and metabolic product of GABA. GHB


FIGURE 6.2. Synthesis and metabolism of γ-hydroxybutyrate (GHB) with major pathways in the solid arrows and minor pathways in dashed arrows. GABA = γ-aminobutyric acid.[55]

occurs in micromolar quantities (1–4 μM) in all parts of mammalian brains and some peripheral organs (heart, kidney, liver, muscle, brown fat), but the highest GHB concentrations appear in the cytosolic and synaptosomal fractions of the striatum, particularly in the developing brain.[51] GABA is the major precursor of GHB, and the GHB concentrations in the brain are approximately 0.1% of the GABA concentrations.[52] Synthesis of GHB occurs throughout the central nervous system (CNS), where GHB is released into the synaptic cleft from storage vesicles by potassium-dependent depolarization; then, GHB uptake into the nerve terminal occurs. GHB synthesis primarily involves the conversion of GABA to succinic semialdehyde via mitochondrial GABA transaminase and the subsequent reduction of succinic semialdehyde to GHB via cytosolic succinic semialdehyde reductase.

Although GHB is biologically active and ubiquitous in the CNS, the exact mechanism of action is unclear. Experimental evidence suggests that GHB acts as a presynaptic, G-protein coupled neurotransmitter and/or a neuromodulator of the GABA_B receptor, particularly in the mesocorticolimbic dopamine pathways. Most physiologic and pharmacologic effects of exogenous GHB probably result from modulation of GABA_B receptors directly as a partial agonist and indirectly through GHB-derived GABA[53]; however, drug discrimination studies suggest that some subtypes of the GABA_A and GABA_B receptors are also involved as a result of the differences in effect between the GABA_B receptor agonist, baclofen and GHB.[54] GABA_B receptors mediate slow inhibitory postsynaptic potentials by activation of calcium channels and G-protein-coupled, inwardly rectifying potassium channels via signaling through the adenylate cyclase system. GHB binding sites occur throughout the brain including the hippocampus, dentate gyrus, olfactory system, nucleus accumbens, septum, caudate putamen, substantia nigra, ventral tegmental area, pons, and the cortex with lower concentrations of binding sites in the amygdala and the thalamus.[55] Under *endogenous* conditions, GHB can increase or decrease neuronal activity by inhibiting the release of neurotransmitters located near the endogenous source of GHB. Volunteer studies indicate that the

administration of 2.5–3.5 g GHB at bedtime doubles growth hormone secretion, primarily during the first 2 hours after sleep onset.[56] The stimulation of growth hormone secretion correlated to an increase in the amount of sleep stage IV (slow wave, nonrapid eye movement sleep). However, the exact mechanism of growth hormone release remains unclear as other neurotransmitter pathways (serotonergic, cholinergic) may affect the increased growth hormone release associated with GHB administration. Additionally, the physiologic importance of growth hormone release remains unclear because there is no direct evidence that short-term elevation in growth hormone increases muscle mass and GHB use does not increase the muscle mass of alcoholic patients.[8]

Mechanism of Toxicity

GHB is a CNS depressant with complex neuropharmacologic and neurophysiologic effects including alteration of dopaminergic transmission in the basal ganglia.[57] The exogenous administration of GHB produces sedation, and at sufficiently high doses, anesthesia. Following exogenous administration, GHB produces behavioral effects by selective agonist activity at the $GABA_B$ receptors. These metabotropic receptors cause slow inhibitory neurotransmission by hyperpolarization of the postsynaptic membrane via a biochemical cascade rather than alteration of electrical activity. Similar to GABA (the primary inhibitory neurotransmitter in the CNS), GHB binding sites are G-protein coupled receptors. The binding of GHB for the $GABA_B$ receptors is weak ($K_i = 80$–120 μM); therefore, supraphysiologic GHB concentrations from endogenous administration are necessary for clinically significant binding of GHB to $GABA_B$ receptors.[58] The binding of GHB to postsynaptic $GABA_B$ receptors increases potassium conductance via inwardly rectifying potassium (GIRK or Kir3) currents. $GABA_B$ stimulation causes multiple pre- and postsynaptic effects including postsynaptic silencing, modulation of intracellular calcium dynamics, and inhibition of neurotransmitter release. The active uptake of GHB from the synaptic cleft terminates GHB activity. Experimental *in vitro* and *in vivo* animal studies indicate that exogenous GHB administration affects a variety of neurotransmitter systems in the brain including dopamine release and synthesis, serotonin turnover, increased dynorphin and enkephalin concentrations, noradrenergic transmission, and inhibition of glutamate release.[55] GHB is not an agonist at the μ-, δ-, or κ-opioid receptors.[59] Experimental data suggests that GHB abuse and withdrawal may result from the inhibition of GABAergic neurons by stimulation of $GABA_B$ receptors and inhibition of presynaptic GABA release in

mesocorticolimbic dopaminergic pathways by GHB receptor activation with subsequent increased dopaminergic activity in these pathways. However, delineation of the exact role of endogenous GHB as a neuromodulator and neurotransmitter requires further studies.[53]

Postmortem Examination

Autopsies of fatalities associated with GHB are nonspecific (e.g., pulmonary edema, visceral congestion). Common postmortem findings include cerebral edema, pulmonary congestion and hemorrhage, usually in association with ethanol and/or other drugs and occasionally with evidence of aspiration.[60]

CLINICAL RESPONSE

Illicit Use

Adverse effects associated with the illicit use of GHB are highly variable; symptoms include euphoria, sedation, memory loss, nausea, vomiting, and lightheadedness. As the dose escalates, agitation, confusion, hallucination, loss of peripheral vision, myoclonus, bradycardia, mild hypothermia, respiratory insufficiency, hypotension, and coma occur, particularly following the concomitant administration of other drugs. Although case reports associate GHB use with seizures,[11] volunteer studies do not document epileptiform changes on the electroencephalogram and random clonic movements of the face and extremities occur during induction of anesthesia with GHB.[61] Additionally, GHB use commonly occurs with the use of other drugs of abuse associated with seizure activity. The onset of action following oral GHB administration is rapid (15–30 min), while the duration of action of GHB is relatively short. Based on questionnaires, the acute effects of a single recreational dose of GHB persists about 2–4 hours (range, <2–6 h).[62] The patient frequently demonstrates anterograde (i.e., after onset of alteration of consciousness), but not retrograde amnesia (i.e., prior to administration).

Overdose

Overdoses of GHB are common complications of GHB use as determined by questionnaires. In a cross-sectional survey of 76 Australian GHB users, 53% of the respondents reported at least 1 overdose as defined by the loss of consciousness with inability to awaken following external stimulation.[63] The percentage of at least 1 overdose in individuals using GHB over 15 times was 75%. The profile of a patient presenting to an emergency department with GHB intoxication is a young male, polydrug user (alcohol, illicit drugs) with altered con-

sciousness. The classical clinical features of GHB intoxication include vomiting, myoclonus, somnolence, obtundation, stupor, coma, bradycardia, respiratory depression, and hypothermia. Paradoxical excitation and aggressive behavior may occur. In a case series of 104 emergency department patients with GHB intoxication, all patients had impaired consciousness and 17% of the cases had a Glasgow Coma Score (GCS) of 3.[64] Other clinical features of GHB intoxication reported in these patients included the following: vomiting, 23%; sinus bradycardia, 20%; agitation, 5%; myoclonus, 3%, and seizures, 3%. Pupil size is variable, and blood pressure is typically normal despite the presence of respiratory insufficiency. Despite severe respiratory depression, violent agitation may occur during attempts to intubate the patient or to insert a urinary catheter. Hypotension is uncommon. In a case series of 170 patients presenting to an emergency department with GHB intoxication, hypotension was present in 6 patients (4%).[65]

The duration of the coma is relatively short with rapid awakening. Even deeply comatose patients awaken within 4–6 hours after ingestion.[66] Recovery typically is spontaneous, frequently abrupt, and often associated with an emergence phenomenon (myoclonic jerks, transient confusion, combativeness).[67] In a case series of 5 unconscious patients (GCS = 3) presenting to an ED, the GCS remained unchanged for a median time of 60 minutes (range, 20–110 min).[68] Awakening from coma (GCS 3→15) was rapid (median, 30 min; range, 20–60 min).

Death following the ingestion of GHB alone is uncommon, and GHB-associated fatalities usually occur in the setting of polydrug use outside the hospital including abuse of sodium oxybate.[69,70] Patients with GHB intoxication typically survive if they arrive at the emergency department without anoxic brain damage.[71] Potential causes of GHB-associated deaths include aspiration, respiratory depression, and traumatic injury.

Abstinence Syndrome

Withdrawal symptoms may occur following the use of prolonged, high-doses of GHB within 1–6 hours following the cessation of GHB use. Typically, these withdrawal symptoms develop in individuals using GHB every 1–3 hours; whereas the daily use of GHB during the treatment of narcolepsy is not usually associated with withdrawal.[72] The minimum daily GHB dose causing withdrawal is difficult to predict because of recall bias and the variable concentrations of GHB in illicit materials. The clinical features of GHB withdrawal are similar to ethanol and sedative-hypnotic (benzodiazepine, barbiturate) withdrawal, but the onset of symptoms (anxiety, delirium) occurs much sooner (i.e.,

<6–12 h) after cessation of use.[73] The symptoms associated with GHB withdrawal are highly variable, depending primarily on the daily dose and frequency of use.[74] The presentation of the GHB abstinence syndrome includes nausea, vomiting, anxiety, tachycardia, insomnia, tremor, agitation, diaphoresis, and hallucinations; rarely withdrawal symptoms progress to delirium, primarily in severely dependent patients. In a review of 38 published cases of GHB withdrawal, a majority of patients had tremor, tachycardia, anxiety, hallucinations, and delirium. Seizures do not usually occur during GHB withdrawal.[73] The abstinence syndrome progresses over the first 2–3 days with mild autonomic instability (diaphoresis, hypertension, tachycardia, tremor), anxiety, and hallucinations. Confusion, disorientation, agitation, or combative behavior may require restraint and sedation. Symptoms of withdrawal typically resolve within 3–12 days, but may persist up to 15 days.[75] Case reports suggest that insomnia, anxiety, dysphoria, and poor memory may persist for several months after withdrawal.[76]

DIAGNOSTIC TESTING

Analytic Methods

SALIVA

GHB is detectable in saliva as determined by gas chromatography/mass spectrometry in selective ion monitoring mode after silyl derivatization.[77] The LLOQ was 0.5 mg/L with coefficients of variation ranging from 2.1–12.5%. However, determination of GHB concentrations in saliva probably does not extend the window of detection when compared with blood or urine.[78]

SCREENING

Rapid colorimetric methods are available to determine the presence of GHB and GBL in urine samples using the ferric hydroxamate test.[79] The limit of detection (LOD) with this method is 0.1 mg/mL in a 1-mL urine sample; this test does not distinguish between GHB and GBL. Positive samples turn purple. More sophisticated qualitative methods for the detection of GHB and GBL include gas chromatography/flame ionization detection.[83] This method can detect both compounds by the analysis of samples with and without acid hydrolysis to convert GHB to GBL. The LOD is 0.5 mg/L. Other screening methods that lack sensitivity at low, endogenous GHB concentrations include ^1H nuclear magnetic resonance spectroscopy, micellar electrokinetic chromatography, capillary zone electrophoresis with indirect ultraviolet absorption, and high performance liquid

chromatography with ultraviolet or ultraviolet-visible spectrophotometry.[80] Commercial immunoassays for the detection of GHB are generally unavailable.

CONFIRMATORY

High performance liquid chromatography with ultraviolet (254 nm) and micellar electrokinetic chromatography techniques are generally less sensitive than gas chromatography/mass spectrometry.[81,82] Gas chromatography/mass spectrometry methods include both the conversion of GHB to GBL by acid hydrolysis (lactonization) and the direct analysis of GHB after liquid-liquid extraction. The latter method typically involves extraction with an organic solvent and derivatization to counter the thermal degradation and improve the chromatographic peak shapes of GHB with heptafluorobutyric anhydride or bis(trimethylsilyl)-trifluoroacetamide (BSTFA) with 1% trimethylchlorosilane (TMCS). Direct methods for the quantitation of GHB include gas chromatography/flame ionization detection,[83] gas chromatography/mass spectrometry with silyl-derivatization,[84] gas chromatography/electron impact/mass spectrometry,[85] gas chromatography/mass spectrometry with selected-ion monitoring,[86,87] and gas chromatography/positive ion chemical ionization/mass spectrometry.[88] Gas chromatography/mass spectrometry is the preferred method for quantitation of GHB. The LLOQ for the above 3 gas chromatography/mass spectrometric methods was 1 mg/L, 1 mg/L, and 2.5 mg/L, respectively. The LLOQ for gas chromatography/tandem mass spectrometry[89] and liquid chromatography/tandem mass spectrometry[90] is similar (i.e., 2.5 mg/L and 1 mg/L, respectively).

STREET SAMPLE ANALYSIS

Many illicit samples of GHB may contain GBL; analysis of illicit samples for GHB precursors by gas chromatography/mass spectrometry or high performance liquid chromatography/ultraviolet-visible spectrophotometry (e.g., GBL, 1,4-butanediol, maleic anhydride) provides information regarding the origin of the samples.[91] Determination of δ^{13}C-values with gas chromatography/combustion-isotope ratio/mass spectrometry is an alternative method for the identification of drug origin and the separation of endogenous production of GHB from external sources.[92]

STORAGE

In vitro production of GHB may occur during storage at ambient temperatures in unpreserved samples or in the presence of certain collection tube additives, par-

ticularly in postmortem blood samples stored >60 days. In a convenience sample of 26 postmortem blood samples stored at 4°C (39.2°F), the mean GHB concentration in containers with sodium fluoride was 19 mg/L compared with a mean GHB concentration of 32 mg/L in containers without preservatives.[93] Analysis of these samples occurred within 2 months of the autopsies. At room temperature, the GHB concentration was approximately 3-fold higher in unpreserved containers than in containers with sodium fluoride. Artificial production of GHB can occur in blood stored in yellow-top anticoagulant-citrate buffer tubes (trisodium citrate, citric acid, dextrose), whereas blood stored in purple-top tubes (edetate disodium acetate, EDTA) usually remains GHB-negative.[94] In general, postmortem blood preserved with sodium fluoride (10 mg/mL) can be stored at either 25°C (room temperature, 77°F) or 4°C (refrigerator, 39.2°F) with little change in the GHB concentration.[80] There was no significant increase in GHB concentrations (i.e., <3 mg/L) in pooled antemortem human serum aliquots stored for 8 months either with or without sodium fluoride preservative when stored at 4°C (39.2°F) or –20°C (–4°F).[95]

GHB is more stable in urine samples than in blood samples, particularly in sodium fluoride-preserved urine samples stored at –20°C (–4°F). The increase in GHB concentrations in urine samples stored over 1 year typically is below 5–7 mg/L, even in preserved (i.e., 1% sodium fluoride) specimens stored at room temperature.[96] In urine samples stored without preservatives at refrigerated temperatures, the *in vitro* production of GHB does not usually exceed the suggested 10 mg/L cutoff. In a study of 100 urine samples stored for about 1 year at room temperature with sodium fluoride, the maximum GHB concentration was 7 mg/L.[97] In a study of endogenous GHB concentrations in pooled urine samples from 2 participants stored at room (~25°C/77°F), refrigerator (5°C/41°F), and freezer (–10°C/14°F) temperatures over 6 months, the greatest increase (~400%) in endogenous GHB concentrations occurred at room temperature, whereas smaller increases occurred in refrigerated samples (~140–200%) and frozen samples (~100%).[98] The GHB concentrations in these samples were below the GHB concentrations (i.e., <1 mg/L) typically associated with GHB use.

Biomarkers

There are few data on the GHB concentrations in vitreous humor. In a case series of postmortem examinations with detectable concentrations of GHB, 3 cases had the following measurable GHB vitreous humor/femoral blood concentrations in mg/L (ratio): 78/97 (0.80), 250/180 (1.39), and 280/210 (1.33).[99] The GHB concen-

tration was measured after conversion of GHB to gamma-butyrolactone and analysis of the latter compound by gas chromatography/flame ionization detection (LOD, 30 mg/L). Although there are few data on the distribution of GHB between whole blood and serum, the lack of protein binding and high water solubility of GHB suggest that the whole blood/serum ratio is similar to ethanol.

BLOOD

THERAPEUTIC/ILLICIT USE.   GHB is a trace, natural constituent of body fluids along with the 2 isomers, α-hydroxybutyric acid and β-hydroxybutyric acid. Although there is no consensus on the optimal antemortem GHB concentration that distinguishes between endogenous production and exogenous administration, several studies suggest that a plasma GHB cutoff of 4–5 mg/L reliably identifies the ingestion of GHB antemortem.[100] In a study of 240 antemortem specimens from individuals without known GHB exposure, the mean GHB concentration was 0.74 mg/L (range, 0.34–5.75 mg/L). The mean endogenous GHB concentration in 50 serum samples from residents of a detoxification program was 1.14 mg/L (range, 0.62–3.24 mg/L; median, 0.97 mg/L).[101] There is substantial intraindividual variation in endogenous GHB concentrations over time of day and during the week.

The presence of other drugs in a majority of GHB intoxication complicates the correlation of plasma GHB concentrations to clinical effects. In a study of the use of GHB as an IV anesthetic, serum GHB concentrations correlated to clinical effects.[102] Occasional eye opening and spontaneous movement occurred at GHB concentrations ≤150 mg/L, whereas serum GHB concentrations exceeding 260 mg/L produced profound coma. Blood and urine samples from patients with rare inborn error of metabolism (i.e., 4-hydroxybutyric aciduria) may contain GHB concentrations exceeding 30 mg/L and 200 mg/L, respectively.[103]

OVERDOSE.   The level of consciousness during GHB-induced coma does not correlate well to plasma GHB concentrations, in part because of the frequent concomitant ingestion of other drugs including ethanol, ecstasy, marijuana, methamphetamine, cocaine, ketamine, and antidepressants. Plasma GHB concentration in patients with GHB overdose typically exceed 100 mg/L. The median plasma GHB concentration in blood from a convenience sample of 54 patients presenting to an emergency department with GHB intoxication was 103 mg/L (mean, 137 mg/L) with a range of 29–490 mg/L.[104] About two-thirds of these patients were unconscious or unresponsive on admission to the ED;

there were no deaths in this series. Approximately two-thirds of the blood samples contained other drugs (e.g., ethanol, methylenedioxymethamphetamine). In a series of 15 unconscious patients presenting to an emergency department with GHB intoxication (GCS ≤8), the median plasma GHB concentration was 212 mg/L (range, 112–430 mg/L).[68] The single patient with only GHB detected in his blood was an 18-year-old man with an initial GCS score of 6. His plasma GHB concentration on presentation was 186 µg/mL, and he awoke within 1 hour of presentation.

In a series of 16 patients with severe GHB intoxication (GCS ≤8), the serum GHB concentration ranged from 45–295 mg/L (median, 180 mg/L), whereas patients with a GCS of 3 had serum GHB concentrations ranging from 72–300 mg/L (median, 193 mg/L).[105] The severe coma in these patients persisted 1–2 hours. Awakening from coma occurs relatively rapidly with relatively small changes in the plasma GHB concentration. The mean plasma GHB concentration (i.e., measured as total GBL) in a case series of 27 patients presenting to EDs in the UK with altered consciousness secondary to GHB use was 245 mg/L (range, 86–551 mg/L).[106] There were no reported sequelae. A 23-year-old woman ingested ethanol and GHB along with smoking marijuana shortly before becoming unconscious.[107] She presented to the emergency department comatose (GCS = 6) with normal vital signs except mild bradycardia (56 bpm) and respiratory depression (8 breaths/min). In admission blood, her serum ethanol and GHB concentrations were 134 mg/dL and 125 mg/L, respectively. She awoke within 1 hour and left the emergency department against medical advice.

POSTMORTEM
GHB Production Animal and postmortem human studies indicate that postmortem production of GHB increases as the postmortem interval increases, depending on the specific analytic technique, type of biologic sample, and storage methods. Potential sources for the postmortem production of GHB include the enzymatic conversion of succinic acid, γ-aminobutyric acid (GABA) and/or putrescine to GHB. Endogenous GHB concentrations in vitreous and in blood samples from different parts of the body are similar in postmortem examinations performed within 48 hours of death. In a study of 25 well-preserved autopsy cases (postmortem interval, 6–48 h), the highest endogenous GHB concentrations occurred in the femoral blood (4.6 ± 3.4 mg/L), whereas the lowest concentration appeared in the urine (0.6 ± 1.2 mg/L) as measured by headspace gas chromatography/flame ionization detection after conversion of GHB to GBL.[108] Some differences in postmortem GHB concentrations may result from the use

of different analytic methods. In 20 postmortem blood specimens (postmortem interval not reported) from cases without known GHB exposure, the blood GHB concentrations ranged from 3.2–168 mg/L as measured by gas chromatography/flame ionization detection and gas chromatography/mass spectrometry after conversion of GHB to GBL (i.e., total GBL).[109]

The exact pathway of postmortem GHB formation remains unclear because of the failure to detect endogenous precursors, 1,4-butanediol or succinate semialdehyde (GABA transamination) as potential sources of GHB formation.[110] Although endogenous GHB concentrations do not correlate to the concentrations of common putrefactive makers (e.g., tryptamine, phenyl-2-ethylamine), experimental studies suggest that *Pseudomonas aeruginosa* species can produce GHB in unpreserved blood specimens.[111] In well-preserved (e.g., sodium fluoride) postmortem blood and urine samples, the presence of GHB concentrations exceeding 30–50 mg/L in blood samples or 20 mg/L in urine samples suggests the presence of exogenous GHB. A study of 38 postmortem blood and 15 urine samples preserved with sodium fluoride from autopsy cases unrelated to GHB ingestion demonstrated mean GHB concentrations of 12.3 mg/L (range, 2–29 mg/L) and 4.8 mg/L (range, 0–10 mg/L), respectively.[112] However, determination of the presence of exogenous GHB in postmortem samples exceeding these cutoffs requires careful analysis of the storage methods (e.g., preservatives), analytic techniques, multiple biologic specimens (e.g., blood, urine, vitreous) and clinical history, particularly when examining postmortem cardiac blood. In 71 autopsy cases (postmortem interval, 12–72 hours) without known GHB exposure, 14 postmortem unpreserved heart blood samples contained GHB concentrations exceeding 50 mg/L (range, 50.8–409 mg/L).[113] The femoral blood and vitreous humor samples in all these cases were below the 50 mg/L cutoff. The heart/femoral blood ratio for 5 cases in this series of presumed endogenous GHB production was 1.24, 1.28, 1.85, 5.65, and 24.3.

GHB Concentrations   Interpretation of the significance of postmortem GHB concentrations requires analysis of sample storage, postmortem interval, and the correlation of the medical/case history to the postmortem GHB concentration. There are limited data on the postmortem redistribution of GHB with heart/femoral blood ratios typically ranging from about 0.5–2. A 35-year-old man was found dead after ingesting wine and GHB at a party. The GHB concentrations in heart and femoral blood samples were 276 mg/L and 461 mg/L, respectively (heart/femoral blood ratio, 0.56)[114] compared with 3,385 mg/L and 2,936 mg/L (heart/femoral blood ratio, 1.15) in a 43-year-old man pronounced dead soon after being found unconscious by relatives.[115] The screen for drugs of abuse and ethanol was negative. The vitreous humor contained 48 mg GHB/L. Heart and femoral blood samples from a 22-year-old woman dying after the ingestion of a single dose of GHB contained GHB concentrations of 648 mg/L and 330 mg/L, respectively (heart blood/femoral blood ratio, 1.96).[116] The autopsy demonstrated no other cause of death and the comprehensive drug screen was negative with the exception of GHB.

In a convenience sample of 78 deaths from throughout the United States attributed to GHB intoxication without co-intoxicants, the median postmortem blood concentration (site not specified) was 347 mg/L with a range of 18–4,400 mg/L.[117] All of the cases with a medical history had a cardiorespiratory arrest prior to the arrival of the paramedics. The median GHB concentration in femoral blood samples from 18 deaths attributed to GHB intoxication was 235 mg/L (range, 55–2,200 mg/L).[118] Although other drugs were present in postmortem blood samples from the vast majority of the samples, almost half of these cases had minor or no clinically significant amounts of other drugs. In a case series of 8 autopsy cases attributed to GHB intoxication (along with other drugs), the mean postmortem/perimortem GHB concentration (method not reported) in blood samples (source not specified) was 231 mg/L (range, 77–370 mg/L). Similar to antemortem samples, the clinical significance of postmortem GHB concentration requires careful analysis of the analytic techniques, storage methods, postmortem interval, and clinical history including resuscitation measures and survival times. The GHB heart/femoral blood ratio in postmortem blood samples from a 38-year-old man found dead at his home was 1.13 (1,052 mg/L/932 mg/L).[119]

URINE

Urine drug of abuse screens do not routinely detect GHB, and rapid immunoassays for the detection of GHB overdose are usually not available in the hospital setting. GHB occurs in the urine as well as other body fluids as a result of endogenous production. Proposed cutoff concentrations of GHB in urine to distinguish endogenous production from exogenous administration range from about 5–10 mg/L with a majority of urine specimens containing GHB concentrations below 1–2 mg/L.[120] In a convenience sample of 119 urine specimens from GHB-free study participants, the maximal urinary GHB concentration was 3 mg/L,[100] whereas the maximum GHB concentration in urine samples from 55 participants without known exposure to GHB was 3.5 mg/L (median, 1.3 mg/L).[121] This study demonstrated substantial intra-individual variation in the GHB concentration in urine that is independent of

TABLE 6.1. Range of Endogenous Concentrations of γ-hydroxybutyrate (GHB) and Associated Isomers in the Urine of Healthy (n = 30) and Diabetic (*n* = 20) Volunteers.[122]

Substance	Healthy (mg/L)	Diabetic (mg/L)
GHB	0.16–2.14	0.17–3.03
α-Hydroxybutyric acid	0.10–2.68	0.14–124
β-Hydroxybutyric acid	8.51–34.7	4.94–4,520

urinary creatinine concentration and standard diets. Some foods (e.g., ripe guava fruit) contain relatively high concentrations of GHB; however, there is no clear evidence that these GHB concentrations produce clinical effects. The urinary GHB concentrations of healthy volunteers and diabetics are similar; however, diabetic patients typically have higher concentrations of GHB isomers, particular during diabetic ketoacidosis.[122] Table 6.1 compares the range of endogenous GHB and GHB isomers in the urine of 30 healthy and 20 diabetic volunteers. The highest concentration of GHB isomers occurred in a diabetic with ketoacidosis. Analysis of 50 urine samples donated by healthy women demonstrated a maximum urinary GHB of 1.46 mg/L as measured by gas chromatography/mass spectrometry with silyl derivation (LOD, 0.1 mg/L).[123] Pregnant women have a modestly higher urine GHB concentration when compared with nonpregnant women. The mean GHB concentration in urine samples from 66 pregnant women was 0.36 mg/L compared with 0.24 mg/L in 69 nonpregnant women as measured by liquid chromatography/tandem mass spectrometry.[124] The mean urine gamma-butyrolactone (GBL) concentration was 4.3-fold higher in pregnant women.

The GHB concentration in urine samples from patients with GHB overdoses usually exceed 1,000 mg/L. The mean GHB concentration (i.e., measured as total GBL) in urine samples from a case series of 27 patients presenting to EDs in the United Kingdom with altered consciousness secondary to GHB use was 1,732 mg/L (range, 5–5,581 mg/L).[106] There were no reported sequelae. The window of detection for GHB following typical recreational doses is approximately 12 hours with peak GHB urine concentrations usually occurring within 3 hours of ingestion as measured by gas chromatography/mass spectrometry. Following the administration of a single GHB (Xyrem®) dose of 50 mg/kg to 16 healthy adults, the percentage of urine samples *below* the 10-mg/L cutoff during specific time intervals after administration were as follows: 3–6 hours, 12.5%; 6–12 hours, 81.3%; 12–24 hours, 100%.[125]

Following large GHB ingestions, the urine contains high GHB concentrations. A 28-year-old man was found comatose after ingesting a liquid confirmed to be GHB.[126] He was intubated on arrival at the emergency department; after transfer to the intensive care unit, he was rapidly extubated. The GHB concentrations in his urine sample from admission and 6-hours postadmission were 3,020 mg/L and 2,324 mg/L, respectively, as measured by gas chromatography/mass spectrometry in selective ion monitoring.

Abnormalities

Evaluation of serum chemistry during GHB intoxication is usually normal including normal serum potassium concentrations. Case reports associate electrocardiographic abnormalities with GHB intoxication including U waves, right bundle branch block, 1st degree A-V block, and ventricular premature beats;[127] however, other ingested drugs may contribute to the appearance of these abnormalities.

Driving

Alteration of consciousness and diminution of motor skills (e.g., depressed consciousness, impaired balance, nystagmus) seriously impairs driving skills of individuals under the influence of GHB.[128,129] Typical behaviors of GHB-intoxicated drivers include erratic driving (weaving, swerving, ignoring road signs), abnormal behavior (falling asleep at a red light, stopping in the middle of the road), ataxia, confusion, disorientation, agitation, slurred speech, and jerking movements along with poor performance on field sobriety tests.[130,131] The rapid elimination of GHB complicates the correlation of GHB blood concentrations to driving impairment. Additionally, individual responses to specific blood GHB concentrations are highly variable. In a series of 6 individuals with similar impairment after arrest for driving under the influence (DUI), the whole blood GHB concentrations ranged from 16–350 mg/L.[132] The latter value was substantially higher than the postmortem blood GHB concentration (174 mg/L, with 20 mg ethanol/dL) from a 36-year-old man found unconscious and failing to respond to cardiopulmonary resuscitation in the emergency department. In these samples, the presence of substantially higher (i.e., 10-fold) GHB concentrations in urine samples suggests an exogenous GHB source. In a case series of 185 individuals arrested for suspected driving under the influence of drugs or ethanol and testing positive only for GHB, the mean GHB concentration in venous blood samples was 92 mg/L (median, 86 mg/L) with an upper limit of 270 mg/L as measured by gas chromatography/flame ionization detection (LLOQ, 8 mg/L).[133] The typical range of time between arrest and blood sampling was

approximately 30–90 minutes (i.e., ~1–3 plasma elimination half-lives). Abnormalities reported by police officers included sedation, unsteady gait, slurred speech, irrational behavior, agitation, jerking, mydriasis, and spitting.[134] The reported blood GHB concentrations (i.e., GHB plus GBL) were similar to a smaller cases series of 8 individuals with only GHB in their toxicology screens after arrest for suspected DUI.[135] Venous blood samples were drawn up to 2 hours after arrest; the blood GHB concentration ranged from 26–155 mg/L, as measured by gas chromatography/mass spectrometry.

TREATMENT

Stabilization

The management of GHB intoxication typically involves stabilization of the airway, support of respirations, and prevention of aspiration. Because of the alteration of consciousness typically associated with GHB intoxication, these patients require monitoring of oxygenation with pulse oximetry and if needed, arterial blood gases. Supportive care includes supplemental oxygenation, suctioning and positioning for spontaneous vomiting, cardiac monitoring (primarily for bradycardia) and IV access. The mouth should be inspected for the presence of mucosal ulcerations suggestive of alkali burns from the sodium hydroxide used to synthesize GHB.[136] If present, the patient should be evaluated for the possibility of serious pulmonary complications from aspiration of alkali material. Intubation is usually unnecessary unless hypoventilation, hypoxemia, or the absence of a gag reflex occurs. When indicated, rapid-sequence intubation usually requires only paralysis with succinylcholine because of the sedation and amnesia associated with GHB intoxication.[137] The hypothermia associated with GHB use is typically mild and responds well to passive warming techniques.

Gut Decontamination

Measures for gastrointestinal (GI) decontamination (e.g., lavage, activated charcoal) are not routinely recommended for GHB intoxication alone because of the rapid absorption of GHB and potential for aspiration secondary to altered consciousness. The decision to use GI decontamination depends on the clinical severity of other ingested substances.

Elimination Enhancement

Measures to enhance the elimination of GHB are usually unnecessary because of the rapid endogenous elimination of GHB.

Antidotes

There are no specific antidotes for GHB intoxication, and naloxone should be administered only for the concomitant presence of opiate intoxication.[138] Experimental studies and case reports indicate that flumazenil does not reverse the clinical effects of GHB.[139] Although case reports and observational studies suggest that low doses of physostigmine may attenuate the coma associated with severe GHB intoxication,[140,141] there is insufficient scientific evidence to support the use of physostigmine in the treatment of γ-hydroxybutyrate toxicity.[142] Consequently, the routine use of physostigmine is not recommended, particularly in the setting of the frequent presence of other drugs of abuse.[143]

Supplemental Care

The recovery from GHB intoxication is rapid as a result of the short plasma elimination half-life of GHB. Typically, patients can be discharged within 6 hours after ingestion following an uneventful recovery. The persistence of symptoms over 6 hours after ingestion suggests the presence of other drugs or complications (trauma, hypoxia, drug overdose). The treatment of withdrawal symptoms typically involves the use of benzodiazepines (starting dose, 10–20 mg diazepam or 2–4 mg lorazepam), frequently in high doses (i.e., daily starting dose, 80–150 mg diazepam) tapered over 7 days.[40] Baclofen is a $GABA_B$ agonist that is a potentially useful for the treatment of benzodiazepine-resistant GHB withdrawal; however, there are inadequate clinical data to determine the efficacy of this drug.

The Clinical Institute Withdrawal Assessment of Alcohol Scale may aid in the management of withdrawal reactions; however, there is a lack of validation of this scale in the treatment of GHB withdrawal. Antipsychotic medications are not usually administered for the treatment of GHB withdrawal, in part because of concern about lowering the seizure threshold. Quetiapine is a potential alternative; however, there are few clinical data to assess the clinical efficacy of this antipsychotic for severe GHB withdrawal. For patients with delirium secondary to GHB withdrawal that is unresponsive to high diazepam doses (i.e., 200 mg/day), the administration of pentobarbital (or chloral hydrate) in the intensive care setting is a therapeutic option.[73] Therapy with pentobarbital begins with small doses (1–2 mg/kg IV) every 30–60 minutes titrated to response. Typically, sensorium and tachycardia of diazepam-resistant patients with severe GHB withdrawal respond to pentobarbital within 2–6 hours.[144] Case reports suggest that patients with severe withdrawal symptoms should be monitored for hyperthermia and rhabdomyolysis.[145]

GHB ANALOGUES

HISTORY

GHB analogues include 1,4-butanediol (1,4-BD), γ-butyrolactone (GBL), and γ-valerolactone (GVL). Restrictions of the sale and use of GHB during the 1990s resulted in the use of GHB analogues (e.g., 1,4-BD, GBL) as precursors and surrogates of GHB.[146] GBL was sold over-the-counter and through the Internet either alone or with instructions and components for the home synthesis of GHB. After a FDA warning regarding the health risks of γ-butyrolactone, γ-butyrolactone supplements were voluntarily recalled in 1999.[147] Subsequently, 1,4-BD products were marketed as replacements for γ-butyrolactone.

IDENTIFYING CHARACTERISTICS

There are several popular GHB analogues as displayed in Figure 6.3. These analogues are distinct chemicals with differing toxicity and pharmacokinetic profiles. GBL (CAS RN: 96-48-0, $C_4H_6O_2$) has a molecular weight of 86.10 g/mol and density of 1.13 g/mL, whereas 1,4-BD (CAS RN: 110-63-4, $C_4H_{10}O_2$) has a molecular weight of 90.10 g/mol and density of 1.02 g/mL. The latter is a lactone-ring analogue of GHB; 1,4-BD is an aliphatic alcohol. γ-Hydroxyvalerate (GHV) is the 5-carbon analogue of GHB. Both GBL and 1,4-BD are water- and alcohol-soluble, colorless compounds. Common names for GBL include Blue Nitro, Blue Nitro Vitality, Fire Water, Gamma-G, GH Revitalize, Remforce, Renewtrient, Revivarant, and Revivarant-G; whereas street synonyms for 1,4-BD include Blueraine, Dream On, Fubar, Pine Needle Oil, Rejuv@Nite, Somatopro, and Thunder.[146]

EXPOSURE

GBL is a list I chemical under the Chemical Diversion and Trafficking Act of 1988 that requires specific record keeping and reporting to the Drug Enforcement Administration for the import, manufacture, distribution, and export of this chemical; 1,4-BD is not included in this list of controlled chemicals. In contrast to the lack of industrial uses for GHB, GBL and 1,4-BD are common chemicals for a variety of industrial or research purposes including the synthesis of polybutylene terephthalate resins, polyurethanes, and tetrahydrofuran. GBL is a constituent of some superglue removers, paint strippers, nonacetone nail-polish remover pads, stain removers, and solvents; unadulterated wine may contain small amounts of GBL. 1,4-BD is a precursor for the industrial synthesis of GBL. The industrial grades of GHB analogues may contain impurities. GBL is frequently substituted for GHB. In a study of 158 emergency department presentations in London during 2006, self-reported use of GHB and GBL was about 95% and 5%, respectively.[148] However, analysis of 225 liquid samples seized from club attendees in the same catchment area during this period demonstrated that only 85 (37.8%) contained GHB, whereas 140 (62.2%) contained GBL. None of the samples contained detectable quantities of 1,4-butanediol.

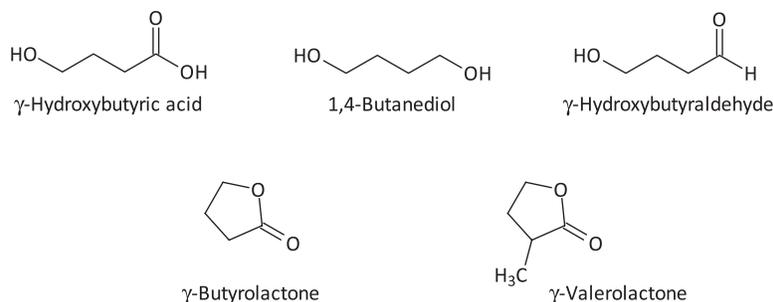
1,4-butanediol is a natural trace constituent of the human body similar to GHB, whereas GBL is not a normal constituent of the body. The synthesis of GHB by saponification of the lactone in GBL via hydroxide anions (sodium hydroxide) is a relatively simple process; whereas the complexity of the conversion of 1,4-BD to GHB limits the use of this method of producing GHB. Processes for the synthesis of GBL include the hydrogenation of maleic anhydride and the dehydrogenation of 1,4-butanediol with acetylene and formaldehyde (classical Reppe process).


FIGURE 6.3. Chemical structures of γ-hydroxybutyric acid and various analogues.

DOSE EFFECT

GBL and 1,4-BD are more potent in animal studies than GHB based on the D_{50} (dose at which the response decreases by 50%). In a study of rats, the D_{50} for GBL, 1,4-BD, and GHB were 116 mg/kg, 151 mg/kg, and 297 mg/kg, respectively.[149] A case series of adverse events from 1,4-BD use associated the ingestion of approximately 1 g 1,4-butanediol with diaphoresis, confusion, agitation, ataxia, and myoclonus without any clinically significant alteration in vital signs, whereas the ingestion of about 6–8 g 1,4-BD was associated with loss of consciousness, urinary incontinence, vomiting, and mild bradycardia.[150] In this report, the estimated ingestions of 1,4-BD by a man and woman found dead in 2 separate incidents were 5.4 g and 20 g based on history from companions.

TOXICOKINETICS

Kinetics

Animal studies indicate that GBL is a prodrug that is rapidly and almost completely absorbed from the GI tract following the oral administration of low therapeutic doses.[151] Higher doses produce relatively lower bioavailability because of capacity-limited transport. Percutaneous absorption of GBL is limited (<10%) based on rodent studies.[152] Animal studies indicate that the conversion of GBL and 1,4-BD to GHB occurs *in vivo*.[153] Limited human data confirms the rapid formation of GHB following the administration of GBL or 1,4-BD. In a doubled-blind, placebo-controlled, crossover study of 8 healthy volunteers receiving 25 mg 1,4-BD/kg, the mean time to maximum plasma concentration (T_{max}) of 1,4-BD was 24 ± 12 min compared with the mean T_{max} for GHB of 39.4 ± 11.2 min after 1,4-BD ingestion.[154] The latter T_{max} is similar to the T_{max} (30–40 min) following the administration of GHB. The mean plasma elimination half-life of 1,4-BD was 39.3 ± 11.0 min.

Drug Interactions

Alcohol dehydrogenase catalyzes the formation of γ-hydroxybutyraldehyde and aldehyde dehydrogenase catalyzes the formation of γ-hydroxybutyrate from γ-hydroxybutyraldehyde. Animal studies indicate that the interaction of ethanol and 1,4-BD is complex, resulting from the inherent properties of this diol (pharmacodynamic interaction) and the ethanol-induced inhibition of the conversion of 1,4-BD to GHB (pharmacokinetic interaction).[155] 1,4-BD may potentiate some of the behavioral effects of ethanol as well as delay and attenuate the formation of GHB.[156]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Similar to GHB, GBL is a natural constituent of the brain that easily crosses the blood–brain barrier.[157] The relatively higher potencies of GBL and 1,4-BD probably do not result from enhanced penetration of the blood–brain barrier by these compounds. Experimental studies indicate that GBL is inactive following intracerebroventricular administration when compared with GHB; thus, the metabolic activation of GBL to GHB probably occurs in the periphery rather than in the brain. In animal studies, GBL has negligible affinity for the GHB receptor. Postmortem examination of fatalities associated with 1,4-BD are usually nonspecific (e.g., pulmonary edema).[150]

CLINICAL RESPONSE

The clinical features of GBL and 1,4-BD intoxication include CNS depression and fluctuating levels of consciousness that are indistinguishable from GHB intoxication.[158,159] Consequently, there are no pathognomonic signs or symptoms to separate poisoning by GHB analogues from GHB intoxication. Like GHB, the ingestion of GBL may cause coma and life-threatening respiratory depression.[160] Myoclonus occurs commonly during GHB and GHB analogue poisoning; the presence of myoclonic jerks may be confused with seizure activity. Although animal studies suggest that GBL and GHB produce electroencephalographic and behavioral changes resembling generalized absence seizures,[161] generalized seizures during intoxication with GBL or 1,4-BD more likely results from hypoxia, hypoglycemia, or the concomitant ingestion of other drugs of abuse (cocaine, methylenedioxymethamphetamine). The common effects associated with GHB analogue induced intoxication include nausea, vomiting, diaphoresis, bradycardia, incontinence, and short duration (i.e., 4–6 h) of coma along with variable pupillary responses.[162] GHB and GHB analogues are not strong cardiac depressants, and hypotension is not usually present even in comatose patients unless accompanied by bradycardia. Rarely, case reports associate fatalities with the ingestion of only 1,4-BD.[163] Potentially, caustic burns of the upper GI tract may occur if the sodium hydroxide used to convert GHL to GHB was incompletely neutralized. Limited animal data suggest that GBL is not carcinogenic or teratogenic.[164]

The clinical features of withdrawal from the chronic use of GHB analogues and GHB are similar including tremors, insomnia, confusion, anxiety, agitation, delirium, hallucinations, and autonomic instability (hypertension, tachycardia, diaphoresis).[165] Case reports

indicate that the abuse of GHB analogues continue 2 months to 4 years prior to the development of withdrawal.[166] Limited human data suggest that abstinence symptoms begin within a few hours of cessation of 1,4-BD use and up to 72 hours after chronic GBL use.[167] These symptoms (e.g., insomnia, anxiety, depression) persist for 3–15 days and in some patients up to weeks after withdrawal.[168] Case reports of seizures during GHB withdrawal are rare and may represent other etiologies.[165]

DIAGNOSTIC TESTING

Analytic Methods

Detection of the use of GHB analogues typically involves the detection of GHB because of the *in vivo* conversion of GBL and 1,4 BD to GHB. Most urine immunoassays for drugs of abuse do not detect GHB or GHB analogues. Chromatographic methods are necessary for the detection and quantitation of GHB and GHB analogues (See section on Analytic Methods for GHB above). Methods to separate GHB and GHB analogues include high performance liquid chromatography high performance liquid chromatography with photodiode array or ultraviolet (254 nm) detection and gas chromatography/mass spectrometry.[169,170]

Biomarkers

Following the oral administration of 25 mg 1,4-BD/kg to 8 healthy volunteers, the mean maximum plasma GHB concentration was 45.6 ± 19.7 mg/L with substantial interindividual variation in the rate of metabolism, particularly in Asian participants.[154]

In postmortem blood (source not reported) from 2 adults found dead after the ingestion of 1,4-BD and ethanol, the 1,4-BD concentrations were 845 mg/L and 1,756 mg/L compared with GHB concentrations of 432 mg/L and 837 mg/L, respectively.[150] A 25-year-old man was found in bed in cardiac arrest (asystole) with a history of ingesting GBL the previous evening.[171] He was pronounced dead in emergency department after unsuccessful cardiopulmonary resuscitation. The postmortem examination demonstrated pulmonary aspiration of gastric contents and pulmonary edema. The total GBL concentration (GBL plus GHB) in postmortem femoral blood was 282 mg/L. There are few data on the postmortem distribution of GHB analogues. In a case report of a 21-year-old man found dead after the ingestion of 1,4-BD, the 1,4-BD concentration in heart and peripheral postmortem blood was similar (78 mg/L and 70 mg/dL, respectively).[169]

Case reports associate nonspecific electrocardiographic changes with GHB and GHB analogue intoxication including the presence of U waves, junctional bradycardia, widened QRS, and right bundle branch block.[159,172]

TREATMENT

The management of intoxication by GHB analogues is supportive, similar to the management of GHB intoxication. The main life-threatening features of intoxication are respiratory depression and aspiration. In rare cases, intubation and mechanical ventilation may be necessary, but most cases of poisoning with clinically significant altered consciousness require only continuous monitoring of blood pressure, cardiac rhythm, and pulse oximetry along with IV access and rapid evaluation of blood glucose. Similar to GHB intoxication, these patients may respond violently to intubation; therefore, rapid sequence intubation with paralytic agents is usually necessary to protect the airway and ventilate the select group of patients with severe respiratory compromise. Gastrointestinal decontamination measures are unnecessary in patients with intoxication by GHB analogues only. There are no effective antidotes to GHB analogue intoxication. The administration of 4-methylpyrazole (fomepizole) potentially blocks the conversion of 1,4-BD to GHB; however, there are inadequate clinical data to determine if the use of this antidote improves clinical outcome. The persistence of coma 4–6 hours after presentation indicates the presence of other causes of coma beside GHB or GHB analogues. GHB abuse frequently occurs with the abuse of other drugs (ethanol, cocaine, methamphetamine, methylenedioxymethamphetamine). The treatment of the abstinence syndrome associated with chronic 1,4-BD or GBL abuse is similar to GHB withdrawal with initial treatment with benzodiazepines and pentobarbital in refractory cases.[173]

Chapter 7

KETAMINE

HISTORY

Calvin Stevens synthesized ketamine hydrochloride at the Park-Davis Laboratories in 1962. Early clinical studies suggested that ketamine was an effective anesthetic agent with less toxicity, little respiratory depression at anesthetic doses, and fewer emergence reactions than phencyclidine.[1] During the late 1960s, ketamine was marketed as the dissociative anesthetic, Ketalar® (JHP Pharmaceuticals, Parsippany, NJ); this compound was used to treat soldiers in the Vietnam War. The abuse potential of ketamine was recognized in the early 1970s,[2] but reports of ketamine abuse in human and veterinary medicine did not appear until the early 1980s in Australia and in the early 1990s in the United States.[3,4]

IDENTIFYING CHARACTERISTICS

Ketamine is the arylcycloalkylamine compound, 2(2-chlorophenyl)-2-(methylamino)-cyclohexanone, which is structurally similar to phencyclidine and cyclohexamine (N-ethyl-1-phenylcyclohexylamine). Figure 7.1 displays the chemical structure of ketamine (CAS RN: 6740-88-1, MW 237.75 g/mol). Ketamine is a chiral molecule that is available in commercial preparations as a racemic mixture of equal amounts of R(−)-ketamine and S(+) ketamine enantiomers. The latter enantiomer is about 2–4 times a more potent analgesic than R(−)-enantiomer, but the R(−)-enantiomer may contribute to the emergence reactions associated with ketamine anesthesia.[5] In mice, the hypnotic effect of the S-(+)-ketamine isomer is approximately 1.5 times greater than the R-(−)-ketamine isomer.[6] Ketamine is a highly lipid soluble, weakly basic amino compound that usually occurs in pharmaceutic preparations as the hydrochloride salt. Table 7.1 lists some physical properties of ketamine.

Trade names for ketamine include Ketalar®, Ketaject® (Phoenix Pharmaceutical, Burlingame, CA), Ketaset®, and Vetalar®. Synonyms for ketamine on the street include K, Kit-Kat, Kay, Jet, Vitamin K, Special K, Super Acid, Super K, Super C, Special LA Coke, and 1980 Acid. In the United States, ketamine is a Drug Enforcement Agency (DEA) schedule III substance (drugs with currently accepted medical indications and abuse potential for low to moderate physical dependence or high psychologic dependence). The usual form of ketamine is a pharmaceutic liquid, but evaporation of this liquid crystalizes ketamine. The crystal residue is ground into a powder, similar in appearance to cocaine or heroin. Like phencyclidine, ketamine is smoked as a cigarette after the addition of ketamine to tobacco or marijuana. Because of the difficulty manufacturing ketamine clandestinely, illicit ketamine is usually a pharmaceutic preparation diverted from legal stocks, particularly from veterinarian clinics. Although ketamine is occasionally an adulterant of heroin, illicit stocks of ketamine are usually relatively pure.

EXPOSURE

Epidemiology

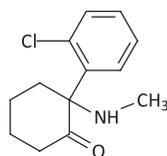
The use of ketamine in the general population is relatively low with the highest prevalence of use in individuals (medical personnel, veterinarian professionals, club drug users) with direct access to this compound.[7,8] The


FIGURE 7.1. Chemical structure of ketamine.

TABLE 7.1. Some Physical Properties of Ketamine.

Physical Property	Value
Melting Point	92.5°C (198.5°F)
pKa	7.5
Molecular Weight	238 g/mol
log P (Octanol-Water)	3.120
Atmospheric OH Rate Constant	7.71E–11 cm^3/molecule-second (25°C/77°F)

abuse of ketamine usually occurs in the setting of poly-drug use. Although the typical pattern of ketamine use involves insufflation of ketamine as one of several club drugs, a subset of ketamine abusers use ketamine intravenously.[9] These high-risk populations include gay men, marginalized youth, and intravenous (IV) polydrug users.[10] Cross-sectional surveys of ketamine users suggest that the negative adverse effects (e.g., poor coordination, difficulty speaking, increased body temperature, blurred vision) associated with ketamine use reduce some of the desire to continue chronic use of ketamine.[11] Experimental medicinal uses of ketamine include the treatment of anorexia, chronic pain, and palliative care.[12]

Sources

The typical source of illicit ketamine is diversion of legal human or veterinarian supplies of ketamine and, less often, illegal importation. Although the structure of ketamine appears relatively simple, the synthesis of this compound requires several complex steps. This process involves the use of numerous solvents, reagents, and precursors (e.g., methylamine, *o*-chlorobenzonitrile, cyclopentyl bromide) as well as heating in a steel pressure vessel (bomb) for several days. Because of this complex synthetic process and the difficulty obtaining these precursors, most illicit ketamine is diverted from pharmaceutic stocks rather than synthesized in clandestine laboratories.

Methods of Abuse

The most common method of ketamine abuse is insufflation and, less commonly, IV administration by poly-drug users.[13] Use of ketamine typically occurs in a carefully preplanned setting that is comfortable, familiar, and secure. Frequently, this setting includes the use of other club drugs (e.g., ecstasy, methamphetamine) in a social setting (e.g., nightclubs, dance parties, rave parties).[14] The use of ketamine by novice users in public or unfamiliar settings is associated with an increased risk of behavioral complications; however, the effect of the environment diminishes as the dose of ketamine increases and psychedelic effects predominate over stimulant effects.[15] Ketamine abusers describe the effects of ketamine use as "falling into a K-hole" where physical immobilization and social detachment persists up to about 1 hour.[16] This experience typically involves spiritual journeys, disengagement with time and space, illusions, and fantasy interactions with famous or fictitious persons. Additionally, some ketamine abusers report near-death experiences manifest by altered perception of time and a strong sense of detaching from their physical body along with a sense of peace and/or joy.[17] Typically, these experiences occur during the first few uses of ketamine. Because of the short elimination half-life of ketamine, abusers usually administer sequential doses of this drug to maintain the psychedelic effects.[18] These ketamine abusers administer ketamine in cyclical binges similar to cocaine or methamphetamine abusers.[19]

DOSE EFFECT

Illicit Use

Recreational doses are highly variable (50–200 mg), in part, because of the rapid development of tolerance to ketamine.[20] Typical illicit doses of ketamine are 25–50 mg intramuscularly, 30–75 mg insufflation, and 75–300 mg orally. The intense, dissociative experience persists approximately 1 hour. Case reports document the daily use of up to 4–7 g ketamine.[21] Insufflating 30–50 mg ketamine (i.e., a small line) produces a dreamy state, whereas the intramuscular administration of 60–125 mg results in a more intense dissociative state ("K-hole").

Medical Use

Ketamine is a rapidly acting, relatively safe anesthetic agent that is a common agent for conscious sedation in children. The bronchodilating properties are useful for the sedation of asthmatic patients requiring intubation. The typical anesthetic dose of ketamine for conscious sedation is 1–2 mg/kg intravenously or 4–5 mg/kg intramuscularly. Experimental uses of ketamine include the use of low-dose ketamine for postoperative pain relief,

for regional or local anaesthesia, and for opioid-sparing effects.[22] The emergence reaction after ketamine administration is not dose-dependent.

Toxicity

In a case series of 9 children receiving intramuscular (IM) or IV ketamine doses up to 50 mg/kg, the primary effect was transient respiratory depression in 4 children and prolonged sedation up to 24 hours in all patients.[23] In another case report, the inadvertent IM administration of 10 times the normal ketamine dose (450 mg) to a 3-year-old child was associated with prolonged sedation and 4 episodes of desaturation relieved by supplemental oxygen and repositioning of the airway.[24] All children recovered without sequelae.

TOXICOKINETICS

Absorption

The bioavailability of oral ketamine is low. In a study of 3 volunteers receiving ketamine 50 mg orally, the average bioavailability was approximately 18% ± 5%, whereas the mean maximum ketamine concentration was about 42 ± 13 ng/mL at 33 ± 13 minutes after administration.[25] For the 25-mg nasal dose, the bioavailability of ketamine was approximately 44% ± 11%; the mean maximum ketamine concentration was about 29 ± 17 ng/mL at 23 ± 10 minutes after administration. In a study of 32 children undergoing halothane administration and receiving 9 mg ketamine/kg intranasally, the mean bioavailability of ketamine was approximately 50%.[26] The mean peak concentration of ketamine in plasma samples was 2,104 ± 965 ng/mL at a mean time of 42 ± 19 minutes after intranasal administration. The peak norketamine concentration occurred about 2 hours after the nasal administration of ketamine.

Distribution

In a study of 12 intensive care patients receiving ketamine, the mean volume of distribution was 16 ± 8.6 L/kg, based on analysis of arterial plasma samples following administration of analgesic doses (2 mg/kg) of IV ketamine.[27] Ketamine rapidly distributes into the brain and highly perfused tissues after IV administration with a distribution half-life of approximately 7–11 minutes. *In vitro* studies of human serum using ultrafiltration indicate that the protein binding of ketamine and norketamine at 30°C (86°F) were approximately 69% and 60%, respectively.[28]

Biotransformation

The major pathway of ketamine biotransformation involves *N*-demethylation to the active metabolite, norketamine, followed by hydroxylation to the much less-active metabolite, dehydronorketamine. Ring hydroxylation without prior *N*-demethylation is a minor metabolic pathway. The principal cytochrome P450 isoform responsible for the *N*-demethylation of ketamine to norketamine is CYP3A4 with relatively minor contributions from CYP2B6 and CYP2C9 isoforms.[29,30] There are few studies on the potency of the active metabolites of ketamine. Based on animal studies, the anesthetic potency of ketamine is about 3–5 times greater than norketamine.[31]

Elimination

The plasma half-life of ketamine is about 2–4 hours.[32] In a study of 31 patients receiving 2 mg ketamine/kg intravenously, the mean plasma elimination half-life was 79 ± 8 minutes,[33] whereas the mean elimination half-life of ketamine in 12 hemodynamically stable, intensive care patients was 4.9 ± 1.6 hours.[27] Although the pharmacokinetics of the *R*-(−)- and the *S*-(+)-enantiomers of ketamine are somewhat similar, the presence of the *R*-(−)-enantiomer inhibits the clearance of the *S*-(+)-enantiomer. In a study of 10 healthy young men receiving an infusion of ketamine, the mean clearance of the *S*-(+)-enantiomer of ketamine from arterial blood was 26.3 ± 3.5 mL/kg/min in the pure form compared with 18.5 ± 0.7 mL/kg/min in the racemic mixture containing 50% of each enantiomer.[34] Elimination of ketamine occurs primarily in the urine as a result of the renal excretion of the conjugated products of glucuronic acid and norketamine or hydroxylated metabolites (e.g., 6-hydroxy-norketamine) of norketamine. Renal excretion of unchanged ketamine and norketamine accounts for <4% of the absorbed dose of ketamine, whereas fecal excretion of ketamine accounts for <5% of the absorbed dose.[35]

Maternal and Fetal Kinetics

Ketamine easily crosses the placenta, and ketamine concentrations in the mother and fetus are similar.[36]

Tolerance

Case reports suggest that both acute and chronic tolerance develops rapidly after the use of ketamine.[21,37,38] Anecdotal reports suggest that chronic use dulls the psychedelic experience associated with ketamine use as

well as memories of ketamine effects.[19] Based on rodent studies, the chronic administration of ketamine induces hepatic cytochrome P450 isoenzymes.[39] Physical dependence does not usually develop following chronic ketamine abuse.[40] However, anecdotal reports suggest that nonspecific symptoms may develop with a few days after cessation of ketamine use including restless, irritability, hypervigilance, and difficulty with concentration.[19]

Drug Interactions

Because biotransformation of ketamine primarily involves the CYP3A4 isoform, drugs that alter this isoform would be expected to affect the metabolism of ketamine. Benzodiazepines (e.g., midazolam, lorazepam) attenuate the altered perception and thought processes associated with the use of ketamine. Although these drugs reduce the ketamine-associated emotional distress, the cognitive or behavioral effects of ketamine are not reduced. Acute administration of diazepam increases the half-life of ketamine. Lamotrigine significantly decreases ketamine-induced perceptual abnormalities, but lamotrigine enhances the mood elevating effects of ketamine. Haloperidol causes little change in the psychosis, perceptual changes, or euphoria associated with ketamine use. Animal studies suggest that the concomitant administration of ketamine (20 mg/kg) and caffeine (20 mg/kg) enhances locomotor activity and reduces coordination, whereas ketamine (200 mg/kg) and caffeine (20–100 mg/kg) produces a dose-dependent increase in seizures and death.[41]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

Ketamine is a dissociative anaesthetic with analgesic and amnestic properties that causes impairment of working and episodic memory during intoxication and the immediate period after the administration of ketamine.[42] Similar to phencyclidine (PCP), ketamine is a noncompetitive antagonist of the N-methyl-D-aspartate (NMDA) receptor for glutamate, but the mechanism of action of ketamine is more complex than PCP because of the interaction of ketamine with many others receptors (opioid, noradrenaline, serotonin, muscarinic cholinergic). These effects also include decreased catecholamine reuptake and the stereoselective inhibition of the dopamine transporter with the S(+)-enantiomer being approximately 8 times more potent than the R(−)-enantiomer (K_i = 46.9 μM and 390 μM, respectively).[43]

The affinity of PCP for the NMDA receptor is approximately 10-fold greater than ketamine. The administration of subanesthetic doses of ketamine to schizophrenic individuals produces short-term activation of psychotic symptoms, which are similar to their usual psychotic episodes.[44,45] Following anesthetic doses (>2 mg/kg), ketamine produces a dose-related increase in heart rate and pressure without altering stroke index.[33] Ketamine does not cause significant respiratory depression except following very large doses or rapid IV administration.

Mechanism of Toxicity

The psychedelic effect of ketamine results, at least in part, from the disruption of the normal thalamocortical filtering of external and internal information to the cortex. Animal studies suggest that subanesthetic doses of ketamine increase dopamine D_2 receptor binding in the hippocampus and decrease glutamate receptor binding in the frontal cortex, while dopamine D_1 receptor binding remains unchanged.[46] Ketamine impairs or antagonizes N-methyl-D-aspartate glutamate receptor neurotransmission and increases glutamate release. This effect causes aberrant perceptual processing of auditory and visual association and reduced integration of aberrant perception in visceromotor function and the sense of self.[47] Additionally, the density of dopamine transporters increase in the striatum, while the density of 5-HT transporters increase in the striatum, the hippocampus, and the frontal cortex. However, in a study of chronic ketamine abusers imaged by positron emission tomography, dorsolateral prefrontal cortex D_1 receptor availability was significantly upregulated when compared with healthy controls.[48] The main dopaminergic receptors in the human cortex are D_1, and sustained reduction in prefrontal dopamine produces an upregulation of prefrontal dopamine D_1 receptors. The cognitive performance of these study participants was normal; therefore, the clinical significance of this study remains unclear. Stimulation of dopamine release is a common effect of most drugs of abuse. NMDA receptors are densely localized in areas of the cerebral cortex and the hippocampus, which are important areas for executive function and memory. Human memory probably involves NMDA receptor-dependent long-term potentiation as well as other processes associated with neuronal learning. Preliminary clinical studies suggest some impairment of episodic memory (recognition of objects and source of information) in chronic ketamine abusers,[49] but the extent and type of these memory impairments remain undefined. Typically, executive function and attention are not affected at subanesthetic doses of ketamine.

Postmortem Examination

In the absence of trauma, postmortem examinations of patients dying of ketamine intoxication are typically unremarkable with nonspecific positive findings primarily involving pulmonary congestion.[50] Postmortem changes associated with death from respiratory depression include cerebral edema, pulmonary edema, interstitial and intra-alveolar hemorrhage in the lungs, and hyperemia of the airways. The postmortem examination of a 34-year-old woman, who died after several poisoning attempts with ketamine, demonstrated widespread fibrosis of cardiac muscle fibers around small arteries along with chronic hypoxic changes in the brain.[51] These latter changes included hemorrhage in the internal capsule and cerebral edema. The causal relationship between ketamine and these changes is unclear.

CLINICAL RESPONSE

Ketamine is a relatively safe anesthetic agent with few serious side effects as a result of the lack of cardiorespiratory depression in therapeutic doses. This drug produces a cataleptic state characterized by open eyes, staring gaze, slow nystagmus, increased salivation, and intact corneal and light reflexes. The major side effect is development of psychotic symptoms during emergence from ketamine anesthesia, particularly in adults and schizophrenic patients.[52] Rarely, laryngospasm occurs following dissociative sedation that may require intubation.[53] The postanesthesia emergence reaction involves alterations in mood and body image, dissociative (extracorporeal) state, vivid illusions, floating sensation, and frank delirium. These vivid dreams and illusions usually disappear shortly after awakening. The incidence of this reaction ranges from about 5–30%, depending on risk factors (age >16 years, female participants, IV ketamine doses >2 mg/kg, IV administration exceeding 40 mg/min).[54] In studies of healthy young adults, subanesthetic doses of ketamine produce dose-related psychedelic effects similar to the IV administration of *N,N*-dimethyltryptamine, manifest by alterations of mood, perception, body awareness, self-control, and mentation.[55] These effects are distinct from schizophrenia, and true hallucinations do not occur. In this study, the visual analog scales for anxiety, suspicious, and meaning were low compared with rating scales for reality, time, surroundings, thought, sound, and being high.

Illicit Use

Based on self-reported cases of ketamine use to a US regional poison center, the symptoms of ketamine intoxication are relatively brief with one-half of cases being asymptomatic on evaluation in the emergency department (ED).[56] The most common complaints were anxiety, chest pain, and palpitations with tachycardia being the most common physical finding. In contrast to patients intoxicated with phencyclidine, rotary nystagmus was rare (i.e., 3 of 20 patients). The most common symptoms in a retrospective study of 233 ketamine abusers presenting to an emergency department in Hong Kong were as follows: impaired consciousness, 45%; abdominal pain, 21%; lower urinary tract symptoms, 12%, and dizziness, 12%.[57] The frequency of abnormal physical findings were as follows: high blood pressure, 40%; tachycardia, 39%; abdominal tenderness, 18%; and white powder in nostril, 17%. Occasional case reports associate cystitis (dysuria, frequency, hematuria, proteinuria, urgency) with chronic ketamine abuse.[58,59]

Desired effects associated with ketamine intoxication include euphoria, depersonalization, derealization, universal empathy, sudden insights into the nature of existence or oneself, and perceptual distortions (sounds, shapes, colorful visions, floating feeling, absence of time, body image). The "K-hole" refers to the development of tunnel vision during intoxication followed by the feeling of rising above the body like a near-death experience. Although some individuals experience recurrent psychoses following repeated binges on ketamine, there is insufficient evidence to support the development of sensitization to the behavioral effects of ketamine.[60]

The principal risk of acute ketamine intoxication is physical trauma resulting from a state of confusion including falls, burns, drowning, or motor vehicle accidents. Adverse effects associated with case series of chronic ketamine users include perforated nasal septum (insufflation), abdominal pain, anorexia, weight loss, ataxia, slurred speech, dizziness, anxiety, hyperexcitability, insomnia, confusion, and blurred vision.[61] Case reports associate ketamine abuse with urinary retention, hydronephrosis, and renal dysfunction.[62]

Overdose

There are relatively few cases of ketamine overdose reported in the medical literature, primarily involving inadvertent administration of excessive ketamine doses to children undergoing sedation or anesthesia. In these patients, the main complications are transient respiratory depression and prolonged sedation up to 24 hours.[23] Fatalities associated with ketamine are usually related to either behavioral-induced trauma or multiple-drug overdose.[63] In a series of 15 nonhospital-associated deaths with detectable postmortem concentrations of ketamine, 12 involved multiple drugs and 2 involved trauma.[64] The other death resulted from natural causes (sarcoidosis).

Abstinence Syndrome

Case reports of abstinence following chronic ketamine abuse associated the development of intense drug craving, anxiety, fatigue, diaphoresis, and tremulousness within 8 hours after cessation of use.[21] Within 24–48 hours after ketamine use ceases, lethargy, depression, and anorexia occur. After a period of deep sleep, the individual feels better with some residual weakness.

Reproductive Abnormalities

Ketamine is an anesthetic agent used during induction for cesarean sections as a method to reduce postoperative pain.[65] Clinical studies suggest that ketamine increases uterine contractions.[66] However, there are few data on the teratogenic effect of ketamine use during the first and second trimester of pregnancy.

DIAGNOSTIC TESTING

Analytic Methods

Techniques to detect ketamine and norketamine in biologic samples include liquid chromatography/ TurboIonSpray®/tandem mass spectrometry,[67] gas chromatography/mass spectrometry,[68,69] liquid chromatography/mass spectrometry in selected ion mode,[70] and high performance liquid chromatography with ultraviolet detection (220 nm).[71] The lower limit of quantitation (LLOQ) for ketamine and norketamine is in the range of 5 ng/mL, as analyzed by isocratic high performance liquid chromatography[72] or gas chromatography/mass spectrometry.[73] The limit of detection (LOD) and LLOQ for ketamine in urine samples analyzed by gas chromatography/mass spectrometry with selected-ion monitoring were 0.5–1.0 ng/mL and 1.5–3.0 ng/mL, respectively, with interassay variation <10%.[68,74] The detection limits for ketamine and norketamine were 0.03 ng/mL and 0.05 ng/mL, respectively, as analyzed by ultra performance liquid chromatography/tandem mass spectrometry.[75] Ketamine and norketamine in plasma samples are stable when transported at 4°C (39.2°F) within 2 days and stored at –20°C (–4°F) for 10 weeks.[76] The plasma concentrations of dehydronorketamine can change initially during refrigeration as a result of the rapid permeation of this compound into erythrocytes.

BLOOD

THERAPEUTIC USE.   Drowsiness and perceptual distortions occur with plasma ketamine concentration from 50–200 ng/mL, whereas analgesia begins at plasma ketamine concentrations >100–160 ng/mL.[32,55] The maximum plasma concentrations of ketamine after the administration of 50 mg orally or 25 mg intranasally range from 30–50 ng/mL at 20–30 minutes after administration.[25] Experimental studies of healthy volunteers indicate that subanesthetic doses (i.e., 200 ng/mL plasma) of ketamine causes general central nervous system depression, perceptual distortions, delusions of reference, and flattening of affect.[77] However, true hallucinations do not occur, and the overall clinical features of ketamine intoxication do not mimic schizophrenia. In a study of healthy, young men, plasma ketamine concentrations of 200 ng/mL were associated with lateral gaze nystagmus and alteration of visual analog scale for euphoria, feelings of unreality, perceptual alterations (shapes, sounds), and difficulty controlling thoughts.[55] There were no significant changes in blood pressure, heart rate, or oxygen saturation when compared with baseline. Plasma ketamine concentrations were undetectable by high performance liquid chromatography within 4–6 hours after intranasal and IV administration.[25] In a study of 5 volunteers receiving subanesthetic doses of IV ketamine, plasma ketamine concentrations exceeding 70 ng/mL were associated with memory impairment and perceptual distortions, as measured by a simple memory test and questionnaire.[78] Analgesic concentrations of ketamine in plasma range from about 100–200 ng/mL, whereas plasma concentrations in patients awakening from anesthesia typically range from approximately 600–1,100 ng/mL. During anesthesia, plasma ketamine concentrations reach 2,000–3,000 ng/mL without significant cardiovascular depression. Behavioral abnormalities do not correlate well to blood ketamine concentrations.

POSTMORTEM.   Fatalities associated with only ketamine use are rare. A 26-year-old man was found dead with a tourniquet on his arm and syringes of ketamine near his body.[50] The death scene suggested that he probably died before the distribution phase of ketamine ended. The ketamine concentrations in postmortem heart and femoral blood were 6.9 mg/L and 1.8 mg/L, respectively (heart/femoral blood ratio, 3.8). There were no other drugs detectable in postmortem blood. A 31-year-old women was found dead in her bathroom with a syringe and bottle of ketamine near her.[79] The postmortem blood sample (source not reported) contained 7 mg ketamine/L, and no other drugs were detected. The postmortem ketamine concentration in a blood sample (site not reported) from an 18-year-old man found dead after the homicidal administration of at least 3 doses of IM ketamine was 27.6 mg/L.[80] High ketamine concentrations (15.2 mg/L) were also

present in postmortem bile samples. A 34-year-old woman was found dead in her apartment after drinking a cup of tea surreptitiously prepared with 300 mg ketamine. Postmortem blood contained 3.8 mg ketamine/L. In a case series on postmortem drug redistribution that included ketamine, the postmortem heart/femoral blood ratios for ketamine in 2 cases were 0.8 and 2.3.[81]

URINE

Ketamine is not a routine drug in urine immunoassay screens for drugs of abuse. Some cross-reactivity occurs between ketamine and phencyclidine on immunoassays. The detection window for ketamine and norketamine in urine is dependent both on the analytic method and individual toxicokinetics. In a study of hospitalized children undergoing ketamine anesthesia, ketamine and norketamine were detectable up to 2 days and 14 days, respectively, as analyzed by gas chromatography/negative chemical ionization/mass spectrometry.[82] Using liquid chromatography/atmospheric pressure chemical ionization/mass spectrometry, the windows of detection for norketamine in urine were 6 days and 11 days, respectively. The LOD for ketamine with these 2 analytic techniques were 20 ng/mL (gas chromatography/negative chemical ionization/mass spectrometry) and 2 ng/mL (liquid chromatography/atmospheric pressure chemical ionization/mass spectrometry), respectively. Over the 16-day observation period, urine samples from 1 child in this cohort receiving ketamine anesthesia did not contain detectable concentrations of ketamine or norketamine by either method. In a case series of 33 urine samples submitted to a reference laboratory from the US Department of Defense criminal investigative agencies for ketamine use, the ketamine and norketamine concentrations ranged from 6–7,744 ng/mL and 7–7,986 ng/mL, respectively, as measured by gas chromatography/mass spectrometry.[68] In a study of 6 healthy volunteers ingesting 50 mg ketamine, urine samples contained detectable amounts of dehydronorketamine up to 10 days as measured by ultra performance liquid chromatography/tandem mass spectrometry.[75]

Abnormalities

Laboratory examination of blood from patients with ketamine intoxication is typically unremarkable. A case report associated the insufflation of ketamine with the development of the Brugada syndrome (coved downsloping 4 mm ST elevation with negative T wave in V_1 and V_2), rhabdomyolysis, renal dysfunction, confusion, and respiratory failure.[83] Additionally, the left ventricular

ejection fraction was 40% together with hypokinesia of the right ventricle.

Driving

There are few data on the effect of ketamine on driving performance. However, the administration of ketamine would be expected to substantially impair driving skills based on the cognitive impairments, perceptual distortions, and thought disorders produced in volunteer studies after the administration of ketamine.[84] Potential impairments include increased distractibility, blurred vision, visual illusions, spatial distortions, increased reaction time, and impaired memory (immediate and delayed recall, working memory).[85]

TREATMENT

Treatment is supportive with careful attention to the evaluation and treatment of any cardiorespiratory dysfunction. Symptoms are typically brief with most patients discharged from the emergency department within 5 hours of presentation.[56] The failure of symptoms to ameliorate after 2 hours of observations suggests another drug or disease process, particularly if seizures, hemodynamic changes, or hyperthermia are present. The most serious adverse effects of ketamine intoxication are respiratory depression, agitation, and rhabdomyolysis. Patients should be placed in a quiet environment with minimal external stimulation. There are no specific antidotes. The treatment of emergence reactions primarily involves the use of benzodiazepines (e.g., adults: lorazepam 1–2 mg, IV, titrated to effect). Preliminary clinical studies suggest that haloperidol (5 mg IM, repeated in 30 minutes if needed) is an alternative to benzodiazepines.[86] However, there are inadequate data to assess the safety or efficacy of haloperidol in this setting.

Chapter 8

METHCATHINONE, MEPHEDRONE, and METHYLONE

METHCATHIONE

HISTORY

Methcathinone was first synthesized in Germany and France in the late 1920s as an intermediate in the synthesis of ephedrine. The optical isomers [$S(-)$- and $R(+)$-methcathinone] were discovered in the following decade. Parke-Davis Pharmaceuticals obtained the patent for $S(-)$-methcathinone in 1957 as an analeptic; however, reports of adverse effects (trembling, seizures, incoordination, spasticity, labored respirations) in animal studies prevented the marketing of this drug.[1] Methcathinone was a popular drug of abuse in the former Soviet Union during the 1970s and 1980s with street names of Ephedrone, Jeff, Cosmos, and Jee Cocktail.[2] During the early 1990s, the first reports associating atypical parkinsonism with intravenous (IV) administration of ephedrone (methcathinone) synthesized by the oxidation of ephedrine or pseudoephedrine with potassium permanganate appeared in Russia. Subsequently, similar case reports associated IV methcathinone abuse with persistent movement disorders in Estonia, Georgia, Latvia, Ukraine, and an Azerbaijani resident in Canada.[3,4] In 1992, methcathinone was added to the list of controlled substances in the United States,[5] followed by cathinone in 1993.

IDENTIFYING CHARACTERISTICS

Methcathinone (CAS RN: 5650-44-2, monomethylpropion) is structurally similar to methamphetamine, and this β-keto-α-methylphenethylamine compound is a more potent stimulant than cathinone based on animal studies.[6] Figure 8.1 displays the structural similarities between the optical isomers of methcathinone, methamphetamine, cathinone, and amphetamine. Methcathinone contains an asymmetric carbon; thus, methcathinone is potentially available as a racemic mixture or as enantiomers [$S(-)$, $R(+)$]. In rodent behavioral studies (locomotor stimulation, drug discrimination), the $S(-)$-methcathinone enantiomer is about 5 times more potent than the $R(+)$-enantiomer.[7] The World Health Organization includes methcathinone in schedule I (i.e., most controlled substance category as a result of high abuse potential) of the United Nations Convention on Psychotropic Substances. Although some analogs of methcathinone (e.g., N-monoethylcathinone, N-mono-n-propylcathinone) produce stimulant effects similar to analogs of methamphetamine in animal studies, the potency of structural analogs of methcathinone are not necessarily predicted by structure–activity relationships of similar methamphetamine structural analogs.[8] Methcathinone has a distinctive pleasant smell (i.e., likened to pistachio ice cream), bitter taste, and dark color that differentiate this drug from amphetamine and cocaine.[1] In addition, methcathinone causes irritation of the mucous membranes in contrast to the anesthetic properties of cocaine.

EXPOSURE

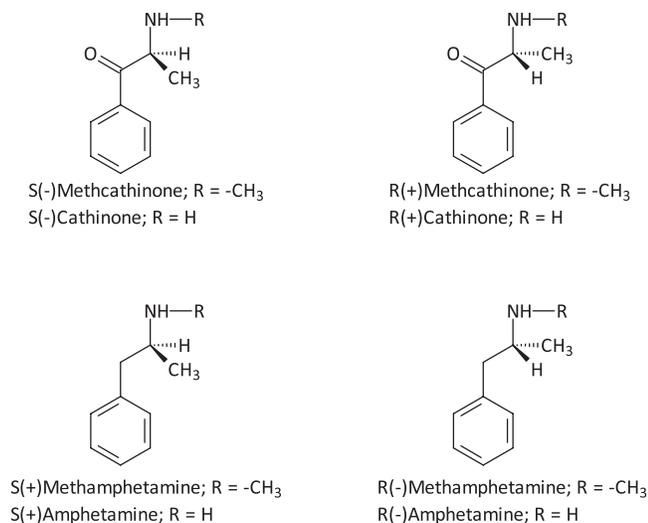
Clandestine laboratories synthesize methcathinone easily by the oxidation of l-ephedrine with household chemicals (sulfuric acid, paint thinner, acetone). Consequently, most illicit methcathinone contains the


FIGURE 8.1. Structural and stereochemical relationships between the optical isomers of methcathinone, methamphetamine, cathinone, and amphetamine.

$S(−)$-enantiomer with small amounts of the $R(+)$-enantiomer as a result of spontaneous racemization of the $S(−)$-enantiomer during extraction procedures. Abuse of methcathinone involves the use of this drug via the IV, pulmonary, or nasal routes. During a typical episode of methcathinone use, the drug user inhales the drug for 24–36 hours until the drug supply is depleted or the drug user is physically exhausted. Desirable effects reported by methcathinone during acute intoxication include intense physical stimulation, sexual arousal, euphoria, and tolerance for alcohol.[1] During binges, methcathinone users report the rapid development of strong psychologic craving and tolerance for this drug.[2]

DOSE EFFECT

The intranasal use (80–250 mg) of methcathinone produces euphoria within 10 minutes along with visual illusions and hallucination followed by a 5- to 8-hour period of feeling invincibility and increased libido.[2] Undesirable side effects associated with these doses include headache, abdominal pain, diaphoresis, and agitation. In a case series of 13 male opiate addicts developing movement disorders after chronic IV ephedrone (methcathinone) abuse, the reported daily use of ephedrone was 8–20 mL 1–6 times daily (mean reported daily use, 42 ± 28 mL).[9]

TOXICOKINETICS

Following the ingestion of recreational doses (e.g., 30 mg) of methcathinone, unchanged methcathinone,

(+) threo-ephedrine (d-pseudoephedrine), (−)-threo-ephedrine (l-pseudoephedrine), and phenylpropanolamine appear in the urine along with small amounts of phenylpropanolamine.[10] Based on 2 trials in a single volunteer, about one-third of this dose appeared in the urine as unchanged methcathinone and about one-half as ephedrine (about 60% l-pseudoephedrine, 40% d-pseudoephedrine); phenylpropanolamine was a minor urinary metabolite (<5%). Reports from methcathinone users indicate that cessation of methcathinone use is associated with prolonged sleep, irritability, dysphoria, hyperphagia, and depression similar to the cessation of acute, high-dose amphetamine use.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Rodent studies indicate that methcathinone is a potent CNS stimulant with effects on the dopaminergic and serotonergic receptors.[11] These effects are species and enantiomer dependent. In mice, both $R(+)$- and $S(−)$-enantiomers produce toxic effects on dopamine neurons based on reduction in dopamine, 3,4-dihydroxyphenylacetic acid (dopamine metabolite), and dopamine uptake in rat brain; the $R(+)$-enantiomer is more potent than the $S(−)$-enantiomer in these studies.[12] Neither enantiomer produces serotonin toxicity at intraperitoneal doses ranging from 40 mg/kg every 2 hours for 4 doses to 120 mg/kg every 2 hours for 2 doses, then 2 doses at 4-hour intervals. Both enantiomers produce dopamine depletion in the stratum of rats with the $S(−)$-enantiomer slightly greater than the $R(+)$-enantiomer at doses of 25 mg/kg and 50 mg/kg twice daily for 4 days. Only the $S(−)$-enantiomer produces serotonin depletion in the hippocampus and neocortex of rats. Following the administration of methcathinone, decreased tyrosine hydroxylase and tryptophan hydroxylase occur along with reductions in dopamine and serotonin in the frontal cortex, neostriatum, and hippocampus. Additionally, methcathinone is a substrate for the dopamine and serotonin transports, resulting in the uptake of methcathinone by dopamine and serotonin neurons.[13] The similarity of the movement disorder associated with IV methcathinone abuse and chronic manganism suggest a role for manganese-induced neuropathy as the cause of this movement disorder in ephedrone addicts. The IV administration of ephedrone produced by oxidation of ephedrine or pseudoephedrine with potassium permanganate releases large amounts of manganese into the blood following IV administration. A case series of 3 IV drug users reported the development of similar extrapyramidal disorders and postural instability following the chronic IV use of a solution of potassium permanganate, ephedrine, and acetylsalicylic acid.[14] In

the 2 addicts recently using this IV solution, their blood manganese concentrations were very high (2,100 ng/mL, 3,176 ng/mL), whereas the addict that did not use the solution for 6 months had a normal blood manganese concentration (2.4 ng/mL; normal <19 ng/mL). The solution these drug abusers injected did not contain methcathinone, suggesting that the motor disorder does not result from methcathinone.

CLINICAL RESPONSE

Acute intoxication with methcathinone produces clinical features similar to stimulant effects of amphetamine abuse. Reported desirable effects from the IV abuse of methcathinone include "rush," "feeling happy," and "sense of flying" within 15 minutes after injection followed by several hours of jocularity and increased alertness. Reported adverse effects of methcathinone use include nausea, abdominal pain, facial erythema, epistaxis, anxiety, irritability, difficulty concentrating, agitation, paranoia, tachycardia, insomnia, and muscle cramps. Complications of chronic methcathinone use include paranoid psychosis with auditory hallucinations, weight loss, dehydration, tremor, agitation, personality changes, antisocial behavior, and depression. Case reports associate the development of paranoia with auditory hallucinations, confusion slurred speech, tremor, disorientation, and intermittent anxiety following sustained, IV use of methcathinone.[2] These symptoms usually resolve over 24–36 hours. Occasionally, transient hypotension and bradycardia may also occur, but these abnormalities usually respond rapidly to supportive care.

Case reports associate the IV abuse of methcathinone synthesized by the oxidation of ephedrine or pseudoephedrine by potassium permanganate with levodopa-resistant atypical parkinsonism, profound hypophonia, and gait disturbances.[15] In a case series of 13 male opiate addicts developing movement disorders after chronic IV ephedrone (methcathinone) abuse, the mean time between the initiation of ephedrone abuse and the first neurologic symptoms was 8.5 ± 3.2 months.[9] Clinical abnormalities include bradykinesias, dystonia, emotional lability, dysarthria, risus sardonicus, involuntary laughter, and retropulsion with falls backwards.[9] These patients did not typically demonstrate olfactory abnormalities or declines in cognitive ability with the exception of mild dysfunction of executive skills and mild depression. These patients had several clinical features distinguishing them from patients with Parkinson disease including particular difficulty walking backward, a symmetric motor disorder that resulted in walking on the first metatarsal-phalangeal joints ("cock walk"), profoundly soft speech, and lack of a resting tremor.

They were unresponsive to levodopa, and the neurologic abnormalities remained after cessation of methcathinone abuse. Progression of neurologic symptoms after cessation of ephedrone use occurs in up to one-third of these patients. Some patients improve slowly, but complete reversal of neurologic symptoms does not usually occur.

DIAGNOSTIC TESTING

Analytic Methods

Analytic methods for the quantitation of methcathinone and other amphetamine analogs in biologic samples include gas chromatography,[16] high performance liquid chromatography with ultraviolet (UV) detection,[17] gas chromatography/mass spectrometry (GC/MS),[18] and liquid chromatography/electrospray ionization/tandem mass spectometry.[19] The lower limit of quantitation (LLOQ) of methcathinone using the latter method is 10 ng/mL with intermediate precision (<15%). The use of high performance liquid chromatography/atmospheric pressure chemical ionization/mass spectrometry allows the quantitation of methcathinone and other underivatized amphetamines in hair samples with a limit of detection (LOD) in the range of 0.20 ng/mg.[20] Commonly available immunoassays do not sufficiently screen methcathinone from other amphetamine analogs. *In situ* derivatization of urine samples by extractive acylation with penta-fluoropropionic anhydride followed by rapid chromatography on a microbore capillary column and MS in selected-ion mode allows the rapid confirmation of various amphetamine analogs including methcathinone.[21] Methcathinone is not a metabolite of phenylpropanolamine or any other over-the-counter medications. Although methcathinone is stable for 3 days in refrigerated samples (2–4°C/35.6°–39.2°F) and in frozen samples (-18°C/-0.4°F) for 2 months, urine samples stored at 2–4°C (35.6°–39.2°F) for 3 months lost about 79% of the methcathinone.[18]

Abnormalities

The magnetic resonance images (MRIs) of patients with ephedrine-induced movement disorders demonstrate hyperintensity T1-weighted signals from the globus pallidus, substantia nigra, dentate nucleus, and the pontine tegmentum.[22] The whole blood manganese concentration in samples from these patients are typically elevated about 3–4 times above the upper reference range; whole blood manganese concentrations remain elevated months after cessation of IV methcathinone produced by potassium permanganate oxidation. Both the MRI

and the blood manganese concentration may be normal in the presence of an obvious movement disorder (bradykinesia, postural instability, slowed facial expressions, dysarthria, generalized dystonia).[23] Blood manganese concentrations do not correlate well to clinical symptoms.

TREATMENT

The treatment of methcathinone intoxication is supportive, similar to amphetamine intoxication. The movement disorders associated with IV ephedrone (methcathinone) abuse and potassium permanganate oxidation does not usually respond to the drugs (L-dopa, amantadine, bromocriptine, trihexyphenidyl) typically used to treat Parkinson disease. There are inadequate clinical data to determine if chelation of elevated manganese concentrations improves the chronic movement disorder associated with IV ephedrone abuse. Although the use of calcium disodium EDTA is associated with partial improvement in some patients, other patients did not improve and patients did not typically recover completely.[22]

MEPHEDRONE (4-METHYLMETH-CATHINONE)

Mephedrone (2-aminoethyl-1-tolyl-propan-1-one, 4-methylmethcathinone) is a β-keto amphetamine that is the synthetic 4-methyl aromatic analogue of methcathinone. Figure 8.2 compares the chemical structure, structural formula, and molecular weight of mephedrone and methcathinone. Common names include 4-MMC, Bubbles, Meph, Meow Meow, Miaow, TopCat, MMCAT, and Crab. Limited analytic data on mephedrone samples purchased from the Internet suggest that these sample contain high concentrations of 4-methylmethcathinone

in a racemic mixture.[24] Mephedrone is an uncontrolled cathinone derivative in many countries with sympathomimetic properties (tachycardia, mydriasis, blurred vision, agitation) similar to methcathinone. This compound is a substitute for ecstasy (MDMA) in the club scene. Mephedrone is an illegal drug in Denmark, Finland, Israel, Norway, Sweden, and the United Kingdom. Potential postprohibition mephedrone-like products include the 2-aminopentanophenone compounds.[25] These monoamine oxidase inhibitors are marketed as Energy 1 (NRG-1) or naphyrone (naphthylpyrovalerone, O-2482), although these products may contain illicit mephedrone or other cathinones/adulterants. In a study of 24 products purchased online from 18 UK-based websites within 6 weeks after the ban on mephedrone and other derivatives (3,4-methylenedioxypyrovalerone, butylone), 70% of the NRG-1 and NRG-2 products contained a mixture of banned cathinones.[26] Mephedrone is usually sold as a white crystalline or off-white–yellow powder (hydrochloride salt), frequently from street vendors and less often on the Internet as "bath salts."[27]

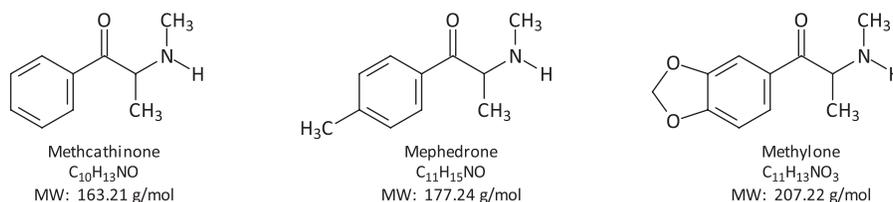
The common methods of administration are ingestion, insufflation, and rarely by injection with heroin. Biotransformation of mephedrone involves hydroxylation at the 4-methyl group followed by oxidation to the corresponding 4-carboxy metabolite and demethylation of the β-keto group to the corresponding alcohol.[28] The clinical features of mephedrone overdose reflect sympathomimetic toxicity similar to cocaine and methamphetamine intoxication including elevated blood pressure, tachycardia, palpitations, mydriasis, hyperactivity, and agitation as well as anxiety, paresthesias, confusion, vomiting, chest pain, and headache.[29] Based on data on 131 telephone enquiries to the UK National Poisons Information Service concerning mephedrone alone or in combination with alcohol, common clinical features reported were as follows: agitation or aggression ($n = 32$, 24%, 95% CI: 18–33%), tachycardia ($n = 29$, 22%, 95% CI: 16–30%), confusion or psychosis ($n = 18$, 14%, 95% CI: 9–21%), chest pain ($n = 17$, 13%, 95% CI: 8–20%), nausea ($n = 15$, 11%, 95% CI: 7–18%), palpitations ($n = 14$, 11%, 95% CI: 6–18%), peripheral


FIGURE 8.2. Comparison of chemical structures, structural formulas, and molecular weights of methcathinone, mephedrone (4-methylmethcathinone), and methylone.

vasoconstriction ($n = 10$, 8%, 95% CI: 4–14%), headache ($n = 7$, 5%, 95% CI: 2–11%), and seizures ($n = 4$, 3%, 95% CI: 1–8%).[30] A 22-year-old man ingested 200 mg mephedrone purchased from an Internet supplier; when he did not develop the desired effects, he injected 3,800 mg intramuscularly into his thighs.[31] Shortly thereafter, he developed chest pressure, diaphoresis, blurred tunnel vision, and a feeling of being unwell. At the emergency department (ED), he was agitated, anxious, and hypertensive (blood pressure = 177/111) with mydriasis. His symptoms resolved after 4 hours of observation and 1 mg oral lorazepam. Other complications associated with the use of mephedrone include hypo-osmotic hyponatremia with encephalopathy manifest by altered consciousness, nausea, vomiting, and elevated intracranial pressure.[32] Elevation of serum creatine kinase and rarely, hyponatremia may occur. Methods of detection include GC/MS in selective ion monitoring mode using methamphetamine-d_{14} as an internal standard.[33] The LOD and LLOQ with this method are 0.010 mg/L and 0.025 mg/L, respectively, with between-day accuracy ranging from 0.2–12.4%.

METHYLONE (3,4-METHYLENEDIOXY-METHCATHINONE)

Shulgin et al investigated the psychoactive properties of methylone in the 1970s; he and Jacob patented the drug as an antidepressant and antiparkinson agent in the middle 1990s. Methylone appeared as a designer drug of abuse in Europe and Japan in the middle 2000s.[34] Methylone (2-methylamino-1-(3,4-methylenedioxyphenyl)propan-1-one, 3,4-methylenedioxymethcathinone) is the β-ketone analogue of 3,4-methylenedioxymethamphetamine (MDMA) as displayed in Figure 8.2. Major metabolic pathways for methylone include 1) *N*-demethylation of the side-chain to methylenedioxycathinone, and 2) demethylenation and *O*-methylation of the hydroxyl group on the benzene ring to form 4-hydroxy-3-methoxymethcathinone and 3-hydroxy-4-methoxymethcathinone. In rodent studies, the kidney excretes most of the metabolites as conjugates with small amounts (i.e., ~3%) appearing in the urine as unchanged methylone.[35] The major urinary metabolite of methylone was 4-hydroxy-3-methoxymethcathinone.

In vitro studies indicate that methylone increases the concentration of monoamine neurotransmitters (serotonin, norepinephrine) in the synaptic cleft by inhibition of the plasma monoamine reuptake transporters with relatively little effect on dopamine concentrations.[36] In contrast to MDMA, the effect of methylone on the vesicular monamine transporter is weak. The clinical effects of methylone are similar to MDMA, although the reported euphoric and stimulatory effects of methylone are milder than MDMA. There are few data on the effects of methylone in humans. Expected adverse effects include mydriasis, diaphoresis, nausea, vomiting, agitation, confusion, dysphoria, tachycardia, and hypertension based on structural similarity to MDMA. Methods for the quantitation of methylone include GC/MS, liquid chromatography/electrospray ionization/mass spectrometry, and gas chromatography/electron impact mass spectrometry.[35,37] Commercial immunoassays for drugs of abuse may be insensitive to the presence of methylone in the urine.[38] The use of GC/MS in electron impact mode allows the quantitation of methylone, mephedrone, and butylone in biologic samples.[28]

Chapter 9

METHYLENEDIOXYMETHAMPHETAMINE (ECSTASY, MDMA)

Nicholas A. Buckley, MD

HISTORY

Ecstasy (3,4-methylenedioxymethamphetamine, MDMA) is a central nervous system (CNS) stimulant that is one of the most commonly abused drugs in the United States, Canada, United Kingdom, Western Europe, and Australia.[1] The structurally similar compound, methamphetamine is a common precursor of MDMA. Merck synthesized MDMA in 1912, and in 1914 Merck received a patent for MDMA as an appetite suppressant. However, Merck never marketed MDMA. The US military conducted the first documented animal toxicity studies on MDMA in the 1950s. This research was part of a program that investigated the effect of psychedelic drugs on animals and humans, presumably as substances that might increase the effectiveness of interrogations. These studies also included the administration of 3,4-methylenedioxyamphetamine (MDA), but not MDMA to human participants. The frequently referenced chemist, Alexander Shulgin became a strong proponent of the use of MDMA in psychotherapy after rediscovering MDMA in the 1970s.[2] In addition to the use of MDMA as an adjunctive treatment during psychotherapy, suggested therapeutic uses of MDMA included the treatment of Parkinson disease, posttraumatic stress disorder, depression, autism, and substance abuse.[1,2] In the mid-1970s to mid-1980s, some psychoanalysts administered MDMA ("Adam") as adjunctive therapy based on the belief that MDMA inhibits the fear response to a perceived emotional threat, which would allow the patient to place the emotional sequelae of past experiences into a more realistic perspective in current relationships.[3]

The use of MDMA occurs primarily in well-developed Western countries, particularly Western Europe, Australia, Canada, and the United States.[4] The first widespread use of MDMA began in the "rave" club scene including dance clubs and at rave parties. The abuse of MDMA increased despite the introduction of legal restrictions in the 1970s and 1980s that proscribed the use and manufacture of MDMA. Most countries with regulatory drug systems subsequently declared MDMA an illegal substance. The use of MDMA became illegal in the United Kingdom in 1977. In 1985, the US Drug Enforcement Agency (DEA) restricted the use of MDMA because of the growing abuse problem, particularly prevalent in Texas.[5] The initial restriction was temporary, based on the structural and pharmacologic similarities of MDMA to banned hallucinogenic amphetamines (e.g., MDA). Some authors proposed that MDMA represented a novel class of drugs, the entactogens (i.e., "touching within") that were not hallucinogenic.[6] However, the DEA did not accept this new classification. Subsequent animal studies on the pharmacologic and toxicologic effects of MDMA on serotonergic and dopaminergic neurons supported the similarity between this substance and the banned substance MDA.[7] In 1988, the DEA permanently restricted the use of MDMA by classifying MDMA as a schedule I controlled substance. The

pharmacologic classification of MDMA remains controversial with many authors referring to MDMA as an entactogen, while others classify MDMA as an amphetamine designer drug or a hallucinogenic amphetamine.

Illicit production of MDMA began in the mid-1980s shortly after the implementation of legal restrictions in the United States. In the late 1990s, a large increase in MDMA use occurred in Western countries beginning in the United Kingdom and other Western European countries as part of the increased popularity of dance party and rave club scenes.[8] Illicit MDMA originated in the Netherlands, Belgium, and Germany. More recently, large increases in MDMA use appeared in the United States and Australia. The rates of MDMA confiscations, MDMA-related hospital visits, reported rates of previous and current use all increased 2- to 20-fold during the 1990s in the United States.[6]

Although the therapeutic use of MDMA remains controversial, some clinical research on the effects of MDMA continues. The US Food and Drug Administration (FDA) approved studies of MDMA in Parkinson disease in the 1990s, and in 2002 the FDA approved human studies of MDMA as an adjunctive treatment for psychotherapy in posttraumatic stress disorder.[9] This clinical trial began in 2004, and a similar trial commenced in Spain. These trials generated some controversy as institutional review board (IRB) approval was initially withheld for over a year because of animal data suggesting that a Parkinson-like syndrome develops in primates receiving recreational doses of MDMA.[10] However, the animal study of primates was subsequently withdrawn because of concern that methamphetamine was inadvertently substituted for MDMA during these experiments.[9]

IDENTIFYING CHARACTERISTICS

MDMA (CAS RN: 42542-10-9) is racemic 3-4 methylenedioxymethamphetamine (1-benzo[1,3]dioxol-5-yl-N-methyl-propan-2-amine). The molecular weight of MDMA is 193.242 g/mol, and the structural formula is $C_{11}H_{15}NO_2$. MDMA is structurally similar to MDA and methamphetamine. Figure 9.1 displays the chemical structure of MDMA and structurally related amphetamine compounds. Methamphetamine-based compounds (e.g., MDMA, MDA) contain substituents on the aromatic ring and act primarily on serotonin receptors, whereas amphetamine-based compounds (e.g., ephedrine, phenylpropanolamine, phentermine) do not contain substituents on the aromatic ring and act primarily on dopamine receptors at therapeutic doses.[11] The $S(+)$- and $R(-)$-enantiomers have different pharmacokinetics and pharmacologic effects;[12,13] however, illicit and therapeutic use of MDMA usually involves the racemic (1:1) mixture of the enantiomers. Most animal toxicology studies on MDMA also administer racemic MDMA. The $S(+)$ form of MDMA is a more potent inhibitor of serotonin reuptake than the $R(-)$-enantiomer.[14,15] The subjective effects of MDMA correlate better to the pharmacokinetic profile of the $S(+)$-enantiomer.[16] The response to MDMA enantiomers may vary between animal species. For example, the hyperthermic response to the $R(-)$-enantiomer differs in non-human primates and rodents.[17]

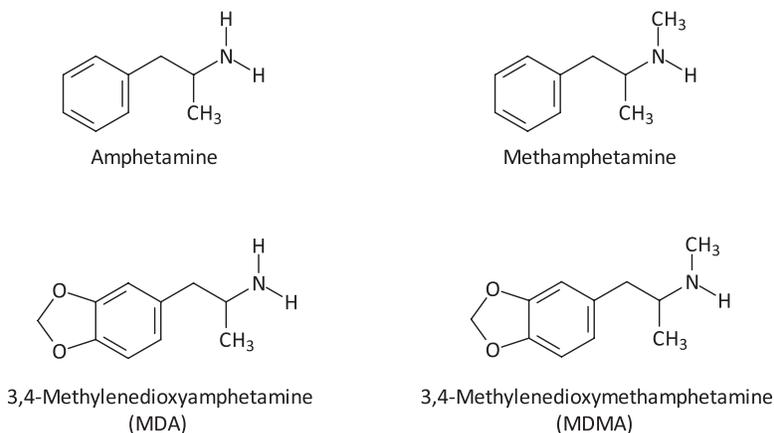
MDMA is a white, crystalline powder that is a weak base with an estimated pK_a value between 9–10. The boiling point of the free base of MDMA is too high to volatilize sufficient amounts of MDMA to cause pharmacologic effects. The salts of MDMA are also not volatile, but the water solubility of these compounds


FIGURE 9.1. Structure of 3,4-methylenedioxymethamphetamine (MDMA), 3,4-methylenedioxyamphetamine (MDA), amphetamine, and methamphetamine.

FIGURE 9.2. Confiscated ecstasy tablets. (Photo courtesy of the US Drug Enforcement Agency)

allows administration via insufflation, ingestion, or intravenous (IV) injection.[18] MDMA hydrochloride has a melting point of 148–153ºC (298–307°F). This salt is soluble in water, chloroform, and alcohol, but not soluble in ether. Besides ecstasy, common street names for MDMA include XTC, E, and Adam. Figure 9.2 displays samples of confiscated MDMA tablets.

EXPOSURE

Epidemiology

Historically, MDMA has been an experimental adjunct to psychotherapy in the United States for a wide variety of disorders including depression and substance abuse. Most countries list MDMA as a substance with no approved use (e.g., Drug Enforcement Agency schedule I of the Controlled Substances Act in United States). MDMA use occurs predominantly in dance clubs and party venues. The use of MDMA became popular as a means to enhance sociability, energy, endurance, and sexual feelings.

Sources

Like amphetamine and MDA, MDMA is a synthetic drug that does not occur naturally. Alexander Shulgin publicized a process for synthesizing MDMA in his book *PIHKAL* (*Phenylethylamines I Have Known and Loved*).[19] The initial precursor of this process was MDA (3,4-methylenedioxyamphetamine), and the process utilized formic acid; however, newer methods for the synthesis of MDMA use nonrestricted precursor agents.

The clandestine manufacture of MDMA now involves a large number of variations of the original synthetic process including safrole bromination, variations of the Leuckart method, and reductive amination with various reducing agents (Al/Hg, $NaBH_4$, $NaBH_3CN$).[20] 3,4-Methylenedioxyphenyl-2-propanone (MDP-2-P) is the starting material in a Leuckart reaction and reductive amination. MDP-2-P is commonly prepared by 2 different synthesis methods: (1) oxidation of isosafrole in an acid medium, and (2) reduction of 1-(3,4-methylenedioxyphenyl)-2-nitropropene.[21] The latter compound is prepared by condensation of piperonal and nitroethane. The end-product of all methods is a racemic mixture of $S(+)$- and $R(-)$-MDMA.

Methods of Abuse

MDMA is nearly always consumed as tablets of "ecstasy." Rarely, MDMA abuse involves other routes of exposure including nasal, pulmonary, rectal, and IV administration.[29] These tablets are typically branded with many colors and logos; there are thousands of different brands of tablets. Ecstasy tablets contain widely varying amounts of MDMA with the usual dose ranging from approximately 30–150 mg; occasionally, other phenethylamine drugs (e.g., MDA, MDEA, PMA, MBDB) are marketed as ecstasy. Analysis of 101 confiscated ecstasy tablets from nightclubs and late night venues in London and Swansea in 2006 demonstrated a mean MDMA content/tablet of 58.7 ± 22.9 mg with a range of 20–131 mg.[22] The vast majority of the tablets (i.e., 96%) contained <100 mg MDMA; there was a bimodal distribution of MDMA content at 20–40 mg and 60–80 mg. Regular users typically ingest 2–3 tablets of ecstasy, whereas the most experienced users may take 10–25 tablets in a single session.[23] Although escalation of the MDMA dose helps maintain the positive drug experience in tolerant users, bingeing (i.e., taking multiple tablets at 1 time or repeated doses during an evening) is relatively uncommon among MDMA users.[24] Frequently, adverse effects increase during dose escalation.

Desired effects of the use of MDMA include enhancement of mood, increased energy, feeling of closeness to others, empathy, increased sociability, mild perceptual disturbances (colors, sounds), sense of well-being, and emotional sensitivity. Structured interviews of recreational MDMA users suggest that the use of MDMA is associated with the perception of greater satisfaction with sex, but sexual performance is often impaired.[25] Early studies suggested that the use of MDMA was self-limited and primarily limited to ingestion.[26] The typical pattern of MDMA abuse is occasional social use with only a small proportion of users ingesting MDMA

more frequently than weekly.[27] Within a subset of intravenous polydrug users, the use of IV MDMA is much higher. However, structured interviews of these polydrug users indicate that the majority of these user switch back from IV MDMA use to oral or intranasal routes of exposure.[28]

Sporadic MDMA users do not usually develop dependence on MDMA; psychological dependence is rare.[29] Although non-human primates self-administer MDMA, the decreasing use of MDMA by these animals suggests a reduction in the reinforcing properties of the drug following continued use.[30] The frequent use of MDMA is usually associated with polydrug use, and most of these MDMA users prefer other drugs. Rarely, case reports associate the abuse of MDMA with self-treatment for post-traumatic stress syndrome.[29] A cohort of daily users of only MDMA has not been identified; therefore, research on the chronic effects of MDMA use in humans is invariably confounded.[31]

DOSE EFFECT

The potency of MDMA and MDA are similar (i.e., effective oral dose 100–160 mg). There are differences in the potency of MDMA stereoisomers with the $S(+)$ isomer of MDMA (effective dose 80–120 mg) being more potent than the $R(-)$-isomer (effective dose 300 mg).[32] Below doses of 1 mg MDMA/kg, volunteer studies indicate a lack of cardiovascular effects; above the 1 mg/kg-dose, the desired psychological effects are prominent along with adverse effects.[33] In a study of 13 MDMA-naïve healthy volunteers, a typical recreational dose (1.7 mg/kg) enhanced mood and caused a sense of well-being along with increased emotional sensitivity.[34] These subjective effects occurred in addition to moderate elevation of blood pressure. In this study, 1 participant developed transient severe hypertension (240/145 for 20 min) that resolved without complications or treatment. In a double-blind crossover study of 8 volunteers familiar with MDMA, the administration of a placebo and 0.5 mg/kg of MDMA produced no discernible subjective effects in a controlled laboratory setting. A 1.5 mg/kg oral dose of MDMA produces significant subjective effects and increased heart rate with the greatest effect 1–2 hours after dosing. In a study of 8 healthy volunteers, the ingestion of 1.5 mg MDMA/kg increased the mean peak values of the heart rate by 28 bpm, the systolic blood pressure by 25 mm Hg, and cardiac output by 2 L/min when compared with baseline.[35] The cardiovascular effects of this MDMA dose were similar to the effects of dobutamine at 20–40 μg/kg/min, but MDMA had no inotropic effects. This dose of MDMA also significantly increases plasma cortisol, prolactin, and dehydroepiandrosterone (DHEA) levels.[36] The administration of MDMA doses up to 1.9 mg/kg to volunteers does not significantly increase body temperature >0.4°C above baseline.[31]

Illicit Use

At recreational doses, MDMA produces dose-dependent subjective responses that are different from classical stimulants or hallucinogens. Most casual users of MDMA typically ingest 1–2 tablets (i.e., about 60–300 mg racemic MDMA) in a social setting (rave, concert, party, disco).[37,38] Tolerance to some of the effects of MDMA develops during chronic use, and more experienced MDMA users typically ingest larger doses than novice users.[23] In a survey of >1,000 ravers/clubbers, 54% reported the use of ≥5 tablets per session, whereas 2% reported the use of ≥20 tablets per session. The variables that potentially affect the response to MDMA include the dose, the presence of impurities or adulterants, individual metabolic rates, ambient temperature, fluid intake, strenuous exercise, cardiovascular fitness, and hyperthermia.[32] The maximum tolerated dose in healthy individuals has not been determined.

Human Toxicity

Available data suggests that serious toxicity from the ingestion of MDMA is idiosyncratic rather than dose-related, reflecting individual variation in the clinical response to MDMA. After the ingestion of 40 tablets of ecstasy by a 19-year-old man, the only adverse effects were a heart rate of 95 bpm, mydriasis, confusion, mild sedation, and retrograde amnesia.[39] A 30-year-old man developed coma and seizures after the ingestion of 50 tablets of ecstasy.[40] His peak recorded core temperature was 38.7°C (101.7°F); he survived with supportive care. The ingestion of 1 tablet of ecstasy by a 13-month-old child was associated with hypertension, tachyarrhythmias, and seizures, but there was no significant increase in body temperature.[41] The child survived with intensive supportive care.

The minimum fatal human dose is difficult to estimate because of the wide variability of drug dose per tablet, concomitant ingestion of other drugs, and the idiopathic response of individuals to MDMA. Compared with the prevalence of MDMA abuse, fatalities associated with MDMA are extremely rare. Additionally, most of these fatalities involve the concomitant ingestion of other substances. However, deaths from MDMA ingestion alone occasionally occur in young healthy adults following the ingestion of recreational doses of MDMA.[42]

Animal Toxicity

MDMA and amphetamine have similar toxicity in animal models. The minimal lethal MDMA dose varies with age, route of exposure, environmental conditions, and animal species. Data from animal studies demonstrated the following LD_{50}: mice, 97 mg/kg intraperitoneal; rats, 49 mg/kg intraperitoneal; guinea pig, 98 mg/kg intraperitoneal; dog, 14 mg/kg IV; and monkey, 22 mg/kg IV.[43] The LD_{50s} of MDMA following ingestion are about 3-fold higher than intraperitoneal administration. However, high ambient temperatures and strenuous activity greatly increase the lethal toxicity of MDMA as seen with other stimulants (e.g., methamphetamine).[44] The IV LD_{50} of MDMA in adult, nontolerant monkeys maintained in primate chairs was approximately 15–20 mg/kg. Young monkeys ($LD_{50} = 5$ mg/kg) and adult monkeys in open cages ($LD_{50} = 2$–3 mg/kg) were more vulnerable, particularly when hyperactivity and elevated body heat occur.[45]

TOXICOKINETICS

The pharmacokinetics of MDMA are nonlinear, resulting in a disproportionate increase in the maximum MDMA concentration as the dose increases.[46] Although there are limited human data, existing pharmacokinetic data suggest that the bioavailability is many times higher, the half-life longer and total and hepatic clearance shorter with increasing doses of MDMA. The irreversible inhibition of CYP2D6 by MDMA and MDA contributes to nonlinear pharmacokinetics of MDMA by increasing bioavailability and reducing clearance of MDMA following repeat dosing.[47,48] Consequently, crossover pharmacokinetic studies in volunteers and recreational MDMA users must be interpreted cautiously because of the potential inhibition of hepatic clearance by repeat dosing. The pharmacokinetics of MDMA are also stereoselective. The bioavailability (f), estimated volumes of distribution (V_d), and clearance (Cl) of the 2 MDMA enantiomers are significantly different. V_d/f was 1.5 times higher for the more potent S(+)-enantiomer; total oral clearance (Cl/f) was 2.5 times higher for the S(+)-enantiomer (131 vs. 55 L/h) compared with the R(−)-enantiomer.[16]

Absorption

Volunteer studies indicate that peak plasma MDMA concentrations occur within 2–3 hours after the ingestion of 100 mg tablets.[46] As a weak base, absorption of MDMA probably occurs predominantly in the small intestine, and the amount of MDMA absorption depends on gastric emptying and pH. There are few data on the bioavailability of MDMA following ingestion because of the lack

of pharmacokinetic data on the IV administration of MDMA. However, pharmacokinetic studies suggest a substantial first-pass metabolism because the time to peak metabolite concentrations occurs prior to the peak MDMA concentration.[16] In a study of 8 healthy volunteers ingesting 100 mg MDMA, the mean maximum MDMA concentration was 222 ± 26 ng/mL at 1–3 hours after ingestion.[46] Table 9.1 lists pharmacokinetic data on peak concentrations and time-to-peak concentrations of MDMA and some of the MDMA metabolites following the ingestion of 100 mg MDMA by 8 healthy volunteers. There are few pharmacokinetic data on MDMA following routes of exposure other than ingestion.

In a study of 8 healthy volunteers receiving low dose (1 mg/kg) and high dose (1.6 mg/kg) MDMA, the mean peak plasma MDMA concentrations were 161.4 ± 11.5 ng/mL and 305.7 ± 16.9 mg/mL, respectively.[49] Peak subjective effects occurred 1–2 hours after ingestion with no secondary peak effects. Figure 9.3 displays the plasma MDMA concentration during the first 47 hours after ingestion of a low dose (1 mg/kg) and higher dose (1.6 mg/kg) of MDMA.

Distribution

MDMA distributes widely throughout the body including the liver, kidney, lungs, and brain. MDMA binds with weak affinity to albumin. Although no human data are available on the percentage of binding of MDMA to proteins, extrapolation of animal and human data from related amphetamine compounds suggests that the binding of plasma MDMA to proteins in humans is low (approximately 20%).[46] The volume of distribution of MDMA in therapeutic doses is about 6 L/kg.[16] The distribution of MDMA is stereoselective. In a postmortem study of the distribution of MDMA enantiomers, the concentration of the R(−)-enantiomer was slightly

TABLE 9.1. Mean (± Standard Deviation) Pharmacokinetic Parameters for 3,4-methylenedioxymethamphetamine (MDMA) and MDMA Metabolites Based on the Administration of 100 mg MDMA to 8 Volunteers).[46]

Compound	C_{max} (ng/mL)	t_{max} (Hours)	$t_{1/2}$ (Hours)
MDMA	222.5 ± 26.1	2.3 ± 1.1	9.0 ± 2.3
MDA	13.1 ± 4.5	6.7 ± 2.6	24.9 ± 14.5
DHMA	154.5 ± 76.6	1.2 ± 0.3	13.4 ± 8.1
HMMA	236.7 ± 87.1	2.3 ± 0.9	11.2 ± 2.9
HMA	7.5 ± 4.0	8.2 ± 1.7	37.4 ± 17.9

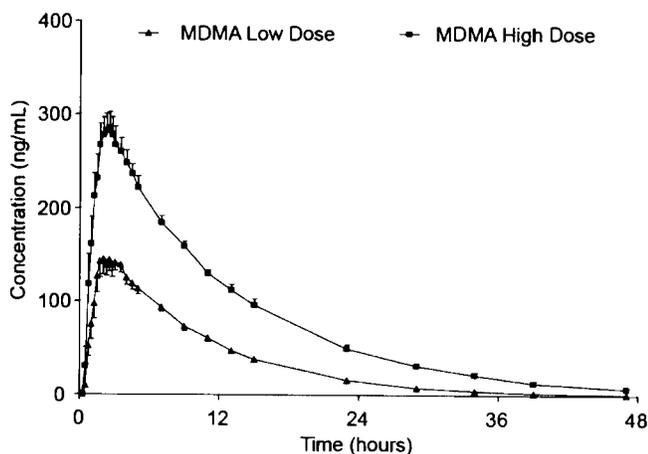
Abbreviations: C_{max} = peak plasma concentration; t_{max} = time to peak plasma concentration; $t_{1/2}$ = plasma elimination half-life; DHMA = 4-dihydroxymethamphetamine; HMMA = 4-hydroxy-3-methoxymethamphetamine; MDA = 3,4-methylenedioxyamphetamine; HMA = 4-hydroxy-3-methoxyamphetamine.


FIGURE 9.3. Mean 3,4-methylenedioxymethamphetamine (MDMA) plasma concentration ($n = 8$) in a double-blind, randomized, controlled clinical trial following the ingestion of low dose (1mg/kg) and high dose (1.6 mg/kg) MDMA. greater than the $S(+)$-enantiomer in the blood, while the concentration of the $R(-)$-enantiomer was substantially greater than the $S(+)$-enantiomer in the bile, vitreous humor, and urine.[50] Most of the tissues contained higher concentrations of $R(-)$-enantiomer than the $S(+)$-enantiomer with the exception of the liver, where the concentrations of the 2 enantiomers were similar.

Biotransformation

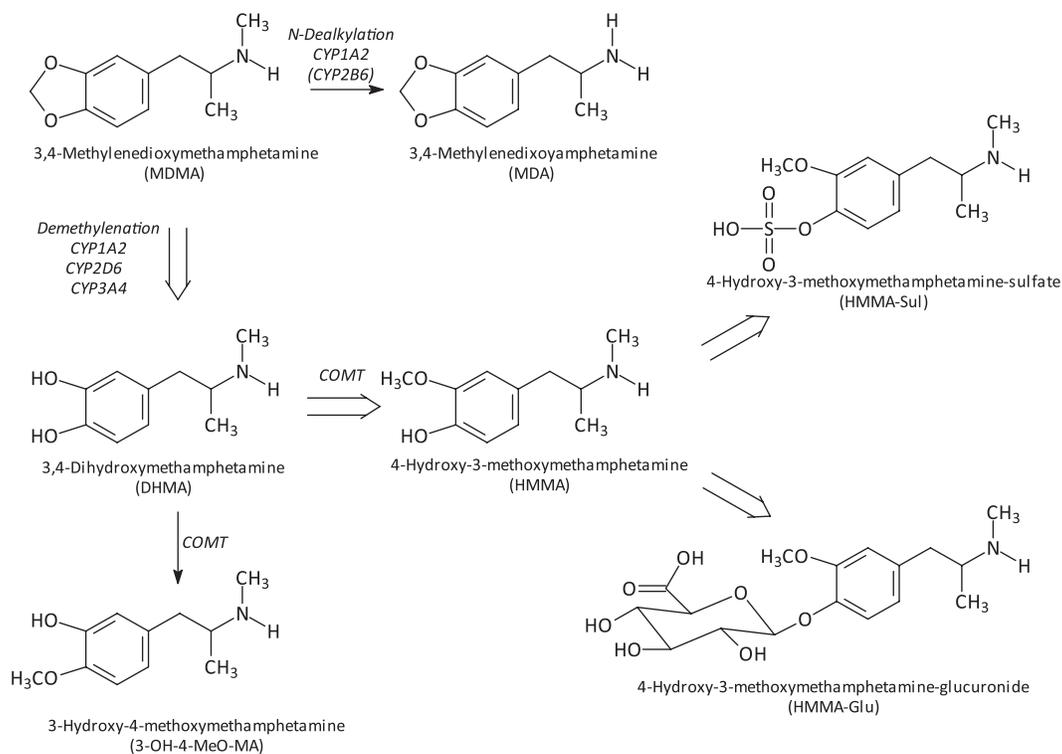
The metabolism of MDMA involves 2 main pathways as demonstrated in Figure 9.4.[51] The major pathway is *O*-demethylenation of MDMA to 3,4-dihydroxy-methamphetamine (DHMA) and the subsequent *O*-methylation by catechol-*O*-methyltransferase (COMT) to 4-hydroxy-3-methoxymethamphetamine (HMMA) and/or conjugation with glucuronide or sulfate. The minor pathway is *N*-dealkylation to 3,4-methylene-dioxyamphetamine (MDA). This pathway subsequently follows a similar metabolic pathway as MDMA with *O*-demethylenation to 3,4-dihydroxyamphetamine (HHA) and *O*-methylation to 4-hydroxy-3-methoxy-amphetamine (HMA). A small proportion of these


FIGURE 9.4. Biotransformation of 3,4-methylenedioxymethamphetamine (MDMA) with major (thicker line) and minor (thinner line) pathways. DHMA = 3,4-dihydroxymethamphetamine; COMT = catechol-*O*-methyltransferase; HMMA = 4-hydroxy-3-methoxymethamphetamine; MDA = 3,4-methylenedioxyamphetamine; HHA = 3,4-dihydroxyamphetamine; HMA = 4-hydroxy-3-methoxyamphetamine.

metabolites undergo further *N*-dealkylation, deamination, and oxidation to benzoic acid derivatives followed by conjugation with glycine. All the psychologically inactive metabolites (HMMA, DHMA, HHA, HMA, benzoic acid derivatives) are subsequently conjugated with glucuronide, sulfate, or glycine.[52]

The main CYPP450 isoenzymes involved with the demethylenation pathway are CYP2D6, CYP1A2, and CYP2B6 as demonstrated in Figure 9.4.[53] *In vitro* studies indicate that this pathway demonstrates biphasic kinetics with high- and low-affinity components. CYP2D6 is the primary CYP450 isoenzyme involved with the low-affinity component, whereas CYP1A2 and to a lesser extent CYP2B6 and CYP3A4 regulate the high-affinity component.[46] The minor pathway of *N*-dealkylation to MDA occurs primarily via CYP1A2 and CYP2B6 isoenzymes. This pathway has a maximal capacity 7- to 40-fold lower than the major demethylenation pathway *in vitro*, and the contribution of this pathway to the overall biotransformation of MDMA is relatively small compared with the demethylenation pathway. Some minor metabolites of MDMA are more neurotoxic *in vitro* than MDMA or MDA including *N*-methyl-α-methyldopamine (DHMA), α-methyldopamine (HHA), and their conjugates (glutathione, *N*-acetylcysteine).[54] However, the clinical significance of these minor metabolites is equivocal because of the low concentration of these metabolites. Although MDA is a metabolite of MDMA, the concentration of MDA is probably too low to cause pharmacologic or toxic effects.[46]

Approximately 5–10% of Caucasians are "poor metabolizers" who lack significant CYP2D6 activity. However, these individuals are not significantly more susceptible to adverse effects from the ingestion of MDMA because this pathway has low capacity and the auto-inhibition of CYP2D6 by repeat dosing of MDMA rapidly converts "extensive metabolizer" phenotype to the "poor metabolizer" phenotype.[55] In a study of poor and extensive metabolizers of CYP2D6, the poor metabolizer had relatively higher concentrations of MDMA after the first dose of 100 mg racemic MDMA, but all participants had similar MDMA concentrations following the second dose of MDMA 24 hours later.[57] CYP2D6 has a high affinity (i.e., low K_m), but this isoenzyme also has a low capacity for MDMA. Other enzymes with higher capacity (e.g., CYP1A2, CYP3A4) metabolize most of the MDMA in humans.[56] Consequently, the metabolism of MDMA at high MDMA concentrations by patients with low CYP2D6 activity (i.e., poor metabolizer) is similar to the more common phenotypes.[57] Additionally, studies of fatalities associated with the ingestion of MDMA do not support an association between variations in CYP2D6 genotype and fatal outcome.[58]

The extrapolation of pharmacokinetic data from animals to humans is limited by the substantial variation in metabolism between various animal species. Although the metabolic pathways via CYP450 isoenzymes are similar between animal species, the amount of MDMA metabolized by various pathways differs between animal species. In rats, the main metabolite is MDA compared with DHMA in humans.[59] Animal studies suggest that some potential MDMA metabolites (e.g., 2,4,5-trihydroxymethamphetamine) may be neurotoxic, but the relevance of these metabolites to human toxicity is unclear.[60]

Elimination

The kidneys excrete from 10–20% of a typical dose of MDMA unchanged in urine, depending on the dose and urine pH.[46] Although there are limited human data, the amount of urinary excretion probably decreases when the urine pH is alkaline. However, changes in urine pH probably do not significantly affect the elimination half-life of MDMA because the relatively clearance of unchanged MDMA in the urine is small. The clearance of MDA formed from the biotransformation of MDMA also varies with urine pH. The average plasma elimination half-life of racemic MDMA is about 7–8 hours following ingestion of recreational doses of MDMA (i.e., 100 mg).[18] The elimination half-lives of the 2 enantiomers of MDMA are variable and dose-related, but the ratio of the *R*(−)-isomer to the *S*(+)-isomer of MDMA always exceeds 1 because of the relatively faster elimination of the *S*-(+)-isomer. Following the ingestion of 100 mg racemic MDMA by healthy recreational drug users, the mean plasma elimination half-lives of *S*(+)-MDMA and *R*(−)-MDMA enantiomers were 4.8 hours and 14.8 hours, respectively.[13] In a study of 8 healthy volunteers ingesting 40 mg racemic MDMA, the plasma elimination half-lives of *S*(+)-MDMA and *R*(−) MDMA enantiomers were 3.6 hours and 5.8 hours, respectively.[16] During the first 29 hours following the ingestion of MDMA by an 8-month-old child sufficient to cause seizures, tachycardia, hypertension, elevated body temperature (38.9°C/102.0°F), and rhabdomyolysis, the estimated serum elimination half-life of MDMA was about 6 hours.[61] The mean Cl/f values of the *S*(+) enantiomer was 131 L/h (range, 51–276 L/h), whereas the mean value for the *R*(−)-enantiomer was 55 L/h (range, 19–109 L/h). In another study of recreational MDMA users, values for the clearance of racemic MDMA ranged from 26–800 L/h with the highest value occurring in only 1 individual ingesting a dose of 50 mg.[46] Renal clearance of MDMA typically ranges from 5–20 L/h. Hepatic clearance is far more variable with values ranging from 15–150 L/h.[16] The main metabolites excreted in the urine are conjugates of HMMA, and

these metabolites account for over 50% of MDMA metabolites in the urine. Unchanged MDMA accounts for the majority of the rest of the measured excretion with an increasing proportion of unchanged MDMA appearing in the urine as the dose of MDMA increases. MDA and HMA conjugates accounted for less than 5% of total MDMA elimination.[46]

Tolerance

Current data indicate that chronic pharmacodynamic tolerance develops following the regular use of MDMA based on the escalation of dose ingested by more experienced ecstasy users. Anecdotally, human volunteers report less desired effects following repeated MDMA doses, and regular MDMA users usually ingest higher doses than naïve MDMA users. In a multicenter Internet study of 109 novice ecstasy users (<10 lifetime occasions), 136 moderate ecstasy users (10–99 lifetime occasions), and 37 heavy ecstasy users (>100 lifetime occasions), the number of novice and heavy users reportedly ingesting more than 10 tablets was 0% and 35%, respectively.[62] Tolerance to some of the acute effects of MDMA occurs rapidly (i.e., within a day); the development of this tolerance is not related to changes in MDMA metabolism as the administration of repeated doses of MDMA is associated with reduced clearance (i.e., higher concentrations).[55]

Interactions

There are many theoretical pharmacokinetic and pharmacodynamic interactions (e.g., inhibition of CYP2D6, CYP1A2, CYP3A4, and CYP2B6) in addition to acidification of the urine (e.g., vitamin C). However, the clinical relevance of these potential interactions is questionable because the biotransformation of MDMA involves several CYP450 isoenzymes and the renal clearance of unchanged MDMA is low. *In vivo* studies of healthy volunteers indicate that inhibitors of CYP2D6 (e.g., paroxetine) increase the plasma MDMA concentration 20–30% compared with control volunteers, but pharmacodynamic effects of pretreatment with paroxetine attenuates the physiologic and psychologic effects of MDMA despite these pharmacologic changes.[63] Other pharmacodynamic interactions include attenuation of the clinical effects of MDMA by serotonin reuptake inhibiting drugs (SSRIs, tricyclic antidepressants), which competitively inhibit the binding of MDMA to the serotonin transporter.[64] The risk of the serotonin syndrome after ingestion of MDMA increases following the concomitant use of stimulants (cocaine, methamphetamine), inhibitors of serotonin metabolism, and monoamine oxidase inhibitors.[65] Case reports of

extremely potent inhibitors of multiple CYP450 isoenzymes (CYP2D6, CYP2B6, CYP3A4, CYP1A2, CYP2C9) suggest that some of these potent inhibitors (e.g., ritonavir) enhance the clinical effects of MDMA[66] and these effects may be potentially fatal.[67] Case reports associated the ingestion of MDMA and moclobemide with the development of fatal serotonin syndrome.[68] A 50-year-old man developed severe hypertension, diaphoresis, agitated delirium, and hypertonicity lasting 5–6 hours after the ingestion of MDMA and the nonselective monoamine oxidase inhibitor, phenelzine.[69] In a cross-over study of 9 healthy volunteers, the concomitant administration of 0.8 g ethanol/kg increased the mean plasma MDMA concentration approximately 13% and the plasma ethanol concentration decreased 9–15%, when compared with the administration of each drug alone.[70] The MDMA–alcohol combination induced longer lasting euphoria and well-being than MDMA or alcohol alone, but MDMA did not reverse the impairment of ethanol on psychomotor skills. Animal studies suggest that the concomitant administration of caffeine with MDMA may potentiate the hyperthermic and cardiovascular response to MDMA,[71,72] but there are few human data to determine the clinical significance of this potential interaction. The coadministration of 100 mg MDMA and 16 mg tetrahydrocannabinol did not result in any statistically significant alternation in plasma MDMA concentrations.[73]

Maternal and Fetal Kinetics

In studies of rats, MDMA and MDA easily cross the placenta with peak amniotic fluid and fetal brain concentrations occurring within 2 hours. The pattern of MDMA and MDA concentrations in the amniotic fluid mirrors the change in maternal plasma concentrations, but the peak concentrations in amniotic fluid were approximately half that of maternal plasma.[74] There are inadequate data in humans to evaluate the pharmacokinetics of MDMA during pregnancy.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

The primary physiologic effects of MDMA result from alterations of the release, uptake, and metabolism of neurotransmitters (serotonin, dopamine, norepinephrine) that cause an acute increase in the intrasynaptic concentration of these neurotransmitters followed by a period of depletion.[51] These compounds are involved in the control of mood, sleep, appetite, reward, thermoregulation, and the autonomic nervous system.[75]

133

In general, the response to MDMA is stronger in women than men including higher ratings for positive mood and altered perception (time, space) as assessed by standardized psychometric rating scales in double-blind, placebo controlled clinical trials with MDMA doses ranging from 70–150 mg.[76] Additionally, the increased sensitivity to MDMA in women is associated with more side effects (difficulty concentrating, thirst, impaired balance, decreased appetite, jaw clenching). The overall psychologic effects of MDMA largely result from the carrier-mediated, presynaptic release of serotonin, whereas the more stimulant-like euphoric effects of MDMA probably result, at least in part, from dopamine D_2 receptor stimulation.[77] In animal studies, the administration of selective serotonin reuptake inhibitors blocks the MDMA-induced release of serotonin and dopamine along with reducing the behavioral effects of MDMA.[78] MDMA has a high affinity for the presynaptic serotonin transporter ($EC_{50} = 8\,\mu M$), and reversal of the serotonin uptake transporter is the main mechanism for the increase in the presynaptic release of serotonin.

Binding to the presynaptic serotonin transporter inhibits reuptake and increases movement of serotonin into the synapse. This action initially causes increased concentrations of serotonin and major serotonin metabolite, 5-hydroxyindoleacetic acid (5-HIAA), but subsequently 5HIAA concentrations decline. The administration of MDMA (20 mg/kg subcutaneously, twice daily for 4 days) to rats caused marked reductions (30–60%) in the concentration of 5HIAA in cerebral cortex, hippocampus, striatum, hypothalamus, and midbrain at 2 weeks after the cessation of MDMA administration.[79] In addition, MDMA caused substantial reductions (50–75%) in the density of [3H]-paroxetine-labeled serotonin uptake sites in these regions of the brain. Long-term, the administration of MDMA causes a significant loss of serotonin and 5-HIAA in most regions of the forebrain. A similar pattern in extracellular serotonin concentrations occurs in animal studies. The administration of MDMA also causes a marked, irreversible inhibition of the rate-limiting enzyme tryptophan hydroxylase in the synthesis of serotonin. The onset of this inhibition begins several hours after peak CNS concentrations occur, and this effect persists many days to weeks until the synthesis of new enzymes. Nonneurotoxic doses of MDMA cause a major loss of tryptophan hydroxylase activity for up to 2 weeks, whereas a neurotoxic dose decreases tryptophan hydroxylase activity for up to 110 days following the administration of MDMA.[80]

In addition to interacting with the serotonin transporter site, MDMA has moderate affinity for serotonin receptors. Serotonergic 5-HT$_2$ receptor stimulation probably accounts for the mild hallucinogen-like perceptual effects associated with MDMA.[81] The affinity of MDMA for the norepinephrine and dopamine transporters is at least 10-fold lower than the serotonin transporter. The effect of MDMA on noradrenaline and dopamine release and the subsequent depletion of these compounds are less potent than the effects of MDMA on serotonin. MDMA binds to many receptors other than the serotonin transporter in 1–100 µM range including 5-HT$_1$ and 5-HT$_2$, H$_1$-histaminic, M$_1$- and M$_2$-muscarinic, and α_1-, α_2- and β-adrenergic receptors.[82] Activation of norepinephrine receptors produces sympathomimetic effects including elevation of blood pressure, whereas the stimulation of dopamine D_2 receptors probably accounts for at least part of the euphoria associated with MDMA.[81] In the rat brain, MDMA has the highest affinity for the serotonin transporter ($K_i = 0.61\,\mu M$) and lesser affinity for the α_2-adrenergic ($K_i = 3.6\,\mu M$), 5-HT$_2$ ($K_i = 5.1\,\mu M$), H$_1$-histaminic ($K_i = 5.7\,\mu M$), and M$_1$-muscarinic ($K_i = 5.8\,\mu M$) receptors.[81] Both enantiomers of MDMA competitively inhibit serotonin catabolism in the brain by monoamine oxidase A (MAOA) and B (MAOB). Based on *in vitro* studies of rat brain homogenates, the inhibition of MAOA and MAOB by MDMA enantiomers is similar. In these studies, the mean IC_{50} values of *S*(+)-MDMA for these 2 enzymes were $44 \pm 6.06\,\mu M$ and $370 \pm 4.68\,\mu M$, respectively, compared with $56 \pm 8.24\,\mu M$ and $378 \pm 6,29\,\mu M$, respectively, for *R*(−)-MDMA.[83] The differences in the mean IC_{50} values between the 2 enantiomers were not statistically significant.

Mechanism of Toxicity

MDMA acts primarily as an indirect serotonergic, dopaminergic, and sympathomimetic drug; therefore, MDMA causes a very wide range of physiologic and behavioral effects in animals and humans. These primarily affect CNS functions (e.g., thermoregulation, thirst, appetite, sleep, motor activity, attention, aggression, sexual and operant behavior) and to a lesser extent, the cardiovascular system. Secondary effects occur on other neurotransmitters and hormones including increased release of acetylcholine in the CNS as well as systemic increases in corticosterone, prolactin, renin, aldosterone, oxytocin, and vasopressin.[51]

Immunohistochemical studies indicate that the administration of MDMA to experimental animals causes the apparent loss of serotonin nerve terminals. Biochemical studies demonstrate loss of [3H]-paroxetine binding to the presynaptic serotonin transporter and a decrease in tryptophan hydroxylase activity. The most common manifestations of acute toxicity from MDMA are predictable from the pharmacologic properties of MDMA. Behavioral effects (e.g., increased activity, impaired hypothalamic homeostatic functions) result in

mild hyperthermia, fatigue, and dehydration. The magnitude of these effects is increased by high ambient temperatures and fluid depletion. The psychologic effects of MDMA can cause acute anxiety, paranoia, and hyperventilation in susceptible individuals.

CENTRAL NERVOUS SYSTEM

ANIMAL.   In animal studies, low doses of MDMA cause increased alertness and physical activity, increased social interaction, and reduced aggression. Larger doses cause stereotyped movements, hyperreactivity, dystonic and dyskinetic postures, piloerection, and salivation.[84] These results are consistent with subjective reports from human studies, where low doses of MDMA result in increased alertness, euphoria, increased confidence, gregariousness, enhanced mental and physical activity, and improved self-esteem.[85] MDMA causes selective and persistent neurotoxic effects on central serotonergic neurons in laboratory animals. In these studies, the administration of MDMA produces persistent reductions in regional brain concentrations of serotonin, the rate-limiting enzyme (tryptophan hydroxylase) of serotonin synthesis, serotonin transporter, and vesicular monoamine transporters up to 8 weeks after administration of MDMA.[86,87] The affinity of MDMA is much less for the dopamine transporter than the norepinephrine transporter.[88] At single MDMA doses (10–20 mg/kg) typically associated with serotonin depletion in rats, increased markers of neurotoxic damage (i.e., cell death, reactive gliosis, silver staining) are not reliably present.[89] Immunohistochemical techniques document a loss of serotonin axons and axon terminals in MDMA-treated animals with higher doses of MDMA (20 mg/kg, subcutaneously, twice daily for 4 days).[90] However, extrapolation of animal data to effects found in humans is complicated by the following factors: 1) animal models of MDMA-induced neurotoxicity do not mimic typical human patterns of ecstasy use, 2) lack of correlation of functional deficits to brain imaging, 3) confounding variables in existing epidemiologic data (polydrug use, drug purity, reporting bias, premorbid personality abnormalities), and 4) the possible role of preexisting deficits in serotonergic systems, impulse control, and cognition that potentially predispose individuals to the abuse of drugs (i.e., MDMA).[85,91] Animal studies indicate that the $S(+)$-isomer of MDMA is more neurotoxic than the $R(-)$-isomer.[92]

HUMAN.   Clinical studies on abstinent MDMA users suggest the possibility of neurotoxic effects of MDMA on brain serotonin neurons, but the findings are inconclusive. In current MDMA users, positron emission tomography (PET) scanning demonstrates alterations of the serotonin transporters in some serotonin-rich areas of the brain (mesencephalon, putamen, caudate, thalamus). The reduction in serotonin density is dose- and time-dependent; the changes correlate to reported use and slowly resolve during long-term abstinence.[86,93] Although these effects are at least partially reversible in some recreational MDMA, studies to date have not determined the full reversibility of these abnormalities. In a study of current MDMA users, former MDMA users, and controls (drug-naïve controls, other psychoactive drugs than MDMA) using the serotonin transporter ligand [11]C-(+)-McN5652, PET scanning detected a statistically significant reduction in serotonin availability in the mesencephalon and thalamus in the current users when compared with controls.[94] These changes persisted at least several weeks, but there was no statistically significant reduction in serotonin availability in former MDMA users, when compared with controls. Subsequent re-analysis of this data using Voxel-based comparisons between the groups with statistical parametric mapping confirmed the reduced serotonin binding potential in the striatum and the thalamus, but not in the neocortical areas of the brain of current MDMA users.[95] Depletion of serotonin is not necessarily synonymous with anatomic damage to neurons.

THERMOREGULATION

In animal studies, MDMA impairs thermoregulation, and the administration of MDMA activates mechanisms that conserve and generate heat. The animal data suggest that MDMA-induced stimulation of serotonergic pathways at relatively warm ambient temperatures causes an elevation in metabolic rate and peripheral vasoconstriction. In male, Long-Evans rats, the administration of 30 mg MDMA/kg doubled the metabolic rate at room temperatures of 20°C (68°F), when compared to the saline placebo group.[96] However, there was no difference in metabolic rate between these 2 groups at a room temperature of 10°C (50°F). This dose of MDMA caused a 3.2°C increase in core temperature at an ambient temperature of 30°C (86°F) compared with no change at 20°C (68°F) and a 2.0°C decrease at a room temperature of 10°C (50°F). Thus, the increased metabolic rate and peripheral vasoconstriction may produce life-threatening elevations in core temperature at high ambient temperatures.

The effect of MDMA on body temperature is complex because this drug affects the release and receptor activation of all 3 major monoamine neurotransmitters (i.e., serotonin, dopamine, norepinephrine).[97] In animal studies, low environmental temperatures reduce the inhibition of serotonin synthesis and the neurotoxicity associated with the administration of MDMA, whereas high environmental temperatures enhance the

hyperthermia and neurotoxicity associated with MDMA.[98,99] Although high ambient temperatures enhance the effect of MDMA on core temperatures, the most important hyperthermic effects probably are centrally mediated. Both serotonin and dopamine are involved in the central control of thermoregulation; however, these effects are primarily mediated by dopamine rather than serotonin based on animal studies. In these studies, the hyperthermic response is blocked by D_1 receptor antagonists, but not by serotonin 5-HT$_2$ antagonists or fluoxetine. Rodent studies suggest that alpha$_1$- and beta$_3$-adrenoreceptors modulate the hyperthermic response to MDMA in some animals;[100] however, alpha$_1$-adrenoreceptor antagonists attenuate the MDMA-induced hyperthermic response to a substantially greater degree than beta$_3$-adrenoreceptor antagonists.[101] This response is relatively small and the clinical significance is unclear.

HYPONATREMIA

The administration of MDMA to healthy volunteers produces a slight increase in body temperature. Following the ingestion of 1.5 mg MDMA/kg by 14 healthy volunteers, the mean peripheral body temperature increased 0.3ºC; the concomitant ingestion of a 5-HT$_{2A}$ antagonist (ketanserin) abolished this increase.[102] Consequently, other factors probably contribute to the development of severe hyperthermia including an idiopathic response, strenuous physical activity, inadequate fluid replacement, and high ambient temperatures. MDMA-induced hyponatremia and cerebral edema is a rare cause of death that is not associated with hyperthermia. Hyponatremia may result from the excessive consumption of water while exercising vigorously during MDMA intoxication. Additionally, the ingestion of MDMA is associated with the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). Animal studies indicate that in addition to MDMA, metabolites (e.g., 4-hydroxy-3-methoxymethamphetamine, HMMA) of MDMA contribute to the increased secretion of antidiuretic hormone, arginine vasopressin.[103,104] Case reports of MDMA-related hyponatremia suggest that the cause of low serum sodium concentrations is multifactorial (i.e., MDMA-induced arginine vasopressin secretion, drug-induce thirst, ingestion of hypotonic fluids).[105]

HEPATOTOXICITY

The variable patterns of hepatotoxicity following MDMA ingestions suggest different mechanisms of toxicity. Severe hepatic damage may occur during MDMA intoxication as a result of severe hyperthermia.[106] However, case reports suggest that hepatic failure in chronic MDMA users may develop in the absence of documented hyperthermia.[107] In some of these cases, the presence of acute, recurrent hepatitis in chronic MDMA users is suggestive of features of autoimmune hepatitis including eosinophilic infiltration of the liver.[108] Typically, the severity of the liver damage does not correlate with the frequency or amount of MDMA consumption; thus, the reaction may be idiopathic or the result of a contaminant.

Postmortem Examination

In animal studies, the administration of lethal doses of MDMA produces pathologic changes resembling experimental hyperthermia. The results are similar in most fatal MDMA intoxications, although there is some variability due to contributory mechanisms of death (cerebral edema, multiorgan failure). In a case series of 5 fatalities related to MDMA, the most common postmortem abnormalities occurred in the liver and ranged from focal hepatocyte necrosis to centrilobular necrosis.[109] Postmortem abnormalities in most of these cases were consistent with hyperthermia. Centrilobular necrosis of the liver is particularly common in MDMA deaths associated with hyperthermia. Sinusoidal congestion and dilation, portal and sinusoidal inflammation, microvesicular fatty changes, and cholestasis may be present in these fatal cases. Myocardial abnormalities predominantly involve contraction band necrosis and patchy foci of necrosis with mixed inflammatory infiltrates, similar to catecholamine-induced myocardial damage. In the brain, perivascular hemorrhage and hypoxic changes are consistent with generalized organ dysfunction, and congestion of the internal organs is usually present. Gross cerebral edema, focal hemorrhage in the brain, uncal herniation, and pituitary necrosis occur in cases associated with fatal hyponatremia. Postmortem examination of individuals who died after MDMA use found a relatively high incidence of cardiovascular disease, similar to cocaine and methamphetamine abusers. A retrospective review of 82 autopsy cases with MDMA listed as a cause of death demonstrated the following pathology: mild atherosclerosis, 18%; moderate atherosclerosis, 9%; severe atherosclerosis, 14%; cardiomegaly, 18%; and ventricular hypertrophy, 7%.[110] Cerebrovascular malformations occurred in 4% of the cases. The median age of these cases was 26 years (range, 17–58 years).

CLINICAL RESPONSE

Illicit Use

The adverse effects of MDMA usually result from an accentuation of the pharmacologic properties (i.e., sym-

pathomimetic stimulation) of MDMA on the cardiovascular and central nervous systems. Serious effects following MDMA use are relatively rare.[37,110] However, the concomitant use of other drugs of abuse (e.g., ethanol, cocaine, amphetamines) and adulteration of ecstasy tablets with other amphetamine designer drugs (e.g., PMA) commonly complicate the clinical presentation of MDMA users and increases the incidence of serious effects (e.g., delusions, delirium, acute psychosis, suicidal ideation, seizures, hyperthermia, hypotension).[111,112] In a case series of emergency department (ED) visits resulting from MDMA use, the concomitant use of cocaine use increased the incidence of panic attacks compared with the use of MDMA alone.[37] Similarly, the concomitant use of opiates or γ-hydroxybutyrate was more commonly associated with deep coma than the use of MDMA alone. Adverse effects associated with the recreational use of MDMA include bruxism,[113] trismus, anorexia, dry mouth, thirst, diaphoresis, blurred vision, impaired gait and balance, restless legs, difficulty sleeping, mydriasis, excitement, tachycardia, palpitations, lethargy, poor concentration, incontinence, paresthesias, and other psychiatric symptoms.[114] With successive doses, the adverse effects become more common and the desired effects less intense. Larger doses may cause an acute panic attack characterized by dysphoria, agitation, and hyperventilation.[115,116] Dysphoria, nausea, vomiting, headache, sweating, apprehension, confusion, and tremulousness complicate the use of MDMA as the dose increases. Altered mental status is the most common abnormality in patients presenting to the emergency department following MDMA use, particularly among naive users.[37] MDMA abuse frequently is associated with minor movement disorders such as tics (e.g., eye blinking, jaw jerks, hip turning, humming, panting, muscle jerks) based on case reports. Table 9.2 compares the frequency of reported clinical abnormalities by patients presenting to 3 EDs with self-reported MDMA intoxication.

Behavioral Abnormalities

The recreational use of MDMA is associated with moderate derealization (i.e., loss of sense that people or objects in your surroundings are real), but not typically with hallucinations. Moderate doses of MDMA generally produce effects described in positive terms by the recipients including a sense of closeness to others, elevation of mood, talkativeness, and less commonly, altered visual perceptions. In a survey of 20 psychiatrists self-administering MDMA, structured interviews revealed the following subjective effects: altered time perception, 90%; increased communication, 85%; decreased defensiveness, 80%; reduced fear, 65%; reduced sense of

137

alienation from others, 60%; altered visual perception, 50%; and reduced aggression.[117] The subjective effects of MDMA typically begin within 30–60 minutes after ingestion and resolve within 4–6 hours.

MENTAL DISORDERS

Determining the chronic effects of MDMA use is complicated by the difficulty identifying a cohort of users of MDMA only. Self-rating questionnaires of heavy recreational ecstasy users (30–1,000 occasions) reveal higher scores for somatization, paranoid ideation, psychosis, anxiety, hostility, phobias, impulsiveness, altered appetite, and difficulty sleeping when compared with non-MDMA users.[118] Symptoms associated with chronic, heavy use of MDMA based on responses to questionnaires include depression, anxiety, volatility, tremors/twitches, and weight loss.[119] Although anxiety is a frequent minor side-effect of MDMA use, occasionally an acute panic attack occurs. Typically, this reaction resolves quickly with supportive care and benzodiazepines, but symptoms (e.g., agoraphobia) may persist for several months.[120] In contrast to amphetamines and methamphetamines, psychosis is an uncommon manifestation of MDMA abuse based on clinical features of patients presenting to EDs with MDMA intoxication.

MEDICAL COMPLICATIONS

Alteration of consciousness following MDMA use is usually not a direct effect of MDMA, and these patients usually have other causes of altered mental status including hyponatremia, hyperkalemia, metabolic acidosis, hyperthermia, seizures, or the concomitant ingestion of CNS depressants.[121] Rare case reports associate MDMA use with subarachnoid hemorrhage,[122] intracerebral hematoma,[123] and cerebral venous thrombosis,[124] but underlying structural abnormalities (e.g. aneurysm, arteriovenous malformation) may account for some of these events.[125,126]

The physiologic response to recreational doses of MDMA includes elevated heart rate, increased blood pressure, and palpitations.[35] Cardiovascular complications associated with MDMA intoxication include hypertension, chest pain, palpitations, dyspnea, and atrial fibrillation.[37,127] Case reports temporally associate the use of MDMA with the development of an acute myocardial infarction both with[128] and without[129] coronary thrombosis. Spontaneous pneumothorax, pneumomediastinum with cervical emphysema, difficulty swallowing, precordial crepitations, dyspnea, and thoracic pain may occur following the ingestion of MDMA as a result of Valsalva-type maneuvers (sustained respiratory muscle activity with a closed glottis) or pro-

tracted vomiting.[130,131] Rarely, case reports associate the ingestion of MDMA with isolated noncardiac pulmonary edema, but this complication usually occurs with multiorgan failure.[132]

MDMA is associated with the serotonin syndrome (confusion, agitation, diaphoresis, hypertonicity, hyperreflexia, shivering, tremor, myoclonus, diarrhea, and autonomic instability). The serotonin syndrome is similar to acute hyperthermia and multiorgan failure associated with MDMA toxicity, but significant physical exertion is not required for the development of hyperthermia in the setting of the serotonin syndrome. Mild cases of serotonin syndrome resolve spontaneously, but severe cases require intensive care.[133]

MDMA is structurally and pharmacologically similar to fenfluramine; the phentermine–fenfluramine combination was associated with valvular heart disease following chronic use as anorexic agents. Like fenfluramine, MDMA causes proliferation of cardiac valvular interstitial cells *in vitro* by activation of the 5-HT_{2B} receptor.[134] A small study of MDMA abusers suggested a possible association between chronic MDMA use and valvular heart disease. In a study of 29 current and past MDMA users, 8 MDMA users (28%) with no other known risk factors had echocardiographic evidence of valvular lesions compared with none for the gender- and age-matched controls.[135] The lesions included valvular stranding and regurgitation of the mitral, tricuspid, or aortic valves as defined by US Food and Drug Administration criteria for appetite suppressant-induced valvular heart disease. The valvular lesions detected in this study were mild to moderate compared with phentermine–fenfluramine associated valvular disease, but the size of the study was small.

Overdose

Table 9.3 outlines the common clinical features of mild to severe MDMA intoxication. In a study of ecstasy-related admissions to Israeli EDs, the most common clinical features of MDMA toxicity were agitation, restlessness, disorientation, shaking, elevated blood pressure, headache, and loss of consciousness.[136] The most common serious complications of acute MDMA toxicity are coma with respiratory insufficiency and severe hyperthermia (>41ºC/105.8ºF) with associated hypertonicity, hyperreflexia, altered consciousness, multiorgan failure, hepatocellular damage, rhabdomyolysis, acute renal failure with myoglobinuria, severe electrolyte disturbance (hyponatremia, hypernatremia, hyperkalemia), and disseminated intravascular coagulation (DIC).[137,138] Patients with severe hyperthermia may collapse at the scene, arriving at the emergency department in cardiopulmonary arrest.[121] The severity and duration

TABLE 9.3. Symptoms by Severity of 3,4-Methylenedioxymethamphetamine (MDMA) Intoxication.

Severity	Signs and Symptoms
Mild	Anxiety, agitation, irritability, insomnia, dizziness, tremor, hyperreflexia, mydriasis, flushing, diaphoresis, thirst, nausea, vomiting, pallor
Moderate	Confusion, delirium, hypertension, tachypnea, tachycardia, premature ventricular contractions, chest discomfort, vomiting, abdominal pain, profuse diaphoresis, mild temperature elevation, hallucinations, panic reaction, elevated creatine kinase
Severe	Hyperpyrexia (>40°C), seizures, coma, focal neurologic signs, shock, disseminated intravascular coagulation, hepatic failure, pulmonary edema, serious electrolyte imbalance ($K^+ > 6.5$ meq/L, $Na^+ < 125$ meq/L), rhabdomyolysis, serious ventricular dysrhythmias

of hyperpyrexia are prognostic indicators of the risk of death. Few patients survive peak core temperatures exceeding 42°C (107.6°F).[139] However, a patient survived MDMA-induced hyperthermia reaching a peak core temperature of 42.9°C (109.2°F). Complications included seizures, rhabdomyolysis, metabolic acidosis, and respiratory failure.[140] Headache, myalgias, light-headedness, paresthesias, weakness, and delirium can be an early symptom of hyperthermia.[121]

Although seizures occur occasionally following ingestion of ecstasy tablets, the development of seizures often indicates ingestion of tablets adulterated with *para*-methoxyamphetamine (PMA).[169] Severe liver disease may occur in MDMA users without hyperthermia.[141] Although these individuals develop jaundice, hypoglycemia, prolonged prothrombin times, and markedly elevated serum hepatic aminotransferase concentrations, hepatic encephalopathy does not usually occur.[142] Rare case reports describe orthotopic liver transplantation for severe hepatic encephalopathy associated with the use of ecstasy.[143]

Fatalities

Death after the use of MDMA alone is very rare, and many deaths from ecstasy follow ingestion of tablets subsequently found to contain substances other than MDMA.[110] The clinical features of lethal MDMA toxicity are similar to the serotonin syndrome. Most MDMA-induced fatalities are associated with hyperthermia along with multiorgan failure, rhabdomyolysis, and DIC. Other causes of death include dilutional hyponatremia

with cerebral edema and uncal herniation, cerebrovascular events, and hepatic failure without hyperthermia.[42] Potential predisposing factors for the development of fatal reactions to MDMA use include use of monoamine oxidase (MAO) inhibitors, ingestion of other stimulants, preexisting cardiovascular disease, and strenuous activity in high ambient temperatures. However, fatalities from the ingestion of MDMA may occur in individuals who are not participating in physical activities.[144]

Abstinence Syndrome

Experimental studies indicate that the administration of multiple daily doses of MDMA does not induce classical manifestations of physical dependence.[145] In contrast to ethanol, sedatives, and opioid withdrawal, there are no physical symptoms that characterize MDMA withdrawal. Symptoms that follow cessation of MDMA use are mild, and these effects may result from mild residual toxicity rather than an abstinence syndrome. Up to about one-third of recreational users of MDMA report difficulty concentrating, myalgias, fatigue, depressive symptoms, and confusion the day following MDMA use.[85] When compared with ethanol control groups, increased depressive symptoms commonly occur during the several days following MDMA use; however, confounding variables (e.g., preexisting psychiatric conditions) complicate the interpretation of these studies.[146] In a 9-day study of regular MDMA users, these participants had increased scores on negative mood parameters (depression, irritability, anxiety, rumination) and cognition (impairment of concentration and memory) 24 hours after using MDMA, when compared with controls (abstinent ecstasy users).[147] The negative cognitive effects resolved after 2 days, and the negative effects on mood persisted 3–4 days. Sleeping was disrupted for 2 days.

Reproductive Abnormalities

There are few data on the reproductive effects of chronic MDMA abuse. A prospective follow-up study of 136 babies exposed to ecstasy *in utero* suggested that maternal MDMA exposure may be associated with a significantly increased number of congenital defects (15.4%, 95% CI: 8.2–25.4), particularly the incidence of cardiovascular (26/1000 livebirths, 95% CI: 3–90) and musculoskeletal (38/1000, 95% CI: 8–109) anomalies.[148] However, these studies are confounded by smoking, heavy alcohol intake, and polydrug use combined with a higher than expected rate of unplanned pregnancies that increase the risk of fetal exposure to potentially harmful substances.[149] Available data to date do not

show strong support for a causal relationship between chronic MDMA use and birth defects; however, data on the use of MDMA during pregnancy are limited.[150]

DIAGNOSTIC TESTING

Analytic Methods

SCREENING

Most urine drug screens do not contain MDMA-specific immunoassays (e.g., DRI Ecstasy, Microgenics Corp., Fremont, CA);[151] therefore, detection of this compound depends on the cutoffs and relative cross-reactivities with commercial reagents for amphetamine and methamphetamine that are not specifically designed to detect MDMA. In general, immunoassays for amphetamines are based on antibodies derived from amphetamine or methamphetamine conjugates that are modified at an amine group. Any amine-containing compound structurally similar (e.g., MDMA) to amphetamine will react with the assay. MDMA cross-reacts at 135% with the ELISA (enzyme-linked immunosorbent assay) methamphetamine assay (Immunalysis, Pomona, CA), but the cross-reactivity of MDMA with the enzyme multiplied immunoassay technique, EMIT II (Dade-Behring/Siemens Healthcare Diagnostics, Deerfield, IL) is only 3%.[152] As a result of the variable degree of cross-reactivity between assays, more specific methods (e.g., high performance liquid chromatography [HPLC], gas chromatography/mass spectrometry [GC/MS]) are required to identify and quantify MDMA.

CONFIRMATORY

Analytic methods for the quantitation of MDMA include GC with nitrogen-selective detection,[153] HPLC with fluorescence detection,[154] capillary electrophoresis,[155] liquid chromatography/electrospray ionization/tandem mass spectrometry,[156] and GC/MS.[157] The limit of detection (LOD) for the latter method is 50 ng/mL.[158] In urine samples, liquid chromatography/electrospray ionization/mass spectrometry[159] and GC/MS[160] can simultaneously quantify MDMA and common metabolites. The lower limit of quantification (LLOQ) for the latter method is about 25 ng/mL. Liquid chromatography/mass spectrometry is an alternative to GC/MS as a confirmation technique that simplifies sample preparation and eliminates derivatization procedures as well as the hydrolysis of urine samples. The LOD using liquid chromatography/electrospray ionization/tandem mass spectrometry for methamphetamine and MDMA in urine samples is 8 ng/mL with a coefficient of variation (CV) between 5–16%.[161] The LLOQ is 28 ng/mL and

26 ng/mL, respectively. The LLOQ for these compounds in oral fluid by GC/MS with electron impact ionization ranges between 5–25 ng/mL with a CV below 8.3%.[162] The HPLC retention data is not as precise as the data obtained by GC/MS methods; therefore, more interference occurs during HPLC procedures compared with GC/MS. Gas chromatography/mass spectrometry with electron impact or chemical ionization separates MDMA from amphetamine, methamphetamine, and related amines including ephedrine, phenylpropanolamine, and phentermine. Gas chromatography/negative ion chemical ionization/mass spectrometry and HPLC with peroxyoxalate chemiluminescence detection are sensitive and accurate methods for the detection of MDMA in human hair.[163,164] Methods to quantify the concentration of R-(−)- and S-(+)-isomers of MDMA and MDA include negative-ion chemical ionization GC/MS[165] and gas chromatography/electron ionization/mass spectrometry with selective ion monitoring.[166]

STREET SAMPLE ANALYSIS

The purity of MDMA tablets and the adulterants added to these tablets varies by year and by country. The purity of MDMA tablets was relatively high before the mid to late 1990s, when the composition of ecstasy tablets varied widely, even among visually similar tablets with the same brand.[167] In some studies of the purity of MDMA tablets, less than one-half of such tablets contained unadulterated MDMA and many tablets contained other compounds.[112] These tablets may contain pharmaceutic preparations with little psychoactive properties including acetaminophen (paracetamol), caffeine, carisoprodol, codeine, dextromethorphan, diazepam, diethylpropion, diphenhydramine, fentanyl, lidocaine, procaine, ephedrine, pseudoephedrine, and zolpidem. However, many tablets contain psychoactive adulterants including MDA, MDEA, methamphetamine, PMA, N-benzylpiperazine (BZP), 1-(3-chlorophenyl)piperazine (mCPP), 2,5-dimethoxy-4-bromophenethylamine (2C-B), 2,5-dimethoxy-4-bromoamphetamine (DOB), cocaine, and ketamine. In a study of the pharmaceutic content of tablets sold as ecstasy across the United States, 39% of the tablets contained only MDMA, 46% contained substances other than MDMA, and 15% were mixtures of MDMA and adulterants.[168] Methamphetamine, MDA, MDEA, caffeine and pseudoephedrine are common adulterant of MDMA tablets in the United States.[112] Rarely, serious toxins (e.g., strychnine) are adulterants of MDMA.[112] The substitution of PMA for MDMA in ecstasy tablets caused a number of deaths in Europe,[169] North America,[170] and Australia.[171] The starting materials (e.g., anise) for synthesizing PMA are substantially less

expensive and more readily available than common starting materials (safrole, isosafrole) for MDMA.[172] In the Netherlands, monitoring of the illicit market between 1993 and 2008 demonstrated a peak MDMA content in confiscated ecstasy of 86% between 2004–2006.[173] After that period, the purity of MDMA tablets decreased with the increasing adulteration of these tablets with mCPP, BZP, and caffeine.

Impurities include by-products of contaminants produced from unintended side reactions as well as by-products of reactions from the starting materials. A 31-year-old man died following a massive MDMA overdose; his postmortem blood contained small amounts of 3,4-methylenedioxy-*N*,*N*-dimethylamphetamine (MDDM or MDDA).[174] The authors of this case report suggested that MDDM was probably a synthetic by-product or contaminant in the MDMA tablets.

Drug profiling involves the extraction of physical and/or chemical profiles from drug samples to collect information on the source and similarity of confiscated batches of drugs. Analysis of these impurities after extraction under alkaline conditions and GC/MS usually identifies the probable method of synthesis and precursor agents.[21] The synthesis of MDMA produces highly variable constituents in the final mixture as a result of differences in manufacturing parameters. Consequently, determination of the presence of organic impurities [e.g., 3,4-methylenedioxyphenyl-2-propanone, 3,4-methylenedioxyphenyl-2-propanol, 3-(3,4-methylenedioxyphenyl)-3-buten-2-one, *N*-formyl-*N*-methyl-3,4-methylenedioxyamphetamine] provides information on the source of the MDMA tablets.[175] Analysis of the physical characteristics (e.g., diameter, thickness, weight, score) of the tablets resulting from compression of the mixed powder during the tablet-pressing process also provides drug intelligence on the source of the MDMA tablets.[176]

STORAGE

MDMA is relatively stable during most storage conditions (-20°C/-4°F, 4°C/39.2°F, 20°C/68°F). In a controlled study of MDMA stored at -20°C (-4°F), 4°C (39.2°F), and 20°C (68°F) in urine and whole blood samples, there was no significant loss of MDMA for 21 weeks and 5 weeks, respectively.[177] Sample degradation limited analysis of MDMA after these times.

Biomarkers

BLOOD

Animal studies indicate that MDMA concentrates in erythrocytes with a mean erythrocyte/plasma ratio of 1.48 ± 0.04, similar to MDA.[178]

PHARMACOLOGY STUDIES.   Pharmacokinetic studies in volunteers indicate that the kinetics of MDMA is non-linear.[179] MDMA doses of 50 mg and 150 mg produce mean peak plasma concentrations of 0.05 mg/L, and 0.46 mg/L, respectively, about 1–2 hours after ingestion.[180] The mean peak plasma MDMA concentration in 6 healthy volunteers about 2 hours after the ingestion of 100 mg MDMA was approximately 0.2 mg/L.[181] These studies indicate that the central (arousal) and peripheral sympathomimetic effects (i.e., elevated heart rate and blood pressure) follow the time-profile of plasma MDMA concentrations, but not necessarily the quantitative plasma concentration of MDMA. At the end of a dance party, the mean plasma MDMA concentration in 27 regular MDMA users (i.e., 1–12 d/mo) was 0.31 ± 0.21 mg/L with a range up to 0.84 mg/L.[182] Individuals in this group reported the following subjective effects at the time of the blood sampling: no effect, 22%; mild effects, 52%; and strong effects, 26%. The reported drug use did not correlate well to the plasma MDMA concentration. Although there was a small progressive increase in temperature during and after MDMA use, MDMA concentrations and temperature were not statistically correlated.

OVERDOSE.   The MDMA concentrations in blood samples from asymptomatic users and users with serious side effects are similar.[42,183] Consequently, the plasma MDMA concentration alone is not a reliable predictor of acute MDMA-induced medical complications. A 17-month-old toddler developed generalized tonic-clonic seizures, elevated temperature (38.5°C/101.3°F), tachycardia, and hypertension after ingesting a tablet of MDMA.[184] The serum MDMA concentration on admission to the emergency department was 0.30 mg/L. The child survived without sequelae following intensive care. Three hours after admission for seizures, elevated temperature (38°C/100.4°F), hypertension, and tachycardia, the serum MDMA concentration in blood samples from a 14-month-old baby was 0.591 mg/L.[185] The child fully recovered with intensive supportive care. A 27-year-old man presented to an emergency department 6 hours after ingesting ecstasy.[128] He was agitated, diaphoretic, and complaining of chest pain with electrocardiographic evidence of an inferior myocardial infarction. His plasma MDMA concentration at admission was 1.1 mg/L with no detectable MDA. A 20-year-old man developed seizures, marked trismus, and a temperature of 38.6°C (101.5°F) soon after ingestion 18 ecstasy tablets.[186] The plasma MDMA concentration was 4.05 mg/L. Thirteen hours following the ingestion of 40 tablets of ecstasy by a 19-year-old man, the serum concentration of MDMA was 4.3 mg/L.[39] Clinical features of toxicity were limited to elevated heart rate,

mydriasis, confusion, lethargy, and retrograde amnesia. The serum MDMA concentration in a 32-year-old woman 3 hours after the ingestion of MDMA was 6.5 mg/L.[187] She was agitated, combative diaphoretic, hypoxic, and hyperthermic (41.6°C/106.9°F). Ten hours after ingestion, she was hemodynamically stable and responsive, but agitated while intubated. She was extubated 25 hours after ingestion, and she survived with intensive supportive care. A 30-year-old man developed seizures, coma, respiratory failure, and modest elevation of his core temperature (38.7°C/101.7°F). His serum S(+)- and R(−)-MDMA concentrations 4 hours after ingestion were 42 mg/L and 44 mg/L as determined by GC/MS. He survived with supportive care.

A 20-year-old presented to the emergency department comatose with hyperthermia (43°C/109.4°F), hypotension, and hyperkalemia (7.7 meq/L).[121] His serum MDMA concentration at admission was 2.4 mg/L; he died 1 hour later. In the same case series, a 22-year-old man presented to an emergency department with coma, hyperkalemia (6.8 meq/L), hypotension, and elevated temperature (38.5°C/101.3°F). His serum MDMA concentration at admission was 0.93 mg/L; he died 58 hours after admission.

Postmortem. Postmortem MDMA concentrations must be interpreted along with other antemortem and postmortem evidence because of the overlap of postmortem MDMA concentrations of fatal acute MDMA intoxication and fatalities associated with trauma during MDMA use. There are limited data on postmortem blood concentrations of MDMA. Deaths occasionally occur in young healthy adults following the ingestion of typical recreational doses of MDMA. In these cases, the postmortem MDMA concentrations overlap with MDMA concentrations from blood samples taken from recreational MDMA users during or after rave parties.[31] Additionally, the use of MDMA frequently occurs with polydrug use. In a case series of 22 deaths with positive postmortem MDMA concentrations, the cases were divided into the following 3 groups with associated mean MDMA concentrations: 1) co-intoxications with cocaine and/or opiates, 0.58 mg/L; 2) intoxications without cocaine or opiates, 1.04 mg/L; and 3) trauma-related deaths, 0.97 mg/L.[188] MDA is a metabolite of MDMA; MDA concentrations up to approximately 10% to 15% of the blood MDMA concentration may be present following the ingestion of MDMA only.[189] In the above case series, the mean postmortem blood MDMA and MDA concentrations were 0.86 mg/L and 0.16 mg/L, respectively. In a case series of 15 deaths attributed to accidental MDMA intoxication, the postmortem blood (site not specified) contained MDMA

concentrations from 0.48–10 mg/L and the range of the MDA concentrations was <0.05–0.15 mg/L.[190]

The MDMA concentrations in femoral blood samples from 9 individuals with fatal MDMA intoxication ranged from 1.2–22 mg/L; the mean and median concentrations were 8.4 mg/L and 4.4 mg/L, respectively.[191] None of these postmortem blood samples contained significant concentrations of other drugs. A 22-year-old man was agitated, acting bizarrely, and mumbling incoherently at a student club.[192] He was initially unconscious with stable vital signs at the ED; he had a sudden cardiopulmonary arrest and could not be resuscitated. At postmortem examination 24 hours after death, his femoral blood contained the following drugs: MDMA, 1.42 mg/L and MDA, 0.17 mg/L. A 19-year-old woman died about 3 hours after ingesting MDMA despite 30 minutes of cardiopulmonary resuscitation.[144] The postmortem femoral blood contained MDMA and MDA concentrations of 3.8 mg/L and trace, respectively. A 19-year-old man died of hyperthermia and multiorgan failure 7 hours after arriving comatose at the ED.[193] The concentrations of MDMA and MDA in autopsy blood (site not reported) were 1.09 mg/L and 0.08 mg/L, respectively, as measured by GC/MS.

MDMA concentrations in blood samples from autopsies may demonstrate postmortem redistribution, particularly in the presence of high MDMA postmortem concentrations in the liver, stomach, and lungs.[194] Case reports suggest heart/femoral blood ratio of MDMA ranging between 1.4–3.9.[194,195] The postmortem/serum perimortem MDMA ratio in blood samples from 2 fatalities from MDMA intoxication were 1.9 for postmortem brachial blood and 1.1 for postmortem femoral blood.[196] Perimortem blood was collected within 1 hour before death.

Urine

The kidney excretes MDMA in the urine beginning shortly after ingestion. Urine amphetamine immunoassays may detect the presence of MDMA following use for approximately 1–2 days, depending on several factors including the dose, duration of use, urine pH, hydration (i.e., urine concentration), analytic method, cutoffs, and individual metabolic and excretion rates. The sensitivity and specificity of individual immunoassays varies. The cross-reactivity of MDMA with reagents in some urine drug screens [e.g., Abuscreen® OnLine HS AMP/MDMA (Abbott Laboratories, Abbott Park, IL), CEDIA®-Amp/MDMA (Microgenics Corp., Fremont, CA), Abbott TDx AMP/MAM: II (Abbott Laboratories, Abbott Park, IL)] is high (>90%), compared with other immunoassays.[197] In a study using a

MDMA cutoff of 0.5 mg/L urine, the false-positive percentage for TDx®-Amp, COBAS®-Amp (Roche, Nutley, NJ), OnLine-Amp/MDMA (Roche Diagnostics Co., Indianapolis, IN), and CEDIA®-Amp/MDMA ranged between 11–21%, whereas the false-negative percentage ranged between 10–17%.[198] The EMIT®-Amp assay (Dade Behring Inc., Deerfield, IL) has high cross-reactivity toward MDMA, but this assay is unlike to detect MDMA at concentrations below 0.5 mg/L concentration. The cutoff concentrations of racemic MDA and MDMA for the EMIT-d.a.u. monoclonal amphetamine/methamphetamine immunoassay is approximately 3 mg/L.[199] The mean urine MDMA concentration in 43 urine samples collected from participants 1–8 hours after a rave party was 19.2 mg/L with a range of 0.11–173 mg/L.[197]

OTHER SAMPLING SITES

The vitreous humor is an alternate sampling site for postmortem MDMA concentrations, particularly following prolonged toxicity. Animal studies indicate that equilibration of the vascular compartment and vitreous humor occurs within 1 hour of the IV administration of MDMA, and MDMA remains relatively stable in the vitreous humor despite high ambient temperatures.[200] An 18-year-old man was found dead after a party the preceding evening.[201] The postmortem MDMA concentrations in samples from the right ventricular blood and the vitreous humor were 0.42 mg/L and 0.36 mg/L, respectively. The vitreous humor from a man found dead with high concentrations of MDMA (33.17 mg/L) in his stomach contained 1.63 mg MDMA/L, whereas the femoral blood contained 1.13 mg/L.[202] The concentrations of MDMA in urine and bile from this case were 0.79 mg/L and 25.42 mg/L, respectively. MDMA concentrations in hair suggest exposure to MDMA, but quantitative MDMA concentrations in hair (i.e., >1 ng/mg) are not reliable measures of the cumulative use of MDMA.[203] The distribution of enantiomers in hair is similar to other tissues with most of the hair specimens demonstrating a predominance of the R(−)-enantiomer.[204] However, the ratio of MDA/MDMA in hair samples from the hair is highly variable. In a study of hair from the heads of 53 chronic ecstasy users, this ratio varied from 1–110% with a mean of 12%.[205]

Abnormalities

BIOCHEMICAL

Leukocytosis occurs frequently after MDMA use.[37] Dilutional hyponatremia is a potential complication of MDMA use, particularly after the ingestion of large amounts of water. Severe hyperkalemia usually occurs in association with hyperthermia, metabolic acidosis, rhabdomyolysis, and renal failure, but hyperkalemia may develop in the absence of renal dysfunction.[206] Disseminated intravascular coagulation (thrombocytopenia, hypofibrinogenemia, hypoprothrombinemia, reduced partial thromboplastin levels, elevated fibrin split products) can occur after MDMA use, usually in association with multiple organ failure, rhabdomyolysis, and hyperthermia. Hypoglycemia is a rare complication of severe MDMA intoxication. Laboratory evidence of hepatic failure (elevated serum hepatic aminotransferases, alkaline phosphatase, bilirubin, prolonged prothrombin time, and activated partial thromboplastin time) may occur in the absence of hyperthermia.[106] Rhabdomyolysis may develop following MDMA use. Laboratory changes include elevated serum muscle enzymes (creatine kinase, aldolase), myoglobinuria, hyperbilirubinemia, hyperuricemia, hypocalcemia, hyperkalemia, renal failure, hyperphosphatemia, and hypokalemia.[121,139] Acute renal failure may develop secondary to acute tubular necrosis (as a result of hypotension), rhabdomyolysis, intravascular coagulation, hypovolemia, or hyperpyrexia. Hypoxemia may result from respiratory paralysis secondary to seizures, noncardiac pulmonary edema, or coma.

NEUROPSYCHOLOGIC

The heavy users have a high incidence of polydrug use (cocaine, lysergic acid diethylamide, amphetamine), and interpretation of the significance of the neuropsychologic scores is complicated by polydrug use as well as potential premorbid personality disorders. Although MDMA causes selective neurotoxic damage of central serotonergic neurones in laboratory animals,[207] the existence of neurotoxic syndrome following chronic MDMA abuse remains unproven as a result of issues related to retrospective data, methodologic flaws, and confounding (polydrug use, reporting bias, drug purity, premorbid personality disorders).[208] Despite substantial methodologic problems, the majority of the evidence suggests that residual alterations of serotonergic transmission occur in chronic MDMA users.[209] These changes at least partially resolve after long-term abstinence. The most consistent findings in heavy MDMA abuse are subtle, small–medium cognitive impairments,[210] particularly in short-term and long-term memory (e.g., verbal more than visual memory) and in the speed of information processing.[211,212] Volunteer studies suggest that verbal memory tasks with high cognitive complexity (e.g., California Verbal Learning Test, Verbal Paired

Associates) are more affected than low cognitive complexity tasks when comparing ecstasy users and non-users.[213] However, the lack of a clear dose-response relationship and similarity of changes in polydrug controls raise questions about the causal nature of this association.[214,215] Other deficits include increased impulsivity, poor problem solving, and deficits in executive skills. Studies of chronic ecstasy users suggest that the most vulnerable cognitive function is associative memory performance rather than working memory or attention, primarily in users who also abuse amphetamines.[216] More basic cognitive tasks are usually preserved including simple and choice reaction times, number vigilance, Stroop task (selective attention), and trail making (visuospatial ability, simple executive function).[217]

Driving

There are few data on the association of MDMA with vehicular accidents and related fatalities. Most studies to date indicate that the presence of MDMA is uncommon in impaired drivers or accident-related fatalities.[115] MDMA is rarely (<1%) detected in drivers associated with fatal accidents, but fatal injuries may result from reckless behavior during MDMA intoxication, particularly in association with ethanol.[218] The relationship between MDMA and driving is complex because of a number of factors including rapid tolerance, idiosyncratic responses, cognitive deficits following acute intoxication, and fatigue associated with strenuous activity during MDMA intoxication. In a case series of 6 drivers arrested for driving while impaired, blood samples contained only MDMA and the range of MDMA concentrations was <0.05–0.58 mg/L as measured by GC/MS.[183] The demeanor of these 6 individuals did not correlate to MDMA concentrations as the person with the highest concentration fell asleep in the police car during his arrest. Most of the individuals displayed muscle twitching, poor balance and coordination, mydriasis, and diaphoresis. In a Norwegian study of 9,013 drivers apprehended during 1998 and 1999 for suspicion of driving under the influence of alcohol or drugs, blood samples from 177 drivers (1.96%) contained detectable amounts of MDMA.[219] The median concentration of MDMA was 0.155 mg/L with a range from 0.019–1.14 mg/L. Many of these drivers were multidrug users, but the study did not separate the drivers into a group of MDMA-only users. In a Swiss study of 440 living drivers suspected of driving under the influence of drugs, blood samples from approximately 6% of the drivers contained MDMA.[220] The median MDMA concentration for this group was 0.218 mg/L with a range from 0.01–2.48 mg/L. In a subsequent Swiss study of 4,794 drivers apprehended for suspected driving under

the influence of drugs,[223] (4.7%) tested positive for MDMA in whole blood samples with a median MDMA concentration of 0.206 mg/L (Mean, 0.279 mg/L; range, 0.011–2.60 mg/L).[221] In a study of 493 drivers suspected of driving under the influence (moving traffic violations, sobriety checkpoints, traffic accidents), the mean blood MDMA concentration was 0.23 mg/L (median, 0.10 mg/L) with a range up to 3.5 mg/L.[222] The blood samples from some of these drivers contained other drugs as measured by GC/MS; the impairment of specific drivers in this series was not reported.

MDMA moderates the impairment in some, but not most driving skills associated with the ingestion of low to moderate doses of ethanol. In experimental studies on light-to-moderate MDMA users, the administration of a single dose of MDMA improved psychomotor performance on a compensatory tracking task and in a weaving and an on-the-road driving task, whereas estimation of time to contact in a dual attention task deteriorated.[223] In volunteer studies, the administration of MDMA (100 mg) and ethanol (0.8 g/kg) produced longer lasting euphoria and well-being than MDMA or ethanol alone.[70] MDMA reversed the sedative effects of ethanol, but the concomitant administration of MDMA did not alter the feeling of drunkenness. Eighteen healthy volunteers participated in a double-blind, placebo-controlled, cross-over study involving the administration of MDMA doses of 0, 75, and 100 mg with (mean blood alcohol content [BAC] = 0.042) and without alcohol.[224] Alcohol alone impaired critical tracking performance (critical tracking task, object movement estimation task) and actual driving performance parameters (i.e., standard deviation of lateral position [SDLP], brake reaction time, and coherence). MDMA alone reduced SDLP and standard deviation of speed. MDMA significantly moderated alcohol-induced impairment of road tracking performance, but MDMA did not modify the ethanol-induced impairments of car-following and laboratory task performance. In studies of simulated driving performance, recreational doses of MDMA did not dramatically alter lateral or longitudinal vehicle control, but the use of multiple drugs with MDMA significantly impaired driving performance.[225] The use of MDMA alone was associated with a decreased sense of risk taking. In a study of 12 healthy volunteers receiving 75 mg MDMA, this dose enhanced speed of manual movements and capacity to steer or track fast moving objects, including a divided attention task, when compared with placebo.[226] Additionally, there was no effect on visual search or planning. However, MDMA impaired the ability to perceive and predict motion, which is a measure of the ability of drivers to judge if another car would collide with their car.

TREATMENT

Stabilization

The major life-threatening complications of acute MDMA toxicity include hyperthermia, electrolyte abnormalities, cerebral edema, hypertension, seizures, ischemic complications, arrhythmias, hepatitis, and trauma. Severe hyperthermia (i.e., temperature >42°C/107.6°F) causes multiorgan failure and DIC, which are very poor prognostic signs. Patients with serious complications require IV access and close monitoring of temperature and electrolytes. Continuous cardiac monitoring is required if the initial electrocardiogram (ECG) or subsequent ECG is abnormal. Supplemental oxygen should be given to hypoxic patients and those with ischemic complications. Respiratory complications are not usually a major feature of toxicity. However, respiratory depression with impaired consciousness may occur, particularly following serious CNS complications (e.g., stroke, cerebral edema, hyponatremia).

Sinus tachycardia is common and this rhythm does not usually require direct pharmacologic intervention. Both hypertension and tachycardia often respond to benzodiazepines (e.g., adults: lorazepam 2 mg or diazepam 5 mg by IV bolus, repeated as required). Benzodiazepines are also the most appropriate first-line treatment for agitation not responding to simple reassurance. Pharmacologic agents are preferable to physical restraints in agitated patients, if possible. Core temperatures should also be measured frequently in any agitated patient, as the temperature may rise rapidly in response to physical activity including resistance to restraints.

Patients with suspected myocardial ischemia should be managed with nitrates, morphine, benzodiazepines, and aspirin. Hypotension may respond to fluid challenges, but often a vasopressor is needed. Beta blockers may lead to increased vasoconstriction and paradoxical worsening of hypertension (by blocking beta$_2$-mediated vasodilatation); in general, these drugs should be avoided.

SEIZURES

Seizures usually respond to benzodiazepines (lorazepam, diazepam). Therapeutic options for the treatment of recurrent seizures include phenobarbital and anesthetic agents (e.g., propofol). Sodium channel blocking drugs (e.g., phenytoin) are unlikely to terminate the seizures associated with MDMA toxicity. Hyperthermia, acidosis, hypoxemia, hyponatremia, and rhabdomyolysis may complicate the clinical course during status epi-

lepticus, and the patient should be evaluated for the presence of these complications. Mild to moderate hyponatremia usually responds to fluid restriction, but the use of hypertonic saline may be necessary with severe hyponatremia (<125 meq/L) associated with seizures. Central pontine myelinosis (osmotic demyelination syndrome) is usually associated with rapid restoration of serum sodium concentrations in patients with chronic hyponatremia; consequently, limitations on sodium replacement probably do not apply to patients with complications from *severe* hyponatremia secondary to acute MDMA intoxication.

AGITATION

Diazepam (Adults: 5 mg IV, children: 0.1–0.3 mg/kg) or lorazepam (1–2 mg IV in adults) are the safest drugs to use for agitation. Although hypotension, seizures, respiratory depression, and dystonic reactions are potential complications of antipsychotic drug use during MDMA intoxication, experimental studies on healthy volunteers receiving 1.5 mg MDMA/kg orally and 1.4 mg haloperidol intravenously did not detect any clinically significant adverse reactions.[227] In this study, the pretreatment of participants with haloperidol did not alter the physiologic responses (blood pressure, heart rate, body temperature) to MDMA compared with MDMA alone. The antipsychotic drugs (e.g., droperidol) should probably be second-line agents. Attention to environmental factors (soft lighting, minimal noise, familiar faces) may also help alleviate agitation.

HYPERTHERMIA

Severe hyperthermia (i.e., >42°C/107.6°F) is a very poor prognostic sign, particularly in association with multiorgan failure (hepatic failure, DIC, hypotension, rhabdomyolysis, hyperkalemia, metabolic acidosis); death may occur within a few days. Temperatures exceeding 39–40°C (102.2–104°F) should therefore be treated aggressively, while the core temperature is continuously monitored. Cooling should always include appropriate use of sedation (benzodiazepines). Other simple measures include removal of clothing, evaporative cooling with water applied with sponging or sprays and fans. Cooling blankets and ice packs may be used, but these measures are probably not superior to evaporative cooling. For refractory hyperthermia, neuromuscular paralysis, sedation, and mechanical ventilation may be necessary to reduce hypertonicity and hyperactivity. Immersion in an ice bath can also be used in refractory cases, but this approach often presents logistical problems. All vital signs should be monitored frequently and cooling measures continued until core temperatures are

below 38.5°C (101.3°F). If the temperature has exceeded 41°C (105.8°F) at any time, laboratory testing is required to detect multiorgan failure. If the hyperthermic patient does not respond rapidly to cooling measures, the IV administration of dantrolene is a therapeutic option. Case reports associate improvement in hyperthermia (42.9°C/109.2°F and 40.2°C/104.4°F), hyperkalemia, and rhabdomyolysis with the early administration of dantrolene (60 mg bolus q10 min ×3 and 1 mg/kg bolus ×3 over 1 hour).[140,228] However, the adjunctive role of dantrolene in the treatment of hyperthermia remains controversial.[139,229]

Gut Decontamination

There are no data to support the use of decontamination procedures on the clinical outcome of MDMA intoxication. Patients with adverse effects following recreational use are unlikely to have significant unabsorbed MDMA; decontamination is not usually warranted. Gut decontamination might be warranted in the case of symptomatic "body packers," and administration of activated charcoal and polyethylene glycol electrolyte lavage solution would be standard treatment. However, smuggling MDMA via body packers has not been reported to date.

Elimination Enhancement

MDMA is a weak base and acidification of urine increases the clearance of unchanged MDMA. However, it is unlikely that alteration of the urine pH will favorably improve the outcome of MDMA toxicity. Adverse effects usually occur early after ingestion and the half-life is relatively short (i.e., about 7–8 h). Most individuals already have acidic urine and systemic acidosis might increase cardiovascular adverse effects. There are no clinical data to confirm the efficacy of urinary acidification. There are no clinical data to support the use of hemodialysis, peritoneal dialysis, multiple-dose activated charcoal, or hemoperfusion. The large volume of distribution (6 L/kg) and the high endogenous clearance of MDMA suggest that these measures will not cause a clinically relevant increase in MDMA clearance.

Antidotes

There is no specific antidote for MDMA intoxication. Benzodiazepines (and occasionally other GABA agonist sedative drugs, such as barbiturates and propofol) provide adequate pharmacologic treatment for most manifestations of MDMA toxicity. Beta blockers are considered relatively contraindicated as they may increase hypertension and increase ischemia as a result of unopposed alpha agonist adrenergic effects. Serotonin antagonists, such as cyproheptadine 4–8 mg orally 3 times daily as needed or chlorpromazine 25–50 mg intramuscularly as needed in volume-replete patients, could be considered where the clinical syndrome resembles severe serotonin toxicity (i.e., severe hyperthermia, marked hyperreflexia with clonus).[133]

Supplemental Care

ANCILLARY TESTS

In severe MDMA toxicity, laboratory examination should include complete blood count, glucose, serum electrolytes, creatinine, blood ureas nitrogen (BUN), calcium, phosphorus, uric acid, creatine kinase, hepatic transaminases, a full coagulation profile (fibrin split products, fibrinogen, prothrombin time, partial thromboplastin time), and urine dipstick analysis (i.e., primarily to look for a positive response to the test for blood that might indicate myoglobinuria). An ECG should be done routinely and neuroimaging should be done in those with impaired consciousness, severe headache, or neurologic signs.

COMPLICATIONS

Severe MDMA toxicity may be complicated by a variety of problems, including multiorgan failure, hyperkalemia, hyponatremia, hepatitis, acute renal failure, rhabdomyolysis, cerebrovascular accident, myocardial infarction, arrhythmias, DIC, and acute respiratory distress syndrome. These conditions should be diagnosed early; however, management of these conditions should follow usual management procedures with appropriate supportive care and monitoring. There are no specific management considerations that relate to MDMA, except for the relative contraindication against using beta-blockers in the treatment of dysrhythmias, myocardial infarction, and hypertension. Hemodialysis may be required to correct electrolyte abnormalities in the presence of renal dysfunction. Patients with isolated fulminant acute liver failure after MDMA use may require liver transplantation.[106] Myoglobinuria is a frequent complication of serious MDMA toxicity. Although urinary alkalinization is frequently recommended for myoglobinuria, alkalinization may decrease MDMA clearance. Consequently, unless there is marked myoglobinuria, generous fluid replacement with high-volume urine flow is preferable to attempts to alter urine pH. Patients with mild MDMA intoxication may be discharged after 4 hours of observation if vital signs including temperature remain stable and the mental status returns to normal baseline.

Chapter 10

PSYCHOACTIVE PHENETHYLAMINE, PIPERAZINE, and PYRROLIDINOPHENONE DERIVATIVES

Brandon Wills, DO, MS
Timothy Erickson, MD

PHENETHYLAMINE COMPOUNDS

The term "phenethylamine or amphetamine (α-methyl phenethylamine) designer drugs" refers to drugs with varying stimulant and psychotomimetic properties that were originally synthesized to avoid legal restriction by altering the structure of known illicit drugs.[1] These synthetic drugs are usually substituted phenethylamine analogs based on variations of the basic phenethylamine structure (benzene ring with an ethylamine group on the first carbon). The 3 main classes of substances of abuse derived from phenethylamine as identified in Table 10.1 include the following: 1) amphetamine stimulants (amphetamine, methamphetamine), 2) single methylenedioxy-substituted amphetamine entactogens (e.g., 3,4-methylenedioxyamphetamine [MDA], 3,4-methylenedioxymethamphetamine [MDMA], 3,4-methylenedioxyethamphetamine [MDEA], N-methyl-1-(1,3-benzodioxol-5-yl)-2-butanamine [MBDB]), and 3) 3-fold ring substituted phenethylamine psychedelics (e.g., 2,5-dimethoxy-4-bromoamphetamine [DOB], 2,5-dimethoxy-4-ethylamphetamine [DOET], 4-methyl-2,5-dimethoxyamphetamine [DOM], 4-iodo-2,5-dimethoxyamphetamine [DOI]). Although originally applied to MDMA and MBDB,[2] amphetamine or phenethylamine designer drugs now refer to other methylenedioxy-substituted amphetamine compounds (e.g., MDEA, MBDB) that reportedly assist individuals experience a "touching from within." The phenethylamine molecule is also the basic chemical structure for endogenous catecholamines, neurotransmitters, and many therapeutic drugs (phenylpropanolamine, amphetamine, ephedrine).

The prototype psychoactive phenethylamine compound is mescaline (3,4,5-trimethoxyphenylethylamine), which is a natural constituent of the peyote cactus [*Lophophora williamsii* (Lem. ex Salm-Dyck) Coult.]. Although mescaline was a model for the studies of the structure-activity relationships of hallucinogenic drugs,[3] most of the synthetic compounds contained the 3-carbon chain of amphetamine.[4] Hence, the term "designer amphetamine drugs." In the early 1950s, Peretz et al. first described the hallucinogenic properties of the mescaline analog, 3,4,5-trimethoxyamphetamine (TMA).[5] In the 1960s and 1970s, Shulgin et al. investigated the clinical effects of a variety of methoxylated amphetamine compounds derived from mescaline.[6] He synthesized the mescaline analog, TMA from elemicin, and he reported that this drug produced changes in sensory perception at about half the usual dose of mescaline. Other drugs investigated by Shulgin et al. during the 1960s included 3-methoxy-4,5-methylenedioxyamphetamine (derived from myristicin) and ethyl homologs of 2,4,5-trimethoxyamphetamine (DOM, DOET).[7,8]

During the 1990s, the illicit drug market for hallucinogenic drugs changed considerably.[9] Newly marketed *para*-substituted methoxy street drugs included

*This list is not exhaustive—there are at least 200 potential substituted phenethylamine stimulant and psychedelic drugs including fluorinated derivatives.

†The family of trimethylamphetamine compounds includes at least 5 other isomers of TMA including TMA-2, TMA-3, TMA-4, TMA-5, and TMA-6.

4-methoxyamphetamine (PMA) and 4-methoxymeth-amphetamine (PMMA) as well as the *para*-substituted methylthio compound, 4-methylthioamphetamine (4-MTA). The newer designer amphetamines are often marketed on the street as MDMA (ecstasy), but these compounds may also be sold as the actual compound or as a street drug that publicize specific properties.[10,11] Table 10.1 classifies some of the most common amphet-amine designer drugs groups based on location and type of substituents. The psychotomimetic properties of

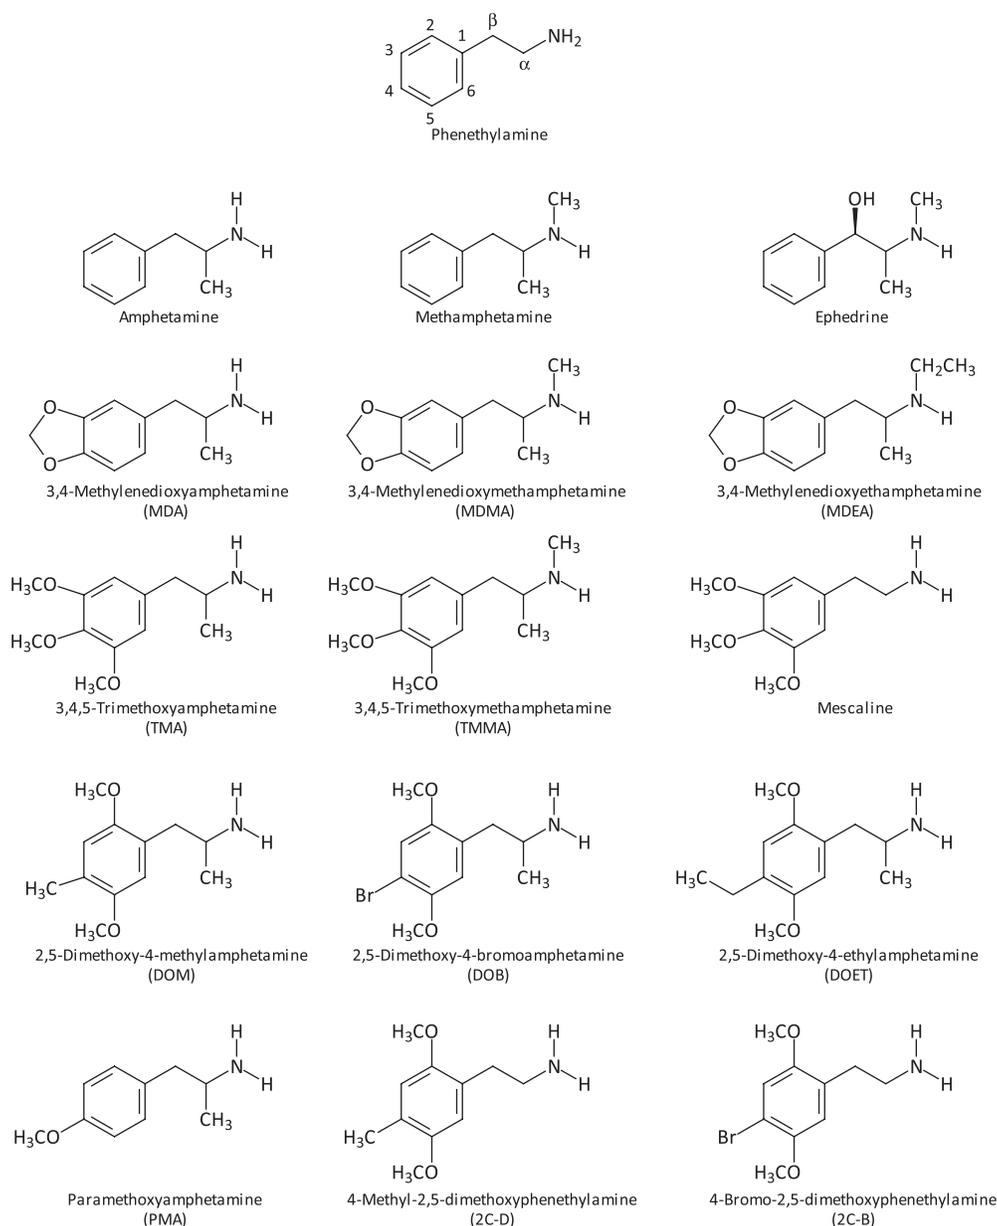
phenethylamine compounds are usually several-fold more potent for the *R* (−)-enantiomers than for the *S* (+)-enantiomers.[12] Substituents often enhance potency, particularly bromine at the *para* position of the benzene ring of phenethylamine compounds.[13] Figure 10.1 compares the chemical structures of various substituted amphetamine designer drugs. Fluoromethoxyamphetamine derivatives are not listed in this figure as these compounds are uncommon and little is known about their properties.[14]


FIGURE 10.1. Comparative chemical structures of phenethylamine and related hallucinogenic compounds.

3,4-Methylene-dioxyamphetamine (MDA)

German scientists synthesized MDA in the early 1910s. In the late 1950s and early 1960s, MDA was patented as a cough suppressant, a tranquilizer, and an appetite suppressant; however, MDA was never marketed for medical purposes.[15] During the 1970s, MDA and MDMA were pharmaceutical adjuncts to psychotherapy;[16] however, the US Drug Enforcement Administration (DEA) added both these drugs to schedule I after reports of the abuse of these drugs in the 1980s.[17] Some controversy surrounded this decision as a result of the subsequent limitations to research, primarily from therapists using MDMA to enhance self-disclosure and promote trust in patients undergoing psychotherapy.[18]

IDENTIFYING CHARACTERISTICS

Like most designer amphetamines, MDA (tenamfetamine, [INN]) exists as the free base or as the salt of various acids. These salts are water soluble; therefore, potential routes of administration include ingestion, insufflation, and intravenous (IV) injection.[19] The high boiling point and low vapor pressure of MDA and other methylenedioxyamphetamine designer drugs limit the use of these drugs via inhalation of vapors.

Table 10.2 lists some physiochemical properties of MDA. In contrast to most amphetamine designer drugs, the S (+)-enantiomer of MDA is more potent than the R (−)-enantiomer.[20]

EXPOSURE

Synthesis of MDA involves the intermediate, nitropropane, which is prepared from 4-methylthiobenzaldehyde, nitroethane, and n-butylamine.[21] Tablets sold as ecstasy

TABLE 10.2. Some Physiochemical Properties of 3,4-Methylenedioxyamphetamine (MDA)

Physical Property	Value
pKa Dissociation Constant	9.67 (25°C/77°F)
log P (Octanol-Water)	1.64
Water Solubility	2.25E+04 mg/L (25°FC/77°F)
Vapor Pressure	1.69E-03 mm Hg (25°FC/77°F)

(MDMA) usually contain a single substance, but analysis of street drugs sold as ecstasy may contain MDA or other structurally similar drugs (MDEA, PMA, MBDB).[22]

TOXICOKINETICS

There are few toxicokinetic data on amphetamine designer drugs other than MDMA. MDA is a metabolite of MDMA biotransformation in humans.[23] The absorption of MDA is relatively rapid with time to peak plasma concentrations of approximately 3 hours.[24] MDA is the parent drug of MDMA and a N-demethylated metabolite of MDMA as well as MDEA.[23] Biotransformation of MDA occurs by demethylenation to the corresponding catecholamine via primarily CYP2D6 based on *in vitro* studies.[25] Postmortem analyses suggest that the bile contains significant amounts of MDA.[26] There are several potential sources of drug-drug interactions with amphetamine designer drugs, but the clinical relevance of these potential drug interactions remains unclear. Although human polymorphism of CYP2D6 or the concomitant ingestion of CYP2D6 inhibitors (e.g., fluoxetine, paroxetine, quinidine) potentially alters the metabolism of amphetamine designer drugs, there is no definite evidence that this potential effect produces clinically significant effects. Theoretically, polymorphism of CYP2D6 may cause decreased metabolism of MDA and MDEA and relatively higher drug concentrations.

HISTOPATHOLOLGY AND PATHOPHYSIOLOGY

In general, animal studies indicate that phenethylamine designer drugs are indirect sympathomimetic agents that increase the release of biogenic amines by binding and blocking the transport of these neurotransmitters including serotonin, norepinephrine, and to a lesser extent, dopamine.[27] Modulation of serotonergic neurotransmission probably mediates the thermoregulatory and altered perceptions associated with the use of these drugs, whereas dopaminergic neurotransmission modulates stimulant effects (e.g., muscle tone). The ability of these drugs to alter neurotransmitter release and clearance varies with both the drug and the receptor density in the particular area of the brain examined.[28] MDA has both central stimulant effects and psychotomimetic properties.[29]

Substituted amphetamines are indirect sympathomimetics with similar pathophysiology as amphetamine and methamphetamine. Psychotomimetic amphetamine designer drugs (e.g., MDMA, MDA) affect serotonergic pathways more than dopaminergic pathways. There are

limited human data on the individual differences between amphetamine designer drugs other than MDMA; however, the pathophysiology of these amphetamine designer drugs is probably similar to MDMA.

CLINICAL RESPONSE

There is very little data regarding tolerance, addition, and abstinence following the use of amphetamine designer drugs including MDA. Presumably, the complications of MDA and MDMA use are similar. Muscle stiffness, depression, fatigue, anxiety, and difficulty concentrating are common complaints within 1 to 2 days after use of amphetamine designer drugs like MDMA.[30] Semistructured interviews of ecstasy users indicate that a majority of individuals feel that they develop tolerance to the effects of drugs purported to be MDMA.[31]

Analytic Methods

SCREENING

The enzyme-linked immunosorbent assays (ELISA) are rapid methods for the detection of methylenedioxy-amphetamine designer drugs in the urine based on using d-amphetamine equivalents as the cutoff.[32] The cross-reactions of MDA with urine amphetamine immunoassays are variable,[96] and screening biologic samples with chromatographic methods (e.g., liquid chromatography/tandem mass spectrometry, gas chromatography/mass spectrometry [GC/MS]) is necessary to confirm the presence of amphetamine designer drugs.[33] The Abbott Abuscreen® ONLINE amphetamine immunoassay (Abbott Laboratories, Abbott Park, IL) tested positive for urine MDA concentrations exceeding 3,000 ng/mL.[34] The cross-reactivity of MDA with the reagents of the Abbott TDx® fluorescence polarization immunoassay (FPIA) amphetamine/methamphetamine II is high (136–170%);[35] additionally, MDA is a minor metabolite of MDEA biotransformation. The cross-reactivity of the other MDA metabolites [3,4-dihydroxyethylamphetamine (DHE), 4-hydroxy-3-methoxyethylamphetamine (HME), 3,4-dihydroxyamphetamine (DHA), 4-hydroxy-3-methoxyamphetamine (HMA) ranged between 0.03% and 0.4%. The presence of MDA concentrations of approximately 10–15% of the MDMA concentration is consistent with MDMA metabolism to MDA;[36] these MDA concentrations do not necessarily indicate the ingestion of MDA.[37] A negative amphetamine immunoassay screen does not exclude the recent use of ring-substituted phenethylamine drugs including MDA. The multiplex cloned enzyme donor immunoassay (CEDIA® Amphetamines/Ecstasy, Microgenics Corp., Fremont, CA) has greater sensitivity and specificity for MDA and other ring-substituted phenethylamine drugs.[38] At the 500-ng/mL cutoff, this immunoassay detects most of these compounds. Table 10.3 lists the cross-reactivity of various ring-substituted phenethylamine compounds with the CEDIA® Amphetamines/Ecstasy assay.

CONFIRMATION

Methods for the confirmation and quantitation of amphetamine designer drugs in biologic samples include thin layer chromatography, capillary electrophoresis,[39] GC/MS,[40,41] liquid chromatography/tandem mass spectrometry,[42] and liquid chromatography/atmospheric pressure chemical ionization/mass spectrometry.[43] The use of liquid chromatography/tandem mass spectrometry allows the detection of tryptamine, piperazine, pyrrolidinophenone, phenylcyclohexyl, and other amphetamine derivates with a limit of detection (LOD) ranging between 1–5 ng/mL. The LOD for methylenedioxy-amphetamine designer drugs using liquid chromatography/atmospheric pressure chemical ionization/

TABLE 10.3. Cross-reactivity of compounds by CEDIA® Amphetamines/Ecstasy Assay. Adapted from Reference 38.

Compound	Concentration (ng/mL)	Cross-reactivity (%)
d-Amphetamine	500	100
d-Methamphetamine	500	100
3,4-Methylenedioxyamphetamine (MDA)	500	113
3,4-Methylenedioxymethamphetamine (MDMA)	250	199
3,4-Methylenedioxyethylamphetamine (MDEA)	250	207
N-Methyl-1-(3,4-methylenedioxyphenyl)-2-butanamine (MBDB)	500	123
1-(3,4-methylenedioxyphenyl)-2-butanamine (BDB)	500	72*
p-Methoxymethamphetamine (PMMA)	300	100
p-Methoxyamphetamine (PMA)	2,000	24†

*Concentration for a positive result, 694 ng/mL.
†Concentration for positive result, 2,174 ng/mL.

mass spectrometry ranges between 1–2 ng/mL compared with 10 ng/mL for GC/MS.[44] The lower limit of quantitation (LLOQ) for GC/MS is 25 ng/mL. Following propylchloroformate derivatization and automated solid-phase microextraction with capillary GC, the LOD for MDA urine samples is about 15 ng/mL.[45] Liquid chromatography using derivatization with 9-fluorenyl-methyl chloroformate allows the relatively rapid quantitation of MDA in the range of 10 ng/mL compared with the more time-consuming method, GC/MS.[46] The analysis time using liquid chromatography/tandem mass spectrometry for the quantitation of MDA in biologic materials is about 20 minutes with a LLOQ in the range of 2 ng/mL.[47] The use of gas chromatography/negative-ion chemical ionization/mass spectrometry allows the quantitation of the enantiomers of MDA, and MDEA in plasma samples with LLOQ for the latter 2 compounds near 5 ng/mL.[48] Analytic methods to profile samples of amphetamine designer drugs (e.g., MDA) include HPLC with fluorometric detection,[49] capillary electrochromatography,[50] GC/MS, and thin-layer chromatography with solid-phase extraction.[51]

MDA is stable in serum, whole blood, and urine when stored under frozen conditions (-20°C/-4°F) for at least 21 weeks.[52] This compound is also stable under refrigeration (4°C/39.2°F) and room temperature (20°C/68°F); however, degradation of the biologic matrix may limit analysis of these samples. MDA is detectable in hair samples utilizing liquid chromatography/atmospheric pressure chemical ionization/mass spectrometry with a LOD of 0.05 ng/mg.[53]

Biomarkers

Animal studies indicate that MDA concentrates in erythrocytes with a mean erythrocyte/plasma ratio of 1.45 ± 0.08, similar to MDMA.[54] A case report suggests that the ratios of vitreous humor/femoral blood for MDA are relatively similar after complete absorption and distribution.[26] Postmortem redistribution of MDA may occur, particularly following prolonged postmortem interval. In postmortem blood drawn over 2 days after death related to MDMA intoxication, samples of the heart and femoral blood contained MDA concentrations of 1.33 mg/L and 0.19 mg/L, respectively, with heart/femoral blood ratio of 7.[55]

TREATMENT

The management of intoxication with amphetamine designer drugs including MDA is similar to the treatment of methamphetamine toxicity. The majority of patients presenting with amphetamine designer drug-induced toxicity require only reassurance, a quiet environment, and benzodiazepines as needed.[135]

Stabilization

Clinical features of serious intoxication with amphetamine designer drugs include coma, shock, acute renal failure, severe hyperthermia (i.e., temperature >40–42°C/104–107.6°F), and seizures. Severely intoxicated patients require IV access, cardiac monitoring, pulse oximetry, an electrocardiogram (ECG), and supplemental oxygen. Respiratory depression does not usually occur during mild to moderate intoxication, but respiratory failure requiring intubation may develop during serious intoxication. All patients with altered consciousness should be evaluated with a rapid blood glucose test (e.g., Accu-Chek®, Roche, Nutley, NJ). Core temperatures must be measured in any agitated patient with initiation of aggressive cooling measures (evaporative cooling, ice water baths) for core temperatures exceeding 40°C (104°F). Hypotension is frequently associated with substantial fluid deficits and these patients require aggressive fluid resuscitation. Lidocaine and amiodarone are drugs of choice for stable monomorphic or polymorphic ventricular tachycardia, particularly in patients with underlying impaired cardiac function. Unstable ventricular rhythms may require cardioversion. Although there are few data on amphetamine designer drugs, the administration of IV sodium bicarbonate is a therapeutic option for wide complex QRS tachycardia, similar to cocaine-induced cardiotoxicity.[56] Shock is a poor prognostic sign that indicates the need for continuous invasive or noninvasive hemodynamic monitoring to optimize the combination of fluid infusion and vasopressors.

HYPERTENSION/TACHYCARDIA

Most patients tolerate sinus tachycardia and hypertension associated with the ingestion of amphetamine designer drugs without pharmacologic intervention, unless elevated blood pressure and/or tachycardia contribute to myocardial ischemia or end organ failure. Both hypertension and tachycardia typically respond to IV benzodiazepines (adults: lorazepam 2 mg or diazepam 5 mg IV bolus titrated to effect).

If hypertension persists and is associated with adverse clinical effects, the use of nitroprusside or a calcium channel blocker is appropriate. Although β-adrenergic blocking agents (e.g., esmolol, labetalol) can reduce clinically significant tachycardia, these drugs potentially exacerbate hypertension by the vasoconstriction caused by unopposed alpha agonist stimulation following blockade of the vasodilating properties of

beta$_2$-adrenergic receptors. Consequently, beta-blockers are usually considered only for very high heart rates because of concern about the development of vasospasm and worsening hypertension. If beta-blockers are administered, then the concurrent administration of a vasodilator (e.g., nitroprusside) should be considered.[57] Intravenous nitroprusside (0.5–8 μg/kg/min) is the drug of choice for hypertensive emergencies with evidence of end organ injury (central nervous system [CNS], cardiac, or renal dysfunction). Intravenous nitroglycerin and phentolamine (2.5–5 mg initial IV bolus) are alternatives to the use of IV nitroprusside.

AGITATION

As a result of the sympathomimetic and psychotomimetic properties of amphetamine designer drugs, the patient often presents with agitation, restlessness, tachypnea, and tachycardia. Treatment options for agitation include diazepam (Adults: 5–10 mg IV, Children: 0.1–0.3 mg/kg), lorazepam (Adults: 1–2 mg IV) or midazolam; these drugs should be titrated to the desired clinical effect.[135] Phenothiazine compounds (chlorpromazine) are not routinely recommended due to potential undesirable side effects (orthostatic hypotension, seizures) even though chlorpromazine has some protective effects against lethal doses of MDA when administered prophylactically in animal models.[58,59] The presumed mechanism of action is dopaminergic blockade, but there are no human clinical data to confirm the efficacy of phenothiazine compounds in humans. Haloperidol is an option for the treatment of delirium in critically ill patients. A calm environment and familiar faces may also help alleviate agitation.

SEIZURES

Seizures are usually self-limited and respond to benzodiazepines (lorazepam, diazepam). Therapeutic options for the treatment of status epilepticus include phenobarbital and anesthetic agents (e.g., propofol, midazolam IV infusion). Hyperthermia, acidosis, hypoxemia, hyponatremia, or rhabdomyolysis may complicate the clinical course during status epilepticus; seriously intoxicated patients should be evaluated for the presence of these complications.

HYPERTHERMIA

Hyperthermia (i.e., core temperature >40–42°C/104–107.6ºF) should be treated aggressively because this complication is frequently associated with a fatal outcome and signs of end-organ failure (hypotension,

hyperkalemia, metabolic acidosis, rhabdomyolysis, elevated serum creatine kinase, coagulopathy).[60] Cooling measures include removal of clothing; cool rooms; cool mist spray to the skin; liberal use of fans, ice baths, and sedation (benzodiazepines). Ice-bath immersion produces the most rapid response, but technical difficulties frequently limit the use of this modality. The use of hypothermic blankets or the application of ice packs often does not produce sufficient cooling for these patients. For refractory hyperthermia, neuromuscular paralysis, sedation, and mechanical ventilation may be necessary to reduce muscle rigidity and hyperactivity. Vital signs should be followed closely (i.e., every 15–20 min) and cooling measures continued until rectal temperatures are below 38.5°C (101.3ºF). Several case reports suggest that IV dantrolene (total dose: 1–10 mg/kg) may reduce muscular hyperactivity and hyperthermia associated with amphetamine designer drug toxicity in patients unresponsive to conventional measures to treat hyperthermia.[61,62] Although many of the clinical features of amphetamine designer drug intoxication resemble the serotonin syndrome, the use of nonselective serotonin antagonists (methysergide, cyproheptadine) has not been well defined because of the lack of clinical data.[63,64] Animal studies suggest that carvedilol (α_1-, $\beta_{1,2,3}$-adrenergic receptor antagonist) is a potential treatment for hyperthermia associated with amphetamine designer drugs.[65,66] However, there are inadequate clinical data to determine the efficacy of this drug for hyperthermia in this setting.

Gut Decontamination

There are few data on the effect of decontamination procedures on the clinical outcome of toxicity associated with amphetamine designer drugs. Most patients present more than 1 hour after ingestion; the use of activated charcoal in these patients is not expected to improve outcome. Additionally, the administration of activated charcoal is difficult and aspiration is a significant risk because many of these patients are agitated upon presentation to the emergency department (ED). In a study of mice, the administration of 1g activated charcoal/kg 1 minute after gavage with 100 mg methamphetamine/kg delayed the onset of toxicity, but did not alter mortality.[67]

Elimination Enhancement

There are few, if any clinical data on the efficacy of hemodialysis, forced acid diuresis, and hemoperfusion during amphetamine designer drug intoxication. The large volume of distribution of these drugs suggests that

these measures will not significantly increase the elimination rate of these compounds. Acidification of the urine potentially increases the incidence of rhabdomyolysis and renal dysfunction.

Antidotes

There are no specific antidotes for the complications associated with the ingestion of amphetamine designer drugs.

Supplemental Care

ANCILLARY TESTS

Depending on clinical judgment and severity of poisoning, laboratory examination for severe intoxications should include complete blood count, serum tests (electrolytes, calcium, phosphorus, uric acid, creatine kinase, hepatic transaminases, creatinine, glucose, blood urea nitrogen), coagulation profile (platelet count, fibrin split products, fibrinogen, prothrombin time, partial thromboplastin time), urinalysis including myoglobin, arterial blood gases, chest x-ray, ECG, cardiac monitoring, and appropriate diagnostic neurologic examinations (i.e., computed tomography [CT], cerebral angiography, lumbar puncture). The use of the urine dipstick is a convenient method to detect the presence of hemoglobin or myoglobin at concentrations above 5–10 mg/L.[68] After the cessation of the myoglobin formation, hepatic metabolism and renal excretion clear plasma myoglobin within 1–6 hours. The presence of myoglobinuria suggests rhabdomyolysis, which necessitates generous fluid replacement; urinary alkalinization is not necessary, particularly because the excretion of amphetamine designer drugs potentially decreases in alkaline urine.

COMPLICATIONS

Severe amphetamine designer drug intoxication may be complicated by acute renal failure, rhabdomyolysis, acute compartment syndrome, subarachnoid hemorrhage, intracerebral hematoma, cerebral edema with transtentorial herniation, disseminated intravascular coagulation (DIC), and adult respiratory distress syndrome. Laboratory examinations and repeat physical examinations are necessary to diagnose these conditions early. Management is primarily supportive, but surgery may be required for intracranial lesions or compartment syndromes. Supportive care for compartment syndrome includes analgesics, elevation of extremities,

elimination of exposure to amphetamine designer drugs, low-molecular-weight dextran, and consideration of the use of anticoagulant or antiplatelet drugs. Fasciotomies are usually unnecessary unless there is clear evidence of high compartment pressures and associated distal ischemia.

Hyponatremia may result from syndrome of inappropriate antidiuretic hormone hypersecretion (SIADH); therefore, hyponatremia may not respond to the IV administration of 0.9% NaCl. Fluid restriction after the replacement of fluid losses is generally the treatment for hyponatremia secondary to SIADH. If severe or life-threatening hyponatremia develops, slow correction with 3% NaCl should be considered.[69] Alterations in the urinary sodium may require up to 24 hours to manifest; hence, urinary sodium concentrations can be misleading within this period.[70]

Patients exhibiting hemodynamic compromise, end-organ injury, hyperthermia, cardiotoxicity, or recurrent seizure activity should be admitted to a monitored bed or intensive care setting. Stable patients who respond to supportive care and sedation may be observed in the emergency department setting and discharged with proper drug counseling referral if there are no significant psychiatric issues.

3,4-Methylenedioxyethamphetamine (MDEA)

Alexander T. Shulgin first reported the psychedelic effects of 3,4-methylenedioxyethamphetamine (MDEA; CAS RN: 82801-81-8) in the late 1970s.[71] MDEA entered the street drug market in the late 1980s as a legal substitute for MDMA. However, MDEA became a DEA controlled schedule I drug in 1987 based on new US laws prohibiting analogs of controlled substances (e.g., MDA, MDMA). In the early 1990s, MDEA became a controlled substance in Germany and the Netherlands. Iwersen and Schmoldt reported the first fatal case of MDEA intoxication in 1996.[72]

EXPOSURE

Although MDMA or ecstasy tablets usually contain a single substance, MDEA is one of several ring-substituted amphetamine compounds (e.g., MDA, MBDB) frequently sold as ecstasy. Analysis of 12 different sets containing 10 confiscated ecstasy tablets each demonstrated that 97% of the tablets contained a single

substance as measured by HPLC and near infrared spectroscopy in reflectance mode.[73] About 47% of the tablets were MDMA, whereas approximately 43% were MDEA. The term "ecstasy" now includes other ring-substituted amphetamine compounds beside MDMA including MDEA, MDA, and MBDB. Besides ecstasy, street names for MDEA include Eve and Intellect. The typical recreational dose of MDEA is 1–3 tablets with the amount ranging from 60–175 mg per tablet.[74] The frequent substitution of MDMA for MDEA or the adulteration of MDEA with MDMA complicates the interpretation of reports on the effects of MDEA that do not include analytic confirmation of the exposure.

TOXICOKINETICS

Absorption

The absorption of MDEA is relatively rapid with time to peak plasma MDEA concentration (C_{max}) ranging between 1.5–3 hours.[24] In a study of 14 healthy volunteers receiving 100–140 mg MDEA hydrochloride, peak plasma MDEA concentrations ranged from 235–465 ng/mL (mean, 332 ng/mL) 1.8–5.0 hours (mean, 2.9 h) after ingestion.[75] The peak plasma MDA concentration (i.e., as a result of MDEA metabolism) occurred 4–7 hours (mean, 5.5 h) after ingestion with a range from 7–33 ng/mL (mean, 23 ng/mL). In a study of 5 healthy volunteers, the mean C_{max} of the $R(-)$-enantiomer of MDEA following the ingestion of 70 mg MDEA was greater than the $S(+)$-enantiomer (127 ± 34 ng/mL vs. 80 ± 30 ng/mL) with similar mean time to maximum concentrations (2.8 ± 0.9 h vs. 2.6 ± 0.6 h).[76]

Biotransformation

The metabolism of amphetamine designer drugs primarily involves O-demethylation and, to a lesser extent, N-dealkylation.[77] *In vitro* studies indicate that humans metabolize methylenedioxy-substituted amphetamine entactogens by 1) demethylenation followed by catechol-O-methyl transferase-catalyzed methylation and/or conjugation with glucuronide or sulfate; and 2) N-dealkylation, deamination, and oxidation (MDMA, MDA, MDEA only) to the corresponding benzoic acid derivatives along with glycine conjugation. The cytochrome P450 isoenzymes, CYP2D1/6 or CYP3A2/4 catalyze the demethylenation pathway along with other cytosolic enzymes. N-Dealkylation occurs via cytochrome P450 isoenzymes CYP2D6 and CYP3A4 with lesser contributions from CYP1A2 and CYP2B6.[78] These reactions are enantioselective with a preference for the S-enantiomers based on *in vitro* studies.[79] N-

Deethylation of MDEA is catalyzed predominately by CYP3A2/4 and to a minor extent by CYP1A2 and CYP2D1.[80] Figure 10.2 compares the metabolic pathways and cytochrome P450 isoenzymes involved with the biotransformation of MDEA and MDA with MDMA. The deethylation of MDEA produces the active metabolite, MDA.

R,S-Methylenedioxyethamphetamine (MDEA) undergoes ring degradation by O-dealkylation to the corresponding 3,4-dihydroxy metabolites followed by methylation of the hydroxyl group at position 3 of the aromatic ring. Degradation of the side chain by N-dealkylation produces the corresponding primary amines, and oxidative N-deamination forms the substituted phenylacetone compounds that are degraded to the corresponding benzoic acids and conjugated with glycine to form substituted hippurates. Following ingestion of 140 mg MDEA by 9 healthy volunteers, the main metabolites detectable in the urine were 3,4-dihydroxyethylamphetamine (DHE), 3,4-methylenedioxyamphetamine (MDA), and 4-hydroxy-3-methoxyethylamphetamine (HME).[81] Although MDA is an active metabolite, there are inadequate data to determine the concentrations of MDA or other metabolites that are sufficient to contribute to the clinical effects of MDEA. Minor metabolites included 3,4-dihydroxyamphetamine (DHA), 4-hydroxy-3-methoxyamphetamine (HMA), piperonyl acetone, 3,4-dihydroxyphenyl acetone, and 4-hydroxy-3-methoxyphenyl acetone. In this study, the peak plasma MDA concentrations (7–33 ng/mL) were relatively low compared with peak plasma HME concentrations (67–673 ng/mL).

Elimination

The major urinary metabolite of MDEA is 4-hydroxy-3-methoxyethlamphetamine (HME). In the above study of 9 human volunteers receiving 140 mg MDEA, urinary HME accounted for elimination of about 32% of the dose during the first 32 hours after ingestion.[81] The mean percentage of the MDEA dose excreted unchanged in the urine during this period was 19%.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

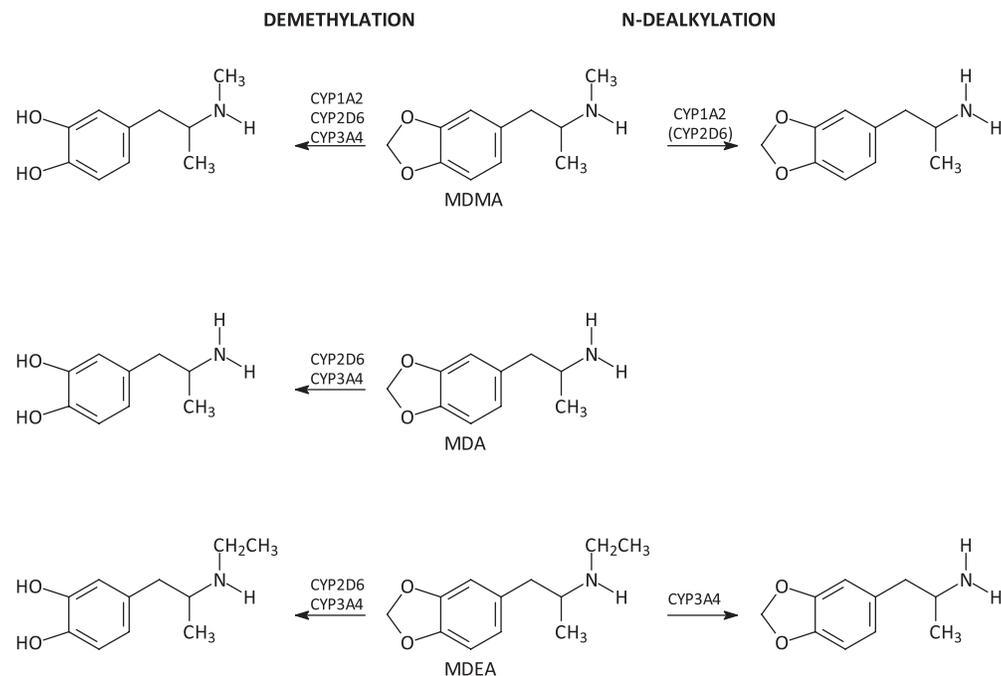
MDEA is an indirect serotonergic agonist, similar to MDMA; additionally, MDEA (and MDMA) release smaller amounts of dopamine and norepinephrine from intracellular stores. The primary site of action is probably the serotonin transporter and the presynaptic plasmalemma where MDEA and MDMA are substrate-type serotonin releasers.[74] Similar to other methylenedioxy-substituted entactogens, direct agonist effects on the


FIGURE 10.2. Human cytochrome P450 (CYP) pathways of the biotransformation of methylenedioxyamphetamine designer drugs, MDMA, MDA and MDEA. Minor CYP isoenzymes are listed in parentheses.

$5-HT_2$ receptors probably account for the psychedelic alterations of perception.

The postmortem examination of fatalities from amphetamine designer drugs including MDEA reveals abnormalities related to hyperthermia, seizures, rhabdomyolysis, DIC, and cardiac arrest associated with fatal intoxications involving MDEA.[82] Thus, autopsy results from of these patients resemble the examination of cases of heat stroke.[83] These histologic changes include evidence of coagulopathy with scattered subcutaneous bruises, hemorrhagic pleural effusion, epicardial petechiae, pulmonary hemorrhage, hemorrhagic gastritis, focal pericardial hemorrhage, and renal tubular necrosis.[84] Other findings include intracerebral hemorrhage and cerebral edema.[137,141] Pulmonary and cerebral congestion are common postmortem finding in deaths related to overdoses. Full rigor mortis may be present with elevated body temperature in the period shortly after death.[85]

CLINCAL RESPONSE

MDEA has both stimulant effects (increased endurance, alertness, sexual arousal) similar to amphetamine as well as psychedelic effects (euphoria, perceptual alterations, sociability, increased sense of empathy and tolerance) similar to MDMA and 3-fold ring-substituted phenethylamine psychedelics (e.g., DOB, DOM). Undesirable side effects following recreational use and during clinical trials include restlessness, muscular tension, agitation, bruxism, restless leg syndrome, muscle stiffness, headache, nausea, anorexia, insomnia, dry mouth, depersonalization, mydriasis, tachycardia, and elevated blood pressure.[74,86] There are inadequate data to determine the prevalence of these adverse effects in patients ingesting MDEA. Most individuals using MDEA or MDMA at dance parties do not develop serious clinical complications, and individual susceptibility may contribute to the occurrence of fatalities after the use of these drugs.[87] Manifestations of serious MDEA intoxication include coma, seizures, hyperthermia, severe rhabdomyolysis, hepatorenal failure, and arrhythmias, similar to severe MDMA toxicity.[88] Vivid auditory and visual hallucinations, dysphoria, agitation, disorientation, and paranoia may occur following the ingestion of typical recreational doses (e.g., 140 mg) of MDEA.[89] Fatalities associated with MDEA involve hyperthermia, DIC, and multiorgan failure, similar to MDA and MDMA.[90]

Although there are few data on single methylenedioxy-substituted amphetamine entactogens other than MDMA, there is concern about the potential neurotoxicity of MDEA and similar compounds based on animal studies, clinical studies, and indirect evidence

from postmortem examination of chronic MDMA users.[91,92] Polydrug use in these individuals limits conclusions regarding the potential causal role of amphetamine designer drugs in the development of these sequelae.

DIAGNOSTIC TESTING

Analytic Methods

Similar to MDMA and 4-substituted amphetamines (PMA, PMMA, PMEA, 4-MTA), MDEA cross-reacts with immunoassays for amphetamines and methamphetamines. In a study of the Bio-Quant Direct® ELISA kit (Bio-Quant, San Diego, CA) for amphetamine, the cross-reactivity of MDEA with a concentration equivalent to 50 ng/mL amphetamine was 18% compared with MDA (282%), PMA (265%), 4-MTA (280%), and MDMA (73%).[93] Following propylchloroformate derivatization and automated solid-phase microextraction with capillary gas chromatography, the LOD for MDEA in urine samples is approximately 5 ng/mL.[45] Liquid chromatography using derivatization with 9-fluorenylmethyl chloroformate allows the relatively rapid quantitation of MDEA in the range of 25 ng/mL compared with the more time-consuming method, GC-MS.[46] The use of gas chromatography/negative-ion chemical ionization/mass spectrometry allows the quantitation of enantiomers of MDA and MDEA in plasma samples with LLOQ for the latter 2 compounds near 5 ng/mL.[48] Analysis of hydrolyzed urine samples with GC/MS allows the quantitation of MDEA metabolites (HMA, HMMA) with an LLOQ in the range of 25 μg/L and coefficient of variation (CV) <15%.[94] Separation of MDEA from MBDB and other regioisomeric 3,4-methylenedioxyphenethylamines requires GC/MS after formation of perfluoroacyl derivatives, heptafluorobutrylamides, and pentafluoropropionylamides.[95] MDEA is detectable in hair samples utilizing liquid chromatography/atmospheric pressure chemical ionization/mass spectrometry with a LOD of 0.05 ng/mg.[53]

High performance liquid chromatography with UV detection is primarily used to analyze methylenedioxyamphetamine designer drugs (e.g., MDEA) in street samples rather than in biologic samples because of the low absorptivity of amphetamines.[49] MDA, MDMA, and MDEA are stable in serum, whole blood, and urine when stored under frozen conditions (–20ºC/–4ºF) for at least 21 weeks.[52] This compound is also stable under refrigeration (4ºC/39.2ºF) and room temperature (20ºC/68ºF); however, degradation of the biologic matrix may limit analysis of these samples.

Biomarkers

BLOOD

A 20-year-old man was arrested for speeding and driving under the influence. His blood MDEA and ethanol concentrations were 0.59 mg/L and nondetectable, respectively.[96] The postmortem blood (source not identified) from a 27-year-old woman, who was found in cardiopulmonary arrest, contained a MDEA concentration of 1.2 mg/L along with diazepam and caffeine.[97] A 21-year-old man was found in cardiopulmonary arrest and resuscitation efforts were unsuccessful.[98] The postmortem examination demonstrated concentric left ventricular hypertrophy and an absence of significant coronary atherosclerosis. The postmortem blood MDEA concentration (site not reported) was 2.0 mg/L along with 0.26 mg propoxyphene/L and 1.0 mg norpropoxyphene/L. A 19-year-old man died despite resuscitative efforts after developing diaphoresis, agitation, hallucinations, muscle spasms, respiratory failure, and coma.[82] A postmortem femoral blood sample contained only 12 mg MDEA/L. Postmortem redistribution of MDEA may occur, particularly following a prolonged postmortem interval.

URINE

An analysis of the performance of 2 different amphetamine reagents (amphetamine/methamphetamine II, amphetamine class) utilizing the Abbott TDx™ immunoassay demonstrated marked variability in the reaction of 22 phenethylamine compounds to the reagents with MDA, PMA, and MDEA demonstrating the highest reactivity.[99,100] At concentrations of 1 mg/L, crossreactivity with other designer drugs (e.g., DOM, DOB, TMA, 2C-B) is unlikely. The Abbott Abuscreen® ONLINE amphetamine immunoassay tested positive for urine MDEA concentrations exceeding 50 mg/L.[34] In urine samples from 9 volunteers ingesting a single dose of 140 mg MDEA, the Abbott TDx® fluorescence polarization immunoassay (FPIA) amphetamine/methamphetamine II was positive for 33–62 hours after ingestion, using the recommended cutoff value of 0.3 mg/L, and confirmation by GC/MS.[35] A negative amphetamine immunoassay screen does not exclude the recent use of amphetamine designer drugs including MDEA.

TREATMENT

Treatment is supportive and similar to the treatment of MDMA or MDA intoxication.

N-Methyl-1-(3,4-methylenedioxyphenyl)-2-butanamine (MBDB)

N-Methyl-1-(3,4-methylenedioxyphenyl)-2-butanamine (MBDB) is the *N*-methyl homologue of BDB and the α-ethyl analogue of MDMA. Illicit samples of MBDB contain a racemic mixture (enantiomer ratio (–/+) = 1). Analysis of illicit samples of MDMA suggest that MBDB is an uncommon substituent for MDMA in ecstasy tablets;[101] recent ecstasy tablets contain primarily MDMA.[102] Analysis of confiscated ecstasy tablets in the United Kingdom from 1994–2003 indicated that MBDB was present in some ecstasy tablets in the late 1990s, but not later.[103] The street name for MBDB is Methyl J. MBDB is a controlled substance in the United States and France. MBDB is a selective serotonin-releasing agent that is less potent than MDMA. In animal studies, MBDB has less dopaminergic and serotonergic activity than other ring-substituted phenethylamine drugs (e.g., MDMA, MDA, MDEA).[2] The principal metabolic pathway for the biotransformation of MBDB is *N*-demethylation to 3,4-methylenedioxybutanamine (BDB); cytochrome P450 isoenzymes involved in this pathway include CYP1A2, and to a lesser extent, CYP2D6 and CYP3A2/4.[104,105] Renal excretion of unchanged MBDB probably accounts for the majority of the elimination of MBDB.[106] The slightly increased renal excretion of the (–) isomer results in some reduction of the enantiomer ratios (–/+) during the elimination phase. Recommended recreational doses of MBDB are higher (i.e., 180–210 mg) than MDMA (80–150 mg).[107] Although the effect of MDMA and MBDB on serotonin receptors is similar, the action of MBDB on dopamine receptors is substantially less than MDMA as a result of less interaction of MBDB with the dopamine transporter.

The clinical effects of MBDB are similar, but less potent than MDMA. Analytic methods for the quantitation of MBDB and other ring-substituted phenethylamine drugs include GC/MS,[108] gas chromatography/tandem mass spectrometry with electron impact and chemical ionization,[109] liquid chromatography/electrospray ionization/tandem mass spectrometry,[110] and LC/MS.[111] The LOD and LLOQ for the latter method are 0.5–1 ng/mL and 2 ng/mL, respectively, along with a CV <15%. MBDB is a relatively rare ring-substituted phenethylamine compound in urine drug screens.[112] In a convenience sample of 10 individuals screening positive for MBDB, the urine MBDB concentration ranged between 0.1 and 24 mg/L as measured by GC/MS with trifluoroacetic anhydride as the derivatizing agent.[113] The sensitivity of most commercial amphetamine immunoassays for MBDB and the metabolite, BDB is relatively low unless the concentrations of these compounds are very high.[114] The exception is sensitivity of the CEDIA® Amphetamines/Ecstasy immunoassay for MBDB and BDB. The treatment of MBDB and MDA intoxication is similar.

4-Methylthioamphetamine (4-MTA)

Nichols et al. first reported the synthesis of 4-MTA in 1992.[115] Identification of 4-MTA in confiscated street drugs first occurred in 1997; the European Union placed 4-MTA on the schedule I of controlled substances in 1999.

IDENTIFYING CHARACTERISTICS

This compound is the methylthio analogue of PMA and a sulfur (thio-substituted) analogue of amphetamine. Typically, 4-MTA ($C_{10}H_{15}NS$) exists in tablets as the hydrochloride salt.

EXPOSURE

Street names for 4-MTA include Flatliner, MK, and S5. Occasionally, tablets sold as ecstasy contain 4-MTA.[116] Synthesis of 4-MTA involves the Leuckart process and the nitropropene route.[117] Precursors of the latter route include 4-methyltiobenzaldehyde, nitroethane, and *n*-butylamine. By-products of the Leuckart synthesis of 4-MTA include 4-methylthiophenyl-2-propanone, 4-methylthiophenyl-2-propanol, and 4-methylthiobenzyl alcohol.[118] *N*-alkyl homologues of 4-MTA include 4-methylthiomethampheamine, 4-methylthioethylamphetamine, 4-methylthiodimethamhpetamine, 4-methylthiopropylamphetamine, and 4-methylthiobutylamphetamine; there are few data on illicit use and effects of these homologues.[119]

DOSE EFFECT

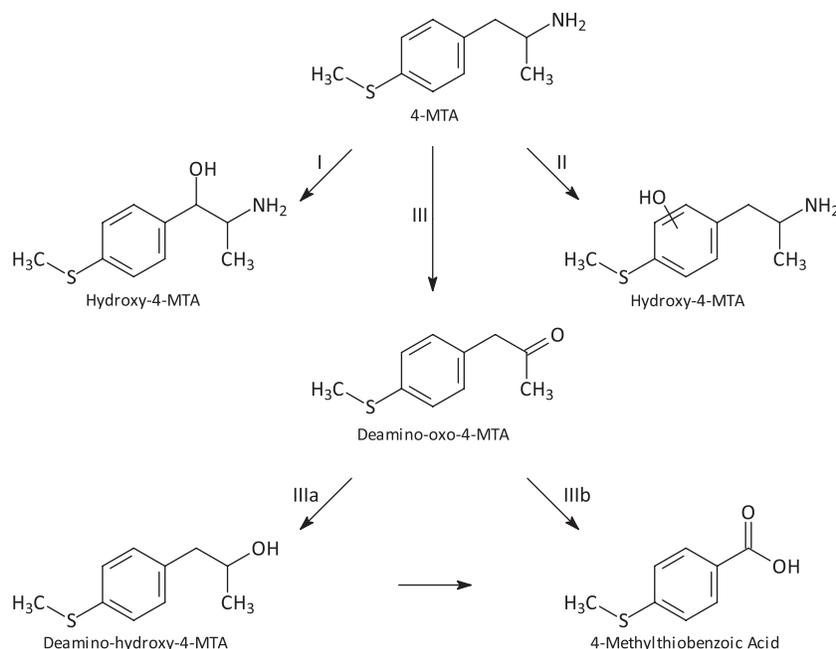
Typical doses of 4-MTA in tablets sold on the street range from approximately 100–140 mg.[120] The ingestion of 6 tablets of 4-MTA was associated with cardiac arrest in a 27-year-old man.[90] *In vitro* studies suggest that substantial interindividual variation in 4-MTA may occur as a result of differences in individual toxicokinetics.


FIGURE 10.3. Proposed phase-I metabolic pathways of 4-MTA in humans. The pathways include β-hydroxylation of the side chain (I), ring hydroxylation (II), oxidative deamination (III) followed by reduction into the corresponding alcohol (IIIa), or degradation of the side chain (IIIb).

TOXICOKINETICS

There are few toxicokinetic data on 4-MTA in humans. 4-MTA undergoes limited biotransformation and substantial renal excretion of unchanged 4-MTA occurs. Figure 10.3 displays the proposed metabolic pathways for the biotransformation of 4-MTA including oxidative deamination, ring hydroxylation, and β-oxidation of the side chain. *In vitro* studies indicate that 4-methylthiobenzoic acid is the major metabolite via oxidative deamination.[121] Although there are few data on the cytochrome P450 isoenzymes involved with the metabolism of 4-MTA, *in vitro* studies suggest that CYP2D6 is an important isoenzyme in the ring hydroxylation of 4-MTA.[122] These studies suggest that CYP2D6 rapid metabolizers are more susceptible to 4-MTA intoxication than CYP2D6 poor metabolizers; however, the clinical significance of this potential effect remains undetermined. Limited kinetic data in an intubated patient with 4-MTA intoxication suggested that the plasma elimination half-life of 4-MTA during poisoning is approximately 7 hours.[123]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

In rodent studies, 4-MTA is a selective serotonin agonist (increases serotonin release, inhibits serotonin uptake)

and an inhibitor of monoamine oxidase A.[124,125] The affinity of 4-MTA for dopamine and norepinephrine receptors is low. The administration of 4-MTA also causes a dose-dependent increase in plasma concentrations of ACTH, corticosterone, prolactin, and renin.[126] Animal studies suggest that 4-MTA intoxication may cause hyperthermia, hypertension, and the serotonin syndrome.[127] The postmortem examinations of patients dying from 4-MTA intoxication are typically nonspecific with the primary finding of visceral congestion. Postmortem examination of a 27-year-old man, who collapsed and died suddenly demonstrated no evidence of hyperthermia, cardiac anomalies, or anatomic causes of death.[128] The postmortem blood contained 4-MTA and trace amounts of MDMA.

CLINICAL RESPONSE

The clinical effects of 4-MTA are similar to PMA and MDMA with the exception that the slower onset of action of 4-MTA compared with the latter 2 drugs.[116,129] Adverse clinical effects associated with the illicit use of 4-MTA include headache, stomach pain, diaphoresis, tachycardia, and tremors. The clinical features of serious intoxication associated with 4-MTA include seizures and respiratory failure.[129]

DIAGNOSTIC TESTING

Similar to MDMA, MDA, and other 4-subsitituted amphetamines (PMA, PMMA, PMEA), 4-MTA cross-reacts with immunoassays for amphetamines and meth-amphetamines. In a study of the Bio-Quant Direct® ELISA kit for amphetamine, the cross-reactivity of 4-MTA with a concentration equivalent to 50 ng/mL amphetamine was 280% compared with MDA (282%), PMA (265%), and MDMA (73%).[93] 4-MTA is one of 31 designer amphetamines, tryptamines, and pipera-zines in serum samples detected by screening with liquid chromatography/tandem mass spectrometry after mixed-mode solid-phase extraction; the limit of detec-tion (LOD) with this method is 2.5 ng/mL.[130] Methods for the quantitation of 4-MTA include gas chromatography/nitrogen phosphorus detection, high performance liquid chromatography with diode array UV detection (HPLC/DAD),[123] GC/MS,[131] and liquid chromatography/tandem mass spectrometry.[128] The limit of 4-MTA detection using GC/MS in electron ion-ization and positive-ion chemical ionization mode is 30 ng/mL.[132]

In a case series of 6 individuals in various stages of intoxication, the 4-MTA concentrations in blood samples ranged from 0.43–2.08 mg/L.[129] The blood 4-MTA concentration did not correlate to the level of intoxication; however, the blood samples from these individuals also contained other drugs (e.g., marijuana). In a case series of 3 patients requiring assisted ventila-tion for 4-MTA intoxication, the plasma 4-MTA con-centration ranged from 0.13–0.76 mg/L.[123]

The postmortem femoral and right heart blood from a 27-year-old man, who died suddenly, contained 4-MTA concentrations of 5.23 mg/L and 7.60 mg/L, respectively.[128] The femoral blood also contained a minor concentration (0.001 mg/L) of MDMA. 4-MTA was the only drug detected in the postmortem blood of a 22-year-old man dying about 5 hours after developing coma and seizures.[131] Reportedly, he had hot skin, diaphoresis, dyspnea, and shaking prior to admission. The postmortem femoral blood contained 4.6 mg 4-MTA/L. Analysis of perimortem blood (i.e., drawn during cardiopulmonary resuscitation) demon-strated 4-MTA concentrations of 4.0 mg/L, respectively, as measured by GC with nitrogen phosphorus detection.

TREATMENT

Treatment of 4-MTA intoxication is supportive, similar to MDA and MDMA intoxication. Potential life-threatening effects include hyperthermia, seizures, coma, respiratory failure, and serotonin syndrome.

4-Methoxyamphetamine and 4-Methoxymethamphetamine (PMA/PMMA)

IDENTIFYING CHARACTERISTICS

4-Methoxyamphetamine (*p*-methoxyamphetamine, PMA) tablets are illegally sold in a variety of shapes and sizes including white tablets with a Mitsubishi symbol on one side.[133] Analysis of 6 tablets found with a deceased man contained the logo "xTc"; analysis of the tablets demonstrated approximately 50 mg of PMA.[134] PMA tablets typically contain between 40–70 mg compared with a mean dose of about 60–70 mg (range, 20–110 mg) in MDMA tablets.[135,136]

EXPOSURE

Epidemiology

Epidemiologic data on PMA and *p*-methoxymetham-phetamine (PMMA) are limited primarily to case reports, postmortem analysis, or drug seizures. Most epi-demiologic data on amphetamine designer drugs refer-ring to MDMA use rather specific phenethylamine derivatives; however, PMA and PMMA may be adulter-ants in street samples of MDMA.[143] The abuse of the various phenethylamine derivatives (e.g., PMA, PMMA) is sporadic and probably much less common than MDMA. Medical reports on PMA exposure include street drugs purportedly sold as ecstasy in Australia,[137,138] the midwestern United States,[133] Canada,[139] Belgium,[134] and Norway.[140] Case reports from Denmark document fatal cases resulting from the ingestion of both PMA and PMMA along with other drugs of abuse.[141]

Impurities

There are no approved medical uses for PMA or PMMA. By-products of the older Leuckart synthesis of PMA using reductive amination include 4-(4-methoxybenzyl)pyrimidine and 4-methyl-5-(4-methoxyphenyl)pyrimidine.[118] Another method for the production of PMA using the Leuckart reaction involves the use of anethole (i.e., main constituent of anise oil).[142] Peracid oxidation converts this precursor to its phenyl acetone analogue. A specific impurity for the use of anethole as a precursor in the Leuckart synthesis of PMA is 4-methoxyphenol. Other impurities in PMA synthesized from this process include 4-methyl-5-(4-methoxyphenyl)pyrimidine,

N-(β-4-methoxyphenylisopropyl)-4-methoxybenzyl methyl ketimine, 1-(4-methoxyphenyl)-*N*-(2-(4-methoxyphenyl)-1-methylethyl-2-propanamine, 1-(4-methoxyphenyl)-*N*-methyl-*N*-(2-(4-methoxyphenyl)-1-methylethyl-2-propanamine, and *N*-(*β*-4-methoxyphenylisopropyl)-4-methoxybenzaldimine. Analysis of PMA tablets demonstrated the presence of by-products of the chemical synthesis of PMA including 4-methoxydimethylamphetamine, 4-methoxyethylamphetamine, and 4-hydroxymethamphetamine from the Leuckart process.[143] The chemical precursors of PMA and MDMA are different; therefore, PMA is an adulterant of MDMA rather than a contaminant. Nicotinamide was the only adulterant in *p*-methoxyamphetamine (PMA) samples confiscated in Australia over 6 years.[135] Substrates of the Leuckart synthesis of PMMA include formic acid, *N*-methylformamide, and *p*-methoxyphenylacetone, whereas 4-methoxybenzaldehyde is a substrate for the synthesis of 4-methoxyamphetamine (PMA).[144,145] *N*,*N*-dimethyl-*p*-methoxyamphetamine and *N*-formyl-*p*-methoxymethamphetamine are by-products of this process.

Methods of Abuse

Similar to other phenethylamine compounds associated with club drugs, PMA and PMMA typically are ingested as tablets, capsules, or powder. Frequently, users believe they are ingesting MDMA rather than PMA or PMMA.[146] Insufflation and IV injection are uncommon, but case reports associate fatalities with the injection of PMA.[137,139] Typically, users ingest 1–2 tablets that contain varying amounts of the purported drug.

DOSE EFFECT

Desired effects from the ingestion of PMA or PMMA involve the alteration of perception. The term "entactogen" refers to drugs that induce euphoria, heighten sexual arousal, and/or promote an empathetic disposition.[135,147] There are limited data in the medical literature on the response to specific doses of PMA or PMMA. Animal studies suggest that the toxicity of PMA and PMMA is similar.[148] In mice, the IV LD_{50} of PMA is about 25 mg/kg compared with 31 mg/kg for MDA (3,4-methylenedioxyamphetamine).[149] Several case series associate the ingestion of 1–5 tablets of PMA with fatalities.[22,137,146] Analysis of tablets from 4 fatal cases of PMA intoxication demonstrated that the amount of PMA in these tablets ranged between 50–90 mg/tablet.[137] Extrapolation of this study suggests PMA doses of 50 mg – 450 mg are potentially fatal. Fatalities from the purported ingestion of typical recreational doses of amphetamine designer drugs suggest the occurrence of idiosyncratic responses.

TOXICOKINETICS

In vitro studies indicate that PMA undergoes *O*-demethylation to 4-hydroxyamphetamine via CYP2D6 (debrisoquine hydroxylase) followed by conjugation.[150,151] Differences in the polymorphic expression of CYP2D6 account for differences in *O*-demethylation between human subjects.[152] CYP1A2, CYP3A4, and catechol-*O*-methyl transferase may also catalyze the demethylation of PMA. Animal studies indicate that the primary metabolite, 4-hydroxyamphetamine, is an active metabolite, but the concentration of this metabolite in the brain after the administration of PMA is probably insufficient to contribute to PMA toxicity.[153] Alternate metabolic pathways of PMA biotransformation in animal models include oxidation to *N*-hydroxy-paramethoxyamphetamine followed by conjugation, *N*-hydroxylation, or deamination.[77]

Parametohoxymethamphetamine (PMMA) undergoes *O*-demethylation by CYP2D6 followed by hydroxylation, catechol-*O*-methyltransferase-catalyzed methylation, and then conjugation.[154] Very little paramethoxymethamphetamine (PMMA) undergoes *N*-demethylation to paramethoxyamphetamine (PMA).[77] *p*-Methoxyethylamphetamine (PMEA) is the *N*-ethylated analogue of PMA that is a relatively recently recognized drug of abuse. Potential metabolites of PMEA include *p*-hydroxyamphetamine (POHAP), *p*-hydroxyethylamphetamine (POHEA), and *p*-methoxyamphetamine (PMA) with *O*-demethylation to POHEA accounting for most of the metabolites.[155]

Marked interindividual variation in the elimination of PMA occurs between individuals, in part as a result of the interindividual variation in CYP2D6 activity. Poor metabolizers of CYP2D6 excrete substantially increased amounts of unchanged PMA in the urine. In a study of 3 volunteers, the 2 volunteers who were extensive metabolizers of CYP2D6 excreted a majority of the PMA dose as the free or conjugated 4-hydroxyamphetamine, whereas the poor metabolizer of CYP2D6 excreted about 50% of the dose as unchanged PMA.[152] Postmortem analyses suggest that the bile contains significant amounts of PMA.[26]

Potential drug interactions include the coadministration of CYP2D6 inhibitors. A case report associated fatal PMA intoxication with a modest blood PMA concentration (0.24 mg/L) in a patient on therapeutic doses of the CYP2D6 inhibitor, fluoxetine.[22] *In vitro* studies indicate that PMA is a weak inhibitor of multidrug resistance transporter, P-glycoprotein.[156]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

In vitro studies indicate that paramethoxyamphetamine (PMA) enhances the effect of serotonin more than MDMA.[20,157] In studies of rats using *in vivo* chronoamperometry, PMA was a potent inhibitor of serotonin uptake and a relatively weak releasing agent of serotonin and dopamine.[158] PMA did not increase locomotor activity in rats, which is dependent on dopamine uptake, in contrast to the effect of MDMA. *In vitro* studies of PMA in mouse brain also indicate that *p*-methoxyamphetamine is an inhibitor of serotonin oxidation by monoamine oxidase A.[159] Other methylenedioxyamphetamine compounds probably do not share this property with PMA, and potentially the increase in extracellular serotonin is greater than after the use of MDMA.

Animal models suggest that paramethoxyamphetamine may be relatively more toxic than other substituted phenethylamine derivatives as a result of the greater enhancement of serotonin release and the delayed onset of action allowing higher doses.[149] In rodent studies, PMMA and PMA in equivalent doses produce dose-related reduction in presynpatic serotonergic markers in the brain after twice-daily injections for 4 consecutive days.[160] Severe toxicity and fatalities resulting from PMA or PMMA share many similar features with MDMA and other phenethylamine entactogens (MDA, MDEA). Postmortem examination of PMA abusers found dead from PMA intoxication typically demonstrate evidence of hyperthermia, DIC (epicardial petechiae, pulmonary hemorrhage, hemorrhagic peritoneal/pleural effusions), skeletal muscle edema/necrosis, and renal tubular necrosis.[84]

CLINICAL RESPONSE

Case reports associate PMA and PMMA with fatalities despite the uncommon use of these drugs, primarily as an adulterant or substitute for MDMA.[140,146,161] Fatalities associated with PMA and PMMA typically involve hyperthermia, seizures, rhabdomyolysis, electrolyte abnormalities, DIC, multiorgan failure, and terminal dysrhythmias.[137,141] This clinical pattern resembles severe serotonin syndrome. Hyperthermia is the most important prognostic factor for potentially fatal cases.[135] Serious complications include intracerebral hemorrhage, cerebral edema,[141] intracerebral hemorrhage with midline shift,[137] and tonsillar herniation. Acute tubular necrosis and acute renal failure may occur, particularly in association with rhabdomyolysis, myoglobinuria, or multiorgan failure.[84,137]

DIAGNOSTIC TESTING

Analytic Methods

Similar to MDMA, MDA, and other 4-subsitituted amphetamines (PMMA, PMEA, 4-MTA), PMA cross-reacts with immunoassays for amphetamines and methamphetamines. In a study of the Bio-Quant Direct® ELISA kit for amphetamine, the cross-reactivity of PMA with a concentration equivalent to 50 ng/mL amphetamine was 265% compared with MDA (282%), 4-MTA (280%), and MDMA (73%).[93] 4-Methoxyamphetamine (PMA) along with other methylenedioxy-phenethylamine drugs are detectable in blood, urine, and postmortem tissue by liquid chromatography/sonic spray ionization/mass spectrometry with a validated calibration curve in the range of 10–1,000 ng/mL (blood and urine) and 20–2,000 ng/g (tissue).[162] The LOD for PMA and MDA in blood and urine for this method is 2.5 ng/mL and 5 ng/mL, respectively, based on a signal-to-noise ratio of 3. Other methods for the quantitation of PMA in biologic samples include GC/MS,[153] HPLC with fluorescence detection,[146] and capillary electrophoresis with diode array detection.[163] The LOD for the latter method is between 50–60 ng/mL. PMA is detectable in hair samples utilizing liquid chromatography/atmospheric pressure chemical ionization/mass spectrometry with a LOD of 0.20 ng/mg.[53]

Analysis of illicit drugs for the presence of synthetic substrates and by-products yields information about the source of the illicit material. Minor variations in reaction conditions (e.g., molar ratio of reagents, temperature) cause characteristic concentrations of by-products. Compounds suggestive of the preparation of PMA from 4-methoxybenzaldehyde via 4-methoxyphenyl-2-propanone using a Leuckart reductive amination include 4-methoxyphenol, 4-methoxybenzaldehyde, 4-methoxyphenyl-2-propanone, and 4-methoxyphenyl-2-propanol, 4-methoxyphenyl-propene as detected by GC/MS after solid-phase extraction.[164] By-products of this older Leuckart synthesis of PMA include 4-(4-methoxybenzyl)pyrimidine and 4-methyl-5-(4-methoxyphenyl)pyrimidine.[118] The absence of these by-products in illicit PMA tablets indicates the use of a synthetic process other than the Leuckart reaction.

Biomarkers

A case report suggests that the postmortem vitreous humor/femoral blood ratios for PMA, MDA, and MDMA are near unity after complete absorption and distribution.[26] Case reports of individuals dying with

PMA and/or PMMA in their postmortem blood usually involve polydrug abuse. Postmortem PMA concentrations in blood samples for PMA abusers dying at home with evidence of hyperthermia from PMA intoxication typically exceed 1 mg/L.[22] In a case series of 6 fatal PMA intoxications, the postmortem femoral blood of 2 individuals found dead contained PMA concentrations of 1.7 mg/L and 4.9 mg/L, whereas the postmortem femoral blood of 2 individuals dying shortly after hospital admission contained PMA concentrations of 2.2 mg/L and 3.7 mg/L.[137] The postmortem blood in these cases also contained lesser amounts of MDMA and/or methamphetamine, as well as other drugs of abuse (cannabinoids, cocaine). In another case series, the PMA concentrations in postmortem peripheral blood of 2 men dying a few hours after hospital admission were 0.78 mg/L (0.78 mg/kg) and 3.4 mg/L (3.4 mg/kg).[141] These blood samples also contained PMMA concentrations of 0.68 mg/L and 3.3 mg/L, as well as MDMA and cocaine metabolites. In a case series of 9 fatal PMA intoxications, the postmortem PMA blood concentration (source unspecified) ranged between 0.3 mg/L and 1.9 mg/L.[139] All died on the scene or within 3 hours of admission to the hospital. Some postmortem redistribution of PMA may occur. Two men and 1 woman presented to the emergency department in extremis, and they died shortly thereafter of PMA intoxication. The postmortem femoral blood of these 3 individuals contained PMA concentrations of 0.6 mg/L, 0.6 mg/L, and 1.3 mg/L.[146] The corresponding heart blood concentrations were 0.7 mg/L, 0.8 mg/L, and 2.3 mg/L, respectively. Limited clinical and postmortem data suggest that PMA concentrations exceeding 0.5 mg/L may be toxic,[137] but the occurrence of idiopathic responses and limited data on patients with PMA intoxication do not permit conclusions based only on the PMA or PMMA concentrations in postmortem blood samples.

In a case series of 8 fatal PMMA intoxications, the PMMA concentration in postmortem heart blood ranged from 1.208–15.824 mg/L as measured by GC/MS.[165] All specimens contained smaller amounts of PMA as well as variable amounts of other drugs (e.g., MDA, MDMA, ketamine, methamphetamine). Postmortem redistribution of PMMA also occurs. The postmortem PMMA and PMA concentrations in femoral blood from a 22-year-old man who died after ingesting ecstasy were 0.85 mg/L and 0.61 mg/L, respectively.[166] The heart blood contained PMMA and PMA concentrations of 2.12 mg/L and 1.94 mg/L, respectively, with corresponding heart/femoral blood ratios of 2.49 and 3.18. A 27-year-old man developed agitation, seizures, altered consciousness, hyperthermia, and cardiac arrest after ingesting an unidentified liquid. The postmortem examination revealed pulmonary congestion and moderate cerebral edema with herniation; the postmortem heart blood sample contained *p*-methoxyethylamphetamine (PMEA) at a concentration of 12.2 mg/L along with another metabolite, *p*-hydroxyethylamphetamine (POHEA).[155] A negative amphetamine immunoassay screen does not exclude the recent use of PMA or PMMA.

Abnormalities

In case reports of confirmed PMA intoxications, electrocardiographic abnormalities include sinus tachycardia, anterolateral ST depression, T wave inversion, QRS prolongation, atrial fibrillation, multifocal PVCs, and supraventricular tachycardia.[135,138] Occasional case reports associate severe hypoglycemia, hypocalcemia, and hyperkalemia with PMA intoxication (with and without hepatorenal dysfunction).[138,140]

TREATMENT

Treatment is supportive and similar to the treatment of MDMA or MDA intoxication.

2,5-Dimethoxyamphetamine (DMA) and the 2,5-Dimethoxyamphetamine-Derived Designer Drugs

2,5-Dimethoxyamphetamine (DMA) is approximately 5 times as potent as mescaline based on human dosing studies;[167] DMA may be substituted for mescaline in illicit street drugs.[168] The dimethoxy-hallucinogens include 4-methyl-2,5-dimethoxyamphetamine (DOM), 4-iodo-2,5-dimethoxyamphetamine (DOI), 4-chloro-2,5-dimethoxyamphetamine (DOC),[169] 4-bromo-2,5-dimethoxyamphetamine (DOB), 4-bromo-2,5-dimethoxymethamphetamine (MDOB), and 2,4,5-trimethoxyamphetamine (TMA-2) These drugs are potent serotonin 5HT$_2$ receptor agonists. The metabolism of these drugs occurs primarily by *O*-demethylation or in case of DOM by hydroxylation of the methyl moiety.[170] Limited experimental clinical data suggest that the effects of 2,5-dimethoxyamphetamine (DMA) persist approximately 7 hours after the ingestion of DMA doses over 75 mg. DMA has the same molecular weight and electron ionization mass spectra as the 5 other positional ring isomers (2,3-dimethoxy-

amphetamine, 2,4-dimethoxyamphetamine, 2,6-dimethoxyamphetamine, 3,4-dimethoxyamphetamine, 3,5-dimethoxyamphetamine). Perfluoroacylation of the amine group allows the identification of the 6 regioisomeric dimethoxyamphetamine compounds by capillary GC.[171]

4-BROMO-2,5-DIMETHOXYAMPHETAMINE (DOB)

EXPOSURE

The synthesis of DOB is relatively simple. Substrates for the synthesis of DOB include 2,5-dimethoxybenzaldehyde and hydroquinone.[13] Intermediates of the former process are 2,5-dimethoxy-β-nitrostyrene and 2,5-dimethoxyamphetamine. DOB hydrochloride is synthesized as a white crystalline powder, but this compound is sold as paper squares similar to LSD.[172] In Australia, DOB is frequently sold as LSD.[13] Classically, DOB is sold as 1-cm^2 pieces of colored paper that are embossed with various figures (bird, beaver, unicorn). These pieces of paper are bonded to a thinner, nonabsorbent sheet, and the DOB concentration of each 1-cm^2 dose usually ranges between 1.4 mg and 4.6 mg.[13] As a result of the diffusion of DOB within the sheet of DOB during the production process, the concentration of DOB in individual pieces may vary depending on the location.

DOSE EFFECT

The ingestion of pieces with high DOB concentrations may cause serious toxicity.[173] DOB is approximately 100–150 times as potent as mescaline based on human dosing studies.[167] In a volunteer study, DOB doses ≤2 mg caused stimulation without perceptual distortion when administered as the hydrochloride salt.[174]

TOXICOKINETICS

DOB (4-bromo-2,5-dimethoxyamphetamine) is another 4-position substituted phenethylamine that probably undergoes O-demethylation followed by conjugation and urinary elimination.[175] There are few data on the cytochrome P450 isoenzymes involved with the metabolism of DOB and other similar dimethoxy-phenethylamine compounds; CYP2D6 probably does not contribute significantly to the biotransformation of DOB.[176]

CLINICAL RESPONSE

DOB is a potent psychotomimetic compound that is the longest-acting substituted amphetamine. Although the effects DOB and LSD are similar, the onset of intoxication following the ingestion of DOB is slower and the duration of action is longer than LSD. Typically, the onset of action of DOB begins within 1 hour of ingestion and peak effects occur about 3–4 hours after ingestion; these peak effects persist 4–10 hours after ingestion, and symptoms of intoxication resolve within 24–36 hours based on experimental studies by Shulgin.[13] Several case reports associated DOB with mydriasis, frightening visual hallucinations, dysphoria, labile emotions, extreme agitation, disorientation, and seizures. Rare case reports associate the ingestion of DOB with fatalities. A 21-year-old woman was found dead with a package of DOB nearby and DOB in her postmortem blood.[177] Severe symptomatic arterial vasospasm developed after the ingestion of DOB, as confirmed by angiography.[178]

Other synthetic, ring-substituted phenethylamine amphetamine derivatives (e.g., 2,5-dimethoxy-4-chloroampheteamine [DOC], 2,5-dimethoxy-4-iodoamphetamine [DOI]) have similar toxic effects including altered consciousness, mydriasis, sinus tachycardia, seizures, temperature elevation, and increased serum creatine kinase based on case reports.[179]

DIAGNOSTIC TESTING

Methods for the identification of DOB in street drug samples involve capillary zone electrophoresis/diode array detection, Fourier-transform infrared spectroscopy (FTIR), and GC/MS.[180] Unlike lysergic acid diethylamide (LSD), 2,5-dimethoxy-4-bromoamphetamine (DOB) is neither light nor heat sensitive; therefore, DOB does not require refrigeration or storage in dark environments.[13]

Two comatose patients were admitted to the hospital after the ingestion of 4-bromo-2,5-dimethoxyamphetamine (DOB) at an unknown time prior to admission.[181] The patient with a serum DOB concentration of 0.013 mg/L on admission survived after developing seizures. The other patient had a serum DOB concentration of 0.019 mg/L on admission as measured by GC/MS; he died 6 days later after developing seizures and severe metabolic acidosis (pH = 6.6). The duration and temperature of storage were not reported. The postmortem blood (source unidentified) of a 21-year-old woman found dead at the scene contained 0.91 mg DOB/L.[177]

TREATMENT

Treatment is supportive, similar to the treatment of MDA or MDMA intoxication.

4-METHYL-2,5-DIMETH-OXYAMPHETAMINE (DOM)

Methyl-2,5-dimethoxyamphetamine (DOM; STP, Serenity-Tranquility-Peace) is approximately 50–80 times more potent than mescaline based on human dosing studies.[182] DOM in doses of 2–3 mg causes mild sympathetic stimulation, euphoria, and perceptual distortions with changes in physiologic parameters (pulse, blood pressure, temperature, pupil size),[183] whereas doses exceeding 5 mg causes excessive sympathetic stimulation and hallucinations based on clinical studies.[184] Higher doses (10–20 mg) of DOM produce unpleasant effects that limit the acceptance of this illicit drug.[185] Biotransformation of DOM primarily involves hydroxylation of the 4-methyl moiety rather than *O*-demethylation of other dimethoxy-phenethylamine compounds (e.g., DOC, DOI, DOC). Volunteer studies suggest that tolerance develops to some of the dysphoric effects of amphetamine designer drugs. In a study of 5 men receiving 6 mg DOM daily for 3 consecutive days, marked attenuation of subjective effects of DOM occurred over the 3-day study.[186] Only 1 participant continued to experience moderately strong effects by the third day, whereas 4 of 5 of the participants experienced extremely intense effects on the first day.

2,5-DIMETHOXY-4-ETHYLAMPHETAMINE (DOET)

2,5-Dimethoxy-4-ethylamphetamine (DOET) is the ethyl homologue of DOM. The oral administration of low doses (1.5 mg hydrochloride salt) of DOET to paid volunteers produced mild euphoria and enhanced self-awareness without perceptual distortions or psychotomimetic effects.[187] Subjective effects began 1–1.5 hours after ingestion with peak effects occurring about 3–4 hours after ingestion. Resolution of effects occurred within 5–6 hours. Doses of DOET up to 4 mg are associated with mydriasis, anxiety, and restlessness.[188] A volunteer study suggested that a 4-mg dose of racemic DOET produces psychedelic effects only when the participants eyes were closed.[8] A pilot study of paid volunteers ingesting up to 4 mg DOET suggest the kidney excretes approximately 10–40% of the DOET dose in the urine within the first 24 hours after ingestion.[189]

4-Bromo-2,5-dimethoxyphenethylamine (2C-B) and the 2C-Designer Series

HISTORY

Shulgin synthesized most of the known members of the 2C-phenethylamine series in the 1970s and 1980s including the production of 2C-B by elemental bromination of 2,5-dimthoxyphenethylamine in acetic acid.[190] In 1975, Shulgin et al. documented the sensory enhancement associated with 2C-B intoxication during experiments with volunteers. Ragan et al. first reported 2C-B in illicit US street samples in 1985.[191] In the late 1990s and early 2000s, analysis of tablets sold in Dutch "smart shops" demonstrated the presence of 4-bromo-2,5-dimethoxyphenethylamine (2C-B) and several other phenethylamine compounds in the 2C-series (2C-T-2, 2C-T-7).[192,193] As 2C-B became a schedule I drug, other members of the 2C-series appeared in illicit drug samples.

IDENTIFYING CHARACTERISTICS

The "2C" refers to the 2 carbon atoms separating the primary amine functionality from the phenyl ring; these drugs also contain methoxy groups at positions 2 and 5 of the aromatic ring and a lipophilic substituent (e.g., alkyl, alkylthio, halogen) in position 4 of the aromatic ring. Street names for 2C-B include Venus, Bromo, Erox, XTC, Synergy, and Nexus.

EXPOSURE

2C-B is the most common illicit drug from the 2C series (2C-B, 2C-I, 2C-D, 2C-E, 2C-P, 2C-T-2, 2C-T-7). 2C-B and other members of the 2C-series are frequently ingested with other club drugs (MDMA, ketamine, MBDB).

DOSE EFFECT

Anecdotal data suggests that recreational doses of 2C-B range from 4–30 mg with lower doses (4–10 mg) producing entactogenic effects, whereas high doses (10–20 mg) cause psychedelic and sympathomimetic effects. In self-reported experimental studies, psychedelic effects began following the ingestion of 2C-B doses from 8–10 mg, and these effects persisted approximately 4–8 hours.[190] Doses of 2C-B exceeding 30 mg may cause frightening hallucinations, agitation, dysphoria, tachycardia, hypertension, and, hyperthermia.

TOXICOKINETICS

There are few human data on the toxicokinetics of 2C-series drugs; existing data suggest that these drugs primarily undergo *O*-demethylation at the 2-position by deamination followed by oxidation to the corresponding acid or and by reduction of the 5-position to the corresponding alcohol.[194] Other metabolic reactions include side chain hydroxylation, sulfoxidation of sulfur containing 2C-compounds, and phase II reactions (glucuronidation, sulfation, *N*-acetylation). *In vitro* studies indicate that the metabolism of 4-bromo-2,5-dimethoxyphenethylamine (2C-B) occurs via oxidative deamination by monoamine oxidase (MAO-A, MAO-B) followed by demethylation, or to a lesser extent, by oxidative deamination catalyzed by cytochrome P450 isoenzymes (CYP2D6).[195,196] Most 2C-series phenethylamine drugs have slightly greater affinity for MAO-A than MAO-B. There is substantial interspecies variation in the biotransformation of 2C-B as well as interindividual variation in humans. Major metabolites of oxidative deamination include 2-(4-bromo-2,5-dimethoxyphenyl)-ethanol (BDMPE), 4-bromo-2,5-dimethoxyphenylacetic acid (BDMPAA), and 4-bromo-2,5-dimethoxybenzoic acid (BDMBA). Urinary metabolites found in a urine sample from a man abusing 2C-B included BDMBA, BDMPAA, and 4-bromo-2-hydroxy-5-methoxyphenethylamine.[197] In rodent studies, the plasma elimination of 2C-B is rapid (i.e., t½ about 1 h) and the volume of distribution is large (16 L/kg).[198]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

In vitro studies indicate that the 2C-series phenethylamine drugs act primarily at the 5-HT$_2$ receptor, displaying agonist and antagonist activity at specific subreceptor sites.[199] 2C-B also demonstrates significant affinity to 5-HT$_{1A}$, 5-HT$_{1B}$, and 5-HT$_{1C}$ serotonin receptors.[200]

CLINICAL RESPONSE

The few medical data on the medical effects of 2C-B and other members of the 2C-B series are primarily from the experimental studies by Shulgin in the 1970s.[107,190] The frequent concomitant ingestion of other illicit drugs complicates the interpretation of anecdotal reports of the effect of these entactogens. 2C-B produces euphoria and increased sensory receptiveness (auditory, olfactory, tactile, visual), whereas adverse reactions include frightening hallucinations, tachycardia, elevated blood pressure, and potentially hyperthermia.

DIAGNOSTIC TESTING

The cross-reactivity of 2C-B and other members of the 2C-series with commercial amphetamine immunoassays is relatively low. Methods for the quantitation of 2C-B and other phenethylamine designer drugs include LC/MS,[201] capillary electrophoresis coupled with electrospray ionization/mass spectrometry,[202] HPLC with UV detection,[203] and GC/MS.[204,205] The LOD and LLOQ for 2C-series phenethylamine drugs are approximately 8–16 ng/mL and 27–53 ng/mL, respectively, with CV <20% using LC/MS.

TREATMENT

The treatment of 2C-B intoxication is supportive, similar to MDMA and MDA toxicity.

Bromo-Dragonfly

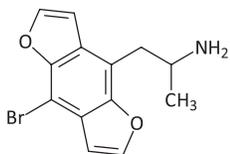
In 1998, Parker et al. synthesized a potent hallucinogen, 1-(8-bromobenzo[1,2-b;   4,5-b′]difuran-4-yl)-2-aminopropane.[206] This compound (bromobenzodifuranylisopropylamine) is a 5-HT$_{2A}$ agonist that is structurally similar to several phenethylamine compounds (e.g., 2C-B, DOB) as demonstrated in Figure 10.4. The name *bromo-dragonfly* derives from the similarity of the structure of this compound to a dragonfly. *In vivo* studies indicate that bromo-dragonfly demonstrate high affinity for 5-HT$_2$ receptors as indicated by the following K$_i$ values: 5-HT$_{2A}$, 0.04 ± 0.01 nM; 5-HT$_{2B}$, 0.19 ± 0.10 nM; 5-HT$_{2C}$, 0.02 ± 0.01.[206] These values indicate that bromo-dragonfly is a more potent ligand for the 5-HT$_{2A}$ receptor than LSD. Bromo-dragonfly has a single stereocenter with the *R*-(−)-enantiomer being relatively higher affinity for the 5-HT$_{2A}$ receptors than the *S*-(+)-enantiomer.[207]


FIGURE 10.4. Chemical structure of bromo-dragonfly.

Peak psychedelic effects of this compound are delayed up to 6 hours; adverse effects from the illicit use of bromo-dragonfly based on anecdotal data include headache, fever, and dysphoria, particularly in inexperienced users. A case report associated the delayed onset (i.e., 8 h) of seizures, severe agitation, hallucinations, mydriasis, and apnea requiring intubation with the use of bromo-dragonfly and ketamine.[208] He recovered without sequelae after developing aspiration pneumonia. Recently, several deaths were attributed to the use of bromo-dragonfly. An 18-year-old woman was found dead in her home the morning after ingesting bromo-dragonfly with her boyfriend.[209] The postmortem examination demonstrated only nonspecific findings (e.g., pulmonary edema, mild cerebral edema, inflammation of the gastric mucosa, renal ischemic changes). Two analyses of femoral blood yielded bromo-dragonfly concentrations of 4.7 ± 0.7 μg/kg as measured by liquid chromatography/tandem mass spectrometry. This concentration was approximately 8-fold higher than the bromo-dragonfly concentration in blood from 2 men hospitalized after ingesting bromo-dragonfly during a techno party as measured by the same analytic method (LOD, 0.2 μg/kg). The bromo-dragonfly concentrations in postmortem urine samples from this 18-year-old woman before and after the addition of β-glucuronidase were 22 ± 2 μg/kg and 33 ± 3 μg/kg, respectively. This difference indicates the presence of the conjugation of some metabolites with glucuronic acid. Desorption atmospheric pressure photoionization is a direct analysis technique rapid detection of hallucinogens in illicit drug samples using a microchip-heated nebulizer with mass spectrometry.[210]

PIPERAZINES

Piperazines are a broad class of chemical compounds that contain a piperazine moiety composed of a 6-membered ring with 2 opposing nitrogen atoms. Many of these compounds are biologically active with therapeutic uses as antidepressants, serotonin receptor antagonists/agonists, and as antifungal and antiviral drugs.

1-Benzylpiperazine (BZP)

HISTORY

The Wellcome Research Laboratories synthesized *N*-benzylpiperazine (BZP) as an anthelminthic agent in 1943. Animal studies in the 1970s suggested that BZP had antidepressant activity, but side effects (stereotypic behavior, hyperactivity) and addictive properties similar to amphetamine prevent the clinical use of this drug in humans.[211] BZP is an active constituent of rave (dance party) drugs originally marketed over the Internet during the late 1990s. These pills were promoted as an herbal high because of the structural similarity between BZP and piperine (1-piperoylpiperidine), the amide of the alkaloid piperidine in black pepper. A variety of benzylpiperazine and α-pyrrolidinophenone compounds rapidly spread in the club drug scene as legal alternatives to MDMA with both stimulant and psychoactive properties.[212] However, the US Drug Enforcement Agency (DEA) added BZP and related drugs to schedule I in 2004 as a result of fatalities associated with the use of these drugs.[213] Australia classified BZP as a restricted substance in 2008.

IDENTIFYING CHARACTERISTICS

BZP is a piperazine derivative that contains a 6-membered heterocycle comprised of 2 nitrogen atoms linked by 2 ethyl chains. Derivatives of piperazine are constituents of many synthetic compounds including antimicrobials, sildenafil, pesticides, plastics, medical radiolabeled tracers, and resins. In the freebase form, BZP is a pale yellow liquid that reacts with air and light; however, the hydrochloride salt is more stable. Benzylpiperazine tablets are sold in dosages of 125 mg BZP dihydrochloride (88 mg free base) and as mixtures of BZP and other piperazines [e.g., 1-(3-trifluoromethylphenyl)piperazine].[214] Street names for BZP and other piperazines include A2, Bliss, BNZ, Bolts, Charge, Exodus, Frenzy, Goodstuff, Grins, Herbal Ecstasy, Herbal Party Pill, Jumps, Kandy, Legal E, Legal X, Nemesis, Red Hearts, and Silver Bullet.[215] The street name "X4" applies to a mixture of 4 piperazine compounds.

EXPOSURE

Piperazine designer drugs are frequently consumed as combinations (party pills, herbal highs) with the most prevalent mixture being BZP and 1-(3-trifluoromethylphenyl)piperazine (TFMPP).[216] BZP is frequently promoted as a legal stimulant to improve vitality, energy, and cognition. In New Zealand, the United Kingdom,

and other European countries, piperazine-based "party pills" are popular dance party drugs for the induction of euphoria and wakefulness. Although BZP is a restricted, schedule I drug in the United States, BZP remains legal in the United Kingdom, Canada, and New Zealand.

DOSE EFFECT

The clinical effects of BZP and *d*-amphetamine are similar. In a double-blind, controlled study of 18 former amphetamine addicts receiving either 10 mg *d*-amphetamine or 100 mg BZP hydrochloride, the physical parameters (i.e., blood pressure, pulse rate, pupil size) of the 2 treatment groups were statistically similar with the exception of a slightly larger pupil size in the BZP group.[211] The 2 groups liked both drugs equally, but they disliked the placebo (lactose). The median number of BZP pills ingested by a convenience sample of women

and men presenting to an emergency department with BZP intoxication was 3 and 4, respectively, with a range of 1–34.[217]

TOXICOKINETICS

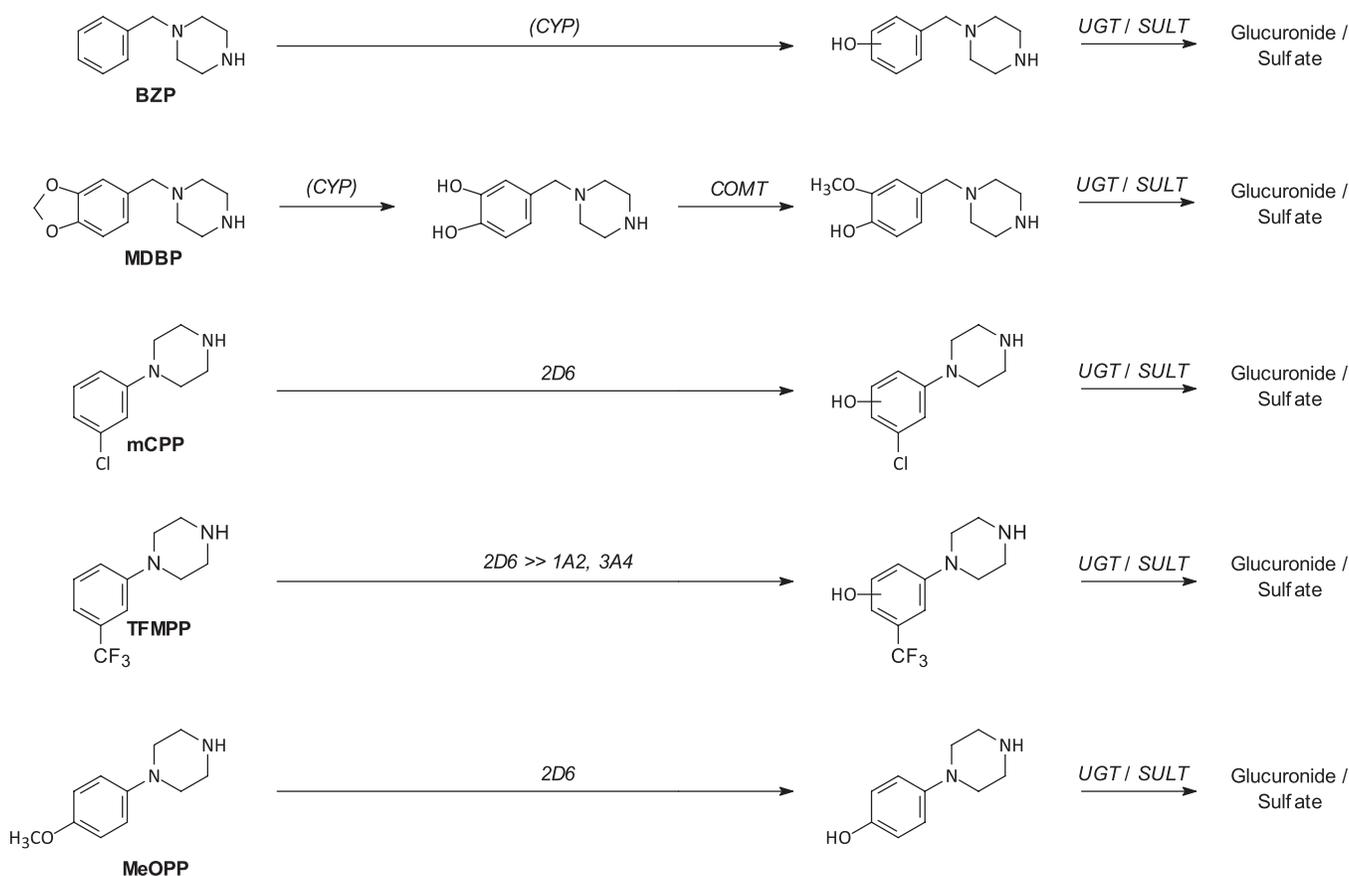
The main isoenzyme catalyzing the metabolism of piperazine-type designer drugs is the cytochrome P450 isoenzyme, CYP2D6, with lesser contributions from CYP1A2 and CYP3A4. The biotransformation of BZP is limited, primarily involving hydroxylation of the aromate to 3-OH-BZP and 4-OH-BZP.[77] *N*-dealkylation to piperazine and the degradation of the piperazine heterocycle to the corresponding ethylenediamine or aniline derivative is another pathway.[77] Phase II reactions include partial glucuronidation or sulfation of the phenolic metabolites, methylation of the catechols, and partial acetylation of the aniline derivatives. Figure 10.5 displays the metabolic pathways of common piperazine derivatives along with


FIGURE 10.5. Major metabolic pathways of common piperazine derivatives. UGT = UDP glucuronyl transferase; SULT = sulfotransferase; COMT = catechol *O*-methyl transferase; BZP = *N*-benzyl piperazine; MDBP = 1-(3,4-methylenedioxybenzyl)piperazine; mCPP = 1-(3-chlorophenyl)piperazine; TFMPP = 1-(3-trifluoromethylphenyl)piperazine; MeOPP = 1-(4-methoxyphenyl)piperazine.

the cytochrome P450 isoenzymes involved with the pathways. The kidneys excrete a substantial amount of BZP unchanged along with the excretion of sulfate conjugates of the hydroxylated metabolites. In a study of 7 healthy adults ingesting 200 mg BZP, the mean maximum plasma concentration (C_{max}) was about 260 ± 19 ng/mL (range, 222–344 ng/mL) with a plasma elimination half-life of about 5.5 ± 0.4 hours.[218] The mean time to the maximum plasma concentration was 75 minutes. The plasma concentration of the major metabolites, 3-OH-BZP and 4-OH-BZP were relatively low ($C_{max} = 13 \pm 1$ ng/mL and 7 ± 1 ng/mL, respectively) as measured by LC/MS. Phenylpiperazine compounds are almost exclusively metabolized prior to renal excretion.[77]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

BZP has both direct and indirect sympathomimetic properties that produce improvement in performance tasks and auditory vigilance based on volunteer studies in healthy adults.[219] In chronically treated rats, BZP increases synaptic concentrations of norepinephrine in the hypothalamus, dopamine in the striatum, and serotonin in the hippocampus.[220] *In vitro* studies indicate that BZP enhances the release of dopamine from the dopamine transporter;[221] BZP has no effect on the release of serotonin from synaptosomes in these studies. *In vivo* microdialysis studies in conscious rats indicate that benzylpiperazine increases the transporter-mediated efflux of dopamine transporter substrate, whereas 1-(3-trifluoromethylphenyl)piperazine (TFMPP) is a selective releaser of serotonin in synaptosomes.[222] In this study, the combination of these 2 drugs facilitated serotonin and dopamine release similar to MDMA; however, several of the 7 rats receiving high doses (10 mg/kg) of BZP and TFMPP developed seizures.

CLINICAL RESPONSE

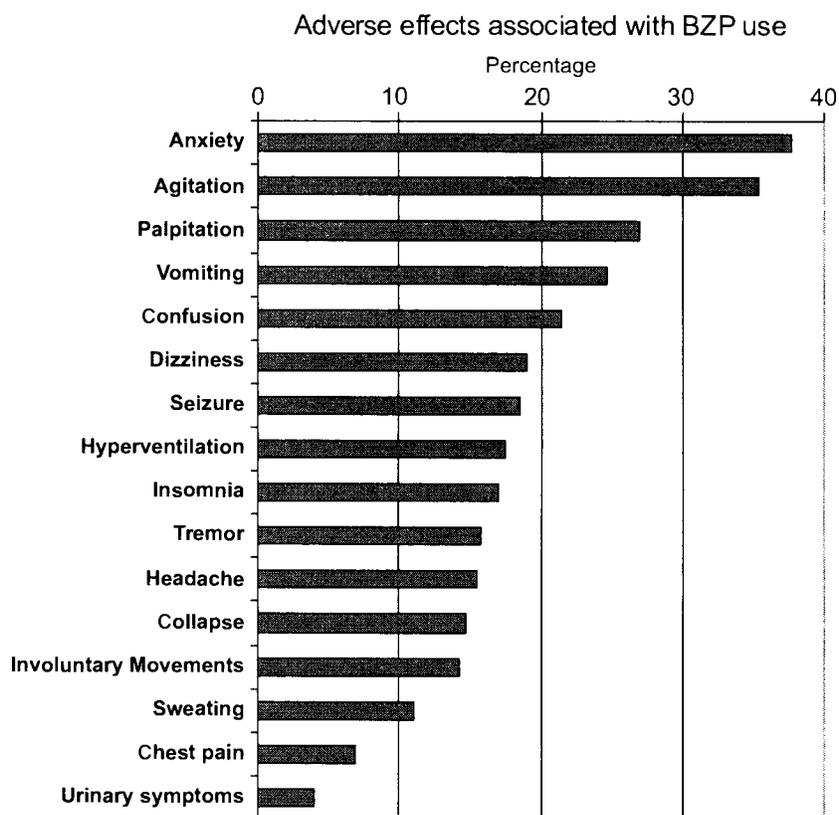
Toxicity associated with 1-benzylpiperazine (BZP) resembles a sympathomimetic toxidrome with tachycardia, anxiety, agitation, mydriasis, headache, nausea, vomiting, palpitations, confusion, and seizures based on case reports.[217] Symptoms during recreational use typically resolve within 4–6 hours. Figure 10.6 displays the clinical features associated with a convenience sample of 88 patients (96 visits) presenting to an Australian emer-


FIGURE 10.6. Clinical features of 1-benzylpiperazine intoxication in a convenience sample of 88 patients presenting to an emergency department. (Reprinted with permission from P Gee, M Gilbert, S Richardson, G Moore, S Paterson, P Graha, Toxicity from the recreational use of 1-benzylpiperazine, Clinical Toxicology, Vol. 46, Issue 9, p. 804, copyright 2008.)

gency department with BZP intoxication confirmed by the presence of BZP in plasma samples.[217] About 30% of the patients had plasma samples positive for only BZP, whereas about 57% of the patients ingested ethanol along with BZP. Two of the patients in this study survived after developing hyperthermia and multiorgan failure. There were no fatalities in this case series during the period of study. Case reports associate the use of BZP with seizures, hyperthermia, DIC, rhabdomyolysis, and hepatorenal dysfunction both as a single drug of abuse and in combination with MDMA.[223]

Toxic effects associated with the combination of BZP and TFMPP include urinary retention, nausea, vomiting, anxiety, insomnia, visual hallucinations, paranoia, depression, chest pain, and seizures based on case reports.[224] An intense hangover may develop from the use of the blended BZP and TFMPP pills. Status epilepticus with severe respiratory and metabolic acidosis may occur following the ingestion of these combination pills.[225] Occasional case reports associate the use of piperazine-type designer drugs with cerebral edema and death, usually in combination with MDMA.[226]

DIAGNOSTIC TESTING

Analytic Methods

Amphetamine immunoassays do not reliably detect BZP and commercial amphetamine immunoassays demonstrate little or no cross-reactivity with BZP, the BZP metabolite, *N*-benzylethylenediamine, or structurally related compounds (e.g., TFMPP, MeOPP).[227] In an analytic study, BZP did not cross-react with a fluorescence polarization immunoassay (AxSYM® amphetamine/methamphetamine II assay, Abbott Laboratories, Abbott Park, IL) at a BZP concentration of 100,000 ng/mL. The reaction of BZP to the reagent in an enzyme-multiple immunoassay (EMIT d.a.u.®, Dade Behring Inc., Deerfield, IL) was weak with 0.4% and 1.3% cross-reactivity at BZP concentrations of 300 ng/mL, and 12,000 ng/mL, respectively. Methods for the quantitation of piperazine designer drugs in biologic samples include gas chromatography/nitrogen phosphorous detection,[212] GC/MS in the selected-ion monitoring mode,[228,229] capillary electrophoresis with GC/MS,[230] HPLC/DAD,[231] and GC/MS with high performance liquid chromatography/electrospray ionization/mass spectrometry.[232] The LOD for BZP, TFMPP, and their main metabolites in urine samples using the latter method ranges between 5–40 ng/mL (scan mode) and between 0.2–1 ng/mL (SIM mode) following enzymatic hydrolysis, solid-phase extraction, and trifluoroacetyl anhydride-ethyl acetate derivatization. For hair samples, methods of quantitation for BZP include GC/MS with

mixed-mode solid-phase extraction and *p*-tolylpiperazine as the internal standard.[233] The LLOQ of the latter method is 0.05 ng/mg.

Biomarkers

An 18-year-old woman developed a seizure after ingesting 5 pills containing BZP. On arrival at the ED, she was agitated, but oriented (Glasgow Coma Scale [GCS] = 15) with mild hypertension and sinus tachycardia (156 bpm).[234] Her serum sample contained only 2.5 mg BZP/L and no other drugs. She was discharged 12 hours after admission with no sequelae. There are few postmortem data on the piperazine compounds. Analysis of postmortem blood (site unreported) from a 17-year-old Swedish man with a history of ecstasy and BZP (A2) abuse contained 1.7 mg BZP/L along with detectable concentrations of MDMA, MDA, and THC.[213] The case report did not provide clinical details. A 17-year-old adolescent died after falling through a roof. The postmortem blood (site unreported) contained BZP and TFMPP concentrations of 1.39 mg/L and 0.15 mg/L, respectively, along with 140 mg ethanol/dL.[231]

Abnormalities

Potentially serious laboratory abnormalities associated with BZP intoxication include hypoglycemia, hyponatremia, and QT_c prolongation; however, ventricular dysrhythmias are unusual despite the presence of multiorgan failure.[223]

TREATMENT

Treatment is supportive and similar to the treatment of MDMA or MDA intoxication.

meta-Chlorophenylpiperazine (mCPP)

meta-Chlorophenylpiperazine (mCPP) is a relatively new synthetic drug that became a drug of abuse throughout Europe during the mid-2000s. Although mCPP can be injected or insufflated in powdered form, the usual route of abuse is oral. Street names for the multicolored tablets include Rolls Royce, Harlequin, Smarties, Rainbow, and X4. The amount of mCPP in illicit tablets ranges from 22–80 mg; these tablets may contain cocaine, MDMA, or the contaminant, *p*-chlorophenylpiperazine.[235]

mCPP is a probe for serotonin function in psychiatric research as well as a potential anorexic drug. Typical oral doses of mCPP used for clinical investigations are 0.5 mg/kg.[236] Case reports associate clinical doses of mCPP with the development of a serotonin-like syndrome.[237] Methods for the quantitation of mCPP in biologic samples include MS with separation by LC or GC. For hair samples, methods of quantitation for mCPP involve GC/MS with mixed-mode solid-phase extraction and *p*-tolylpiperazine as the internal standard.[233] The LLOQ of the latter is 0.05 ng/mg.

TOXICOKINETICS

The absolute bioavailability and clearance of mCPP is highly variable with large interindividual differences that complicate the therapeutic administration of this drug.[238] The absolute bioavailability ranged from 12–84% (mean, 39%) in a study of 12 healthy men ingesting 0.4 mg mCPP/kg.[239] The mean time to peak mCPP plasma concentrations was 2.19 ± 0.70 hours with a range from 1.40–4.08 hours. The biotransformation of piperazine derivatives is greater for phenylpiperazine (mCPP, TFMPP) than benzylpiperazine derivatives (e.g., BZP). The major metabolic pathway for the biotransformation of mCPP is hydroxylation of the aromatic ring via the cytochrome P450 isoenzyme, CYP2D6. Alternate metabolic pathways involve the degradation of the piperazine ring to *p*-hydroxy-mCPP and then conjugation to glucuronide or sulfate. Phenylpiperazine compounds are almost exclusively metabolized prior to renal excretion.[77] In a study of 12 healthy men, the plasma elimination half-life of mCPP ranged from 2.6–6.1 hours after ingestion.[239] mCPP is a minor metabolite of nefazodone and the main active metabolite of trazodone;[240] additionally mCPP is a metabolite of etoperidone and mepiprazole.[241] The co-administration of these drugs and mCPP increases the steady-state plasma mCPP concentration in poor metabolizers of CYP2D6, particularly in combination with the CYP2D6 inhibitor, fluoxetine.[242]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

The binding profile of *m*-chlorophenylpiperazine (mCPP) is complex; mCPP is a central serotonin agonist and a vascular serotonin antagonist with affinity for most serotonin receptors (1A, 1B, 1D, 2C) and for α_2-adrenergic receptors. The affinity of mCPP for 5-HT$_{2C}$ receptor subtypes is high, whereas the affinity of mCPP for serotonin 1A, 1B, and 1D receptor subtypes is substantially less. This drug is also an antagonist of 5-HT$_3$ and 5-HT$_{2A}$ receptor subtypes.[243]

CLINICAL RESPONSE

mCPP is a stimulant and psychedelic compound with effects similar to MDMA. In clinical studies of patients receiving 0.5 mg mCPP/kg, 3 patients developed symptoms of a serotonin-like syndrome.[237] Other adverse effects reported from clinical trials include heightened sensitivity toward light and noise, fear of losing control, shivering, lightheadedness, and anxiety.[239] Peak subjective and physiologic effects typically occur about 1–2 hours after ingestion and resolve within 4–8 hours. The clinical effects associated with mCPP intoxication include nausea, diaphoresis, agitation, restlessness, myoclonus, and hypomania based on clinical studies and case reports. A 29-year-old woman developed nausea, anxiety, agitation, and visual hallucinations a half hour after ingesting her third tablet of mCPP. Vital signs were stable and there were no ECG abnormalities. She was discharged after 8 hours of observation. Laboratory testing revealed the presence of cocaine metabolites and ethanol (70 mg/dL).

DIAGNOSTIC TESTING

Analytic methods for the quantitation of mCPP include HPLC[244] and liquid chromatography/atmospheric pressure chemical ionization/tandem mass spectrometry. In a study of 12 healthy volunteers receiving 0.4 mg mCPP/kg, the mean peak plasma mCPP concentration was 53 ± 35 ng/mL with a range between 12.9 and 104.6 ng/mL.[239] The presence of mCPP in biologic samples does not necessarily imply the ingestion of this drug because mCPP is a metabolite of some antidepressants (e.g., trazodone, etoperidone, mepiprazole, nefazodone). A plasma sample from a 29-year-old woman with mCPP intoxication (nausea, anxiety, agitation, hallucinations) contained 320 ng mCPP/mL.[235] Her urine sample contained 2,300 ng mCPP/mL.

TREATMENT

Treatment is supportive, similar to the treatment of MDMA or MDA intoxication.

1-Piperonylpiperazine (MDBP)

1-Piperonylpiperazine (MDBP) is a relative weak inhibitor of serotonin uptake.[245] The primary metabolic pathway of 1-piperonylpiperazine [1-(3,4-methylenedioxybenzyl)piperazine, MDBP] is demethylenation of

the methylenedioxy moiety and subsequent methylation to N-(4-hydroxy-3-methoxybenzyl)piperazine followed by partial glucuronidation or sulfation.[246] The kidneys excrete a substantial amount of MDBP unchanged. Methods for the quantitation of MDBP in biologic samples include GC/MS.[247] Treatment is supportive and similar to the treatment of MDMA or MDA intoxication.

1-(4-Methoxyphenyl) piperazine (MeOPP)

The biotransformation of piperazine derivatives is greater for MeOPP than BZP. MeOPP and most other phenylpiperazine compounds are almost exclusively metabolized prior to renal excretion. The major metabolic pathway for the biotransformation of MeOPP is O-demethylation of the methoxy moiety. CYP2D6 is the major cytochrome P450 isoenzyme involved in the O-demethylation of MeOPP.[248] In rodent studies, metabolites of MeOPP include 1-(4-hydroxy phenyl) piperazine and 4-hydroxyaniline.[249] Amphetamine immunoassays do not reliably detect MeOPP or related compounds (e.g., BZP, TFMPP). Methods for the quantitation of MeOPP in biologic samples include MS with separation by LC or GC. Reliable detection of MeOPP and related drugs (BZP, TFMPP) in urine samples requires GC with nitrogen phosphorus detection or GC/MS in selected-ion monitoring mode after mixed-mode solid-phase extraction and derivatization with heptafluorobutyric anhydride.[229] The LLOQ for the latter method is 5 ng/mL. For hair samples, methods of quantitation for MeOPP involve GC/MS with mixed-mode solid-phase extraction and p-tolylpiperazine as the internal standard.[233] The LLOQ of the latter is 0.05 ng/mg. Treatment is supportive and similar to the treatment of MDMA or MDA intoxication.

1-(3-trifluoromethylphenyl) piperazine (TFMPP)

In 2002, TFMPP was temporarily added to the schedule I controlled substances list under the US Controlled Substances Act; however, TFMPP was removed from this list in 2004 after further review.[250] The sale of TFMPP is banned in Australia, Belgium, Denmark, Greece, New Zealand, and Sweden. The nonselective serotonergic agonist, 1-(3-trifluoromethylphenyl)piperazine (TFMPP) is usually ingested as a mixture with BZP.[251] The combination of BZP and TFMPP enables drug users to reproduce the dopaminergic and serotoninergic effects of MDMA.[252]

TOXICOKINETICS

The major metabolic pathways for the biotransformation of TFMPP is alteration of the aromate by hydroxylation and by degradation of the piperazine moiety to N-(3-trifluoromethylphenyl)ethylenediamine, N-(hydroxy-3-trifluoromethylphenyl)ethylenediamine, 3-trifluoromethylaniline, and hydroxy-3-trifluoromethylaniline.[253] Phase II reactions included glucuronidation, sulfonation, and acetylation of phase I metabolites. In rodent and human studies, p-hydroxy-TFMPP (4-OH-TFMPP) is the main urinary metabolite.[254,255] Studies of human liver microsomes indicate that the CYP2D6 is also the major isoenzyme catalyzing the hydroxylation of TFMPP along with minor contributions by CYP1A2 and CYP3A4.[256] TFMPP is almost exclusively (i.e., >98–99%) metabolized prior to renal excretion.[77] In a study of volunteers ingesting 60 mg TFMPP, the mean peak plasma TFMPP concentration (24 ng/mL) occurred about 1½ hours after ingestion; the mean plasma elimination half-life was 2 and 6 hours.[254] In vitro studies suggest that potential drug interactions may result from the ingestion of TFMPP with drugs that inhibit CYP2D6, CYP1A2, and CYP3A4 similar to benzylpiperazine.[257] Potential drug interactions occur between BZP and TFMPP because of similar metabolic pathways; however, the clinical significance of these potential interactions is not well defined.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

TFMPP is a centrally active, aryl piperazine compound with serotoninergic properties.[258] In vivo microdialysis studies in conscious rats indicate that TFMPP is a selective releaser of serotonin in synaptosomes, whereas benzyl piperazine increases the transporter-mediated efflux of serotonin and dopamine transporter substrate.[221] The action of TFMPP on various serotonin receptor types is complex. Rodent studies suggest that 5-HT$_{1B}$, 5-HT$_{1C}$, and possibly σ-receptors mediate the effects of TFMPP, whereas this compound does not bind strongly to 5-HT$_{1A}$, 5-HT$_2$, dopaminergic, or adrenergic receptors.[259]

CLINICAL RESPONSE

The combination of BZP and TFMPP produces sympathomimetic and dissociative symptoms. Clinical effects

associated with the ingestion of this combination by 3 patients presenting to an emergency department were nausea, vomiting, malaise, anxiety, agitation, mydriasis, ataxia, clonus, and sinus tachycardia.[260] All recovered without sequelae with supportive care.

DIAGNOSTIC TESTING

Methods for the quantitation of TFMPP and related drugs (MeOPP, BZP) in urine samples include GC with nitrogen phosphorus detection, chiral capillary electrophoresis,[261] liquid chromatography/electrospray ionization/mass spectrometry,[254] and GC/MS.[262] The ranges of BZP and TFMPP concentrations in serum samples from 3 patients intoxicated with these drugs ranged from 260–270 ng/mL and 30–60 ng/mL, respectively. They recovered without sequelae. Amphetamine immunoassays do not reliably detect TFMPP and related compounds (e.g., BZP, MeOPP). For hair samples, methods of quantitation for TFMPP involve GC/MS with mixed-mode solid-phase extraction and

p-tolylpiperazine as the internal standard.[233] The LLOQ of the latter is 0.05 ng/mg.

TREATMENT

Treatment is supportive and similar to the treatment of MDMA or MDA intoxication.

PYRROLIDINO-PHENONES

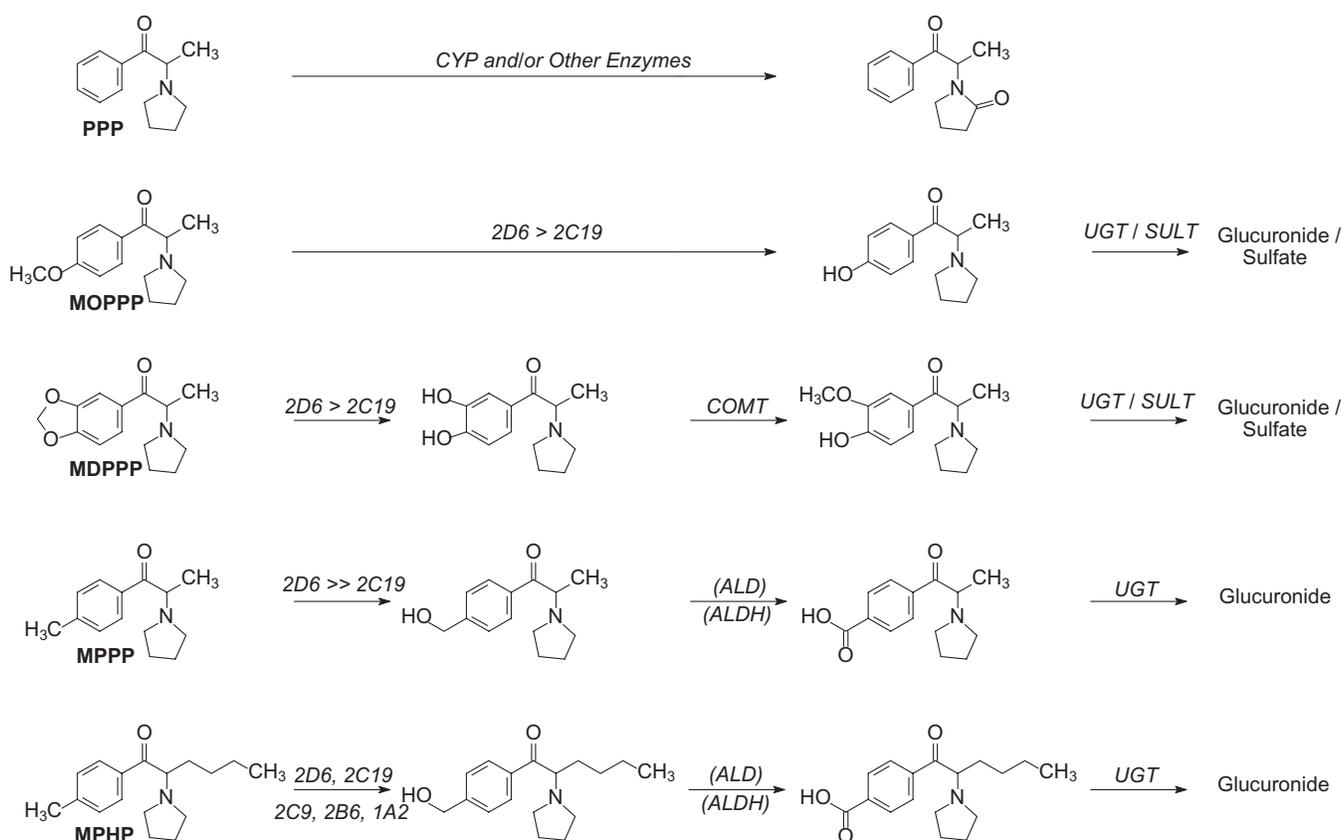
α-Pyrrolidinophenone compounds along with a variety of benzylpiperazine compounds rapidly spread as drugs of abuse in the club drug scene during the late 1990s. These drugs gained popularity as legal alternatives to MDMA with both stimulant and psychoactive properties.[212] Extensive metabolism of pyrrolidinophenone


FIGURE 10.7. Major metabolic pathways of common pyrrolidinophenone derivatives. UGT = UDP glucuronyl transferase; SULT = sulfotransferase; COMT = catechol *O*-methyl transferase; ADH = alcohol dehydrogenase; ALDH = aldehyde dehydrogenase; PPP = pyrrolidinopropiophenone; MOPP = R,S-4′-methoxy-α-pyrrolidinopropiophenone; MDPPP = R,S-3′,4′-methylenedioxy-α-pyrrolidinopropiophenone; MPPP = R,S-4′-methyl-α-pyrrolidinopropiophenone; MPHP = R,S-4′-methyl-α-pyrrolidinohexanophenone.

derivatives occurs in humans, primarily as a result of hydroxylation catalyzed by the cytochrome P450 isoenzyme, CYP2D6, and to a lesser extent by CYP2C19.[263] Pyrrolidinopropiophenone (PPP) undergoes ring oxidation to the corresponding lactam or degradation by double dealkylation to cathinone and subsequent keto reduction.[246] Although 4′-hydroxy-PPP is a common metabolite of PPP and MeOPP, 2″-oxo-PPP is a unique metabolite of PPP biotransformation; therefore, the presence of this latter metabolite indicates the ingestion of PPP.[264] *R*,*S*-3′, 4′-methylenedioxy-α-pyrrolidinopropiopenone (MDPPP) undergoes demethylenation of the methylenedioxy group followed by partial 3′-methylation of the resulting catechol, oxidative deamination to the corresponding diketo compounds and/or hydroxylation of the pyrrolidine ring with dehydrogenation to the corresponding lactam; the main metabolite is 4′-hydroxy-PPP.[265] Common metabolites of *R*,*S*-4′-methoxy-α-pyrrolidinopropiophenone (MOPPP) and MDPPP include 3′,4′-dihydroxy-PPP, 3′-methoxy-4′-hydroxy-PPP, and 3′-methoxy-4′-hydroxy-2-oxo-propiophenone. In addition to CYP2D6, CYP2C19 is potentially involved with the *O*-demethylation of MOPPP and MDPPP.[77] Figure 10.7 displays the major metabolic pathways of common pyrrolidinophenone compounds. Treatment is supportive and similar to the treatment of MDMA or MDA intoxication.

Chapter 11

TRYPTAMINE DESIGNER DRUGS

N,*N*-DIETHYL-TRYPTAMINE (DET)

N,*N*-Diethyltryptamine (DET) produces psychedelic effects similar to dimethyltryptamine (DMT) or mescaline. In contrast to DMT, DET is a synthetic substance that has not been found in the plant kingdom. *In vitro* studies indicate that DET significantly inhibits monoamine oxidase ($I_{50} = 5 \times 10^{-3}$M).[1] Rodent studies suggest that DET is about one-half as potent as DMT following intraperitoneal administration as measured by alteration of behavior.[2] The intravenous (IV) injection of 10 mg DET/kg into rodents was associated with clonic convulsions.[3] DET undergoes 6-hydroxylation to 6-hydroxy-*N*,*N*-diethyltryptamine (6-HDET) and *N*-deethylation to *N*-ethyltryptamine and indole-3-acetic acid (free and conjugated 3-IAA). Human studies suggest that elimination of 6-HDET and 3-IAA in the urine account for <20% of the administered dose of DET.[4] In a study of volunteers, the administration of 1 mg DET/kg was associated with elevated blood pressure, mydriasis, disinhibition, and visual distortions.[4] Adverse effects included anxiety, tremors, nausea, vomiting, and a feeling of unpleasantness. The intramuscular administration of 0.65 to 0.85 mg DET/kg to normal test participants produced the onset of vertigo, mydriasis, nausea, sweating, tremor, and elevated heart rate and blood pressure within 8 to 15 minutes.[3] Within 30 minutes after injection, elation, distortions of time and vision, loosening of associations, and a feeling of intoxication replaced earlier effects. These effects resolved within 3 hours. Some volunteers experienced unpleasant after-effects (e.g., mild fatigue, headache, depres-

sion, insomnia). These adverse effects resolved within 24 hours. Treatment of DET intoxication is supportive, similar to the treatment of 5-methoxy-diisopropyltryptamine (5-MeO-DIPT; Foxy) intoxication.

5-METHOXY-*N*,*N*-DIISOPROPYL-TRYPTAMINE (FOXY)

Shulgin and Carter synthesized 5-methoxy-diisopropyltryptamine (5-MeO-DIPT) in 1980.[5] Their report documented the hallucinogenic properties of this compound following oral administration, similar to *N*,*N*-dimethyltryptamine (DMT). Reports of the abuse of this hallucinogen appeared in the late 1990s and early 2000s.[6] In 2003, this compound was amended into schedule I of the US Controlled Substances Act; Japan banned the use of 5-MeO-DIPT in 2005.

IDENTIFYING CHARACTERISTICS

5-Methoxy-diisopropyltryptamine is one of several designer tryptamine compounds that also include 5-methoxy-α-methyltryptamine, α-methyltryptamine, 5-methoxy-*N*,*N*-dimethyltryptamine, *N*,*N*-diethyltryptamine, and *N*,*N*-dipropyltryptamine. 5-MeO-DIPT is a potent hallucinogen that is structurally related to DMT and bufotenine (5-hydroxy-*N*,*N*-dimethyltryptamine, CAS RN: 487-93-4). Popular street names for this synthetic substance include Foxy, Foxy Methoxy, and 5MEO. Synthesis of 5-MeO-DIPT involves the

conversion of 5-methoxy indole via the corresponding indole-3-glyoxylamide. All these compounds are agonists for serotonin 5-HT$_2$ receptors; their hallucinogenic properties depend on their affinity for these receptors.

DOSE EFFECT

The administration of oral doses of up to 6–10 mg 5-MeO-DIPT (Foxy) to healthy volunteers produced relaxation, mild auditory illusions (i.e., lowering of tone), and talkativeness that peaked about 1–1.5 hours after administration and resolved within 4 hours.[5] Adverse effects included nausea, vomiting, diarrhea, muscle spasms, muscle hyperactivity, and agitation. The intense sensory disturbances commonly associated with dimethyltryptamine and psilocybin use were absent.

TOXICOKINETICS

The relatively good oral bioavailability of 5-methoxy-diisopropyltryptamine is unusual among tryptamine compounds because of the resistance of this drug to degradation by gastrointestinal monoamine oxygenase.[5] Figure 11.1 displays the metabolic pathways of 5-methoxy-diisopropyltryptamine biotransformation. As suggested by the analysis of urine from volunteers

ingesting 5-MeO-DIPT, the major metabolites probably result from demethylation (5-hydroxy-diisopropyltryptamine, 5-OH-DIPT) and hydroxylation (6-hydroxy-5-methoxy-N,N-diisopropyltryptamine, 6-OH-5-MeO-DIPT).[7,8] Side chain degradation by N-deisopropylation to the corresponding secondary amine (5-methoxy-N-isopropyltryptamine, 5-MeO-NIPT) is probably a minor pathway, and the formation of the N-oxide is minimal. Presumed metabolites of 5-methoxy-diisopropyltryptamine include 5-methoxy-isopropyltryptamine, 5-methoxy-isopropyltryptamine-N-oxide, 5-methoxy-indole acetic acid, and 5-hydroxy-indole acetic acid. In rat liver microsomal fractions, kinetic and inhibition studies indicate that CYP2C11 and CYP3A2 mediates side-chain N-dealkylation, whereas CYP2D2 and CYP2C6 mediate the aromatic ring O-demethylation.[9]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

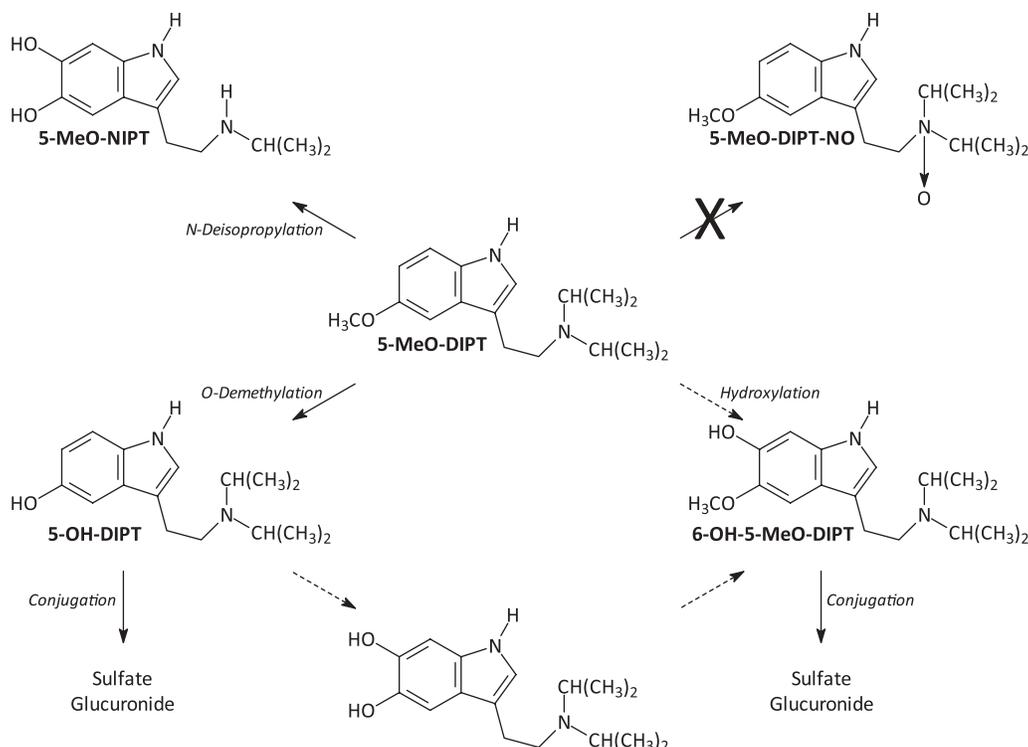
In vitro studies indicate that 5-MeO-DIPT has high affinity for 5-HT$_{1A}$ receptors and somewhat less affinity for 5-HT$_{2A}$ and 5-HT$_{2C}$ receptors; however, animal studies suggest that 5-HT$_{2A}$ receptors are the important sites of action for the hallucinogenic effects of 5-MeO-DIPT.[10] *In vitro* studies also suggest that 5-MeO-DIPT


FIGURE 11.1. Metabolic pathways of 5-methoxy-diisopropyltryptamine (5-Meo-DIPT) in humans. 5-Meo-DIPT is metabolized mainly by demethylation and hydroxylation. Most of the 6-OH-5-Meo-DIPT formed by hydroxylation is excreted as its conjugates.

acts as a competitive serotonin transporter (SERT) inhibitor.[11] SERT belongs to the Na$^+$-dependent transporter family that is responsible for the uptake of serotonin (5-HT) following the release of 5-HT into the synaptic cleft. The hallucinogenic effects of 5-MeO-DIPT are probably mediated by multiple molecular targets in the serotonergic system.

CLINICAL RESPONSE

Adverse effects associated with the use of Foxy include nausea, vomiting, mydriasis, auditory and visual hallucinations, formication, tachycardia, hypertension, confusion, echolalia, and paranoia based on case reports.[12,13] Tremors and seizures are rare. Other adverse effects associated with the recreational use of 5-MeO-DIPT include restlessness, agitation, and muscle tension. Case reports associate the use of 5-MeO-DIPT with rhabdomyolysis and transient acute renal failure.[14] Recurrent seizures are more common following intoxication with 5-methoxy-α-methyltryptamine than with 5-MeO-DIPT. The onset of action following the ingestion of Foxy is relatively rapid (<2 h) with symptoms persisting approximately 3–6 hours. Case reports suggest that flashbacks can occur following the chronic use of 5-methoxy-*N*,*N*-diisopropyltryptamine.[15]

DIAGNOSTIC TESTING

Methods for quantification of 5-MeO-DIPT metabolites include liquid chromatography/mass spectrometry, liquid chromatography/tandem mass spectrometry, and gas chromatography/mass spectrometry (GC/MS). Methods for the simultaneous detection and quantitation of designer tryptamine, β-carboline, and other phenethylamine compounds including 5-MeO-DIPT involves micellar electrokinetic chromatography (MEKC),[16] GC/MS, liquid chromatography/electrospray ionization/mass spectrometry, and mass spectral fragmentation.[17,18] The limit of detection (LOD) for DET using cation-selective exhaustive injection-sweep-MEKC was about 2 ng/mL. A 23-year-old man presented to the emergency department (ED) with nausea, vomiting, formication (tactile hallucinations), and paranoia after ingesting Foxy 3 hours earlier.[13] A serum sample drawn 1 h after admission to the emergency department contained 0.14 mg 5-MeO-DIPT/L as measured by GC/MS. Analysis by GC/MS detected 5-MeO-DIPT concentrations of 1.7 mg/L in a urine sample collected from a 21-year-old man 4 hours after the ingestion of a homemade capsule containing 5-MeO-DIPT. He developed visual hallucinations and mydriasis, but his symptoms resolved by the time of the sample collection.

A 29-year-old man developed intense agitation after the rectal administration of 5-MeO-DIPT; he died a few hours later in the hospital. Postmortem blood (site not reported) contained the following concentrations: 5-MeO-DIPT, 0.412 mg/L; 5-OH-DIPT, 0.327 mg/L; and 5-MeO-NIPT, 0.020 mg/L.[19] The urine sample from a 21-year-old man contained 1.7 mg 5-MeO-DIPT/L as measured by GC/MS.[20] Clinical features of intoxication at the time of presentation included mydriasis, mild hallucinations, and difficulty moving his extremities. At the time of the sampling 4 hours after ingestion, the patient was asymptomatic. Analysis of a urine sample collected 35 hours after the ingestion of 50 mg 5-MeO-DIPT detected the presence of 5-MeO-DIPT as measured by liquid chromatography/mass spectrometry (LOD, 3 ng/mL).[7] Urine drug screens used in the clinical setting do not commonly detect the various tryptamine designer drugs.[21]

TREATMENT

The treatment of 5-MeO-DIPT is supportive. Life-threatening medical reactions following exposure to tryptamine compounds are extremely rare. All patients should be evaluated for organic disease with vital signs, physical examination, and a thorough history that includes current symptoms, premorbid function, and prior medical and psychiatric conditions. Vital signs should include an accurate rectal temperature that is repeated if the patient deteriorates. The sympathomimetic effects of tryptamines are usually mild and transient, except in patients with underlying cardiovascular disease. Important aspects of the management of tryptamine-related panic attacks include reduction of sensory stimulation and reassurance that the frightening images are drug-related, similar to the treatment of harmala alkaloid intoxication. Continuous interpretations of sensory misperceptions and pseudo-hallucination are necessary to reduce the anxiety associated with a "bad trip."

α-METHYLTRYPT-AMINE (AMT) and α-ETHYLTRYPTAMINE (AET)

α-Methyltryptamine (AMT) and α-ethyltryptamine (AET) are synthetic drugs derived from tryptamine

with *N,N*-dimethyltryptamine (DMT) being the prototypical hallucinogen in this group. During the early 1960s, α-ethyltryptamine (Monase®, Upjohn Company) was marketed in the United States as an antidepressant and stimulant, but the drug was removed shortly after introduction because of the occurrence of serious blood disorders. Since the 1980s, AET has been sold illicitly as a substitute for MDMA (ecstasy).[22] Clinical trials and animal studies during the early 1960s evaluated the efficacy of α-ethyltryptamine acetate (Monase®) and α-methyltryptamine as neuroleptic agents for schizophrenia and depression. AMT (Indopan) was marketed in the Soviet Union during the 1960s as an antidepressant. AMT was one of the hallucinogenic drugs used by Ken Kesey during the 1960s as recorded by Alexander Shulgin.[23] In 2003, the US Drug Enforcement Administration (DEA) added α-methyltryptamine and 5-methoxy-*N,N*-diisopropyltryptamine (5-MeO-DIPT, Foxy) to schedule I of the Controlled Substances Act.[24,25] Previously, α-ethyltryptamine and *N,N*-dimethyltryptamine were included in this list.

IDENTIFYING CHARACTERISTICS

Both α-ethyltryptamine (etryptamine, CAS RN: 2235-90-7, $C_{12}H_{16}N_2$) and α-methyltryptamine (indopan, CAS RN: 299-26-3, $C_{11}H_{14}N_2$), possess central stimulant and hallucinogenic activity.[26] Both optical isomers of α-ethyltryptamine are active; the stimulant properties reside primarily in the (−)-enantiomer, whereas the (+) enantiomer has hallucinogenic properties. Street names for α-ethyltryptamine include Love Pearls and ET; α-methyltryptamine is known as Day Tripper and IT-290. Table 11.1 lists some physiochemical properties of α-ethyltryptamine, which is a reversible monoamine oxidase inhibitor and monamine-releasing substance (i.e., serotonin, dopamine).

DOSE EFFECT

Humans

The administration of up to 300 mg α-ethyltryptamine acetate daily for 2 months to psychiatric inpatients and outpatients was associated with occasional side effects including facial flushing, headache, gastrointestinal dis-

TABLE 11.1. Some Physiochemical Properties of α-Ethyltryptamine.

Physical Property	Value
Melting Point	97°C (206.6°F)
log P (Octanol-Water)	2.170
Water Solubility	510 mg/L

tress, insomnia, and irritability.[27] A case report associated the ingestion of 700 mg α-ethyltryptamine with fatal hyperthermia and agitated delirium.[22]

In studies of volunteer inmates, α-methyltryptamine was a more powerful psychotomimetic agent than α-ethyltryptamine with effects similar to LSD. The most common adverse effects associated with the ingestion of 20 mg α-methyltryptamine were mydriasis, nervous tension, and restlessness.[28] The most prominent effects following the ingestion of 150 mg α-ethyltryptamine by these volunteers were anorexia and the feeling of intoxication. The ingestion of an estimated 100 mg AMT was associated with agitation, confusion, disorientation, hallucination, diaphoresis, mydriasis, and sinus tachycardia.[29] The patient recovered with supportive care.

Animals

In animal studies, the oral administration of up 30 mg α-ethyltryptamine/kg body weight and up to 20 mg α-methyltryptamine/kg body weight daily for 28 days produced no obvious clinical effects or histologic abnormalities.[30] Chronic oral administration of α-methyltryptamine and α-ethyltryptamine in daily doses up to 10 mg/kg body weight for 1 year produced some transient salivation, muscle tension in a group of rats, but no histologic changes were detected.[31] The administration of daily doses up to 30 mg α-ethyltryptamine/kg to dogs caused transient sign of intoxication, but no permanent changes or histologic evidence of tissue damage.

TOXICOKINETICS

Early pharmacokinetic studies suggest the absorption of AET is rapid with a relatively wide volume of distribution; intoxication may occur following ingestion as well as insufflation. AET undergoes 6-hydroxylation to the inactive metabolite, 3-(2-aminobutyl)-6-hydroxyindole. Elimination occurs primarily via the kidney with a plasma half-life of approximately 8 hours.[32] In rodent studies, elimination of AMT occurs primarily by renal excretion of unchanged AMT.[33] The primary urinary metabolites in these studies were 2-oxo-AMT, 6-OH-AMT, 7-OH-AMT, and 1′-OH-AMT. Limited data in humans suggests that liver excretes little AET in the bile, whereas a majority of the dose of AET appears in the urine within 12–24 hours.[32]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

In rodent studies, multiple doses of AET (8 × 30 mg/kg/sc) produce reductions in serotonin and 5-hydroxy-

indole acetic acid (5-HIAA) concentrations in the hippocampus and frontal cortex similar to MDMA.[34]

CLINICAL RESPONSE

Clinical features associated with the ingestion of AET or AMT include nausea, agitation, restlessness, lethargy, euphoria, confusion, distortion of images (color, shape), and visual hallucinations.[29] Mild elevations of blood pressure and temperature typically occur; other effects include mydriasis, salivation, diaphoresis, clenching of the jaw, and tachycardia. Depersonalization may also occur, but alteration of visual perception is uncommon. In volunteer studies, the onset of action of α-methyltryptamine is relatively slow with an onset of action being 3–4 hours and the duration of action being about 12–24 hours.[28] The onset of action of α-ethyltryptamine is about 30–90 minutes.[28] The duration of intoxication following ingestion of AET was approximately 6 hours with subsequent feelings of lethargy and sedation.

DIAGNOSTIC TESTING

Analytic Methods

A sensitive (LOD, 1 ng/mL) and selective method for the determination for α-methyltryptamine and 5-methoxy-*N*,*N*-diisopropyltryptamine involves extraction using Extrelut® column (Merck & Co., Inc., Whitehouse Station, NJ), with an internal standard, bupivacaine, followed by derivatization with acetic anhydride and analysis by gas chromatography/electrospray ionization/mass spectrometry in selected ion monitoring.[35]

Biomarkers

A 19-year-old woman became disoriented and vomited after ingesting α-ethyltryptamine.[36] Later, she developed cardiac arrest; she could not be resuscitated by bystanders or by the paramedics. She was pronounced dead at the scene; postmortem examination demonstrated pulmonary edema, generalized visceral congestion, and some epicardial petechiae. Analysis of postmortem samples demonstrated the following α-ethyltryptamine concentrations: heart blood, 5.6 mg/L; vitreous humor, 2.4 mg/L; bile, 22.0 mg/L; and gastric contents, 52.9 mg. α-Ethyltryptamine can cross-react with some immunoassays for amphetamines. Analysis of postmortem blood from a fatality involving hyperthermia after the use of α-ethyltryptamine demonstrated 1.1 mg α-ethyltryptamine/L.[22] Postmortem blood from the iliac vein of a young college student found unre-

sponsive after ingesting α-methyltryptamine about 12 hours previously contained 2.0 mg α-methyltryptamine/L.[37] The amount of α-methyltryptamine in the gastric contents was 9.6 mg.

TREATMENT

Treatment of AMT or AET intoxication is supportive, similar to 5-MeO-DIPT intoxication. Although life-threatening medical reactions following exposure to tryptamine compounds are extremely rare, case reports associate the use of these drugs with severe hyperthermia. All patients should be evaluated for organic disease with vital signs, physical examination, and a thorough history that includes current symptoms, premorbid function and prior medical and psychiatric conditions. Vital signs should include accurate rectal or core temperatures that are repeated if the patient deteriorates. As measured by rectal thermocouple, a core temperature exceeding 40.5°C (105°F) indicates the need to cool the patient (e.g., ice water bath, evaporative cooling) and to monitor vital signs every 10–15 minutes after stabilization. Ice packs and the use of hypothermic blankets are alternative measures when an ice bath is not available. The patient should be removed when the core rectal temperature drops to 39°C (102°F). Less severe temperature elevations (38–40°C/100.4–104°F) can be treated by placement in a cool room, removal of clothes, minimization of physical activity, sedation with benzodiazepines as needed, tepid sponging, or evaporative methods (cool mist spray, fans). These patients should receive aggressive fluid resuscitation to maintain adequate urine output and to minimize the effects of rhabdomyolysis.

Chapter 12

DIURETICS, IPECAC, and LAXATIVES

Cyrus Rangan, MD

Patients with anorexia nervosa (i.e., purge) and bulimia nervosa (i.e., binge/purge) frequently experience recurrent episodes of attempted weight loss by calorie restriction, self-induced vomiting, and/or the surreptitious use of pharmaceutic drugs (diuretics, syrup of ipecac, laxatives). Bulimic patients couple binge eating with behavior intended to promote weight loss (diuretics/laxatives/emetics, self-induced vomiting, strenuous exercise, fasting), whereas anorexic patients control their dietary intake much more than bulimics. Both anorexic and bulimic patients often abuse other drugs including ethanol and various types of diet pills.[1] Chronic abuse of syrup of ipecac, diuretics, and laxatives may cause tolerance to the anorexic effects of the drugs along with a desire to increase dosing to control weight.[2] The combination of dietary restrictions and abuse of over-the-counter preparations may result in electrolyte imbalance (hypokalemia, hypocalcemia, hypomagnesemia), protein-calorie malnutrition, and cardiac dysrhythmias.[3] The psychologic impact of this abuse is consistent with the pre-existing eating disorder rather than a direct toxic effect of the abused pharmaceutic agents. These patients appear preoccupied with weight-control, calorie intake, or continuous exercise, even with apparently average or thin body habitus. They hide their body shape with baggy clothes, and surreptitiously use frequent trips to the bathroom for purging and catharsis. Often, they express self-defeating statements after food consumption and display low self-esteem, mood swings, and depression. A perfectionist personality frequently accompanies eating disorders, which may intensify after self-imposed escalation of dosage regimens of diuretics, syrup of ipecac, and/or laxatives.

DIURETICS

Classification of diuretics include the following: 1) the loop diuretics or inhibitors of the $Na^+/K^+/2Cl^-$ symporter (e.g., bumetanide, ethacrynic acid, furosemide), 2) inhibitors of the Na^+/Cl^- symporter (thiazide diuretics), 3) carbonic anhydrase inhibitors (e.g., acetazolamide), 4) osmotic diuretics (e.g., glycerin, mannitol, urea), 5) inhibitors of renal epithelial Na^+ channels (e.g., amiloride, triamterene), and 6) mineralocorticoid receptor antagonists (e.g., spironolactone). Abuse of diuretics causes net weight loss and multiple systemic toxicities by promoting the excretion of water and electrolytes; however, these drugs neither prevent the absorption of food nor accelerate the metabolism or excretion of nutrients. The World Anti-Doping Agency (WADA) added diuretics to the list of prohibited substances in 1988. During 2008, diuretics accounted for 7.9% (436 cases) of all adverse analytic findings reported by WADA laboratories with hydrochlorothiazide (137 cases) and furosemide (104 cases) representing the most common abused diuretics.[4] Abuse of diuretics in the competitive sports world results from the use of these drugs to induce rapid weight loss to meet a weight category and to mask the administration of other doping agents by reducing urine

drug concentrations. There is no evidence that the use of diuretics improves athletic performance as the dehydration associated with diuretic use impairs maximal exercise capacity and muscular strength.[5]

Furosemide

IDENTIFYING CHARACTERISTICS

Furosemide [5-(aminosulfonyl)-4-chloro-2-((furanylmethyl)amino)benzoic acid, $C_{12}H_{11}ClN_2O_5S$] is a commonly abused diuretic. Figure 12.1 displays the chemical structure of furosemide (CAS RN: 54-31-9). Table 12.1 lists some physiochemical properties of furosemide.

EXPOSURE

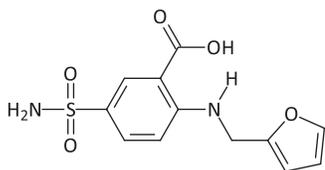
Although many individuals with eating disorders use diuretics, relatively few of these individuals continue the use of diuretics on a regular basis.[2] A commonly reported use for diuretics in these patients is the control of weight gain secondary to premenstrual water retention. The prevalence of diuretic use in patients with bulimia nervosa is particularly high. In a study of 275 bulimic women, approximately one-third of these patients reported the use of diuretics for weight control and about 10% in this series used diuretics daily.[6] Reported weekly diuretic use in 14 regular diuretic users ranged from 1–14 times.[7] Furosemide is a synthetic benzoic-


FIGURE 12.1. Chemical structure of furosemide.

TABLE 12.1. Some Physiochemical Properties of Furosemide.

Physical Property	Value
Molecular Weight	330.7441 g/mol
Melting Point	295°C (563°F)
log P (Octanol-Water)	2.03
Water Solubility	73.1 mg/L (30°C/86°F)
Vapor Pressure	3.23E-10 mm Hg (25°C/77°F)

sulfonamide-furan "loop" diuretic and saluretic for treatment of edema, congestive heart failure, and chronic renal insufficiency.

DOSE EFFECT

Typical daily doses of furosemide are 1–3 mg/kg body weight in children and 20–600 mg in adults depending on the severity of the underlying illness (lower doses for hypertension and edema, higher doses for chronic renal failure). A 25-year-old woman developed syncope, nausea, vomiting, dizziness, hyponatremia, and hypokalemia after taking 200 mg of furosemide daily for 3 days while fasting to reach a specific weight target.[8] Interpretation of clinical data on toxicity associated with chronic abuse of diuretics is complicated by variable intake of fluid and electrolytes as well as the unreliability of histories for the surreptitious use of diuretics and other drugs (diet pills, herbs, ipecac, laxatives). Chronic abuse of 12.5 mg furosemide/kg daily and 375 mg 18 hours prior to admission resulted in muscle weakness, carpopedal spasms, myalgias, and tetany secondary to electrolyte depletion (calcium, magnesium, potassium).[9] Abuse of furosemide may reach 2 g daily for extended periods with relatively minor changes in serum electrolytes, depending on dietary habits and the extent of abuse of other weight control measures.[10]

TOXICOKINETICS

Kinetics

Furosemide is rapidly absorbed after ingestion with about 60% bioavailability.[11] The volume of distribution is small (0.11 L/kg) with high protein binding (~98–99%). The liver conjugates about 35% of the absorbed dose of furosemide with glucuronic acid. The kidney excretes the remainder as unchanged furosemide. Following therapeutic doses of furosemide, the serum half-life averages approximately 1.5 hours, but serum half-life may exceed 20 hours after chronic ingestion of high doses of furosemide.[11] Total systemic clearance of furosemide is about 2 mL/min/kg body weight.

Furosemide crosses the placenta during the peripartum period with similar furosemide concentrations in umbilical cord and maternal blood 8–10 hours after daily oral doses of 25–40 mg.[12] In general, diuretics are considered safe for use in lactating mothers despite the secretion of furosemide into breast milk.[13]

Tolerance

Gradual tachyphylaxis to diuretics develops after long-term administration; repeat use of loop diuretics may

initiate and perpetuate alternating diuresis and reflex water retention, leading to weight fluctuations.[14] Hypertrophy occurs in the distal tubule in response to elevated tubular sodium concentrations and the enhanced reabsorption of sodium and water. Coadministration of thiazide restores diuresis in therapeutic settings by blocking distal tubule sodium reabsorption.[15] Diuretic abuse may involve dual diuretic administration when loop diuretics fail to control weight.

Drug Interactions

The concomitant administration of furosemide with ceftazidime increases the serum concentrations of the latter; however, there are few data on the clinical significance of this potential interaction.[16] Case reports suggest that the administration of an aminoglycoside (e.g., gentamicin) followed by furosemide may increase the risk of ototoxicity.[17] The concomitant administration of phenytoin or phenobarbital with furosemide may decrease serum furosemide concentration by about 50–65% as a result of a reduction in the gastrointestinal (GI) absorption of furosemide.[18] Case reports associate the ingestion of chloral hydrate within 24 hours prior to the administration of furosemide with diaphoresis, flushing, anxiety, and hypertension similar to degreaser's flush.[19,20] The combination of furosemide and corticosteroids may result in severe potassium depletion, possibly augmented by steroid-induced overproduction of endogenous aldosterone.[21] Potassium depletion by furosemide may potentiate myocardial sensitivity to digoxin toxicity.[22] The concomitant administration of herbal diuretic preparations (e.g., licorice, gossypol) with furosemide may potentiate the electrolyte abnormalities associated with chronic furosemide abuse.[23]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

Furosemide binds reversibly to the sodium-potassium-chloride symporter complex in the thick ascending loop of Henle, blocking the reabsorption of sodium and chloride; consequently, interstitial hypertonicity decreases along with water reabsorption. The persistence of these electrolytes in the lumen of the thick ascending limb abolishes the 10-millivolt transepithelial potential gradient, which is the driving force for calcium and magnesium efflux into the interstitial space. Subsequently, reabsorption of calcium and magnesium decreases. Furosemide significantly enhances urinary potassium excretion both by reducing potassium reabsorption in

the loop of Henle and by enhancing distal tubular potassium secretion.[24]

Mechanism of Toxicity

Furosemide induces ototoxicity by altering the electrolyte composition of endolymph, and inducing edema of the stria vascularis, presumably by inhibition of electrolyte symporters similar to those found in the ascending limb of the loop of Henle.[25] Hyponatremia and hypokalemia are common complications of furosemide abuse. Diminished sodium and chloride reabsorption from overuse or abuse of diuretics causes hyponatremia. The resulting increased delivery of sodium to the distal tubule activates the renin-angiotensin system; subsequently, production of aldosterone increases along with increased secretion of potassium and hydrogen ions into the distal tubule.

Case reports associate the rapid correction of severe hyponatremia in patients chronically abusing furosemide with central pontine myelinolysis.[26] During prolonged hyponatremia from chronic furosemide abuse, the brain minimizes cerebral edema by extruding osmotically active particles (e.g., amino acids, sodium, potassium) from the intracellular compartment. The rapid expansion of extracellular fluid during the quick correction of chronic hyponatremia with hyperosmotic saline rapidly reduces brain size; damage of myelin sheaths subsequently occurs.[27,28] Although the central pons is the most sensitive area of the brain, other areas of the brain may undergo myelinolysis. A mutation in the gene (SLC12A3) for the thiazide-sensitive NaCl coporter in the distal convoluted tubule is responsible for hypokalemic metabolic alkalosis and hypomagnesemia associated with Gitelman syndrome that simulates chronic diuretic abuse.[29]

CLINICAL RESPONSE

Illicit Use

Overdoses of diuretics rarely cause acute toxicity; however, significant dehydration and electrolyte imbalance occurs following the chronic abuse of diuretics by patients with eating disorders. The abuse of furosemide is associated with signs of dehydration including thirst, lethargy, poor skin turgor, postural hypotension, syncope, dry mucous membranes, tachycardia, and fatigue. Delirium, rhabdomyolysis, and renal dysfunction (acute tubular necrosis) may result from severe dehydration and hypokalemia. Tinnitus with temporary or irreversible deafness may occur following chronic abuse of high doses of furosemide.

Central Pontine Myelinolysis

Case reports associate the rapid correction of chronic hyponatremia secondary to anorexia nervosa and diuretic abuse with the development of confusion, delirium, oculomotor abnormalities, dysarthria, dysphagia, spastic weakness, and quadriparesis or pseudobulbar palsy. The onset of symptoms of this disorder may occur several hours to a week after the correction of the serum sodium concentration. A 35-year-old woman became severely hyponatremic (serum sodium, 91 mEq/L) and hypokalemic (serum potassium, 1.6 mEq/L) following the chronic abuse of furosemide (400 mg daily) and the ingestion of large volumes of water.[26] The serum sodium was corrected rapidly within the first 32 hours (1 mEq/L/h); she became agitated, labile, and tremulous within 2–3 days. Four days later, she was dysphagic, ataxic, and dysarthric; initially, she had a flaccid quadriplegia that subsequently became spastic. Several months of physical therapy were necessary to regain her gait and speech. Pancreatitis, nephrocalcinosis, ureteral stones, and hypercalciuria may occur following long-standing diuretic abuse.[30]

Pseudo-Bartter Syndrome

Case series associate the surreptitious use of diuretics with hyperreninemic hypokalemic metabolic alkalosis in the presence of normal blood pressure and normal urinary excretion of sodium and chloride, similar to Bartter syndrome. The latter syndrome is a rare genetic abnormality that causes chronic hypokalemic alkalosis in adults. Distinguishing these 2 syndromes may be difficult when the patient does not admit the use of diuretics. In a study of 5 patients with pseudo-Bartter syndrome and 6 patients with Bartter syndrome, the plasma sodium potassium, chloride, bicarbonate, renin, and aldosterone concentrations of the 2 groups were similar, whereas the serum magnesium and uric acid concentrations were greater in the pseudo-Bartter syndrome group.[31] Gitelman syndrome is the hypocalciuric variant of Bartter syndrome that causes hypomagnesemia in adults. This syndrome causes hypokalemic metabolic alkalosis and hyperreninemic hyperaldosteronism with normal blood pressure similar to Bartter syndrome and diuretic abuse.

Abstinence Syndrome

Discontinuation of chronic diuretic use may cause rebound edema and weight gain that requires days to weeks to resolve.[32] Fluid retention with paradoxical diuresis may be particularly prominent during the first several days after cessation of diuretic abuse. This transient weight gain may be associated with bloating, abdominal distention, and ankle edema. The perception of increased weight gain after cessation of diuretic use encourages resumption of diuretic abuse by anorectic and bulimic women.

Reproductive Abnormalities

Diuretics are not recommended during pregnancy, secondary to neonatal kidney and electrolyte abnormalities, especially during the third trimester. The US Food and Drug Administration classifies furosemide as category C (little or no adverse animal data, no controlled human studies) in pregnancy.

DIAGNOSTIC TESTING

Analytic Methods

Analytic techniques for the quantitation of furosemide in biologic samples include high performance liquid chromatography (HPLC) with spectrofluorometric detection,[30] gas chromatography/electron capture negative ionization/mass spectrometry,[33] and solid-phase extraction followed by high pressure liquid chromatography/electrospray ionization/tandem mass spectrometry.[34] This latter method detects 35 diuretics and metabolites at urinary concentrations significantly below 100 ng/mL, whereas the limit of detection (LOD) for gas chromatography/electron capture negative ionization/mass spectrometry is typically <5–10 ng/mL. WADA established a single minimum required performance level (MRPL) of 250 ng/mL for the detection for diuretics in urine by accredited laboratories, typically by gas chromatography/mass spectrometry (GC/MS), liquid chromatography/mass spectrometry (LC/MS), or liquid chromatography/tandem mass spectrometry with electrospray ionization.[35] Similar to hydrochlorothiazide and triamterene, the short half-life of furosemide limits detection of this diuretic in urine samples collected 24–48 hours after administration.

Biomarkers

Detection of surreptitious diuretic use involves sequential measurements of urine chloride concentrations and the analytic confirmation of diuretics in urine samples. Patients abusing diuretics typically develop hypokalemic metabolic alkalosis with normal urine chloride excretion during periods of abstinence. Wide variation in the urinary excretion of potassium, sodium, and chloride suggests diuretic use. Urine concentrations of these

ions increase shortly after ingestion of diuretics, whereas maximum reduction in the urinary concentration of these ions occurs during the postdiuretic phase. Consequently, measurement of urinary chloride excretion does not necessarily distinguish between Bartter syndrome and the use of furosemide because furosemide impairs tubular reabsorption of chloride similar to Bartter syndrome. Diuretic use causes contraction of extracellular fluid and increases proximal tubule solute reabsorption. The presence of reduced uric acid and fractional lithium clearances (i.e., markers of postproximal solute delivery) along with reduced renal response to a standard infusion of furosemide separate diuretic use (pseudo-Bartter syndrome) from Bartter syndrome.[31]

Abnormalities

The characteristic electrolyte profile associated with furosemide abuse is a hyponatremic, hypochloremic, and hypokalemic metabolic alkalosis. However, the presenting serum and urinary electrolyte abnormalities associated with diuretic abuse may be complicated by the concomitant use of laxatives, self-induced vomiting, or dietary restrictions. The hypokalemia associated with diuretic abuse may be severe (e.g., 1.3 mEq/L) in association with normal serum chloride concentrations and elevated serum bicarbonate.[36] Although serum sodium and magnesium concentrations are often normal, occasionally mild to moderate hyponatremia and hypomagnesemia develop along with hypokalemia.[37] Hyponatremic hypotonic dehydration along with hypokalemia following chronic furosemide abuse typically occurs in the setting of excessive water ingestion and/or the abuse of other diuretics (e.g., hydrochlorothiazide).[38] Rarely, hyperglycemia and hyperuricemia may result from the chronic abuse of diuretics.[38] Excessive diuresis and dehydration may cause a transient decrease in glomerular filtration rate and elevation of serum blood urea nitrogen. A paradoxical diuresis may continue for several days after drug cessation. Magnetic resonance imaging (MRI) of the brain in patients with central pontine myelinolysis demonstrates ventricular dilation and extensive central pontine lesions. The size of the MRI lesion does not correlate well with the initial serum sodium concentration or the severity of neurologic abnormalities.[39]

TREATMENT

Initial medical management should be directed at the correction of fluid and electrolyte imbalance along with the restoration of a normal diet. These patients should

be evaluated for electrolyte (sodium, potassium, chloride, magnesium, calcium) and acid–base abnormalities, anemia, pancreatitis, rhabdomyolysis, volume depletion, renal dysfunction, and electrocardiographic abnormalities. Fluid replacement typically involves replacement of sodium and chloride losses with saline. Rare complications include cardiac dysrhythmias, hearing loss, hyperuricemia, and pancreatitis. Severe chronic hyponatremia should be corrected relatively slowly (<0.55 mEq/L/h) to prevent the development of central pontine myelinolysis.[26] The serum sodium should be <135 mEq/L with the first 48 hours of treatment; hypernatremia should be avoided. Peripheral edema may occur during the first few weeks after cessation of diuretic abuse, which usually responds to salt restriction. Hospitalization may be necessary to correct hypokalemic metabolic alkalosis and to stop the use of diuretics and other methods to control weight.

Hydrochlorothiazide

IDENTIFYING CHARACTERISTICS

Hydrochlorothiazide [2H-1,2,4-benzothiadiazine-7-sulfonamide, 6-chloro-3,4-dihydro-1,1-dioxide, $C_7H_8ClN_3O_4S_2$] is another commonly abused diuretic. Figure 12.2 displays the chemical structure hydrochlorothiazide (CAS RN: 58-93-5). In conditions within the body, hydrochlorothiazide is moderately soluble in water. Table 12.2 lists some physiochemical properties of hydrochlorothiazide.

EXPOSURE

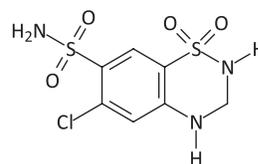
Hydrochlorothiazide is a synthetic compound available as monotherapy for the treatment of hypertension or edema, and more frequently in combination therapy with other pharmaceuticals (e.g., angiotensin converting enzyme inhibitors, potassium sparing diuretics). This diuretic is distributed as a pill or capsule; however, this drug is not available commercially in a parenteral form.


FIGURE 12.2. Chemical structure of hydrochlorothiazide.

TABLE 12.2. Some Physiochemical Properties of Hydrochlorothiazide.

Physical Property	Value
Molecular Weight	297.7391 g/mol
Melting Point	274°C (525.2°F)
pKa Dissociation Constant	7.9
log P (Octanol-Water)	–0.07
Water Solubility	722 mg/L (25°C/77°F)
	1,080 mg/L (37°C/98.6°F, pH 7.4)
Vapor Pressure	1.32E-09 mm Hg (25°C/77°F)

TOXICOKINETICS

The oral bioavailability of hydrochlorothiazide is relatively high (i.e., about $70 \pm 15\%$). In a study of 10 healthy volunteers receiving 25 mg hydrochlorothiazide daily for 45 days, the mean time to peak hydrochlorothiazide concentration was 2.8 ± 0.40 hours.[40] The apparent volume of distribution and mean terminal plasma elimination half-life vary several-fold among pharmacologic studies of clinical doses of hydrochlorothiazide (i.e., 25–100 mg), at least partially as a result of differences in the postdose sampling times between studies. The mean apparent volume of distribution in the studies with longer monitoring periods are in the range of approximately 3–4 L/kg.[41] In a study of 4 healthy adults receiving a single dose of 100 mg hydrochlorothiazide and monitored for 48 hours, the mean V_d was 3.48 L/kg.[42] The mean apparent volume of distribution (V_d) was 2.58 ± 0.30 L/kg in a study of 12 healthy volunteers receiving hydrochlorothiazide doses up to 200 mg.[43] The mean terminal plasma elimination half-lives of the studies with longer monitoring periods are in the range of approximately 9–12 hours.[41] A study of 12 healthy volunteers receiving a single dose of 25–200 mg hydrochlorothiazide demonstrated a mean terminal plasma half-life of 9.75 hours.[43] In a study of 10 healthy volunteers receiving 25 mg hydrochlorothiazide daily for 45 days, the plasma elimination half-life was 8.00 ± 2.50 hours.[40] Elimination of hydrochlorothiazide occurs almost exclusively by renal excretion of unchanged drug. Although hydrochlorothiazide is excreted in breast milk, case reports suggest that the daily ingestion of 50 mg hydrochlorothiazide by lactating mothers does not produce detectable hydrochlorothiazide concentration (i.e., <20 ng/mL) in breast feeding infants.[44]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Thiazide diuretics inhibit sodium and chloride reabsorption in the cortical diluting segment of the proximal segments of the distal tubule and the distal portion of the ascending loops of Henle; however, hydrochlorothiazide does not limit the reabsorption of calcium or magnesium. The increased amount of sodium leaving the proximal tubule results in a reflex increase in aldosterone secretion that enhances sodium reabsorption from the distal tubule. The exchange of sodium for potassium causes an increased loss of potassium in the urine. Hydrochlorothiazide is a relatively weak diuretic compared with furosemide, but hydrochlorothiazide produces a dose-dependent loss of potassium in the urine that is greater than furosemide. Marked hypokalemia is uncommon unless the dose of hydrochlorothiazide is large or the patient has Cushing syndrome. The inhibition of the renal tubular excretion of uric acid may cause an attack of gout in susceptible patients.

CLINICAL RESPONSE

Similar to furosemide, chronic abuse of hydrochloride may cause severe electrolyte and fluid imbalance, pseudo-Bartter syndrome, and central pontine myelinolysis (i.e., after the rapid correction of hyponatremia). Complications of the therapeutic use of hydrochlorothiazide include hemorrhagic pancreatitis, acute gout, and hyperglycemia in diabetic patients.[45]

DIAGNOSTIC TESTING

Analytic Methods

Analytic techniques for the quantitation of hydrochlorothiazide in biologic samples include thin layer chromatography (TLC),[46] high performance liquid chromatography (HPLC) with UV detection,[47] HPLC with electrochemical detection,[48] liquid chromatography/tandem mass spectrometry,[49] and GC/MS. The LOD for TLC is approximately 5,000 ng/mL compared with 300 ng/mL for GC/MS and approximately 1 ng/mL for liquid chromatography/tandem mass spectrometry.[50] *In vitro* studies indicate that hydrochlorothiazide concentrates in erythrocytes. The concentration of hydrochlorothiazide is about 10-fold higher in erythrocytes than plasma;[51] limited pharmacokinetic data suggests that whole blood hydrochlorothiazide concentrations are about 2.5-fold higher than plasma hydrochlorothiazide concentrations.[52] Degradation products of hydrochlorothiazide in aqueous media (e.g., 4-amino-6-chloro-1,3-benzenedisulphonamide) allows the detection of

diuretic use up to 120 hours after administration when analyzed by liquid chromatography/tandem mass spectrometry.[53]

Biomarkers

In a study of 10 healthy volunteers receiving 25 mg hydrochlorothiazide daily for 45 days, the mean peak plasma hydrochlorothiazide concentration was 200 ± 40 ng/mL.[40] Limited pharmacokinetic data suggests that peak hydrochlorothiazide concentrations following therapeutic doses are higher in elderly patients compared with healthy young adults. In a study of 6 healthy young and 6 elderly volunteers receiving 25 mg hydrochlorothiazide daily, the mean peak plasma hydrochlorothiazide concentrations on day 1 were 298 ± 27 ng/mL and 484 ± 32 ng/mL, respectively.[54] On day 8, these 2 plasma concentrations (356 ± 18 ng/mL and 615 ± 43 ng/mL, respectively) were not significantly different than day 1. The mean peak plasma hydrochlorothiazide concentration in 4 healthy adults ingesting 100 mg hydrochlorothiazide was about 657 ng/mL.[42]

Abnormalities

The use of hydrochlorothiazide inhibits the urinary excretion of calcium with associated development of increased serum total and ionized calcium concentrations.[55] Abnormalities associated with the use and abuse of hydrochlorothiazide include pancreatitis, volume contraction and alkalosis, hypokalemia, hyponatremia, hyperuricemia, and reduced carbohydrate tolerance.[56,57]

TREATMENT

Treatment of complications associated with hydrochlorothiazide abuse is supportive, similar to furosemide abuse.

SYRUP OF IPECAC

HISTORY

The naturalist, Georg Marggraf and the physician Willem Pison first reported the use of ipecacuanha root (Rio ipecac) based on their travels in Brazil during the early 1900s.[58] Le Gras imported ipecacuanha root from South America in the latter 17th century as a treatment for flux (dysentery) and the ague (fever).[59] Jean-Adrien Helvetius used ipecacuanha root to treat members of the French Royalty for dysentery; both the root and powder became widely available in Europe during the 18th century. Pelletier isolated emetine from the mixture of alkaloids in extracts of ipecac, while working at the School of Chemistry in Paris in 1817. Later, the major methoxylated alkaloid retained the name emetine, whereas the other principal alkaloid with a free phenol group was named, cephaeline.[60] In 1908, Harrison first described ipecac poisoning when his stable boy developed severe vomiting and died soon after the incidental ingestion of fluid extract of ipecac (vinum ipecacuanha).[61] The pathology of muscle damage caused by the administration of emetine as an anthelminthic was described in the 1920s.[62] Although multiple deaths were attributed to the use of emetine during the first half of the 19th century, the lack of sufficient clinical details in these case reports limits conclusions regarding the contribution of toxic myocarditis to these deaths.[63] In the late 1950s, dehydroemetine was introduced as a more efficacious and less toxic treatment for amebiasis than emetine. Emetine was investigated as a chemotherapeutic agent for cancer treatment in the early and mid-19th century.[64] The more potent fluid extract of ipecac was removed from the US Pharmacopeia in the mid-1960s because of the severe toxicity associated with use of the extract instead of the syrup. In the United States, the use of emetine for the treatment of amebiasis ceased in the 1960s. The use of syrup of ipecac as an emetic for the treatment of poisonings has declined dramatically over the last 2 decades.

IDENTIFYING CHARACTERISTICS

Structure

The active ingredients in syrup of ipecac are emetine (CAS RN: 483-18-1) and cephaeline (CAS RN: 483-17-0). Figure 12.3 and Figure 12.4 display the chemical structures of emetine and cephaeline, respectively. Table 12.3 and Table 12.4 list some physiochemical properties of emetine (methyl cephaeline, $C_{29}H_{40}N_2O_4$) and cephaeline ($C_{28}H_{38}N_2O_4$), respectively.

log P (Octanol-Water)	4.890

Form

Syrup of ipecac is available in liquid form. Ipecac fluid extract is 14-fold more potent than syrup of ipecac. The United States Pharmacopeia (USP) guidelines state that syrup of ipecac should contain 1.23–1.57 mg/mL total ether soluble alkaloids (minimum 90% cephaeline and emetine).[65] However, the content of these alkaloids varies with manufacturing processes; the actual content of cephaeline and emetine may not meet the USP standards. Typically, the amount of cephaeline exceeds the amount of emetine in a 30-mL bottle of syrup of ipecac with a ratio ranging from approximately 1.5–3.

EXPOSURE

Although eating disorders occur in either gender and in various age groups, young women comprise the vast majority of patients with eating disorders. In a 5-year study of outpatients presenting to a suburban eating disorder clinic, there were 815 females (98.1%) and 16 males (1.9%) ranging in age from 11–74 years.[66] Of the 851 outpatients, 3.1% had a history of chronically abusing ipecac and 1.1% admitted the current abuse of ipecac. Anorexic and bulimic patients also use digital stimulation to induce vomiting.

The principal alkaloids in syrup ipecac are emetine and cephaeline; the sources of these compounds are the ground roots of *Psychotria ipecacuanha* (Brot.) Standl. (*Cephaelis ipecacuanha*, *Cephaelis acuminata*, *Uragoga acuminata*) from the Rubiaceae family. This small perennial shrub reaches 20–40 cm in height with opposite decussate leaves and white flowers (compact cymes). The twisted, fragmented roots are 6–15 cm in diameter. Although the structure of cephaeline and emetine are similar, emetine is the focus of the majority of toxicologic research on syrup of ipecac because of its relatively greater toxicity.[67]

DOSE EFFECT

Medical Use

Syrup of ipecac is no longer recommended for the standard treatment of poisonings. Previous single-dosing recommendations were 5–10 mL (120–240 mL water) in children aged 6–12 months, 15 mL (120–240 mL water) in children aged 1–12 years, and 15–30 mL (240 mL water) in adolescents and adults. The dose may be repeated in all age groups if vomiting has not occurred within 20–30 minutes after initial administration. There are limited data on the threshold doses and dose response for muscle damage following abuse of ipecac. In phase I dose-ranging studies of emetine as an intravenous (IV) chemotherapeutic agent, severe muscle weakness began at cumulative IV doses of approximately 15 mg/kg.[64] The suggested emetine dose for chemotherapy was 1.5 mg/kg intravenously weekly for a minimum total dose of 15 mg/kg.

Toxicity

In the older medical literature, a toxic cumulative emetine dose during therapeutic use was approximated at 20 mg/kg;[68] however, this toxic threshold is difficult to evaluate because of the potential effect of unreported medical conditions (e.g., parasitic infections, liver abscess, pneumonia, sepsis) associated with patients treated for amebiasis during this period. A 4-year-old boy received 60 mL ipecac fluid extract after ingesting commercial antacid tablets containing oil of peppermint, calcium carbonate, magnesium carbonate, and

magnesium trisilicate.[60] He was discharged home; he continued to vomit and developed diarrhea and fever. About 36 hours after the initial visit, he was hospitalized in profound shock with a heart rate of 200 beats per minute; he died 8 hours later. Death was ascribed to ipecac poisoning, but the actual cause of death was unclear because of multiple potential causes.

The surreptitious use of syrup of ipecac and the lack of laboratory confirmation of chronic abuse limit the estimation of the cumulative toxic dose necessary to cause damage. Consequently, the total emetine dose required to produce the onset of myopathy varies widely (i.e., 500–36,000 mg). [69] The escalating weekly abuse of syrup of ipecac from 30–210 mL over 6 months by a 19-year-old woman was associated with moderate to marked muscle weakness, waddling gait, dyspnea, palpitations, left atrial enlargement, and a reduced left ventricular ejection fraction (40%).[70] She also had mild elevation of serum muscle enzymes and hepatic aminotransferases along with normal electrolytes except mild hyperkalemia (5.4 mEq/L). She improved markedly with abstinence. A 26-year-old woman developed mild generalized motor weakness, dyspnea, QT_c prolongation (480 ms), and mild global ventricular dysfunction (ejection fraction, 45%).[71] She admitted the use of approximately 1,300–2,000 mL syrup of ipecac, and she improved following cessation of ipecac use. A prospective review of cases of chronic syrup of ipecac abuse revealed a range of 100–2,000 estimated lifetime doses.[72] A severe skeletal myopathy developed in the patient who had ingested 2,000 doses.

TOXICOKINETICS

Absorption

Both emetine and cephaeline are rapidly absorbed from the GI tract after ingestion, but the amount absorbed is highly variable depending primarily on the amount of emesis produced by syrup of ipecac. In a study of 12 volunteers receiving 30 mL syrup of ipecac (~25 mg cephaeline, ~15 mg emetine), all volunteers vomited and the recovery of both alkaloids was $76 \pm 14\%$ of the administered dose.[73] Peak plasma alkaloid concentrations occurred within 1 hour as measured by HPLC with fluorescence detection. The LOD for cephaeline and emetine was 1 ng/mL and 2.5 ng/mL, respectively. In a study of 10 healthy volunteers receiving 30 mL syrup of ipecac (45 mg cephaeline, 13.8 mg emetine), the mean peak plasma cephaeline concentration was 16.5 ± 13.5 ng/mL at 20.5 ± 10.9 minutes, whereas the mean peak plasma emetine concentration was 9.6 ± 4.1 ng/mL at 19.0 ± 8.1 minutes.[74] In a study of 10 emergency department patients

receiving 30 mL syrup of ipecac as a gastric decontamination measure, the range of plasma concentrations at 30 minutes after administration were as follows: cephaeline, nondetectable–73 ng/mL; emetine, nondetectable–68 ng/mL.[75] All patients vomited within 30 minutes after administration of syrup of ipecac.

Distribution

Volume of distribution (V_d) of emetine is probably large based on the prolonged excretion of emetine from the body during chronic use; however, determination of the V_d is limited by few data on pharmacokinetics in volunteer studies or patients abusing syrup of ipecac.

Biotransformation

There are few *in vivo* data on the biotransformation of emetine and cephaeline in humans. *In vitro* studies in human hepatic microsomal enzyme systems indicate that CYP2D6 converts emetine to cephaeline and 9-*O*-demethylemetine, whereas CYP3A4 catalyzes the conversion of emetine to cephaeline, 9-*O*-demethylemetine and 10-*O*-demethylemetine.[76] In rats, cephaeline (6′-*O*-demethylemetine) undergoes rapid conjugation with glucuronide (cephaeline-6′-*O*-glucuronide) and primarily biliary excretion, whereas emetine is demethylated to cephaeline and 9-*O*-demethylemetine before glucuronidation.[77] The biliary excretion of emetine metabolites is substantially lower than cephaeline metabolites (i.e., 57% vs. 7% of the administered dose, respectively).

Elimination

The elimination of cephaeline and emetine from the plasma following absorption is relatively rapid (i.e., 12–24 h), depending on the absorbed amount of these alkaloids. In a study of 12 volunteers receiving a single dose of 30 mL syrup of ipecac (~25 mg cephaeline, ~15 mg emetine), neither alkaloid was detectable in plasma 6 hours after administration as measured by HPLC with fluorescence detection.[73] All of these volunteers vomited after administration of syrup of ipecac. Two volunteers receiving 20 mL syrup of ipecac (~17 mg cephaeline, ~10 mg emetine) did not vomit, and their plasma contained detectable concentrations of these 2 alkaloids 24 hours after ingestion. The persistence of these alkaloids in the urine suggests that they may accumulate after chronic administration, particularly if vomiting does not occur after use; however, there are few data confirming or quantitating the accumulation of these alkaloids. The plasma elimination half-life of these 2 compounds in rodent studies follows a biexponential

decrease with a half-life of approximately 3–9 hours (cephaeline) and 65–163 hours (emetine).[77]

Maternal and Fetal Kinetics

The P-glycoprotein transport protein on the placental syncytiotrophoblast prevents maternal–fetal transfer of emetine;[78] however, forceful vomiting induced by syrup of ipecac may cause premature uterine contractions in pregnant mothers.[79] The alkaloids of syrup of ipecac are not known to transfer into breast milk.

Tolerance

Chronic abuse of syrup of ipecac can lead to physiologic tolerance, prompting the user to increase dosing to induce vomiting. Although tolerance to the emetic effects may develop, escalation of the dose of ipecac may cause increased adverse effects (diarrhea, tachycardia, myopathy).[80]

Drug Interactions

There are few data on the drug interactions associated with the use of syrup of ipecac.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

Emetine and cephaeline in syrup of ipecac irritate stomach epithelium; stimulation of gastric mucosal sensory receptors activates the vomiting center in the brain. These alkaloids also directly stimulate the chemoreceptor trigger zone in the area postrema of the medulla.[81]

Mechanism of Toxicity

Accumulation of emetine following chronic syrup of ipecac ingestion causes damage to both skeletal and cardiac muscle, but the injury pattern is not unique to emetine or the abuse of syrup of ipecac. In animal studies, emetine affects phase 0 depolarization, similar to quinidine.[82] Emetine blocks cardiac L-type calcium channels and fast sodium channels *in vitro*,[83] suggesting an electrochemical contribution to the cardiotoxicity of emetine and the development of cardiac dysrhythmias.[84,85] The use of emetine as an anthelminthic is associated with a variety of electrocardiographic changes including PR and QT_c prolongation, nonspecific ST-T changes, and T-wave inversions, but serious cardiomy-

opathies following the use of emetine as an anthelminthic are rare.[86]

Muscle

Isolated necrotic fibers and granular basophilic fibers appear in microscopic examination of muscle biopsy from patients with myopathies associated with emetine use; however, hypertrophic fibers are usually absent.[87] There is a predominance of type I fibers and a slight decrease in the average diameter of muscle fibers along with swollen core-targetoid fibers and intracytoplasmic inclusion bodies in the type I fibers. Type II-A and II-B fibers occasionally may be affected.[88] Perifascicular atrophy and inflammatory cell infiltrates are usually absent.[70] Electron microscopy reveals sarcomeric and sarcotubular abnormalities including Z-line streaming, myofibrillar disorganization, and increased lysosomal activity.[89] Expansion of electron dense material extends into the A- and I-bands; occasionally, the entire sarcomere or adjacent sarcomeres become involved. The granular breakdown of myofilaments and sarcomeres results in the formation of cytoplasmic bodies, which include the Z-band material. These cytoplasmic bodies appear as central granular electron-dense cores of various shapes and sizes surrounded by electron-lucent halos containing 7- to 10-nm filaments and glycogen granules in the marginal zone.[90] The necrotizing myopathy associated with syrup of ipecac abuse differs from the vacuolar myopathy associated with hypokalemia in bulimic patients abusing diuretics and laxatives.

There is substantial variation in the toxicity of emetine between animal species with dogs being particularly sensitive.[91] In rat studies, emetine causes a necrotizing myopathic process with vacuolar degeneration, disruption of myofibrils, and fine cytoplasmic body formation, probably as a result of direct toxicity at the subcellular level.[92] These pathologic changes in muscle are not associated with recognizable morphologic or physiologic alterations in the neurons innervating the muscle units.[93] Examination of myocardial biopsies from dogs administered 3.3–32 mg/kg over 5–32 days demonstrated partial to complete loss of mitochondrial cristae with the rest of the myocardial fine structure intact.[94] These changes occur in both type 1 and type 2 fibers. Electron microscopy reveals degenerative changes primarily in type 1 fibers including Z-band streaming, paucity of mitochondria, dense body formation in the sarcoplasm, and sarcotubular lesions.[95] The severity and distribution of these abnormalities increase with increasing exposure time. Muscle tissue exhibits anaerobic glycolysis with lactate formation; the loss of

myosin ATPase and myosin dehydrogenase resolve spontaneously after cessation of syrup of ipecac abuse.[90]

HOMEOSTASIS

Repeated vomiting from chronic ingestion of syrup of ipecac may cause hypochloremic metabolic alkalosis and hypokalemia resulting from chloride depletion, contraction of extracellular volume, secondary hyperaldosteronism, increased renal tubular sodium absorption, and increased urinary excretion of potassium.[96] Metabolic alkalosis results from the loss of hydrogen ion from the gastric secretions and the renal tubular secretion of hydrogen ion with the absorption of bicarbonate. The transcellular potassium redistribution from the extracellular to the intracellular compartments maintains the alkalosis. Low urinary chloride reflects the contraction of intravascular volume, and to a lesser extent, loss of chloride in gastric secretions.

Postmortem Examination

Dilated cardiomyopathy and evidence of cardiac muscle injury occur in cases of chronic syrup of ipecac abuse. In a case of Munchausen syndrome by proxy with documented postmortem cephaeline and emetine concentrations, the postmortem examination of a 47-month-old child revealed ascites, bilateral pleural effusions, and biventricular dilation.[97] The skeletal muscle examination by light microscopy was normal, but examination of cardiac muscle demonstrated myofibrillar degeneration and myocytolysis in the outer third of the left ventricular free wall without inflammation or fibrosis. Electron microscopy revealed local zones of myofibrillar lysis with periodic clumps of Z-band material resembling cytoplasmic bodies. Rare case reports on the administration of emetine for amebiasis associated therapeutic emetine doses with interstitial myocarditis; however, the contribution of emetine to these deaths is unclear.[98]

CLINICAL RESPONSE

Illicit Use

Clinical features of chronic ipecac abuse include diarrhea, vomiting, abdominal cramps, muscle stiffness and weakness, mild tremor, fatigue, and peripheral edema. Frequent vomiting may cause erosion of the tooth enamel (perimolysis), particularly of the posterior occlusal surfaces of the maxillary incisors.[99] These changes may result in excessive sensitivity to temperature changes in the mouth, particularly when eating hot or cold food. Old amalgams may rise above the surface of the tooth as a result of the erosion of the enamel. Self-induced vomiting may cause trauma to the dorsum of the dominant hand, manifest by lesions ranging from superficial ulcerations to hyperpigmented scars.[100] Other abnormalities of the upper GI tract include chronic pharyngitis, benign parotid enlargement, and esophagitis.[101,102] Gastrointestinal complications of the abuse of ipecac include esophageal rupture (Boerhaave syndrome), mucosal tear at the gastroesophageal junction (Mallory-Weiss syndrome), hemorrhagic gastritis, reflux esophagitis, and ileus.[103] Malnutrition may cause dermatologic abnormalities similar to dermatomyositis; however, the lack of inflammation of muscle tissue on biopsy distinguishes emetine myopathy from dermatomyositis.[104] Follicular hyperkeratosis may result from vitamin C deficiency. Repeated vomiting from chronic ingestion of syrup of ipecac may cause aspiration pneumonitis.

BEHAVIORAL ABNORMALITIES

Behavioral and mental status changes are not usually associated with emetine toxicity.

MEDICAL COMPLICATIONS

In studies of emetine for the treatment of amebiasis, the most common adverse effects other than local pain were general weakness and electrocardiographic changes in about one-half of the patients along with precordial chest pain in about one-third of the patients.[105] Other toxic effects included diarrhea, nausea, and less commonly tachycardia.

PERIPHERAL MYOPATHY.   Case reports of patients with anorexia nervosa or bulimia nervosa associate the chronic abuse of ipecac with reversible myopathy, manifest by proximal muscle weakness, waddling gait secondary to extensor muscle weakness in the hips, winged scapula, dysphagia, and weakness of the neck flexors. Typically, severely affected patients have difficulty arising from a chair or horizontal position, lifting their arm over their neck, climbing stairs, and crossing their legs. Often, Gower's sign (standing by the patient, bring the hands proximally up the legs) is positive. Proximal muscles are more affected than distal muscles. Examination of mental status, cranial nerves, muscle bulk, coordination, and sensation are usually normal. Although deep tendon reflexes (DTRs) may be sluggish, reflexes typically are normal. The neuromuscular abnormalities associated with chronic abuse of syrup of ipecac are similar to the myopathy associated with the

administration of emetine.[106] Occasionally, these patients may develop mild sensory disturbances, tremors, and myalgias. Muscle strength typically returns to baseline within several weeks to 5 months.

CARDIOMYOPATHY. Rarely, congestive heart failure is associated with anorexia nervosa and bulimia, particularly during the initial phase of nutritional rehabilitation.[107] Although mild global left ventricular dysfunction and nonspecific electrocardiographic changes are common in patients with marked skeletal myopathy from ipecac abuse, fulminant heart failure does not usually occur in patients abusing ipecac. A 26-year-old woman developed skeletal muscle weakness, dyspnea on exertion, mild basilar rales, QT_c prolongation (480 ms), and mild left ventricular dysfunction (ejection fraction, 45%) after abusing syrup of ipecac for 5 months.[71] She did not develop any dysrhythmias, and she improved with cessation of ipecac use. Other cardiac abnormalities associated with the abuse of syrup of ipecac include left atrial enlargement and mitral valve prolapse.[70] Clinical signs of congestive heart failure occur rarely following the use of emetine as an anthelminthic, primarily following IV administration or the ingestion of concentrated liquid extract.

Fatalities

Sudden death is a complication of anorexia nervosa and bulimia (e.g., refeeding phase, liquid-protein diets, starvation-induced QT_c prolongation), even in the absence of ipecac abuse.[108,109] Although case reports associate sudden death with the abuse of ipecac in the clinical setting of anorexia nervosa and bulimia, the contribution of ipecac is not clearly defined. Several of these case reports document complications (myocarditis, pericarditis, pulmonary embolism, pneumonia) not usually associated with the alkaloids in syrup of ipecac.[110,111] A 17-year-old adolescent developed generalized myalgias, bilateral ankle swelling, progressive skeletal muscle weakness, hypotension, intractable congestive heart failure, and cardiac arrest unresponsive to medical management.[112] Subsequently, 12 empty bottles of syrup of ipecac were found under her bed. The postmortem examination demonstrated vacuolar degeneration and focal myocardial necrosis. The urine screen was positive for emetine, but emetine apparently was not detected in the postmortem blood.

Abstinence Syndrome

An abstinence syndrome has not been associated with the cessation of syrup of ipecac abuse.

Reproductive Abnormalities

Abuse of syrup of ipecac causes maternal volume depletion with potential effects on fetal homeostasis, amniotic fluid volume, and uterine and placental perfusion; however, these effects are not well reported in the medical literature.

DIAGNOSTIC TESTING

Analytic Methods

Techniques for the quantitation of emetine and cephaeline in biologic samples include spectrophotometry,[113] thin layer chromatography (TLC),[114] high performance liquid chromatography (HPLC) with fluorescence detection,[115] reverse-phase liquid chromatography with UV detection at 254 nm,[116] and HPLC with photodiode array detection.[117] The LOD for these 2 alkaloids in urine as measured by liquid chromatography with fluorescence detection was 5 ng/mL compared with 1 ng/mL and 2.5 ng/mL for plasma samples. The LOD and the lower limit of quantitation (LLOQ) using liquid chromatography with UV detection for analyzing emetine was 50 ng/mL and 100 ng/mL, respectively. Emetine and cephaeline are stable in frozen (−20°C/−4°F) plasma or urine for at least 90 days.[118]

Biomarkers

BLOOD

Figure 12.5 displays the mean plasma cephaeline and emetine concentrations during the first 3 hours after administration of 30 mL syrup of ipecac (45 mg cephaeline, 13.8 mg emetine) to 10 healthy volunteers.[74] A 14-year-old adolescent was admitted to the hospital with nausea, vomiting, diarrhea, and abdominal pain after head trauma from an automobile accident. Subsequently, his surreptitious use of the syrup of ipecac was discovered when analysis of admission blood yielded a serum emetine concentration of >10-fold higher than the upper limit of normal.[119] A 34-month-old child was hospitalized for intractable vomiting, myopathy, and elevated serum creatine kinase.[120] The diagnosis of Munchausen syndrome by proxy was made after LC/MS analysis of 2 serum samples revealed emetine concentrations of 21 ng/mL and 26 ng/mL.

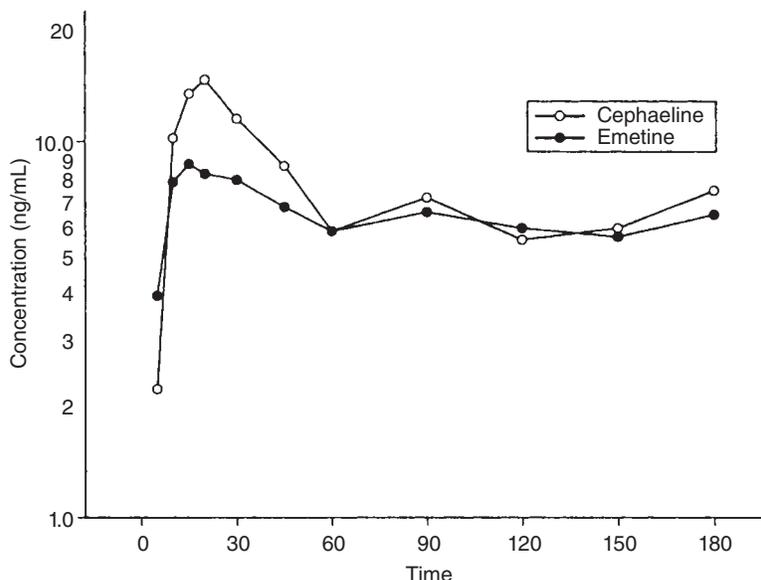
A 26-year-old woman complained of dyspnea, palpitations, and fatigue after consuming 3–4 bottles of ipecac syrup daily for 3 months.[121] In the hospital, she developed biventricular cardiac failure and intractable ventricular fibrillation. Postmortem examination revealed pericardial effusions, a small pulmonary emboli, and


FIGURE 12.5. Mean cephaeline and emetine concentrations during first 3 hours after the administration of 30 mL syrup of ipecac to 10 healthy volunteers. (Reprinted with permission from EJ Scharman, MJ Hutzler, GJ Rosencrance, TS Tracy, Single dose pharmacokinetics of syrup of ipecac, Therapeutic Drug Monitoring, Vol. 22, Issue 5, p. 438, copyright 2000.)

diffuse interstitial edema of the heart. As measured by fluorescence spectrophotometry, emetine was detected in the following tissues: liver, 14 µg/g; kidney, 7.4 µg/g; blood, 2.4 µg/g; bile, 1.9 µg/g; pericardial fluid, 0.7 µg/g; and cerebrospinal fluid, 0.1 µg/g.

URINE

The kidney excretes relatively small amounts of cephaeline and emetine in the urine following the ingestion of syrup of ipecac depending in part on the amount expelled in the vomitus. In a study of 12 volunteers receiving a single 30-mL dose of syrup of ipecac, the urinary excretion of cephaeline and emetine during the first 48 hours after dosing accounted for $0.73 \pm 0.30\%$ and $0.79 \pm 0.24\%$, respectively, of the administered dose.[73] However, these 2 alkaloids were detectable in urine of the volunteers for at least 2 weeks, and in 1 individual up to 12 weeks after administration as measured by HPLC with fluorescence detection. The urine emetine concentration in a child hospitalized for Münchausen syndrome by proxy was 100 ng/mL.[120] One week later, the urine emetine concentration declined to 78 ng/mL.

Abnormalities

Chest X-ray may reveal aspiration pneumonitis in patients with chronic abuse of syrup of ipecac or pneumomediastinum from protracted vomiting. Two-

dimensional echocardiography in patients with marked skeletal myopathy may demonstrate reduced left ventricular ejection fraction, which often is asymptomatic.

ELECTRODIAGNOSTIC STUDIES

Electromyographic features of the myopathy associated with chronic abuse of ipecac include occasional fibrillations, complex repetitive discharges, myopathic motor-unit potentials, and increased insertional activity, particularly in proximal muscles.[69] These abnormalities are usually reversible after cessation of the use of syrup of ipecac. The amplitude of evoked action potentials and nerve conduction velocities are typically normal.

ELECTROCARDIOGRAM

The most common electrocardiographic changes in patients undergoing cancer treatment with emetine were ST-T wave abnormalities, QT prolongation, and premature ventricular contractions.[64,105] Electrocardiographic abnormalities frequently occur in patients with skeletal muscle weakness and evidence of emetine toxicity. The changes associated with the chronic abuse of ipecac include non-specific ST-T wave changes, T-wave inversions, QRS and QT_c prolongation, and sinus tachycardia. These changes are non-specific and may occur without laboratory evidence of electrolyte abnormalities. These changes usually resolve with abstinence from syrup of ipecac.

Blood

The chronic abuse of syrup of ipecac by bulimic patients is frequently associated with mild elevation of serum hepatic aminotransferases (alanine aminotransferase, aspartate aminotransferase), lactate dehydrogenase, and serum muscle enzymes (creatine phosphokinase, aldolase).[122] Hyponatremia, hypochloremia, hypokalemia, hypocalcemia, and hypomagnesemia may be observed with chronic abuse of syrup of ipecac, particularly in combination with diuretics and laxatives.

TREATMENT

Similar to the abuse of diuretics, initial medical management should be directed at the correction of fluid and electrolyte imbalance along with the restoration of a normal diet after an initial evaluation of the adequacy of respiration and cardiac function. These patients should be evaluated for electrolyte (sodium, potassium, chloride, magnesium, calcium), and acid-base abnormalities, muscular weakness, anemia, rhabdomyolysis, volume depletion, renal dysfunction, cardiomyopathy, and electrocardiographic abnormalities. Fluid replacement typically involves replacement of sodium and chloride losses with saline. Rare complications include cardiac dysrhythmias. Vasopressors and invasive monitoring with central venous, pulmonary wedge pressure or noninvasive hemodynamic monitoring may be necessary for severe hypotension associated with severe cardiomyopathy.

Severe hyponatremia should be corrected relatively slowly (<0.55 mEq/L/h) to prevent the development of central pontine myelinolysis. Peripheral edema may occur during the first few weeks after cessation of purging behaviors, which usually responds to salt restriction. Hospitalization may be necessary to correct hypokalemic metabolic alkalosis and to stop the use of ipecac or other surreptitious methods to control weight. Emetine-induced myopathy is usually reversible and resolves spontaneously including return of normal cardiac function.[3]

LAXATIVES

The 5 major classes of laxatives include the following: 1) lubricant (liquid paraffin, mineral oil), 2) bulk (psyllium), 3) stool softeners, 4) osmotic (lactulose, magnesium sulfate/citrate, sodium sulfate, sorbitol), and 5) stimulant (aloes, bisacodyl, buckthorn, cascara, castor oil, danthron, frangula, phenolphthalein, rhubarb,

sagrada, senna, sodium picosulfate).[123] Danthron (synthetic anthraquinone) and phenolphthalein (diphenylmethane derivative) are banned from sale in the United States as a result of animal studies suggesting an increased risk of cancer.[124] Plant preparations (e.g., aloe, cascara, frangula, rhubarb, senna) contain anthranoid compounds, which are alternatives to other stimulant laxatives (bisacodyl, castor oil, phenolphthalein). The abuse of laxatives involves 1) patients with psychiatric disorders (anorexia nervosa, bulimia nervosa) who surreptitiously use laxatives to lose weight, 2) individuals desiring a specific stool regimen, and 3) patients with Munchausen syndrome who surreptitiously abuse laxatives themselves or administer laxatives to their children (Munchausen syndrome by proxy). The Munchausen syndrome involves the appearance of chronic factitious illness resulting from a desire to manipulate and deceive the medical profession for secondary gain (attention, sympathy, removal from conflict).

In a study of patients with eating disorders, laxative abusers demonstrated more perfectionism and avoidant personality features compared with nonlaxative abusers.[125] Laxative-abusing anorexia nervosa patients had high scores on the histrionic scale, whereas laxative-abusing bulimia nervosa patients had the higher pathologic scores on drive for thinness, body dissatisfaction, passive-aggressive and borderline personality, ineffectiveness, and lack of introspection. In a study of 5,355 young women, individuals abusing laxatives were older, had poor perceived health, and were less likely to seek treatment compared with women engaged in self-induced vomiting.[126] Additionally, laxative-abusing patients with eating disorders also display higher levels of depression and self-directed hostility compared with individuals self-inducing vomiting.[127] Stimulant laxatives are the most commonly abused laxatives by individuals with eating disorders including diphenylmethane compounds (bisacodyl), castor oil, and anthraquinones (aloe, cascara, senna).

Bisacodyl

IDENTIFYING CHARACTERISTICS

Bisacodyl (CAS RN: 603-50-9, $C_{22}H_{19}NO_4$) is a diphenylmethane stimulant laxative used to treat constipation and to promote bowel evacuation; this compound [2-(4,4'-diacetoxydiphenylmethyl)pyridine] is the acetic acid diester of the laxative, diphenol 2-(4,4'-dihydroxy-diphenyl)methyl-pyridine. Table 12.5 lists some physiochemical properties of bisacodyl. Figure 12.6 displays

TABLE 12.5. Some Physiochemical Properties of Bisacodyl.

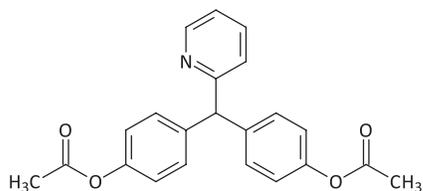
Physical Property	Value
Molecular Weight	361.3906 g/mol
Melting Point	133.5°C/272.3°F
log P (Octanol-Water)	3.370


FIGURE 12.6. Chemical structure of bisacodyl.

the chemical structure of bisacodyl. The active metabolite is deacetylbisacodyl or bisacodyl diphenol (dihydroxydiphenylpyridyl methane, CAS RN: 603-41-8). Sodium picosulfate is the sulfate conjugate of bisacodyl that also has laxative properties.

EXPOSURE

Bisacodyl is available as pills, capsules, and rectal suppositories, usually as over-the-counter preparations. Trade names include Bisac-Evac®, Correctol® (Bristol-Myers, Squibb, Princeton, NJ), Dulcolax® (Boehringer Ingelheim, Ingelheim am Rheim, Germany), Ex-Lax Ultra® (Pharmaceutical Corp., East Hanover, NJ) , Feen-a-Mint® (Schering Plough Healthcare Products, Memphis, TN), and Fleet Laxative® (Fleet Laboratories, Lynchburg, VA), Typically, these preparations are available as 5 mg enteric coated tablets or 10 mg suppositories.

DOSE EFFECT

The typical therapeutic dose of bisacodyl for bowel evacuation prior to medical procedures or the treatment of constipation is 5–15 mg orally or rectally. Thresholds for toxic doses of laxatives depend on nutritional and fluid intake, which varies significantly among patients with eating disorders. A single therapeutic dose of bisacodyl may cause diarrhea; however, the cumulative dose to produce dehydration and electrolyte disturbances is highly variable.

TOXICOKINETICS

Absorption

The absorption of bisacodyl depends on the formulation (e.g., enteric coated tablet, solution, dragée, suppository). Following administration of suppositories, the absorption of bisacodyl is minimal despite the relatively prompt onset of laxative effects (15–60 min). In a study of 16 volunteers receiving a single 10 mg bisacodyl suppository, the mean time to maximum serum concentration of the active deacetylated metabolite, bis-(p-hydroxyphenyl)-pyridyl-2-methane (BHPM, bisacodyl diphenol) was 0.67 ± 0.11 hours with a mean total serum BHPM concentration (free plus conjugate) of 35.48 ± 2.60 ng/mL (range, 10–55 ng/mL).[128] Following ingestion of a solution containing 10 mg bisacodyl, the mean peak total bisacodyl concentration (free + conjugated) in plasma samples from 12 healthy volunteers was 236 ± 59 ng/mL with a mean time to peak concentration of 1.7 hours.[129] Plasma BHPM concentrations were nondetectable in 6 of these 12 volunteers after administration of a single 10 mg bisacodyl suppository despite the rapid onset of catharsis (mean, 20 ± 10 minutes).

Biotransformation

Endogenous esterases in the wall of the large intestine rapidly hydrolyze bisacodyl to the active metabolite [bis-(p-hydroxyphenyl)-pyridyl-2-methane, BHPM].[130] In contrast to the formation of BHPM, bacterial action is necessary to convert sodium picosulfate or sennosides to their respective active metabolites. Following hydrolysis, BHPM undergoes conjugation with glucuronide before excretion in the urine. Glucuronidation of BHPM occurs in the intestinal wall rather than the liver. BHPM appears in the stool as the free form.

Elimination

The elimination of bisacodyl depends on the dosage form. In a study of 16 volunteers receiving 10 mg bisacodyl suppository, urinary BHPM accounted for $3.4 \pm 0.5\%$ of the administered dose.[128] Following the ingestion of 10 mg bisacodyl enteric-coated tablets by 5 healthy volunteers, urinary excretion of BHPM glucuronide accounted for approximately 10% of the bisacodyl dose during the first 48 hours after ingestion.[130] A majority of the administered dose of bisacodyl appears in the stool as free BHPM. Following ingestion of a solution containing 10 mg bisacodyl, approximately $43 \pm 15\%$ of the administered dose appeared in the urine as BHPM gluc-

uronide compared with approximately $9 \pm 3\%$ for the dragée and $3 \pm 1\%$ for the suppository.[129] In a study of 5 healthy volunteers receiving two 5-mg coated bisacodyl tablets, the mean percentage of BHPM glucuronide in the urine was $10.5 \pm 1.1\%$.[130] Analysis of bile from patients receiving bisacodyl indicates that the glucuronide conjugate of deacetylbisacodyl, but not free bisacodyl or deacetylbisacodyl appears in the bile.[131] The liver excretes an estimated 10–30% of the bisacodyl dose in the bile.

Maternal and Fetal Kinetics

The transfer of bisacodyl to breast milk is minimal, primarily because of the poor absorption of this compound from the GI tract.[132]

Tolerance

Although some laxative abusers report the necessity of higher doses of laxatives to achieve the desired effects, the development of tolerance to the effects of stimulant laxatives is not well documented in humans.[133]

Drug Interactions

Major drug interactions between laxatives and pharmaceutic drugs have not been identified. Stimulant laxatives may increase intestinal transit, theoretically reducing drug absorption; however, there are insufficient data to conclude that the use of cathartics significantly alters the absorption of pharmaceutic drugs.[134]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Following hydrolysis of bisacodyl by endogenous esterases, the active metabolite (BHPM) promotes secretion of electrolytes and water along with stimulation of bowel motility by inducing low-grade endothelial inflammation, mediated by activation of the cyclic AMP and cyclic GMP pathways. Chronic use of stimulant laxatives causes dehydration, hyponatremia, and hypokalemia, which are exacerbated by poor mineral intake in patients with eating disorders.[133] Cathartic (atonic) colon is a historic term initially described in 1943 by Heilbrun from case reports of anatomic alteration of the colon secondary to chronic stimulant laxative use, manifest by loss of haustral folds, pseudostrictures (sandglass formed spasms), dilated lumen, and gaping of the ileocecal valve with a predilection for the terminal ilium and right side of the colon.[135] The major histopathologic changes involve mononuclear infiltration of the mucosa

and submucosa of the colon and terminal ileum. Typically, the atrophy, thinning, and mild ulceration of the mucosa and muscular layers of the terminal ileum and ascending colon develop with normal mucosal patterns usually, but not always in the remainder of the colon.[136] In a retrospective review of a convenience series of 29 chronically constipated women with stimulant use (>3 times weekly for >1 y) and 26 women without stimulant laxative use, colonic redundancy and dilation were common in both groups; however, loss of haustral folds was more common in the stimulant laxative group (27.6% vs 0%, $P \leq .005$).[137] Loss of haustral markings occurred in 15 (40.5%) of the stimulant laxative users in the following locations: 1) left colon, 6 patients, 2) right colon, 2 patients, 3) transverse colon, 5 patients, and 4) entire colon, 2 patients. Most case reports of cathartic colon involve middle-aged women using therapeutic doses of laxatives for several decades prior to 1960, raising issues regarding the presence of preexisting abnormalities leading to laxative use and the potential complication of the concomitant ingestion of other toxins (e.g., podophyllin) as a result of the lack of prospective studies.[138,139] A case-control study of 11 matched pairs of chronically constipated women did not detect pathophysiologically significant differences in the electron microscopic examination of endoscopic biopsies of the left colon and rectum between the women chronic stimulant laxative use (>1 y) and those without laxative use.[140]

CLINICAL RESPONSE

Catharsis occurs within 1 hour of the rectal administration of therapeutic doses (i.e., 10 mg) of bisacodyl as a result of the direct action of the active metabolite (BHPM) on intestinal mucosa; however, following ingestion of a bisacodyl solution, the onset of catharsis is delayed approximately 6 hours after administration.[129] Clinical features of laxative abuse in general are nonspecific including abdominal and/or rectal pain, large volume chronic diarrhea alternating with constipation, bloating, nausea, vomiting, edema, myalgias, dehydration, and weight loss.[141] The typical range of bowel movements in healthy adults is 3 times daily to 3 times weekly,[123] whereas stool frequency often exceeds 10 bowel movements daily in chronic laxative abusers. A majority of chronic laxative abuser report nocturnal bowel movements in contrast to most organic causes of diarrhea.[142] Stool volume usually exceeds 1 L daily, and the stool may contain blood.[143] Additionally, these patients may develop peripheral edema, protein-losing gastroenteropathies, malabsorption, fat soluble vitamin deficiencies (A, D E, K), and mild steatorrhea

(>10 g/24 h) as a result of chronic laxative abuse.[144,145] Rarely, case reports associate the chronic abuse of bisacodyl with recurrent renal stones (uric acid/ammonium acid urate) as a result of acidification of the urine during chronic laxative abuse.[146] Historical case reports of cathartic colon primarily involve chronically constipated women with long-term use of therapeutic doses of stimulant cathartics rather than women with eating disorders and stimulant laxative abuse (e.g., bisacodyl).

Clinical features of hypokalemia associated with laxative abuse include muscle cramps, generalized weakness, fatigue, headache palpitations, and abdominal pain (ileus). The differential diagnosis of chronic diarrhea includes inflammatory bowel disease (e.g., Crohn disease), malabsorption syndrome, hormone-related secretory diarrhea (e.g., thyrotoxicosis), and primary or secondary lactase deficiency.

The International Agency for Research on Cancer (IARC) and the US National Toxicology Program do not list bisacodyl as a suspected carcinogen. In a 26-week study of p53(+/-) mice receiving up to 8,000 mg bisacodyl daily by gavage, bisacodyl did not induce drug-related neoplasms.[147] Additionally, bisacodyl did not increase micronuclei in polychromatic erythrocytes or cause transformations in the *in vitro* Syrian hamster embryo cell transformation assay. Although drug tolerance may moderate many of the GI symptoms, case reports associate the development of colonic ischemia following long-term abuse of bisacodyl susceptible patients.[148] Withdrawal symptoms from chronic laxative abuse include rebound edema, constipation, and drug craving.

DIAGNOSTIC TESTING

Analytic Methods

Methods for the detection and quantitation of bisacodyl and BHPM (bisacodyl diphenol) in biological samples include high performance thin layer chromatography,[149] high performance liquid chromatography with diode array detection,[150] GC/MS after trimethylsilylation,[151] capillary GC/MS,[152] and GC/MS with bisphenol A as the internal standard and derivatization of bisacodyl diphenol as a methylated compound. The LOD for BHPM using the latter method in serum is 5 ng/mL compared with 10 ng/mL for capillary GC/MS after enzymatic hydrolysis in the full-scan mode with a coefficient of variation <15%, similar to GC/MS analysis of urine samples after trimethylsilylation.[151] Simple thin layer chromatography techniques can identify bisacodyl and bisacodyl diphenol by blue/light purple coloration after the addition of acetate buffer and glucuronidase;[153]

however, both thin layer chromatography and gas chromatography with flame ionization detection lack specificity in the detection of bisacodyl and other laxatives in urine samples. High performance thin layer chromatography (HPTLC) is the primary commercial screening method to determine the presence of diphenolic (bisacodyl, phenolphthalein) and anthraquinone (cascara, senna) laxatives in biologic samples (urine, stool) after pretreatment of the sample with β-glucuronidase and subsequent column extraction.[154,155] In a study of 11 volunteers receiving 20 mg bisacodyl (standard dose, 5 mg), the sensitivity and specificity for detecting bisacodyl in urine samples using this method is 73% and 91%, respectively.[156] The positive predictive value of these results indicate that the false-positive rate is high (i.e., about 30%) when the prevalence of bisacodyl use in the tested population is <10%. The window of detection of bisacodyl in urine is <24–48 hours after use when screening with HPTLC.

High performance liquid chromatography with UV spectrophotometric diode array detection (225 nm) identifies bisacodyl in urine samples with a LOD of 100 ng/mL.[157] The LOD for bisacodyl diphenol in urine samples using this method is 0.04 µg/mL. Gas chromatography/mass spectrometry is highly specific for bisacodyl in urine after enzymatic cleavage of conjugates. In a study of 8 volunteers ingesting 10 mg bisacodyl, hydrolyzed urine samples collected 12 hours after ingestion from 7 volunteers were positive for bisacodyl as measured by GC/MS.[158] Bisacodyl was not detectable in urine samples collected 24 hours or 48 hours after ingestion. The major bisacodyl metabolite (BHPM, bisacodyl diphenol) is detectable in urine samples by HPLC with a LLOQ in the range of 0.5 µg/mL after hydrolysis.[159] Maximum excretion of the urinary metabolite occurs on the second day after ingestion of bisacodyl. In a study of 3 volunteers ingestion 10 mg bisacodyl, hydrolyzed urine samples collected within 48 hours after ingestion contained 1,000–5,000 ng bisacodyl diphenol/mL compared with 17,000 ng/mL in a random urine sample collected from a 43-year-old woman surreptitiously abusing bisacodyl.[159]

Biomarkers

URINE

Following the ingestion of single doses of laxatives, the parent compounds are detectable only for a few days after use. Following hydrolysis of urine samples with glucuronidase, bisacodyl is detectable by HPTLC up to 32 hours after ingestion of a 5-mg dose.[149] However, this method produces false-positives, and the sensitivity is substantially less for senna than bisacodyl.[156] Bisacodyl

and phenolphthalein are detectable in urine samples up to 4 days after the ingestion of single doses of these laxatives, when measured by electron beam ionization GC/MS with computer-controlled multiple-ion detector (LOD, 10–500 ng/mL).[151] Gas chromatography/mass spectrometry after enzymatic cleavage of conjugates followed by extractive methylation, detects bisacodyl and other stimulant laxatives (anthraquinone, phenolphthalein) and their metabolites in human urine with greater than 96% specificity.[152] As measured by GC/MS, bisacodyl was detectable in hydrolyzed urine in 7 of the 8 volunteers 12 hours after ingestion of 10 mg bisacodyl.[158] The bisacodyl concentrations in stool samples obtained 24 and 48 hours after ingestion were not detectable (level of quantitation not reported).

STOOL

The daily stool weight on a Western diet does not usually exceed 225 g, whereas the volume and weight of the stool increases during laxative abuse.[160] As stool volume reaches 3 L daily, the fecal sodium concentrations approach serum sodium concentrations. In secretory diarrhea secondary to stimulant laxative use (bisacodyl, phenolphthalein, senna), the stool osmolal gap is usually small (<30–40 mOsmol/L).[161] Stool osmolality below plasma osmolality suggests the addition of water to the stools sample; the presence of stool sodium concentrations exceeding plasma suggests the addition of urine to the stool.

Abnormalities

Diarrhea is typically defined as both increased frequency (>3 stools/d) and liquidity; however, patients often do not consider increased frequency of defecation alone as diarrhea.[162] The classification of diarrhea based on stool appearance and clinical characteristics includes the following: 1) watery (liquid stool without fat/blood cells), 2) fatty (positive Sudan stain), and inflammatory (leukocytes on Wright's stain or positive fecal lactoferrin assay).[163] Watery diarrhea is further divided into osmotic diarrhea (fecal osmotic gap >50 mOsm/kg) and secretory diarrhea (malabsorption of fecal electrolytes). The clinical evaluation of chronic diarrhea (>4 weeks duration) is extensive with an infectious etiology being less likely than acute diarrhea (typically, <2 weeks duration). Table 12.6 lists the major causes of chronic diarrhea. Laxative abuse usually causes watery diarrhea as result of the abuse of osmotic laxatives (osmotic diarrhea) or nonosmotic laxatives (secretory diarrhea). Fecal leukocytes may appear following chronic laxative abuse in the absence of fever and bloody diarrhea; consequently, the presence of fecal leukocytes does not exclude the diagnosis of laxative abuse.

The effect of chronic laxative abuse on serum electrolytes and acid-base status is variable and multifactorial as a result of differences in dietary intake and compensatory mechanisms. Metabolic disturbances associated with chronic laxative abuse include fecal sodium and water loss, hypokalemia, metabolic alkalosis with secondary hyperaldosteronism, and renal retention of sodium. Resulting electrolyte abnormalities include hyponatremia, hypokalemia, and hypochloremia. The amount of sodium depletion depends on stool volume, dietary salt intake, and the renin-angiotensin-aldosterone system; however, hyponatremia does not usually occur because of concomitant water loss. The severity of the potassium deficit depends on the severity of the laxative abuse, dietary potassium intake, and plasma aldosterone concentrations; hypokalemia may be severe and associated with rhabdomyolysis. Case reports indicate that ventricular dysrhythmias (e.g., *torsades de pointes*) may occur in the setting of hypokalemia and bisacodyl abuse. A 45-year-old woman required cardioversion for 2 episodes of *torsade de pointes* while hospitalized for the evaluation of chronic diarrhea and hypokalemia ($K^+ = 2.4$ mEq/L).[164] Analytic testing revealed bisacodyl in her urine and she admitted laxative abuse. Hypokalemia facilitates the development of hypochloremic metabolic alkalosis.

TREATMENT

Stabilization

Medical management of the complications associated with chronic stimulant abuse including bisacodyl should be directed at the correction of fluid and electrolyte imbalance along with the restoration of a normal diet after an initial evaluation of the adequacy respirations and cardiac function. These patients should be evaluated for electrolyte (sodium, potassium, chloride, magnesium, calcium) and acid-base abnormalities, anemia, rhabdomyolysis, volume depletion, renal dysfunction, cardiomyopathy, and electrocardiographic abnormalities. Fluid replacement typically involves replacement of sodium and chloride losses with saline; initial treatment begins with isotonic crystalloid solutions, 1–2 L in the adult patient or 10–20 mL/kg in the pediatric patient, followed by maintenance IV infusion and concurrent treatment of electrolyte disturbances (hypokalemia) depending on renal and myocardial function. Subsequent therapy includes volume repletion and gradual correction of hyponatremia and other electrolyte disturbances. Severe hyponatremia should be corrected relatively slowly (<0.55 mEq/L/h) to prevent the development of central pontine myelinolysis. Blood gas analysis may be necessary in more severely ill patients with acid-base

TABLE 12.6. Major Causes of Chronic Diarrhea.[163]

Secretory Diarrhea	Osmotic Diarrhea	Inflammatory Diarrhea	Fatty Diarrhea
Nonosmotic laxative abuse	Osmotic laxative abuse (Mg^{++}, SO_4^{-2}, PO_4^{-3}, lactulose, polyethylene glycol)	Inflammatory bowel disease (Ulcerative colitis, Crohn disease, diverticulitis, ulcerative jejunoileitis)	Malabsorption syndromes (Mucosal diseases, short bowel syndrome, postresection diarrhea, small bowel bacterial overgrowth, mesenteric ischemia)
Congenital electrolyte malabsorption	Carbohydrate malabsorption	Invasive bacterial infection (*Clostridium, Escherichia coli,* tuberculosis)	Maldigestion (Pancreatic insufficiency, reduced luminal bile acid)
Bacterial toxins		Ulcerating viral infection (*Cytomegalovirus, Herpes simplex*)	
Ileal bile acid malabsorption		Invasive parasites (Amebiasis)	
		Ischemic colitis	
Inflammatory bowel disease (Ileal Crohn disease, lymphocytic colitis, collagenous colitis, diverticulitis)		Radiation enterocolitis	
Vasculitis		Neoplasia (Carcinoma of colon, lymphoma)	
Drugs and poisons			
Disordered regulation (Postvagotomy, postsympathectomy, diabetic neuropathy, hyperthyroidism, Addison disease, irritable bowel syndrome, functional diarrhea)			
Neuroendocrine tumors (Gastrinoma, VIPoma, somatostatinoma, mastocytosis, carcinoid syndrome, medullary carcinoma of the thyroid)			
Neoplasia (Carcinoma of colon, lymphoma, villous adenoma)			
Epidemic secretory diarrhea (Brainerd)			
Idiopathic secretory diarrhea (Sporadic)			

disturbances. Rare complications of chronic laxative abuse include cardiac dysrhythmias (*torsade de pointes* or simply "torsade"). The treatment of torsade includes IV magnesium sulfate and, if necessary, overdrive pacing.

Supplemental Care

Psychologic dependence on laxatives occurs in patients with eating disorders; however, physical dependence does not develop other than some bloating and weight gain following cessation of use. Supportive care for patients with chronic laxative abuse include high-calorie, high fiber diet, gradual regularization of stools habits (bulk preparations, saline enemas), and potassium supplements and/or potassium sparing drugs (spironolactone) as needed.[165] Constipation may complicate the recovery period; the use of bulk-type laxatives, bran, regular exercise and adequate hydration are preferable to recurrent use of stimulant or osmotic laxatives. Peripheral edema during the first few weeks after cessation of laxative abuse usually responds to salt restriction. Hospitalization may be necessary to correct severe electrolyte imbalance and to stop the use of laxatives or other inappropriate methods to control weight. Psychotic behavior may occur as a manifestation of pre-existing psychopathology associated with the eating disorder.

Cascara

IDENTIFYING CHARACTERISTICS

Cascara fluid extract contains anthranoid compounds, primarily anthrone *C*-glycosides including cascaroside A [glycoside of barbaloin, 8-*O*-(β-D-glucopyranosyl) barbaloin] and the following free dihydroanthraquinone derivatives: aloe-emodin (CAS RN: 481-72-1), emodin (CAS RN: 518-82-1), and chrysophanol (chrysophanic acid, CAS RN: 481-74-3).[166] Cascaroside A has a molecular weight of 580.53 g/mol with a chemical formula of $C_{27}H_{32}O_{14}$; cascaroside B is the diasteroisomer of cascaroside A. Figure 12.7 displays the chemical structures of these anthraquinone compounds. Anthranoid compounds refer to compounds with sub-

stitutions at C_{10} in the basic anthrace ring as follows: anthrones, C_{10}-H_2; anthraquinones, C_{10} = O; dianthrones, C_{10}-additional anthrace ring. These substances occur as an anthranoid moiety (aglycon) linked with a sugar (e.g., glucose). The hydrophilic properties of these glycosides limit GI absorption.

EXPOSURE

The botanic source of cascara sagrada (cascara) is the bark from the erect shrub, *Frangula purshiana* Cooper (*Rhamnus purshiana* DC.). Various preparations of cascara include casanthranol, cascara sagrada bark, cascara fluid extract, cascara sagrada extract, and cascara sagrada fluid extract. Dried bark of cascara sagrada contains approximately 8–10% hydroxyanthraquinone glycosides; these hydroxyanthracene derivatives have hydroxy groups at the C_1 and C_8 positions and sugar groups at the hydroxyl moiety (*O*-glycosides) or at the C_{10} position (*C*-glycosides). Fingerprint chromatography by HPLC with ultraviolet (UV) and evaporative light scattering (ELS) detection allows the identification and origin of botanic samples of cascara.[167] In 2002, the US Food and Drug Administration (US FDA) concluded that cascara is not generally recognized as safe and effective because of the lack of information submitted to the US FDA during a review of over-the-counter (OTC) laxatives; consequently, the US FDA banned the use of cascara along with aloe in OTC preparations.[168]

DOSE EFFECT

The daily recommended dose for cascara for children is 150–500 mg (~10.5–50 mg hydroxyanthracenes) and 300–1,000 mg (~21–100 mg hydroxyanthracenes). The toxic dose of cascara in humans is not well defined. Although melanosis coli is indicative of cascara abuse over at least 4–12 months, patients abusing these laxatives do not invariably develop this condition even after years of anthraquinone laxative use.

TOXICOKINETICS

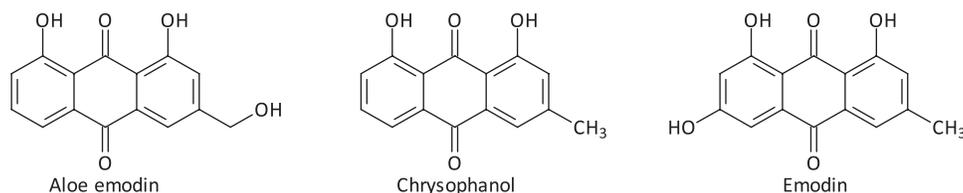
Anthrone *C*-glycosides (Cascaroside A–D) in cascara are prodrugs. The absorption of these large molecules is


FIGURE 12.7. Chemical structures of 3 common anthraquinone compounds in cascara.

limited until glucosidases in colonic bacteria catalyze the cleavage of the sugar moiety and the formation of free compounds (aglycones). In contrast to the dianthrone *O*-glycosides (e.g., sennosides A and B in senna), bacterial flora in the GI tract do not easily metabolize the anthrone *C*-glycosides; therefore, the laxative response of different animal species to cascara varies substantially.[169] The released anthranoid aglycones (free anthrones) diffuse to the intestinal wall where they alter intestinal secretions and motility.[170] Animal studies suggest that some hydroxylation of these aglycones occurs after absorption in addition to the conjugation of the anthrone compounds to glucuronides and sulfates. Prolonged action of cascara results from the biliary excretion and enterohepatic recirculation of these compounds. The maternal use of cascara is compatible with breastfeeding.[171] Most laxative abusers report the necessity of higher doses of laxatives to achieve the desired effects.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Melanosis coli is a complication of anthraquinone laxative abuse (e.g., cascara), marked by intestinal macrophages filled with a lipofuscin pigment in the lamina propria of the colon. Electron microscopy of these pigmented lesions reveals apoptosis of surface epithelial cells in the colon and phagocytosis of resulting apoptotic bodies by intraepithelial macrophages. These macrophages migrate to the lamina propria where intracellular degradation of the apoptotic bodies results in the formation of lipofuscin.[172] Lipofuscin pigmentation may spread to the submucosa and into pericolonic lymph nodes.[173]

CLINICAL RESPONSE

The onset of action of the laxative effects of cascara is about 6–8 hours. Most of the clinical features of chronic laxative abuse are nonspecific with the exception of melanosis coli. Chronic anthraquinone laxative abuse (cascara, senna) may cause the benign condition (i.e., melanosis coli), manifest by the asymptomatic accumulation of dark brown-black discoloration (lipofuscin-like, pigment-laden macrophages) in the submucosa of the colon in a pattern similar to alligator skin. This process occurs primarily following chronic ingestion of anthraquinone laxatives, but occasionally melanosis coli is associated with bisacodyl or phenolphthalein abuse as well as lead and mercurous chloride poisoning.[174] Extensive melanosis coli may be difficult to distinguish from inflammatory or ischemic bowel disease during endoscopic visualization. Confirmatory diagnosis of melanosis coli is made via biopsy.[175] Rarely, the abuse of cascara is associated with gastric melanosis.[176] Pathologic changes associated with melanosis coli typically appear after 4–12 months of laxative abuse, and these abnormalities disappear over a similar period. Rare case reports associate the use short term use of cascara (3 times daily for 3 d) with the development of portal hypertension and severe cholestatic hepatitis that resolved following cessation of cascara use.[177] The liver biopsy demonstrated moderately severe acute and chronic portal inflammation including a large number of eosinophils suggesting an immune-mediated hepatitis. Experimental studies indicate that cascara lacks long term carcinogenic potential as defined by the absence of initiating properties and weak or absent promoting activity.[178,179]

DIAGNOSTIC TESTING

Analytic methods for the quantitation of anthranoid compounds in cascara sagrada and cascara sagrada fluid extract include thin layer chromatography,[180] capillary electrophoresis,[181] and HPLC with UV detection (254 nm).[166] The use HPLC with fluorescence detection (excitation 435 nm and emission 515 nm) allows the quantitation of aloe-emodin, rhein, emodin, and chrysophanol in plasma samples with a LLOQ of 6.5 ng/mL, 20 ng/mL, 40 ng/mL, and 15 ng/mL, respectively.[182] Rare case reports associate chronic cascara use with severe hypokalemia, hypocalcemia with tetany, metabolic acidosis, and renal dysfunction.[183]

TREATMENT

Medical management of the complications associated with chronic stimulant abuse including cascara should be directed at the correction of fluid and electrolyte imbalance along with the restoration of a normal diet after an initial evaluation of the adequacy of respirations and cardiac function. Symptomatic patients should be evaluated for electrolyte (sodium, potassium, chloride, magnesium, calcium) and acid-base abnormalities, anemia, rhabdomyolysis, volume depletion, renal dysfunction, cardiomyopathy, and electrocardiographic abnormalities. Treatment is supportive, similar to bisacodyl abuse.

Castor Oil

IDENTIFYING CHARACTERISTICS

Castor oil (CAS RN: 8001-79-4) is a colorless to pale yellow viscous liquid with a slightly acrid taste and a

specific gravity of 0.945–0.965 at 25°C (77°F).[184] This compound is poorly soluble in water (<1 mg/mL at 20°C/68°F) with a viscosity of 283 cP at 37°C (98.6°F). The boiling point of castor oil is 313°C (595.4°F); the maximum absorbance of this compound is 270 nm. Other names for castor oil include ricinus communis seed oil, castor seed oil, oleum ricini, ricinol, and ricinus oil. The major constituent in castor oil is the unsaturated fatty acid, ricinoleic acid (CAS RN: 141-22-0, $C_{18}H_{34}O_3$). This C_{18} aliphatic fatty acid is structurally similar to some dietary fats (e.g., oleic acid) and to hydroxylated C_{18} fatty acids that occur in the gut as a result of enzymatic hydration of unabsorbed dietary fats by colonic bacteria. Ricinoleic acid is a colorless liquid that is insoluble in water. Table 12.7 lists some physiochemical properties of ricinoleic acid. Ricinine is a piperidine alkaloid (3-cyano-4-methoxy-N-methyl-2-pyridone, CAS RN: 524-40-3) that occurs in both castor beans and castor oil. Table 12.8 lists some physiochemical properties of ricinine. Figure 12.8 displays the chemical structures of ricinoleic acid and ricinine.

EXPOSURE

The seeds of *Ricinus comminus* L are the source of this ancient cathartic known to early Egyptians, Greeks, and Romans.[185] The castor bean contains ricin, ricin agglutinin, and ricinine. Ricinine is a biomarker for ricin because both compounds share a similar plant source in the castor bean and leaves. Methods of extraction include the use of solvents or mechanical techniques (crushing, grinding, cold pressing). The latter process leaves a residue (pomace) that contains most of the ricin and an allergen. Ricin is water soluble and this toxin does not partition easily into the oil extract; however, castor oil does contain some ricinine. Ricinoleic acid is the major constituent of castor oil, accounting for about 80–90% of the fatty acid content. As measured by GC,

a sample of castor oil contained the following fatty acids: 1) ricinoleic acid, 82%; 2) C_{18} acids (linoleic oleic, stearic acids), 16%; and 3) palmitic acid, 2%.[186] This seed oil is a fragrance ingredient and skin-conditioning agent in cosmetics (e.g., emollient, surfactant), a folk remedy for the induction of labor, and an industrial lubricant; the many hydroxylated triacylglycerols in the seed oil are a raw material for surface coatings and polymer formulations. The main medicinal use of castor oil is as a purgative. The oil seed extract is a popular lay drug for the induction of labor in a nonmedical setting; however, there are inadequate clinical data to support this indication.[187] Castor oil is classified by the US Food and Drug Administration as generally recognized as safe and effective for use as a stimulant laxative. Finished food may contain castor oil (<500 ppm) as a diluent, release/antisticking agent, or flavoring agent; castor oil is also a plasticizer in rubber food containers.[184] Castor oil was a component of some mummification balms detected in Egyptian mummies (e.g., Ptolemaic era, circa 100 BC).[188]

DOSE EFFECT

The acceptable daily castor oil intake is 0.7 mg/kg body weight as established by the Joint Food and Agriculture Organization/World Health Organization Expert Committee.

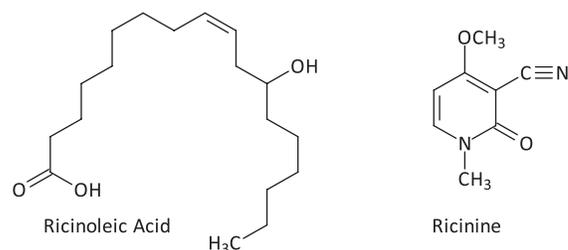

FIGURE 12.8. Chemical structure of ricinoleic acid.

TOXICOKINETICS

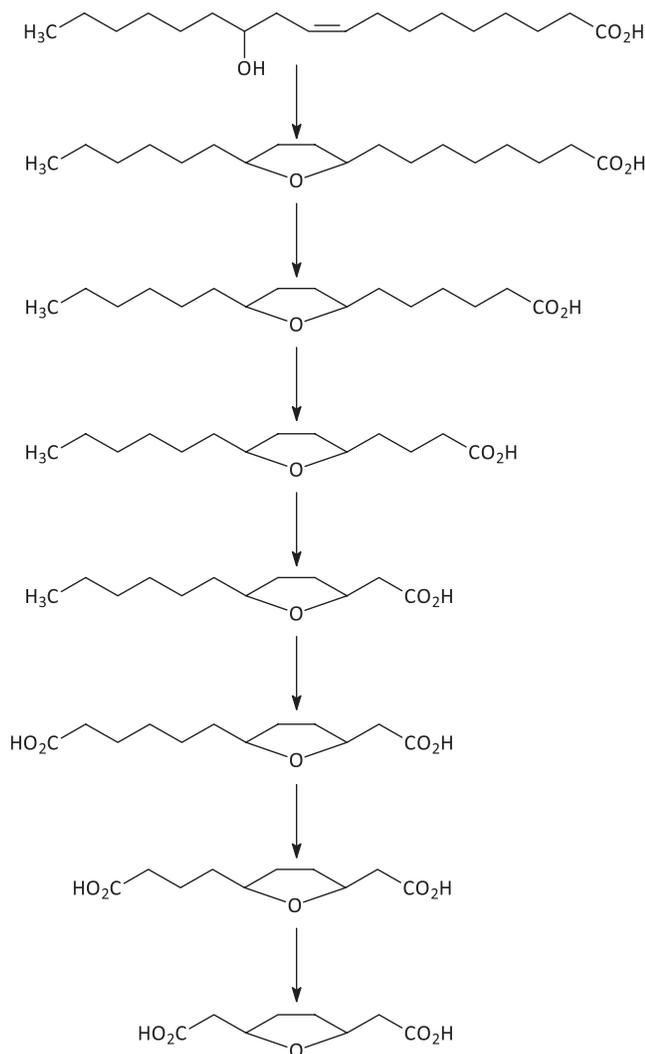
There are few clinical data on the toxicokinetics of castor oil and ricinoleic acid in humans. Animal studies indicate that pancreatic enzymes hydrolyze castor oil to glycerol and ricinoleic acid. Esterification of ricinoleic acid occurs in the intestinal epithelial cells, followed by entry into the chyle and distribution into adipose tissue similar to other fatty acids.[189] Potential metabolites from the cyclization of a hydroxylated β-oxidation intermediate include epoxydicarboxylic acids, primarily 3,6-epoxyoctanedioic and 3,6-epoxydodecanedioic acids with lesser amounts of 3,6-epoxydecanedioic acid. 3,6-Epoxyoctanedioic acid is a normal constituent of urine; however, the source of this fatty acid is unknown.[190] Figure 12.9 displays the proposed biotransformation of ricinoleic acid.


FIGURE 12.9. Proposed metabolism of ricinoleic acid.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Long chain fatty acid in castor oil including ricinoleic acid inhibits net water and electrolyte absorption at the luminal surface, resulting in the secretion of electrolytes and water. The presence of hydroxyl groups on these fatty acids delays absorption and increases the purgative effect by prolonging exposure of the colon to these compounds. Although potassium losses exceed sodium or chloride losses in healthy patients, the loss of electrolytes in the stool is typically negligible; however, laxative abuse increases the loss of sodium in relation to the potassium. Subsequently, activation of the renin–angiotensin–aldosterone system reduces sodium losses by increasing the excretion of potassium in the urine and stool. Electron scanning studies of the morphology of rabbit colon during perfusion studies with sodium ricinoleate suggest that this compound may cause desquamation of surface epithelial cells;[191] however, the relevance of these *in vitro* studies to doses of castor oil ingested by humans is unclear.

CLINICAL RESPONSE

Similar to other stimulant laxatives, adverse reactions associated with the abuse of castor oil include electrolyte and fluid imbalance. The subcutaneous (SC) injection of a large dose (i.e., 500 mL) of castor oil by a 28-year-old transsexual was associated with immediate local pain, abdominal and chest pain, headache, vomiting, tinnitus, hematuria, and jaundice.[192] She developed fever, tachycardia, renal failure, respiratory distress with pulmonary infiltrates, hypoxemia requiring intubation, hepatitis, hemolysis, and thrombocytopenia. She recovered from the multiorgan failure, but she required hemodialysis for 1½ months. Characteristic features of patients chronically abusing castor oil include very watery stool with a large amount of oil drops floating on the fecal surface that contain mostly ricinoleic acid. Castor oil and hydrogenated castor oil (castor wax) contain several allergens that produce a variety of allergic reactions including contact dermatitis,[193] fixed drug eruption,[194] and cheilitis.[195]

DIAGNOSTIC TESTING

Analytic methods for the detection and quantitation of components in castor oil include thin layer chromatography,[196] GC,[190,197] liquid chromatography/mass spectrometry with evaporative light scattering,[198] refractive index, flame ionization,[199] negative ion atmospheric pressure chemical ionization or positive ion matrix-

assisted laser desorption ionization,[200] and matrix-assisted laser desorption/ionization time-of-flight MS.[201] Ricinine is a biomarker for ricin formed after the ingestion of castor bean because both substances share the same plant source; additionally, ricinine is a minor constituent of castor oil. The use of solid phase extraction followed by liquid chromatography/tandem mass spectrometry, LC/MS and matrix-assisted laser desorption/ionization time-of-flight/mass spectrometry,[202] or isocratic high performance liquid chromatography/electrospray ionization/tandem mass spectrometry[203] allows the quantitation of ricinine in urine samples. The LLOQ for the latter method is 0.083 ng/mL. The initial urine from a 28-year-old transsexual with multiorgan failure after the SC injection of an estimated 500 mL castor oil contained 41 ng ricinine/mL.[192] Ricinine is stable in human urine when stored at 25°C (77°F) or 5°C (41°F) for 3 weeks.

TREATMENT

Medical management of the complications associated with chronic stimulant abuse including castor oil should be directed at the correction of fluid and electrolyte imbalance along with the restoration of a normal diet after an initial evaluation of the adequacy of respirations and cardiac function. Toxicity associated with the abuse of castor oil typically involves GI symptoms. Symptomatic patients should be evaluated for electrolyte (sodium, potassium, chloride, magnesium, calcium) and acid-base abnormalities, anemia, rhabdomyolysis, volume depletion, hepatorenal dysfunction, cardiomyopathy, and electrocardiographic abnormalities.

The SC or IV injection of castor oil has been associated with multiorgan failure similar to ricin toxicity.[192] These patients require a careful evaluation of their respiratory and cardiac function along with hemodynamic monitoring in an intensive care setting for the development of hepatorenal failure, respiratory distress, hemolysis, and disseminated intravascular coagulation. Treatment is supportive; there are no antidotes or effective methods to enhance the elimination of the toxin(s).

Senna

IDENTIFYING CHARACTERISTICS

The main active ingredients in senna are dianthrone compounds (sennosides A–D) from the anthraquinone family. The most common sennosides are the highly hydrophilic R,R-isomer sennoside A (CAS RN: 81-27-6, $C_{42}H_{38}O_{20}$, MW: 862.7391 g/mol) and the R,S-isomer sennoside B (CAS RN: 128-57-4); these compounds hydrolyze to the corresponding aglycone (sennidin) and 2 molecules of glucose.[204] The metabolite, rhein is the main active ingredient of senna. Senna contains a variety of rhein compounds including rhein-8-glucoside, rhein-8-diglucoside, and rhein anthrone-8-glucoside as well as aloe emodin dianthrone diglucoside, aloe emodin glucoside, and chrysophanol glucosides. Trade names include Ex-Lax® regular strength (Novartis Consumer Health, Parsippany, NJ), Senokot® (Purdue Products, L.P., Stamford, CT), Castoria®, and Black Draught.

EXPOSURE

The purgative properties of senna were known to the Ayurvedic and allopathic systems of medicine. The sources of senna are the dried leaves and fruits of *Senna alexandrina* P. Mill. (formerly, *Cassia acutifolia* or *C. angustifolia*). In a convenience sample of market formulations of senna leaf from several commercial sources, the mean percentage of total sennosides was $2.15 \pm 0.06\%$ w/w with the following distribution: A—$0.62 \pm 0.05\%$; B—$0.81 \pm 0.09\%$; C—$0.25 \pm 0.03\%$; and D—$0.46 \pm 0.07\%$, as measured by HPTLC.[205] Senna is available as pills, capsules, and rectal suppositories, usually in over-the-counter preparations.

DOSE EFFECT

In rodent studies, the acute toxicity of the active ingredients of senna (sennosides A and B) is relatively low compared with other fractions (rhein-8-glucoside, fraction IV) with low laxative activity; the estimated lethal oral dose of these laxative drugs exceeds 5,000 mg/kg.[206] The regular use of anthracene laxatives over 4–12 months is associated with the development of melanosis coli.[141] Case reports associate the chronic abuse of senna tablets with finger clubbing, hypercalcemia, nephrocalcinosis, and renal dysfunction. The chronic use of 100–200 Senokot® tablets daily was associated with finger clubbing that resolved after cessation of use and recurred after resuming Senokot® abuse for 2–3 months.[207] A 36-year-old woman with anorexia nervosa and a 6-year history of ingesting 50–100 senna tablets (12.5 mg/tablet) daily developed postural hypotension, dehydration, hypercalcemia, finger clubbing, hypertrophic osteoarthropathy, nephrocalcinosis, and renal dysfunction.[208] Chronic dehydration from the senna and the large amount of daily calcium (i.e., calcium sennosides) probably accounted for the clinical features of hypercalcemia rather than a direct toxic effect of senna.

TOXICOKINETICS

The isomers sennosides A and B are natural prodrugs. In humans, these hydrophilic compounds pass through the upper intestinal tract to the lower GI tract where intestinal bacteria hydrolyze these dianthrone-*O*-glucosides to the corresponding anthraquinone aglycone followed by the reduction of these compounds to the corresponding pharmacologically active anthrone (i.e., rhein anthrone). Physiochemical factors and increased peristalsis limit the absorption of rhein anthrone by the large intestine; therefore, most of the rhein anthrone appears in the feces.[209] Rhein is the oxidized product of rhein anthrone. Peak rhein concentrations occur about 3–5 hours and 10–11 hours after administration, probably as a result of the absorption of free rhein in the senna and the absorption of rhein after the degradation of sennosides.[210] The mean elimination half-life of rhein is about 7 hours.[210] Animal studies indicate that excretion of absorbed anthraquinone aglycone compounds occurs in the bile and urine after conjugation to glucuronide or sulfate.[211]

The transfer of senna to breast milk is minimal, primarily because of the poor absorption of this compound from the GI tract.[132] In particular, the excretion of rhein in breast milk following the use of senna is small. After the ingestion of a senna laxative containing 15 mg sennosides daily for 3 days, the concentration of rhein in breast milk was <10 ng/mL in 94 of 100 breast milk samples from 20 lactating women.[212] The stools of the breastfeeding infants remained normal during maternal use of senna. Most laxative abusers report the necessity of higher doses of laxatives to achieve the desired effects.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Senna-based alkaloids are composed of dianthrone diglucosides (sennosides A and B) and an aglycone (rhein anthrone). Intestinal bacteria hydrolyze the glucosides from the aglycone, after which both substances interact with inflammatory cells in the colon.[213] Sennosides increase paracellular permeability of small molecules by stimulating chloride secretion, which is electrochemically and osmotically balanced by an efflux of sodium and water via the paracellular pathway.[214] Rhein directly irritates colonic epithelial cells and indirectly stimulates secretion via neurohumoral mechanisms,[215] thereby enhancing intestinal transit and water secretion.[216] The rarity of the association between hepatitis and chronic senna use/abuse suggests an idiopathic reaction.

CLINICAL RESPONSE

Illicit Use

Case reports associated chronic abuse of senna tablets (e.g., calcium sennosides) with finger clubbing, hypercalcemia, bilateral medullary renal calcifications, and renal dysfunction.[207,208] Several case reports suggest a possible association between the use and abuse of tea from senna fruits and leaves and liver dysfunction.[217] A 77-year-old man developed cholestasis and hepatitis after ingesting senna daily for 3 months.[218] The liver biopsy demonstrated bridging hepatocellular necrosis and canalicular cholestasis. Fatigue, abdominal pain, and jaundice resolved within 1 month of the cessation of senna use; the serum bilirubin and hepatic aminotransferases also returned to normal values during this period. There was no rechallenge. Other case reports document the recurrence of a toxic hepatitis following reintroduction of senna in a 26-year-old nurse ingesting sennoside B and large amounts of folia sennae tea[219] and in a 28-year-old poor metabolizer (homozygous for CYP2D6*4 variant) drinking an herbal tea from senna leaves.[220]

Abstinence Syndrome

Withdrawal symptoms from chronic laxative abuse include rebound edema, constipation, and drug craving. Abdominal cramping, constipation, bloating, mood swings, fatigue, and malaise may persist for several weeks after cessation of senna abuse. Case reports suggest that rebound edema and congestive heart failure may occur in susceptible patients within the first 2 weeks after cessation of stimulant laxative abuse.[221]

Reproductive Abnormalities

Senna is generally considered safe for use during pregnancy with animal studies failing to demonstrate fetal risks when administered during pregnancy. Case-control studies also do not demonstrate increased risk of congenital malformations from the use of senna during pregnancy. In an analysis of the Hungarian Case-Control Surveillance System of Congenital Abnormalities, the adjusted odds ratio (OR) for the congenital abnormalities for pregnant women ingestion 10–30 mg senna daily was 1.0 (95% CI: 0.9–1.1).[222] There were no statistically significant associations between any congenital abnormality and senna use during pregnancy, although the OR for neural tube deficits was marginal (OR, 1.8, 95% CI: 1.0–3.0).

Carcinogenesis

Although a retrospective study of 3,049 patients undergoing diagnostic colorectal endoscopy suggested an increased risk of colorectal cancer (RR, 3.04; 95% CI: 1.18–4.90) in patients chronically using anthranoid laxatives,[223] most experimental and epidemiologic data do not support a causal link between chronic laxative use (cascara, senna) and colorectal cancer.[224,225] The International Agency for Research on Cancer (IARC) and the US National Toxicology Program do not list senna as a suspected carcinogen.

DIAGNOSTIC TESTING

Analytic methods for the detection and quantitation of sennosides and rhein in solid samples include spectrophotometry,[226] fluorometry, high performance thin layer chromatography,[227] HPLC with UV detection,[228] ion pair HPLC,[229] and GC/MS after hydrolysis and extractive methylation.[152]

TREATMENT

Medical management of the complications associated with chronic stimulant abuse including senna should be directed at the correction of fluid and electrolyte imbalance along with the restoration of a normal diet after an initial evaluation of the adequacy of respirations and cardiac function. Symptomatic patients should be evaluated for electrolyte (sodium, potassium, chloride, magnesium, calcium) and acid-base abnormalities, anemia, rhabdomyolysis, volume depletion, hepatorenal dysfunction, cardiomyopathy, and electrocardiographic abnormalities. Treatment is supportive.

Osmotic Laxatives

Osmotic laxatives include lactulose, magnesium sulfate/citrate, sodium sulfate, and sorbitol. The adult dose of 70% sorbitol is 1–2 mL/kg.[2] The recommended adult dose of 10% magnesium citrate is 250 mL. The administration of a single, large therapeutic dose of magnesium sulfate (13.9 g) to 7 healthy volunteers was not associated with a significant increase in the serum magnesium concentration.[230] Magnesium and sodium increase intestinal water by retention as sulfate or phosphate ions; additionally, magnesium induces the release of cholecystokinin and subsequent intraluminal accumulation of water and electrolytes. Lactulose increases the presence of osmotically active molecules in the colon along with flatulence and intestinal colic.

Typical laxative screens detect stimulant laxatives, but not osmotic laxatives. Methods to detect the abuse of osmotic diuretics include determination of stool osmolal gap, fecal sulfate (sodium sulfate containing laxatives), fecal phosphate (phosphate containing laxatives), and fecal magnesium (magnesium containing laxatives).[231] The sum of the sodium and potassium concentrations multiplied by 2 approximates the sum of ionic constituents in the stool; the difference between this estimation and the stool osmolality is the osmolal gap. The presence of a large stool osmolal gap and normal stool osmolality suggests the use of saline laxatives. The osmolar gap following abuse of saline cathartics usually exceeds 100 mOsmol/L.[143] The chronic use of sodium sulfate (Glauber's salt) or magnesium sulfate (Epsom salt) increases the sulfate concentration in urine. Typically, the daily urinary excretion of magnesium and sulfate is <16 mEq and <60 mEq, respectively.[143] As measured by atomic absorption spectrophotometry, diarrheal stools should contain <24 mEq magnesium/L unless the patient is ingesting magnesium containing compounds. Hypocalcemia occasionally results from chronic laxative abuse, particularly in association with hyperphosphatemia from chronic abuse of phosphorous containing osmotic cathartics; complications of hypocalcemia include tetany and osteomalacia in association with vitamin D deficiency.[232]

Phenolphthalein

Phenolphthalein was originally a colorant for wine. Following absorption, limited excretion of phenolphthalein occurs in the urine. Enterohepatic recirculation results in the excretion of phenolphthalein glucuronide in the bile and subsequent laxative action. Dermatologic changes associated with phenolphthalein use include Steven-Johnson syndrome, bullous photodermatitis, toxic epidermal necrolysis, and fixed drug eruption with hyperpigmentation.[233,234] Free phenolphthalein in urine turns pink following the addition of alkalizing agents; however, most phenolphthalein in urine exists as conjugates. These conjugated forms (sulfates, glucuronides) do not become pink unless the conjugates are hydrolyzed by β-glucuronidase or acid hydrolysis. These methods are not specific because these procedures produce pink urine following the ingestion of beet (*Beta vulgaris* L.), rhubarb (*Rheum* spp.), and bromsulfophthalein. Pink discoloration in the diapers of a child with unexplained chronic diarrhea and weight loss suggests the diagnosis of Münchausen syndrome by proxy. Treatment is supportive.

Chapter 13

NORADRENERGIC AGENTS

Cyrus Rangan, MD

During the late 1930s, studies involving narcoleptic patients demonstrated that amphetamines suppress appetite and promote weight loss; by the 1940s, amphetamines were marketed as both single therapy and combination treatment for the control of appetite and loss of weight. Subsequently, numerous case reports associated the use of amphetamine-containing appetite suppressants ("rainbow pills") containing thyroid hormones, digitalis, laxatives, diuretics, and sedatives, with addictive behavior, hypertension, cardiotoxicity, and death.[1] In 1961, scientists at McNeil Laboratories (Fort Washington, PA) synthesized the oxazoline derivative, aminorex; in the following year, these scientists discovered the appetite suppressant properties of aminorex. This drug became available as an appetite suppressant in Switzerland, Austria, and Germany for over-the-counter (OTC) sale in 1965. Between 1965 and 1972, the incidence of primary pulmonary hypertension in these 3 countries increased 10-fold.[2] A majority of the new patients with pulmonary hypertension had taken aminorex for weight loss; the female to male ratio among these patients was 4:1. The first epidemic of pulmonary hypertension related to appetite suppressants ended when aminorex was withdrawn from the market in 1972.[3] Since the 1960s, researchers have developed numerous structurally related amphetamine-type anorexiants including ephedrine, diethylpropion, phentermine, phenmetrazine, phendimetrazine, and phenylpropanolamine; however, the US Food and Drug Administration (FDA) has banned several diet-control preparations (dexfenfluramine, fenfluramine, phenmetrazine, phenylpropanolamine) amid reports of serious adverse reactions.

A small proportion of patients using amphetamine-based appetite suppressants may escalate dosage voluntarily as tolerance develops to the anorectic effects; drug-seeking behavior may begin because of a physiologic addiction to amphetamine compounds.

Abusers of noradrenergic appetite suppressants usually prefer oral preparations; however, some abusers with highly addictive behavior may seek alternate routes of recreational abuse (insufflation, injection).

DIETHYLPROPION

IDENTIFYING CHARACTERISTICS

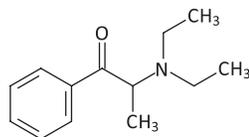
Diethylpropion (CAS RN: 90-84-6) is an *N,N*-diethyl cathinone analog [2-(diethylamino)-1-phenyl-1-propanone] with a structural formula of $C_{13}H_{19}NO$. Synonyms include amfepramone, α-benzoyltriethylamine, and propiophenone, whereas trade names include Adiposon, Anorex® (Klein-Becker, Salt Lake City, UT), Obesitex, Silutin, Tenuate, Tepanil, and Tylinal. Figure 13.1 displays the chemical structure of the phenylethylamine compound, diethylpropion. Diethylpropion displays minor sympathomimetic properties with stimulant activity much less than dextroamphetamine. The pharmaceutic preparation of diethylpropion is a racemate; experimental studies suggest that the (+) and (−) isomers of diethylpropion undergo spontaneous racemization at physiologic pH.[4] Under microscopic analysis, diethylpropion appears as very small prisms


FIGURE 13.1. Chemical structure of diethylpropion.

that crystalize to forms ranging from thin, elongated laths to long rods.[5]

EXPOSURE

Diethylpropion was introduced in 1962 as an anorexiant for the short-term treatment of obesity in conjunction with diet and exercise; this sympathomimetic drug was an alternative to dextroamphetamine with fewer cardiovascular and central nervous system (CNS) side effects. In a meta-analysis of 13 randomized clinical trials of diethylpropion and weight loss, the mean weight loss of obese patients receiving 75 mg daily for 6–52 weeks was 3.0 kg (95% CI: –1.6 to 11.5 kg) when compared with placebo (lifestyle modification only).[6] The weight loss effect was modest and some studies did not demonstrate a statistically significant difference between the treatment and placebo groups. Diethylpropion is available as tablets and capsules under US Drug Enforcement Administration (DEA) schedule IV.

The abuse of diethylpropion is relatively rare;[7,8] the euphoria associated with diethylpropion is substantially less than dextroamphetamine or phenmetrazine.[9] These studies indicate that intravenous (IV) abuse of diethylpropion is unlikely because of the large number of tablets required to simulate the effects of dextroamphetamine. Most case reports of diethylpropion abuse involve individuals with polydrug abuse and previous experience with other amphetamine compounds (e.g., dextroamphetamine, phenmetrazine).[10] Although the use of diethylpropion initially may produce a feeling of well-being and talkativeness, the development of marked anxiety and agitation after 24–72 hours limits the continued use of this drug.[11]

DOSE EFFECT

Diethylpropion is formulated as 25 mg tablets or capsules for oral administration up to 3 times per day, or as 75-mg sustained-release tablets. The acute toxic dose of diethylpropion depends on tolerance; limited clinical data suggests that toxicity may develop in nontolerant adults at diethylpropion doses exceeding 750 mg.[12] A case report associated the development of anxiety, depression, labile mode, anorexia, insomnia, phobias,

ideas of reference with the chronic abuse of diethylpropion by a 27-year-old woman; she reported the use of 50–100 75-mg tablets daily (range up to 300 tablets).[13]

TOXICOKINETICS

The gastrointestinal (GI) tract absorbs diethylpropion well, with peak plasma diethylpropion concentrations occurring within 2 hours.[14] Diethylpropion undergoes extensive biotransformation with de-alkylation being the main metabolic pathway. The liver metabolizes diethylpropion via 1) N-deethylation to N-ethylaminopropiophenone and aminopropiophenone, 2) carbonyl reduction to N,N-diethylnorephedrine, and 3) deamination to benzoic acid with subsequent conjugation to glycine and the formation of hippuric acid.[15,16] N,N-Diethylnorephedrine undergoes de-alkylation to N-ethylnorephedrine. Norephedrine (phenylpropanolamine) is a minor metabolite of diethylpropion; p-hydroxylation is probably an insignificant pathway for the biotransformation of diethylpropion. All metabolites of diethylpropion are metabolically active. The kidney excretes minor amounts (i.e., <2%) of diethylpropion as unchanged drug depending on urinary pH.[17] The terminal plasma elimination half-life of diethylpropion is approximately 8 hours.[14] Limited pharmacologic data suggests that saturation kinetics may occur at supratherapeutic diethylpropion doses (e.g., 400 mg).[18]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Augmentation of norepinephrine and dopamine activity in the hypothalamus suppresses appetite, mildly dampens olfactory and gustatory acuity, and produces anorexia.[19] Amphetamine compounds may increase levels of leptin, a satiety-signaling neuromodulator and decrease concentrations of the neuromodulator (neuropeptide Y) that stimulates hunger, decreases energy expenditure, and increases fat storage.[20,21] Diethylpropion and phentermine induce appetite suppression via similar mechanisms.

CLINICAL RESPONSE

Dry mouth and insomnia were the most frequent adverse events in a clinical trial involving the administration of 50-mg diethylpropion twice daily for 6 months; there were no significant differences in blood pressure, pulse rate, electrocardiogram, echocardiography, or clinical chemistries when comparing the values at the end of the treatment phase with the baseline of 37 obese, healthy volunteers.[22] Occasional case reports

associate the use of diethylpropion with the development of acute psychosis, paranoia, and less-common affective symptoms.[23] These case reports often involve patients with histories of prior drug abuse, excessive diethylpropion use, or prior psychiatric disorders (e.g., depression, neurosis). Clinical features of the psychosis include auditory and visual hallucinations, paranoid delusions, feeling of influence (by telepathy), ideas of surveillance, ideas of reference, and thought broadcasting.[24,25] Although most of these patients did not have a prior history of psychotic disorders, follow-up of some of these patients suggests a typical clinical course of chronic paranoid schizophrenia in the absence of continued diethylpropion abuse.[26] The dose, time course, and duration of diethylpropion use is highly variable with some psychotic episodes occurring within a few weeks of the initiation of therapeutic diethylpropion doses while other episodes occur within a week of the cessation of chronic diethylpropion use.[27,28] Abrupt discontinuance following chronic diethylpropion abuse may result in apathy, depression, lethargy, anxiety, myalgias, abdominal pain, and sleep disturbances marked by diminished rapid eye movement (REM) that requires several weeks to resolve.

Rare case reports associate the therapeutic use of diethylpropion with transient ischemic attacks and possible cerebral vasospasm,[29] *torsade de pointes* in a patient with QTc prolongation (0.52 msec) and marked hypokalemia (2.4 mEq/L),[30] and primary pulmonary hypertension in a patient with BMPR2 gene mutation.[31] However, the causal role of diethylpropion in the etiology of these abnormalities is unclear because of the presence of multiple etiologic factors and the lack of known pathologic mechanisms.

DIAGNOSTIC TESTING

Analytic methods for the detection and quantitation of diethylpropion include gas chromatography (GC) with flame ionization,[16,32] high performance liquid chromatography (LC) with UV detection (254 nm),[4] gas chromatography/electron impact/mass spectrometry,[15] and GC/MS with heptafluorobutyric derivation.[33] The use of high performance capillary electrophoresis with confirmation by GC/MS in electron impact ionization mode allows the detection of diethylpropion in solid samples (e.g., Chinese herbs).[34] The limit of detection (LOD) with this method is 0.4 µg/mL with intraday precision <3%. Diethylpropion is unstable in alkaline media and relatively stable in neutral to acidic conditions. In refrigerated (4°C/39.2°F) plasma samples, diethylpropion was undetectable within 1 week under alkaline conditions (pH = 11), whereas little deterioration in diethylpropion occurred during the same period in samples stored under neutral (pH = 7) and acidic (pH = 5) conditions.[32] The peak plasma diethylpropion concentration after a single oral dose of 400 mg is ~300 ng/mL 2 hours after ingestion.[18]

TREATMENT

The treatment of diethylpropion is supportive, similar to phenylpropanolamine intoxication.

EPHEDRINE

IDENTIFYING CHARACTERISTICS

Ephedrine is β-hydroxylated methamphetamine [(1R,2S)-2-methylamino-1-phenylpropan-1-ol, CAS RN: 299-42-3], which has a structural formula of $C_{10}H_{15}NO$. Figure 13.2 displays the chemical structure of ephedrine. Table 13.1 lists some physiochemical properties of ephedrine.

Do-do tablets were OTC cough and cold preparations, which contained 222 mg ephedrine hydrochloride, 30 mg caffeine, and 50 mg theophylline sodium glycinate. Rare case reports associated the abuse of this medication as a substitute for amphetamine.[35]

EXPOSURE

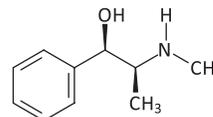
Ephedrine has less addicting potential than amphetamine or methamphetamine; however, occasional case


FIGURE 13.2. Chemical structure of ephedrine.

TABLE 13.1. Physiochemical Properties of Ephedrine.

Physical Property	Value
Melting Point	34°C (93.2°F)
Boiling Point	255°C (491°F)
pKa Dissociation Constant	10.252
log P (Octanol-Water)	1.13
Water Solubility	6.36E+04 mg/L (30°C/86°F)
Vapor Pressure	8.30E-04 mm Hg (25°C/77°F)

reports appear in the English, Russian, and Japanese medical literature documenting ephedrine abuse and addiction, usually in polydrug abusers.[36] A 33-year-old woman was admitted for an 18-month history of ephedrine abuse that began with the use of 50 mg daily for appetite suppression.[37] Her ephedrine use escalated to 1,500 mg daily as a result of tolerance, rebound somnolence and fatigue, and an inability to abstain despite her job loss for stealing the drug at work. On presentation for inpatient treatment, she was disheveled and emotionally labile with poor cognition; she had a sinus tachycardia and normal systolic blood pressure. Her only other known addiction was nicotine.

Ephedrine is distributed as a synthetic pharmaceutic preparation or as a herbal dietary supplement (e.g., ma huang) derived from plants (e.g., central Asian evergreen shrub, *Ephedra sinica*).[38] The typical ma huang preparation contains 1–2% total alkaloids with ephedrine and pseudoephedrine comprising ~90% of the total alkaloid content;[39] however, the total ephedra alkaloid content may range up to 8%.[40] In a study of 35 commercial oral ephedrine-based diet-control agents and bronchodilators, the total ephedra alkaloid content ranged from 5.97–29.3 mg per dose for administration 1–3 times daily.[41] In the United States, ephedrine was sold as a tablet, capsule, or constituent in an intranasal spray until the FDA banned the commercial sale of this drug as an OTC agent in 2004 based on an unreasonable risk of illness or injury under the conditions of use recommended or suggested in labeling.[42] Clinical uses for ephedrine included the treatment of spinal anesthesia-induced hypotension, bronchoconstriction, upper respiratory tract symptoms, obesity, depression, narcolepsy, and Stokes-Adams attacks.[43]

DOSE EFFECT

Maximal daily therapeutic doses of ephedrine range up to 120 mg. Tolerance to the effects of ephedrine develops during ephedrine abuse, resulting in reported daily ephedrine doses ranging up to 10–20 times the therapeutic dose. In a case series of 5 patients admitted for inpatient treatment of ephedrine addiction, the mean reported ephedrine dose was 1,450 mg with a range up to 2,500 mg.[37] Following the ingestion of 50–100 mg ephedrine daily for 10 days to improve athletic performance, a 19-year-old woman developed hemodynamically stable ventricular tachycardia that was resistant to cardioversion and amiodarone.[44] Sixty hours after admission when the ingested ephedrine would be expected to be eliminated (no plasma ephedrine concentrations reported), electrophysiology studies revealed an reproducible ventricular tachycardia; she underwent successful ablation of the dysrhythmia. She

remained in normal sinus rhythm at her 1-year follow-up examination.

TOXICOKINETICS

The absorption of therapeutic ephedrine doses from the GI tract and nasal mucosa is relatively complete (i.e., >90%) with peak plasma ephedrine concentrations occurring within ~2 hours.[45] The approximate volume of distribution of ephedrine is approximately 3 ± 1 L/kg. About 8–20% of the absorbed ephedrine dose undergoes N-demethylation to norephedrine, whereas oxidative deamination of ephedrine to 1-phenylpropan-1,3-diol followed by side-chain oxidation to benzoic acid and hippuric acid accounts for approximately 4–13% of the absorbed dose.[46] The liver metabolizes approximately 4% of ephedrine to norephedrine via N-demethylation and converts a minor proportion to inactive, renally excreted metabolites via conjugation, deamination, and p-hydroxylation. The kidneys excrete the majority of the ephedrine dose unchanged in urine along with a small proportion of inactive conjugates, depending upon urine pH and species.[47] The plasma half-life of ephedrine ranges from ~5.7–7.1 hours.

The combination of ephedrine and other stimulants (caffeine, theophylline) with a monoamine oxidase inhibitor (phenelzine) can produce serious drug interactions. A 28-year-old woman developed hypotension, sinus tachycardia, neuromuscular irritability, rhabdomyolysis, encephalopathy, and hyperthermia after ingesting a combination tablet (18.31 mg ephedrine hydrochloride, 30 mg caffeine, 100 mg theophylline) 8 hours prior to admission.[48] She had stopped her 60-mg daily intake of phenelzine the preceding day. She recovered after a complicated 3-week hospitalization that included 17 days on a respirator for acute respiratory distress syndrome.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Ephedrine is both a direct and indirect sympathomimetic compound. Catecholamine reuptake complexes on adrenergic nerve membranes transport ephedrine from intercellular spaces into the nerve cell. The nerve cell packages ephedrine into presynaptic storage vesicles together with endogenous norepinephrine, dopamine, or serotonin. Ephedrine increases the alkalinity of the vesicle, thus lowering the threshold for action potentials to induce vesicle exocytosis. As a result, incoming action potentials release elevated molar concentrations of neurotransmitters, along with ephedrine, into the synapse, thus characterizing the indirect sympathomimetic effect of ephedrine.[49] Once in the synaptic space, ephedrine is a weak direct agonist of postsynaptic

adrenergic receptors with an affinity higher for β-receptors than for α-receptors.[49] Augmentation of peripheral norepinephrine activity mildly stimulates thermogenesis in brown adipose tissue.[50] In ephedrine-caffeine combination preparations, caffeine antagonizes adenosine and inhibits cellular phosphodiesterase, thus enhancing adipose tissue thermogenesis.[51] In the lung, ephedrine produces bronchodilation through stimulation of bronchial β$_2$-adrenergic receptors.[52]

Hyperthermia from ephedrine poisoning is mediated in part by effects on the hypothalamus, caudate, and putamen.[53] The combination of ma huang or ephedrine with caffeine enhances cardiotoxicity compared with ephedrine alone.[54] Chronic abuse of ephedrine may cause dilated left ventricular hypertrophy with impaired systolic function without evidence of myocardial infarction or fibrosis.[55] Hyperventilation may occur via direct bronchial adrenergic receptor stimulation, and via indirect response to increased cardiac output induced by ephedrine.[56]

Patients with ephedrine intoxication may exhibit left ventricular hypertrophy and coronary artery disease in up to 33% of cases; however, ephedrine deaths are commonly associated with chronic stimulant abuse including the abuse of other drugs associated with coronary disease (e.g., cocaine). Heat stroke and rhabdomyolysis are uncommon findings in postmortem examinations of cases where postmortem blood samples contain detectable concentrations of ephedrine, when compared with amphetamine or methamphetamine abuse deaths.[57]

CLINICAL RESPONSE

Potential adverse effects associated with the use and abuse of ephedrine include mydriasis, nausea, vomiting, CNS hyperstimulation, headache, tremor, excess sweating, chest pain, tachycardia, palpitations, chest pain, hypertension, constipation, urinary retention, and euphoria.[58,59] Case reports associate ephedrine use and abuse with ischemic and hemorrhagic stroke,[60] intestinal ischemia,[61] and myocardial infarction,[62] frequently in patients with underlying disease (atherosclerosis, berry aneurysm).[63] Rare case reports associate ephedrine abuse with emergence of bipolar symptoms[64] and paranoid psychosis manifest by delusions, auditory hallucinations, and clear consciousness.[65] Some of these patients had predisposing factors (family history, abnormal premorbid personality, polydrug abuse); the role of ephedrine in these cases was not well defined. Potentially, abrupt cessation of high doses of ephedrine may cause fatigue, depression, and suppressed REM sleep; however, an abstinence syndrome following ephedrine abuse is not well defined. Fatalities following ephedrine abuse

may result from intracerebral hemorrhagic stroke, myocardial infarction, or cardiomyopathy.[63,66] These individuals often have underlying vascular disease along with polydrug abuse.[67] Consequently, the contribution of ephedrine abuse to these deaths is unclear.

DIAGNOSTIC TESTING

Methods for the quantitation of ephedrine in biologic samples include HPLC with UV detection,[68] HPLC with fluorometry and derivatization with 9-fluroenylmethyl chloroformate,[69] liquid chromatography/tandem mass spectrometry,[70] and GC/MS. The lower limit of quantitation (LLOQ) for ephedrine using HPLC with fluorometry is 2 ng/mL with a coefficient of variation in the range of 12% near the LLOQ. Ephedrine is stable in urine samples stored at 37°C (98.6°F) for 1 week and in refrigerated (4°C/39.2°F) and frozen (−20°C/-4°F), sterile urine samples for up to 2 years.[71] There was no significant loss of ephedrine in frozen samples undergoing 3 cycles of freezing and thawing to room temperature.

Dosing for weight control at 45–50 mg per day results in steady-state ephedrine concentrations of 95–135 ng/mL. The ingestion of 22 mg (−)-ephedrine hydrochloride by 10 hospital outpatients produced a mean peak plasma ephedrine concentration of 79.4 ng/mL (range, 52.7–138.8 ng/mL) compared with a mean peak plasma ephedrine concentration of 87.4 ng/mL (range, 44.0–118.6 ng/mL) following the ingestion of 11 mg 3 times daily for 2 weeks.[72] The mean peak plasma ephedrine concentration following the ingestion of 50 mg ephedrine by 16 healthy volunteers was 137.8 ± 33.1 ng/mL (range, 80.2–206.9 ng/mL).[45] After ingesting over twice the daily recommended dose of a combination tablet containing ~10 mg ephedrine and 100 mg caffeine for 2 days, a 22-year-old woman developed palpitations, nausea, tremulousness, abdominal pain, vomiting, S-T segment depression, and inverted T-waves.[73] The serum ephedrine concentration ~8 hours after the last dose was 150 ng/mL; the serum caffeine concentration was not reported. She was discharged after 2 days without sequelae. The postmortem blood ephedrine concentrations in a series of nontrauma-related fatalities ranged from 20–12,350 ng/mL with a blood ephedrine concentration below 490 ng/mL in 50% of the cases.[67] A majority of these decedents also tested positive for other drugs (e.g., cocaine, opiates); therefore, the role of ephedrine in these deaths is difficult to determine. Associated morbidities included left ventricular hypertrophy with coronary artery disease (33%), hepatic steatosis (21%), and nephrosclerosis (17%). Limited postmortem data suggest that ephedrine does not undergo significant postmortem redistribution.[74]

TREATMENT

The treatment of ephedrine intoxication is similar to the treatment of phenylpropanolamine toxicity.

PHENDIMETRAZINE

IDENTIFYING CHARACTERISTICS

Phendimetrazine is 3,4-dimethyl-2-phenylmorpholine (CAS RN: 634-03-7, $C_{12}H_{17}NO$) as displayed in Figure 13.3; the salt, phendimetrazine tartrate is the active ingredient of Adipost, Bontril, Obezine, Plegine, Prelu-2, Statobex, and Obex-LA (South Africa). The latter product is a sustained release preparation (105 mg *d*-phendimetrazine bitartrate). Under microscopic analysis, phendimetrazine appears as thin, square plates to square prismatic forms.[5] Phendimetrazine exists as *d*- and *l*-diastereoisomers.[75] Table 13.2 lists some physiochemical properties of phendimetrazine.

EXPOSURE

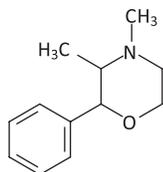
Phendimetrazine is a synthetic amphetamine derivative. Both phendimetrazine and phenmetrazine were introduced in the 1950s as sympathomimetic weight-control medications inducing less euphoria, insomnia, and tachycardia than other amphetamine derivatives; however, the current use of phendimetrazine is infrequent. The abuse of phendimetrazine is also uncommon, even among drug abusers.[76] Phendimetrazine is avail-


FIGURE 13.3. Chemical structure of phendimetrazine.

TABLE 13.2. Some Physiochemical Properties of Phendimetrazine.

Physical Property	Value
Molecular weight	
Phendimetrazine	191.2694 g/mol
Phendimetrazine tartrate	341.3563 g/mol
log P (Octanol-Water)	1.700

able in the United States as a DEA schedule III drug in both tablet and capsule forms.

DOSE EFFECT

Typical doses of phendimetrazine for the short-term treatment of obesity are 35 mg tablets or capsules 3 times per day or 105 mg sustained-release tablets.

TOXICOKINETICS

Peak serum phendimetrazine concentrations occur ~1 hour after the ingestion of immediate-release preparations and 1–2 hours after the ingestion of sustained release preparation.[77] Phendimetrazine undergoes extensive biotransformation including *N*-demethylation to phenmetrazine[78] as well as the formation of *N*-hydroxyphenmetrazine and the *N*-oxide of phendimetrazine.[79] The kidney excretes only ~10–30% of the phendimetrazine dose as unchanged drug.[78,79] The approximate plasma half-life of immediate-release phendimetrazine is approximately 2 hours, whereas the plasma half-life of the sustained-release preparation is ~9 hours.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Phendimetrazine is an indirect-acting sympathomimetic drug that causes mild CNS stimulation and blood pressure elevation, similar to other noradrenergic appetite suppressants. Therapeutic doses of phendimetrazine cause early satiety and decreased appetite.

CLINICAL RESPONSE

Phendimetrazine and phenmetrazine are associated with similar physiologic and psychological effects, similar to other noradrenergic appetite suppressants including anxiety, agitation, nervousness, paranoia, psychosis, and hallucinations. A case report associates the use of phendimetrazine, phentermine, and an unknown "thyroid" medication over 3 days with the development of diffuse peripheral arterial spasm that responded to nifedipine.[80] The patient remained asymptomatic 6 months later with no further use of these medications. Rare case reports associate chronic phendimetrazine use with dilated cardiomyopathy that resolved with cessation of phendimetrazine use[81] and acute interstitial nephritis (in combination with phentermine) that also resolved following cessation of these 2 drugs.[82] Rare case reports associate therapeutic use and abuse of phendimetrazine with rhabdomyolysis. A 23-year-old woman developed nausea, vomiting, chest pain, myal-

gias, and dark urine after ingesting 75 mg phendimetrazine daily for 3 days.[83] Her serum creatine phosphokinase (now creatine kinase, CK) peaked at 7,224 U/L on the second hospital day; her kidney function remained normal and she was discharged on the fifth hospital day without sequelae.

DIAGNOSTIC TESTING

Analytic methods for the quantitation of phendimetrazine in biologic samples include thin layer chromatography, gas chromatography with flame ionization detection[84] or nitrogen phosphorous detection,[85] and GC/MS with acetic acid derivation.[86] Phendimetrazine does not concentrate in erythrocytes; therefore, whole blood and serum concentrations of phendimetrazine are similar. Peak serum phendimetrazine concentrations following therapeutic doses of phendimetrazine range from ~0.05–0.24 mg/L, whereas peak serum phendimetrazine concentrations associated with the ingestion of 35 mg immediate-release phendimetrazine range up to 0.09–0.10 mg/L.[77,87] A 21-year-old man collapsed while working at a restaurant; resuscitation at the workplace and the hospital was unsuccessful.[86] Postmortem blood (site unspecified) contained 0.3 mg phendimetrazine/L as measured by gas chromatography/flame ionization detection. A 38-year-old man was found dead 4 days after disappearing during a desert race.[88] His postmortem blood contained 0.67 mg phendimetrazine/L; no other drugs were detected as measured by gas chromatography/flame ionization detection.

TREATMENT

The treatment of phendimetrazine toxicity is supportive, similar to phenylpropanolamine intoxication.

PHENMETRAZINE

IDENTIFYING CHARACTERISTICS

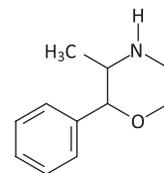
Phenmetrazine is a synthetic morpholine amphetamine derivative (3-methyl-2-phenylmorpholine, CAS RN: 134-49-6). Figure 13.4 displays the chemical structure of phenmetrazine ($C_{11}H_{15}NO$). Phenmetrazine hydrochloride was the active ingredient of Preludin. Under microscopic analysis, phenmetrazine is an elongated lath-like crystal in stellate arrangement.[5] Table 13.3 lists some physiochemical properties of phenmetrazine.


FIGURE 13.4. Chemical structure of phenmetrazine.

TABLE 13.3. Some Physiochemical Properties of Phenmetrazine.

Physical Property	Value
Molecular Weight	
Phenmetrazine	177.2429 g/mol
Phenmetrazine hydrochloride	213.7038 g/mol
log P (Octanol-Water)	1.490

EXPOSURE

Phenmetrazine was introduced in the 1950s along with phendimetrazine as sympathomimetic weight-control medications with less euphoria, insomnia, and tachycardia than other amphetamine anorexiants;[89] however, phenmetrazine was subsequently classified as a schedule II drug in 1971 as a result of reports of psychotic reactions and high addiction potential. Methods of phenmetrazine abuse involve both oral and IV administration. Phenmetrazine remained a popular drug of abuse during the 1970s that replaced amphetamine as a stimulant in some IV polydrug users.[90] This drug was a substitute for cocaine and amphetamine in heroin abusers; after dissolution of phenmetrazine in water, the solution was used to "cook" the heroin prior to injection. The use of phenmetrazine as a primary drug of abuse is uncommon.[91] Eventually, phenmetrazine was withdrawal from the US market.

DOSE EFFECT

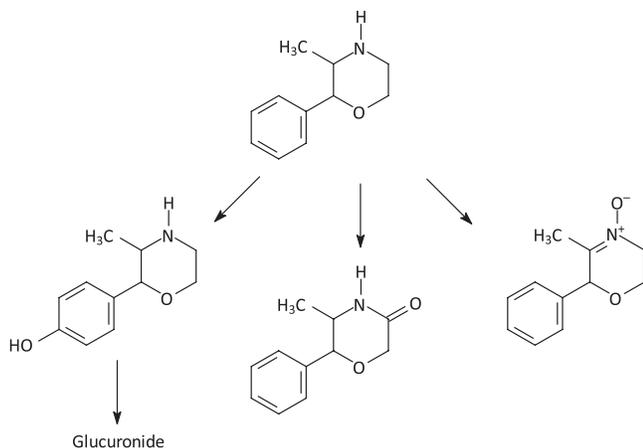
The recommended therapeutic dose of phenmetrazine is 25 mg 3 times daily. The lethal dose of phenmetrazine is not well defined; the LD_{50} is 15–20 mg/kg for adult monkeys and ~5 mg/kg for young monkeys. The chronic abuse of 750–900 mg daily was associated with the development of acute paranoid psychosis that resolved with hospitalization and chlorpromazine therapy.[92]


FIGURE 13.5. Biotransformation of phenmetrazine.

TOXICOKINETICS

Phenmetrazine is well absorbed by the GI tract with immediate- and sustained-release preparations reaching peak concentrations within ~2 hours and 5 hours, respectively.[93] This drug undergoes *p*-hydroxylation followed by glucuronide conjugation and oxidation via CYP3A and CYP2D6 to lactam metabolites [5-methyl-3-oxo-6-phenylmorpholine, 3-methyl-2-(4'-hydroxyphenyl)morpholine]. Figure 13.5 displays the biotransformation of phenmetrazine. In a study of urine samples from volunteers receiving 25 mg [^{14}C] phenmetrazine hydrochloride, lactam metabolites accounted for a mean 19% (range, 17–21%) and the total (free plus conjugated) *p*-hydroxylated metabolite accounted for a mean 22% (range, 16–26%) of the administered dose within the first 24 hours.[94] *N*-hydroxyphenmetrazine nitrone (5–7%) was a minor metabolite. The kidney excreted a mean 19% (range, 11–25%) as unchanged phenmetrazine during the first 24 hours. Over 72 hours, a mean of 92% (range, 85–100%) of the administered dose appeared in the urine. There is substantial intraspecies variation in phenmetrazine biotransformation, similar to amphetamine and methamphetamine. The plasma elimination half-life of phenmetrazine following ingestion of single therapeutic doses of immediate release phenmetrazine is ~8 hours.[93]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Phenmetrazine primarily blocks the reuptake of dopamine and to a lesser extent, norepinephrine into presynaptic adrenergic nerve cells; additionally, phenmetrazine inhibits monoamine oxidase, leading to an increased prevalence of synaptic catecholamines. Centrally, phenmetrazine exerts this effect on the tuberoinfundibular system, leading to appetite suppression.[95] Postmortem examination of fatal cases of phenmetrazine are nonspecific, common to individuals dying from drug abuse. Autopsy examination of a 17-year-old adolescent found dead with fresh track marks and only phenmetrazine in postmortem blood revealed pulmonary edema and aspiration of material deep into the bronchi.[96]

CLINICAL RESPONSE

Phenmetrazine is a CNS stimulant that produces clinical effects similar to other amphetamine-type appetite suppressants. Toxic effects associated with phenmetrazine abuse include stereotyped activity, agitation, anxiety, insomnia, anxiety, and restlessness. Case reports associate phenmetrazine abuse with a psychosis similar to amphetamine-induced psychosis and with the exacerbation of underlying schizophrenia with paranoid ideations. Clinical features include auditory hallucinations, labile affect, agitation, elation, delusions, ideas of reference, fear, and paranoia.[97] Typically, these psychotic symptoms occur following the ingestion of large doses of phenmetrazine (i.e., 10–30 tablets in the setting of continue abuse) and resolve within 1–2 days of abstinence.[98] Case reports associate the IV administration of phenmetrazine with fever, diaphoresis, diffuse myalgias, headache, GI distress, hypotension, rhabdomyolysis, and intravascular coagulation.[99] This clinical pattern simulates septic shock, but the blood cultures from these patients were negative. Fatalities associated with the abuse of phenmetrazine include patients with hyperthermia, agitation, and bizarre behavior (excited delirium-type clinical presentation), trauma/suicide, sudden death (i.e., found dead at home), and underlying cardiovascular disease.[100] Most of these fatalities involve polydrug abuse, primarily IV drug use.

DIAGNOSTIC TESTING

Analytic methods for the quantitation of phenmetrazine in biologic samples include gas chromatography with electron capture detection,[101] gas chromatography/flame ionization detection,[94,102] gas chromatography/mass spectrometry (GC/MS) with derivatization involving 2,2,2-trichloroethyl chloroformate or isooctane and methyl chloroformate,[103,104] and GC/MS with selected ion monitoring, chemical ionization, and 4-carbethoxyhexafluorobutyryl chloride derivatization.[105] The LOD for phenmetrazine in urine samples using the latter method is 0.2 mg/L with between-run precision of ~3%. The LLOQ for the latter method in urine samples is

0.05 mg/L with an intraday coefficient of variation <9%. Ephedrine may interfere with the quantitation of phenmetrazine by GC/MS during the derivation process as a result of the reaction of ephedrine and formaldehyde under high-temperature injection.[106] The use of gas chromatography/flame ionization detection and GC with electron capture detection allows comparison of seized drugs for the determination of common sources of illicit phenmetrazine samples.[107] Phenmetrazine cross-reacts with urinary amphetamine immunoassays (e.g., EMIT) only at high phenmetrazine concentrations (e.g., >6 mg/L).[108]

The therapeutic plasma phenmetrazine concentrations range from 0.07–0.13 mg/L; the mean plasma phenmetrazine concentration following ingestion of a single 75 mg phenmetrazine tablet was approximately 0.13 mg/L as measured by radioimmunoassay (tritiated acetic anhydride).[93] In a convenience series of 7 arrested drivers (car theft, drug addiction), the blood phenmetrazine concentrations ranged from 0.2–4 mg/L as measured by GC/MS.[103] Most of these drivers failed field sobriety tests. Postmortem blood from a 17-year-old adolescent found dead with fresh track marks contained a phenmetrazine concentration of 4 mg/L, whereas a liver sample contained 5 mg/L as measured by GC/MS.[96] No other drugs were detected in the postmortem blood. A 29-year-old woman was found dead at her home with evidence of recent IV drug abuse; the postmortem blood (site not reported) contained 16 mg phenmetrazine/L and no other detectable drugs.[100] A 25-year-old man developed hyperthermia, tachycardia, hypotension, and paranoid psychosis after the IV injection of phenmetrazine.[100] He died 3 hours after admission to the hospital; postmortem blood contained 5 mg phenmetrazine/L and no other detectable drugs as measured by GC/MS.

TREATMENT

The treatment of phenmetrazine toxicity is supportive with initial attention directed toward assessment and stabilization of respiration, circulation (myocardial ischemia, hypotension), and temperature, similar to phenylpropanolamine intoxication. Seriously intoxicated IV phenmetrazine abusers may develop hypotension, hyperthermia, agitation, and disseminated intravascular coagulation. The presence of hyperthermia (i.e., core body temperature >40°C/104°F) requires aggressive treatment of agitation with benzodiazepines and evaporative cooling measures. Treatment of hypotension includes IV saline and vasopressor infusions (e.g., dopamine) for patient unresponsive to fluid therapy. Patients unresponsive to dopamine may respond to α-receptor agonists (e.g., norepinephrine).

PHENTERMINE

IDENTIFYING CHARACTERISTICS

Phentermine (CAS RN: 122-09-8) is an α-methyl amphetamine derivative (1,1-dimethyl-2-phenylethylamine, $C_{10}H_{15}N$). Figure 13.6 displays the chemical structure of phentermine. Trade names for this compound include Adipex-P (phentermine hydrochloride, 37.5 mg), Ionamin (15 mg and 30 mg phentermine as the cationic exchange resin complex), and Omnibex. Table 13.4 lists some physiochemical properties of phentermine.

EXPOSURE

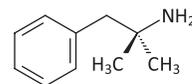
Phentermine is a sympathomimetic amine approved by the FDA in 1959 for short-term weight loss in combination with diet and exercise. Phentermine and fenfluramine were part of the popular off-label anorexiant, Fen-Phen until 1997, when the FDA banned fenfluramine because of the association of this combination with cardiac valvular disease. Phentermine remains on the US market for the treatment of obesity as a single agent and as combination capsule with fluoxetine.[109] Phentermine is available as a sustained-release resin complex (37.5 mg) and immediate release capsules (15 mg, 30 mg) under DEA schedule IV. In a meta-analysis of 9 randomized clinical trials of phentermine and weight loss, the mean weight loss of obese patients receiving 15–30 mg daily for 2–24 weeks was 3.6 kg


FIGURE 13.6. Chemical structure of phentermine.

TABLE 13.4. Some Physiochemical Properties of Phentermine.

log P (Octanol-Water)	1.9
Water Solubility	1.86E + 04 mg/L (25°C/77°F)
Vapor Pressure	0.096 mm Hg (25°C/77°F)

241

(95% CI: 0.6–6.0 kg) when compared with placebo (life-style modification only).[110]

DOSE EFFECT

The therapeutic dose of phentermine base is 15–30 mg daily. The ingestion of approximately 560 mg phentermine over 8 hours was associated with pressured speech, tactile and visual hallucinations, and refractory seizures; she recovered without sequelae after treatment with benzodiazepines (diazepam, lorazepam), fosphenytoin, propofol infusion, and supportive care in the intensive care unit.[111]

TOXICOKINETICS

When ingested as a sustained release resin, peak phentermine concentrations occur within ~8 hours. Phentermine undergoes minimal p-hydroxylation, N-oxidation, and N-hydroxylation, followed by conjugation.[112] The approximate volume of distribution of phentermine is approximately 3–4 hours. The plasma half-life of phentermine in the resin complexes of pharmaceutic preparations ranges from ~19–24 hours; however, in a study of 5 adults receiving phentermine in an aqueous solution with urine pH <5, the plasma elimination half-life was approximately 7–8 hours. Within the first 24 hours, the kidney excreted 71.7–83.6% of the phentermine dose unchanged with 0.7% p-hydroxylated conjugates, and 5% N-hydroxylated and N-oxidized conjugates.[112]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Phentermine is a weak sympathomimetic amine that induces appetite suppression similar to diethylpropion by increasing norepinephrine release and inhibiting uptake, resulting in increased sympathetic activity. Phentermine is also a weak monoamine oxidase (MAO) inhibitor that typically does not produce significant MAO activity at therapeutic doses. In rat brain tissue, the IC_{50} of phentermine for MAO_A and MAO_B was 143 μM and 285 μM, respectively, compared with 2 nM and 18 nM, respectively, for the potent MAO inhibitor, harmaline.[113]

CLINICAL RESPONSE

Adverse effects associated with the therapeutic use of phentermine for obesity include headache, irritability, anxiety, insomnia, palpitations, hypertension, depression, and breathlessness.[114] Several case reports associate high doses of phentermine (60–90 mg daily) with the

restlessness, irritability, pressured speech with flight of ideas, paranoid delusions, and auditory hallucinations with clear consciousness. Predisposing factors include a strong family history of affective disorder.[115] Repeat dosing of phentermine against medical advice resulted in the recurrence of the psychosis.[116] A 37-year-old woman developed the subacute onset of severe left parieto-occipital headache along with left-sided facial and extremity numbness that resolved within 1 week.[117] She had recently begun the use of phentermine for weight loss; her cerebral magnetic resonance imaging (MRI) scan and conventional 4-vessel cerebral angiography were normal 7 days after the onset of symptoms. A 48-year-old woman developed chest pain and a subsequent witnessed cardiac arrest (ventricular tachycardia/fibrillation) requiring defibrillation and intubation.[118] Her peak serum creatine phosphokinase (now creatine kinase or CK) and fraction were elevated at 716 U/L and 36.1 U/L, respectively; coronary angiography demonstrated a left ventricular ejection fraction of 35% with mild diffuse nonobstructive coronary artery disease. Her only medication was phentermine (dose not reported); 5 days after admission when the expected phentermine concentration would be nondetectable, the electrophysiology study demonstrated inducible sustained ventricular tachycardia. There were no reported plasma phentermine concentrations. Marked lethargy, syncope, QTc prolongation (512 msec), and polymorphic ventricular tachycardia developed in a 23-year-old woman who ingested illicit diet pills containing phentermine and chlorpheniramine based on a urine drug screen.[119] She was successfully treated with IV magnesium sulfate infusion and recovered without sequelae. No plasma phentermine concentrations were reported. Another case report associated the development of chest pain and subsequent ventricular fibrillation responsive to cardioversion in a moderately obese 37-year-old woman on phentermine, thyroid preparation, and trichlormethiazide.[120] Her cardiac workup was normal including coronary angiogram and electrophysiology testing with the exception of mild hypokalemia (2.9 meq/L). Case reports associate daily phentermine therapy with acute interstitial nephritis,[121] ruptured superior mesenteric artery aneurysm,[122] and peripheral vascular disease;[123] however, the role of phentermine in causing these diseases is unclear.

DIAGNOSTIC TESTING

Analytic Methods

Short retention times along with poor peak shape and resolution complicate analysis of small molecules (e.g., phentermine) with GC; consequently, most quantitative

methods include derivatization. Analytic methods for the quantitation of phentermine in biologic samples include gas chromatography/flame ionization detection and N-trifluoroacetamide derivatization,[124] gas chromatography with nitrogen phosphorus detection and amantadine as the internal standard,[125] GC/MS with N-trifluoroacetamide derivatization,[126] high performance liquid chromatography with fluorescence detection (excitation, 325 nm; emission, 430 nm),[127] ultra performance LC/MS,[128] and GC/MS using pentafluoropropionic anhydride derivatization and N-propylamphetamine as the internal standard.[129] The LOD for the latter method is 500 ng/mL, whereas the LOD and LLOQ for gas chromatography with nitrogen phosphorus detection is 5 ng/mL and 20 ng/mL, respectively (precision and accuracy <10%). Potential interference with the quantitation of phentermine may occur a as result of the partial co-elution of phentermine (1.72 min) and methamphetamine (1.81) at m/z 150 in polydrug samples; the use of an optimized gradient helps alleviate this problem.

Biomarkers

Following therapeutic doses of phentermine, the plasma phentermine concentration varies substantially between individuals. Plasma phentermine concentrations do not correlate well to weight loss or failure to lose weight in obese adults. In a 20-week study of obese adults receiving phentermine resinate, the mean steady-state plasma phentermine concentration in 13 adults with sustained weight loss was 203.0 ± 67.6 ng/mL compared with 212.9 ± 114.1 ng/mL in 11 adults without significant weight loss as measured by gas chromatography with nitrogen specific detection (LOD, 2 ng/mL).[114] Headache and palpitations developed in a 25-year-old woman ingesting 60 mg phentermine daily during this study. She withdrew from the study when her steady-state plasma phentermine concentration was 381 ng/mL. In a study of 21 healthy adults receiving 30 mg phentermine hydrochloride (24.1 mg base) daily for 14 days, the mean peak plasma phentermine concentration on day 14 was 116 ± 31.7 ng/mL (range, 65.3–192.0 ng/mL) compared with 142 ± 40 ng/mL (range, 65.7–234 ng/mL) for the ingestion of the 30 mg phentermine base.[130] Phentermine fatalities were associated with postmortem phentermine concentrations of 1,500 ng/mL and 7,600 ng/mL; the latter case involved a 32-year-old man found dead with also 12 mg ethchlorvynol/L and 10 mg amobarbital/L (toxic concentration) as measured by gas chromatography with nitrogen phosphorus detection.[131] Limited postmortem data suggests that phentermine undergoes postmortem redistribution. The central/peripheral blood phentermine ratio from 1 postmortem case was 1.7:1.[74]

TREATMENT

The treatment of phentermine toxicity is supportive, similar to phenylpropanolamine intoxication.

PHENYL-PROPANOLAMINE

IDENTIFYING CHARACTERISTICS

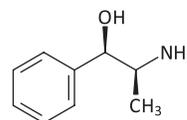
Phenylpropanolamine (CAS RN: 14838-15-4) is the β-hydroxylated amphetamine, 1-alpha-(1-aminoethyl) benzyl alcohol (norephedrine). This weakly basic compound is an indirect-acting sympathomimetic amine that is structurally related to ephedrine. Figure 13.7 displays the chemical structure of l-phenylpropanolamine [(−)-norephedrine, $C_9H_{13}NO$]. This structure has 4 potential stereoisomers with phenylpropanolamine comprising the enantiomeric forms, d-phenylpropanolamine and l-phenylpropanolamine. The other 2 potential stereoisomers are the enantiomeric forms of the diastereoisomer norpseudoephedrine. Table 13.5 lists some physiochemical properties of phenylpropanolamine. Pharmaceutic preparations contain a racemic mixture of phenylpropanolamine hydrochloride (CAS


FIGURE 13.7. Chemical structure of phenylpropanolamine.

TABLE 13.5. Some Physiochemical Properties of Phenylpropanolamine.

Physical Property	Value
Molecular Weight	
Phenylpropanolamine	151.2056 g/mol
Phenylpropanolamine hydrochloride	187.6665 g/mol
pKa Dissociation Constant	9.44 (20°C/68°F)
log P (Octanol-Water)	0.67
Water Solubility	1.49E+05 mg/L (25°C/77°F)
Vapor Pressure	8.67E-04 mm Hg (25°C/77°F)

RN: 154-41-6). The melting point of phenylpropanolamine hydrochloride is 194°C (381.2°F). Most of the sympathomimetic activity of the racemic mixture resides in the *l*-enantiomer.

EXPOSURE

The medical uses of phenylpropanolamine included the treatment of nasal congestion, priapism, and control of urinary incontinence. Phenylpropanolamine was a popular OTC treatment for upper respiratory tract symptoms and for weight loss (e.g., Acutrim®, J.B. Laboratories, Holland, MI; Dexatrim®, Chattem, Inc., Chattanooga, TN; Prolamine™, Super Odrinex™) in combination with exercise and dietary restriction. The latter preparations frequently contained ephedrine and/ or caffeine in addition to phenylpropanolamine. In 2000, the FDA requested drug companies to discontinue all OTC phenylpropanolamine-containing products as a result of studies demonstrating an increased risk of hemorrhagic stroke in women using phenylpropanolamine for weight-control.[132] Phenylpropanolamine analogs are present in certain plants; however, medicinal phenylpropanolamine is manufactured synthetically.[133]

DOSE EFFECT

The recommended daily dose of phenylpropanolamine for weight loss is 25–75 mg immediate-release or 75 mg sustained-release capsules up to a daily maximum of 150 mg. In volunteer studies, the administration of therapeutic doses of phenylpropanolamine (e.g., 75 mg sustained release) does not cause euphoria or stimulant activity.[134] Cardiovascular and CNS complications following the use and abuse of phenylpropanolamine are rare events in comparison to the large number of individuals exposed to phenylpropanolamine. These adverse events are not clearly dose-related as these events occur following therapeutic use, abuse, and overdose. A majority of hemorrhagic strokes in 2 case-control studies of phenylpropanolamine in appetite suppressants and OTC preparations involved the use of daily phenylpropanolamine doses ≤ 75 mg, suggesting that many of these complications are idiosyncratic events in susceptible patients.[135,136] In a case series of 16 strokes associated with the use of phenylpropanolamine, the phenylpropanolamine dose ranged from 75–675 mg.[137] In this case series, a 19-year-old woman developed a right frontal hemorrhage after intentionally ingesting 675 mg phenylpropanolamine. She had uncontrolled hypertension on admission (180/110); moderate disability remained after discharge from the hospital. Most patients in this case series ingested phenylpropanol-

amine in combination with other decongestants for 1 to several days prior to the onset of symptoms. The average therapeutic dose of phenylpropanolamine produces a small, but statistically significant increase in systolic blood pressure that is more prominent with higher doses, shorter administration, and immediate release formulations.[138,139] In a meta-analysis of 33 clinical trials involving 2,165 patients, the average increase in systolic blood pressure was 5.5 mm Hg (95% CI: 3.1–8.0), whereas the diastolic blood pressure increased an average of 4.1 mm Hg (95% CI: 2.2–6.0) with no effect on heart rate. The phenylpropanolamine doses ranged from 25–150 mg with the high-dose studies (n = 7) demonstrating higher posttreatment changes in systolic (mean pooled difference, 9.46 mm Hg; 95% CI: −19.17–38.09) and diastolic (mean pooled difference, 6.54 mm Hg; 95% CI: −14.27–27.35) blood pressures than pooled values of the 33 trials as a whole.

TOXICOKINETICS

Absorption

The GI absorption of phenylpropanolamine is relatively good. In a study of 24 healthy male volunteers receiving a single dose of 25 mg phenylpropanolamine as a syrup, the mean calculated absolute bioavailability was $61.9 \pm 6.5\%$ (range, 49.1–73.2%).[140]

Distribution

In a study of 24 healthy male volunteers receiving a single dose of 25 mg phenylpropanolamine as a syrup, the mean steady-state volume of distribution was approximately 1.7 L/kg (range, 1.5–2.2 L/kg). The mean volume of distribution following the administration of a single 25 mg phenylpropanolamine solution to 5 healthy volunteers was 3.26 ± 0.75 L/kg compared with a steady-state volume of distribution of 4.08 ± 0.91 L/kg following the ingestion of a 25-mg phenylpropanolamine solution every 4 hours for 7 doses.[141]

Biotransformation

Phenylpropanolamine undergoes minimal *p*-hydroxylation and conjugation in the liver with approximately 4% of the dose excreted as urinary metabolites of phenylpropanolamine.

Elimination

The kidney excretes most of the absorbed dose of phenylpropanolamine as unchanged drug. In a study of 16

healthy volunteers receiving 6 doses of 25 mg phenyl-propanolamine over 36 hours, the mean total urinary phenylpropanolamine excretion within 36 hours after the last dose was 75%.[142] The mean maximum phenyl-propanolamine concentration in urine samples (mean urine pH = 6.3 ± 0.3) was 112 ± 50 mg/L 4 hours after the last dose. Urinary alkalinization decreases the urinary clearance of phenylpropanolamine and increases the plasma phenylpropanolamine elimination half-life. Alkalization of the urine (mean pH ~7.5) in 4 healthy male volunteers resulted in an approximate mean reduction of the urinary phenylpropanolamine clearance of ~33%, when compared with placebo (no sodium bicarbonate).[143]

The serum half-life of phenylpropanolamine is ~3–4 hours. In a study of 5 healthy volunteers receiving single doses of 25 mg and 100 mg phenylpropanolamine, the mean serum half-lives were 3.8 hours and 4.3 hours, respectively.[141] Following alkalization in the above study, the mean plasma phenylpropanolamine half-life increased from 4.03 ± 0.41 hours to 5.39 ± 0.34 hours.

Tolerance

There are few data on the issue of tolerance following the chronic use of phenylpropanolamine. Animal studies suggest that short term use (<2 weeks) of phenylpropanolamine does not reduce the weight loss associated with the administration of 20 mg *d,l*-phenylpropanolamine as measured by interscapular brown adipose tissue thermogenesis in adult male Sprague-Dawley rats.[144]

Drug Interactions

Case reports associate the ingestion of phenylpropanol-amine by patients on monoamine oxidase inhibitors (MAOIs) with the development of hypertensive crisis similar to the association with structurally similar drugs (phenylephrine, pseudoephedrine). Adverse effects in these case reports include malignant hypertension, headache, fever, and intracranial hemorrhage.[145] The use of other drugs (e.g., meperidine) associated with hyper-tensive crises and MAOIs complicate the determination of causality in some of these cases.[146] The concomitant ingestion of caffeine and phenylpropanolamine may increase blood pressure more than the ingestion of the same dose of phenylpropanolamine alone; however, the effect is relatively small and the clinical significance of this difference is unclear on a population basis.[139] Case reports associate severe hypertension in a 27-year-old woman ingesting indomethacin while receiving 85 mg *d*-phenylpropanolamine daily for several months[147] and in a 31-year-old man ingesting 75 mg phenylpropanol-

amine daily for 2 days while treated with methyldopa and oxprenolol for hypertension.[148] In the former case, rechallenge reproduced the same blood pressure eleva-tions associated with indomethacin. Both these patients had headaches, but neither patient had clinically signifi-cant end organ dysfunction.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Phenylpropanolamine is a prominent peripheral and weak CNS adrenergic stimulant. Phenylpropanolamine enhances the release of norepinephrine, resulting in the direct stimulation of α-adrenergic receptors. Although phenylpropanolamine also has some α_2-adrenergic activity, rodent studies indicate that the anorectic effects of phenylpropanolamine result primarily from the stim-ulation of α_1-adrenergic receptors in the paraventricular hypothalamus.[149,150] Animal studies suggest that the ano-rectic effects of phenylpropanolamine differ from dex-troamphetamine, which stimulates dopaminergic and β-adrenergic receptors.[151] Although *in vitro* studies suggest that phenylpropanolamine has some dopami-nergic activity, this dopaminergic effect is substantially less potent than dextroamphetamine.[152] Rodent studies indicate that phenylpropanolamine causes little presynaptic release of serotonin.[153] Peripheral stimula-tion of α-adrenergic receptors produces vasoconstric-tion, reduces tissue hyperemia, edema, and nasal congestion, and increases nasal airway patency. Phenylpropanolamine blunts the release of synaptic norepinephrine associated with standing as a result of dose-dependent α_1-agonist, α_2-agonist, and indirect sympathomimetic effects.[149,154]

CLINICAL RESPONSE

Use/Abuse

Adverse effects associated with the use of phenylpropa-nolamine include severe headache, hypertension, intra-cranial hemorrhage, and rarely fatal strokes.[155] Most of these cases involve women under 30 years of age ingest-ing therapeutic doses of phenylpropanolamine, often in combination with other drugs (e.g., caffeine, antihista-mines). Cutaneous reactions include fixed drug eruptions.[156]

Mental Disorders

Psychiatric manifestations associated with the therapeutic use of phenylpropanolamine include mania, paranoid schizophrenia, hallucinations, paranoid delusions, depres-sion, agitation, and anxiety.[157,158] Frequently, these patients

ingest several additional medications and have previous histories of mood disorders or family histories of psychosis. In several patients, recurrent psychotic symptoms developed following rechallenge with phenylpropanolamine.[159] No single set of symptoms describes the psychiatric abnormalities associated with phenylpropanolamine use is these case series; furthermore, these abnormalities appear idiopathic as the dose of phenylpropanolamine ranges from therapeutic doses to large overdoses.

Medical Complications

CENTRAL NERVOUS SYSTEM

Case reports associate the use and abuse of both diet pills and OTC cough and cold preparations containing phenylpropanolamine in the preceding 24 hours with the development of intracranial hemorrhages.[160,161] About one-third of these cases involve supratherapeutic doses of phenylpropanolamine. The vast majority of these intracranial lesions are hemorrhagic strokes with and without evidence of vasculitis; only rarely are these strokes ischemic. The presence of cerebral aneurysm, tumor, or arteriovenous malformation increases the risk of hemorrhage stroke following the use of phenylpropanolamine. Most of the hemorrhage strokes are intracerebral; occasionally, subarachnoid hemorrhages occur. In a case series of 15 strokes associated with the use of phenylpropanolamine as a cough and cold preparation, there were 12 cases of intracerebral hemorrhage, 2 cases of subarachnoid hemorrhage, and 1 case of mild subarachnoid combined with a small fronto-orbital hemorrhage.[137] Most, but not all patients presented with hypertension. None of these cases involved the use of phenylpropanolamine as an appetite suppressant.

The Hemorrhagic Stroke Project was a case-control study of 702 patients with subarachnoid or intracerebral hemorrhage within 30 days before enrollment that demonstrated an increased risk of hemorrhagic stroke in women using appetite suppressants containing phenylpropanolamine.[135] For women using appetite suppressants containing phenylpropanolamine with 3 days of developing symptoms of a stroke, the adjusted odd ratio was 16.58 (95% CI: 1.51–182.21; $P = .02$). Although this study suggested that the use of phenylpropanolamine-containing OTC cough and cold preparations also were associated with an increased risk of stroke (adjusted OR = 3.13, 95% CI: 0.86–11.46) this association was not statistically significant ($P = .06$); there was no association of stroke and phenylpropanolamine use in men. Subsequent discovery suggests that chance, recall, selection bias, and confounding may contribute to the positive findings in this study.[162] A Mexican case-control study of 177 patients with intracranial hemorrhage and no structural intracranial lesions did not confirm the Hemorrhagic Stroke Project when comparing each case with 3–4 controls matched for age, sex, and place of residence.[163] The OR was 0.95 (95% CI: 0.68–1.34, $P = .77$).

CARDIOVASCULAR SYSTEM

Phenylpropanolamine may increase blood pressure depending on dose and individual sensitivity. In a study of 37 healthy young adults receiving a single dose of 85 mg phenylpropanolamine, 12 participants developed supine diastolic blood pressures exceeding 100 mm Hg in comparison to 4 of 34 participants receiving 50 mg phenylpropanolamine.[164] Although higher phenylpropanolamine doses are associated with higher blood pressure, experimental studies suggest that the serum phenylpropanolamine concentration does not correlate directly to systolic or diastolic blood pressure.[165] Furthermore, adverse effects associated with these blood pressure changes are typically mild.

Myocardial injury following the use or abuse of phenylpropanolamine is rare. Case reports associate both the ingestion of single therapeutic (50 mg) and overdoses (2 g with 8 g caffeine) with severe hypertension, ST-T wave depression, and mildly elevated CK-MB fractions; symptoms included headache, dyspnea, nausea, blurred vision, and chest pain.[166,167] The M-mode and 2-dimensional echocardiography along with technetium pyrophosphate cardiac scintigraphic scanning were normal; all symptoms and the electrocardiographic abnormalities resolved within 36–48 hours. Coronary angiography may be normal; cardiac isoenzymes elevations are typically mild and return to normal values within a few days.[168] The use of phenylpropanolamine as an appetite suppressant is not clearly associated with pulmonary hypertension or cardiac valvular disease. Associated findings include ventricular extrasystoles, ventricular tachycardia, and tingling in the extremities.[149]

DIAGNOSTIC TESTING

Analytic Methods

Techniques for the quantitation of phenylpropanolamine in biologic fluids include gas chromatography with nitrogen specific detection[169] or electron capture detector,[170] capillary GC with trifluoroacetic anhydride derivatization and electron capture detection,[171] radioenzymatic assay,[172] HPLC with ultraviolet detection (220 nm)[173] and (205 nm),[174] high performance liquid chromatography with postcolumn fluorescent derivatization,[175] liquid chromatography with fluorescence

detection,[176] high performance liquid chromatography/ atmospheric pressure chemical ionization/mass spectrometry,[177] and GC/MS. High performance liquid chromatography with the use of the chiral derivatizing agent, 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl isothiocyanate to form diastereomeric thiourea derivatives followed by reverse-phase chromatography and UV detection (254 nm) allows the quantitation of the enantiomers of phenylpropanolamine in plasma.[178] The LLOQ for this method is 10 ng/mL with an interday coefficient of variation <5%. The LLOQ with high pressure liquid chromatography is 4 ng/mL with an interday coefficient of variation below 15%. The LOD for HPLC with UV detection (205 nm) in plasma is 0.4 ng/mL, whereas the LOD for liquid chromatography/ atmospheric pressure chemical ionization/mass spectrometry is ~1 ng/mL. High performance liquid chromatography with UV detection at 220 nm is less sensitive with a LOD for phenylpropanolamine in serum samples of ~ 25 ng/mL.

Biomarkers

The mean peak serum phenylpropanolamine concentration following the ingestion of a single 100 mg phenylpropanolamine solution was approximately 397 ng/mL (range, 310–480 ng/mL).[141] Figure 13.8 displays the time course of serum phenylpropanolamine concentrations following the administration of a syrup containing 25 mg, 50 mg, or 100 mg phenylpropanolamine. In a study of 8 healthy male volunteers receiving a single dose of 100 mg phenylpropanolamine, the mean peak serum phenylpropanolamine concentration was 474 ± 176 ng/mL as measured by HPLC.[179] In a study of the effect of phenylpropanolamine on patients with neurogenic bladder dysfunction, the mean steady-state plasma phenylpropanolamine concentration in 4 patients receiving 100 mg daily was 263 ng/mL compared with 312 ng/mL in plasma samples from 5 patients receiving 200 mg daily.[180] The maximum plasma phenylpropanolamine (642 ng/mL) in this study was not associated with adverse effects.

Fatal phenylpropanolamine concentrations are not well defined because of the lack of documentation of postmortem blood concentrations in individuals dying as a result of phenylpropanolamine intoxication. Although case reports document postmortem concentrations ranging from 2,000–48,000 ng/mL,[181] the circumstances surrounding these deaths are not well described and the contribution of phenylpropanolamine to these deaths remains unclear. In a case series of 12 pediatric deaths with detectable phenylpropanolamine concentrations, the blood phenylpropanolamine concentration (site not reported) ranged from 40–840 ng/mL.[182] Phenylpropanolamine was not an official cause of death in any of these cases. In a study of postmortem redistribution, the mean heart/femoral whole blood ratio in 3 blood samples containing phenylpropanolamine was 2.4 (range, 0.8–4.6).[74]

Abnormalities

In a cases series of 12 patients undergoing cerebral angiography after developing intracranial lesions following the ingestion of phenylpropanolamine, 8 patients (67%) had evidence of vasculitis.[137] Four of these patients had follow-up cerebral digital subtraction angiography with complete resolution of the signs of vasculitis.

FIGURE 13.8. Serum phenylpropanolamine Concentrations following the administration of a syrup containing 25 mg, 50 mg, or 100 mg phenylpropanolamine. (From SS Scherzinger, R Dowse, I Kanfer, Journal of Clinical Pharmacology, Steady state pharmacokinetics and dose-proportionality of phenylpropanolamine in healthy subjects, Vol. 30 Issue 4, p. 373, copyright © 1990 SAGE Publications, Reprinted by permission of SAGE Publications.)

TREATMENT

Stabilization

The treatment of phenylpropanolamine toxicity is supportive with initial attention directed toward assessment and stabilization of respiration, circulation (myocardial ischemia, hypotension), and temperature. Agitation and combativeness may complicate the initial evaluation; rapid control of behavioral abnormalities may require benzodiazepines (Adult: lorazepam 1–2 mg IV or intramuscular [IM], or diazepam 2–5 mg IV); repeat doses

may be necessary. Continued agitation despite adequate benzodiazepine therapy may respond to the addition of butyrophenones (Adult: haloperidol 2–5 mg IV/IM or droperidol 1.25–5 mg IV/IM); butyrophenones should be used with caution in patients with elevated body temperature, QT_c prolongation, or seizures. Consequently, benzodiazepines are the drug of choice for sedation. Additional supportive measures as indicated by the clinical situation include IV fluid therapy, supplemental oxygen, electrocardiographic monitoring, monitoring of urine output, and intubation for respiratory failure. Catecholamine depletion may cause hypotension in severe phenylpropanolamine intoxication. Treatment of hypotension includes IV saline and vasopressor infusions (e.g., dopamine) for patients unresponsive to fluid therapy. Patients unresponsive to dopamine may respond to α-receptor agonists (e.g., norepinephrine). Patients with chest pain or dyspnea should be evaluated for myocardial ischemia (electrocardiogram, cardiac enzymes) and treated with nitroglycerin, aspirin, and morphine as indicated. Central nervous system depression may indicate the presence of intracerebral bleeding and the need for imaging studies of the brain.

Hyperthermia

The presence of hyperthermia (i.e., core body temperature >40°C/104°F) requires aggressive treatment of agitation with benzodiazepines and evaporative cooling measures. These measures involve spraying or sponging the patient with tepid water, accompanied by evaporation with an electric fan. Applying small ice packs to the axillae and groin may augment cooling. Intubation and chemical paralysis may be necessary in patients with severe agitation and persistent hyperthermia. Cooling blankets, antipyretics, ice baths, and alcohol baths are not typically effective for patients with core temperatures above 40°C/104°F. There are inadequate clinical data to determine of efficacy of dantrolene for the treatment of stimulant-induced hyperthermia. Patients with hyperthermia should be monitored with rectal or esophageal probes, if available.

Hypertension

Patients with phenylpropanolamine generally tolerate elevated blood pressures as long as there is no evidence of end organ failure. Severe, persistent hypertension should be treated with the IV administration of a short-acting antihypertensive agent (e.g., Adults: nitroprusside 0.3–10 μg/kg/min IV; nitroglycerin 5–100 μg/min IV titrated to effect). β-Adrenergic blockers should be used with caution because of the theoretical potential for unopposed α-adrenergic stimulation and worsening hypertension. The safest β-blockers in this situation are short-acting drugs (e.g., esmolol 500 μg/kg/minute IV bolus followed by 50 μg/kg/minute titrated to effect up to 500 μg/kg/min) and β-blockers with α-adrenergic blocking properties (e.g., labetalol 20 mg IV over 2 minutes, followed by 40 mg at 10-min intervals as needed). Marked sustained hypertension may respond to an α-blocking agent (e.g., Adult: phentolamine 1–10 mg IV).

Dysrhythmias

Sinus tachycardia is the most common dysrhythmia during phenylpropanolamine toxicity. Typically, the presence of sinus tachycardia without hemodynamic compromise does not require treatment other than benzodiazepines for sedation. Ventricular dysrhythmias are treated with standard therapeutic measures (amiodarone, lidocaine). The use of β-adrenergic blocking agents should be used with caution because of the potential of unopposed α-adrenergic stimulation and subsequent hypertension.

Gut Decontamination

Gut decontamination measures are unlikely to benefit patients presenting over 1 hour after the ingestion of phenylpropanolamine or patients using other routes of administration (injection, insufflation). Induction of emesis is contraindicated for phenylpropanolamine ingestion; there are inadequate data to recommend the use of gastric lavage following phenylpropanolamine ingestion. The administration of single-dose activated charcoal is a therapeutic option for patients presenting within 1 hour of ingestion, particularly for sustained-release products; however, there are limited clinical data to confirm the efficacy of this decontamination measure.

Elimination Enhancement

Although the urinary elimination of weakly basic drugs such as phenylpropanolamine increases in acidic urine, the risk of urine acidification in this setting outweighs the potential benefits. There are no data to support the use of forced diuresis or hemodialysis to enhance the renal elimination of phenylpropanolamine.

Antidotes

There are no specific antidotes to phenylpropanolamine intoxication.

Supplemental Care

Serum electrolytes, creatinine, blood urea nitrogen, CK, transaminases, and myoglobin should be monitored in

patients with serious phenylpropanolamine toxicity. Patients with hyperthermia should be monitored for the development of disseminated intravascular coagulation with complete blood count, coagulation studies, fibrinogen, and fibrin degradation products. Excessive muscle overactivity and hyperthermia may cause rhabdomyolysis, hyperkalemia, and renal dysfunction. Treatment of patients with rhabdomyolysis (i.e., serum CK >1,000–2,000 U/L) includes generous fluid replacement and correction of metabolic acidosis. Alkalinization of the urine to prevent the renal deposition of myoglobin and subsequent renal damage may reduce the renal clearance of phenylpropanolamine and similar phenethylamine compounds. Chronic abusers of dieting agents including phenylpropanolamine may require long-term treatment for psychosis, anxiety, or depression with antipsychotics and antidepressants. Treatment for addiction to phenylpropanolamine or similar drugs includes drug counseling, cognitive-behavioral therapy, and motivational interviewing.[183]

Chapter 14

SEROTONINERGIC and MIXED AGENTS

FENFLURAMINE WITH AND WITHOUT PHENTERMINE

HISTORY

Fenfluramine was developed in the early 1960s as an anorexic drug with less stimulating side effects than existing amphetamines. Beginning in France in 1963, fenfluramine and dexfenfluramine became a commonly prescribed appetite suppressants for the short-term treatment of obesity. Between 1963 and 1996, about 50 million European patients received dexfenfluramine or fenfluramine as an appetite suppressant.[1] The US Food and Drug Administration (FDA) approved the use of fenfluramine for the short-term treatment of obesity in 1973. In 1984, Weintraub and associates proposed the use of the combination fenfluramine and phentermine as a means to reduce the dose and adverse effects of these 2 drugs while maintaining weight loss from appetite suppression.[2] Between 1996 and 1998, approximately 5 million US patients used prescription appetite suppressants (i.e., fenfluramine, dexfenfluramine with or without phentermine) with a 4:1 ratio of women to men.[3] In the early 1990s, French investigators reported a cluster of 10 patients with primary pulmonary hypertension and a close temporal relationship between fenfluramine use and the development of exertional dyspnea.[4] Connolly et al published the first case series of 24 women (18 from Fargo, ND) with the development of valvular heart disease during the use of the combination of fenfluramine and phentermine for 1–28 months. Most of these patients had mitral regurgitation (92%) and aortic regurgitation (79%); 5 patients required valve replacement. On September 15, 1997, the manufacturers of fenfluramine and dexfenfluramine withdrew these medications from the US market.

IDENTIFYING CHARACTERISTICS

Fenfluramine is a trifluoromethyl derivative of amphetamine. Figure 14.1 compares the chemical structures of fenfluramine, phentermine, and amphetamine. The drug fenfluramine is a racemic mixture of the active dextro-isomer, dexfenfluramine and the inactive isomer, *l*-fenfluramine. Fenfluramine was marketed under the trade name of Pondimin.

EXPOSURE

Epidemiology

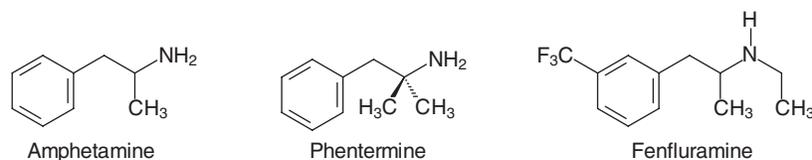
The use of appetite suppressants is common among the approximately 44% of women and 29% of men in the United States trying to lose weight.[5] Surveys of US adults suggest that up to one-third of adults that use prescription weight loss pills are not obese.[6] Additionally, up to one-third of adults continued using fenfluramine or dexfenfluramine after these drugs had been withdrawn from the US market. About 10% of the users of prescription appetite suppressants obtained these medications from illegitimate sources (e.g., friends, family).


FIGURE 14.1. Chemical structures of fenfluramine, phentermine, and amphetamine.

Sources

Fenfluramine is a serotonin-releasing drug that suppresses food intake centrally. The administration of fenfluramine and other appetite suppressants produces limited weight loss (i.e., average <10% baseline weight) with a plateau in weight loss occurring by 4–6 months.[7] Withdrawal of the drug typically results in return of the patient to the baseline weight; the administration of fenfluramine does not result in permanent reduction of appetite.

DOSE EFFECT

Illicit/Medical Use

Originally, fenfluramine was marketed as an antidepressant; fenfluramine dosages for the treatment of depression ranged up to 120 mg.[8] Subsequently, the use of fenfluramine primarily involved the treatment of obesity. Current clinical data suggests that the prevalence of valvular heart disease in patient receiving fenfluramine increases with increasing dose and duration of use. In a case series of 14 women undergoing valve replacement for valvular disease associated with anorexic agents, 13 women received a mean dose of 58.5 ± 22.3 mg fenfluramine and 32.1 ± 11.4 mg phentermine daily for an average of 12.1 ± 7.3 month prior to presentation.[9] None of these patients had echocardiograms prior to the initiation of fenfluramine-phentermine therapy. Although the combination of these 2 drugs allows the use of lower individual doses, the combination also enhances pulmonary vasoconstriction and valvular heart disease.[10] Clinical studies suggest that the prevalence of valvular regurgitation increases with duration of therapy; however, the relationships of dose and duration of fenfluramine use to the development of valvulopathy are not well defined because of the presence of confound variables in many studies. In a multicenter, controlled investigation of valvular heart disease in fenfluramine/phentermine users, the prevalence of aortic regurgitation (i.e., primarily mild aortic regurgitation) occurred only in the group of patients receiving

TABLE 14.1. Comparison of Adjusted Odds Ratios, *P* values, and Duration of Treatment in Study by Jollis JG et al. [12]

Duration of Treatment (Days)	Adjusted Odds Ratio	*P* Value
90–180	1.5	.23
180–360	2.4	.002
361–720	4.6	<.001
>720	6.2	<.001

this drug combination for >3 months.[11] The prevalence of moderate or severe mitral or aortic regurgitation was not statistically different in the fenfluramine/phentermine users and the control group (no fenfluramine/phentermine use in the last 5 years). In a study of 1,163 fenfluramine-phentermine users and 672 control patients (no fenfluramine/phentermine within 5 years), the adjusted odds ratio of mild or more severe aortic regurgitation compared with controls increased with duration of treatment as listed in Table 14.1.[12] Fenfluramine/phentermine-associated valvular disease primarily involved aortic regurgitation in patients receiving these drugs for over 6 months. The prevalence of moderate or severe mitral regurgitation was not statistically different between the 2 groups.

Many of the earlier reports on valvular heart disease and fenfluramine use involved the combination of fenfluramine and phentermine. In a single-center, retrospective cohort study designed to evaluate the prevalence of cardiovascular abnormalities in patients randomized to treatment with either fenfluramine alone or placebo, there was no increased risk of valvulopathy.[13] The duration of fenfluramine treatment was up to 3 months; the median posttreatment follow-up was 4.4 years (range, 4.1–4.9 years).

Toxicity

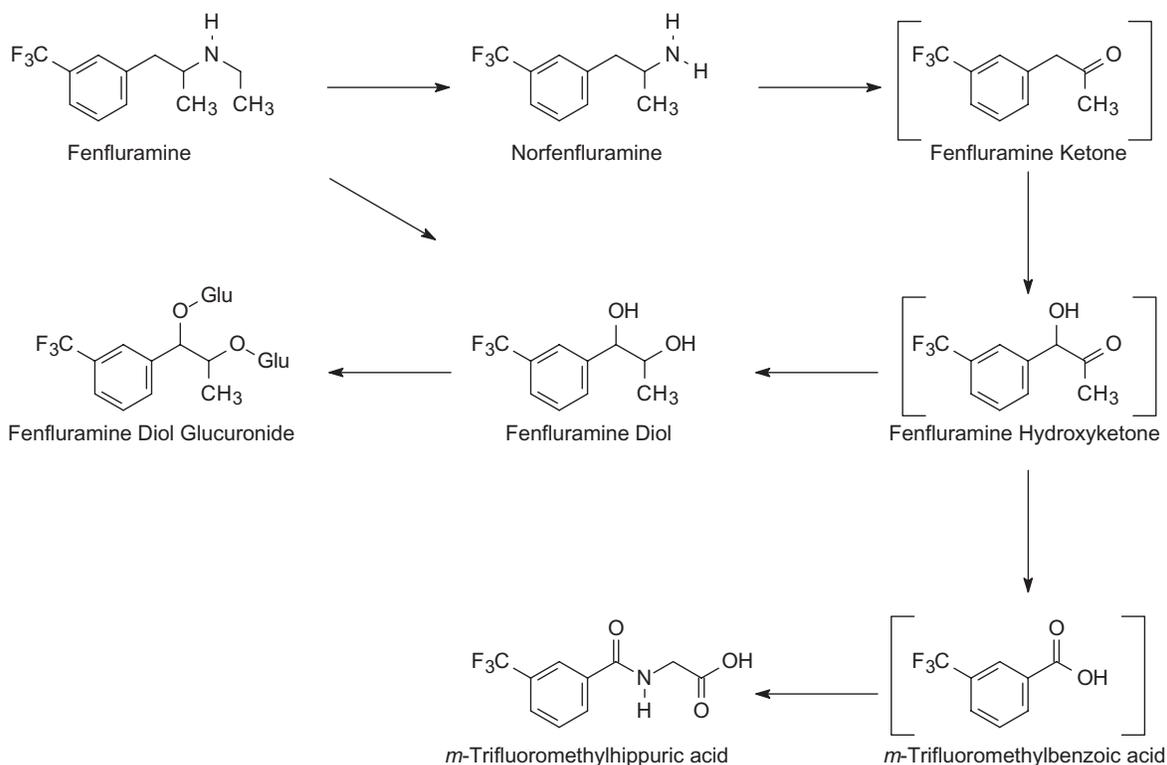
The ingestion of an estimated 300 mg fenfluramine by a 13-year-old girl was associated with drowsiness, vomiting, and mydriasis.[14] Her vital signs were stable and she recovered uneventfully. A seizure and cardiopulmonary arrest occurred 2 hours after the ingestion of 1,600 mg


FIGURE 14.2. Proposed metabolic pathway for racemic fenfluramine.[16]

fenfluramine by a 17-year-old girl.[15] She failed to respond to 1 hour of cardiopulmonary resuscitation and she was pronounced dead. The body temperature was not reported.

TOXICOKINETICS

Absorption

Radioactive tracer studies in humans indicate that the absorption of fenfluramine from the gastrointestinal tract (GI) is relatively complete. In a study of 4 volunteers receiving 1 mg [^{14}C] *d,l*-fenfluramine hydrochloride, the average recovery of radioactivity in the urine exceeded 90%.[16] Peak plasma concentration of fenfluramine and norfenfluramine occur approximately 4 hours and 4–6 hours after ingestion, respectively.[17]

Biotransformation

Fenfluramine undergoes de-ethylation to norfenfluramine. Subsequent potential pathways involve oxidative deamination to fenfluramine ketone and *C*-oxidation to the fenfluramine diol and fenfluramine hydroxyketone.

The latter compound undergoes biotransformation to *m*-trifluoromethylbenzoic acid. Conjugation with glycine produces fenfluramine diol glucuronide and the main urinary metabolite, *m*-trifluoromethylhippuric acid. Under normal urinary pH, this latter compound accounts for a majority of the fenfluramine dose excreted by the kidneys.[18] Figure 14.2 displays the proposed metabolic pathways for racemic fenfluramine.

Elimination

Elimination of fenfluramine results primarily from hepatic metabolism and the renal excretion of urinary metabolites. The mean plasma elimination half-life of *d*-fenfluramine after the ingestion of 60 mg racemic fenfluramine by 8 healthy volunteers daily for 15 days was 19 ± 2 hours compared with 25 ± 3 hours for *l*-fenfluramine.[19] The metabolite, *d*-norfenfluramine persists about 1.5–2 times longer in the plasma than *d*- fenfluramine. Furthermore, the mean plasma elimination half-life is longer for *l*-norfenfluramine than *d*-norfenfluramine. In the same study, the mean plasma elimination half-life of *l*-norfenfluramine was 50 ± 5 hours compared with 34 ± 4 for *d*-norfenfluramine.

257

The elimination of fenfluramine and norfenfluramine in the urine is pH dependent. In alkaline urine unchanged fenfluramine and norfenfluramine account for approximately 2% of the dose excreted by the kidney; whereas in acidic conditions (pH ~5), unchanged fenfluramine and norfenfluramine account for approximately 35–50% of the dose excreted in the urine.[20] Under normal conditions with alteration of urinary pH, these 2 compounds accounted for 6–23% of the excreted dose. The urinary elimination half-life of fenfluramine is pH-dependent. At urinary pH of 5.0, the elimination half-life of fenfluramine is about 11 hours. Within the first 24 hours after an estimated fenfluramine overdose of 30 mg/kg by child, the plasma elimination half-life was approximately 8–9 hours.[21]

Tolerance

Although fenfluramine is an efficacious appetite suppressant, the effectiveness of appetite suppressants decreases over time, particularly after 3 months.[22] In a 34-week, double-blind clinical trial of 121 overweight patients (mean body weight, 154% ± 1.2% ideal body weight), the treatment group received 60 mg extended-release fenfluramine plus 15 mg phentermine.[23] The mean initial weight loss in the treatment group during the first 18 weeks was approximately 10%, however, during the last 10 weeks of the study, there was no significant weight loss in the treatment group.

Drug Interactions

There are limited data on the synergistic action of phentermine and fenfluramine. Although some epidemiology studies suggest synergism, the existing studies lack adequate experimental design and power to yield definitive conclusions regarding the effect of the addition of phentermine on the prevalence of fenfluramine-induced valvular disease. In a reader-blinded, controlled, multicenter study, the prevalence rates and relative risk (RR) of mild or greater aortic regurgitation were 8.9% in the dexfenfluramine group (RR = 2.18; 95% CI: 1.32–3.59), 13.7% in the phentermine/fenfluramine group (RR = 3.34; 95% CI: 2.09–5.35), and 4.1% in the untreated group.[11] The differences in the prevalence rates for the dexfenfluramine and fenfluramine/phentermine groups compared with the control group were statistically significant ($P < .001$). In a study of 257 obese patients with a history of appetite suppressant use and 239 control participants, the odds ratio (OR) for cardiac-valve abnormalities based on the FDA criteria was as follows: dexfenfluramine only, 12.7 (95% CI: 2.9–56.4); dexfenfluramine and phentermine, 24.5 (95%

CI: 5.9–102.2); and fenfluramine and phentermine, 26.3 (95% CI: 7.9–87.1).[24] Comparisons between the groups was limited because the duration of treatment differed between the 3 groups.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Histopathology

The valvulopathy associated with fenfluramine involves regurgitation with plaques on the valve resulting from the proliferation of myofibroblastic cells with myxoid stroma.[25] Stenosis is not associated with this valvulopathy. Pathologic examination of diseased valves from patients undergoing valve replacement demonstrate a glistening white appearance without the yellow discoloration or calcification associated with rheumatic heart disease. The presence of thick valves with numerous onlays composed primarily glycosaminoglycans and increased vascularity and inflammation of the underlying valve helps separate fenfluramine-induced valvular disease from normal and rheumatic valves.[26] Reduced valve mobility results from diffuse leaflet thickening and tethering of the chordae, particularly the posterior leaflet resulting in central regurgitation. Microscopic findings include smooth muscle cell hyperplasia along with abundant extracellular matrix and focal proliferation and fibrosis on the surface of the leaflet without obvious signs of inflammation or necrosis. The resulting formation of plaques has a "stuck-on" appearance (valve onlays) to normal-appearing underlying structures. Rare case reports also associated fenfluramine/phentermine use with the development of fibroproliferative plaques in pulmonary arteries of patients with pulmonary hypertension.[27] The proliferation of smooth-muscle cells and fibroblasts occurs without elastic fibers or destruction of underlying structures. The pathology associated with fenfluramine-associated valvular heart disease is similar to the cardiac pathology found with the carcinoid syndrome and valvulopathy associated with ergot and methysergide.

Mechanism of Action

Fenfluramine is a serotoninergic agent that increases the release of serotonin and inhibits the reuptake of serotonin from nerve terminals. This drug modulates the normal appetite by decreasing the desire to eat and the eating rate. In volunteer studies, 60 mg fenfluramine slows the local rate of eating and eliminates the characteristic decline in the rate of feeding across the course of a meal with a subsequent mean reduced caloric intake

of 26%.[28] The mediators of serotonin-induced satiety include the 5-HT$_{2C}$ and 5-HT$_{1B}$ receptors.[29] *In vitro* studies indicate that fenfluramine and norfenfluramine have low affinity for 5-HT$_{1B}$ receptors, moderate affinity for 5-HT$_{2C}$ receptors, and high affinity for 5-HT$_{2B}$ receptors.[30]

Mechanism of Toxicity

The pathophysiologic mechanism of fenfluramine-associated valvular disease remains unknown. Potential mechanisms of toxicity include 1) direct vasoconstriction and inhibition of nitric oxide production by valvular endocardium,[31] and 2) activation of mitogenic effects of the 5-HT$_{2B}$ receptor via protein kinase cascade, resulting in proliferation of fibromyxoid plaques.[32] The latter action may result from the effects of norfenfluramine rather than fenfluramine because the binding of this active metabolite for the 5-HT$_{2B}$ receptor if much greater than the parent compound, fenfluramine.[33] Furthermore, the concentration of 5-HT$_{2B}$ and 5-HT$_{2A}$ receptor transcripts in heart valves is at least 300-fold higher than 5-HT$_{2C}$ receptor transcripts.[34]

Postmortem Examination

Autopsy findings following fatal fenfluramine overdose are usually nonspecific with the presence of pulmonary edema, mild cerebral congestion, and occasionally right ventricular dilation. Cardiac abnormalities are typically absent.

CLINICAL RESPONSE

Illicit/Medical Use

In clinical trials, adverse effects include drowsiness, lightheadedness, dry mouth, nausea, vomiting, diarrhea, and urinary frequency. These effects are dose-related and usually mild.

Valvular Heart Disease

Valvular regurgitation and heart disease occurs in patients receiving fenfluramine or dexfenfluramine with or without phentermine as well as ergot alkaloids (ergotamine, methysergide), dopamine agonists (pergolide, cabergoline) and possibly 3,4-methylnedioxy-methamphetamine (MDMA, ecstasy).[35] Most of these cases involve mild or moderate valvulopathy with the primary long-term complication being aortic insufficiency in a minority of these individuals.[36] Valve repair or replacement is usually unnecessary. In an observa-

tional study of 5,743 fenfluramine users examined by echocardiography from 1997–2004, 38 (0.66%) of these patients required cardiac surgery.[37] Of these 38 patients, 25 had clear evidence of fenfluramine-related valvular damage. Although initial case series and uncontrolled surveys suggested that the prevalence of cardiac valvular abnormalities ranged up to 30–40%,[38] acquisition and interpretation biases probably caused an overestimation of the true prevalence of valvular disease in patient receiving fenfluramine or the combination of fenfluramine and phentermine. Most controlled studies report prevalence rates for FDA case definitions (moderate or greater mitral regurgitation and/or mild or greater aortic regurgitation) in the range of 5–15% compared with 3–6% in control groups.[39,40] However, the risk estimates vary widely between studies. Analysis of 6 controlled cohort studies of fenfluramine, dexfenfluramine and/or phentermine yielded a RR = 2.32 (95% CI: 1.79–3.01, $P < .00001$) for aortic regurgitation with an attributable rate of 4.9%.[41] The relative risk ratio for mitral regurgitation was 1.55 (95% CI: 1.06–2.25, $P = .02$) with an attributable rate of 1.0%. In contrast, another analysis of published studies with echocardiographic assessment of cardiac valve regurgitation in patients exposed to fenfluramine or dexfenfluramine and suitable controls reported the following summary of relative risks: mild or greater aortic regurgitation, 19.6 (95% CI: 16.3–23.5, $P < .00001$); moderate or greater mitral regurgitation, 5.9 (95% CI: 4.0–8.6, $P < .00001$).[42]

Potential factors affecting the prevalence of valvular regurgitation include advancing age, obesity, gender, rheumatic fever, and other drugs (e.g., ergotamine, methylsergide). Although aortic root diameter at the sinuses of Valsalva is proportional to body size and increases with age, a population-based sample indicated that the use of fenfluramine or dexfenfluramine with or without phentermine is associated with aortic regurgitation independent of aortic dilation or fibrocalcification.[43]

Following cessation of fenfluramine use, the valvulopathy associated with these appetite suppressants do not usually progress, and many patients experience a regression of the valvulopathy over time.[39] Improvement in the regurgitation is more common than worsening of regurgitation; even moderate to severe mitral or aortic regurgitation may improve over the first few years after cessation of fenfluramine use, particularly in the first 6 months.[44,45] In a follow-up study of the original cohort of patients from Fargo, North Dakota with appetite suppressant-induced valvulopathy, serial echocardiograms were obtained a mean of about 1 year apart for 38 patients with at least mild mitral regurgitation and 43 patients with at least mild aortic regurgitation.[46]

Mitral regurgitation improved by at least 1 grade in 17 patients (P = .001) and aortic regurgitation improved by at least 1 grade in 19 patients (P = .004). No change in severity of mitral and aortic regurgitation occurred in 19 and 22 patients, respectively. Two patients in each group experienced worsening of regurgitation by at least 1 grade. Regression usually occurs within 6 months of the cessation of drug use; typically the regression involves multiple affected valves rather than a single valve. Rare case reports associate the development of valvular disease several years after the discontinuation of prolonged treatment with fenfluramine and dexfenfluramine.[47] To date, an excess prevalence of valvular heart disease has not been reported for phentermine when used as monotherapy for obesity.

Clinical features of patients with valvular disease include atypical chest pain, murmur, palpitations, and evidence of congestive heart failure (peripheral edema, dyspnea on exertions, reduced exercise tolerance, orthopnea, paroxysmal nocturnal dyspnea).

PULMONARY HYPERTENSION

Primary pulmonary hypertension (i.e., mean pulmonary arterial pressure >25 mm Hg at rest) is a rare, often fatal disease that is particularly common in women in their third or fourth decade of life. Anorexic drugs (e.g., fenfluramine, dexfenfluramine, diethylpropion) are suspected factors in the development of primary pulmonary hypertension along with cocaine use, human immunodeficiency virus, oral-contraceptive use, and aminorex fumarate;[48] however, current data does not support a definite causal connection between fenfluramine and primary pulmonary hypertension because of the presence of confounding variables and genetic susceptibility (e.g., germline bone morphogenetic protein receptor).[1] The prevalence of severe anorexic drug-associated pulmonary hypertension varies substantially between countries with prevalence relatively low in the United Kingdom compared with France. Exposure to fenfluramine compounds occurred in 15 (20%) of patients with primary pulmonary hypertension referred to a French speciality center compared with 2 (4%) of 55 patients referred to an English Heart Lung Transplant center with primary pulmonary hypertension.[4,49] An additional patient in the latter group was exposed to diethylpropion. In a retrospective review of patients referred to the French National Reference Center for Pulmonary Hypertension from 1986–2004, approximately 18% had a history of fenfluramine use (mean, 6 months; range, 3–12 months).[50] The clinical course, median survival rates, and genetic features of the fenfluramine-associated cases were not different than the patient with idiopathic pulmonary hypertension. Review of newly diagnosed patients at 13 tertiary pulmonary hypertension centers in the United States from 1998–2001demonstrated an increased prevalence of appetite suppressant use in the referral consistent with prior studies, but there was no dramatic increase in referrals in the period of time immediately after the withdrawal of fenfluramine and dexfenfluramine from the US market.[51]

Overdose

Clinical features of fenfluramine intoxication include facial flushing, diaphoresis, mydriasis, agitation, sinus tachycardia, hypertension, muscle rigidity, trismus, muscle fasciculations, and clonus. In serious overdoses, seizures, hyperthermia, coma, respiratory depression, intractable ventricular fibrillation, and death.[52] The onset of symptoms typically is rapid with serious cardiorespiratory complications occurring within the first 1–4 hours after ingestion.[53] Drowsiness, sinus tachycardia, and mydriasis may persist 24–48 hours after large fenfluramine overdoses.

Abstinence Syndrome

Case reports suggest that abrupt cessation of large doses of fenfluramine may result in depression, insomnia, and anorexia reaching a maximum about 4 days after withdrawal. In a study of 11 patients receiving 80 mg fenfluramine daily for 28 days, self-reported rating indicated a depression of mood following cessation of fenfluramine use.[8] Peak scores occurred 4 days after fenfluramine use stopped. A similar decline in mood developed in 20 patients receiving 60 mg fenfluramine daily for 28 days following cessation of fenfluramine.[54] These effects typically are mild and resolve spontaneously.

Reproductive Abnormalities

There are few data on the reproductive outcomes of women using fenfluramine and phentermine during pregnancy. Existing data provides no clear evidence that the use of these drugs during pregnancy causes adverse reproductive outcomes. In a controlled prospective cohort study of women contacting the California Teratogen Information Service during pregnancy, 233 women were controls and 98 women were in the first trimester fenfluramine/phentermine exposure group.[55] The study detected no significant difference in prematurity, spontaneous pregnancy loss, or the overall frequency of minor or major anomalies between the 2 groups.

DIAGNOSTIC TESTING

SI Units

$$1 \ ng/mL = 4.32 \ nM$$
$$1 \ nM = 0.231 \ ng/mL$$

Analytic Methods

Short retention times, poor peak shapes, and low resolution complicate the analysis of small molecules, such as phentermine and fenfluramine. Methods for the quantitation of fenfluramine include gas chromatography (GC),[56] high performance liquid chromatography with UV detection (HPLC/UV, 210 nm),[57] isocratic HPLC/UV with derivation by 4-(4,5-diphenyl-1H-imidazsole-2-yl)benzoyl chloride,[58] and gas chromatography/mass spectrometry (GC/MS) with pentafluoropropionic anhydride derivatization.[59] The limit of detection (LOD) for the latter 2 methods is 10 ng/mL and 500 ng/mL, respectively. Following headspace-solid phase microextraction and derivations with heptafluorobutyric acid, the LOD for fenfluramine using GC/MS is 5 ng/g.[60] The use of chiral HPLC allows the quantitation of the enantiomers of fenfluramine and the metabolite, norfenfluramine.[61] The use of GC/MS in selected ion monitoring mode allows the quantitation of numerous phenylalkylamine derivatives in hair samples including fenfluramine (LLOQ = 0.02 ng/mg).[62]

Biomarkers

Blood

THERAPEUTIC. Following the administration of therapeutic doses (e.g., 60 mg daily) of fenfluramine, the peak plasma fenfluramine concentrations range from about 50–150 ng/mL. In a volunteer study of 5 fasting men receiving 60 mg fenfluramine, the mean peak plasma fenfluramine concentration was 63 ± 4.5 ng/mL at 2–4 hours after ingestion as measured by gas chromatography with flame ionization detection.[63] The mean peak plasma norfenfluramine concentration was about 16 ng/mL at 4–6 hours after ingestion. In a convenience sample of 13 obese adult women, the mean daily intake of fenfluramine was 149 ± 24 mg between the 4th and 16th week of the study.[64] The mean plasma fenfluramine and norfenfluramine concentrations in samples drawn during evaluations at the study site every 2 weeks were 239 ± 32 ng/mL and 93 ± 29 ng/mL, respectively. In a study of 8 healthy volunteers receiving 60 mg racemic fenfluramine daily for 15 days, the mean steady state d-fenfluramine and d-norfenfluramine concentrations

were 43 ± 6 ng/mL and 16 ± 2 ng/mL, respectively, compared with 67 ± 11 ng/mL for l-fenfluramine and 24 ± 3 ng/mL for l-norfenfluramine.[19] Maximum concentrations of these 2 compounds during this study were 65 ± 9 ng/mL and 21 ± 3 ng/mL, respectively.

OVERDOSE. Case reports associated plasma fenfluramine concentrations ranging from 240–850 ng/mL with tachycardia, mydriasis, confusion, agitation, and muscle stiffness. A 3½-year-old girl developed diaphoresis, facial flushing, muscle stiffness, mydriasis, shallow, irregular respirations, hypertension, and altered consciousness after the ingestion of a large dose of fenfluramine.[21] The plasma fenfluramine concentration 7½ hours after ingestion was 1,140 ng/mL as measured by gas chromatography. At that time, the patient was improving, and the plasma norfenfluramine concentration was 280 ng/mL.

POSTMORTEM. Case reports associate fatal fenfluramine intoxication with postmortem fenfluramine blood concentrations ranging from 650–28,000 ng/mL.[65,66] The case at the lower end of the range involved a severely hyperthermic 13-year-old child, who died 3½ hours after ingestion of fenfluramine. The body temperature was not reported in the 17-year-old girl whose postmortem fenfluramine blood concentration was 28,000 ng/mL. She failed to respond to 1 hour of cardiopulmonary resuscitation and was pronounced dead 3 hours after ingesting a large dose of fenfluramine.[15] Several hours after ingestion, the fenfluramine concentrations in postmortem liver samples typically are several fold higher than blood. A 36-year-old woman was found dead, and autopsy examination did not reveal any anatomic causes of death.[67] Postmortem samples from heart blood and brain contained a fenfluramine concentration of 7.27 mg/L and 155 mg/L, respectively.

Abnormalities

The echocardiographic abnormalities associated with appetite suppressants are not unique. The morphology of these changes may mimic other diseases, presenting as degenerative, myxomatous, nonspecific, rheumatic valve morphology.[68]

TREATMENT

Treatment for fenfluramine overdose is supportive. Immediate life-threatening effects include progressive obtundation and respiratory depression following severe overdose. Serious complications of fenfluramine overdose usually present within the first few hours of

ingestion. These patients require cardiac monitoring, pulse oximetry, and careful observation for the development of seizures and ventricular dysrhythmias. Sinus tachycardia, hypertension, and agitation are common complications of mild to moderate fenfluramine intoxication; these effects usually require only benzodiazepine therapy and a calm environment. There are few data on the efficacy of decontamination procedures for fenfluramine intoxication; the administration of activated charcoal is a therapeutic option if the patient presents to the healthcare facility within 1 hour of ingestion. However, there are inadequate clinical data to conclude the administration of activated charcoal improves outcome. There are no effective antidotes for the treatment of fenfluramine intoxication.

Treatment for appetite suppressant-associated valvulopathy (fenfluramine or dexfenfluramine with or without phentermine) include discontinuation of the anorectic drug, cardiac physical examination, and echocardiography in symptomatic patients (heart murmurs, associated physical findings and/or symptoms). Doppler echocardiogram is an alternative to standard echocardiography in obese patients with very large body habitus.

DEXFENFLURAMINE

HISTORY

In 1996, the FDA approved the use of dexfenfluramine as an appetite suppressant; Interneuron Pharmaceuticals (Lexington, MA) manufactured dexfenfluramine and Wyeth-Ayerst Laboratories marketed this drug under the trade name, Redux. Previously, dexfenfluramine and fenfluramine were marketed extensively in Europe for the treatment of obesity. Both Wyeth-Ayerst Laboratories and their parent company American Home Products Corporation (Madison, NJ) agreed to voluntarily withdraw their drugs on September 17, 1997 as a result of reports on the association of this drug with cardiac valvular insufficiency. The latter company also withdrew their drug, Pondimin (fenfluramine).

IDENTIFYING CHARACTERITICS

Dexfenfluramine (CAS RN: 3239-44-9) is the *d*-isomer of fenfluramine that is distributed as the hydrochloride salt (MW 267.7 g/mol). This drug has most of the same anorectic properties as the racemic mixture of fenfluramine. Dexfenfluramine was marketed under the trade name, Redux (Interneuron Pharmaceuticals, Inc.).

EXPOSURE

Dexfenfluramine is no longer available in the United States or in most global markets.

DOSE EFFECT

In a case series of 14 women undergoing cardiac surgery for valvular disease associated with anorexic agents, 1 woman received dexfenfluramine (30 mg daily for 13 months) and phentermine (60 mg daily for 6 months, concomitantly).[10] The estimated ingestion of 1,800 mg dexfenfluramine was associated with clonus, coma, hypertension, sinus tachycardia, seizures, and respiratory failure.[69] She recovered within 48 hours after intensive supportive care including endotracheal intubation.

TOXICOKINETICS

Absorption

The average bioavailability of dexfenfluramine in obese and nonobese individuals is approximately 60% and 70%, respectively.[70] Peak plasma concentrations of dexfenfluramine occur about 3–5 hours after ingestion, whereas peak nordexfenfluramine concentrations occur about 6–8 hours after ingestion. The peak plasma concentrations of nordexfenfluramine are approximately one-half of the peak fenfluramine concentrations.

Distribution

Dexfenfluramine is highly lipophilic and has an extensive volume of distribution. In a study of 10 obese volunteers (mean $145 \pm 13\%$ ideal body weight) and 10 healthy, nonobese volunteers ($93 \pm 8\%$ ideal body weight), the steady-state volume of distribution was 11.2 ± 6.2 L/kg and 13.7 ± 2.7 L/kg, respectively.[70] These findings are consistent with the similar distribution of fenfluramine into lean tissue and excess body fat.

Biotransformation

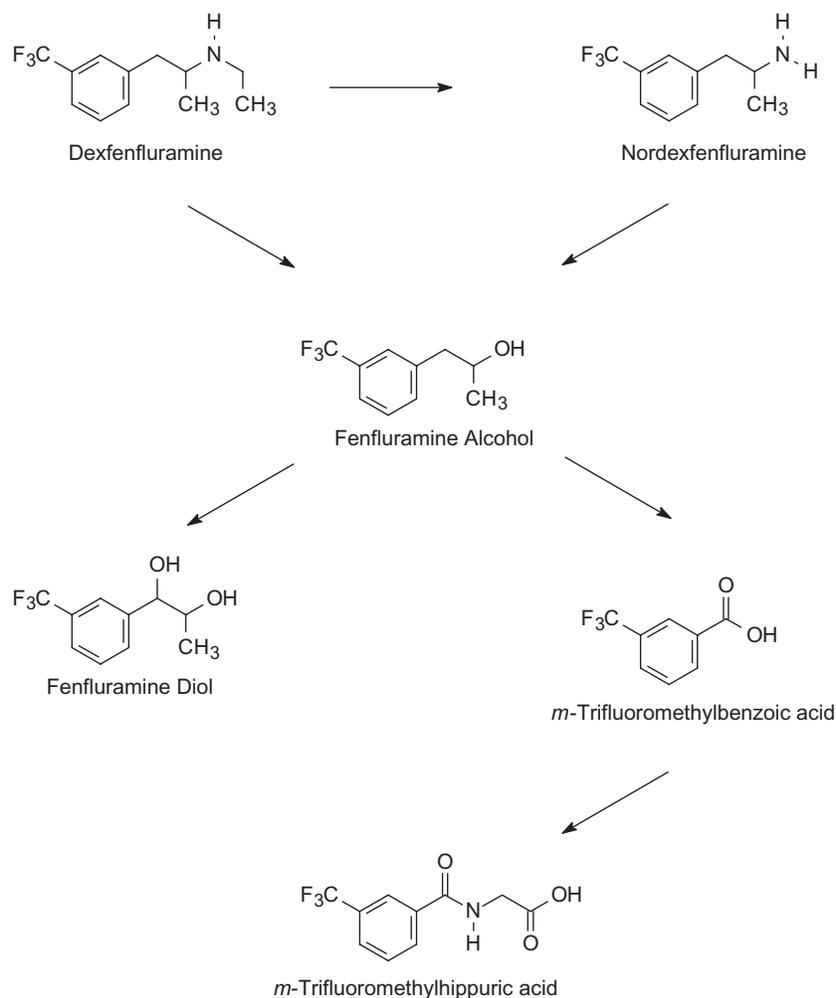
Dexfenfluramine undergoes extensive hepatic metabolism with first-pass metabolism accounting for about 20% of the administered dose.[71] Figure 14.3 displays proposed pathways for the metabolism of dexfenfluramine. *In vivo* studies indicate that the biotransformation of dexfenfluramine to the active metabolite, nordexfenfluramine involves CYP2D6 isoforms; however, CYP2D6 does not catalyze the metabolism of nordexfenfluramine.[72]


FIGURE 14.3. Proposed metabolic pathways of dexfenfluramine.[72]

Elimination

Following oral administration, the terminal plasma elimination half-lives of obese and nonobese healthy volunteers are similar. After the ingestion of 30 mg dexfenfluramine hydrochloride (25.9 mg dexfenfluramine base) by 5 obese and 5 nonobese volunteers, the mean terminal plasma elimination half-lives were 16.5 ± 7.1 hours and 14.5 ± 2.6 hours, respectively.[70] The appearance of the dealkylated active metabolite (nordexfenfluramine) in the plasma were slower than dexfenfluramine; however, this metabolite persisted much longer in the plasma than dexfenfluramine.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Pathologic examination of diseased valves associated with dexfenfluramine use reveals glistening white valve leaflets, diffuse, irregular cusp thickening, lack of commissural fusion, and shortened and fused chordae tendineae.[35] Histopathologic examination demonstrates an avascular collagenous matrix surrounding the valve with preservation of underlying valve structure along with proliferation of smooth muscle cells and myofibroblasts.

Mechanism of Action

Like fenfluramine, dexfenfluramine decreases the normal appetite by reducing the desire to eat (i.e., premeal hunger ratings) and decreasing the eating rate.[73] The other isomer of fenfluramine, *l*-fenfluramine, is inactive. Unlike fenfluramine, dexfenfluramine is a pure serotonin agonist. Selective serotonin receptor antagonist (5-HT$_1$ and 5-HT$_2$) studies in rodents indicate that the hypophagia associated with dexfenfluramine administration results from 5-HT$_{1B}$ or 5-HT$_{2C}$ activity.[74,75]

Mechanism of Toxicity

Dexfenfluramine inhibits neuronal serotonin reuptake via inhibition of the serotonin transporter, increased release of serotonin, and the subsequent stimulation of serotonin receptors.[76] Inhibition of the serotonin transporter also occurs in smooth muscle cells, pulmonary endothelium, and platelets. In isolated tissue preparations, dexfenfluramine causes pulmonary vasoconstriction by the inhibition of potassium channels and membrane depolarization, and increases the resistance in pulmonary arteries by an influx of extracellular calcium into the smooth muscle cells. The major metabolite, nordexfenfluramine produces a relatively greater degree of vasoconstriction in these preparations than dexfenfluramine.[77] Activation of 5-HT_2 receptors by nordexfenfluramine causes the influx of extracellular calcium and the release of calcium from the sarcoplasmic reticulum of the pulmonary artery smooth muscle cells, resulting in pulmonary constriction. The development of drug-induced valvular disease probably involves a complex interaction between various factors including serotonin transporter, serotonin, 5HT_{2B} receptors, and individual susceptibility with subsequent activation of protein kinases and potentiation of transforming growth factor β.[35]

CLINICAL RESPONSE

Illicit/Medical Use

In clinical trials, common adverse effects include diarrhea, malaise, dry mouth, and somnolence.[78] These symptoms typically are transient and mild. Similar to fenfluramine, the use of dexfenfluramine is associated with an increased prevalence of valvular regurgitation compared with control populations (no appetite suppressant use).[79] The prevalence of cardiac valvular disease in patients receiving dexfenfluramine varies between studies as a result of the presence of methodologic differences including ages of groups, concomitant treatment with phentermine, prior treatment with other appetite suppressants, dose, duration of treatment, and time since discontinuation of treatment. In a study of 172 dexfenfluramine patients, 172 unexposed controls matched for age, sex, and body mass index, and 68 unmatched participants (51 dexfenfluramine patients, 17 controls), the prevalence of FDA-grade regurgitation in the dexfenfluramine patients was 7.6% compared with 2.1% for controls (OR = 3.82, P = .01). The prevalence of FDA-grade regurgitation in other studies of dexfenfluramine patients ranged from 6.9% (P = NS)[80] to 17% (P < .01),[24] when compared with unexposed controls. This difference resulted primarily from the increased frequency of mild aortic regurgitation in the dexfenfluramine group. Studies of the valvulopathy associated with fenfluramine and dexfenfluramine have not detected a significant difference in the prevalence of cardiac disease or the type of pathology following the use of these 2 drugs.[81] Heart murmurs associated with dexfenfluramine-induced valvular disease typically are systolic murmurs, grade I–II/VI.[82]

Similar to fenfluramine, short-term use (i.e., <3 months) of dexfenfluramine is not usually associated with clinically significant cardiac valvular disease. In a clinical trial prior to the discontinuation of dexfenfluramine, there was a small increase in the prevalence of minor degrees of aortic and mitral regurgitation following short-term dexfenfluramine use (mean, 72.5 ± 22.5 days). The natural history of dexfenfluramine and fenfluramine/phentermine-associated valvular disease is similar including medical history, physical findings, ejection fraction, pulmonary artery systolic pressures, and cardiovascular events.[83] Following cessation of therapy, progression of aortic valvular regurgitation is unlikely and regression of aortic regurgitation occurs in a substantial number of previously treated patients.[84] A follow-up study of these patients within 3–5 months after discontinuation of dexfenfluramine no longer detected a difference between the treatment and placebo group.[85] Rare case reports associate dexfenfluramine use with severe regurgitation that requires valve replacement.[86]

Overdose

Fenfluramine and dexfenfluramine produce similar effects following an overdose including mydriasis, sinus tachycardia, hypertension, agitation, elevated body temperature, muscle stiffness and rigidity, clonus, and hyperreflexia.[87] The clinical features of serious intoxications include coma, seizures, respiratory failure, and hyperthermia.

DIAGNOSTIC TESTING

Analytic methods for the quantitation of dexfenfluramine and fenfluramine are similar. Following the administration of therapeutic doses (e.g., 30 mg daily) of dexfenfluramine, the peak plasma dexfenfluramine concentrations average approximately 20 ng/mL. In a study of 18 healthy, young adults, the mean concentrations of dexfenfluramine following single 15 mg and 30 mg doses of fenfluramine were 10.04 ± 3.36 ng/mL and 23.46 ± 6.51 ng/mL, respectively.[88] In a study of 8 healthy volunteers receiving 30 mg dexfenfluramine daily for 15 days, the mean steady state *d*-fenfluramine and *d*-

norfenfluramine concentrations were 45 ± 5 ng/mL and 19 ± 3 ng/mL, respectively.[19] Maximum concentrations of these 2 compounds during this study were 70 ± 5 ng/mL and 26 ± 5 ng/mL, respectively. Echocardiographic changes of cardiac valves associated with dexfenfluramine or fenfluramine are similar. Thickening of the valvular leaflets and subvalvular apparatus occurs with variable degrees of leaflet retraction and reduced leaflet mobility. In more severe cases, variable degrees of valvular regurgitation appear but significant obstruction is not usually present.

TREATMENT

Treatment is supportive.

SIBUTRAMINE

HISTORY

Sibutramine originally was developed as an antidepressant in the 1980s,[89] later the use of this compound was limited to the treatment of obesity as a result of the ability of sibutramine to decrease food intake and increase satiety. In 1997, the FDA approved the use of sibutramine for the long-term treatment of obesity, and by 2001 this drug was marketed in Italy, United Kingdom, and Australia. In 2002, sibutramine was withdrawn from the Italian market because of 2 deaths and 50 adverse events (e.g., tachycardias, dysrhythmias, hypertension) reported in sibutramine users. The European Committee for Proprietary Medicinal Products assessed the risk-benefit ratio of sibutramine and this drug subsequently was reinstated in Italy. Similar assessments by the FDA and Health Canada resulted in favorable conclusions regarding the safety of sibutramine; however, sibutramine was withdrawn from the US markets in 2010 when the Sibutramine Cardiovascular Outcomes Trial (SCOUT) demonstrated an increased risk of nonfatal myocardial infarction and nonfatal stroke in patients with preexisting cardiovascular disease receiving sibutramine compared with placebo.[90] Sibutramine was withdrawn from Europe in early 2010.

IDENTIFYING CHARACTERISTICS

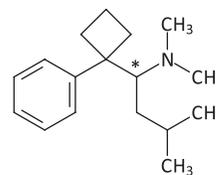
Sibutramine (CAS RN: 106650-56-0, C_{17}-H_{26}ClN) is a tertiary amine compound with an asymmetrical carbon as demonstrated in Figure 14.4. Meridia® (Abbott Laboratories, Abbott Park, IL) and Reductil® (Abbott Laboratories) are trade names for the racemic mixture


FIGURE 14.4. Chemical structure of sibutramine. Asterisk denotes stereocenter.

of sibutramine (*N*-{1-[1-(4-chlorophenyl)cyclobutyl]-3-methylbutyl}-*N*,*N*-dimethyl amine) hydrochloride monohydrate.

EXPOSURE

Sibutramine had been the most commonly used appetite suppressant until withdrawal from the US and European markets in 2010. The primary action of sibutramine is satiety. Similar to fenfluramine and dexfenfluramine, sibutramine reduces food intake and appetite in humans. In a double-blind, placebo-controlled, 14-day study of obese participants, 30 mg sibutramine reduced caloric intake by 23% at day 7 and by 26% on day 14 compared with placebo.[91] The World Anti-Doping Agency (WADA) added sibutramine to the list of prohibited substances in 2006. Some "herbal" weight loss products (e.g., Chinese slimming capsules, Chinese slimming tea) may contain sibutramine, which may be added without listing the content of sibutramine on the label.[92,93]

Postmarketing surveillance suggests that the abuse potential of sibutramine is substantially less than phentermine. In a study of 8,780 questionnaires completed on intake to 58 drug abuse treatment programs, the percentage of respondents indicating that they knew of the use of sibutramine to "get high" was 0.9% compared with 2.8% for phentermine ($P < .001$). Experimental human studies indicate that sibutramine lacks the amphetamine-type abuse liability when administered acutely. In a volunteer study comparing 25 mg and 75 mg sibutramine with 20 mg *d*-amphetamine and placebo, 25 mg sibutramine produced subjective effects indistinguishable from placebo.[94] The 75 mg sibutramine dose was poorly tolerated as a result of unpleasant side effects (e.g., anxiety, confusion, decreased vigor) in contrast to the positive mood associated with 20 mg *d*-amphetamine.

DOSE EFFECT

Sibutramine is a selective monamine reuptake inhibitor with established efficacy in weight loss along with modification of lifestyle and diet. At therapeutic doses

(10–20 mg daily), sibutramine reduces food intake by increasing satiety and attenuates the fall in metabolic rate associated with weight loss. A meta-analysis of sibutramine with lifestyle modification reported a mean pooled difference in weight loss of 4.45 kg (95% CI: 3.62–5.29 kg) at 12 months, when compared with placebo (lifestyle modification only).[95]

TOXICOKINETICS

Absorption

The absorption of sibutramine is rapid with bioavailabilities in the range of 75%. Sibutramine undergoes extensive first-pass metabolism.

Biotransformation

Sibutramine is a tertiary amine that undergoes extensive biotransformation in the liver to the active amine metabolites, M1 (mono-desmethyl sibutramine, norsibutramine) and M2 (di-desmethyl sibutramine, nor-norsibutramine). These demethylated metabolites are hydroxylated on the cyclobutane ring or the isopropyl chain, followed by conjugation with glucuronide to inactive metabolites. Figure 14.5 displays the proposed met-

abolic pathways for the biotransformation of sibutramine. *In vitro* studies indicate that CYP2B6 is the primary catalyst for the *N*-demethylation of sibutramine to M1 and M2.[96] Although CYP2C19, CYP3A4, and CYP 3A5 catalyze the formation of M1 at high substrate concentrations (>5 μM), the contribution of these isoforms to sibutramine metabolism probably is minor because these high substrate concentrations are not usually present following therapeutic doses. The demethylation of sibutramine to M1 and M2 is rapid with M2 being the major metabolite in human plasma. Following the ingestion of 15 mg sibutramine by 12 young volunteers, the mean peak plasma M1 concentration was 3.2 ± 1.3 ng/mL at 2.5 ± 0.9 hours after ingestion compared with 7.8 ± 1.8 ng/mL at 3.2 ± 1.4 hours for M2.[97]

Elimination

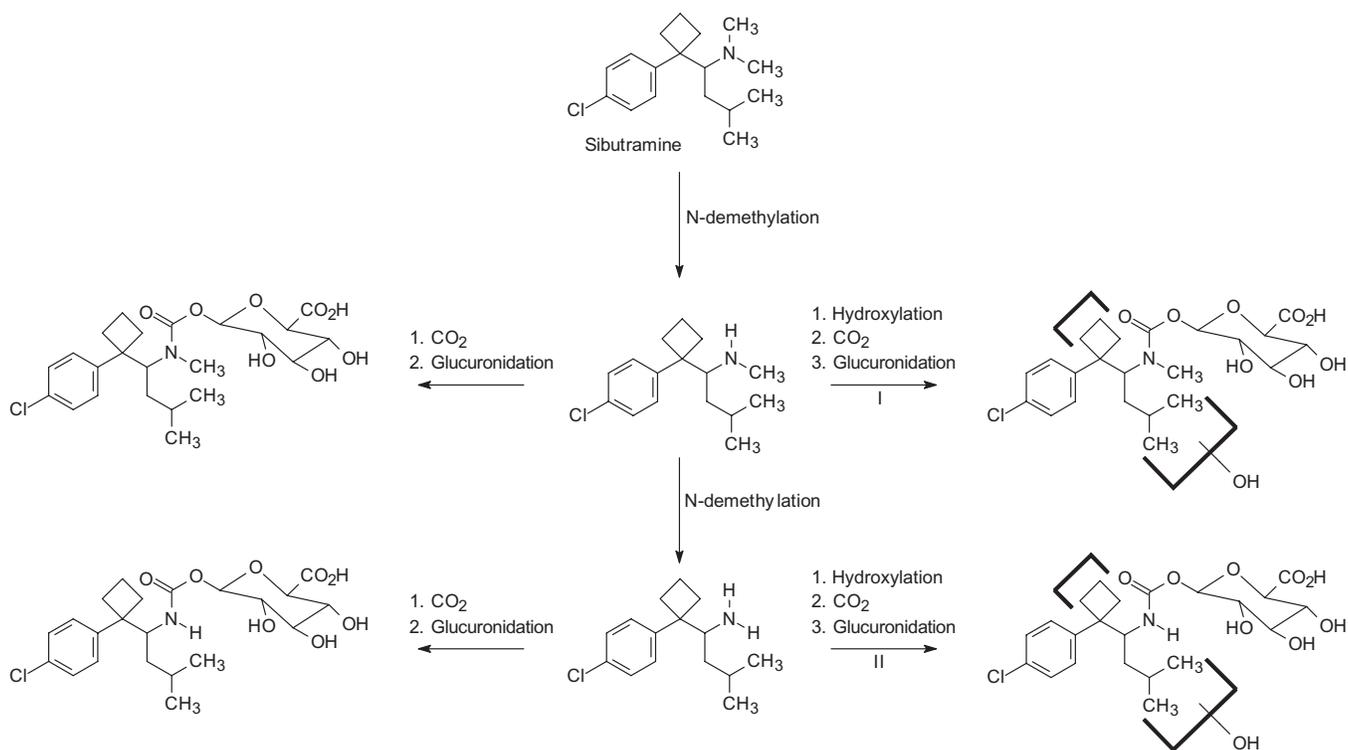
The main urinary metabolites are the carbamoyl glucuronides formed from M1 and M2 along with their hydroxylated analogs.[98] The kidney excretes little unchanged sibutramine in the urine; M1 and M2 are minor metabolites in the urine. The elimination of sibutramine in similar in young adults and the elderly. The mean plasma elimination half-lives in 12 young and 12 elderly adults following the ingestion of 15 mg


FIGURE 14.5. Proposed main pathways for the biotransformation of sibutramine. The reaction order indicated for hydroxylation and glucuronidation in pathways I and II is tentative.[98]
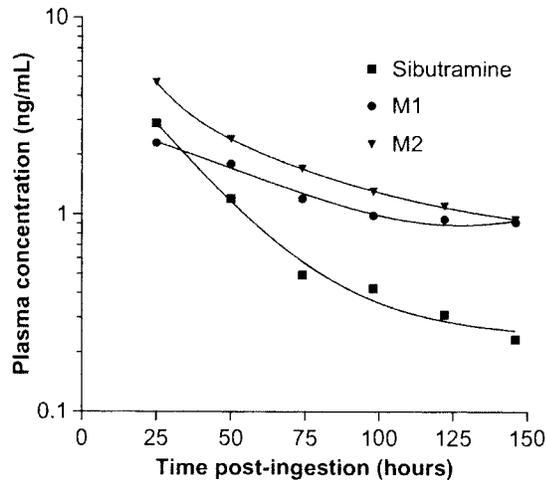

FIGURE 14.6. Plasma concentrations of sibutramine (solid square), mono-desmethyl sibutramine (M1, solid circle), and di-desmethyl sibutramine (M2, solid inverted triangle) following a sibutramine overdose by a 4-year-old girl. (Reprinted with permission from F Bucaretchi, EM de Capitani, SM Mello, R Lanaro, RF Barros, LCR Fernandes, JL Da Costa, S Hyslop, Serotonin syndrome following sibutramine poisoning in a child, with sequential quantification of sibutramine and its primary and secondary amine metabolites in plasma, Clinical Toxicology, Vol. 47, Issue 6, p. 599, copyright 2009.)

sibutramine were 19.0 ± 5.4 hours and 22.4 ± 6.2 hours, respectively.[97] Case reports suggest that the elimination of sibutramine and the metabolites is nonlinear following a sibutramine overdose. Figure 14.6 displays the plasma concentrations of sibutramine and reactive metabolites (M1, M2) beginning 25 hours after a sibutramine overdose (23 mg/kg) by a 4-year-old girl.

Tolerance

In short-term studies, tolerance does not develop to the hypophagia induced by sibutramine. Follow-studies of initial responders indicate that response to sibutramine remains after 10 months of therapy. In a randomized, double-blind, placebo-controlled study of 36 obese men and women, the amount food consumed following 15 mg sibutramine daily for 14 days was approximately 16% less than placebo.[99] After a 10-month, open-label treatment with 15 mg sibutramine and dietary advice, mean weight loss in responders was significantly less than nonresponders (11.8 ± 6.2 kg vs. 6.8 ± 2.7 kg, respectively, $P < .05$). The Sibutramine Trial of Obesity Reduction and Maintenance (STORM) trial detected little evidence of tolerance to the use of sibutramine over the 24 months of treatment.[100]

Drug Interactions

Potential drug interactions include the concomitant use of CY3A4 inhibitors (e.g., ketoconazole, erythromycin) and highly protein-bound drugs (e.g., warfarin, phenytoin); however, there are few clinical data and the clinical significance of these potential interactions is unclear. Additionally, sibutramine inhibits the reuptake of serotonin; the concomitant administration of selective serotonin reuptake inhibitors and monoamine oxidase inhibitors (MAOIs) potentially increases the risk of serotonin syndrome.[101]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

Sibutramine is a selective inhibitor of the presynaptic reuptake of serotonin, norepinephrine, and to a lesser extent, dopamine.[102,103] The rise in plasma dopamine is small compared with the increase in plasma norepinephrine. *In vivo* studies in rodents with monoamine receptor antagonists indicate that hypophagia associated with sibutramine involves α_1-adrenergic, α_2-adrenergic, 5-HT$_{2A}$, 5-HT$_{2C}$ receptors.[104] In rodent studies, sibutramine increases energy expenditure (i.e., thermogenesis) with M2 being much more potent than the parent compound, sibutramine.[105,106] Sibutramine has little affinity for the 5-HT$_{2A}$ receptor. This drug inhibits norepinephrine reuptake at least 10-fold more than serotonin reuptake.[107]

Mechanism of Toxicity

Sibutramine-induced inhibition of norepinephrine reuptake potentially increases blood pressure and heart rate. The therapeutic use of sibutramine may cause a slight increase in blood pressure in both normotensive and hypertensive patients, particularly during the initial phase of treatment. A meta-analysis of 21 placebo-controlled, double-blind, randomized trials of sibutramine demonstrated an increase in systolic (1.6 ± 10 mm Hg) and diastolic (1.8 ± 7 mm Hg) blood pressures in treated patients. The large standard deviation resulted from the interaction of the direct effect of sibutramine on blood pressure and weight-loss induced reduction of blood pressure. In studies of high-risk obese older women with cardiovascular disease and diabetes mellitus, the therapeutic use of sibutramine is associated with small median increases in pulse rate and small median decreases in systolic and diastolic blood pressure.[108] Elevation of blood pressure in obese patients treated with sibutramine does not usually result in

cessation of treatment, and blood pressure typically is controlled with the usual antihypertensive agents.[109]

CLINICAL RESPONSE

Illicit/Medical Use

Common adverse effects associated with the therapeutic use of sibutramine include anorexia, nausea, constipation, dry mouth, headache, palpitations, tachyarrhythmias, and insomnia.[110,111] In a retrospective review of California Poison Control System data on sibutramine exposures, the most common clinical features of symptomatic individuals were tachycardia, chest pain, agitation, irritation, dizziness, vertigo, nausea, and vomiting.[112] Most of the reported exposures to sibutramine were unintentional; 40% of the 62 exposures were asymptomatic.

Valvular Disease

To date, an increased prevalence of cardiac valvulopathy has not been associated with the use of sibutramine. In a double-blind, placebo-controlled, parallel-arm study of 210 obese type II diabetic patients, the prevalence of left-sided cardiac valve dysfunction was similar for the sibutramine group (2.3%, 3/133) and the placebo group (2.6%, 2/77).[113] The duration of the study was 12 months with a 12-month open-label extension. In a study of 106 obese patients with minimal tricuspid regurgitation on echocardiographic examination, there was slight, statistically significant increase in systolic blood pressure and heart rate at follow-up compared with baseline.[114] There was no statistically significant difference in aortic or mitral valve function, and no significant increase in pulmonary artery pressures. The mean duration of follow-up was 24 months.

Dysrhythmias/Myocardial Infarction

Case reports and drug monitoring programs document a variety of adverse cardiac effects in patients receiving sibutramine including atrial fibrillation, supraventricular tachycardia, QT_c prolongation,[115] *torsade de pointes*, ventricular tachycardia, myocardial infarction in a women with normal coronary arteries,[116] QT_c prolongation with ventricular fibrillation and cardiac arrest in a women with normal coronary arteries,[117] cardiomyopathy,[118] and heart block.[119] However, a causal connection between sibutramine and these events was not clearly established. In some of these case reports, QT prolongation and ventricular dysrhythmias occurred in susceptible patients with predisposing genetic abnormalities

(e.g., cardiac potassium channel subunit mutation).[120] In clinical studies of sibutramine, small increases in heart rate and systolic blood pressure occur in the treatment group compared with baseline; however, these changes are balanced by reduction in BMI.[121] Additionally, some clinical trials suggest that the use of sibutramine in patients with cardiovascular disease increases the risk of adverse cardiac events. In a study of 10,744 overweight or obese patients with preexisting cardiovascular disease, the risk of a primary outcome event was 11.4% in the sibutramine group compared with 10.0% in the placebo group (hazard ratio [HR], 1.16; 95% CI: 1.03–1.31; P = .02).[90] Although the rates of cardiovascular deaths were similar in the 2 groups, the rates of nonfatal myocardial infarction in the sibutramine and placebo groups were 4.1% and 2.6%, respectively (HR, 1.28; 95% CI: 1.04–1.57; P = .02).

Behavioral Abnormalities/Mental Disorders

Psychiatric complications associated with sibutramine therapy are rare, primarily involving patients with preexisting psychiatric disorders. Case reports associate the development of acute delirium in a patient with delusional disorder on sibutramine for 2 weeks,[122] acute psychosis in an adolescent with Kleine-Levin syndrome,[123] panic attacks in women with a history of a stable panic disorder,[124] an affective psychosis (agitation, irritability, hugging strangers) in a woman without a history of abuse or psychiatric disorders,[125] and a manic episode in a patient with a bipolar disorder following the initiation of sibutramine therapy.[126] Other case reports associated the development of acute psychosis in patients without prior documented psychiatric disorders.[127,128] A 26-year old woman developed catatonia and psychosis while taking excessive doses of sibutramine (up to 60 mg daily) and following a restrictive diet.[129] Symptoms included mutism, flat affect, immobility, paranoid ideations, and auditory hallucinations. She improved dramatically following the cessation of sibutramine and the administration of risperidone. The psychosis resolved within 1 month of cessation of sibutramine therapy. The use of sibutramine is not associated with hepatotoxicity in clinical trials.

Overdose

There are few data on the clinical effects of sibutramine during an overdose. The clinical features of sibutramine intoxication probably are an exacerbation of the pharmacologic properties of this drug. A case report associated the development of serotonin syndrome (diaphoresis, tachycardia, hypertension, agitation, insomnia, incoordination, hypertonia, hallucinations)

with the ingestion of approximately 400 mg sibutramine (23 mg/kg) 25 hours prior to admission.[130] She developed mild rhabdomyolysis, but there were no significant abnormalities in the electrocardiogram or other blood chemistries. She was discharged with no sequelae after 6 days of supportive care.

Reproductive Abnormalities

There are few data on the reproductive effects of sibutramine. Case series suggest that this drug is not a major teratogen.[131] There were no malformation in 10 women exposed to sibutramine during their pregnancy.[132] In a convenience series of 52 women exposed to sibutramine during their first semester, there were no congenital abnormalities detected in their neonates within the first month of life.[133] Although there were 7 cases of hypertensive complication, the lack of a control group limits conclusions regarding the clinical significance of these complications.

DIAGNOSTIC TESTING

Analytic Methods

Techniques for the quantitation of sibutramine and active metabolites in biologic samples include HPLC,[134] isocratic LC with UV detection,[135] gas chromatography/electron ionization/mass spectrometry with methyl and trimethylsilyl derivation,[136] and liquid chromatography/electrospray ionization/tandem mass spectrometry.[137,138] Analysis with liquid chromatography/tandem mass spectrometry using a Chiralcel AGP chiral stationary-phase column allows the quantitation of sibutramine enantiomers.[139] The LOD for sibutramine metabolites using gas chromatography/electron ionization/mass spectrometry ranges from 10–50 ng/mL. The lower limit of quantitation (LLOQ) for liquid chromatography/electrospray ionization/tandem mass spectrometry ranges from about 0.1–0.3 ng/mL, whereas the coefficient variation ranges from about 2–5%. Gas chromatography/mass spectrometry methods are available to detect banned stimulants in urine including sibutramine (LOD, 10 ng/mL) that meet the standards of WADA.[140] Using liquid-liquid extraction, liquid chromatography/electrospray ionization/tandem mass spectrometry, and collision-induced dissociation, sibutramine and desmethyl metabolites in urine samples are detectable in the range of 6–40 ng/mL.[141] Sibutramine and related metabolites are not found in saliva with GC/MS, probably because extensive binding of conjugated metabolites to proteins limits diffusion of these compounds into saliva.

Biomarkers

In a study of fasted volunteers, mean peak plasma concentrations of sibutramine and the major metabolite, M2 were 2.98 ± 1.63 ng/mL and 7.65 ± 1.22 ng/mL, respectively.[142] The time to mean peak plasma concentrations were 1.14 ± 0.29 hours and 3.75 ± 1.78 hours, respectively. There are few data on the blood concentrations associated with sibutramine intoxication. Following ingestion of 10 mg sibutramine hydrochloride (8.37 mg free sibutramine), the hydroxylated metabolites are detectable for up to 60 hours as measured by GC/MS (LOD, 10 ng/mL).[136]

Abnormalities

Rare case reports document severe hyponatremia with sibutramine therapy, manifest by headache, nausea, generalized weakness, and confusion.[143] Although the etiology of the hyponatremia was ascribed to syndrome of inappropriate antidiuretic hormone (SIADH), there were no measurements of antidiuretic hormone concentrations. Severe hypoglycemia and coma developed in a patient receiving sibutramine for obesity and lorazepam for insomnia.[144]

TREATMENT

Treatment is supportive.

Chapter 15

ANABOLIC-ANDROGENIC STEROIDS

HISTORY

The use of drugs to enhance physical performance has occurred since the beginning of recorded time. Ancient Greeks ate mushrooms and sesame seeds to enhance performance, and Roman gladiators used stimulants to increase endurance.[1] In modern sports, documentation of the abuse of performance-enhancing drugs appeared in the early 1900s, when athletes ingested stimulants (cocaine, amphetamines, ephedrine, strychnine) to alleviate fatigue and increase focus.[2] Anabolic-androgenic steroids (AASs) are now the most common illicit drugs used to enhance performance at the modern Olympic Games along with stimulants, primarily by weightlifters and athletes in track and field.[3] The AASs are a group of synthetic derivatives of testosterone with both skeletal muscle-building (anabolic) and masculinizing (androgenic) effects. In 1889, physiologist Charles E. Brown-Sequard reported improvement in a variety of his body functions (strength, intellect, force of urine stream) following the injection of an extract of testicles from the dog and guinea pig. The primary natural male hormone, testosterone was first isolated from the testis of bulls in 1935 by David et al.[4] Butenandt[5] and Ruzicka[6] independently synthesized testosterone in the same year, and both chemists received the Nobel Prize in 1939 for their work. Most of the AASs were developed during the 1950s when chemists attempted unsuccessfully to separate the anabolic and androgenic properties of these testosterone derivatives.[7] Nandrolone, the 19-nor analog of testosterone was the first anabolic steroid with sufficient dissociation of androgenic and anabolic prop-

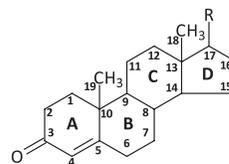
erties to justify introduction into clinical practice during the 1950s.[8] Dr. John Ziegler, an American physician-weightlifter, administered AASs to 3 future American weightlifting champions after learning of the success of AAS-using Russian weightlifters at the 1954 World Championships.[9] In 1958, the US Food and Drug Administration (FDA) approved the use of methandrostenolone (Dianabol) for the treatment of hypogonadism, resulting in the increased availability of this steroid. By the mid-1960s, the use of AASs to enhance performance in sports spread, particularly among weightlifters and other strength athletes. An estimated one-third of the US Track and Field athletes in the 1968 pre-Olympic training camp were using AAS.[10] From 1966 until the collapse of the German Democratic Republic (GDR) in 1990, hundreds of East German physicians and scientists performed doping research and administered prescription drugs as well as unapproved experimental drug preparations to adult and adolescent athletes of both sexes.[11]

In 1963, the Council of Europe defined doping in sports as a result of the death of a Danish cyclist at the 1960 Olympics, the death of a UK cyclist at the Tour de France, and the prevalence of potentially life-threatening drugs in sports.[2] In 1964, the International Olympic Committee (IOC) unanimously voted to ban doping in sports. By 1967, the IOC established a Medical Commission with responsibilities to prohibit doping, to develop the Olympic Movement Anti-Doping Code, and to formulate a list of prohibited substances. In 1974, the IOC banned the use of AASs and testing for AASs by immunoassay screening and gas chromatography/

mass spectrometry confirmation began in 1976.[12] In 1984, the use of testosterone was also banned. From the 1960s through the 1980s, the German Democratic Republic established a systematic doping program for thousands of their athletes that included the use of parenteral preparations of epitestosterone propionate to avoid detection of illicit AASs.[11]

In 1988, the IOC stripped Ben Johnson of his Olympic gold medal and world record in the 100-meter dash for using an AAS. In the same year, the distribution or possession of AASs with intent to distribute without a valid prescription became a felony, when US Federal Food, Drug and Cosmetic Act (FFDCA) was amended as part of the Anti-Drug Abuse Act. In 1990, the Anabolic Steroids Control Act defined an AAS as any drug or hormonal substance chemically and pharmacologically related to testosterone (other than estrogens, progestins, and corticosteroids) that promotes muscle growth. These synthetic compounds became DEA schedule III drugs as defined by the US Controlled Substances Act. Later, this act was amended by the Anabolic Steroid Control Act of 2004; on January 20, 2005, the amended Controlled Substance Act added both anabolic steroids and prohormones to the list of controlled substances, making possession of the banned substances a federal crime. In response to continuing demand for illicit AASs, designer AAS appeared as a means to avoid detection of these illicit drugs. An example was the synthesis of tetrahydrogestrinone from the palladium-charcoal catalyzed hydrogenation of gestrinone by the Bay Area Laboratory Cooperative, an American nutritional supplement company. However, analyses and legal action resulted in the banning of several athletes as a result of the use of these synthetic steroids. Subsequently, major league baseball revamped their AAS policy calling for a 50-game ban for first-time offenders (up from 10 days), a 100-game penalty for second-time offenders (up from 30 days), and a lifetime ban for a third positive test. Previously, a baseball player could be suspended for life only after the fifth positive test.

IDENTIFYING CHARACTERISTICS

Steroids are organic molecules with a tetracyclic ring system; all steroids with the exception of retinoic acid are derived from cholesterol. There are 4 major classes of natural steroid hormones (androgens, corticoids, estrogens, progestogens) with testosterone being the principal male androgenic steroid. AASs are synthetic compounds similar in chemical structure to testosterone (MW 288 g/mol). Figure 15.1 displays the chemical structures of common AASs. There are 3 major classes of AASs (oral, injectable oil-based, injectable water-


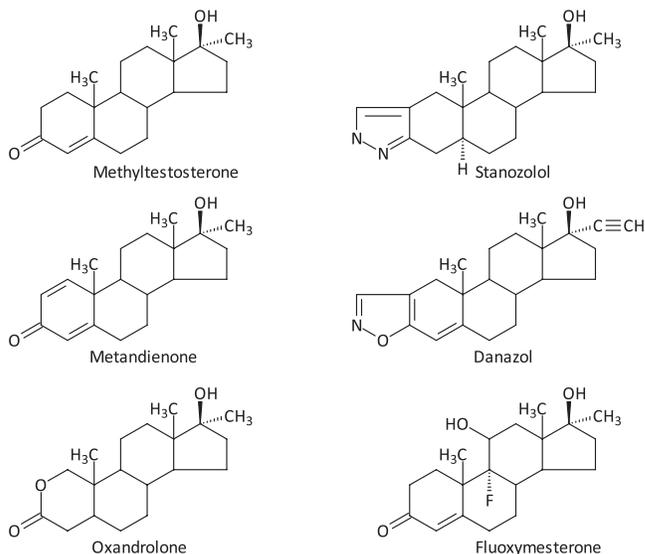
Compound	R
Testosterone	—OH
Testosterone Propionate	—O—OCOCH$_2$CH$_3$
Testosterone Enantate	—O—CO(CH$_2$)$_5$CH$_3$
Testosterone Cipionate	—O—COCH$_2$CH$_2$— (cyclopentyl)
Nandrolone Decanoate	—O—CO(CH$_2$)$_8$CH$_3$ *(no methyl group at position 19)*
Nandrolone Phenpropionate	—O—CO(CH$_2$)$_2$— (phenyl) *(no methyl group at position 19)*


FIGURE 15.1. Chemical structures of some common anabolic-androgenic steroids including testosterone. The compounds in the upper table are for parenteral administration, whereas the 6 compounds in the lower portion of the figure are for oral use. The 4 rings of the testosterone molecule are labeled A–D as indicated in the structure at the top.[122]

based) and at least 30 anabolic-androgenic steroid compounds. Table 15.1 lists the common oral and injectable anabolic-androgenic steroids. Abuse of other forms of AASs includes the use of buccal (Striant), sublingual (tetrahydrogestrinone), and transdermal (testosterone cream) preparations; these short-acting preparations

are typically testosterone-based. The advantage of the buccal, sublingual, and transdermal preparations is the rapid clearance within 1 week after even large doses compared with 2–14 days for oral preparations and 4 weeks for water-soluble parenteral preparations. Nonsteroidal selective androgen receptor modulators (SARMs) are experimental substances (e.g., bicyclic hydantoin, analogues of aryl propionamide, quinoline, tetrahydroquinoline) that may offer better dissociation of the biologic and anabolic effects of steroids; although these substances are not routinely available, the World Anti-Doping Agency (WADA) added these substances to the prohibited list in 2008. Up-to-date information on the list of banned substances is available on the WADA Web site (http://www.wada-ama.org/en/).

TABLE 15.1. Common Oral and Injectable Anabolic-Androgenic Steroids.

Oral AAS	Injectable AAS
Ethylestrenol	Boldenone undecylenate
Fluoxymesterone	Clostebol
Mesterolone	Drostanolone propionate
Metandienone	Isocaproate, decanoate
Metenolone	Methenolone enanthate
Methandrostenolone	Nandrolone decanoate
Methyltestosterone	Nandrolone phenpropionate
Methenolone acetate	Testosterone cypionate
Mibolerone	Testosterone enanthate
Norethandrolone	Testosterone propionate
Oxandrolone	Trenbolone*
Oxymetholone	Trenbolone acetate†
Stanozolol†	
Testosterone undecanoate	

*Veterinary steroid.
†Intramuscular use less common.

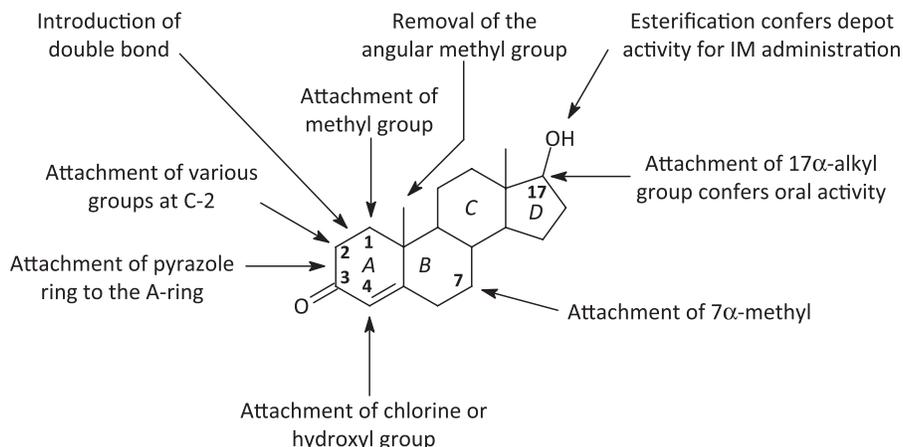
Testosterone (CAS RN: 58-22-0, 17-beta-hydroxyandrost-4-en-3-one) is the prototype for all AASs. Figure 15.2 displays modifications of the basic testosterone structure. Modification of testosterone during the synthesis of AASs involves the following three methods: alkylation of the 17β-hydroxyl group, esterification at the 17α-position, or modification of the steroid nucleus to enhance anabolic properties. Although all currently available anabolic steroids have androgenic properties, the anabolic properties are greater for synthetic AASs than for testosterone. Some structural modifications improve bioavailability and prolong the duration of action, whereas other modifications reduce anabolic effects while enhancing androgenic effects. Esterification at the 17β-hydroxy position increases lipophilic and androgenic properties while improving intramuscular bioavailability. In general, alkylation of the 17α-hydroxy position retards hepatic degradation and improves oral bioavailability, but these compounds typically are less potent than 17β-esters.[13] Weaker formulations of AASs are often marketed as prohormones in dietary supplements, particularly dehydroepiandrosterone (DHEA), 19-norandrostenediol, androstenedione, 19-norandrostenedione, 1-testosterone, and prostanozol.[14] The lack of the 17α-alkyl moiety results in extensive first-pass metabolism, and the anabolic effect of DHEA and androstenedione are limited by their weak binding to the androgen receptor despite some conversion to testosterone. The effect of these AASs are substantially greater on women than men because of the relatively larger increase in testosterone in the former. Tetrahydrogestrinone (THG; 13-ethyl-17-hydroxy-18,19-dinor-17α-pregn-4,9,11-trien-3-one), norbolethone (CAS RN: 1235-15-0; 13-ethyl-17-hydroxy-18,19-dinor-17α-pregn-4-en-3-one) and madol


FIGURE 15.2. Basic structure of testosterone with an overview of structure–activity relationships.[51]

(17 α-methyl-5α-androst-2-en-17β-ol) are designer anabolic steroids, which were synthesized to avoid detection during use.[15,16] However, THG is a nonspecific androgen agonist that binds many steroid hormone receptors, particularly the glucocorticoid receptors.[17]

EXPOSURE

Epidemiology

Data on the actual prevalence of AAS use are limited by recall and reporting biases associated with illicit drug use. Many studies of AASs use focus on adolescents. In a nationwide study of 3,403 12th-grade male students in 46 private and public US high schools during the 1980s, 6.6% of the respondents admitted to ever using AASs based on their response to questionnaires.[18] The individual participation rate was low (50.3%). Almost 40% of the respondents admitted to the administration of 5 or more cycles of AASs. Further studies performed at local and statewide levels have confirmed similar findings indicating that 3–12% of high school male adolescents use AASs at some time in their lives. These studies indicate that about one-third of the high school students use AASs for appearance rather than athletic performance. In 1999, the National Institute on Drug Abuse Monitoring the Future study indicated that approximately 2.7% of US 8th and 10th graders and 2.9% of 12th graders admitted to the use of AASs at least once.[19] For 10th graders, the prevalence of AAS use increased to 2.7% in 1999 from 2.0% in 1998. For all 3 grades, the 1999 levels represented a significant increase from 1991, when 1.9% of 8th graders, 1.8% of 10th graders, and 2.1% of 12th graders admitted AAS use at least once. The data on adolescent use of AAS in 2004 and 1999 were similar with 2.5% of 12th graders reporting the use of AASs at least once.[20] Risk factors for the use of AASs among adolescents include male sex, participation in strength-related sports, and use of other illicit drugs.[21] In college and professional athletics, the prevalence of AAS abuse is less defined because of the ramification of AAS use. However, the prevalence of AAS use among these groups is probably substantially higher than high school students, particularly in football players and male track and field athletes.[22] Between 1972 and 2000, there were 29 athletes disciplined for positive AAS drug tests.[3] However, the abuse of AASs is probably more widespread among these athletes because of the difficulty detecting all AAS use and the small number of doping charges compared with the number of positive drug tests. Current trends suggest that most AAS abusers are nonathletes using these drugs for cosmetic purposes.[23] The most common steroids involved with doping are testosterone and nandrolone based on WADA data[24] and retrospective autopsy data.[25] In 2006, 34 WADA-accredited laboratories analyzed almost 200,000 urine samples with positive findings in approximately 2%.[26] Of the positive samples, AASs accounted for 45% of the adverse findings with the most common AASs being testosterone, nandrolone, stanozolol, and methandienone.

Sources

Anabolic-androgenic steroids were developed to treat hypogonadism, a condition in which the testes do not produce sufficient testosterone for normal growth, development, and sexual functioning. Clinical studies suggest that the use of AASs (e.g., nandrolone) or testosterone improves lean body mass in patients with mild to moderate cachexia secondary to chronic illness (e.g., human immunodeficiency virus [HIV]).[27] The use of testosterone and AAS has not been effective for the treatment of the catabolic states associated with severe burns or muscle-wasting diseases. Historical uses of AASs include anemia, hereditary angioedema, metastatic breast cancer, protein deficiencies following trauma or severe infections, and certain psychiatric disorders (involutional psychoses, depression).[28]

Origin

In the United States, AASs are DEA schedule III drugs of the Controlled Substances Act. The primary sources for illicit AASs in the United States are manufacturing facilities in Mexico.[23] Traffickers from the United States enter Mexico and purchase AASs at pharmacies in Baja, California, where AASs are available by prescription. They subsequently smuggle the AASs back into the United States. Other sources of illicit AAS in the United States include Russia, Poland, Hungary, Spain, Italy, Greece, Canada, and the Netherlands as well as some clandestine labs in the United States. The diversion of legitimate pharmaceutic preparations provides a much smaller portion (i.e., 10–15%) of illicit AASs compared with other illicit sources.[29] Information on the administration and procurement of AASs is widely available on the Internet.[30]

Impurities

There are few data on the purity of illicit samples of AASs as a result of the lack of regulation. Consequently, there are no assurances that the chronic AAS abuser knows the dose or type of AAS. The difficulty determining doses used by AAS abusers limits the ability of

studies to elucidate the effect of AAS abuse. Frequently, illicit samples of AASs do not contain declared ingredients or concentrations of ingredients. Analysis of 70 products confiscated from illegal sources demonstrated 17 (35.4%) of the 48 steroidal compounds did not contain labeled ingredients as measured by liquid chromatography/tandem mass spectrometry, gas chromatography/mass spectrometry with nitrogen phosphorus detection, gel electrophoresis, and immunological tests.[31] Visual inspection did not distinguish original products from counterfeits.

Methods of Abuse

The pattern of AAS abuse among athletes is quite variable, and the dosing intervals are not usually regular. These patterns include stacking, tapering, plateauing, cycling, and pyramiding. Many AAS abusers are polydrug users including the abuse of traditional recreational drugs and misuse of prescription drugs.[32] Athletes typically administer AAS intramuscularly (IM) with or without oral preparations in cycles lasting 6–12 weeks with periods of abstinence between these cycles as a means to reduce adverse effects.[29] The abuse of transdermal patches, sublingual tablets, dermatologic gels, and nasal sprays is rare. In an attempt to maximize anabolic gains and minimize side effects, some AAS users start with low doses at the beginning of a cycle and then steadily increase the dose until a gradual "tapering" phase at the end of a cycle (i.e., "pyramid" regimen). Frequently, these athletes use more than 1 steroid simultaneously (i.e., "stacking") or use several AASs in overlapping patterns to avoid the development of tolerance (i.e., "plateauing"). In an Internet study of 207 weightlifters and bodybuilders using AASs, the steroid regimens included a mean of 3.1 agents with cycles ranging from 5–10 weeks and AAS doses 5–29 times above physiologic replacement doses.[33] Often these athletes ingest other drugs (i.e., "array") as a means to reduce adverse effects and enhance the effect of AASs. These additional medications include human chorionic gonadotrophin, anti-acne drugs, oral hypoglycemic agents, analgesics, ketoconazole shampoo, stimulant amino acids, erythropoietin, aminoglutethimide, diuretics, and estrogen antagonists.[34] The abuse of AASs continues, in part, because of the effectiveness of these regimens with training programs and the perceived difficulty detecting AAS use, particularly in weightlifters.[35] Commonly abused steroid supplements (i.e., precursors of testosterone and related hormones) include androstenedione and DHEA. The latter compound is an endogenous hormone secreted by the adrenal cortex in response to adrenocorticotropin (ACTH).[36]

DOSE EFFECT

The dose of AAS used by athletes depends on individual needs and the athletic requirements of the particular sport. Endurance athletes use AAS doses near or slightly below physiologic replacement concentrations (i.e., about 7 mg testosterone daily) as a means to block catabolism, while sprinters typically use 1.5–2 times replacement concentrations.[29] Traditional strength athletes use much higher doses (i.e., 10–100 times replacement concentrations) to "bulk up." Generally, the dose of AASs is lower in women than men.

Data from human test participants indicate that AAS produce a dose-dependent and sex-dependent increase in lean body mass and strength, but the changes are highly variable and relatively small without an accompanying conditioning and strength program.[37] The administration of AAS to men participating in weight training consistently produces increased strength when compared with controls (i.e., weight training alone).[28] The endogenous testosterone production during male adolescence produces a sex differential in lean body mass similar to the increment in lean body mass caused by the administration of exogenous AAS to adults.[38] However, different androgen-dependent processes have different testosterone dose-response relationships. In a study of 61 eugonadal men receiving a long-acting gonadotropin-releasing hormone agonist to suppress endogenous testosterone secretion, changes in leg press strength, leg power, thigh and quadriceps muscle volumes, hemoglobin, and insulin-like growth factor 1 (somatomedin C) positively correlated to testosterone concentrations.[39] Changes in fat mass and plasma high-density lipoprotein (HDL) cholesterol were negatively correlated to the testosterone dose.

Although adverse effects following AAS administration are usually dose related, there are few data on the long-term physiologic effects of chronic AAS use, particularly in women. In addition to dose and duration of use, long-term toxicity depends on the age of initiation, gender, steroid structure, and concurrent illicit use of other drugs. The daily production of testosterone in healthy men is about 4–10 mg compared with about 1 mg in healthy women.[40] Psychotic symptoms associated with AAS abuse typically occur in individuals using >1 g testosterone weekly, but the development of psychologic changes is highly variable. In a randomized, placebo-controlled, crossover trial of 56 healthy men aged 20–50 years, the administration of testosterone cypionate for 6 weeks in doses increasing to 600 mg/wk caused little psychologic change in most participants (i.e., 84%).[41] The regimen produced mild hypomania in 12% and marked hypomania in 4% of the men.

TOXICOKINETICS

Most of the data on the kinetics of testosterone and AASs is derived from the pharmacokinetics of these compounds in animals or in hypogonadal males receiving therapeutic doses of AASs.[42] There are few data on the toxicokinetics of AASs in individuals abusing AASs at doses up to 10–100 times the therapeutic dose.

Absorption

Despite the rapid absorption of testosterone, the systemic bioavailability of oral testosterone is low as a result of extensive first-pass hepatic metabolism. Structural modifications of testosterone produce synthetic testosterone derivative (anabolic-androgenic steroids), which increase bioavailability and prolong the duration of action. Alkylation of the 17-α position of testosterone produces oral AAS, whereas esterification of the 17-β position results in injectable AAS (e.g., lipid-soluble cypionate or enanthate). The duration of action of these esters depends on the rate of absorption from the site of administration as determined by the chain length of the acid moiety and the formulation. Hydrolysis of these esters *in vivo* prolongs the duration of action compared with testosterone. Anabolic-androgenic steroids can diffuse across the skin and mucous membranes, allowing other delivery modes including transdermal patches, nasal sprays, and buccal tablets. Following oral administration of 120 mg testosterone undecanoate, volunteer studies indicate that plasma concentrations of testosterone are detectable for about 1–6 hours after administration using gas chromatography/tandem mass spectrometry.[43] There are dramatic individual variations (i.e., 10-fold) in the peak total plasma testosterone concentrations. In a study of 61 eugonadal men receiving long-acting gonadotropin-releasing hormone agonist to suppress endogenous testosterone secretion, the mean nadir testosterone concentrations ranged from 2.53–23.7 ng/mL following weekly injections of testosterone enanthate doses of 25–600 mg for 20 weeks.[39]

Distribution

Anabolic-androgenic steroids are bound in the plasma to sex-hormone-binding globulins. Although testosterone is highly protein bound (i.e., 98%) in plasma, the binding of AAS to sex-hormone-binding globulins is highly variable based on animal studies.[44]

Biotransformation

The metabolism of endogenous testosterone involves the conversion to the estrogenic compound, estradiol via steroid aromatase and the androgenic compound, 5α-dihydrotestosterone via 5α–steroid-reductase. Comparatively, the biotransformation of AASs is quite complex.[45] Table 15.2 lists the principal urinary metabolites of common AASs. The initial and rate-liming step in testosterone metabolism is reduction of the C4-C5 double bond on the A ring with 5α-reductase and 5β-reductase. Hydroxylation of testosterone by CYP450 isoenzymes results in the formation of a variety of minor urinary metabolites of testosterone. Single-dose human excretion studies indicate that 6-β-hydroxylation is also a minor pathway for the biotransformation of boldenone (17β-hydroxyandrosta-1,4-dien-3-one) and 17α-methyltestosterone.[46] However, 6β-hydroxylation of the B-ring is the major metabolic pathway for 4-chloro-1,2-dehydro-17-α-methyltestosterone, methandienone, and fluoxymesterone because the presence of a C1-C2 double

TABLE 15.2. Major Urinary Metabolites of Common Anabolic Androgenic Steroids.

Compound	Major Urinary Metabolite
17α-Alkyl Esters (*Oral*)	
Methandienone	17α-Methyl-5β-(α)-androstan-3α,17β-diol; 17α-methyl-5β-androst-1-en-3α,17β-diol; 17α-methyl-1,4-androstadien-6β,17β-diol-3-one
17α-Methyltestosterone	17α-Methyl-5β-(α)-androstan-3α,17β-diol
Oxandrolone	17-Epimer *
Oxymesterone	17α-Methyl-5-androstan-3,4,17-triol isomers
Stanozolol	3′-Hydroxystanozolol, 4β-hydroxystanozolol
17β-OH Esters (*Parenteral*)	
Boldenone	5β-Androst-1-en-17β-ol-3-one
Drostanolone	2α-methyl-5α-androstan-3-ol-17-one
Methenolone	18-Hydroxylated and several metabolites
Nandrolone (19-nortestosterone)	19-Norandrosterone (19-noretiocholanolone)

*Urinary excretion of unchanged oxandrolone also occurs.

bond in the former 2 steroids and the C9 α-fluorine atom in the latter compound blocks A-ring reduction. Metabolic changes (e.g., 12-hydroxylation) of AASs at the C-ring are minor. D-ring metabolism by the enzymatic oxidation of 17β-hydroxysteroid dehydrogenase to form the corresponding 17-keto steroid is a major metabolic pathway for testosterone and all AASs with secondary 17β-hydroxy groups (e.g., boldenone, clostebol, drostanolone, mesterolone, methenolone, nandrolone, norclostebol, stenbolone).[47] The main urinary metabolites of testosterone are androsterone (3α-hydroxy-5α-androstan-17-one), etiocholanolone (3α-hydroxy-5β-androstan-17-one), epiandrosterone (3β-hydroxy-5α-androstan-17-one), 5α-androstane-3α, 17β-diol, and 5β-androstane-3α,17β-diol.

Elimination

In individuals without AAS use, only small amounts (i.e., about 1%) of endogenous testosterone appears unchanged in the urine. Phase II conjugation reactions couple AASs and associated metabolites with glucuronic acid or sulfate before excretion in the urine. The vast majority (i.e., about 90%) of the absorbed dose of testosterone appears in the urine as glucuronide or sulfate conjugates. In a study of 8 hypogonadal males, the terminal elimination half-lives of 500 mg and 1,000 mg IM doses of testosterone undecanoate were 18.3 ± 2.3 days and 23.7 ± 2.7 days, respectively.[48] The mean residence times were 21.7 ± 1.1 days and 23.0 ± 0.8 days, respectively. Not all anabolic steroids undergo phase II reactions. Unconjugated AASs in human urine include oxandrolone, fluoxymesterone, 4-chloro-1,2-dehydro-17α-methyltestosterone, and formebolone along with metabolites of oxandrolone, methandienone, and stanozolol.[45] There is very limited (i.e., about 5%) enterohepatic recirculation of testosterone.

Maternal and Fetal Kinetics

Anabolic-androgenic steroids readily cross the placenta. Abnormal urogenital virilization occurs in females secondary to prenatal exposure to exogenous or endogenous androgens. In rodent studies, the parenteral administration of testosterone on gestational days 14–18 causes urogenital sinus elongation in a female mouse fetus.[49]

Drug Interactions

There are few data on the drug interactions of AASs. Rare case reports associate enhancement of anticoagulant effects with the use of AASs (e.g., oxymetholone).[50]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

Testosterone is both an active hormone and a prohormone for the formation of the more active androgen, 5α-dihydrotestosterone (DHT) via 5α-reductase. Figure 15.3 displays the synthesis and metabolism of testosterone and other endogenous steroids. The production of testosterone occurs predominantly (i.e., 95%) in the Leydig cells of the testes and, to a lesser, extent in the adrenal glands. The secretion of androgens from the adrenal cortex is insufficient to maintain male sexuality. Women also secrete small amounts of testosterone from the ovaries and adrenal glands including DHEA and androstenedione. Testosterone acts as an androgen either directly by binding to the androgen receptor or indirectly by conversion to DHT. This latter compound binds more avidly to the androgen receptor than testosterone. Dihydrotestosterone amplifies the action of androgen and conveys specific function to the androgen-androgen receptor complex.[51] The conversion of testosterone to DHT is especially important for the appearance of virilization in female AAS users because high levels of 5α-reductase activity in the male accessory sex glands limits the effect of DHT. Activation of the intracellular, ligand-dependent androgen receptor complex by testosterone and AAS results in the production of RNA, DNA, and the subsequent enhancement of protein synthesis including increased amounts of actin and myosin in skeletal muscles. The androgen receptor belongs to the nuclear receptor family that contains a DNA-binding domain, a ligand-binding domain, and at least 2 transcriptional activation domains. The enzyme, aromatase controls the androgen/estrogen ratio by catalyzing the conversion of testosterone to estradiol in other tissues (e.g., adipose tissue, brain). Anabolic-androgenic steroids (e.g., methandienone, nandrolone, stanozolol) with the most potent anabolic effects also possess the relatively greatest androgenic effects. The interactions of AAS with the androgen receptors in various tissues vary between compounds in this group, and these variations account for differences in the anabolic and androgenic effects of these compounds. The use of AAS increases skeletal muscle mass and strength when used in combination with intensive strength training and high-protein, high-calorie diets.[52]

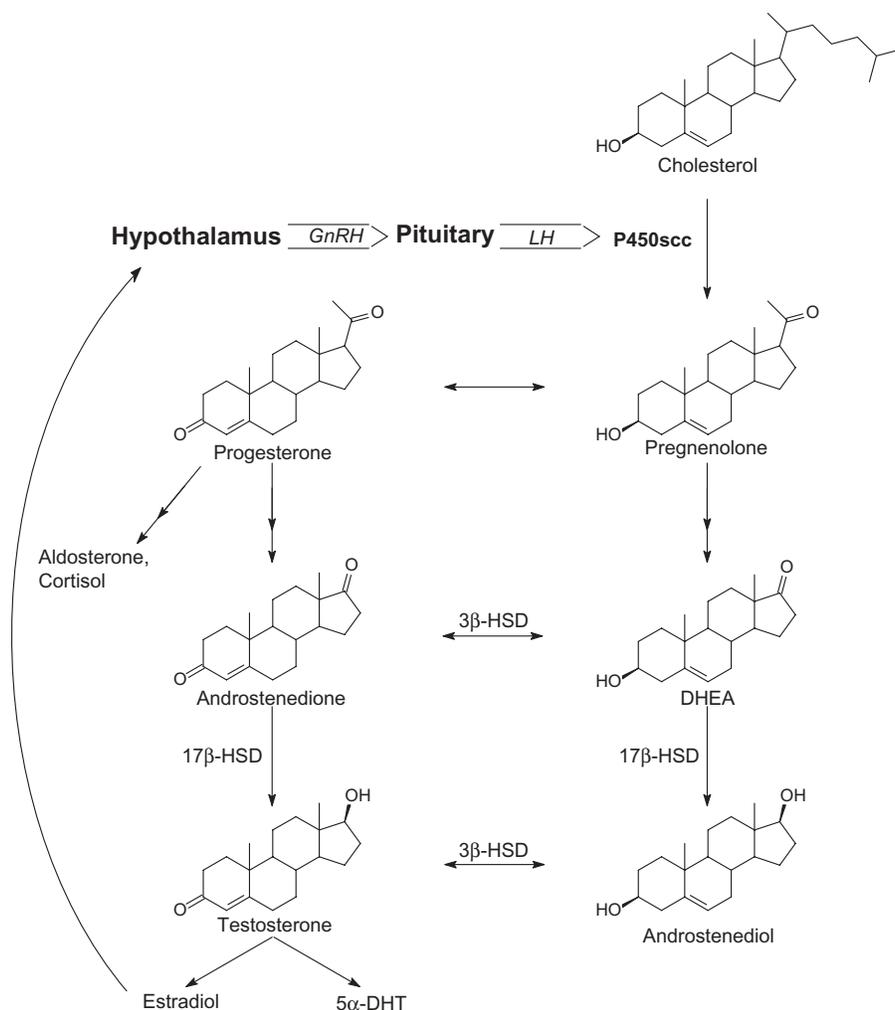
Endogenous testosterone is responsible for sexual maturation at all stages of development throughout the life of males. Increased AAS plasma concentrations suppress gonadotropin-releasing hormone, endogenous testosterone secretion, luteinizing hormone, and follicle-stimulating hormone by a negative-feedback


FIGURE 15.3. Biochemical synthesis and metabolism of endogenous steroids. The administration or formation of testosterone causes a downregulation of luteinizing hormone and a reduction in the endogenous formation of steroids via a negative feedback mechanism. GnRH = gonadotropin releasing hormone; LH = leuteinizing hormone; P450scc = cholesterol-side-chain-cleavage enzyme; 3β-HSD = 3β-hydroxysteroid dehydrogenase; 17β-HSD = 17β-hydroxysteroid dehydrogenase; DHEA = dehydroepi-androsterone; 5α-DHT = 5α-dihydrotestosterone.

mechanism. Endogenous androgens stimulate RNA polymerase, resulting in an increased production of protein. These proteins are responsible for normal male sexual development, including the growth and maturation of the prostate, seminal vesicle, penis, and scrotum. During puberty, androgens cause a sudden increase in growth and development of muscle along with redistribution of body fat and deepening of the voice. Continued endogenous testosterone secretion produces increased hair (beard, body hair), fusion of the epiphyses, termination of growth, and the maintenance of spermatogenesis. Testosterone also affects the formation of erythropoietin, the balance of calcium, and blood glucose concentrations.

Mechanism of Toxicity

Most of the adverse effects following the use of AASs result from the enhancement of normal physiologic response to testosterone by either direct receptor agonist activity or suppression of steroid biosynthesis. In general, toxic effects associated with AAS abuse involve the following: 1) anabolic side effects, 2) enhanced androgenic effects, 3) estrogenic side effects, 4) antiandrogenic effects from the suppression of the hypothalamus–pituitary–adrenal/gonadal axes, 5) hepatotoxicity, and 6) neuropsychiatric effects.[53] Methodologic issues limit the determination of the toxic effects of illicit AAS use including the extraordinary doses and

types of AASs used by athletes compared with medical use, reporting bias of self-reports, the paucity of well-documented pathologic findings, and the lack of well-defined postmortem markers of AAS use.[53] Most medical data on the toxic effects of AAS abuse involve case reports rather than epidemiologic studies. Pathologic abnormalities from AAS abuse are best-documented in the cardiovascular system, reproductive system, liver, and serum lipids. Animals studies suggest that AAS can cause dysplasia of collagen fibrils and decreased tensile strength, and potentially the use of these drugs could cause disruption of connective tissue.[54]

CARDIOVASCULAR SYSTEM

Potential adverse effects of AAS on the cardiovascular system include atherogenesis, thrombosis, vasospasm, myocarditis, concentric left ventricular hypertrophy, myocardial fibrosis, hypertrophic cardiomyopathy with ventricular dysrhythmias, and direct myocardial injury.[55] However, the contribution of AAS use to these potential adverse cardiovascular effects remains unclear.[56] Chronic AAS use enhances hepatic triglyceride lipase activity, resulting in reduction of high-density lipoproteins and elevation of low-density lipoproteins.[57,58] Although these changes are reversible within several months of cessation of AAS use, chronic AAS use theoretically increases the risk of cardiac disease.[30] Potentially, the chronic abuse of AAS enhances coagulability and thrombosis, but the clinical importance of this potential adverse effect also remains unclear. Studies of chronic AAS abuse in weightlifters suggest that some anabolic-androgenic steroid-using weightlifters have accelerated activation of their hemostatic system as evidenced by increased generation of both thrombin and plasmin. A study of AAS-positive steroid using weightlifters indicated that these individuals had a higher percentage of abnormally high plasma thrombin–antithrombin complexes along with elevated plasma concentrations of prothrombin fragment 1, antithrombin II, and protein S, when compared with non-AAS-using controls.[59] Additionally, the plasma concentrations of tissue plasminogen activator and its inhibitor were lower in AAS users than in controls.

Clinical studies on bodybuilders suggest that chronic AAS use impairs vascular reactivity independent of the smooth muscle hypertrophy and vascular stiffness associated with bodybuilding.[60] Anabolic-androgenic steroids decrease the production of cyclic guanosine monophosphate (cGMP) by inhibiting guanylyl transferase. As a result, AASs potentially inhibit the ability of nitric oxides to relax smooth muscles in the coronary arteries resulting in coronary artery vasospasm and potentially sensitizing AAS users to sudden death.[55]

Case reports associate the chronic use of anabolic steroids with sudden death and contraction band necrosis in the myocardium.[61] In these cases, no other cause of death was apparent, but the role of chronic, high-dose anabolic steroid use in these deaths remains unclear. Athletes with certain genetic mutations and structural abnormalities may be particularly vulnerable to the use of anabolic steroids including athletes with accessory AV pathways, latent structural heart diseases (dilated cardiomyopathy, arrhythmogenic right ventricular dysplasia type II, myocarditis, segmental arrhythmogenic ventricular cardiomyopathy, coronary artery anomalies), latent Brugada syndrome, mutations of the long QT syndrome genes, and other genetic mutations of ion channels (cardiac ryanodine receptor gene defects, calsequestrin gene defects).[62,63] Pathologic evidence of some of these abnormalities may not appear on postmortem examination. The use of diuretics to mask the use of anabolic steroids may predispose these athletes to serious ventricular dysrhythmias from hypokalemia and dehydration.

LIVER

Cholestatic jaundice with intrahepatic cholestasis and variable degrees of hepatocellular necrosis on liver biopsy is the most commonly reported serious pathologic abnormality of the liver associated with AASs abuse.[64] Rarely, case reports associate the presence of multiple, dilated liver cysts filled with blood in the liver (peliosis hepatitis) with chronic use of AASs.[65] The pathogenesis of peliosis hepatis is unknown. Other pathologic abnormalities of the liver detected in the autopsy of AAS abusers include focal nodular hyperplasia and adenomas.[66,67]

REPRODUCTIVE SYSTEM

Although the same androgen receptor mediates both the anabolic and androgenic effects of steroids, the specific structural characteristics of individual AASs determines the balance between anabolic and androgenic effects. Masculinization results from the presence of high doses of AASs in women. The aromatase cytochrome P450 (CYP19) enzyme complex converts testosterone to estradiol, which binds to the estrogen receptor. Although this conversion usually accounts for a small percentage of testosterone biotransformation at physiologic doses, excess amounts of testosterone increase the formation of estradiol. Gynecomastia is a consequence of excessive estradiol concentrations in chronic male AAS abusers that result from the peripheral conversion of excess testosterone to estradiol. Drugs used by male AAS abusers to prevent the feminizing effects

of estradiol include the use of aromatase inhibitors (e.g., anastrozole, aminoglutethimide) and drugs that block estrogen receptor (clomiphene, tamoxifen).

Postmortem

Concentric left ventricular myocardial hypertrophy is a common pathologic finding following the chronic use of AAS. A 21-year-old, previously healthy weightlifter collapsed during a bench press workout, and paramedics found him in ventricular fibrillation. For the preceding several months, he used parenteral AASs (nandrolone, 19-nortestosterone). Postmortem findings included marked cardiac hypertrophy, regional myocardial fibrosis, and focal myocardial necrosis along with hepatosplenomegaly and renal hypertrophy.[68] There was no evidence of recent myocardial inflammation. Other autopsies of AAS abusers have not demonstrated cardiac hypertrophy, but histologic examination of cardiac tissue also detected focal myocardial necrosis. The postmortem examination of 2 cases of sudden death in 2 previously healthy chronic AAS abusers (i.e., bodybuilders) demonstrated focal myocardial necrosis (contraction band necrosis) without evidence of significant coronary artery disease or myocardial hypertrophy.[61] Other pathologic changes associated with cardiac arrest in previously healthy athletes following AAS use (e.g., oxymesterone) include hypertrophic cardiomyopathy, acute cellular necrosis,[69] interstitial fibrosis, and myocarditis.[70] Typically, there is no evidence of coronary thrombosis in these cases of sudden death. However, evidence of recent (i.e., 2 weeks) myocardial infarction may occur in these cases without evidence of coronary artery disease.[71] Rarely, the abuse of androgenic-anabolic steroids are associated with the development of blood-filled cysts (peliosis) involving the liver, spleen, bone marrow, lymph nodes, and lung. A 29-year-old bodybuilder was found dead at home; an autopsy demonstrated peliosis of the lung with the left pleural cavity filled with blood.[72]

CLINICAL RESPONSE

Illicit Use

There are limited data on the short-term complication of AAS use with most data involving case reports. The long-term health effects of chronic AAS abuse are not well defined because of the difficulty studying illicit drug use and the highly variable dosages involved with AAS abuse. Clinical and laboratory studies indicate that the administration of AASs causes physiologic changes, primarily in the liver, reproductive system, and serum lipids.[64,73] The use of AAS produces an unfavorable change in the blood lipid profile (i.e., elevated low-density lipoprotein, reduced high-density lipoprotein) with potentially increased risk of coronary heart disease; although conflicting, some data suggest left ventricular hypertrophy may persist after cessation of AAS use as a result of elevated blood pressure during use.[74,75] Other potential adverse effects include glucose intolerance (i.e., increased peripheral insulin resistance), hyperinsulinism, behavioral and mood changes, cerebrovascular accidents, prostate abnormalities, edema, and immune dysfunction. Most physiologic changes associated with AAS use are reversible within several months of the cessation of AAS use.[29]

Behavioral Abnormalities

Individual behavioral and psychiatric responses to chronic AAS abuse are extremely variable, depending on pre-existing psychiatric conditions, personality, and type and dose of AAS. Case reports and some epidemiology studies associate chronic AAS use with changes in behavior, mood, and somatic perceptions in a small subset of chronic AAS abusers.[76,77] Psychiatric complication associated with chronic AAS use include mania, aggression, and agitation, but no large-scale epidemiologic studies have confirmed a causal relationship between chronic AAS abuse and severe psychiatric complications (e.g., psychosis).[78,79] Depression may occur, particularly in the immediate period after cessation of use, along with fatigue, decreased libido, insomnia, anorexia, and headaches.[80,81] Studies suggest that male AAS users have more frequent and prolonged periods of anger, aggression, irritability, and hostility than nonusers.[82,83] Multivariate models based on data from the National Longitudinal Study of Adolescent Health ($N = 6,823$) indicate that young men using anabolic-androgenic steroids report greater involvement in violent behaviors than nonusers after control for the effects of key demographic variables, previous violent behavior, and polydrug use.[84] In a study of 2 sets of male monozygotic twins with only 1 twin using AASs, the use of AASs was associated with anxiety, hostility, aggressiveness, and paranoid ideations as determined by comparing responses to a Symptoms Check list-90 and the Hostility and Direction of Hostility Questionnaire.[85] Behavioral abnormalities include distractibility, delirium, delusions, irritability, paranoia, impulsivity, insomnia, hostility, anxiety, agitation, aggression, violence, and mood lability.[86,87] These behavioral effects are dose dependent with effects ranging from mild effects (increased confidence, enhanced self-esteem, euphoria) to serious behavioral abnormalities

(mood swings, grandiose thinking, paranoia, impulsivity, hostility, violence, and antisocial behavior).[80]

MOOD DISORDERS

The true prevalence of these neuropsychiatric disorders is difficult to determine, but relatively few individuals develop these adverse effects; they are found primarily in high-dose chronic AAS abusers. In a study of 88 AAS-using athletes and 68 nonusers, the incidence of major mood disorders (mania, hypomania, major depression) was significantly more frequent ($P < .01$) in steroid users compared with nonusers.[88] Additionally, these mood disorders were more frequent ($P < .001$) in current AAS users than in abstinent AAS users.

MEDICAL COMPLICATIONS

CARDIOPULMONARY. Several case reports associate the chronic use of AAS with serious cardiovascular complications including acute myocardial infarction, cardiac arrest, and hypertrophic cardiomyopathy without significant cardiac valvular or coronary artery disease.[68,70] Case reports associate chronic AAS abuse with myocardial infarctions in young men with and without evidence of coronary artery occlusion; the presence of coronary artery disease in these athletes occurs despite the lack of known risk factors for coronary artery disease.[89,90] The development of an acute myocardial infarction was associated with high-dose AAS abuse (e.g., 6 weeks daily, 2 years intermittently) by a 44-year-old recreational bodybuilder with diffuse coronary artery disease and multiple myocardial risk factors including polycythemia, smoking, and family history of early coronary artery disease.[91] Left ventricular hypertrophy is a common structural abnormality in bodybuilders with AAS abuse. A study of 21 bodybuilders with reported AAS abuse suggests that concentric hypertrophy of the left ventricular wall and impaired diastolic function are common complications of steroid abuse.[92] Echocardiographic studies of these athletes demonstrated increased left ventricular posterior wall thickness and end-diastolic volumes as well as decreased ratios of ventricular end-diastolic diameter to body mass. A case report of 2 previous healthy bodybuilders associated sudden cardiac death with chronic AAS abuse.[61] There was evidence of focal myocardial necrosis without clinically significant coronary artery disease, but the role of chronic AAS abuse in the cardiac arrest remains unclear. Ventricular dysrhythmias are not commonly associated with chronic AAS abuse. Several case reports associate persistent atrial fibrillation with chronic AAS use.[93] A 22-year-old man developed generalized weakness, diaphoresis, anxiety, and dyspnea.[94] The electrocardiogram revealed rapid atrial fibrillation and the echocardiogram indicated an early cardiomyopathy. He had gynecomastia, and he admitted to the recent injection of anabolic steroids. Although there is no direct evidence that AASs are thrombogenic in humans, case reports suggest a possible causal relationship between AAS use and thrombogenic events (e.g., massive pulmonary embolus, cerebral thrombosis, cardiomyopathy with congestive heart failure, biventricular thrombi, hepatorenal dysfunction).[95,96] Studies on the association between chronic AAS use and hypertension or left ventricular hypertrophy are inconsistent.[97]

CENTRAL NERVOUS SYSTEM. Several case reports associated chronic AAS abuse with the development of seizures, ischemic midbrain lesions with residual dysfunction (hemiparesis, aphasia, dysarthria),[98] and thrombotic strokes,[99] but the causal link between cerebrovascular accidents and chronic AAS abuse is unproven. A 34-year-old bodybuilder developed an acute right hemiparesis and dysarthria after using various AAS for 4 years.[100] He had a simple partial seizure. At discharge, he had mild motor weakness in the right upper extremity with no sensory changes. A 21-year-old man developed a generalized tonic-clonic seizure left-sided hemiparesis after using 6–8 mg ethylestrenol daily for 6 weeks.[101] Angiography demonstrated an occlusion of the right anterior cerebral and right middle cerebral arteries. In a retrospective cohort study of 248 patients testing positive for the presence of AAS in connection with receiving medical care, the incidence of unspecified convulsions was increased in the AAS-positive group (RR = 53.9, 95% CI = 7.0–415.7) when compared with controls (i.e., patients testing negative for AAS at the same institution).[102] One of the AAS-positive patients with seizures died. However, there are few data from cohort or case-control studies to confirm the causal link between AAS abuse and seizures.

IMMUNE SYSTEM. Anabolic-androgenic steroids are potentially immunosuppressive based on a study suggesting that chronic AAS abuse reduces immunoglobulins (i.e., IgA), increases natural killer cell activity, and increases mitogen response to staphylococcal antigens.[103] There were no significant differences in T-cell subsets among steroid users and nonusers in this study. However, the clinical relevance of these potential immunosuppressive effects is unclear. Sporadic case reports associated infectious complications from the parenteral use of AASs including local abscess at the site of injection,[104] septic arthritis,[105] HIV,[106] and hepatitis,[107] usually as a result of sharing contaminated needles.

285

LIVER.   Case reports associate AAS abuse with hepatic enlargement, peliosis hepatis, serious cholestatic jaundice [2,17-dimethyldihydrotestosterone (methasterone)],[108,109] and hepatorenal failure, particularly following the use of oral 17α-alkylated AAS (e.g., methandrostenolone, methyltestosterone, oxymetholone, oxandrolone, stanozolol).[66,110] Typically, non-17-alkylated anabolic steroids are not associated with hepatocellular damage.[111] Jaundice typically resolves several months after cessation of AAS use, and liver transplantation is not usually necessary. Case reports also associate the use of high doses of AAS with the development of hepatocellular necrosis. A 26-year-old male bodybuilder reportedly used testosterone enanthate (500 mg IM twice weekly), stanozolol (40 mg orally/day), and methylandrostenediol (30 mg/day orally for 5 weeks). He subsequently developed evidence of severe hepatitis with hepatic dysfunction that required a prolonged hospitalization.[112] Peliosis hepatis is a rare illness characterized by blood-filled spaces within the hepatic parenchyma that typically occurs in association with a variety of chronic wasting diseases (e.g., tuberculosis, malignancy). This condition has been associated with both the chronic use of pharmacologic doses of AAS and the chronic, intermittent abuse of AAS by bodybuilders.[65] The appearance of peliosis hepatis is not related to the dose of AAS or duration of use.[66] Some athletes using AAS take polyunsaturated phospholipids and vitamin B complex (Compound N) to reduce the elevation of hepatic aminotransferases often associated with the use of AAS;[113] however, there are inadequate data to determine the efficacy of this combination supplement.

MUSCULOSKELETAL SYSTEM.   The use of supraphysiologic doses of testosterone increases muscle mass and maximal voluntary strength in a dose-dependent manner, but there is no definitive evidence that testosterone improves performance in endurance events.[114,115] Rare case reports associate a general necrotizing myopathy with the chronic use of AAS. A 23-year-old man developed diffuse myalgias and severe rhabdomyolysis with anuria.[116] Although he developed a viral upper respiratory tract infection 1 week prior to the development of rhabdomyolysis, muscle biopsy and serum testing revealed no evidence of inflammation or immune disease. He had a history of chronic AAS abuse. Other case reports associate localized rhabdomyolysis of the deltoid muscles with chronic AAS injections in the same location.[117] There are few data in the medical literature regarding the effect of chronic AAS abuse on the function of connective tissue. Several case reports associate the chronic abuse of AAS with disruption of connective tissues including spontaneous rupture of ligaments and muscles.[118,119] In adolescents, premature closure of the epiphyseal plates during chronic AAS use can stunt bone growth.[120]

SKIN.   The most common dermatologic effects of AAS abuse are alopecia, male pattern baldness, and hirsutism, particularly in women. Other adverse dermatologic effects include keloid formation, sebaceous cysts, comedones, seborrheic furunculosis, folliculitis, striae, and acne. A common triad of chronic AAS abuse is the combination of acne, striae, and gynecomastia. Hyperplasia of the pilosebaceous glands and increased sebum production cause a high incidence of acne in chronic AAS abusers. These effects become prominent about 1 month after initiation of AAS abuse, depending on the dose and frequency of use.[121] Gynecomastia in males is a common adverse effect of chronic AAS abuse. These effects are not readily reversible, particularly in adolescents.[122] Adverse effects in women following chronic AAS use include masculinization (male pattern baldness, hirsutism), acne, oily skin, and breast atrophy.[123] The virilizing effects of AAS use by women are similar to the clinical features of the virilizing syndrome associated with congenital adrenal hyperplasia and adrenal carcinoma.

Reproductive Abnormalities

All AASs suppress gonadotropin secretion and therefore suppress endogenous testicular function. Adverse effects of AASs on the male reproductive system include reduced hormone levels (gonadotrophic hormones, endogenous testosterone, sex-hormone-binding globulin), impotence (erectile dysfunction),[124] alterations in sperm morphology, and reductions in sperm count, sperm motility, and the size of the testicles.[125] These changes are not responsive to the administration of human chorionic gonadotropin, and resolution of the alterations in sperm count occurs several months after cessation of AAS use with some individuals requiring up to 30 weeks of abstinence.[126] Although chronic AAS abuse produces hypogonadism, decreased serum testosterone and impaired spermatogenesis, these changes are reversible within a few months to 1 year following cessation of AAS use.[127,128] Abnormalities of the female reproductive system following chronic AAS abuse include menstrual irregularity, deep voice, increased libido, and increased clitoris size along with elevated sex-hormone-binding globulin. Anabolic-androgenic steroids are contraindicated in pregnant women (i.e., Pregnancy Category X) with potential effects including masculinization of the female fetus, clitoral hypertrophy of the female fetus, decreased birth weight, and premature bone maturation.[126]

Carcinogenesis

Rarely, case reports associate chronic *oral* AAS abuse with the development of hepatocellular adenomas, which usually regress along with minor elevations of serum hepatic aminotransferase concentrations after cessation of AAS abuse.[129] These tumors are not malignant, but occasionally surgical removal is necessary because of liver dysfunction or intrahepatic bleeding.[130] Other case reports associate chronic AAS abuse with the following cancers: kidney,[131] prostate (adenocarcinoma),[132] testes (leiomyosarcoma),[133] and liver (hepatocellular carcinoma, angiosarcoma).[134,135] However, there are inadequate data (i.e., cohort or case-control studies) to causally link chronic AAS use with cancer.

DIAGNOSTIC TESTING

Most clinical laboratories in healthcare facilities do not routinely perform analysis of urine samples for AASs. Clinically, abuse of AASs is suspect in male bodybuilders and weightlifters with small testes, low sperm counts, high hematocrit and hemoglobin values, and low serum sex-hormone-binding globulin concentrations. The presence of hirsutism, balding, and acne in a women athlete also suggests the use of AASs.

Analytic Methods

Analysis of steroids is a complicated process because of the large number of compounds (i.e., >7,000), thermal lability, poor volatility, and low UV extinction coefficients. Because of the rapid metabolism of AAS, detection times for determining the use of these drugs increase by analyzing urine samples for AAS metabolites, primarily by gas chromatography/mass spectrometry (GC/MS). Increasing useful, newer analytic methods to supplement gas chromatography/mass spectrometry include liquid chromatography/mass spectrometry and carbon isotope mass spectrometry for the detection of testosterone. Confirmation of AAS use involves the comparison of the electron impact mass spectrum with GC retention times of the trimethylsilyl derivatives of the steroid and/or the corresponding metabolites to synthesized or isolated reference standards. Analytic methods for qualitative and/or quantitative determinations of AAS typically employ gas or liquid chromatography combined with electron, chemical, or atmospheric pressure ionization followed by analyses using quadrupole, ion trap, linear ion trap, or hyphenated techniques.[136] The 2 common atmospheric-pressure ionization modes are electrospray ionization and atmospheric-pressure chemical ionization. The limit of detection for liquid chromatography/tandem mass spec-

trometry is approximately 25–50 pg/mL.[137,138] Other methods for the detection of AAS in urine samples include micellar electrokinetic capillary chromatography, high performance liquid chromatography, capillary gas chromatography, and liquid chromatography with electrochemical detection.[139,140] Analysis by liquid chromatography/electrospray/tandem mass spectrometry with simultaneous acquisition of precursor ion scan (m/z 105, 91, 77) allows the detection of prohormones derived from nutritional supplements even in the presence of impurities and/or degradation products in unconjugated urine samples.[141] Liquid chromatography/tandem mass spectrometry is more specific than radioimmunoassay for the quantitation of testosterone and dihydrotestosterone with the latter method typically reporting higher concentrations as a result of interfering serum steroids.[142] Compared with gas chromatography/mass spectrometry, liquid chromatography/tandem mass spectrometry after double extraction by solid-phase extraction allows the quantitation of AASs (e.g., nandrolone) without the hydrolysis and derivatization steps.[143] Measurements of testosterone and dihydrotestosterone in fluoride-containing blood tubes (e.g., gray-top) are usually approximately 15–20% lower than blood collected in plain containers (e.g., red-top).

The diagnosis can be confirmed by one of several tests, depending upon the compound to be tested. Storage of urine samples at 37°C (98.6°F) for several days results in the deconjugation of most steroid glucuronide and sulfate compounds.[144] Anabolic-androgenic steroids are not thermally labile, but small elevations of testosterone may result from the contamination of urine samples with *Candida albicans*. However, these changes are unlikely to cause false-positive tests.[145]

Biomarkers

Human urinary steroid profiles contain several statistically stable parameters, including the testosterone/epitestosterone ratio, and testosterone metabolites (androsterone, etiocholanolone, 5β-androstane-3α,17β-diol, 5α-androstane-3α,17β-diol).[137] Testosterone is one of the few compounds in athletic drug-testing programs that have a threshold. Analytic methods cannot distinguish between testosterone administered exogenously and testosterone produced endogenously. Initially, these programs used a testosterone to epitestosterone ratio of 6:1,[146] but now the WADA lowered the ratio to 4. Individuals using testosterone suppress the production of both testosterone and epitestosterone, resulting in replacement with only testosterone and elevated testosterone/epitestosterone ratio. The distribution of this ratio for both male and female athletes is approximately log-normal with a mean of about 1.0.[147]

Limitations of this ratio result from the effects of microbial degradation, excessive ethanol consumption, pharmacogenetic factors, pathologic conditions, and alteration of the ratio during puberty.[148] This ratio returns to baseline after cessation of testosterone use, whereas the ratio remains elevated for the rare athlete with a naturally increased ratio. Serial testing of the testosterone/epitestosterone ratio over at least 1 month after an event help determine the use of doping if the individual coefficient of variation exceeds 60% in 3 or more urine samples during this period.

Efforts to escape detection include the administration of epitestosterone or human chorionic gonadotropin to increase epitestosterone concentrations to produce a more favorable ratio; thus, the WADA established a threshold of 200 ng/mL for urinary epitestosterone to detect attempts to alter this ratio.[149] The ratio of testosterone to luteinizing hormone is also high (i.e., >30) in the urine of men using testosterone as a result of the testosterone-induced suppression of the secretion of luteinizing hormone.[150] This ratio is not useful in women. An alternative method for the detection of doping with AASs involves analysis of the ratio of the 2 stable carbon isotopes, $^{13}C/^{12}C$ with gas chromatography/combustion/isotope-ratio mass spectrometry. Exogenous testosterone or precursors contain less ^{13}C than endogenous homologues; consequently, urinary steroids with low $^{13}C/^{12}C$ ratios indicate pharmaceutic sources.[151] Urinary reference ranges for the $^{13}C/^{12}C$ ratio require correction for diet.[152] Similarly, recommended confirmatory procedure for the detection of 5α-dihydrotestosterone (DHT) abuse in male athletes uses the DHT/epitestosterone ratio in urine.[153] These ratios exceed reference standards within 24 hours of IM injection of DHT and return to baseline values within 1 month of the cessation of DHT use. Case reports suggest that the ingestion of AAS-contaminated meat (e.g., clostebol) can produce false-positive test results for AAS abuse.[154]

Norandrosterone is a human urinary metabolite of nandrolone (19-nortestosterone) that occurs naturally in trace amounts, particularly in pregnant women.[155] In a study of 30 healthy men without a history of AAS use, the range of the urinary excretion rates were 0.03–0.25 µg/24 hours or 0.01–0.32 ng/mL in nonfractionated 24-hour urine. To account for interindividual variability and the log-normal distribution, a threshold of 19-norandrosterone endogenous concentration of 2 ng/mL was established that represented the geometric mean plus 4 standard deviations. The maximum norandrosterone concentration in this group of urine samples was 0.63 ng/mL with a mean concentration of 0.078 ng/mL.[156] Almost all (i.e., about 95%) urine samples from healthy men have nondetectable concentrations of norandrosterone, and only very rarely do nondoping urine samples contain norandrosterone concentrations above the IOC-accredited laboratory cutoff of 2 ng/mL when corrected for urine specific gravity.[2] Both norandrostenedione and norandrostenediol are dietary supplements available in the United States, but all major sports organizations prohibit the use of these supplements. Potentially, these substances could be accidentally ingested by individuals, who subsequently could test positive for norandrosterone.

Abnormalities

Although some studies of athletes who chronically use AASs demonstrate asymptomatic elevation of serum hepatic aminotransferases,[66] most longitudinal studies of these athletes do no report changes in the common liver enzymes.[159] When present, the elevations of liver enzymes resolve without evidence of permanent pathologic changes following cessation of AAS use. Rarely, case reports associate evidence of severe hepatocellular necrosis (e.g., elevated serum hepatic aminotransferases, hyperbilirubinemia, hypoprothrombinemia) with chronic, intermittent AAS abuse.[112]

The total cholesterol concentration remains relatively unchanged during AAS use, but the concentrations of low density lipoprotein and apolipoprotein B increase about 30–50%, while the concentrations of high-density lipoprotein and apolipoprotein A1 decrease about the same amount.[157,158] There is substantial variation in the effect of different AAS on the cholesterol profile.[159,160] These alterations typically resolve within about 5 months after cessation of steroid use.

TREATMENT

The treatment of acute or chronic AAS abuse is supportive, and there are no specific measures directed to the medical complication of AAS abuse. There are no clinical data to guide the treatment of AAS overdose including the efficacy of decontamination measures. The acute symptoms associated with AAS typically are transitory (nausea, vomiting) and should respond to general treatment regimens (antiemetics). The most important aspect of treating AAS abuse is the cessation of AAS use.[161] Coordination of efforts to stop the use of AAS may benefit from therapy with a psychiatrist or an addiction specialist as well as medical treatment by an endocrinologist for the endocrine effects associated with chronic AAS abuse.[162] The treatment of agitation during AAS use and agitation during the use of other substances of abuse is similar; treatment includes the administration of benzodiazepines (lorazepam) and

antipsychotic agents (haloperidol, atypical antipsychotics) when associated with psychotic features.[86]

Chapter 16

CLENBUTEROL and SALBUTAMOL (ALBUTEROL)

JAMES RHEE, MD
TIMOTHY ERICKSON, MD

CLENBUTEROL

HISTORY

In 1972, the International Olympic Committee (IOC) banned the use of β_2-agonists including clenbuterol because of concern about the stimulant properties of this class of drug. During the next several decades, the approach of the IOC to the use of inhaled β_2-agonists by athletes changed in response to information on the prevalence of asthma in elite athletes and the lack of anabolic effects of inhaled β_2-agonists.[1] The prevalence of the use of inhaled β_2 agonists by athletes is similar to nonathletes from the *same* country, but β_2-agonist use by athletes varies by sport with the use being high in endurance athletes. During the Sydney and Athens Olympic games, the use of inhaled β_2-agonists by cyclists, triathletes, and swimmers exceeded 11% compared with <2% for weightlifters, boxers, and wrestlers.[2] Similarly, the prevalence of β_2 agonists by cross-country skiers and speed skaters at the Salt City Winer Olympic games exceeded 10.5% compared with <3% for alpine skiing and bobsledding athletes.[3]

Clenbuterol was marketed primarily as a veterinary drug to treat asthma in large animals and to improve muscle mass and muscle/fat ratios in meat-producing animals.[4] During the 1980s, bodybuilders and power athletes began using clenbuterol as an anabolic agent. In addition, the illicit use of clenbuterol to increase muscle mass and reduce fat in food-producing and show animals occurred during the late 1980s.[5] During the early 1990s, several outbreaks of clenbuterol toxicity occurred as a result of the consumption of veal and beef contaminated as a result of the illicit feeding of animals with clenbuterol.[6] The increased use of clenbuterol by bodybuilders and power athletes resulted in the addition of this β_2-agonist to the World Anti-Doping Agency (WADA) list of prohibited drugs. Two athletes competing in field events were disqualified for clenbuterol use during the Barcelona Olympic Games in 1992.[1] This drug is also prohibited by the Association of Official Racing Chemists.

IDENTIFYING CHARACTERISTICS

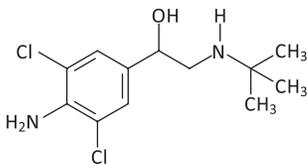
Clenbuterol (CAS RN: 37148-27-9) or 4-amino-α-[(tert-butylamino)methyl]-3,5-dichlorobenzyl alcohol has a structure similar to other phenethanolamine β-adrenergic agonists as displayed in Figure 16.1. This colorless microcrystalline powder is soluble in water, ethanol, and methanol; the molecular weight is 313.65 g/mol. Beta$_2$-adrenergic agonists contain various substitutions to prevent degradation and to increase selectivity for the β_2-adrenergic receptor. Clenbuterol is structurally similar to albuterol, differing from the latter by the presence of 2 chlorine atoms and an amine group on the benzene ring. These changes purportedly enhance oral absorption, beta$_2$-adrenergic receptor activity, and resistance to inactivation by catechol-*O*-methyl transferase.[7]


FIGURE 16.1. Chemical structure of clenbuterol.

Clenbuterol is not available as a pharmaceutic preparation in the United States for human use. In some European and South American countries, clenbuterol is available in tablets (10 μg, 20 μg) and as a powder for formulating solutions of varying clenbuterol concentrations. Commercial parenteral preparations are also available.

EXPOSURE

Epidemiology

The prevalence of abuse of clenbuterol or other beta-agonists is not well-documented. According to the WADA in 2004, β_2-adrenergic agonists accounted for 11.5% of all the "adverse analytic findings," defined as "a report from a laboratory or approved testing entity that identifies in a specimen the presence of a prohibited substance or its metabolites or markers (including elevated quantities of endogenous substances) or evidence of the use of a prohibited method.[8]

Sources

Clenbuterol is not approved by the US Food and Drug Administration (FDA), but this drug is approved for the treatment of asthma in some Southern European and South American countries. This drug is approved as oral syrup for the treatment of bronchoconstriction in horses, and illicit sources of clenbuterol in the United States include diversion of veterinary medicine and illegitimate importation. Clenbuterol is the only β-agonist approved in the European Union (EU) for the treatment of nonfood animals including chronic obstructive pulmonary disease in horses and the control of parturition in cattle and sheep.[9] The use of clenbuterol for improvement of the muscle/fat ratio (repartition agent) or muscle mass (anabolic agent) is not approved in the EU.[10] Some dietary supplements marketed through the Internet may contain clenbuterol.[11]

Sources of poisoning with clenbuterol include food poisoning and the contamination of heroin. Several case series report the occurrence of clenbuterol toxicity following the ingestion food contaminated with clenbuterol.[12] Typically, these outbreaks of food poisoning

involve veal, bovine liver, or beef with clenbuterol concentrations exceeding 0.1 μg/kg.[13,14]

Methods of Abuse

The usual route for the abuse of clenbuterol is ingestion as a result of the high oral bioavailability of clenbuterol. Consequently, the administration of clenbuterol parenterally offers no significant increase in bioavailability. Additional drugs used by athletes to enhance the effects of clenbuterol and reduce side effects include niacin, pseudoephedrine, ephedrine, and phenylpropanolamine.[15]

DOSE EFFECT

The recommended adult human dose of clenbuterol in the treatment of asthma is 20–40 μg orally twice daily or 20 μg by inhalation given at 8-hour intervals.[16] There are limited published data on the toxic effects of supratherapeutic doses of clenbuterol. In a controlled clinical study of 5 patients with depression, the ingestion of 100–150 μg clenbuterol daily for 3 weeks was associated with tremor, restlessness, and agitation in all 5 patients.[17] The range of a typical "anabolic" dose of clenbuterol for athletes is about 60–100 μg daily for 6–12 weeks.[18] A case report documented the use of much larger doses of clenbuterol (e.g., 1,575 μg daily for 1½ months) in combination with anabolic steroids.[19] This bodybuilder developed myocardial fibrosis, ventricular hypertrophy, and reduced left ventricular ejection fraction (i.e., 40%).

TOXICOKINETICS

Kinetics

In a study of 9 healthy male volunteers, peak plasma clenbuterol concentrations (i.e., about 0.3 ng/mL) occurred 2–3 hours after the ingestion of a single dose of 20 μg clenbuterol.[20] The bioavailability of a single dose is relatively high (i.e., about 70–80%). The systemic absorption of clenbuterol via inhalation is substantially less than the oral route. *In vitro* studies indicate that clenbuterol is highly protein bound (50–98%);[21] the volume of distribution is also relatively large.

There is evidence of multiple metabolites following hepatic metabolism of clenbuterol, but the structures of these me olites have not been elucidated. The main metabolite is probably a 4-mono-nitro compound and a secondary metabolite formed by dechlorination.[22]

In volunteer studies, renal excretion of unchanged clenbuterol accounts for about 30% of the absorbed dose of clenbuterol.[20] Biliary excretion and renal excretion of conjugated metabolites (i.e., mostly sulfates) account for the remainder of clenbuterol elimination.

The plasma elimination half-life of clenbuterol is approximately 25–39 hours.[14]

Tolerance

Adrenergic receptor desensitization occurs within approximately 2 weeks in rodents following the administration of clenbuterol.[23] Tolerance to β_2-agonists results from the down-regulation of β_2-receptors following daily exposure,[24,25] but this tolerance is rapidly reversible within about 3 days following cessation of use.[26]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

Beta-adrenergic agonists activate β-adrenergic receptors located throughout the body. The β_1-adrenergic receptor subtype occurs in the myocardium, and stimulation of these receptors cause inotropic and chronotropic effects. Beta$_2$-adrenergic receptors throughout the body are located in smooth muscle (lung, gastrointestinal tract, uterus, vascular system), skeletal muscle, hepatocytes, and the myocardium. Selective β_2- adrenergic agonists stimulate the β_2-adrenergic receptors by the following mechanisms: 1) directly activating the β_2-receptor (albuterol), 2) transport into a membrane depot (formoterol), and 3) interacting with a receptor-specific auxiliary binding site (salmeterol).[27]

Stimulation of the β_2-adrenergic receptor results in activation of intracellular adenylyl cyclase and the increased conversion of adenosine triphosphate (ATP) to cyclic $3'5'$-adenosine monophosphate (cAMP). cAMP is a major second messenger that activates intracellular protein kinases and ultimately produces biologic effects. These effects include bronchodilation, skeletal muscle arteriolar dilation, splanchnic venodilation, insulin secretion, decreased gut motility, hepatic gluconeogenesis, skeletal muscle glycogenolysis, skeletal muscle potassium uptake, and mast cell silization.

In animal models, the chronic administration of clenbuterol decreases fat deposition, reduces protein breakdown, and stimulates hypertrophy of skeletal muscles, particularly type II fibers.[28,29] The injection of rats with clenbuterol at a dose of 1 mg/kg daily for 15 days reduced epididymal fat pad mass (mean, 39%) while increasing body weight (mean, 9%), protein content (mean, 8%) and water content (mean, 7%) compared with controls.[30] These changes persisted at least 9 days after termination of treatment. However, the doses used in these animal studies are much higher than the doses recommended for humans, and the use of these high doses would be expected to produce adverse effects associated with excessive β_2-adrenergic stimulation.

Although not well studied in humans, existing data do not support improvements in muscle mass or athletic performance in healthy adults using clenbuterol.[31] In animal studies, the administration of clenbuterol increases the rate of muscle protein deposition and independently promotes lipolysis. Skeletal and cardiac muscle hypertrophy, but not hyperplasia occur in animal-feed clenbuterol.[32] The increase in protein synthesis results primarily from inhibition of protein degradation rather than increases in protein synthesis.[23] These animal studies do not demonstrate any alteration of plasma testosterone, insulin, or growth hormone concentrations; furthermore, the anabolic effects may diminish with prolonged treatment.

Mechanism of Toxicity

Toxicity from β_2-adrergic agonists results from excessive β_2 stimulation along with loss of β_2-selectivity following a supratherapeutic dose. Stimulation of β_2-adrenergic receptors promotes smooth muscle relaxation, activate glycogenolysis in the liver, and increases potassium uptake in skeletal muscle. Tachycardia is a common manifestation of toxicity secondary to β_2-adrergic agonists. Mechanisms for the development of tachycardia during an overdose include the following: 1) reflex tachycardia from β_2-adrenergic mediated peripheral vasodilation, 2) direct stimulation of the β_1-adrenergic receptors, and 3) activation of β_2-adrenergic receptors in the right atrium and left ventricle. Beta$_2$-adrenergic receptors stimulate the sodium-potassium ATPase pump and cause an intracellular shift of potassium into the cells, resulting in a relative hypokalemia. Hyperglycemia results from increased glycogenolysis, primarily in the liver. Intracellular sequestration of magnesium and phosphorus also occurs, resulting in hypomagnesemia and hypophosphatemia.[33]

Long-term animal studies suggest the possibility that the chronic administration of β_2-adrenergic agonists alter the structure of the heart. The administration 2 mg clenbuterol/kg daily to rats for 16–18 weeks caused cardiac hypertrophy when compared with controls (no clenbuterol).[34] The structural changes included an increased absolute heart mass of approximately 19% and an increased heart mass/body mass ratio of about 20%.

CLINICAL RESPONSE

Illicit Use

Clinical data on the acute and chronic toxicity of clenbuterol use by athletes is limited. Adverse effects of

β_2-agonists include headache, muscle tremor, muscle cramps during intense exercise, and palpitations.[35] Similarly, toxicity associated with clenbuterol-adulterated heroin includes palpitations, tachycardia, hypotension, tremor, anxiety, diaphoresis, nausea, vomiting, hypokalemia, hypophosphatemia, and hyperglycemia.[36] Rare case reports associate anabolic regimens including clenbuterol use with serious cardiac events. An acute myocardial infarction (peak creatine kinase 1,060 IU/L) occurred in an otherwise healthy 26-year-old bodybuilder using both anabolic steroids (testosterone propionate, cypionate, enanthate, methandrostenolone, stanozolol) and clenbuterol.[37] He stopped using anabolic steroids and started using clenbuterol about 4 weeks before his myocardial infarction. His coronary angiogram was normal. Another case report associated the development of a non-Q wave myocardial infarction with the use of clenbuterol by a 17-year-old male bodybuilder.[38] He reported the use of clenbuterol 40 mg daily for 2 weeks; then a 2-day hiatus prior to the onset of retrosternal chest pain. He denied the use of anabolic steroids. Echocardiography demonstrated hypokinesis of the apex along with mild left ventricular hypertrophy, and an angiogram 5 days after admission was normal. There are few data on the effect of the chronic administration of β_2-adrenergic drugs in humans at doses illicitly used by athletes; therefore, the clinical significance of these animal studies is unclear.

Overdose

The clinical features associated with overdoses involving clenbuterol are characteristic of β_2-adrenergic agonists. Clenbuterol is a long-acting drug that produces prolonged β_2-stimulation during an overdose including headache, dizziness, lightheadedness, tinnitus, muscle weakness, tremor, diaphoresis, nausea, vomiting, anxiety, agitation, chest pain, palpitations, sinus tachycardia (135–160 bpm), hypotension, hypokalemia, hypophosphatemia, metabolic acidosis, and hyperglycemia.[39,40] The most common manifestation of clenbuterol toxicity are tachycardia, agitation, and hypokalemia. Sinus tachycardia is the most common dysrhythmia associated with clenbuterol intoxication, and signs of intoxication can persist up to about 24 hours.[33] A 31-year-old man developed palpitations, dyspnea, and a supraventricular tachycardia (ventricular rate = 254 bpm) after the ingestion of clenbuterol hydrochloride.[41] About 16 hours after ingestion, an electrocardiogram revealed atrial fibrillation with a ventricular rate of 125–147 bpm; later, he was cardioverted to a normal sinus rhythm. Serious ventricular dysrhythmias do not usually occur during clenbuterol intoxication. Mydriasis is an incon-

sistent sign of β_2-adrenergic toxicity.[42] Clenbuterol does not typically cross the blood-brain barrier; therefore seizures do not usually occur during an clenbuterol overdose. This drug is an adulterant of heroin and cocaine, and the insufflation of a white powder containing clenbuterol has been associated with the acute onset of chest pain, palpitations, tremors, headache, nausea, vomiting, and subsequently pulmonary edema with respiratory failure.[43]

Food Poisoning

Outbreaks of clenbuterol toxicity have occurred in Europe (Spain, France, Italy, Portugal) and China following the consumption of clenbuterol-contaminated food, primarily liver from ruminants. In a study of 4 cases of food poisoning involving clenbuterol-contaminated bovine liver, bovine muscle, and lamb meat in Portugal, the most common symptoms were tachycardia, tremors, nausea, and stomach pains as demonstrated in Table 16.1.[44] Random samples of contaminated meat contained approximately 1 mg clenbuterol/kg.

In a series of 15 patients with clinical features of food poisoning after consuming clenbuterol-contaminated veal, the onset of symptoms (palpitations, headache, tachypnea, tremors) occurred between 0.5–3 hours after eating.[12] Symptoms resolved within 3–5 days.

DIAGNOSTIC TESTING

The diagnosis of β_2-adrenergic agonist toxicity in the acute setting is based on the presence of the clinical features of excessive β-adrenergic stimulation. Analytic methods confirm the presence of excessive amounts of β-adrenergic agonist, usually in urine samples.

TABLE 16.1. Incidence of Toxic Effects Associated with the Consumption of Clenbuterol-Contaminated Meat by 50 Patients.[44]

Clinical Effect	Number	% of Total
Tachycardia	41	82
Distal tremors	38	76
Nausea	37	74
Stomach ache	34	68
Diarrhea	25	50
Temperature >37.5°C (99.5°F)	18	36
Headache/dizziness	18	36
Myalgias/weakness	11	22
Hypertension	9	18
Vomiting	9	18
Dry mouth/voice change	5	10

Analytic Methods

Immunoassays (e.g., enzyme-linked immunosorbent assay [ELISA]) are available to screen for the presence of clenbuterol, but cross-reactivity with salbutamol and mabuterol limits the specificity of these tests.[45] For confirmation of the presence of clenbuterol, analytic methods include capillary electrophoresis,[46] high performance liquid chromatography with ultraviolet detection,[47] liquid chromatography/electrospray ionization/mass spectrometry,[48,49] gas chromatography/electrospray ionization/tandem mass spectrometry,[50] and gas chromatography/mass spectrometry.[51] Gas chromatography/mass spectrometry is a sensitive method for the analysis of clenbuterol in urine samples with a detection limit in the range of 0.02 ng/mL.[52] For capillary electrophoresis with laser-induced fluorescence, the limit of detection (LOD) for clenbuterol in biologic samples is about 0.7 ng/mL.[53] The LOD for clenbuterol and salbutamol with liquid chromatography/electrospray tandem mass spectrometry is near 0.1–0.5 ng/mL.[54,55] Using liquid chromatography/tandem mass spectrometry with ion trap technology, the LOD and LLOQ of clenbuterol in liver samples were 0.11 μg/kg and 0.21 μg/kg, respectively.[56]

Biomarkers

Following the ingestion of 80 μg clenbuterol by healthy volunteers, peak plasma concentration of clenbuterol occurred about 2.5 hours after ingestion.[21] In this study, the peak plasma clenbuterol concentration was about 5 ng/mL compared with a steady-state plasma clenbuterol concentration of 0.6 ng/mL following the ingestion of 40 μg clenbuterol twice daily for 4 days. A 28-year-old woman developed tremulousness, vomiting, palpitations, sinus tachycardia, hyperglycemia, hypokalemia, and hypomagnesemia after ingesting a powder containing clenbuterol.[33] Three hours after her ingestion, her serum clenbuterol concentration was 2.93 ng/mL as measured by liquid chromatography/mass spectrometry.

Abnormalities

Laboratory abnormalities associated with β_2-adrenergic overdose include hypokalemia, hypophosphatemia, hypomagnesemia, hyperglycemia, and metabolic acidosis. The severity of hypokalemia correlates to serum clenbuterol concentration. The differential diagnosis of the triad of hypokalemia, hyperglycemia, and hyperlactatemia includes theophylline and caffeine toxicity as well as β-adrenergic agonist overdose.

TREATMENT

The treatment of clenbuterol toxicity is similar to the treatment of other β_2-adrenergic agonists with management focused on symptomatic and supportive care. The principal difference between clenbuterol and other β_2-adrenergic agonists is potency and duration of action. The clinical features of clenbuterol toxicity persist much longer (e.g., half-life 25–39 hours) than salbutamol (half-life 3–6 hours). Patients with signs of clenbuterol toxicity should be monitored closely for dysrhythmias and hypotension secondary to vasodilation with an electrocardiogram, cardiac monitoring, and frequent vital signs. These patients should also be evaluated for the presence of metabolic and electrolyte abnormalities.

Gut Decontamination

The administration of activated charcoal to alert patients who ingest clenbuterol within 1 hour prior to presentation is a therapeutic option,[57] but there are no clinical data to confirm the clinical efficacy of activated charcoal on the outcome of clenbuterol intoxication.

Antidotes

Case reports suggest that α- and β-adrenergic antagonists are *potential* antidotes for β-adrenergic agonist toxicity, particularly following the development of a clinically significant tachydysrhythmia or hypotension unresponsive to intravenous (IV) fluid therapy.[58] However, there are no specific IV β_2-blockers. Typically, noninvasive cardiac monitoring in patients with tachycardia, lactic acidosis, and hypotension demonstrate low systemic vascular resistance with high cardiac output. Nonselective β-adrenergic antagonists should not be administered prematurely or indiscriminately because excessive use of these drugs in the setting of a clenbuterol overdose may cause a serious deterioration in the vital signs as a result of unopposed α-adrenergic stimulation. Although case reports suggest that β-adrenergic antagonist can be administered to asthmatic patients judiciously,[59] these drugs must be administered cautiously to patients with a history of bronchospasm or chronic obstructive pulmonary disease. Theoretically, the initial use of a short-acting β-adrenergic antagonist is advantageous [e.g., esmolol drip, IV metoprolol (5 mg initial IV bolus to adults)] to quickly reverse any adverse effects from the use of these drugs. If the patient responds to initial doses of a short-acting β-adrenergic antagonist and no adverse effects occur, a longer-acting β-adrenergic antagonist (e.g., propranolol 0.5–1 mg intravenously) can be administered to control clinically

significant symptoms of intoxication. Metabolic abnormalities (e.g., hypokalemia, hyperglycemia, hypomagnesemia) resolve with improvement in clinical symptoms; therefore, only supportive care is necessary for these metabolic abnormalities.

Supplemental Care

Most patients with tachycardia and hypotension secondary to β-adrenergic agonist intoxication respond to supportive care with IV saline and vasopressors usually are not required. Hypokalemia typically results from an intracellular shift of potassium rather than a loss of extracellular potassium. Consequently, the total body burden of potassium is not reduced during β-adrenergic agonist poisoning; therefore, potassium supplements should be administered cautiously as small potassium infusions only in the setting of severe or symptomatic hypokalemia. Aggressive treatment of this relative hypokalemia potentially can cause hyperkalemia when the β-adrenergic agonist activity of these drugs resolve. The hypomagnesemia, hypophosphatemia, and hyperglycemia do not usually require therapy, unless severe abnormalities occur. Seizures are uncommon during β-adrenergic agonist toxicity, and IV benzodiazepines are the anticonvulsants of choice. If seizures occur, other sources of seizures should be considered including toxicity by other sympathomimetic agents or theophylline.

SALBUTAMOL (ALBUTEROL)

HISTORY

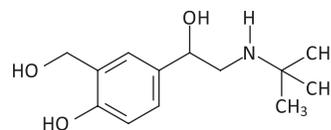
In 1972, the International Olympic Committee (IOC) banned the use of β₂-agonists because of concern about the stimulant properties of this class of drug. During the next several decades, the approach of the IOC to the use of inhaled β₂-agonists by athletes changed in response to information on the prevalence of asthma in elite athletes and the lack of anabolic effects of inhaled β₂-agonists.[1] In 1993, the Medical Commission of the International Olympic Committee re-introduced the notification requirement for inhaled β₂-agonist and limited the use of inhaled β₂-agonists to salbutamol and terbutaline. Inhaled formoterol was added to this list in 2001. During that year, the IOC established the Independent Asthma Panel to oversee the required submission of evidence of asthma or exercise-induced


FIGURE   16.2. Chemical   structure   of   salbutamol (albuterol).

asthma by athletes using β₂-agonists. Accepted evidence includes positive bronchoconstrictor response, positive methacholine   challenge,   positive   bronchodilator response, and confirmatory medical records.

IDENTIFYING CHARACTERISTICS

Albuterol (CAS RN: 18559-94-9) is the official generic name in the United States, whereas salbutamol (CAS RN: 35763-26-9) is the name recommended by the World Health Organization. Figure 16.2 displays the chemical structure of salbutamol (albuterol). Salbutamol is a racemic mixture of 2 enantiomers: $S(+)$- and $R(-)$-salbutamol. The $R(-)$ has most of the pharmacological activity, whereas the $S(+)$ enantiomer is inactive.[60]

EXPOSURE

The IOC permits the use of salbutamol in athletes with documented asthma or exercise-induced asthma after the approval of a therapeutic use exemption by an independent medical panel. This β₂-agonists is the only one approved by WADA with the following limitation: 1) the use of only the inhalant is permitted as salbutamol is both a stimulant and an anabolic agent when administered   orally, 2)   the   maximum   permitted   use   is 1,600 μg/24 hours, and 3) the presence of urine salbutamol concentrations exceeding 1,000 ng/mL is presumed evidence of salbutamol abuse.[61] The IOC requires documented evidence of bronchoconstriction prior to the use of these β₂-agonists. All oral β₂-agonists are prohibited. Although salbutamol is available in inhaled form, the lack of anabolic effects by this route limits the abuse of this β₂-adrenergic agonist.

DOSE EFFECT

Although inhaled dose of salbutamol typically do not cause ergogenic or anabolic effects, the oral administration   of   salbutamol   to   non-asthmatic   individuals can improve muscle strength, anaerobic power and endurance. However, the typical oral dose used for ergogenic effects is 10–20-fold higher than the maximal therapeutic dose of inhaled salbutamol (800–1,600 μg daily).[62]

TOXICOKINETICS

Absorption/Distribution

In contrast to the high bioavailability of clenbuterol, the average absorption of salbutamol is about 50% of an oral dose. In a study of 10 healthy volunteers ingesting 4 salbutamol doses of 4 mg divided over 24 hours, the mean systemic bioavailability was 50% ± 4%.[63] The mean bioavailability of salbutamol in 10 healthy volunteers following inhalation of 400 µg and the ingestion of 4 mg was 57.4% ± 14.9% and 63.3% ± 10.9%, respectively.[64] In 10 healthy volunteers receiving IV salbutamol, the mean V_d was 156 L ± 38 L.[63]

Biotransformation

Salbutamol metabolism occurs in the intestine and liver almost exclusively by conjugation with sulfate at the phenolic group. The active $R(-)$-enantiomer undergoes a higher rate of conjugation with sulfur than the inactive $S(+)$-enantiomer; therefore, the kidneys excrete a relatively larger portion of free $S(+)$ in the urine after ingestion than after inhalation. The free $S(+)/R(-)$ ratio is close to unity during the first hour after inhalation of salbutamol because of the lack of salbutamol biotransformation in the lung.[65] Following oral administration the free $S(+)/R(-)$ ratio typically exceeds 2.5 as a result of the higher conjugation of the active $R(-)$-enantiomer. Because of the variable ingestion of inhaled salbutamol, the free $S(+)/R(-)$ ratio >2.5 alone is not sufficient evidence of the ingestion of salbutamol.[66] There are few data on the potential saturation of the sulfate pathway following the ingestion of high doses of salbutamol.

Elimination

The plasma half-life of salbutamol (albuterol) is substantially less than clenbuterol with a mean half-life of about 3–6 hours.[67] The kidneys excrete salbutamol as a mixture of unchanged drug and conjugated metabolites, primarily as sulfates. Experimental studies in healthy volunteers indicate that urine salbutamol concentrations depend on the route of exposure with oral or subcutaneous administration of salbutamol producing higher and more prolonged urine salbutamol concentrations than inhalation.[68] The ratio of free/conjugated drug depends on the route of administration. Following the oral administration of 16 mg salbutamol divided over 24 hours, the mean urinary excretion of unchanged salbutamol and the sulfate conjugate was 31.8% ± 1.9% and 48.2% ± 7.3%, respectively.[63] Following IV administration of salbutamol, the mean urinary excretion of unchanged salbutamol and the sulfate conjugate was

64.2% ± 7.1% and 12.0% ± 3.1%, respectively. The values resulting from the administration of salbutamol by these 2 routes were significantly different ($P < .001$). In a study of asthmatic patients ingesting ^{3}H-salbutamol, approximately 76% (range, 65–84%) of the dose was excreted over 3 days in the urine with a majority of the excretion occurring in the first 24 hours as measured by total radioactivity.[69] During this period, the feces contained about 4% of the absorbed dose (range, 1–7%). In a study of 10 healthy volunteers, the mean urinary elimination half-lives of salbutamol following ingestion (4 mg) and inhalation (400 µg) were 5.7 hours ± 1.4 hours and 6.1 hours ± 2.1 hours, respectively.[64]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

There are limited data on anabolic effects and physical performance parameters following the doses of β_2 agonists typically used to treat asthma. In a study of 12 healthy volunteers receiving 16 mg sustained-release, *oral* salbutamol daily for 3 weeks, quadriceps strength increased 12% ± 3% compared with placebo.[70] However, the effect was variable as there was no change in grip strength in either hand during the trial. Most double-blind, controlled clinical trials do not demonstrate a statistically significant improvement in physical performance of atopic or non-atopic athletes treated with *therapeutic* doses of *inhaled* β_2-agonists including salbutamol and terbutaline, even at supratherapeutic doses up to 1200 µg daily.[62] A double-blind, placebo-controlled study of 7 nonasthmatic, elite cyclists demonstrated no ergogenic benefit of a therapeutic dose of inhaled salbutamol.[71] Measures of physical performance included maximum heart rate, endurance sprint time, peak power, and total work.

In contrast to the lack of ergogenic effects following the therapeutic use of *inhaled* salbutamol, the administration of *oral* doses of salbutamol has been associated with improved strength and endurance during intense submaximal exercise. A randomized, placebo-controlled, double-blind study of 8 recreational, nonasthmatic athletes demonstrated increased endurance during intense submaximal exercise (cycling) following the administration of oral salbutamol 12 mg daily for 3 weeks.[72] The cycling time was significantly increased ($P < .05$) after 3 weeks of salbutamol administration (30.5 min ± 3.1 min) compared with placebo (23.7 min ± 1.6 min). In a double-blind randomized cross-over study of 16 non-asthmatic men, the mean endurance times on a cycle ergometer for the placebo and treatment (i.e., 4 mg salbutamol) groups were 3,039 ± 1,031 seconds and 3,439 ± 1,287, respectively. The difference was not statistically significant ($P = .19$).[73] However, following the

exclusion of 4 athletes with adverse effects, the mean endurance of the salbutamol group was statistically different ($P < .05$) than the placebo group.

CLINICAL RESPONSE

Similar to clenbuterol, the clinical features associated with overdoses involving salbutamol are characteristic of β_2-adrenergic agonists including headache, diaphoresis, tremor, anxiety, lightheadedness, tinnitus, nausea, vomiting, chest pain, palpitations, tachycardia, hypotension, hyperglycemia, metabolic acidosis, hypokalemia, and hypophosphatemia. Serious ventricular dysrhythmias do not usually occur during salbutamol intoxication despite the presence of hypokalemia.[74] Rare case reports temporally associate the therapeutic use of inhaled or IV salbutamol with the development of myocardial injury in patients without evidence of coronary artery obstruction.[75]

DIAGNOSTIC TESTING

Analytic Methods

Immunoassays (e.g., ELISA) are available to screen for the presence of salbutamol, but this technique demonstrates cross-reactivity with other β_2-adrenergic agonists including clenbuterol.[76] Analytic methods to quantify salbutamol in biologic samples in addition to liquid chromatography/thermospray/tandem mass spectrometry include high performance liquid chromatography with fluorometric detection,[77] liquid chromatography/ electrospray ionization/mass spectrometry in selected ion monitoring with nadolol as the internal standard,[78] capillary electrophoresis with ultraviolet detection (205 nm),[79] and gas chromatography/mass spectrometry.[80] The latter method requires extraction (liquid-liquid, solid-phase) and derivatization. Analysis of urine with ultraperformance liquid chromatography/tandem mass spectrometry and electrospray ionization in positive ion mode, the lower limit of quantitation (LLOQ) for salbutamol is about 0.2 ng/mL with intraassay precision and accuracies <8.4%.[81] In comparison, the LLOQ following analysis by liquid chromatography/electrospray ionization/mass spectrometry is 10 ng/mL with an accuracy of ± 2.6%. Using solid-phase extraction and derivatization with N-methyl-trimethylsilytrifluoroaceta mide, the LOD and LLOQ for salbutamol using gas chromatography/mass spectrometry were 30 ng/mL and 111 ng/mL, respectively.[82] In this study, the stability of free salbutamol in urine samples was relatively stable over 60 days in frozen storage ($-18°C/-0.4°F$) and in refrigeration ($4°C/39.2°F$). The estimated loss of free salbutamol over this period was 2–4% and 8–12%, respectively. Rare case reports associate the use of high doses of salbutamol (albuterol) with elevated serum concentrations of creatine kinase, primarily following ingestion and less often with inhaled doses.[83]

Biomarkers

PLASMA. Peak plasma concentrations of salbutamol following the ingestion of therapeutic doses (4–8 mg) by healthy volunteers range from 10–18 ng/mL.[63] Following the ingestion of an estimated 320 mg salbutamol, a 16-year-old asthmatic developed tremor, hypokalemia, and sinus tachycardia.[74] Her plasma salbutamol concentration about 2 hours after ingestion was 449 ng/mL. She recovered without sequelae. The whole blood/plasma ratio of salbutamol is approximately 1. Following the IV administration of salbutamol to healthy volunteers, the mean whole blood/plasma ratio was 0.96 ± 0.13.[63]

URINE. Both the total and free salbutamol concentrations and the ratio of $S(+)$- and $R(-)$-enantiomers are useful biomarkers for distinguishing oral and therapeutic (inhaled) use of salbutamol. The World Anti-Doping Agency established urine total (free plus glucuronides) salbutamol concentration exceeding 1,000 ng/mL in urine samples (uncorrected for urine specific gravity) as an indication of the potential oral use of salbutamol. In experimental studies of healthy volunteers receiving 200–800 µg salbutamol via inhalation, peak urine nonsulfonated salbutamol concentrations up to about 900 ng/mL occurred approximately 1 hour after administration.[84] Several factors besides individual variation in biotransformation of salbutamol can cause falsepositive results using the WADA criteria including the administration of high doses (e.g., 800–1,000 µg over 3 hours prior to competition) and dehydration.[85,86] Immunoassays (e.g., ELISA) measure total salbutamol concentrations in urine samples, whereas gas chromatography/mass spectrometry detects nonsulfated (unconjugated) salbutamol.

The conjugation rate of the $S(+)$-enantiomer is higher than the $R(-)$-enantiomer following oral salbutamol administration when compared with inhalation of salbutamol. The $S(+)/R(-)$ ratio usually exceeds 2.5 after oral use of salbutamol compared with <2.5 following inhalation of salbutamol.[87] However, some false-positive results occur, probably as a consequence of swallowing some of the dose of inhaled salbutamol.

Abnormalities

Laboratory abnormalities associated with β_2-adrenergic overdose include hypokalemia, hypophosphatemia, hypomagnesemia, hyperglycemia, and metabolic acido-

sis.[88,89] The severity of hypokalemia correlates to serum salbutamol concentration.[33]

TREATMENT

The treatment of clenbuterol and salbutamol toxicity is similar. The clinical features of clenbuterol toxicity persist much longer (e.g., half-life 25–39 hours) than salbutamol (half-life 3–6 hours).

Chapter 17

ERYTHROPOIETIN STIMULATION and OTHER BLOOD DOPING METHODS

JAMES RHEE, MD
TIMOTHY ERICKSON, MD

HISTORY

Erythropoietin stimulation is one of several methods of blood doping. Broadly defined, blood doping refers to the practice of increasing the oxygen-carrying capacity of blood to enhance oxygen delivery to working muscles and tissues with the expectation of improving endurance and athletic performance. Originally, the term referred to the use of autologous or allogenic blood transfusions by athletes; however, the term currently is applied to several other methods that increase the red blood cell count or oxygen-carrying capacity including the following: 1) use of blood substitutes (modified hemoglobin solutions, perfluorochemicals, allosteric effectors of hemoglobin), and 2) artificial stimulation of erythropoiesis (recombinant erythropoietin, gene therapy, erythropoietin mimetics).[1] Additional methods used by some athletes to increase red cell mass include stimulation of endogenous erythropoietin (living and training at high altitude, sleeping in altitude tents).[2] Blood doping is common in endurance athletes (e.g., cycling, cross-country skiing, distance running, rowing, triathlon). The use of blood products as means to enhance strength and resistance to disease dates back at least to the work of Fuster in 1865 as well as later research during the 19th century conducted by Deschiens, Catillon, Adrian, and Richet.[3] At the beginning of the 20th century, several pharmaceutical companies developed blood products derived from animal blood for use in humans. However, interest in these products faded after the Second World War with the discovery of antibiotic therapy.

Since the 1960s and 1970s, blood transfusions have been a popular method to enhance endurance by increasing hemoglobin, aerobic capacity or maximal oxygen uptake ($VO_{2\,max}$), and time to exhaustion at 95% $VO_{2\,max}$. After the 1984 Summer Olympic Games, the US Olympic Committee disclosed the use of blood transfusions by 7 of 24 members of the US Olympic cycling team during training for the Summer Olympics.[4] However, at that time there was no Olympic ban on the use of these blood products. Shortly thereafter, the International Olympic Committee banned all forms of blood doping defined as the administration of blood, red blood cells (RBCs), artificial oxygen carriers, or related blood products to an athlete.[5]

In 1906, Paul Carnot, Professor of Medicine at the Sorbonne in Paris and his research assistant research, Mlle. C. Deflandre postulated the existence of a humoral factor (hémopoïétine) that controlled erythropoiesis.[6,7] They discovered an increase in erythrocytes in rabbits after several days of injecting serum from anemic rabbits; however, lack of confirming studies dampened interest in this area of research for 5 decades. In 1948, Bonsdorff and Jalavisto proposed the replacement of the term hémopoïétine by erythropoietin to limit this term to red cell production.[8] Research in the 1950s confirmed the production of this humoral factor in response to anemia and hypoxia.[9,10] Isolation of native human erythropoietin did not occur until 1977. In 1983, Fu-Kuen Lin and a research team at Amgen, Inc. (Thousand

Oaks, CA) cloned the gene for human erythropoietin, the endogenous hormone responsible for stimulating RBC production. Subsequently, recombinant human erythropoietin (rHuEPO) was developed for the treatment of certain types of anemia and released in Europe in 1987. The US Food and Drug Administration (FDA) approved the use of Epogen® for the treatment of anemia in patients with end-stage renal disease in 1989 as a means to improve survival, cognitive function, and the quality of life for renal patients.[11]

During the first year of the release of rHuEPO in Europe, 5 Dutch cyclists died of unknown causes.[12] This cluster of deaths raised concerns about the use of ergogenic aids including rHuEPO. The International Olympic Committee (IOC) banned the use of rHuEPO as an ergogenic aid in 1990,[13] but deaths of cyclist from causes (e.g., pulmonary embolism, myocardial infarction, stroke) associated with rHuEPO use continued during the 1990s.[5] During this period, the popularity of blood transfusion among endurance athletes decreased dramatically. The abuse of rHuEPO to improve athletic performance continued into the 2000s, particularly in elite and nonprofessional endurance athletes (e.g., cycling, marathon running, cross-country skiing).[14] Four athletes lost their medals at the Salt Lake City 2002 Winter Olympics after testing positive for the hyper-glycosylated erythropoiesis-stimulation protein, darbepoetin alpha, which has a prolonged terminal half-life that allows less frequent dosing than rHuEPO.

Following implementation of reliable tests to screen for EPO-stimulating substances, the use of blood transfusions by endurance athletes has increased substantially.[15] Other potential methods used by athletes to increase oxygen transport and endurance capacity include intermittent transient hypoxia, other erythropoiesis-stimulating substances (continuous erythropoiesis receptor activator, erythropoiesis-mimetic peptides such as hematide), EPO gene therapy, or mimetics (hypoxia-inducible transcription factors pathway), allosteric effectors of hemoglobin (RSR-13, RSR-4), and blood substitutes (e.g., modified hemoglobin-based oxygen carriers, perfluorochemicals).[16]

IDENTIFYING CHARACTERISTICS

Structure

Endogenous human erythropoietin (EPO, CAS RN:11096-26-7) is a 165-amino acid, 30.4-kDa glycoprotein derived from the cleavage of a 27-amino acid leader sequence from a 193-amino acid transcript of chromosome 7 (7q11-22). Subsequently, glycosylation of 4 amino acids (Asn24, Asn38, Asn83, Ser126) and the loss of the carboxyl-terminal arginine from the 166-amino

acid residue produces the 165-amino acid hormone.[17] Two disulfide bonds in the human erythropoietin molecule join cysteine residues at positions 29 and 33 and at 7 and 161. The presence of N-linked carbohydrate chains with terminal sialic acids limits the hepatic clearance of EPO. The structure of EPO is similar to growth hormone, prolactin, granulocyte colony-stimulating factor, and interleukin 6.[18]

The term "epoetin" refers to recombinant human erythropoietin (rHuEPO, CAS RN:113427-24-0) that has an amino acid sequence homologous to endogenous erythropoietin. Although the amino acid sequences of rHuEPO and EPO are identical, rHuEPO has microheterogeneities and minor differences in the glycosylation pattern compared with EPO.[19,20] The addition of Greek letters to epoetin delineates differences in the carbohydrate moieties between different epoetin molecules (e.g., alpha, beta, delta, omega). As a result of these differences in composition, the beta isoform is slightly more basic than the alpha form.

Darbepoetin alfa is a hyper-glycosylated erythropoietin analogue that is biochemically distinct from recombinant human erythropoietin (rHuEPO). In contrast to the 3 N-linked carbohydrate chains in rHuEPO, darbepoetin alfa contains 5 N-linked carbohydrate chains with a resultant carbohydrate content of 51% compared with 40% for rHuEPO.[21] Darbepoetin alfa has a molecular weight of 37.1 kDa and contains up to 22 sialic acid molecules compared with a maximum of 14 sialic acid residues in rHuEPO. Newer EPO analogues include protein conjugates (synthetic erythropoiesis protein) that contain precision-length, monodisperse, negatively charged polymers instead of oligosaccharides.[22] Continuous erythropoietin receptor activator (CERA) incorporates a long polymer chain that substantially extends the erythropoietic activity of this molecule.[23] Oral HIF-1α stabilizers (e.g., FG-2216) are currently under investigation as substitutes for rHuEPO.[24]

Form

Blood doping involves a variety of techniques that increase oxygen transport in the blood. Table 17.1 lists various techniques and substances used to alter oxygen-carrying capacity.

Recombinant human erythropoietin (rHuEPO) mimics endogenous erythropoietin (EPO) and stimulates the production of erythrocytes similar to EPO. Both endogenous EPO and rHuEPO are compendiums of different isoforms. Endogenous erythropoietin has a net negative charge based on the presence of 8–14 sialic acid residues. The net negative charge of rHuEPO differs from EPO based on the number of sialic acid residues. Darbepoetin alfa (new erythropoiesis-stimulating

TABLE 17.1. Blood Doping Techniques and Substances.

Technique	Substances	Forms
Blood transfusion	Autologous blood, allogeneic blood	
Blood substitutes	Perfluorocarbons	Perflubron emulsion
	Hemoglobin-based oxygen carriers	PolyHeme®, HemoLink™, Hemopure®
Recombinant human EPO (rHuEPO)	Epoetin alfa	Epogen®, Eprex®, Epoxitin®, Epypo®, Erypo®, Espo®, Globuren®, Procrit®
	Epoetin beta	Epogin®, Marogen®, NeoRecormon®, Recormon®
	Epoetin delta	Dynepo™
	Epoetin gamma	
	Epoetin omega	Epomax®, Hemax®
Other erythropoiesis-stimulating substances	Darbepoetin alpha	Aranesp®
	Continuous erythropoiesis receptor activator (CERA)	
	Erythropoietin-mimetic peptide	Hematide™
Allosteric hemoglobin modulators	RSR-13	Efaproxiral
	RSR-4	
Supplementation	Iron, cobalt chloride	
Alteration of inspired oxygen	Hypoxic gas mixtures

protein [NESP]) is an analogue of EPO that also stimulates erythropoiesis. Erythropoietin mimetics are peptide and nonpeptide molecules that simulate the action of EPO on dimerizing EPO receptors. Epoetin alfa is available as a solution in the following concentrations: 2,000 units/mL, 4000 units/mL, 10,000 units/mL, and 20,000 units/mL, whereas darbepoetin alpha is available in 0.025 mg/mL, 0.04 mg/mL, 0.06 mg/mL, and 0.2 mg/mL solutions.

EXPOSURE

Epidemiology

The World Anti-Doping Agency (WADA) bans blood doping including blood transfusions, methods to enhance or transport oxygen, and erythropoiesis-stimulating agents (erythropoietin, darbepoetin alpha, hematide).[25] DNA-recombinant human erythropoietin has been administered to patients with chronic renal failure and anemia since the late 1980s. By the middle of the 1990s, rHuEPO was the drug of choice for endurance athletes seeking to improve performance, including cyclists in the Tour de France.[14] The advantages of rHuEPO include ease of use, efficacy, and the absence of the risks associated with blood transfusions. In addition, detection of rHuEPO is technically difficult. The estimated prevalence of rHuEPO by elite endurance athletes ranges from about 3–7%.[14] In a study of 1,015 Italian athletes, the prevalence of blood doping was 7% based on interviews.[26] The type of blood doping was not specified in the report. The use of rHuEPO is probably much less common among young noncompetitive athletes compared with other ergogenic aids (anabolic-androgenic steroids). In a study of 571 Danish general practitioners, none of these physicians reported the use of rHuEPO among their patients; almost all of the reported use of ergogenic aids in this population involved androgenic-anabolic steroids.[27]

Sources

Renal interstitial cells adjacent to the proximal tubules secrete most (i.e., 90%) of endogenously produced EPO in response to hypoxia or reduced erythrocyte concentrations.[28] The liver accounts for most of the remaining production of EPO with small amounts of EPO synthesized in the brain.[29] Recombinant human erythropoietin is produced from mammalian cell lines after insertion of the human erythropoietin gene. The nomenclature for epoetin uses epoetin with a Greek letter to differentiate the same amino acid sequence with varying glycosylation patterns. Different cell lines produce these different isoforms that also vary in pharmacokinetics.[30] The sources of epoetin alfa and epoetin beta are recombinant DNA from Chinese hamster ovary cells after the

insertion of the human erythropoietin gene. Epoetin delta is derived from genetically engineered human fibrosarcoma cell lines, whereas the source of epoetin omega is baby hamster kidney cells. Murine C127 cells are the source for epoetin gamma. Darbepoetin alfa is a glycosylated analog of rHuEPO produced by DNA technology in Chinese hamster ovary cells that binds to the erythropoietin receptor similar to endogenous EPO, resulting in a longer elimination half-life than endogenous EPO. Due to the illicit demand and the high cost of these drugs, there is an underground market for stolen or counterfeit EPO products.[31] Additionally, human and animal blood has also been falsely marketed as EPO to unsuspecting athletes carrying an additional risk of viral infection (e.g., hepatitis C, human immunodeficiency virus [HIV]).[32,33]

Methods of Abuse

Routes of illicit rHuEPO use include intravenous (IV), intramuscular (IM), and subcutaneous (SC) administration. The poor oral bioavailability of rHuEPO limits the use of this route of administration based on animal studies.[34] The athlete using blood doping seeks a competitive advantage to improve athletic performance. The use of rHuEPO increases oxygen-carrying capacity of the blood, improves endurance, and enhances self-esteem, particularly in endurance athletes attributing their self-worth to their athletic performance. Psychologic studies of endurance athletes suggest that the administration of rHuEPO produces a significant increase in their physical condition and their commitment to training.[35] The perception of improved physical condition causes a hedonic link to endurance training and the use of rHuEPO.

The use of transfusions involves either the infusion of autologous blood (i.e., recipient and donor the same) after recovery of the recipient/donor from the effects of previously collected blood or the allogeneic transfusion of blood collected from a cross-matched donor to the recipient.[36] Although allogeneic transfusion can be detected in the recipient by erythrocyte genotyping, autologous transfusions are much more difficult to detect.[37] The typical autologous blood transfusion involves the withdrawal of 1–4 units of blood (450–1800 mL) several weeks before competition.[38] The plasma is reinfused immediately, and the erythrocytes are either refrigerated or frozen. Subsequently, the erythrocytes are infused 1–7 days before endurance events. The average increase in hemoglobin and time to exhaustion at 95% $VO_{2\ max}$ using typical blood doping is approximately 7% and 34%, respectively.[12] The decreased responsiveness of Hb-based oxygen carriers and perfluorocarbons to 2,3-DPG limits the effective-

ness and the abuse of these substances when compared with packed erythrocytes.[39] Additionally, these artificial substances are easily detected by routine laboratory tests and visual changes of the blood.

DOSE EFFECT

Medical Use

The FDA approved the use of rHuEPO for the treatment of anemia associated with chronic renal failure, zidovudine-treated HIV, cancer patients on chemotherapy, and the reduction of allogenic blood transfusions in anemic patients undergoing elective surgery with a high risk for perioperative blood loss. Anemia of chronic renal failure and chemotherapy-induced anemia associated with nonmyeloid malignancies are also an indication for darbepoetin alpha. Other uses of erythropoiesis-stimulating agents include treatment of critical care patients exhibiting severe anemia, blood loss, reduced red cell life span, impaired iron availability, and inhibition of erythropoiesis by inflammatory cytokines.[40] There are no FDA-approved uses of erythropoiesis-stimulating agents in healthy individuals or athletes.

The dose of erythropoiesis-stimulating agent depends on the indication and age beginning with an initial dose and titrating to desired effect (e.g., Hg = 10–12 g/dL, avoidance of transfusions). A typical adult dose of epoetin alfa is 50–300 U/kg 3 times a week by IV or SC routes; however, higher doses may be required. The response to epoetin alfa varies with underlying disease, dose, and dosing regimen. The administration of 500 μg/kg epoetin alfa 3 times weekly to 5 anemic renal dialysis patients resulted in a mean increase of 10 percentage points in the hematocrit after 3 weeks of therapy.[41] The baseline mean hematocrit of this group was 19 ± 3%. A dose-dependent increase in hemoglobin occurs within 2–6 weeks of administration of EPO drugs. In a study of healthy volunteers given single SC doses of rHuEPO (epoetin alfa) ranging from 300–2,400 IU/kg, the mean percentage of reticulocytes began increasing 3–4 days after administration and the maximum response occurred 8–11 days after administration.[42] Saturation of the response to rHuEPO occurred at doses above 1,800 IU/kg. The reticulocyte count returned to baseline 22 days after administration. The response was linear up to 1,800 IU/kg, but above that dose the dose-response curve flattens. Multiple, smaller rHuEPO doses (e.g., 150 IU/kg 3 times weekly) produced more modest (1–2% reticulocytes), sustained responses. Overall, stimulation of a reticulocyte response was more effective following repeated SC administration of rHuEPO than the equivalent dose as a single injection. Following

the SC administration of 10–500 IU/kg epoetin beta in monthly doses to 16 healthy volunteers, the maximum reticulocyte count occurred about 3–4 days after administration.[43]

The initial adult dose of darbepoetin alfa is 0.45–2.25 µg/kg IV or SC once weekly, depending on the underlying cause of the anemia, followed by smaller weekly doses unless higher doses are necessary to produce the desired response. Less frequent doses (e.g., every 2–3 weeks) may be sufficient depending on the indication. Doses of erythropoiesis-stimulating agents are modified at monthly intervals to maintain an acceptable hemoglobin level without hemoglobin concentrations exceeding 12 g/dL or increasing >1 g/dL in 2 weeks.[44] The recommended target hemoglobin concentration for therapeutic indications should not exceed 12 g/dL. Volunteer studies indicate that the use rHuEPO is not associated with elevated blood pressure in anemic chronic renal failure patients with the target hemoglobin of <12 g/dL.[45] In clinical trials, an increase in hemoglobin greater than approximately 1g/dL in 2 weeks was associated with a higher frequency of cardiac arrest, strokes, seizure, worsening hypertension, fluid overload, congestive heart failure, and acute myocardial infarction.[46]

Experimental Studies

Limited data from the study of healthy students and endurance athletes suggest that the administration of moderate doses of rHuEPO can modestly increase oxygen-carrying capacity.[47,48] A review of these studies indicated the SC administration of rHuEPO in doses of 60–232 U/kg weekly for 4–6 weeks produces the following increases: 1) hemoglobin, 9–14%; 2) hematocrit, 11–19%; and 3) VO_{2max} (aerobic capacity, maximal oxygen uptake), 7–9%; and enhanced endurance performance (time to exhaustions on a standard work load), 9–17%.[14] An estimated 1 g/dL increase in hemoglobin in an athlete with an exercise cardiac output of 25 L/min would increase oxygen transport about 335 mL/min (i.e., about 8% increase above normal VO_{2max} of 4,000 mL O_2/min).[49] The response of the hematocrit to rHuEPO was more modest in other studies. In a study of 11 healthy male students (mean age, 26 ± 6 year) receiving 2,000 U rHuEPO/thrice weekly for 6 weeks, the mean hematocrit increased ($P < .05$) from an initial value of 43 ± 2% to 45 ± 2% at the end of the study.[50]

Toxicity

There are limited data on toxic doses of erythropoiesis-stimulating agents associated with the clandestine use of these agents by athletes; potentially, therapeutic doses used in anemic patients may cause adverse effects (e.g., stroke, myocardial infarction, congestive heart failure, hypertension, embolism) following abuse of these agents by athletes or other individuals. The injection of a single dose of rHuEPO probably does not produce toxicity with the exception of short-term elevation of serum hepatic aminotransferases following very high doses. In a clinical study, the inadvertent administration of 318,000 U erythropoietin on the second day of a 3-day course of 33,000 U daily was associated with an approximate 10-fold increase in the serum alanine aminotransferase and aspartate aminotransferase that resolved over 3 months.[51] The hemoglobin increased about 1 g/dL over the admission value; the hemoglobin return to preadmission level within 3 months. Healthy volunteers have tolerated 2,400 U/kg as a single dose without complications.[42]

The effects of erythropoiesis-stimulating drugs require multiple injections over a prolonged period. The risks of adverse effects increases with Hb > 12–13 g/dL and/or with a high rate of hemoglobin increase (i.e., >1 g/dL per 2-week period). The maximum dosage of these agents has not been determined. In patients with end-stage renal disease, no direct toxicity was detected with larger doses of 1,500 U/kg 3 times weekly for 3–4 weeks based on pharmaceutical company data.[52] Doses of up to 8 µg/kg weekly and 15 µg/kg every 3 weeks have been administered to cancer patients for up to 12–16 weeks without complications.[46] A 42-year-old man with acquired immunodeficiency syndrome (AIDS) inadvertently injected himself with 10,000 U rHuEPO daily for several weeks.[53] Subsequently, he developed polycythemia (hematocrit 77%) along with confusion, abdominal pain, and foot pain. He recovered after erythropheresis with mild skin loss over his toes. The inadvertent administration of 384,000 U rHuEPO over 3 days to 2 patients with acute myocardial infarctions was associated with modest elevation of serum hepatic aminotransferase concentrations that resolved over 3 months.[51] The hemoglobin concentrations increased approximately 1 g/dL, and then returned to baseline in 3 months.

TOXICOKINETICS

Absorption

The participants in most pharmacokinetic studies on rHuEPO are patients with chronic renal disease, and there are limited data on the pharmacokinetics of this substance in healthy volunteers or in elite athletes. The average bioavailability of SC epoetin alfa ranges from approximately 14–40%.[54,55] The mean bioavailability of

rHuEPO after the SC administration of 50 U/kg to 6 healthy volunteers was 36% ± 23%.[56] In a single-dose pharmacokinetic study of rHuEPO in pediatric patients with chronic renal disease, the bioavailability of rHuEPO following SC administration of 40 U rHuEPO/kg was approximately 40%.[57] The time to peak concentration for epoetin alfa administered SC ranges from about 5–24 hours. Following the administration of single doses of rHuEPO (300 IU/kg to 2,400 IU/kg) to healthy volunteers, the time to peak rHuEPO concentration ranged from 15.6 ± 5.8 hours to 28.8 ± 7.8 hours.[42] The peak EPO concentration ranged from 429 ± 86 mIU/mL (300 IU/kg dose) to 6,819 ± 764 mIU/mL (2,400 IU/kg dose).

Following SC administration, the mean bioavailability of darbepoetin alfa and rHuEPO in adults are similar. In a study of 11 peritoneal dialysis patients, the mean bioavailability of darbepoetin alfa after the SC administration of about 100 U/kg was approximately 37%.[58] In a study of pediatric patients with chronic kidney disease, the mean bioavailability of darbepoetin alfa was slightly higher (i.e., 54%) compared with the adult patients and patients receiving rHuEPO.[59] Subcutaneous darbepoetin alpha reaches peak concentration within 34–54 hours after administration.[60]

Distribution

rHuEPO and darbepoetin alfa are rapidly distributed with similar volumes of distribution (V_d). Following the IV administration of 100 U/kg to 11 peritoneal dialysis patients, the mean V_d of rHuEPO and darbepoetin alfa were 48.7 ± 2.1 mL/kg and 52.4 ± 2.0 mL/kg, respectively.[58] The volume of distribution of these 2 compounds approximates the plasma volume.[61]

Biotransformation

Epoetin and darbepoetin alpha undergo extensive liver metabolism, desialation and clearance via the hepatic galactose pathway.[54] The galactose binding proteins in hepatic cells rapidly clear erythropoietin from the circulation. Erythropoietin contains *N*-glycans and *N*-acetyllactosamine repeats. The sialic acid of recombinant erythropoietin is probably necessary for this glycoprotein hormone to circulate without degradation, and the desialation of erythropoietin allows the recognition of these galactose-terminated glycoproteins by receptors on the cell surface of hepatocytes.[62,63] Subsequent endocytosis and lysosomal digestion of the asialo-erythropoietin result in the clearance of erythropoietin from the blood.

Elimination

The elimination of rHuEPO probably follows nonlinear saturation kinetics (i.e., Michaelis-Menten).[64] The elimination of rHuEPO primarily results from biotransformation with renal excretion of unchanged rHuEPO accounting for a small portion (<5%) of the total elimination. Over the first 24 hours after administration of 3 different doses of rHuEPO (10 U/kg, 100 U/kg, 500 U/kg) to 10 healthy volunteers, the overall mean percentage of rHuEPO excreted unchanged in the urine was 1.74% ± 1.04%.[65] In this study, the clearance of rHuEPO was nonlinear in doses ranging between 10 U/kg and 500 U/kg intravenously, and Michaelis-Menten elimination kinetics described best the elimination kinetics of rHuEPO. The serum half-life of rHuEPO directly correlates to sialic acid-containing carbohydrate content of the molecule as well as the dose and route of administration.[66] In a study of healthy volunteers receiving 50 U rHuEPO/kg, the mean half-life was 4.5 ± 0.9 hours following IV administration compared with 25 ± 12 hours after SC administration.[56] Similarly, the mean plasma half-life of EPO following IV doses of < 100 IU/kg was approximately 5 hours.[54] Studies in healthy volunteers suggest that the terminal half-life of epoetin beta is slightly longer (i.e., about 20%) than epoetin alfa when administered in equivalent doses.[67] The renal clearance of rHuEPO uncorrected for bioavailability averages about 48–50 mL/h/kg.[64] Assuming a bioavailability of 35% the corrected renal clearance of rHuEPO is about 17 mL/h/kg.

The addition of 2 sialic acid-containing carbohydrate chains to darbepoetin alpha compared with rHuEPO prolongs the serum half-life of darbepoetin alfa in patients with chronic kidney disease or cancer.[68] Following the IV administration of a 100 U/kg-dose to adult patients with end-stage renal disease, the mean serum half-lives of rHuEPO and darbepoetin alpha were 8.5 ± 2.4 hours and 25.3 ± 2.2 hours, respectively.[58] The SC administration of darbepoetin alfa to these patients increased the mean serum half-life to 48.8 ± 5.2 hours. After SC administration of rHuEPO to athletes, the serum erythropoietin concentration returns to baseline values about 7 days after administration compared with 4 days in the urine.[69]

Maternal and Fetal Kinetics

Hematopoiesis occurs independently in maternal and fetal circulations in response to endogenous erythropoietin. The human placenta forms a barrier to endogenous and recombinant erythropoietin, thus allowing the use of recombinant erythropoietin (rHuEPO) in the

treatment of maternal pregnancy and postpartum anemia.[70] There are few data on the excretion of epoetin alfa or darbepoetin alfa into breast milk.

Tolerance

There are few data on the specific factors that limit the hematologic response of some renal dialysis patients to the chronic administration of rHuEPO.[11] Although the therapeutic effects of erythropoietin are dose-dependent at low dose, increased biologic response in humans is not typically observed following the administration of doses exceeding 300 U/kg 3 times weekly.[71]

Drug Interactions

Preliminary data in patients with cancer suggest that concurrent chemotherapy may influence the pharmacokinetics of epoetin and darbepoetin alfa.[21] Patients on iron preparations for iron-deficiency anemia require monitoring while on EPO therapy. A functional iron deficiency developed in 13 of 18 patients with chronic EPO therapy. The decreased heme synthesis exceeded the ability of the reticulocyte to release iron to transferrin, and a relative iron deficiency develops as a result of the drop in the reticulocyte count and transferrin saturation.[41]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

Oxygen stores in the body are relatively low compared with the oxygen requirements of the body. The basal oxygen consumption rate is 4 mL/kg/min compared with total body oxygen stores of 20 mL/kg (i.e., 5 minutes of basal oxygen needs).[72] The ability of the tissues to meet oxygen demands depends in part on the number of erythrocytes (red cell mass). The kidneys and to a lesser extent, the liver and brain secrete the glycoprotein, erythropoietin (EPO), which increases the number of circulating erythrocytes (red cell mass) and thus oxygen delivery to muscle tissue.[73] Endogenous human erythropoietin is the primary regulator of red blood cell formation. The red cell mass is constant in a specific individual; however, this mass varies up to about 10% between healthy individuals of the same age and gender. Endogenous human erythropoietin couples long-term oxygen requirements to erythrocyte and hemoglobin production by acting on the early erythroid progenitor cells (erythroid burst-forming units, erythroid colony-forming units, pronormoblasts) in the bone marrow to stimulate growth and prevent apoptosis. This hormone is the paradigm of oxygen-related genes that are controlled by the main regulator of oxygen homeostasis, hypoxia inducible factors (e.g., HIF-1, HIF-2, HIF-3). These heterodimeric proteins are transcription factors that modulate a variety of genes in response to relative low-oxygen conditions. HIF-1 is the primary factor, consisting of 2 subunits, HIF-1α and HIF-β. Both HIF-1α and HIF-β are necessary to generate an active transcription complex in conjunctions with coactivators (e.g., p300/CREB).[74] HIF-1α resides in the cytoplasm where oxygen-dependent degradation occurs as a result of the hydroxylation by prolyl 4-hydroxylases. HIF-1β resides in the nucleus away for the action of these enzymes. Under hypoxic conditions, HIF-1α survives to penetrate the nucleus and forms a heterodimer with HIF-1β.

Endogenous human erythropoietin binds to the homodimeric erythropoietin receptor on the surface of colony-forming unit-erythroid cells (CFU-E), proerythroblasts, and basophilic erythroblasts in the red bone marrow, initiating cellular transcription and differentiating these cells into mature red blood cells.[54] Activation of erythropoietin receptors on the earliest committed erythroid progenitor cells (i.e., erythroid burst-forming units) initially increases proliferation of these cells along with the ability of the progenitor cells to survive and reach the reticulocyte stage. Conformational changes in specific domains on the EPO receptor also cause autophosphorylation and activation of the Janus kinase 2 pathway with subsequent signal transduction. Hematide is a small molecule analog of EPO that also binds to this receptor, but the structure of this dimeric erythropoietin-mimetic peptide is unrelated to the sequence of endogenous EPO. Animal studies suggest that the increase in red cell mass is associated with a reduction in the contribution of anaerobic metabolism to overall energy production, as a result of increased muscle glycogen and free fatty acids along with a decrease in lactate.[75]

Erythropoietin modulates a spectrum of cellular processes in addition to progenitor stem cell development, including cellular integrity and angiogenesis. Downregulation of EPO synthesis results from a variety of mechanisms including hyperoxia, increased catabolism by an expanded erythroid progenitor cell pool, blood hyperviscosity, renal disease, transfusion-dependent anemia, and the cytokines synthesis secondary to inflammatory, infectious, and neoplastic disorders.

Mechanism of Toxicity

Most research on the pathophysiology of the adverse effects of rHuEPO involve medical use rather than the illegitimate use during blood doping with very limited research on normal volunteers. Furthermore, differences in cardiovascular dynamic between renal failure

patient and athletes limits extrapolation of data from anemic chronic renal failure patients to healthy adults. The administration of rHuEPO enhances endothelial activation and platelet reactivity and increases systolic blood pressure during submaximal exercise in healthy adults.[76] These effects potentially increase the risk for thromboembolic events (myocardial infarction, stroke, pulmonary embolism, deep vein thrombosis), ischemia, hypertension and hypertensive encephalopathy, congestive heart failure, and hyperviscosity syndromes. Potentially, mechanisms for the adverse cardiovascular effects of chronic rHuEPO misuse include increased blood viscosity, hypertension, and the vasoconstrictive properties of erythropoietin.[77] Additionally, the increased hematocrit and dehydration associated with intense exercise may reveal previously undetected cardiovascular abnormalities in some athletes.

BLOOD VISCOSITY

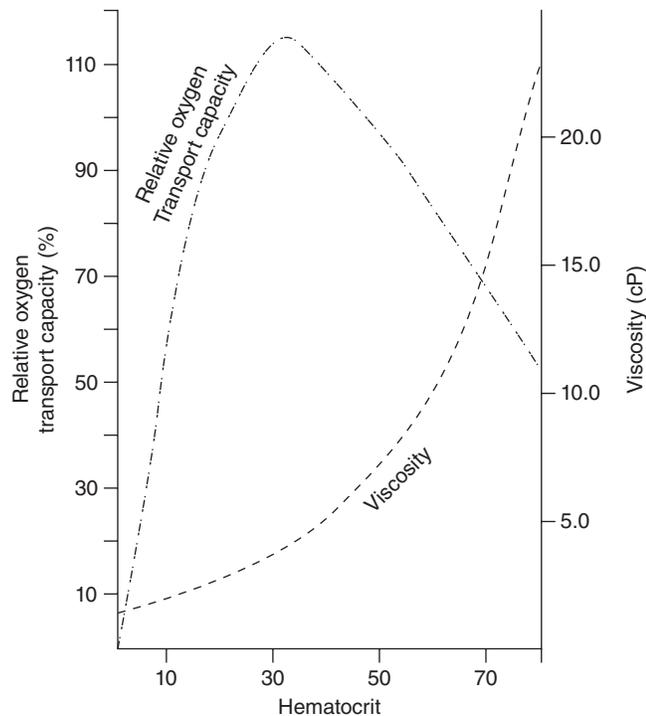
Oxygen transport capacity does not necessarily increase as the hematocrit increases. In normal individuals as the hematocrit increases above 40%, the relative oxygen transport capacity of the blood decreases due to increasing blood viscosity. Figure 17.1 displays the relationship between hematocrit, blood viscosity, and oxygen trans-


FIGURE 17.1. Correlation of oxygen transport in the brain to hematocrit and blood viscosity. (Reprinted from the American Journal of Emergency Medicine, Vol. 11, KR Brown, W Carter Jr., GE Lombardi, Recombinant erythropoietin overdose, p. 620, Copyright 2003, with permission from Elsevier.)

port in the brain. Adverse side effects of chronic rHuEPO use potentially result from this increased viscosity and the impairment of oxygen delivery.[78] In controlled clinical studies of chronic renal failure patients with anemia, comparison of traditional hemoglobin targets (10-12 g/dL) to increased rHuEPO (epoetin alfa) doses resulting in hemoglobin >13 g/dL suggested that higher doses caused increased cardiovascular events and significant increases in hypertension.[79] However, the risk of death and cardiovascular events (congestive heart failure, myocardial infarction, stroke) may vary with comorbidity among these patients. A reanalysis of this (CHOIR) study using Cox regression indicated that there was an increased risk of cardiovascular events following high compared with low-dose in subgroups without heart failure or diabetes mellitus, but not in the subgroup with congestive heart failure or diabetes mellitus.[80] Consequently, factors in addition to blood viscosity affect the risk of adverse cardiovascular events. Furthermore, the relative importance of blood viscosity and these other factors may vary between healthy individuals, patients with renal disease, and athletes using erythropoiesis-stimulating agents.

HYPERTENSION

Elevation of arterial blood pressure is a suspected cause of the excess cardiovascular events associated with high doses of erythropoiesis-stimulating agents. In normal individuals, the use of erythropoiesis-stimulating agents is associated with an increase in the average mean arterial pressure at rest (e.g., 6 mm Hg following 5,000 U for 15 weeks to maintain hematocrit near 50%)[81] and an increase mean systolic blood pressure (i.e., 14 mm Hg) during submaximal exercise at 200 W after 6 weeks of 20–40 U rHuEPO/kg thrice weekly to maintain the hematocrit near 50%.[82] The effect of rHuEPO on blood pressure in normal individuals is independent of red blood cell volume. Neither rHuEPO therapy or blood transfusions increase total blood volume because the associated increase in red blood cell volume is accompanied by quantitatively similar decrease in plasma volume.[83] In healthy adults, the use of rHuEPO produces blood pressure elevation, whereas transfusions to the same hematocrit produces no increase in blood pressure over baseline (i.e., pretreatment).[84] Consequently, the hypertension associated with rHuEPO therapy is independent of blood viscosity.

THROMBOSIS

In general, partial correction of anemia to subnormal levels (e.g., 36%) in uremic patients does not cause adverse effects with the exception of hypertension

during the first 8 weeks of therapy.[50] However, the risk of thrombotic events increases as the hematocrit exceeds normal levels. Potential mechanisms of toxicity include enhanced thrombogenesis secondary to endothelial activation and increased platelet reactivity.[38] An elevation of the red cell mass causes a reduction in cerebral blood flow. Changes in cerebral blood flow potentially increase the risk of thrombosis, transient ischemic attacks, cerebral vascular accidents, cerebral ischemia, and altered mental status.[79]

VASCULAR-DEPENDENT MECHANISMS

Animal and *in vitro* data suggest that rHuEPO may cause arterial vasoconstriction by both endothelium-dependent and endothelium-independent impairment of arterial vasodilation.[83] Potential mechanisms include changes in nitrous oxide production and the production of vascular endothelin and endothelial prostanoids.[85,86] Neither of these mechanisms account for all of the vasoconstriction associated with the use of rHuEPO.

IMMUNE REACTIONS

Rarely, case reports associated chronic rHuEPO therapy with a severe, progressive, normocytic, normochromic anemia of sudden onset with almost complete absence of erythroid precursor cells in the bone marrow.[87] This pure red cell aplasia is associated with the development of antibodies to this product. Although most of the original cases involved the use of epoetin alpha outside the United States, subsequent case reports associated pure red cell aplasia with all commercial formulations of EPO.[88] The clinical features of red cell aplasia also occur in malnutrition, other drug reactions, and a variety of other infectious, malignant, and autoimmune diseases. In all cases of red cell aplasia associated with erythropoiesis-stimulating agents, neutralizing antierythropoietin antibodies are present. Although pure red cell aplasia usually occurs after the production of neutralizing antierythropoietin antibodies, not all patients with these antibodies will develop anemia.[89] Thus, the exact mechanism of the formation of these antibodies is unconfirmed. Subsequently, these antibodies cross-react and inactive endogenous EPO.

Postmortem Examination

Pathologic findings associated with erythropoietin primarily involve the effects of increased viscosity including cerebral ischemia and thrombosis, myocardial thrombosis, cardiac muscle damage, and deep venous thrombosis.

CLINICAL RESPONSE

Medical Use

Identification of complications associated with the medical use of rHuEPO is complicated by the administration of these drugs to patients with severe chronic diseases. In early dose-finding clinical studies primarily in patients with chronic renal failure, adverse effects associated with the long-term use of rHuEPO included arterial hypertension, iron deficiency, thromboembolism (e.g., renal thrombosis),[44] mesenteric ischemia,[53] hypertensive encephalopathy with seizures (i.e., often with history of seizure disorders),[90] flu-like syndrome varicose veins, myalgias, arthralgias, headache, and hyperkalemia.[91,92] Hypertension and seizures do not usually occur in patients on short-term therapy with erythropoiesis-stimulating agents (e.g., autologous blood transfusions). Cardiovascular complications (e.g., ischemic chest pain, unstable angina, and myocardial infarctions) associated with rHuEPO therapy also occur primarily in patients with end stage renal disease.[93,94] Adverse dermatologic effects in these patients include pruritic papules,[95] angioedema/anaphylaxis (i.e., secondary to gelatin),[96] and local pain at the injection site.[97] Rarely, case reports of patients with chronic renal disease associated the use of rHuEPO with the formation of neutralizing anti-EPO antibodies and the development of red cell aplasia.[98]

Several malignant cell lines express EPO and EPO receptor mRNA that respond to hypoxic stimuli by increasing the secretion of EPO. *In vitro* studies suggest that EPO may stimulate the proliferation of neoplastic cells and protect these cells from apoptosis;[99] however, there are currently no data to indicate that there is an increased risk of cancer in patients treated with rHuEPO. There are no specific adverse effects uniquely associated with rHuEPO therapy. Extrapolation of the frequency and type of adverse effects in these clinical studies of rHuEPO to healthy adults and elite athletes is limited by differences in predisposing factors (e.g., blood viscosity, vascularity, risk factors for thromboembolism) and the lack of data on healthy individuals.

CARDIOVASCULAR

Approximately 20–30% of chronic renal failure patients treated with epoetin alfa develop hypertension or worsening of existing hypertension.[100] The change in blood pressure is usually associated with an excessive (i.e., hemoglobin > 12–13 g/dL) or a rapid rise in hematocrit. In a case series of anemic renal dialysis patients, 1 patient developed hypertensive encephalopathy with

peak blood pressure of 220/140 mmHg during rHuEPO therapy.[101] The patient recovered uneventfully after reduction of hemoglobin concentration and antihypertensive therapy. In a study of 1,598 end-stage renal failure patients on chronic darbepoetin alfa therapy, the percentage of adverse effects were as follows: hypertension, 23%, hypotension, 22%; peripheral edema, 11%; cardiac dysrhythmias, 10%; vascular access thrombosis, 8%; angina, 8%; and congestive heart failure, 6%.[102]

CENTRAL NERVOUS SYSTEM

Adverse neurologic effects associated with the medical use of rHuEPO include headache, dizziness, confusion, visual disturbances, cerebral ischemia, transient ischemic attacks, cerebral vascular accidents, and seizures.[103] A case report associated the onset of venous thrombosis of the sagittal and transverse sinuses with the therapeutic use of rHuEPO by a 37-year-old end-stage renal disease patient.[104] The patient complained of headache, and he recovered uneventfully following treatment with heparin and analgesics.

Illicit Use

There are few clinical data on the medical complication of EPO abuse; expected complications are similar to the complications associated with high-dose, therapeutic use, particularly cardiovascular and thrombotic events including hypertension. Potentially, life-threatening cerebral and cardiac thrombotic events may occur during the dehydration and plasma contraction associated with heavy exercise in elite athletes using rHuEPO. A 62-year-old man developed polycythemia (hematocrit, 70.4%) after the surreptitious injection of rHuEPO.[105] Subsequently, he developed worsening hypertension, exacerbation of chronic lung disease, and new-onset angina. His clinical abnormalities included labored breathing, cyanosis, diaphoresis, hypotension, tachycardia, and acidosis. Respiratory failure required endotracheal intubation with mechanical ventilation, IV hydration, and serial phlebotomies. He refused to divulge the amount of rHuEPO injected.

Overdose

Based on limited clinical data, healthy individuals tolerate large, single doses of rHuEPO without complications. In a clinical study of rHuEPO, 2 patients with myocardial infarctions inadvertently received about 10 times the intended dose of 33,000 U on the second of 3 days of therapy; the patients remained asymptomatic.[51] Repeated, prolonged supratherapeutic doses of rHuEPO potentially cause serious morbidity related to hyperviscosity or immune reactions (red cell aplasia, allergic reactions). Case reports associated the excessive use of rHuEPO with polycythemia, altered mental status, mesenteric ischemia, myalgias, and arthralgias. Following the inadvertent administration of high doses of rHuEPO, a 42-year-old man with AIDS developed confusion, abdominal pain, and pain in his feet.[53] The hemoglobin on presentation was 23.2 g/dL with a hematocrit of 77.1%. His symptoms resolved after treatment including IV fluids, phlebotomy, and 2 sessions of erythropheresis. The only sequelae involved minor skin loss over his toes.

Fatalities

Blood doping is a suspected cause of sudden death in young athletes, particularly in cyclists. The chronic abuse of rHuEPO by elite cyclists is an alleged cause of several deaths from cardiovascular complications.[106,107] Between 1987 and 1990, 19 Belgian and Dutch cyclists died of uncertain causes suspected to be related to the use of rHuEPO.[108] However, there are few data on the clinical features or pathologic abnormalities present in these athletes during the period leading up to their deaths.

Abstinence Syndrome

There is no abstinence syndrome associated with chronic rHuEPO therapy or abuse. However, animal studies suggest that after cessation of chronic rHuEPO therapy, inhibition of endogenous erythropoietic activity may persist, leading to the development of rebound anemia several weeks after treatment ends. Recovery of erythropoietic activity typically follows the occurrence of rebound anemia by 2 months after cessation of treatment.[109] Some factors favoring thrombosis also remain elevated after cessation of rHuEPO therapy. In a study of renal dialysis patients treated with rHuEPO, factor VIII von Willebrand factor antigen and fibrinogen remain elevated after the cessation of rHuEPO therapy, and a significant increase in the concentration of D-dimer occurred.[110]

Reproductive Abnormalities

The FDA lists epoetin and darbepoetin alfa in Pregnancy Category C.[22] The administration of epoetin alfa at 5 times the typical human dose (500 U/kg) to pregnant rats was associated with an increased incidence of decreased body weight, delayed eye opening, and decreased caudal vertebrae in offspring based on pharmaceutical company data.[52] Darbepoetin alpha studies

demonstrated decreased weight in animal models, but no evidence of teratogenetic effects were reported in the pharmaceutical company data.[111] Case reports suggest that rHuEPO is an effective therapy for pregnant patients with severe anemia and renal failure.[112] Complications typically associated with rHuEPO therapy were not reported in the neonates or mothers.[112,113] Treatment with rHuEPO and IV iron increases the mother's capacity to donate blood for autologous and intrauterine transfusions.[114]

DIAGNOSTIC TESTING

Analytic Methods

The effects of rHuEPO continue after the elimination of rHuEPO; however, there is no single, long-term biomarker of rHuEPO use. Direct testing for rHuEPO during competition is impractical because of the complex biotransformation and rapid elimination half-life (i.e., 3–4 days) of rHuEPO.[115] The strategy approved by the International Olympic Committee (IOC) for the detection of rHuEPO use in athletes involves both indirect testing for the effects of rHuEPO and direct testing for the presence of rHuEPO by isoelectric focusing and double immunoblotting.[116] These methods separate rHuEPO from endogenous EPO based on differences in the pattern and extent of glycosylation. There are no direct screening methods for the detection of oxygen carriers, and the best screening method for the detection of hemoglobin-based oxygen carriers is direct visualization of plasma discoloration. The detection limit for this technique is <1% hemoglobin-based oxygen carrier in plasma.[117] The presence of elevated plasma hemoglobin concentrations alone are not sufficient proof of blood doping because 1) hemolysis of erythrocytes during extreme exercise, and 2) storage increases the plasma hemoglobin concentration. The standard cyanmethemoglobin method does not distinguish between endogenous hemoglobin and hemoglobin-based oxygen carriers. Confirmatory methods for the detection of hemoglobin-based oxygen carriers include electrophoresis, size-exclusion high performance liquid chromatography, and liquid chromatography/tandem mass spectrometry.[118] The detection of perfluorocarbons requires specific, expensive analyzers and flow-measuring devices.[119] Methods to detect the presence of the plasma volume expander, dextran in urine samples include liquid chromatography/tandem mass spectrometry.[120] The assay limit of detection (LOD) was 3.8 μg/mL and the lower limit of quantitation (LLOQ) was 12.5 μg/mL. Conventional laboratory techniques do not typically detect gene doping because the detection of gene doping requires molecular techniques with the ability to recognize EPO transgenes and gene transfer vectors.

INDIRECT METHODS

These methods disclose abnormal stimulation of erythropoietic activity by comparing various hematologic parameters in peripheral blood with baseline or population norms. Indirect methods for the detection of rHuEPO use include macrocytic hypochromic erythrocytes, serum soluble transferrin receptor concentration (sTfr), and a combination of 5 biomarkers of enhanced erythropoiesis (hematocrit, reticulocyte percentage, macrocytic erythrocyte percentage, serum EPO, sTfr). Often, the combination of indirect measures of EPO use is called a blood passport; both the International Ski Federation and the International Cycling Union use blood passports to detect blood doping. Changes in these parameters may persist up to 4 weeks after cessation of rHuEPO use based on rHuEPO injections 3 times weekly for up to 8 weeks.[121] However, use of less frequent injections of rHuEPO (e.g., 60–65 IU/kg body weight once weekly) decreases the sensitivity of these indirect methods to detect EPO use.[122]

INDIVIDUAL TESTS.   The use of macrocytic erythrocyte percentage as a marker of rHuEPO administration is a specific, but insensitive technique. In a study of 20 amateur athletes receiving 30 U rHuEPO/kg every other day for 45 days, the use of 0.6% macrocytic erythrocytes as the cutoff detected about 50% of the individuals using rHuEPO.[123] The percentage of macrocytic erythrocytes in blood samples from the 240 elite athletes in the control group did not exceed this cutoff value (i.e., no false-positives). Analytic methods for the detection of serum soluble transferrin receptor (sTfr) include enzyme-linked immunosorbent assay (ELISA), immunoturbidimetry, and a nephelometric technique.[124] This substance is released primarily from erythropoietic progenitors; thus, this test is an indirect marker of erythropoiesis.

ON/OFF MODEL.   The Australian Institute of Sport and the Australian Sports Drug Testing Laboratory developed 2 mathematical models for the detection of rHuEPO use based on Fischer's discriminant analysis of changes in indirect makers of hematopoiesis during the administration of rHuEPO to recreational athletes.[125] The ON model is a screening test to determine the need to collect urine samples for the detection of rHuEPO use. This model utilizes 5 erythrocyte and serum parameters (hematocrit, reticulocyte count, percentage macrocytic erythrocytes, serum EPO, serum sTfr) to screen for the current use of rHuEPO. This model is highly

sensitive during the last 2 weeks of rHuEPO administration and a few days after cessation; however, the sensitivity drops dramatically a few days after stopping the injection of low to moderate doses of rHuEPO.[126] False-positives occur rarely. The OFF model uses 3 indirect markers (hematocrit, percentage macrocytic erythrocytes, serum EPO) to detect the recently (i.e., last 14 days) discontinuation of rHuEPO use; this model is more sensitive than the ON model during the later stages of rHuEPO use up to the last few days prior to cessation.

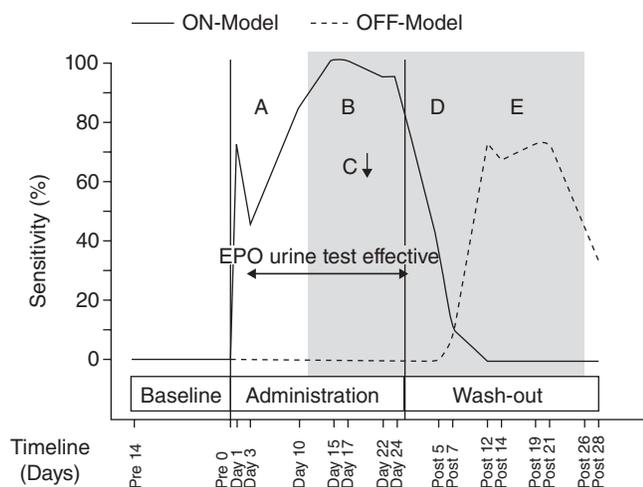
The OFF model is the only model to detect rHuEPO use >1 week after cessation of use. Figure 17.2 displays the sensitivity of the ON and OFF models in relation to the time of rHuEPO use. The OFF model did not completely separate rHuEPO use from controls; therefore, a confirmatory test (e.g., isoelectric patterning) is required to confirm recent rHuEPO use. The sensitivity of the OFF model up to 3 weeks after cessation of use was 67–72% with no false-positive tests.[127] Some adjustment of the ON- and OFF-model scores for training modalities is necessary because studies of male endurance athletes training at high altitudes demonstrate moderately higher ON-model scores compared with training at sea level.[128] However, physical fitness, training workloads, and sport do not substantially alter the indirect serum biomarkers for the detection of rHuEPO use.[129]


FIGURE 17.2. Sensitivity of ON and OFF models for the detection of rHuEPO use. The shaded area represents the period of enhanced performance.[162] Scenario A: period of rapid increase in rHuEPO concentration before performance enhancement; Scenario B: steady-state rHuEPO use-high dose; Scenario C: steady-state rHuEPO use-low dose; Scenario D: period of increasing OFF model scores while ON model scores decrease; Scenario E: postadministration period with elevated OFF model scores. (Reprinted with permission from R Kazlauskas, C Howe, G Trout, Strategies for rhEPO detection in sport, Clinical Journal of Sport Medicine, Vol. 12, Issue 4, p. 234, copyright 2002.)

Second-generation models (ON-he, ON-hes, OFF-he, OFF-hes) based on standard discriminant analysis are more sensitive than original models, particularly for the detection of the cessation of rHuEPO use and low rHuEPO doses during maintenance regimens.[130] These second-generation models use hemoglobin, reticulocyte percentage, serum erythropoietin, and serum transferrin receptor concentrations rather than volume-dependent parameters (i.e., macrocytic erythrocytes). The incorporation of volume-independent blood parameters allows increased storage and transport times between sample collection and analysis. Longitudinal monitoring of athletes (e.g., hemoglobin, reticulocyte percentage) substantially improves the detection of rHuEPO use weeks after injections cease, particularly when compared with historical values.[131] Blood samples refrigerated for up to 24 hour at 4°C are suitable for the determination of indirect hematologic parameters associated with rHuEPO use.[132] Third-generation models use the athlete's baseline values (hemoglobin, hematocrit, reticulocyte count, third-generation OFF score) rather than population-derived thresholds to reduce within-subject variability.[121]

DIRECT METHODS

IMMUNOASSAYS.   Most standard immunoassays do not distinguish endogenous EPO from recombinant forms of erythropoietin. Immunoassays for the analysis of serum EPO include chemiluminescent immunoassay (CHEM) and ELISA. The LOD and LLOQ are lower for CHEM than ELISA. In an interlaboratory validation study of these 2 immunoassays, the LOD for CHEM was 0.2 mIU/mL compared with 0.6 mIU/mL for ELISA.[133] The LLOQ for CHEM and ELISA were 0.5 mIU/mL and 2 mIU/mL, respectively. The erythropoiesis-mimetic peptide, hematide does not cross reaction with EPO antibodies; thus, conventional tests for rHuEPO do not detect the misuse of this drug.[134]

ELECTROPHORESIS.   The International Olympic Committee Medical Commission (WADA technical document TD2007EPO) approved the use of isoelectric focusing with double immunoblotting and chemiluminescence detection as the confirmation of rHuEPO in urine samples from participating athletes. The second blotting step ("double-blotting") is necessary to avoid nonspecific binding of the secondary antibody and keep interfering urinary proteins on the first membrane.[135] Isoelectric focusing in a horizontal slab-gel containing carrier ampholytes in a pH ranging from 2–6 separates discrete isoforms of endogenous and recombinant EPO based on mass and charge differences in the *N*- and

O-glycans of the isoforms. rHuEPO is less anionic than endogenous EPO;[136] the slightly greater number of sialic acid residues in the glycosylated side chains of the rHuEPO molecule compared with endogenous EPO also allows the separation of these 2 molecules using the isoelectric patterning method in a pH gradient electrical field.[137] The use of rHuEPO by athletes suppresses the production of endogenous EPO, resulting in a continuous shift to the recombinant IEF-profile depending on the serum half-life and the dose of rHuEPO. Some atypical isoelectric focusing patterns result from the partial desialylation, which potentially causes false-negative (but not false-positive) results.[138] To reduce false-positive results, a positive test requires detection of at least 3 consecutive bands with 2-fold greater intensity than those in the acidic region.[39] The use of electrophoresis to detect rHuEPO in urine samples is limited by expense and the short detection interval (i.e., <24–48 hours after the last injection).[139] The unique gene activation technology used to produce epoetin delta limits the effectiveness of current analytic techniques used to detect rHuEPO use.[38] The use of isoelectric focusing techniques requires precautionary measures to prevent EPO degradation by endogenous proteases in urine.[137] Alternate electrophoretic methods for the detection of rHuEPO in urine samples include sodium dodecyl sulfate-polyacrylamide gel electrophoresis and 2-dimensional (2D) electrophoresis. The former method separates proteins based on their apparent molecular mass; an upstream immunoaffinity purification step allows the detection of EPO isoforms.[140] The 2D electrophoretic method combines separation by charge (isoelectric focusing) and by molecular mass (sodium dodecyl sulfate-polyacrylamide gel electrophoresis), resulting in greater resolution than either method alone.[141]

MASS SPECTROMETRY. Mass spectrometric methods for the detection of rHuEPO and darbepoetin alpha in urine samples include liquid chromatography/mass spectrometry,[142] electrospray ionization mass spectrometry (ESI/MS) with separation by either high performance liquid chromatography or capillary electrophoresis,[143] and matrix-assisted laser desorption/ionization mass spectrometry applying a high-resolution time-of-flight mass analyser in the linear mode.[144] The use of enzymes (e.g., trypsin) to cleave the intact glycoproteins allows more detailed structural characterization of EPO isoforms, when analyzing the subsequent peptides/glycopeptides or glycans with a high-resolution time-of-flight mass analyser in the linear mode or electrospray ionization mass spectrometry.[73] The latter method can be operated either on-line or off-line, whereas a high-resolution time-of-flight mass analyser

in the linear mode is primarily an off-line method. Dynepo™ (erythropoietin-delta; Shire Pharmaceuticals, Dublin, Ireland) has no distinct glycosylation pattern that distinguishes this substance from endogenous EPO by direct EPO testing. Although the addition of proteases to urine samples dramatically reduces the sensitivity of these assays, direct tests for protease activity are available to detect sample manipulation.

Biomarkers

BLOOD

In a given individual, the plasma EPO concentration is relatively constant; however, there is about a 2-fold variation among individuals independent of gender, age, and red cell mass.[145] The effects of rHuEPO continue after the elimination of rHuEPO; therefore, analysis of blood primarily involves the detection of indirect biomarkers that suggest rather than confirm rHuEPO use. Increases in the hemoglobin and hematocrit begin about 2–6 weeks after the administration of rHuEPO. Elevation of serum EPO suggests the use of rHuEPO, but standard analytic techniques do not discriminate between endogenous EPO and rHuEPO. Both short-term aerobic exercise and endurance training do not significantly alter the serum erythropoietin (EPO) concentration.[146] In a study of 46 long-distance runners during a training period, the mean serum EPO concentrations of the endurance runners (19.7 ± 5.5 U/L) and sedentary controls (19.7 ± 9.2 U/L) were not statistically different, as measured by radioimmunoassay.[147] There was no statistically significant difference in the serum EPO concentration of a subset (17) of these endurance runners, when comparing the mean serum EPO before and after a 6-hour race. The mean serum EPO concentration was significantly lower ($P < .05$) in a group 15 male triathletes than in a group of 45 male long-distance runners.[148] However, there were no significant differences in the mean serum EPO concentration in female and male athletes in various sports when compared with sedentary controls. Data on the effect of circadian rhythms on the serum EPO concentration are conflicting with some studies demonstrating no effect[149] and other studies indicating lower serum EPO concentration in the morning and higher concentrations in the evening.[150]

The serum sTfr concentration depends on the erythroid proliferation rate and cellular iron demands. Suggested threshold for detection of rHuEPO use based on a 200 U/kg dosing regimen was a serum sTfr concentration exceeding 10 μg/mL.[151] The ratio of sTfr/serum ferritin depends on the amount of rHuEPO administered. In the same study using the 200 U/kg dosing

regimen, statistical analysis indicated a threshold value for the sTfr/serum ferritin ratio of 403 compared with 153 for a 50 U/kg dosing regimen.[48] In contrast to the serum sTfr, the sTfr/serum ferritin ratio is independent of the hematocrit. The use of the sTfr/serum protein ratio has the advantage of being unaffected by the administration of iron supplements that are commonly used by endurance athletes on rHuEPO. The serum sTfr remains elevated for about 1 week after cessation of rHuEPO use compared with about 2 weeks for the sTfr/serum protein ratio.[152] However, these values return to baseline before the ergogenic effect of rHuEPO ceases. Therefore, the use of sTfr or ratios involving sTfr is most useful for out-of-competition testing.

Urine

The typical concentration of EPO in the urine of non-athletes is about 1 IU/L (10 pg/L), whereas the upper limits of elite male and female athletes is 13.5 IU/L and 7.7 IU/L, respectively.[137] Isoelectric focusing differentiates between rHuEPO, endogenous EPO, and darbepoetin alpha, but not Dynepo™ (erythropoietin-delta).[153] The sensitivity of this method decreases dramatically more than 3 days after use of rHuEPO, whereas the longer half-life of darbepoetin alpha allows detection up to about 1 week.[14] In a study of volunteers receiving epoetin alfa 3 times weekly at a dose of 50 IU/kg for 3 weeks, the sensitivity of isoelectric focusing was 100% and about 50% for urine samples collected 3 days and 7 days, respectively, after cessation of the injections.[154] Case reports suggest that the use of microdoses of rHuEPO (i.e., <10% of initial doses) as a maintenance dose reduces the detection interval for rHuEPO in the urine.[155] The detection interval for darbepoetin alfa in urine samples is substantially longer than most forms of rHuEPO. In a study of 3 healthy men, darbepoetin alfa was detectable in urine samples for up to 7 days after the injection of 40 μg (60 IU), as measured by isoelectric focusing.[156] Case reports suggest that false-positive results for epoetin beta occur rarely under conditions of extreme exercise following the analysis of postexercise, highly concentrated, protein-rich urine using isoelectric focusing.[157] Additional tests to identify false-positive results include indirect markers of altered erythropoiesis or 2D electrophoresis.[158]

Abnormalities

Abuse of rHuEPO can decrease endogenous EPO production, depress reticulocytosis, and cause anemia.[159] Blood abnormalities associated with chronic rHuEPO use include thrombosis (increased D-dimer), refractory anemia (decreases reticulocyte count), and hyperkale-mia. The inadvertent administration of 384,000 U rHuEPO over 3 days was associated with modest elevation of serum hepatic aminotransferase concentrations, but no liver dysfunction developed.[51]

TREATMENT

Stabilization

The treatment for excessive use of erythropoiesis-stimulating agents is supportive including withdrawal from these agents and close monitoring for the development of ischemic (angina, myocardial infarction, congestive heart failure, mesenteric ischemia) and thrombotic (cerebral embolism/infarction, deep vein thrombosis, pulmonary embolism) complications. There are no known antidotes for overdoses of erythropoiesis-stimulating agents.

Polycythemia

Life-threatening ischemic and thrombotic complications frequently occur when the hematocrit exceeds 60%. Patients presenting with a hematocrit above this level require emergent phlebotomy along with fluid replacement or in very emergent situations, erythropheresis (i.e., selective removal of erythrocytes with reinfusion of the remaining portion of the blood) in sufficient amounts to decrease the hematocrit to levels near 55%. The ultimate hematocrit target over the first week of therapy is <45% while maintaining intravascular volume.[53] In a patient with a hematocrit of 72% following an inadvertent overdose of rHuEPO, phlebotomy and 2 sessions of erythropheresis removed 898 mL and 640 mL red blood cells, respectively.[53] Reducing his hematocrit below 45% resolved his symptoms of abdominal pain, confusion, and peripheral ischemia. Repeat phlebotomy or erythropheresis may be necessary in the first 4–5 days after cessation of erythropoiesis-stimulating agents because of the continuing presence of erythropoiesis-stimulating agents during this period. In less urgent, asymptomatic patients, phlebotomy (500 mL with fluid replacement) may suffice every other week.

Hypertension

Hypertension is a common adverse effect associated with erythropoiesis-stimulating agents that is multifactorial (e.g., preexisting hypertension, rapid increase in hematocrit, low baseline hematocrit, genetic predisposition, high-dose therapy). The elevation in blood pressure usually responds to conventional therapy including reduction and/or discontinuation of

erythropoiesis-stimulating agents, antiplatelet therapy, standard antihypertensive agents (beta-blockers, vaso-dilators), and fluid removal (diuretics or dialysis in patients with end-stage kidney disease).[160,161] ACE-inhibitors and calcium antagonists are options to beta-blockers and vasodilators as choices for an antihypertensive agents. Rarely, hypertensive encepha-lopathy complicates the use of rHuEPO in patients with end-stage renal disease. Other than the reduction of elevated hemoglobin concentrations as outlined in the Stabilization section, the treatment of hypertensive encephalopathy in these patients is similar to standard therapy for hypertensive encephalopathy including the IV use of nitroprusside (initial infusion rate 0.1 μg/kg/min titrated to desired end point with typical average infusion 0.5–8 μg/kg/min) or, in cases with coronary ischemia, nitroglycerin (10–20 μg/min increased by 5–10 μg/min every 5–10 minutes until desired response).

Gut Decontamination

Decontamination measures are unnecessary because of the poor oral bioavailability of erythropoiesis-stimulating agents.

Elimination Enhancement

The large molecular weight of erythropoiesis-stimulating agents limits the efficacy of extracorporeal methods of removal. Hemodialysis for complications following the use of erythropoiesis-stimulating agents primarily involves the correction of fluid and electrolyte balance in patients with chronic renal disease. Plasmapheresis theoretically could reduce the circulating erythropoiesis-stimulating agents, but there are no clinical data to support the routine use of plasmapheresis.

Supplemental Care

The presence of severe vomiting or diarrhea indicates the need to monitor fluid/electrolyte balance and evalu-ate the patient for mesenteric ischemia. Asymptomatic patients with elevated hematocrit from chronic use of erythropoiesis-stimulating agents require monitoring of hematocrit and blood pressure for at least 1 week after cessation of therapy. Patients with pure red cell aplasia usually require regular packed red blood cell transfu-sions until the anemia resolves and the antierythropoi-etin antibodies disappear. In cases of pure red blood cell aplasia related to drugs other than erythropoiesis-stimulating agents, the anemia typically remits within 1–2 weeks; however, there are inadequate data to deter-mine the course of pure red blood cell aplasia in indi-viduals abusing erythropoiesis-stimulating agents. In the

absence of kidney transplantation, the treatment of pure red blood cell aplasia usually involves prednisone (1 mg/kg/d starting dose).[88]

Chapter 18

HUMAN CHORIONIC GONADOTROPIN

HISTORY

In the late 1920s, Zondek and Ascheim discovered a hormone in the urine of pregnant women that simulated some of the effects of pregnancy in immature female mice.[1] Various modifications of their assay based on biologic activity were developed as a means to diagnose pregnancy until the introduction of immunoassays in the 1970s.[2] Screening for the abuse of human chorionic gonadotropin (hCG) in athletic events began in the early 1980s, when urine screens from some elite athletes demonstrated abnormally large concentrations of hCG. The International Olympic Committee (IOC) banned the use of hCG in 1987. The Medical Commission of the IOC introduced testing for peptide hormones and analogues in 1989, including hCG and related releasing factors (adrenocorticotropic hormone, human growth hormone, erythropoietin). This testing involved immunoassay screens rather than confirmatory methods of analysis (i.e., gas chromatography/mass spectrometry). Only men are tested for hCG because of the lack of effect of this compound on muscle mass and athletic performance in women. In 1999, an initiative by the IOC resulted in the Lausanne Declaration on Doping in Sport and the formation of the World Anti-Doping Agency (WADA) to provide scientific research, education, and monitoring of the use of doping agents in sports; WADA now supervises the implementation of the World Anti-Doping Code including the use of hCG and other doping agents by elite athletes. This private Swiss law agency is funded both by the IOC and world governments.

IDENTIFYING CHARACTERISTICS

Structure

Human chorionic gonadotropin (hCG, CAS RN:9002-61-3) is a highly glycosylated, endogenous hormone that belongs to a family of dimeric, structurally similar glycoprotein hormones (thyroid stimulating hormone, follicle stimulating hormone, leuteinizing hormone). Human chorionic gonadotropin consists of a α-subunit of hCG (hCGα, MW: 14 kDa and a β-subunit (hCGβ, 23.5 kDa). HCGα is part of leuteinizing hormone, follicle-stimulating hormone, and thyroid-stimulating hormone in addition to hCG; therefore, the biologic specificity of these hormones resides in hCGβ. Luteinizing hormone (LH) and hCG have similar affinities for the same target cell receptors in the Leydig cells and similar structure with the exception that hCG has an additional 29-amino acid residues at the C-terminal region containing 4 antigenically distinct, *O*-linked sialic acid capped glycosylation sites. The highly glycosylated β-carboxy terminus on hCG facilitates detection by specific immunoassays or mass spectrometry. Various forms of aberrant glycosylation are common in tumor-derived hCG.

The blood and urine contain a variety of isoforms, fragments, and degradation products of hCG in addition

TABLE 18.1. Nomenclature for Human Chorionic Gonadotropin (hCG) and hCG-Related Molecules.[27]

Molecule	Symbol	Description
Intact hCG	hCG	Purified hCG without nicked forms or free subunits
Nicked hCG	hCGn	Partially degraded hCG with missing peptide bonds in hCGβ40–hCGβ50 region
α-Subunit of hCG	hCGα	Purified hCGα-subunits without intact dimeric hCG or other related molecules
β-Subunit of hCG	hCGβ	Purified hCGβ-subunits without intact dimeric hCG or other related molecules
Nicked β-Subunit of hCG	hCGβn	Partially degraded hCGβ with peptide bonds in hCGβ40–hCGβ50 region
β-Core fragment of hCG	hCGβcf	Residues hCGβ-6 to hCGβ-40 joined by disulfide bonds to hCGβ-55 to hCGβ-90

Abbreviations: hCG = Human chorionic gonadotropin.

to the pure hormone. The heterogeneity of hCG forms in biologic fluids (intact hCG, free subunits, fragments or nicked forms) result from production and metabolic processes as well as degradation during storage (e.g., nicked forms of hCG). Although hCGβ has some growth-promoting activity in *in vitro* studies of cancer cells,[3] the function of free hCG subunits including hCGβ remains unclear. Table 18.1 lists the descriptions of intact hCG and related molecules. Most free subunits of hCG lack biologic activity under normal physiological conditions. The free β-subunit (hCGβ) is a 22-kDa polypeptide consisting of 145 amino acid residues with 4 *O*-linked and 2 *N*-linked carbohydrate chains. The core fragment (hCGβcf) of hCGβ is a 10-kDa 2-chained polypeptide linked by disulfide bonds. This core fragment lacks several sequences present in whole hCGβ; production of hCGβcf probably results from the proteolytic degradation of hCG and hCGβ by the kidney. About one-half of the hCG immunoreactivity in urine results from hCGβcf; however, most commercial hCG assays do not detect this core fragment.[4] The free α-subunit (hCGα) is a glycosylated 14-kDa polypeptide consisting of 92 amino acid residues and 2 *N*-linked carbohydrate chains. The serum concentration of hCGα is substantially higher than hCGβ with the latter compound accounting for about 1% of the total hCG.[5] Partially degraded forms of hCG (hCGn) and hCGβ (hCGβn) also occur in the serum and urine as a result of the spontaneous cleavage of amino acids at various positions between amino acids 44–48. The hCG produced in early pregnancy and by trophoblastic cancers is highly glycosylated, but the hyper-glycosylated hCG

(hCGh) decreases to a few percent after 10 weeks of pregnancy.[6] The various forms of hCG produce differences in antigenicity. The substantial variation of hCG forms in sialic acid (charge), carbohydrate, and peptide structure dramatically affect the recognition of hCG in urine by commercial hCG assays based on the sandwich principle.[7]

Form

Human chorionic gonadotropin is available for exogenous administration in various prescription formulations as either purified hCG derived from the urine of pregnant women or by production through recombinant DNA technology.

RECOMBINANT

Ovidrel® (choriogonadotropin alfa; Serono Laboratories, Inc., Randolph, MA) is a subcutaneous (SC) preparation of recombinant hCG (rhCG) that consists of noncovalently linked α- and β-subunits similar to endogenous hCG. The primary amino structures of the α-subunit of rhCG and endogenous hCG are identical, whereas the glycoform pattern differs slightly between recombinant and endogenous forms in the extent of branching and sialylation of oligosaccharides. The glycosylation patterns of the β-subunits of rhCG and endogenous hCG are also very similar, but not identical. Thus, the antigenicity of rhCG is not identical to the forms of hCG derived from the urine of pregnant women. Furthermore, the core fragment, hCGβcf accounts for much of the immunoreactivity in urine of pregnant women with the exception of the first 5–7 weeks of pregnancy when hCG is the predominant form.

PURIFIED HCG

Pregnyl® (Organon International, Roseland, NJ) is an injectable, highly purified preparation of hCG obtained from the urine of pregnant women. This preparation contains equal amounts of hCG isoforms and the core fragment (hCGβcf) that is available in sterile, lyophilized 10 mL-vials for intramuscular administration. Other pharmaceutic sources of hCG derived from pregnant women include Profasti® (Serono Laboratories, Inc., Randolph, MA) and Novarel® (Ferring Pharmaceuticals Inc., Suffern, NY). Each vial contains either 5,000 IU or 10,000 IU, and administration of the lyophilized powder requires reconstitution with a diluent. The urine from athletes using commercial hCG preparations derived from the urine of pregnant women contains little hyperglycosylated hCG (hCGh) that normal appears primarily in early pregnancy.

EXPOSURE

Epidemiology

Human chorionic gonadotropin is listed as a prohibited drug by WADA.[8] Abuse of hCG in male power athletes usually results from the use of this hormone to stimulate testosterone production before competition or to prevent testicular atrophy/shutdown after prolonged courses of testosterone and anabolic androgenic steroids.[9] Human chorionic gonadotropin is an attractive alternative to LH because the latter hormone is supplied in small doses and has a much shorter plasma half-life compared with hCG. There are inadequate data on the prevalence of hCG use among amateur or elite athletes to determine the extent of hCG use among these athletes. The main medical indication for the administration of hCG is the restoration of endogenous testosterone production and normalization of blood testosterone concentrations in gonadotropin-deficient men (e.g., delayed male puberty).

Sources

The primary natural sources of hCG are the syncytiotrophoblastic cells of the growing placenta and the developing embryo. Other sources in addition to the normal placenta include trophoblastic disease (hydatiform mole, choriocarcinoma), ectopic pregnancy, gonadal cancers (ovarian, testicular, extragonadal teratoma), and nontrophoblastic tumors. Medical uses for hCG include prepubertal cryptorchidism, selected cases of hypogonadotropic hypogonadism in men, and the induction of ovulation and pregnancy in the anovulatory, infertile woman with secondary ovarian failure. There are numerous Internet sources for pharmaceutic preparations of hCG; however, there are inadequate data to determine the source of hCG as an ergogenic aid.

Methods of Abuse

Illicit use of hCG by male power athletes usually involves the use of hCG to stimulate testosterone production, to reduce testicular atrophy during anabolic androgenic steroid use, and/or to normalize the testosterone/epitestosterone (T/E) ratio after the administration of anabolic androgenic steroids.[10,11] The latter 2 effects are the most common reasons for the abuse of hCG because hCG is more expensive and less efficient than testosterone and anabolic androgenic steroids for the enhancement of muscle strength. Some male athletes use pharmaceutic preparations of hCG to stimulate testosterone production before competition to improve performance. The administration of hCG often occurs with the mistaken belief that the use of hCG will help avoid the detection of anabolic steroid use by reducing the testosterone/epitestosterone ratio. The administration of hCG stimulates the endogenous production of both testosterone and epitestosterone without increasing the urinary T/E ratio above normal values. This hormone is also administered with cycles of anabolic steroids in an attempt to prevent reduced spermiogenesis and testicular atrophy. The abuse of hCG by female athletes is unlikely because hCG has negligible, if any, stimulation of blood testosterone concentrations in healthy young women; therefore, the use of hCG by women does not improve athletic performance.

DOSE EFFECT

Medical Use

Therapeutic use of the gonadotropins, LH and chorionic gonadotropin, is uncommon and primarily involves the stimulation of steroid production by the gonads. Recommended doses of purified hCG for prepubertal cryptorchidism include 5,000 USP Units (IU) every second day for 4 injections or 500 USP Units 3 times weekly for 4–6 weeks with an increase to 1,000 USP Units 3 times weekly for 4–6 weeks if the response is inadequate. Dosage regimens for hypogonadotropic hypogonadism include 500–1,000 USP Units 3 times a week for 3 weeks, followed by the same dose twice a week for 3 weeks or 4,000 USP Units 3 times weekly for 6–9 months. The latter dose is reduced to 2,000 USP Units 3 times weekly for an additional 3 months, if needed. For many years, purified urinary hCG (uhCG) has been administered to induce the final maturation of follicles and to support the luteal phase of the cycle in women. The dose of uhCG for the induction of ovulation and pregnancy in anovulatory, infertile woman without primary ovarian failure is 5,000–10,000 USP Units 1 day following the last dose of menotropins. The dose of 250 μg rhCG (Ovidrel®) has similar efficacy for infertile women as 5,000–10,000 USP Units uhCG. There are no common off-label uses of hCG in routine clinical medical practice; the use of hCG to treat obesity lacks validation by clinical data.

Illicit Use

Anecdotal data suggests that steroid abusers often use once monthly injection of 2,500-5,000 IU of hCG during an anabolic steroid cycle.[12] During the last 2 weeks of the anabolic steroid cycle, the dose of hCG typically increases to 10,000–20,000 IU divided into 2–4 injections. Other athletes inject 500–1,000 IU daily during a

cycle. There are few data on hCG doses associated with acute or chronic toxicity, in part because of the lack of reporting of illicit hCG use.

TOXICOKINETICS

Absorption

Based on volunteers studies, the bioavailability of hCG is slightly greater after intramuscular (IM) injection than SC injection and greater in nonobese than obese women. Typically, the absolute bioavailability via IM and SC routes ranges from approximately 40–50%. In a study of 6 men and 6 women, the mean absolute bioavailability of 125 μg rhCG IM was 0.47 ± 0.11 compared with 0.39 ± 0.11 for subjects receiving the same dose subcutaneously.[13] A study of 12 nonobese and 12 obese women (body mass index ≥ 28 kg/m^2) compared the area under the plasma concentration-time curve (AUC) from zero to infinity after IM and SC injection of the 2 groups.[14] In nonobese women and obese women, the mean AUC was approximately 24% and 58% higher, respectively, following IM than SC injection. Figure 18.1 demonstrates the plasma hCG concentrations after IM and SC injection of 10,000 IU hCG into obese and nonobese women. Following IM injection of 10,000 IU of equal amounts of hCG and hCGβcf (Pregnyl®) into nonpregnant women, peak serum concentrations of approximately 200–300 IU hCG/L occurred about 1 day after administration.[15] In a study of 404 women receiving 10,000 IU hCG IM, the mean serum concentration was 204.2 IU/L (range, 51–644 IU/L) 12 hours after administration.[16] Peak serum concentrations of LH following IM or SC injections of 5,000 IU are approximately 20 IU/L 1 day after administration.[4]

Distribution

In a study of 6 women and 6 healthy men receiving 250 μg r-hCG IV, the mean steady-state volume of distribution of rhCG was 6.7 ± 1.2 L.[13] During the same study, the steady-state volume of distribution in 12 subjects receiving 5,000 IU of hCG (urine-derived) intravenously was 6.6 ± 2.6 L.

Biotransformation/Elimination

There are limited data on the biotransformation and elimination of hCG; the kinetics of hCG is complex, depending on the formulation, analytic techniques, and phase of pregnancy. Human chorionic gonadotropin undergoes proteolytic degradation both in the liver and the kidney. Hepatic metabolism accounts for about 80% of the elimination of endogenous hCG, whereas the kidney excretes about 20% of the hCG dose, primarily as subunits (e.g., hCGβcf) and nicked forms.[17] The elimination half-lives of endogenous hCG, purified uhCG, rhCG, and hCG subunits vary substantially. The serum half-life of intravenous (IV) purified hCG is biphasic with an average rapid phase of about 5–6 hours and a slow phase of approximately 24–36 hours as measured by radioimmunoassay.[18,19] As measured by immunofluorometric assays, the clearance of hCG in serum samples from 6 women 3 weeks postpartum followed a 3-component model with reported median half-times of about 3½ hours, 18 hours, and 53 hours. The clearances of hCG subunits (hCGα, hCGβ) are more rapid than purified hCG following IV administration with hCGα cleared more rapidly than hCGβ. The serum elimination half-lives in the former study were about ¼ hour and 1¼ hours for hCGα, and approximately ¾ hour and 4 hours for hCGβ. In the study using immunofluorometric assays to detect hCG in postpartum women, the half-lives of hCGα were substantially shorter than hCGβ and purified hCG. The median reported half-times of hCGα were about ½ hour, 6 hours, and 22 hours compared with approximately 1 hour, 24 hours, and 194 hours for hCGβ. The mean serum elimination half-life of hCG was 1.56 ± 0.12 days after the IM injection of 10,000 IU of equal amounts of hCG and hCGβcf (Pregnyl®) to nonpregnant women, as measured by radioimmunoassay.[15] In a study of 404 women receiving 10,000 IU hCG IM, the mean serum half-life of hCG

hCG (IU/L)

FIGURE 18.1. Plasma human chorionic gonadotropin concentrations following intramuscular or subcutaneous injection in obese and nonobese women. (Reprinted from CCW Chan, EHY Ng, MMY Chan, OS Tang, EYL Lau, WSB Yeung, P Ho, Bioavailability of hCG after intramuscular or subcutaneous injection in obese and non-obese women, Human Reproduction, 2003, Vol. 18, p. 2295, by permission by Oxford University Press.)

was approximately 48 hours.[16] The terminal serum half-life of hCG and rhCG is similar. For healthy subjects receiving 125 µg rhCG IM and SC, the mean serum elimination half-life was 26.6 ± 6.5 hours and 28.3 ± 5.8 hours, respectively, as measured by immunoradiometric assay (MAIAclone™, Serono Biodata, Italy).[13]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Both purified urinary hCG and rhCG are potent, long-acting analogs of LH that produce sustained and dose-dependent increases in blood testosterone concentrations by stimulating the secretion of testosterone from Leydig cells. The biologic action of hCG and LH on the surface receptors of the Leydig cells in the testes are similar, but the plasma half-life of hCG is substantially longer than LH. In men, the administration of hCG produces a consistent, sustained increase in plasma testosterone concentrations. Stimulation of testosterone secretion following the injection of hCG is rapid with a 50% increase in plasma testosterone concentration occurring within 2 hours of the IM administration of 6,000 IU hCG.[20] Maximum increases in plasma testosterone concentrations following single IM injections of hCG occur about 2–4 days after the administration of hCG, and the elevation of testosterone concentrations persists up to 6 days.[21] A single IV dose of 125 µg rhCG or an IM dose of 6,000 U uhCG approximately doubles the serum testosterone concentration within about 2–4 days after administration.[13,22]

Large doses of hCG increase the production of aromatase activity in the Leydig cells and subsequently increase the secretion of estradiol by the aromatization of testosterone. Rising estradiol concentrations partially suppress CYP17 activity (17-α-hydroxylase/17,20-lyase) and the hCG-induced increase in testosterone synthesis by a negative feedback mechanism.[23] There is no direct correlation between concentrations of hCG and testosterone in the blood; the testosterone concentration has a biphasic pattern after hCG administration.[10] A study of 40 men over the age of 60 years with partial androgen deficiencies (i.e., blood testosterone <15 nmol/L) demonstrated that twice weekly SC injections of 5,000 IU rhCG increased body weight and lean body mass approximately 1 kg and 2 kg, respectively, over 3 months.[24] These changes were not associated with increased shoulder/knee strength, enhanced physical activity, or improvements in coordination or gait.

In young, healthy women, limited data suggest that hCG causes no clinically significant change in the blood testosterone concentration.[11] The ovaries, adrenal gland, and some extraglandular sources produce small amounts of testosterone in women, but there is no regulation of testosterone by estradiol as occurs in men by a homeostatic negative feedback mechanism. In addition to the very low endogenous blood testosterone concentrations in women, hCG does not stimulate testosterone production as both hCG and LH increase the secretion of testosterone by the Leydig cells in men. Consequently, hCG in women causes no significant androgenic response to high concentrations of hCG including the massive concentrations of hCG produced by the placenta during pregnancy.

CLINICAL RESPONSE

There are few data on the ergogenic effect of the supraphysiologic doses of hCG on muscle mass or strength in women or men. Furthermore, there is no clear evidence in the published literature that the use of hCG increases strength or improves endurance in athletes. Although hCG does initially increase the serum testosterone concentration, there are inadequate data to determine if the increased testosterone concentrations persist and result in improved strength and/or athletic performance. The expected side effects associated with the misuse of hCG and anabolic steroids are similar with the exception of more gynecomastia following hCG use. The administration of hCG to men increases spermatogenesis despite anabolic steroid-induced suppression of gonadotropin secretion in the presence of continued high serum estradiol concentrations. The administration of exogenous testosterone to normal men markedly increases blood testosterone and estradiol concentrations while suppressing gonadotropin, testicular testosterone, and sperm production. Case reports suggest that in the setting of profound symptomatic hypogonadotrophic hypogonadism secondary to anabolic steroid abuse, the administration of hCG stimulates the production of testosterone by the testes.[25] In a study of 5 healthy men receiving 200 mg testosterone weekly, the IM administration of 5,000 IU hCG 3 times weekly normalized the sperm count as assessed by sperm concentrations, motility, and morphology.[26] Although the use of hCG attenuated some of the reduction in spermatogenesis, some studies suggest that this regimen transiently impairs semen quality. In a study of 18 healthy male power athletes using massive doses of anabolic androgenic steroids, there was a significant positive correlation between the use of hCG during the steroid cycle and the presence of morphologically abnormal spermatozoa.[12] Additionally, there was a concomitant decrease in sperm mobility. The overall effect of hCG on male reproduction is unclear. There are no data on hCG overdoses in the medical literature.

DIAGNOSTIC TESTING

Conversion Factors

Standardization of assays for a heterogeneous analyte (e.g., hCG) is difficult because hCG is a family of closely related molecules (e.g., intact hCG, hCGβ, hCGα, hCGn, hCGβn, hCGβcf) rather than a single species.[27] Table 18.1 lists the nomenclature and description of the family of hCG molecules. Equating micrograms of rhCG to levels of biologic activity of uhCG is complicated by the issues related to mass units, molar conversions, purity of the substance, and standardization of biologic activity, particularly the end point used to determine bioactivity. The standard dose of urinary hCG is 5,000 IU of bioactivity. As measured by *in vitro* testosterone production by the Leydig cell method, the median biopotency of uhCG was 14,100 IU/mg (95% CI: 12,500–16,000 IU/mg).[28] Using an *in vivo* seminal vesicle weight method in male rats, the median biopotency for uhCG was 15,400 IU/mg (95% CI: 14,200–16,800 IU/mg) in 1 study, and 10,300 IU/mg (95% CI: 8,360–12,600 IU/mg) in another study.[28] The estimated potency of 250 μg rhCG is approximately 6,500 IU uhCG.[29]

Analytic Methods

Radioimmunoassay (RIA) was the original assay for hCG, but cross-reaction with LH limits the use of conventional RIA methods.[30] Concentrations of hCG in serum and urine samples are highly dependent on the specific assay as a result of differences in assay design and specificity for the different forms of hCG and associated fragments. Degradation of LH during storage increases the cross-reactivity of this compound with monoclonal antibodies for hCG.[31] The use of soft ionization techniques allows the quantitation of large biologic molecules (e.g., hCG) including matrix-assisted laser desorption and ionization time of flight and electrospray ionization. The concentrations (1 μmol/L) of urinary proteins are about 1,000-fold lower than plasma, whereas the hCG concentration (<10 pmol/L) in urine samples from healthy men is >100,000-fold lower than plasma proteins. Thus, analysis of hCG in urine requires extraction by immunopurification followed by reduction, alkylation, and digestion with trypsin.[4] Quantitation results from the detection of nonglycosylated forms by mass spectrometry. Gonadotropins are much less stable in urine than in serum, and hCG is somewhat more stable than LH. Both hCG and LH are stable in storage at 4°C (39.2°F) with 0.02% azide.[32] Storage of urine samples at room temperature substantially reduces hCG immunoreactivity. An *in vitro* study indicated that urinary hCG reactivity decreased over 10% after 5 days of storage at room temperature and 70% after 90 days of storage at room temperature.[33] Freezing at –20°C (–4°F) causes rapid loss of immunoreactivity.

Biomarkers

BLOOD

Serum samples from men and nonpregnant women contain small amounts of hCG: men <60 years have <1.3 IU/L; men >60 years have <2.3 IU/L; premenopausal women have <1.0 IU/L); and postmenopausal women have <4.8 IU/L.[31] In nonpregnant women, the upper reference limit increases during menopause from 3 IU/L (8.6 pmol/L) to around 5 IU/L (15.5 pmol/L) with values in healthy women ranging up to 8–10 IU/L.[15] The upper reference ranges for men below and above 50 years of age are approximately 0.7 IU/L (2.1 pmol/L) and 2 IU/L (6.1 pmol/L), respectively, with occasional concentrations ranging up 3–4 IU/L. Following IM injection of 10,000 IU of equal amounts of hCG and hCGβcf (Pregnyl®) to nonpregnant women, the serum hCG concentration remained above the upper reference range for 7–11 days. The serum hCG concentration increases in several conditions besides pregnancy including gestational trophoblastic disease, testicular cancer, and other tumors (e.g., biliary, pancreatic). In men and nonpregnant women, the administration of estrogen and progestogen lowers the serum hCG by approximately 50%, whereas the administration of gonadotropin-releasing hormone causes about a 3-fold increase in serum hCG.

URINE

The World Anti-Doping Agency requires a limit of detection of 5 IU/L for hCG in urine samples from athletes; published recommended limits for the cutoff of positive samples range from 10–25 IU/L.[34,35] However, WADA has not set recommendations regarding assay specificity other than to require that the hCG assay be positive in 2 different assays. Substantial variation occurs in results of hCG concentrations between various immunoassays as a result of a difference in reactivity between these assays and various isoforms/degradation products of hCG. Although current urine hCG immunoassays are sensitive within WADA guidelines, quantitative data from different immunoassays of hCG are not directly comparable.[33] Most commercial hCG assays measure hCG and hCGβ together, but the results are expressed in IU/L based on hCG units. These immunoassays reflect molar concentrations of protein rather than bioactivity. There is

substantially more heterogeneity in hCG forms in urine than in the serum.[36] After the IM administration of 10,000 IU of equal amounts of hCG and hCGβcf, the urine concentrations of hCGβcf dropped below the upper reference limit 2–3 days earlier than hCG.[15] In a study of urine samples from 1,400 athletes, the median concentration of hCG was 0.8 IU/L with a range of 0–24 IU/L.[37] As measured by Serono MAIAclone IRMA (Serono Diagnostics, Fleet, UK), only 3 of the data points exceeded 5.0 IU/L. The median hCG concentration in urine samples from 120 healthy adults was 0.4 IU/L with a range of nondetectable to 4.6 IU/L. In a study of 5,663 male athletes, the mean hCG concentration in spot urine samples was 0.56 IU/L with a range of nondetectable to 43.03 IU/L.[38] The limit of detection as measured by microparticle enzyme immunoassay (Abbot IM_x® system, Abbott Park, IL) was 0.21 IU/L. Statistical evaluation of the data indicated a far outside value of 2.28 IU/L with a suggested upper limit of 5 IU/L. Recommended reference ranges for total hCG in urine for menstruating women and men <50 years of age are 13.6 pmol/L and 8.0 pmol/L, respectively.[4]

Although hCG and LH are biologically similar, cross-reactivity of highly specific monoclonal antibodies typically is <1%.[39] The administration of hCG produces up to 2- to 3-fold increases in plasma testosterone concentrations, but only minor changes in the urinary testosterone/epitestosterone ratio because hCG stimulates the production of both testosterone and epitestosterone.[40] Using immunoassays and a urine hCG threshold of 5 IU/L, experimental studies in healthy young men suggest that the urine remains positive for hCG about 1 week following a single injection of a 750 µg rhCG dose, whereas the false-negative rate on postinjection day 8 for a 250 µg rhCG dose was 5 out of 12 (42%) injections.[41] The use of nandrolone decanoate by the subjects did not alter these results. The use of hCG substantially alters the testosterone/leuteinizing hormone ratio in spot urine samples because of the fall in LH secretion secondary to the negative feedback from increasing testosterone concentrations. Potentially, use of the testosterone/leuteinizing hormone ratio is a method for the detection of illicit hCG use in sports.[41]

TREATMENT

There are no reported unique treatments for complications resulting from the chronic use of hCG. Treatment is supportive after cessation of hCG use.

Chapter 19

HUMAN GROWTH HORMONE and INSULIN-LIKE GROWTH FACTOR

HUMAN GROWTH HORMONE

HISTORY

The presence of a substance (growth hormone) secreted by the anterior pituitary was discovered in the 1920s, when experimental zoologists demonstrated a growth-maintaining compound in the anterior lobe of amphibian brains.[1] In 1929, Putnam et al produced the disease associated with excessive growth hormone secretion (acromegaly) in an English bulldog following the daily injection of a sterile aqueous extract of bovine anterior pituitary glands for 14 months.[2] Pituitary dwarfism is associated with inadequate production of the peptide hormone, hGH that is secreted by the somatotroph cells located in the anterior pituitary gland. In the 1930s, scientists began searching for an exogenous source of growth hormone to treat human dwarfism;[3] however, Li and Evans did not isolate growth hormone from bovine pituitary glands until 1944.[4] By the early 1950s, sufficient amounts of bovine and ovine pituitary extract were available to conduct clinical studies on the use of nonprimate pituitary extracts for the treatment of pituitary dwarfism. Ultimately, these clinical trials demonstrated that nonprimate pituitary extracts are inactive in humans.[5] Virilization and premature epiphyseal closure complicated the subsequent use of testosterone and chorionic gonadotropin to treatment of pituitary dwarfism in children. Li and Papkoff first purified hGH in 1956.[6] During the early 1960s, clinical trials by the Pituitary Hormone Committee of the UK Medical Research Council began using injections of extracts from acetone-preserved human cadaveric pituitary glands for the treatment of children with short stature from growth hormone deficiencies. The National Hormone and Pituitary Program was the main source of hGH in the United States beginning in 1963, resulting in the administration of pituitary-derived hGH to thousands of US children. Substantial numbers of these children grew to near normal adult height, particularly when treated early with adequate doses of the extract.[7] However, these trials were halted in 1985 because of the discovery of the transmission of a rare, fatal disease characterized by the rapid progression of dementia (Creutzfeldt-Jacob disease) in several US and British patients following injection of infectious prions present in cadaveric pituitary glands administered during the 1960s and 1970s. Contaminated cadaveric hGH was the most common iatrogenic cause of Creutzfeldt-Jacob disease with 139 cases reported by 2000.[8] A long-term cohort study of 1,908 UK patients treated with pituitary growth hormone between 1959 and 1985 revealed that 6 patients died of Creutzfeldt-Jacob disease.[9]

During the early 1980s, the development of recombinant growth hormone (rhGH) using recombinant technology resulted in the replacement of human pituitary extracts with rhGH for those children with growth

hormone deficiencies. The US Food and Drug Administration (FDA) approved the clinical use of rhGH (Protropin®, Genentech, South San Francisco, CA) for the treatment of growth hormone deficiency in 1985. In 1987, Leung et al elucidated the amino acid sequence of the growth hormone receptor, demonstrating a new class of transmembrane receptors.[10] Later that year, Abdel-Meguid et al determined the 3-dimensional crystalline structure of porcine GH, which is similar to hGH.[11] In 1996, the FDA approved the use of rhHG for the treatment of wasting or cachexia in patients with acquired immunodeficiency syndrome (AIDS).

The use of hGH in athletics for the enhancement of size, athletic performance, and muscle strength began in the 1980s, particularly among swimmers, cyclists, and competitive bodybuilders. Although this substance was initially promoted for strength disciplines (e.g., football, baseball), the lipolytic actions of hGH was attractive to endurance athletes as a means to reduce fat mass. This hormone was touted as an expensive, fashionable new athletic drug by the steroid guru, Dan Duchaine.[12] Growth hormone was promoted as an anabolic agent that had synergistic effects with anabolic steroids. Ben Johnson, the former Canadian sprinter and world record holder in the 100 meter dash, admitted using a regimen including hGH after his gold medal was revoked following a positive steroid test at the 1988 Seoul Olympic Games. These regimens gained popularity because of the difficulty detecting the use of hGH. In 1996, the International Olympic Committee launched the Human Growth Hormone 2000 project with the goal of developing reliable screening tests for the use of hGH,[13] but the search for sensitive tests for hGH remains complicated. Recombinant human growth hormone (rhGH) was confiscated at a variety of elite athletic events including the 1998 World Swimming Championships and the Tour de France.[14] The 1994 World Aquatic Championship breast stroke silver medalist, Yuan Yuan was sent home from the 1998 World Aquatic Championships in Perth, Australia when she was caught trying to smuggle 13 vials of hCG into Australia. As a result of the difficulty detecting rhGH use more than a day after cessation of rhGH use, the first athlete disciplined for rhGH use occurred in 2010. A UK rugby player, Terry Newton tested positive for hGH in a blood sample, and he received a 2-year ban for using rhGH ostensibly to increase muscle mass.[15] Since the early 1990s, growth hormone has also been promoted as an antiaging drug. During this time, human studies suggested that growth hormone-deficiencies in elderly patients accounted for reduction in lean body mass, increases in fat mass, and thinning of the skin.[16] However, currently there is no clear evidence that the use of hGH improves longevity or the quality of life.

IDENTIFYING CHARACTERISTICS

Structure

About 70–75% of circulating hGH (Somatropin, CAS RN:12629-01-5) is a 191-residue, 22 kDa peptide, whereas about 5–10% occurs as a 20 kDa isoform as a result of alternative mRNA splicing. Dimers and oligomers of hGH also occur in the plasma along with acidic, acylated, deaminated, and fragmented forms. Recombinant hGH (rhGH) occurs only as a 22 kDa peptide. The binding of hGH to the 2 different growth hormone-binding proteins increases the heterogeneity of hGH isoforms in plasma.[17] The practical consequence of the wide variation in hGH isoforms is the substantial variation in the affinity of different immunoassays for the natural isoforms and fragments of hGH. Recombinant human growth hormone occurs only in the 22 kDa-form that allows differentiation of exogenous hGH use by examining the ratio of 22 kDa- and non-22 kDa-forms.

Form

Human growth hormone is available in injectable forms derived from recombinant technology including Genotropin® (Pfizer, New York, NY), Norditropin® (Novo Nordisk, Inc., Princeton, NJ), Nutropin® (Genentech, South San Francisco, CA), Humatrope® (Eli Lily, Indianapolis, Indiana), Serostim® (Serono, Inc., Rockland, MA), and Saizen® (Serono, Inc., Rockland, MA). These commercial recombinant forms of hGH have the following 2 origins: 1) modified *Escherichia coli* strain (Genotropin®, Norditropin®, Nutropin®, Humatrope®), and 2) mammalian cell line (mouse C127) (Serostim®, Saizen®). The molecular weight of the rhGH is 22.125 kDa, identical to the 22 kDa-form of endogenous hGH. As a result of the popularity of hGH as an antiaging agent, all-natural supplements have been formulated as a low-cost method to stimulate the endogenous secretion of hGH. These naturopathic preparations contain a variety of amino acids (L-arginine, L-isoleucine, L-glutamine, L-glycine, L-lysine, L-tyrosine, L-valine) that are available as capsules, pills, powders, and nasal sprays. Somatrem (*N*-methionyl-human growth hormone) was the first biosynthetic form of growth hormone that contained an extra methionyl amino acid on the *N*-terminus (i.e., 192 amino acid residues). The commercial form of somatrem was Protropin® (Genentech), but manufacture of this form by Genentech ceased in 2004. Sustained release preparations of rhGH are now available for the treatment of growth hormone deficiencies that allow injections every 1–2 weeks instead of daily injections.[18,19]

EXPOSURE

Epidemiology

Although doping with hGH is a significant issue in elite sports based on seizures and anecdotal reports, determination of the prevalence of hGH abuse is complicated by the difficulty developing reliable commercial assays and detecting hGH use more than a day after cessation of hGH. Additionally, the physiologic increases in bone and collagen turnover during normal puberty limit studies to determine the prevalence of hGH use in adolescent athletes as detected by the marker method.[20] Despite the fact that the ergogenic effects of systemic administration of rhGH by athletes and bodybuilders remain unproven, the lack of accurate detection methods contributes to the prevalence of rhGH abuse by sports personnel.[21] Frequently, the use of rhGH is part of a multiple drug regimen that includes anabolic steroids. In an anonymous self-administered questionnaire of 100 athletes attending 4 gymnasiums for weight training, 12% of the athletes admitted the use of hGH, usually in addition to anabolic steroids and other ergogenic drugs.[22] The use of hGH extends to young adolescents. Based on an anonymous questionnaire of 432 adolescents in 2 suburban Chicago high schools, 11 males (5%) and 1 female admitted to the past or present use of hGH.[23] This study indicated that adolescent hGH users often also abuse anabolic steroids. Although many press articles during the 2000 Olympic Games suggested that rhGH was a popular performance-enhancing drugs among athletes, the lack of confirmatory laboratory data limits conclusions regarding the prevalence of rhGH use among elite athletes.[24]

Sources

Endogenous hGH is an anabolic peptide hormone secreted by the anterior pituitary gland. The original products available for hGH replacement were derived from the pituitary glands of human cadaver; however, the human use of cadaver-derived hGH was halted during the 1980s after documentation of the transmission of the prion-medicated spongiform encephalopathy (Creutzfeldt-Jakob disease) with this type of hGH preparation. Pituitary-derived hGH (cadaveric growth hormone) is available on the Internet and may be sold illicitly as rhGH with a risk of developing Creutzfeldt-Jakob disease.[25,26] Cadaveric growth hormone contains the full range of growth hormone isoforms; therefore, cadaveric growth hormone is indistinguishable from endogenously derived growth hormone. Somatrem and rhGH are polypeptide hormones produce by recombinant DNA technology. Pharmaceutic preparations of rhGH are derived from recombinant technology; inser-

tion of the hGH gene into the genome of mammalian or *E. coli* cell lines produces large quantities of 22 kDa-hGH in cell cultures. Subsequently, rhGH is isolated and purified for parenteral administration. These parenteral preparations contain preservatives including benzyl alcohol, *m*-cresol, and phenol.[27]

Methods of Abuse

The administration of hGH usually involves the subcutaneous (SC) or intramuscular (IM) injection of pharmaceutic preparations diverted from legal sources. Typically, the use of hGH is part of a regimen that includes anabolic steroids.

DOSE EFFECT

The mean daily secretion of hGH in adults is about 0.5 mg.

Medical Use

Indications for hGH primarily involves children with growth hormone deficiency and growth retardation. These conditions include pituitary dwarfism, short bowel syndrome, chronic renal insufficiency, Ullrich-Turner syndrome, and Prader-Willi syndrome. Approved US indications for the treatment of adults include HIV-associated wasting or cachexia, short bowel syndrome, and certain types of hGH deficiencies.[28] Over 90% of adults with growth hormone deficiency have pituitary disease, primarily from a pituitary adenoma or the treatment of a tumor.[29]

The recommended dose of hGH depends on the medical condition, gender, and age, titrated to response (e.g., normalization of plasma IFI-I concentrations in adults) and the presence of side effects.[30] In children with growth hormone deficiency, the usual daily doses range from 5–25 µg/kg body weight.[31] In general, the daily dose of rhGH in GH-deficient adults is smaller than doses in children, typically beginning as 150–300 µg and titrated up to 1 mg (3 IU). High-dose regimens in growth hormone-deficient children use up to 80 µg/kg. Although the use of SC rhGH is approved for use in adult cachexia, there is no clear benefit from the use of rhGH in these patients.[32] Off-label uses of rhGH include the treatment of obesity, osteoporosis (70 µg/kg/week divided in 3 subcutaneous injections for 12 months), muscular dystrophy, and infertility, but there are inadequate clinical data to support of efficacy and safety of rhGH for these uses.[31]

Illicit Use

Athletes anecdotally use hGH in doses substantially higher (i.e., up to 5–15 times) higher than the medical

doses used to supplement children with short stature or adults with wasting diseases. These supratherapeutic doses of hGH typically range from 2 mg 3 times weekly to over 5 mg daily.[33,34] Cycles typically continue 6–12 weeks, usually in combination with anabolic steroids in power sports and erythropoietin in endurance sports. A common dose of hGH for body building is 16 mg/week divided in 3 doses subcutaneously.

Toxicity

There are few data reported on the toxicity of hGH following administration of specific doses of hGH. A minimum toxic dose for hGH has not been established; side effects occur with therapeutic doses. The IM LD$_{50}$ in a mouse and rat model exceeds 40 IU/kg (~15 mg/ kg). The administration of porcine growth hormone in doses up to 1 IU/kg/day for 14 weeks to dogs was associated with the development of diffuse glomerulosclerosis (thickening of the glomerular basal lamina, diffuse increase of the mesangial matrix) morphologically similar to diabetic nephropathy.[35]

TOXICOKINETICS

Absorption

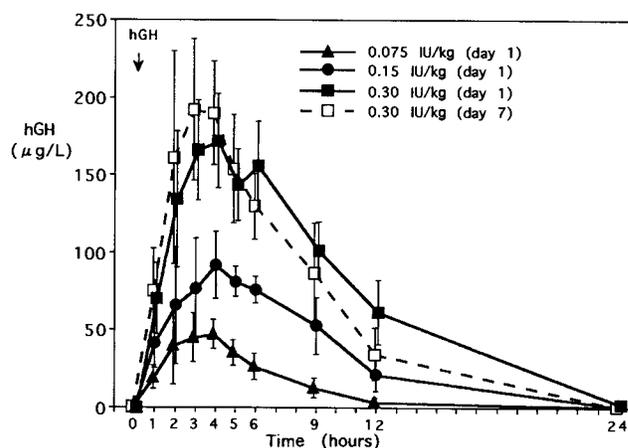
Absorption of hGH depends on several factors including the formulation, site of injection, and delivery method (SC, IM); prolonged absorption may result from depots of hGH in SC or IM tissue. Following SC administration of rhGH, peak serum hGH concentrations occur within approximately 3–6 hours. In a study of 6 healthy adults, the SC administration of hGH (bio-hGH 0.2 U/kg) produced a mean hGH concentration of 106 ± 10 mIU/L at 3.3 ± 0.5 hours after administration.[36] In a study of 6 subjects receiving 1.2 IU rhGH (Genotropin®, Pfizer, New York, NY) subcutaneously, mean maximum serum hGH concentrations of 5.56 ± 0.91 mIU/L (95% CI: 3.79–7.33 mIU/L) occurred about 4.75 hours (95% CI: 2.25–5.75 hours) after administration.[37] The SC injection of 0.3 IU rhGH (Norditropin, Novo Nordisk Pharma, Tokyo, Japan)/kg to 12 healthy adults resulted in a mean peak hGH concentration of approximately 180 µg/L about 4 hours (range 3–5 hours) after administration.[38] Figure 19.1 displays the changes in serum growth hormone within 24 hours after SC administration of single rhGH doses of 0.075 IU/kg, 0.15 IU/kg, and 0.3 IU/kg as well as after the 7th daily dose of 0.3 IU/kg. The mean bioavailability (AUC$_{sc}$/ AUC$_{iv}$) of rhGH in this study was approximately 63% (95% CI: 55–71%) as a result of degradation at the site of injection. Typically, the bioavailability of subcutaneously injected hGH in high therapeutic doses ranges


FIGURE 19.1. Serum growth hormone concentrations after single subcutaneous rhGH doses of 0.075 IU/kg, 0.15 IU/kg, and 0.3 IU/kg, as well as after the 7th daily dose of 0.3 IU/kg. (Reprinted with permission from T Tanaka, Y Seino, K Fujieda, Y Igarashi, S Yokoya, K Tachibana, Y Ogawa, Pharmacokinetics and metabolic effects of high-dose growth hormone administration in healthy adult men, Japan Endocrine Journal, Vol. 46, p. 607, copyright 1999.)

from approximately 50–70%; there are inadequate pharmacokinetic data to determine the bioavailability of supratherapeutic hGH doses used in sports doping. Intranasal absorption of physiologic amounts of hGH requires the presence of a permeability enhancer (e.g., didecanoyl-L-alpha-phosphatidylcholine, sodium tauro-24,25-dihydrofusidate) in the product formulation. In a study of 16 healthy young adults without known allergies, the mean peak serum hGH concentration was 28.22 ± 20.85 ng/mL following intranasal application of 6 IU (2 mg) hGH (8% didecanoyl-L-alpha-phosphatidylcholine) with a mean t$_{max}$ of 54.5 ± 30.5 minutes.[39]

Distribution

The estimated volume of distribution for hGH in healthy adults receiving therapeutic doses of hGH is < 1 L/kg; as a peptide, hGH probably distributes into extracellular water. In an Australian study of 6 healthy young adults receiving 0.2 IU bio-hGH/kg/day subcutaneously for 5 days, the mean volume of distribution was reported as 77.7 ± 22.8 L with mean body weights of 81.1 ± 4.3 kg.[36] The mean volume of distribution of the central compartment in a study of 14 healthy men receiving 8.64 IU rhGH (Saizen®) as a single SC injection was 0.35 L/kg (95% CI: 0.28–0.42 L/kg).[40] Animal studies indicate that hGH can penetrate the blood–brain barrier and enter the central nervous system despite the absence of a specific transport system for hGH.[41]

Biotransformation/Elimination

Biotransformation of hGH occurs primarily by metabolism in the liver, kidney, and peripheral tissues with only small amounts (i.e., <0.01%) of hGH excreted unchanged by the kidneys based on rodent studies.[42] The renal tubules reabsorb most of the hGH filtered by the glomeruli. The clearance of hGH depends on several variables including hGH concentrations, body composition, insulin, growth hormone-binding protein, and IGF-binding protein-1. The effect of age on hGH clearance is minimal.[43] The mean clearance of SC somatropin in growth-hormone-deficient adult patients is approximately 0.3 L/h/kg. The plasma elimination half-life of rhGH following IV infusion is very short (i.e., about 15 minutes).[44] The estimated mean plasma half-life of hGH in 12 healthy adults was 17 ± 1.7 minutes.[45] Although the plasma half-life of hGH and rhGH is similar following IV administration, the terminal serum elimination half-life of rhGH following SC administration is 2–4 hours following single SC injections as a result of prolonged absorption and distribution.[40] Serum hGH concentrations are not usually detectable within 20–24 hours after SC injection of therapeutic doses (e.g., up to 0.3 IU/kg) of rhGH.[38,46] Recombinant hGH probably does not degrade into the 20-kDa isoform.

Maternal and Fetal Kinetics

There are few data on maternal and fetal kinetics of rhGH including excretion into breast milk.

Drug Interactions

An *in vivo* study of healthy elderly men indicated that the administration of rhGH induces CYP1A2 and, to a lesser extent, inhibits CYP2C19.[47] There was no effect on CYP2D6 or CYP3A4. Based on this study, drug interactions between rhGH and drugs requiring CYP1A2 are possible, but there are no clinical data to determine the clinical relevance of these potential interactions. Interactions with other CYP450 isoenzyme are unlikely. *In vitro* studies indicate that the administration of rhGH does not alter the efficacy of antiretroviral drugs.[48]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

Growth hormone (GH) is a peptide hormone secreted by the somatotrope cells in the anterior pituitary in a pulsatile fashion, producing anabolic and anticatabolic effects by affecting the function of a wide range of tissues throughout the body primarily mediated by GH-induced secretion of a another peptide hormone, insulin-like growth factor (IGF). Growth hormone is the most abundant pituitary hormone. The human pituitary gland secretes hGH in multiple, short (i.e., 20–30 minute) secretory bursts following a circadian rhythm (e.g., daily GH peak occurs at night within the first hour of sleep) as a result of alternating secretion of growth hormone-releasing hormone and growth hormone. Secretory hGH rates fall asymptotically to zero between the pulsatile release of hGH. There is marked individual variation in the secretion of endogenous growth hormone. In a study of 12 healthy men, the mean endogenous production of hGH during a 24-hour period was 0.25 ± 0.033 mg/m^2.[45] During this 24-hour period, production of 67% of the hGH occurred within a 4.4-hour period and 95% of the hGH production occurred within an 8.8-hour period. Amino acids (e.g., ornithine, L-arginine, tryptophan, L-lysine) increase hGH through an unknown mechanism; naturopathic products containing these amino acids are available to promote the secretion of growth hormone.[49] However, there are inadequate data to support the efficacy of these natural products.

PHYSIOLOGY

The somatotrope cells of the anterior pituitary secrete hGH (somatotropin) in response to a variety of factors including growth hormone-releasing factor (somatorelin, CAS RN:83930-13-6), somatostatin (inhibitory), and ghrelin. The source of the latter is the stomach and to a lesser extent, hypothalamus. Other factors affecting the pulsatile release of hGH from the pituitary include exercise, stress, sleep, low calorie diet, estrogen, and androgen. Somatorelin is a peptide amide that causes the release of growth hormone from the anterior pituitary gland, whereas somatostatin is a hormone found in the pancreas and hypothalamus that inhibits the release of hGH. Hypoglycemia, high temperature, deep sleep, and stress increase hGH secretion; carbohydrate-rich diets, obesity, and β-adrenergic agonists decrease hGH secretion. The release of hGH during exercise is dose-related with more intense exercise causing larger releases of hGH, particularly anaerobic exercise.[50] Exercise stimulates the secretion of hGH up to 5- to 10-fold, whereas starvation reduces hGH secretion. Ageing is associated with declining hGH secretion. In a study of 21 healthy subjects aged 21–71 years, the production of hGH decreased by a mean of 14% per decade.[51]

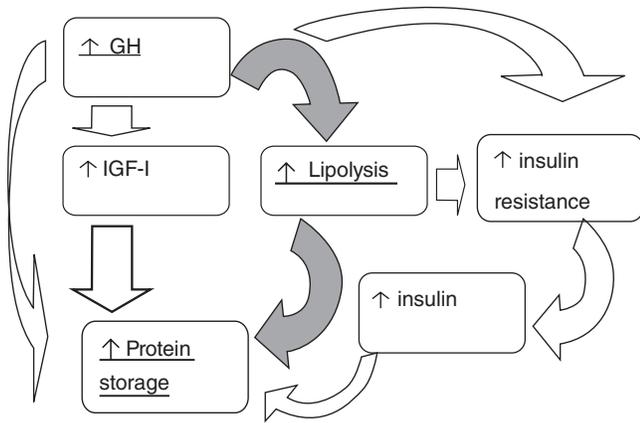
The effects of hGH binding to specific growth hormone receptors found on every cell of the body are primarily anabolic and lipolytic including enhancement of amino acid uptake, promotion of renal and hepatic gluconeogen-


FIGURE 19.2. Schematic representation of the metabolic actions of growth hormone (GH), which directly stimulated lipolysis. Protein storage results from the breakdown of protein, stimulation of protein synthesis, and inhibition of hepatic amino acid degradation. (Reprinted from Clinical Nutrition, Vol. 28, N Moller, MH Vendelbo, U Kampmann, B Christensen, M Madsen, H Norrelund, JO Jorgensen, Growth hormone and protein metabolism, p. 599, Copyright 2009, with permission from Elsevier.)

esis, stimulation of protein synthesis, and increased fat resorption. The stimulation of lipolysis and lipid oxidation results in the increased formation of free fatty acids and ketone bodies; the indirect anabolic effects on protein storage are less dramatic.[52] Figure 19.2 displays a schematic representation of the metabolic actions of growth hormone. Binding to the GH receptors activates the tyrosine kinase, Janus kinase 2, and the Janus kinase/signal transducers and activators of transcription (JAK/STAT) pathway, resulting in cellular proliferation, differentiation, and migration, reduced apoptosis, regulation of metabolic pathways, and cytoskeletal reorganization.[53] These effects are primarily mediated by insulin-like growth factor I (IGF-1). Other effects of hGH include enhancement of bone and collagen turnover and the regulation of selective aspects of metabolic function (e.g., lipolysis, body composition). The anabolic effects of hGH are independent of the actions of testosterone. Growth hormone receptors are glycosylated transmembrane glycoproteins that occur in many tissues (e.g., liver). Human growth hormone contains 2 binding sites that form a dimer when attached to the GH receptor. Binding of hGH to hepatic receptors causes the secretion of anabolic somatomedins (e.g., IGF-1).

Adolescents and Adults

Peak GH secretion occurs during the prepubertal growth spurt and after the mid-20s with GH secretion decreasing about 14% every decade.[54] Detrimental changes in body composition, muscle strength, and somatotropic function occur during the normal aging process. Supplementation of elderly patients with rhGH does not increase body weight, but hGH reduces fat mass and increases lean body mass.[55] Although older adults increase muscle strength as a result of resistance exercise training, these strength gains stabilize after several months, and subsequent improvement in muscle strength is modest despite continued training. Although hGH induces protein anabolic effects in healthy adults, there is little evidence that supraphysiologic hGH doses produce protein anabolic effects in addition to the effects of exercise in healthy adults with normal hGH concentrations.[56] Supplementation with rhGH does not augment the response to strength training in elderly men.[57] In acromegaly, muscle mass increases, but these muscles are relatively weak compared with normal musculature. The use of rhGH by GH-deficient patients improves aerobic exercise capacity (i.e., maximal oxygen consumption while exercising at maximum capacity, VO_{2max}), but hGH does not increase muscle mass or strength beyond the expected norms for healthy adults of the same age and gender.[58]

Athletes

There is substantial evidence that hGH supplementation increases lean body mass in athletes, particularly in men co-administering testosterone. In a meta-analysis of 9 clinical studies (mean duration, 4 weeks), the mean increases in muscle mass in the hGH-treated group was 2.1 kg (95% CI: 1.3–2.9 kg) compared with controls (no treatment).[59] However, the increase in lean body mass probably results from extracellular fluid accumulation rather than increased muscle mass. In a study of 30 healthy, young adults receiving 0.1 or 0.2 IU rhGH/kg, the mean increases in the pooled treatment group compared with placebo were as follows: body weight, 2.7%; fat free mass, 5.3%; total body water, 6.5%; and extracellular water (ECW), 9.6%.[60] The mean intracellular water of the treatment and placebo groups was not statistically different. As intracellular water reflects muscle mass, the results suggest that extracellular water and fluid retention accounts for the increase in lean body mass. Consequently, hGH has little anabolic effect. Short-term use of hGH does not increase the incorporation of amino acids into skeletal muscle protein or reduce the catabolism of whole body protein in experienced weightlifters.[61]

There are no well-controlled studies demonstrating convincing evidence that hGH doses used in clinical studies improve aerobic exercise capacity or increase muscle strength in power athletes with highly lean body mass.[62,63,64] Evaluation of anecdotal reports of

improvement in strength or endurance following use of hGH are difficult to evaluate because hGH is usually part of a regimen that includes other ergogenic agents. Although the use of hGH increases IGF-1, maximum strength during concentric contraction of biceps and quadriceps muscles does not increase in these athletes following hGH use.[65] In a study of 96 recreational athletes receiving 2 mg rhGH daily for 8 weeks, muscle strength as measured by dead lift dynamometer and muscle power as assessed by jump height were not significantly different between the treatment and placebo groups.[66] The addition of rhGH to a group receiving testosterone (250 mg IM weekly) in this study did not improve these muscle parameters over the effects of testosterone alone. Similarly, there was no significant difference between placebo and treatment groups on aerobic exercise capacity as measured by VO_{2max}. Anaerobic capacity assesses the ability to generate relatively high power output over a brief duration from anaerobic energy sources (phosphocreatine degradation, glycogenolysis). The Wingate test (30-second all-out sprint capacity) is a measure of anaerobic capacity. In the above study of recreational athletes, the 8-week course of rhGH increased anaerobic capacity (Wingate test) an average of about 6% (95% CI: 0.8–10.5%) in men with the addition of testosterone increasing the benefit to an average of approximately 8% (95% CI: 3.0–13.6%) compared with the placebo group. Some limitations of these studies include the small number of study subjects, the use of doses below the supratherapeutic doses of hGH covertly used by many athletes, and the lack of power of these studies to detect the small differences (i.e., 0.5–1%) in physical performance that separate Olympic champions from their competitors. Additional limitations include the extrapolation of randomized clinical trials with the power to detect differences of 20–30% to elite competition where 1% difference in performance separates gold medal winners from other top performers.[67]

Mechanism of Toxicity

Human growth hormone is the main stimulus for the release of IGF-1. The effects of hGH are primarily mediated by the action of IGF-1; consequently, the adverse effects of hGH and IFG-I are expected to be similar to diseases associated with growth hormone excess (i.e., acromegaly with fluid retention, hypertension, cardiomyopathy, and diabetes mellitus).[68] Normal hGH levels are an important factor in the development and function of the cardiovascular system.[69] Although hGH improves muscle and cardiac function in hGH-deficient patients, there are few data on the effects of chronic hGH use by healthy subjects on the risk of increased morbidity and/or mortality from cardiovascular disease. Chronic hGH decreases high-density lipoprotein (HDL), which is a risk factor for coronary heart disease.[70] Chronic growth hormone *deficiency* is associated with impaired cardiac performance, reduced left ventricular systolic function, dilated cardiomyopathy, and congestive heart failure.[71] Growth hormone excess (acromegaly) is associated with an increased risk of hypertension, cardiomyopathy, cardiovascular disease, diabetes mellitus, osteoporosis, and impotence.

CLINICAL RESPONSE

Medical Use

Adverse effects of hGH during medical use include insulin resistance, pre- and postpubertal gynecomastia, arthralgias, edema, headache, erectile dysfunction, low-grade fevers, and carpal tunnel syndrome.[72,73] In clinical trials using hCG to treat GH-deficient adult patients, the most common side effects are edema, arthralgias, and myalgias. The large muscle mass associated with acromegaly is associated with myopathy and relative weakness.[74] Case reports associate sudden death with the early treatment phase of Prader-Willi syndrome with growth hormone,[75,76] but the presence of other potential complicating factors (e.g., pneumonia, sleep apnea, pulmonary hypertension) limit conclusions regarding the causal role of hGH. Complications of treating familial short stature with rhGH include non-ketotic hyperglycemia,[77] hypothyroidism, benign intracranial hypertension,[78] and acute pancreatitis.[79] In patients with GH deficiency, replacement therapy with rhGH improves mood and sense of well-being. Clinical studies indicate that withdrawal of rhGH treatment from adults with severe GH deficiency produces detrimental psychologic effects manifest by fatigue, pain, irritability, and depression.[80] Rarely, case reports associated the development of hypersensitivity reactions (pruritus, urticaria) with rhGH therapy, particularly with the use of somatrem.[81,82]

Illicit Use

The abuse of hGH in athletes typically involves the use of supraphysiologic doses of this compound in cycles with other ergogenic aids. In addition, determining the long-term safety of hGH use is difficult as a result of problems associated with collecting clinical data on off-label and illicit uses of hGH. Many adverse effects from supraphysiologic doses of hGH result from fluid retention. Case reports associate the use of high doses of

rhGH with the development of entrapment syndromes (e.g., carpel tunnel syndrome) manifest by paresthesias and dysesthesias of the hands and feet.[83,84] Other complaints associated with the use of rhGH include myalgias, arthralgias, myositis, peripheral edema, diaphoresis, fatigue, and lightheadedness. Chronic use of supraphysiologic doses of hGH are associated with the clinical features of acromegaly, an insidious, chronic debilitating disease associated with soft tissue and bony overgrowth as a result of growth hormone excess. Complications of chronic hGH use involve slipped capital femoral epiphysis, premature physial closure, coarse facial features, voice change, hypercalcemia and renal stones, enlargement of facial bones, increased skull circumference, macroglossia, myopathy, congestive heart failure, cardiomegaly, goiter, impotence, insulin resistance, and diabetes mellitus. Dermatologic changes during chronic rhGH use include increased skin viscosity, oily skin, enhancement of melanocytic (nonmalignant) nevi, and local complications of parenteral drug use.[85] Case-control studies suggest an increased risk of prostate cancer in subjects with elevated serum IGF-1 concentrations,[86] but there is no direct evidence that the doses of rhGH used by athletes increase the risk of prostate cancer.

Overdose

There are inadequate clinical data to evaluate the effects of a massive overdose of hGH.

Abstinence Syndrome

An abstinence syndrome associated with cessation of the chronic use of rhGH in healthy subjects is not well defined. Physiologically, the administration of exogenous hGH suppresses the secretion of endogenous hGH, but there are few data on the clinical and pathologic effects of chronic suppression of hGH secretion. In patients with severe growth hormone deficiencies, withdrawal of rhGH therapy results in fatigue, pain, irritability, and depression. However, the effects of hormone deficiency are difficult to separate from a true withdrawal syndrome.

Reproductive Abnormalities

There are no well-controlled studies of reproductive abnormalities associated with the use of rhGH in healthy subjects. The FDA classifies rhGH in pregnancy category B (fetal harm possible, but unlikely) and somatrem in pregnancy category C (lack of animal and human studies).

$$1 \text{ mg} = 2.7027 \text{ IU}$$

Analytic Methods

The IOC classifies hGH in prohibited class E; therefore, the use of hGH by athletes is doping. However, detection of hGH use is difficult as a result of wide individual variation in hGH secretion, analytic problems separating exogenous and endogenous hGH, and the relatively short half-life of rhGH; most infractions result from the confiscation of ampules.

Screening

The detection of exogenous hGH is complicated by the presence of endogenous hGH. Radioimmunoassay (RIA) and immunoradiometric assays (IRMA) detect whole hGH isoforms, whereas immunofunctional assay methods (IFA) detect only biologically active hGH isoforms. Consequently, the hGH concentrations by IFA are about 27–30% lower than determinations by RIA or IRMA because of the interference by GH-binding protein and the inclusion of several different molecular forms of hGH by the latter methods.[87] IFA is an ELISA method that incorporates 2 binding sites of the transmembrane growth hormone receptor. Nonfunctional isoforms do not bind to the growth hormone-binding protein; therefore, these isoforms of hGH are not detected by this method. However, the presence of isoform fragments, which contain binding sites for antibodies, can cause overestimation of the serum hGH concentration when high concentrations of rhGH are present.[88]

Confirmatory

Practical analytic methods to separate exogenous rhGH use from endogenous hGH based on serum or urine hGH concentrations are not well studied. Analysis by sodium dodecyl sulfate/polyacrylamide gel electrophoresis with tandem mass spectrometry allows the quantitation of hGH isoforms including the 20 and 22 kDa isoforms, 9 and 12 kDa fragments, and glycosylated 23 kDa GH variants.[89] The direct measurement of 22 kDa-/20 kDa-hGH isoforms is a potential biomarker of hGH abuse as this ratio increases following the

TABLE 19.1. Characteristics of Growth Hormone-Dependent Markers.[97]

Marker	Source	Physiologic Role	Disappearance Half-Time (h)	Effect Acute Exercise
Insulin-like growth factor I (1GF-1)	Liver	Mitogenic protein	89.5	+20%

†Affected by gender.

administration of 22 kDa isoforms (rhGH).[90] Other methods to detect hGH misuse require analysis of specific biomarkers from the GH/IGF-1 axis and bone markers because these specific variables are sensitive to exogenous rhGH rather than changes in endogenous hGH related to exercise. The detection of hGH abuse with only 1 parameter is difficult, and analysis of several different serum marker may be necessary (e.g., IGF-1, IGFBP-3, ALS, N-terminal propeptide of pro-collagen III [PIIINP], C-terminal cross-linked telopeptide of type I collagen [ICTP], osteocalcin, leptin).[91] ICTP and PIIINP are GH-dependent peripheral markers of bone and collagen turnover, respectively. Reference ranges for each marker in each gender are available, but these reference ranges have not been formally accepted by governing bodies for the detection of hGH abuse in sports.[92,93]

Biomarkers

BLOOD

Blood sampling is necessary to detect hGH abuse because of the low concentration of hGH and related peptides in urine samples. Direct measurement of hGH as a means of detecting hGH abuse is complicated by the diurnal variation in hGH secretion and the increase in serum hGH in response to exercise. In a study of 17 physically fit men exercised to exhaustion, the mean serum total growth hormone increased from a baseline value of 5.2 ± 2.2 mIU/L to 72.8 ± 10.9 mIU/L at the termination of exercise.[14] The administration of rhGH increased the pre-exercise serum total growth hormone and markedly attenuated the response of hGH to exer-

cise. The 2 main investigative methods for detecting hGH abuse are 1) the isoform method, the detection of altered endogenous pituitary hGH isoforms, and 2) the marker method, the measurement of hGH-dependent proteins (i.e., GH-dependent biomarkers including IGF, IGF-binding proteins, and collagen peptides).[94] The latter peptides include osteocalcin, the marker of bone resorption (*C*-terminal telopeptide of type I collagen, ICTP), and the marker of connective tissue synthesis (*N*-terminal propeptide of type III procollagen, PIIIP). These tests are an alternative to the direct analysis of hGH, but the cut-off concentrations of these tests for hGH abuse are not well defined.[95,96] Table 19.1 lists the characteristics of the biomarkers chosen to detect hGH abuse by the GH-2000 Project. In general, these biomarkers are unaffected by injury and do not display diurnal variation.[97]

ISOFORM METHOD.   Recombinant growth hormone consists only of the 22-kDa isoform, whereas endogenous hGH contains several different isoforms. The circulating isoforms of endogenous hGH are the 191 amino acid 22-kDa and 20-kDa variants with several other minor monomeric size variants. The former isoform accounts for about 50–70% of the circulating hGH compared with 5–15% for the latter isoform. The 20-kDa isoform lacks 15 amino acids (residues 32–46) of the 191 amino acid sequence of the 22-kDa isoform. Administration of rhGH suppresses the secretion of endogenous hGH by the pituitary as a result of a negative feedback system. Consequently, abnormally high serum concentrations of the 22-kDa isoform suggest the use of rhGH.[98] In studies of normal children and children with hGH deficiency,

the administration of rhGH (22-kDa variant) increases the 22-kDa/20-kDa hGH ratio.[95] This ratio increases because the serum concentration of 22 kDa increases, whereas the serum concentration of the 20-kDa variant remains low to undetectable. In adults, the usefulness of this ratio as a screening test is limit by the short time (i.e., about 3 hours after injection) available for analysis of this ratio, unless depot hGH is administered. A confirmation test is required of all positive samples because of the variable affinity of different immunoassays for the variety of hGH isoforms. The isoform method does not detect the use of cadaveric, pituitary-derived growth hormone.[99] Exercise increases the serum concentration of the 22-kDa isoform;[100] therefore, post-race testing may reduce the sensitivity of this screening test. Based on studies in children with short stature receiving rhGH, endogenous hGH secretions returns to baseline within 48 hours after administration.[101]

Marker Method.   The anabolic effects of hGH produces several proteins, and alterations in the serum concentration or ratios of these proteins suggests the use of endogenous hGH. These proteins include IGF-1, IGF binding proteins, and markers of bone and collagen turnover.

The potential advantage of these biomarkers (e.g., IGF-1, PIIIP) is the extended window of detection, which reaches several weeks compared with a 1–2 days for the ratio of hGH isoforms.[87] During the medical use of rhGH, IGF-1 is the most common biochemical marker of hGH use. Potential bone and soft tissue biomarkers, which change with exogenous hGH administration, include procollagen III terminal peptide (PIIIP), osteocalcin, and bone alkaline phosphatase.[102] Although endurance exercise transiently activated bone and collagen turnover, the administration of rhGH produces a substantially greater increase than endurance exercise alone.[103] Currently, no 1 biomarker provides sufficient sensitivity and specificity to allow the use of a single test; the normal gender- and age-specific reference limits of these compounds in athletes currently are under study.[104,105] Immunoassays of the blood from athletes indicate that some variation in IGF-binding proteins and ICTP occurs between elite athletes, recreational athletes, and sedentary individuals as well as some differences between the type of elite athlete (e.g., swimming, gymnastics, weightlifting).[106]

Urine

The very short elimination half-life of hGH and the low concentrations (i.e., <0.1%) of this compound in urine samples limits the practicality of using urine samples as a means of detecting hGH abuse. Although hGH is officially banned by the IOC, there is no official limit for hGH in the urine.

Abnormalities

Case reports associate both hyperglycemia and hypoglycemia with the use of rhGH as part of a regimen for body building.[107,108] In patients with hypopituitarism, supplementation with 6–25 µg/kg/day up to a maximum of 1.48 mg for 6 months increased fasting serum glucose, total serum cholesterol, and the peripheral conversion of T4 to T3.[109] The short-term administration of 0.2 IU/kg daily for 5 consecutive days to 6 healthy adults produced statistically significant increases in fast serum glucose, free fatty acids, and serum T_3.[36] During this experiment, a marked reduction in urinary sodium exaction occurred. Potential blood abnormalities associated with chronic hGH use include hypernatremia, hyperphosphatemia, and elevated alkaline phosphatase as well as abnormalities suggestive of hypothyroidism. Abnormal lipid profiles may occur during chronic hGH use including elevated serum cholesterol and triglyceride concentrations, but these changes are not specific to hGH use. In a volunteer study of 12 healthy, young adults, the SC injection of 0.3 IU rhGH/kg daily for 1 week was associated with an increase in the serum triglyceride concentration when compared with baseline.[38] Case reports associate hematuria with the therapeutic use of rhGH.[18]

TREATMENT

There are inadequate clinical data on the treatment of toxicity associated with the chronic use of rhGH to determine the efficacy of specific aspects of clinical management other than cessation of illicit hGH use. The treatment of adverse effects associated with chronic rhGH use is supportive. Primary attention should be directed at identifying and correcting any serum electrolyte, lipid, or glucose abnormalities. Hypothyroidism is a rare complication of the therapeutic use of rhGH, and thyroid function should be evaluated when suggested by the clinical presentation. Human growth hormone use typically occurs in combination with other ergogenic aids (anabolic steroids, erythropoietin); therefore, these patients should be evaluated for complications of anabolic steroid and erythropoietin use including a complete blood count (CBC). There are no antidotes for rhGH, and the rapid clearance of this compound limits the usefulness of any extracorporeal methods for removal. Referral to an endocrinologist may be necessary for complicated cases of chronic hGH use.

INSULIN-LIKE GROWTH FACTOR

IDENTIFYING CHARACTERISTICS

Somatomedin C (CAS RN:67763-96-6) is a synonym for the 70-amino acid, 7.65 kDa peptide, insulin-like growth factor I (IGF-1). This single chain polypeptide with 3 cross-linking disulfide bridges is structurally similar to proinsulin.[110] Insulin-like growth factor II (IGF-2, CAS RN:67763-97-7) is another somatomedin compound. IGF-1 and IGF-2 are straight chain polypeptides consisting of 70 and 67 amino acid residues, respectively. IGF-2 is an important fetal growth factor, whereas IGF-1 is primarily an adult HG factor that mediates many of the anabolic effects of growth hormone. IGF-1 circulates in the plasma as a 150 kDa complex formed by the IGF peptide, IGF binding protein III (IGFBP-3), and the acid-labile subunit (ALS). Minor amounts of IGF-1 are bound as 45 kDa-binary complexes containing IGFBP-1, IGFBP-2, IGFBP-3, or IGFBP-5.

EXPOSURE

Unlike growth hormone, there is no readily available natural source of IGF-1; therefore, the source of IGF-1 is recombinant human DNA technology (rhIGF-1). The following 2 pharmaceutic preparations of IGF-1 are available for the treatment of growth disorders in children: 1) Increlex® (recombinant human IGF-1; Tercica, Brisbane, CA); and 2) Iplex® (mecasermin rinfabate; INSMED Incorporated, Richmond, VA).[111] The latter product is recombinant human IGF-1 in equal molar concentration with the major binding protein, IGFBP-3 that together form a ternary complex in blood with the acid-labile subunit. Increlex® contains rhIGF-1 alone. Potential medical uses for rhIGF-1 include the treatment of growth disorders, severe insulin resistance (Rabson-Mendenhall syndrome), osteopenia, and burns.

The prevalence of doping with IGF-1 is difficult to determine, in part because of the complicated analytic processes required to detect IGF-1 use. The abuse of IGF-1 is probably much less common than the abuse of hGH, but abuse of rhIGF-1 is expected to increase as improvements in the detection of hGH use occur.[112] Suspected use of rhIGF-1 by athletes involves use as an anabolic and lipolytic agent either alone or in combination with hGH and anabolic androgenic steroids. Purported benefits of rhIGF-1 use include improvements in muscle growth, tissue and ligament repair, skin rejuvenation, sexual function, energy, endurance, fat reduction, mood, mental acuity, bone density, immune balance, and aging.[113] None of these claims are supported by clinical studies. IGF-1 appears on the World Anti-Doping Agency list of prohibited substances.[114]

TOXICOKINETICS

IGF-1 circulates in the blood bound to a family of highly specific IGF-binding proteins (IGFBP-1 through IGFBP-6), with about 80% of the circulating IGF-1 bound to a ternary complex consisting of IGF-1, IGFBP-3, and an 85 kDa glycoprotein acid-labile subunit (ALS).[115] The free fraction of IGF-1 is negligible (<1–5%). In the serum, GH-dependent IGFBP-3 binds approximately 90% of IGF-1 even though IGF-2 occupies most of the binding sites on IGFBP-3.[116] The binding of free IGF-1 markedly prolongs the serum IGF-1 half-life. The serum elimination half-lives of bound IGF-1 (binary, ternary complexes) and IGFBP-3 are about 16–20 hours, whereas the half-life of free IGF-1 is only a few minutes based on tracer studies in healthy volunteers.[117] Peak serum IGF-1 concentrations after the SC administration of 40 μg rhIGF-1/kg to healthy volunteers occurs about 7 hours after administration with the trough serum IGF-1 concentration was increased by a mean of 277 ± 50 ng/mL from baseline.[118] The volume of distribution of IGF-1 is relatively low (0.20–0.36 L/kg).

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Human growth hormone stimulates the release of IGF-1, primarily from the liver. As growth hormone secretion falls with aging, serum IGF-1 concentrations also decline along with decreases in muscle mass and increases in fat mass.[119] IGF-1 mediates the effect of hGH including activation of tyrosine kinase, Janus kinase 2, the Janus kinase/signal transducers, and activators of transcription (JAK/STAT) pathway, resulting in cellular proliferation, differentiation and migration, reduced apoptosis, regulation of metabolic pathways, and cytoskeletal reorganization.[120] Insulin and nutritional status also modulate IGF-1 synthesis. The anabolic effects of both growth hormone and IGF-1 are probably mediated through the induction of amino acid transporters in the cell membrane.

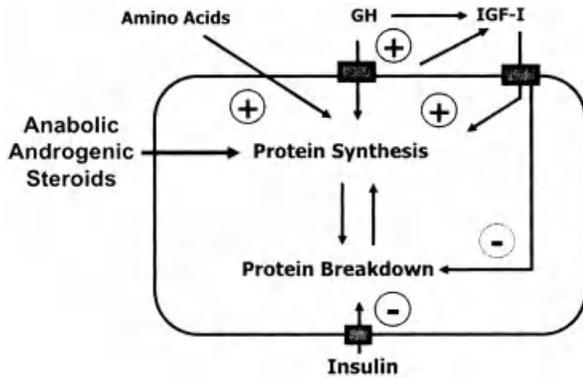
The actions of IGF-1 and insulin on carbohydrate metabolism, lipid formation, and protein synthesis are similar, but not identical. Insulin, IGF-1, and growth hormone act synergistically in regulating protein synthesis as displayed in Figure 19.3. Together these hormones efficiently store nutrients during the postprandial period while minimizing protein breakdown. IGF-1


FIGURE 19.3. Synergistic interactions of insulin-like growth factor I (IGF-1), growth hormone, and insulin on protein regulation. (Reprinted from Endocrinology and Metabolism Clinics of North America, Vol. 39, I Erotokritou-Mulligan, RIG Holt, Insulin-like growth factor I and insulin and their abuse in sport, p. 36, Copyright 2010, with permission from Elsevier.)

mediates the side effects of hGH; the adverse effects of IFG-I and hGH are similar (e.g., acromegaly).[68] Production of IGF-2 also occurs in the liver, kidney, and peripheral target tissues in response to the secretion of hGH. Although IGF-1 has potential effects on competitive athletes similar to rhGH (e.g., reduced glycogen breakdown during endurance activities, reduced muscle breakdown during power or sprinting events), there are inadequate clinical data to determine if these effects result in improved athletic performance.

CLINICAL RESPONSE

There are few data on the adverse effects associated with the use of rhIGF-1 by athletes. Adverse effects reported in studies of rhIGF-1 for insulin-resistant diabetes mellitus and growth hormone deficiency in children include headache, myalgias, fluid retention, jaw pain, tonsillar hypertrophy, alteration of facial features, and hypoglycemia.[121,122]

DIAGNOSTIC TESTING

IGF-1 is the most common biochemical marker of the medical use of rhGH; the methodology for detecting rhIGF-1 abuse is based on the analytic methods developed for the detection of exogenous rhGH use. These methods are based on GH-sensitive biomarkers rather than the measurement of pituitary GH isoforms because the ratio of endogenous GH isoforms is unaffected by IGF-1 administrations and IGF-1 exists as a single isoform in humans. The kidney excretes very small amounts of IGF-1 and methods for analyzing urinary IGF-1 are complex and lengthy; therefore, blood is the preferred sample for analyzing IGF-1 and related biomarkers (e.g., PIIIP). The serum concentration of IGF-1 is relatively stable during the day with little change during exercise,[123] and this marker increases several fold after administration of exogenous hGH. Almost all (99%) IGF-1 in the blood is bound to binding proteins (IGFBP-1 to IGFBP-6), and total IGF-1 is typically measured because free IGF-1 is less responsive to exogenous hGH administration. Serum concentrations of IGF-1 are relatively high compared with other peptide hormones, reaching up to about 800 ng/mL. The major determinants of variability in serum IGF-1 concentrations are age and gender with ethnicity and sport type having relatively minor influences. Based on cross-sectional studies of elite athletes, age accounts for a majority (i.e., about 80%) of the variability in serum IGF-1 concentrations with a significant negative correlation with age for both IGF-1 and collagen markers.[124] The contribution of gender was smaller than age. The influence of ethnicity on serum IGF-1 concentrations is relatively minor; a study of 1,085 elite athletes of a variety of different ethnicities demonstrated statistically significant differences only between Afro-Caribbeans (i.e., about 20% lower) and white Europeans.[125]

Methods for the quantitation of IGF-1 in biologic media include high performance liquid chromatography/electrospray ion trap/mass spectrometry,[126] ultra high performance liquid chromatography/tandem mass spectrometry in selected reaction monitoring,[127] and liquid chromatography/tandem mass spectrometry with immunoaffinity purification.[128] rhIGF-1 has an identical amino acid sequence as endogenous IGF-1; thus, separation techniques based on electrical charge differences (e.g., electrophoresis) do not distinguish between rhIGF-1 and endogenous IGF-1. The use of sodium dodecyl sulfate or strong acids with ethanol allows the determination of total IGF-1 by cleaving the noncovalent bond between IGF-1 and the IGF-1 binding proteins 3 and 5. Smaller IGF-1 binding proteins (e.g., 1 and 4) do not bind as well as other IGF-1 binding proteins; consequently, some of IGF-1 bound to these smaller binding proteins are not extracted during this process.[129] Potential abnormalities following the chronic use of IGF-1 include hypoglycemia and elevated serum hepatic aminotransferases based on clinical studies.

TREATMENT

Treatment is supportive.

Chapter 20

NUTRITIONAL SUPPLEMENTS

Ergogenic aids are techniques or regimens that increase performance capacity, improve the efficiency to perform work, or enhance the ability to recover from exercise. Diet has been part of Olympic training at least since Roman and Greek times, and diets used for ergogenic purposes included various combinations of dried figs, moist cheese, wheat, meat, white bread sprinkled with poppy seeds, fish and pork, along with the limited use of wine.[1] The US Food and Drug Administration (FDA) defines a dietary supplement as follows: 1) a product (other than tobacco) intended to supplement the diet that bears or contains 1 or more of the following dietary ingredients: a vitamin, mineral, amino acid, herb or other botanical; 2) a dietary substance for use to supplement the diet by increasing the total dietary intake; or 3) a concentrate, metabolite, constituent, extract, or combination of any ingredient described previously. In general, nutritional supplements are not produced under the same strict quality control measures as pharmaceutic drugs. The FDA monitors structure/function claims under the Dietary Supplement Health Education Act of 1994, but the FDA does not routinely monitor the quality of these supplements with the same scrutiny as pharmaceutic drugs.

The potency and composition of nutritional supplements may vary substantially between different sources. Additionally, nutritional supplements may contain adulterants not listed on the label. The World Anti-Doping Agency (WADA) does not ban dietary supplements or caffeine.[2] However, nutritional supplements may contain prohibited stimulants (e.g., ephedrine, sibutramine) or anabolic androgenic steroids (androstenedione, dehydroepiandrosterone) that are not listed on the labels.

The latter compounds in these intentionally faked products include both classic anabolic steroids (boldenone, dehydrochloromethyl-testosterone, methandienone, oxandrolone, stanozolol) and newer designer steroids (e.g., androstatrienedione, methasterone, prostanozol).[3] Androstenedione (CAS RN: 63-05-8) and dehydroepiandrosterone (DHEA, CAS RN: 2283-82-1) are popular endogenous steroid precursors that are weak androgenic compounds; the body converts DHEA to androstenedione, which subsequently is converted to testosterone or estrone.[4]

Currently, there are a large number (>250) of dietary supplements being used as ergogenic aids, but there are few data on the ergogenic properties of most of these compounds. In a meta-analysis of dietary supplements, 6 of these supplements had more than 2 studies that met the criteria for inclusion in the meta-analysis.[5] Of these 6 supplements, only creatine and, to a lesser extent, β-hydroxy-β-methylbutyrate demonstrated statistically significant increases in net lean mass and strength.

CREATINE

HISTORY

Chevreul originally discovered creatine in the late 1830s, and Liebeg confirmed the existence of creatine in 1847.[6] However, creatine was not isolated until the early 1900s.[7] In 1926, Chanutin suggested that creatine was associated with skeletal muscle anabolism.[8] However, the use

of creatine as an ergogenic aid did not begin until the 1970s, when athletes from the Soviet Union and the Eastern bloc countries used creatine supplementation to enhance performance. The use of creatine by athletes in the United States and United Kingdom did not begin until the early 1990s.[9] During the 1992 Barcelona Olympics, high profile athletes associated improved performance in power and sprint events with the use of creatine supplements. Creatine is not listed on WADA's list of banned substances.

IDENTIFYING CHARACTERISTICS

Physiochemical Properties

Creatine (α-methyl guanidino acetic acid, CAS RN: 57-00-1) is a nitrogenous organic acid composed of 3 amino acids (arginine, glycine, methionine) that is formed endogenously by methylation of guanidinoacetic acid found primarily in muscle. Figure 20.1 displays the chemical structure of creatine ($C_4H_9N_3O_2$). Creatine salts (e.g., glycinate, citrate, malate, ethyl ester, pyruvate) are relatively water soluble and easily dissolved in sports drinks or gels. In contrast, creatine monohydrate must be consumed soon after dissolved in solution to avoid precipitation. Table 20.1 lists some of the physiochemical properties of creatine.

Form

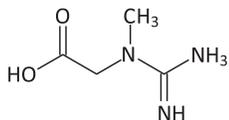
Creatine supplements appear commercially in several forms as a result of the relatively poor solubility of creatine monohydrate compared with some creatine salts. Creatine monohydrate is the most common form of creatine supplements, available as a powder from a


FIGURE 20.1. Chemical structure of creatine.

TABLE 20.1. Some Physical Properties of Creatine.

Physical Property	Value
Melting Point	303°C (577.4°F)

Vapor Pressure	7.90E-04 mm Hg (25°C/77°F)

variety of sources including health food stores, grocery stores, and pharmacies. Creatine is a component of many protein supplements, sport drinks, and energy bars that is also available as capsules and tablets. Each gram of creatine monohydrate provides 0.879 g creatine.

EXPOSURE

The liver, kidneys, and pancreas produce endogenous creatine by the methylation of guanidinoacetic acid from dietary sources of arginine and glycine.[6] The diet is the exogenous source of creatine (3–7 g/kg), particularly meat, fowl, and fish. The typical US diet provides about 1 g creatine daily; endogenous creatine production and the diet are about equal sources of creatine for the human body. Clinical trials on the ergogenic effects of creatine supplementation use doses about 3- to 12-fold higher than the daily dietary intake of creatine.[10] Exogenous and endogenous sources account for approximately equal amounts of creatine in the body.

Creatine is a nonessential, legal food supplement that is regulated in the United States as a food supplement rather than a drug. Although creatine is a natural constituent of fish and meat, most creatine in dietary supplements is produced synthetically by reacting sarcosine (CAS RN: 107-97-1) with cyanamide (CAS RN:420-04-2). Potential contaminants of the manufacturing process include creatinine, dicyandiamide, dihydrotriazine, and trace metals (e.g., arsenic).[11] Creatine monophosphate is a very common nutritional supplement used primarily as a method to increase strength and power; this substance is the most widely marketed nonsteroidal, nonstimulant ergogenic aid.[12] In a survey of 674 high school athletes from Georgia and Tennessee, 16% of these athletes used creatine to enhance athletic performance based on responses to questionnaires distributed by their athletic trainers or coaches.[13] In this study, creatine use increased with age and was more prevalent among male than female athletes (23% vs. 2%, respectively). Frequently, adolescents used creatine supplements at dosages exceeding standard recommendations. In a study of the use of complementary medicine and dietary supplements by the US adolescent population, 4.7% of the participants reported they ever used creatine supplements on the survey.[14] The use of creatine by college athletes probably is probably at least several times higher than adolescent athletes.[15]

DOSE EFFECT

The common dose of creatine is an initial oral loading dose of 15–20 g daily for 5–7 days followed by a maintenance dose of 3–5 g daily for up to 6 months.[16]

Anecdotally, higher daily maintenance doses (e.g., 10 g) are used, but there are few medical data on the dose effect of these regimens. Because of concern about reduced response to creatine and a slow decrease in muscle creatine during maintenance dosing, creatine regimens frequently include a 4-week wash-out period following 8–10 weeks of maintenance dosing.[17] The observed safe level of creatine for chronic supplementation in healthy adults is approximately 5 g/day based on risk assessment.[10]

TOXICOKINETICS

Absorption

The absorption of oral doses of creatine probably involves active transport (i.e., with sodium- and chloride-dependent transporters) similar to the uptake of amino acids and peptides by transporters.[18] There are inadequate pharmacokinetic data to determine the absolute bioavailability of creatine. The dissolution rate and solubility may limit the bioavailability of the capsules and chewable tablets formulations of creatine. The bioavailability of creatine is probably <100% as a result of the potential for saturation of the active transport process and degradation of creatine in the gut.[18] The absorption of creatine may be dose-dependent. Creatine is not subject to first-pass metabolism. Peak plasma concentrations of creatine usually occur within 2–3 hours after ingestion. In a study of 6 healthy volunteers, the mean peak plasma creatine after the ingestion of 71 mg creatine monohydrate/kg was 102.1 ± 11.2 mg/L at 1.9 ± 0.88 hours after administration.[19] The steady-state plasma concentration of creatine after administration of 71 mg/kg 4 times daily for 6 days was 97.4 ± 13.0 mg/L.

Distribution

Although uptake of creatine occurs in a variety of cells (erythrocytes, nervous tissue, spermatozoa, retina), the main site of creatine absorption is skeletal muscle.[20] Therefore, skeletal muscle contains most of the creatine in the body; in muscle, creatine exists as either the free or phosphorylated form in a ratio of approximately 2:3 depending on muscle fiber type. The average pool of creatine is about 2 g/kg, and the storage capacity of skeletal muscle is finite.[21] About 95% of creatine is distributed to skeletal muscle; the remaining occurs in the heart, brain, and testes. Creatine enters the muscle cell in the free form against a concentration gradient as a result of the action of the sodium-dependent transporter, creatine transporter-1. The creatine transporter is specific for creatine, but the chemical structure of the creatine transporter is similar to the transporters for

dopamine and γ-aminobutyric acid (GABA). Several factors increase creatine uptake into muscle including exercise, insulin, catecholamines, insulin-like growth factor 1 (IGF-1), and simultaneous ingestion with carbohydrates, probably as a result of insulin-induced enhancement of creatine transport into muscle.[22,23] The volume of distribution is probably near total body water (i.e., about 45 L).[24] Protein binding of creatine in plasma is negligible (<10%) as a result of the hydrophilic properties of creatine.[25]

Biotransformation

Animal studies indicate that creatine undergoes spontaneous (i.e., nonenzymatic) degradation in the blood almost exclusively to creatinine.[26,27] Increasing the stores of creatine in muscle elevates serum creatinine concentrations.[18] Metabolism of creatine to methylamine is a minor pathway.[28] Formaldehyde is a potential metabolite of methylamine as a result of the enzymatic action of semicarbazide-sensitive amine oxidase; however, the extent of formation is probably small.[29] Figure 20.2 displays the synthesis, metabolism, and phosphorylation of creatine.

Elimination

Clearance of creatine involves biotransformation to creatinine, renal filtration, and irreversible uptake into skeletal muscle.[18] In a study of 6 healthy volunteers, the mean terminal plasma elimination half-life of creatine after a single dose (71 mg/kg) and 4 doses daily for 6 days was 2.0 ± 0.68 hours and 2.7 ± 0.63 hours, respectively.[19] Urinary excretion accounts for the loss of about 2 grams of creatine daily, primarily as creatinine. The elimination rate of creatine in the urine is not well defined following creatine supplementation, but the renal clearance of free creatine in patients without supplementation is probably near the glomerular filtration rate. With increasing supplementation, the amount of creatine in the urine increases. Although the percentage of clearance by metabolism to creatinine, renal elimination of creatine, and skeletal muscle uptake; the latter mechanism probably accounts for most of the clearance of creatine during creatine supplementation.[18] Total creatine concentrations return to baseline values within 1 month after cessation of creatine supplementation.[30] During this period, urinary creatinine concentrations are elevated.

Maternal and Fetal Kinetics

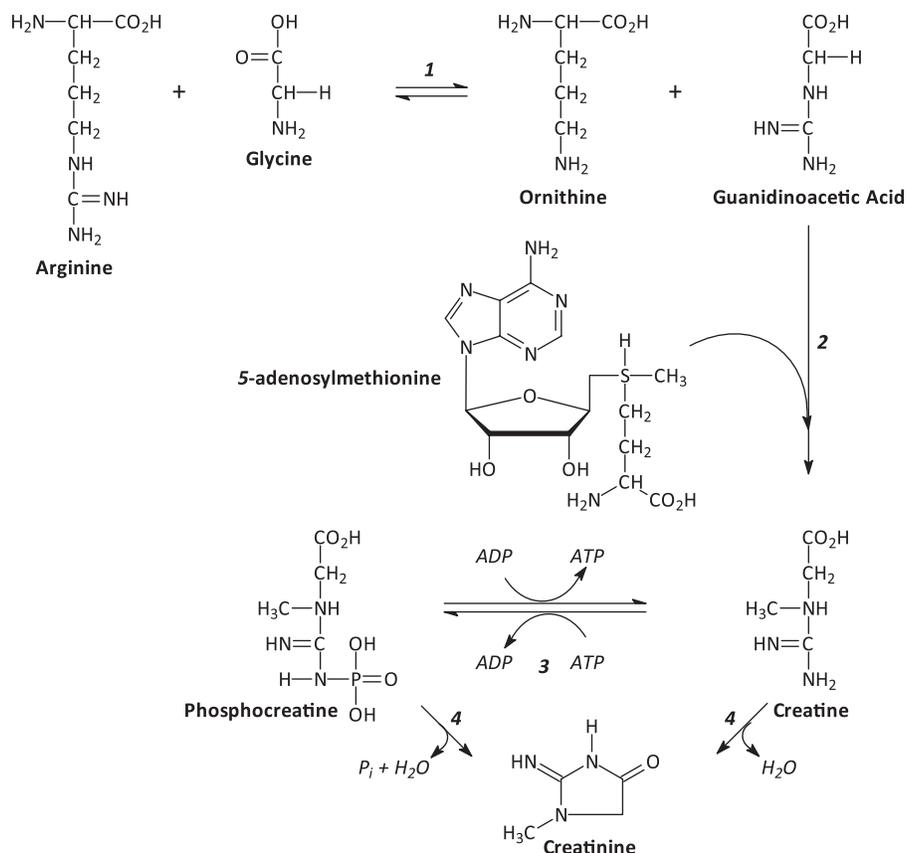
There are few data on the maternal fetal kinetics of creatine.


FIGURE 20.2. Synthesis, metabolism, and phosphorylation of creatine. Enzymes for the chemical reactions include the following: 1) arginine:glycine amidino-transferase, 2) guanidinoacetate *N*-methyltransferase, 3) creatine kinase, and 4) none—spontaneous conversion.[28]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

The skeletal muscles contain over 95% of the total creatine in the human body. The primary ergogenic effect of creatine supplementation involves improvement in repeated short bouts (i.e., <1 minute) of high-intensity, repetitive physical activity rather than endurance events.[31] During these activities (e.g., sprinting, jumping, cycling), the amount of phosphocreatine stored in the muscle determines the amount of energy available based on the rephosphorylation of adenosine diphosphate (ADP) to adenosine triphosphate (ATP). Beside repeated short bouts of high-intensity physical exercise, creatine supplementation increases maximal force or strength of both dynamic and isotonic contractions. There is little evidence to support the use of creatine to improve isometric muscular performance or endurance activities.[16] Creatine, in the phosphorylated form (phosphocreatine) helps buffers hydrogen ions during

maximal exercise in muscle cells along with maintaining the adenosine triphosphate/adenosine diphosphate ratio in both skeletal muscle and brain tissue that is critical for normal cellular function. During physical activity, phosphocreatine maintains adenosine triphosphate (ATP) concentrations by donating a phosphate to adenosine diphosphate (ADP). Short-term creatine supplementation (20 g daily for 5–7 days) increases total creatine content in the muscles of healthy young adults by about 10–30% and phosphocreatine stores in muscle by approximately 10–40%.[32] Creatine supplementation does not increase muscle glycogen content at rest or after exhaustive exercise.[33] In the brain, similar creatine supplementation protocols increase creatine and phosphocreatine concentrations about 9% and 4%, respectively, as measured by nuclear magnetic resonance spectroscopy.[34,35]

The use of creatine probably increases the energy available for maximal force of dynamic or isotonic contractions, particularly in less-trained individuals.[36] The benefit of creatine depends on the study group with the greatest gains in nonelite athletes, and volunteer studies

are inconsistent regarding the positive effects of creatine on athletic performance.[37] In the positive studies, short-term creatine supplementation improves single-effort sprint performance about 1–5% and maximal power (peak power, total work)/strength (maximal force or strength) about 5–15%.[32] Up to approximately 30% of individuals do not respond to creatine supplementation.[38] In a study of National Collegiate Athletic Association division I players with at least 1 year of college football experience, creatine supplementation did not increase strength gains compared with a control group (placebo).[39] However, a study of red-shirt freshmen indicated that creatine supplementation produces a statistically significant increase in strength, peak torque (300° knee flexion only), and anaerobic capacity as assessed by the Wingate protocol, when compared with placebo (sodium phosphate monohydrate) and control (no supplementation).[40] All participants underwent 4 weeks of resistance training. Body fat, global muscle strength, and extracellular fluid did not demonstrate statistically significant differences between these groups. In a study of healthy young adults, postexercise supplementation with protein-carbohydrate (10 g casein, 75 g glucose) produced similar increases in strength after a resistance exercise training program, when compared with creatine-carbohydrate (10 g creatine, 75 g glucose) supplementation.[41] However, mean total body mass increased more ($P < .05$) for creatine-carbohydrate group (+4.3 kg, 5.4%) compared with protein-carbohydrate group (+1.9 kg, 2.4%). The increase in body mass results primarily from increased intracellular water in muscle cells rather than an increase in protein synthesis or decrease in muscle proteolysis. The results of creatine supplementation on muscle mass and muscle performance in older men (>60 years) is equivocal.[42]

Creatine does not prevent myalgias or muscle breakdown that follows intense exercise, and there is little evidence that creatine supplementation increases isometric muscular exercise.[43] Additionally, there is little evidence that creatine loading improves the adverse effects of neuromuscular fatigue on power output. Five days of creatine loading (20 g dicreatine citrate/day) had minimal effect on the electromyographic fatigue threshold as measured in the vastus lateralis of the right thigh of 16 college-age men performing a discontinuous cycle-ergometer exercise.[44]

The mechanism of action of creatine is not well defined. Possible mechanisms of action include increased phosphocreatine-enhanced rephosphorylation of adenosine diphosphate, buffering of pH changes, increased diffusion of high-energy phosphates into myosin heads, and increased muscle hypertrophy.[45,46] There is equivocal evidence that creatine supplementation improves

muscle strength in disease states (e.g., atherosclerosis, congestive heart failure, neuromuscular diseases).[47,48] Although some studies suggest that creatine supplementation improves performance of older adults and sleep-deprived young adults on some cognitive and psychomotor tests,[49] 6 weeks of creatine supplementation (0.03 g/kg/d) did not improve cognitive function in healthy, rested young adults.[50] Neuropsychologic testing included simple reaction time, code substation, logical reasoning symbolic, running memory, Sternberg memory recall, and mathematical processing.

Mechanism of Toxicity

There are limited data on the potential of creatine supplementation to cause chronic toxicity. Most reported data on toxicity is derived from clinical studies on healthy adults or patients with muscle wasting. There are inadequate data to determine the mechanism of toxicity of permanent adverse effects, if any, associated with the use of creatine supplementation at standard doses.

CLINICAL RESPONSE

In most open label studies and randomized clinical trials to date, creatine supplements were associated with infrequent and relatively minor side effects, when reported.[10] However, not all studies specifically report measuring adverse effects or other safety outcomes. A few case reports document more severe effects (e.g., renal dysfunction, atrial fibrillation, rhabdomyolysis), but the precise role of creatine in the causation of these abnormalities is unclear. Side effects most commonly associated with the use of creatine supplements based on anecdotal reports include gastrointestinal (GI) distress, muscle cramps, and renal dysfunction.[51] Currently, there are no clinical data to indicate that creatine supplementation causes liver dysfunction.

Gastrointestinal Distress

The most common adverse effect associated with creatine supplementation in clinical trials evaluating the effect of creatine supplementation on athletic performance is GI distress (nausea, vomiting, diarrhea), particularly if ingested during exercise.[52,53] In a placebo-controlled trial of creatine monohydrate in patients with amyotrophic lateral sclerosis, 3 of 175 patients in the treatment group ceased using creatine because of severe GI complaints (diarrhea, vomiting) compared with none in the placebo group.[54] Most clinical studies on creatine supplementation do not report a significant incidence of adverse effects as compared with baseline.[55] In a 28-day study of elite college football players

receiving phosphorus and creatine (15.75 g) supplementation daily, there were no complaints of GI symptoms.[56]

Muscle

Based on responses to questionnaires, the most common adverse effects associated with creatine supplementation in high school athletes were muscle cramps, increased thirst, and stomach cramps.[13] However, there was no control group to determine the effect of physical exercise alone on the development of these symptoms. Follow-up studies up to 5 years suggest that supplementation with common doses of creatine up to 80 g daily does not alter hepatic or renal function.[57,58] In the above 28-day study on elite athletes, there were no complaints of excess muscle cramps.[56] Volunteer studies suggest that creatine supplementation can increase anterior compartment pressures of the lower leg during the period immediately after exercise.[59] However, the clinical significance of this increase remains unclear. Rhabdomyolysis and an acute quadriceps compartment syndrome developed in a weight lifter on long-term, high-dose creatine supplementation (25 g daily for 1 year).[60] The chest x-ray demonstrated cardiomegaly, pulmonary venous congestion and bilateral effusions, attributed to pulmonary edema secondary to iatrogenic fluid overload. There were no laboratory tests for other ergogenic aids.

Renal Dysfunction

Clinical studies indicate that creatine supplementation does not alter glomerular filtration rate, glomerular permeability, or renal tubular reabsorption, when taken in standard doses (20 g/d for 5 days, <5 g thereafter) by healthy young adults.[51,61] Several case reports suggest that creatine supplementation may decrease renal function in patients with preexisting renal disease. A 25-year-old man had normal renal function while receiving cyclosporin for focal segmental glomerular sclerosis; 7 weeks of creatine supplementation at 2 g/day was associated with a decrease in creatinine clearance from 93 mL/min prior to supplementation to 54 mL/min after supplementation.[62] The creatinine clearance returned to baseline values after cessation of creatine supplementation. Another case report associated creatine supplementation (10 g daily 6 weeks prior to surgery) with the development of nonoliguric renal dysfunction and rhabdomyolysis immediately after arthroscopic knee surgery.[63] These 2 patients responded to medical therapy and they did not develop any permanent sequelae. A case report associated the development of lactic acidosis and acute renal failure with the use of creatine for 2

months by a 42-year-old bodybuilder treated with metformin for his diabetes mellitus.[64]

Cardiovascular

Cardiovascular effects are not usually associated with the use of creatine supplementation. A case report of a 30-year-old man associated the development of atrial fibrillation with the loading phase of creatine supplementation.[65] Although there was no other obvious cause of this dysrhythmia, the causal link between atrial fibrillation and creatine supplementation is unclear.

Carcinogenesis

Creatine is not considered a carcinogen. Nitrosation of creatine to the animal carcinogen, *N*-nitrososarcosine, probably does not occur to any clinical significant extent based on pharmacology studies.[66] Although creatine supplementation potentially stimulates the production and renal excretion of methylamine and formaldehyde, there are inadequate data to determine if this enhanced production increases the risk of cancer.

DIAGNOSTIC TESTING

Analytic Methods

Creatine supplementation interferes with serum and urine creatinine measurements as a result both of increased daily excretion of creatinine from the degradation of creatine and analytic interference of creatine with some creatinine assays. In addition to creatine and bilirubin, the presence of ascorbic acid in biological samples interferes with enzymatic methods for determining creatinine concentrations.[67] The effect of creatine on creatinine determination depends on the specific method, and the presence of creatine can either falsely increase or decrease the serum creatinine concentration. Inulin clearance is an alternative to the use of creatinine to evaluate kidney function, but there are no human data on the use of inulin in the setting of creatine supplementation. A liquid chromatography method with ultraviolet detection is available for the determination of creatine in commercial products.[68] Methods to determine creatine in biologic samples include isocratic high performance liquid chromatography.[25] The lower limit of quantitation for creatine with this assay is about 5 mg/L.

Abnormalities

Clinical studies on the use of creatine supplements indicate that creatine supplementation causes no significant

long-term changes in measures of renal function in young healthy adults.[61] Although creatine supplementation initially increases serum and urine creatinine concentrations during use, follow-up studies of athletes using creatine supplementation do not indicate that the use of these supplements permanently alters serum measurements of liver, kidney, or muscle function. Both serum and urine creatinine concentrations increase during creatine supplementation, resulting in no significant change in urine creatinine clearance. In a study of healthy young participants receiving a loading dose of creatine (20 g daily for 5 days) followed by a maintenance dose (3 g daily for 9 weeks), there were no clinical significant changes in serum markers of hepatorenal function or muscle damage during the study.[69] These serum markers included sodium, potassium, urea, creatinine alkaline phosphatase, alanine aminotransferase, bilirubin, creatine kinase, albumin, and γ-glutamyl transferase. A study of 116 National Collegiate Athletic Association Division 1A college football players did not detect clinically significant difference in a number of urinary and blood markers of liver, kidney, and muscle function when comparing athletes with and without creatine supplementation (daily maintenance creatine doses of 5–10 g for up to 21 months).[70] The biomarkers included serum creatine kinase, serum electrolytes, hepatic aminotransferases, serum alkaline phosphatase, hemoglobin, and serum uric acid. Creatine supplementation was associated with a statistically significant increase in the magnetic resonance pool of creatine in the deep frontal cerebral white matter in some,[71] but not all studies.[72] The reason for the differences (e.g., dosage, duration of treatment, analytical method, study group) are unclear.

TREATMENT

There are few data on the treatment of toxicity associated with creatine use. Any adverse effects associated with the use of creatine typically resolve with cessation of use and respond to supportive care.

β-HYDROXY-β-METHYLBUTYRATE (HMB)

IDENTIFYING CHARACTERISTICS

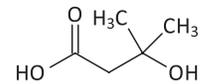
β-Hydroxy-β-methylbutyrate (β-hydroxyisovaleric acid, CAS RN:625-08-1) is a metabolic product of leucine


FIGURE 20.3. Chemical Structure of β-hydroxy-β-methylbutyrate (HMB).

TABLE 20.2. Some Physical Properties of β-Hydroxy-β-Methylbutyrate.

Physical Property	Value
Melting Point	−80°C (−112°F)
log P (Octanol-Water)	−0.020

that is a precursor of cholesterol. Leucine is an important amino acid and precursor for protein synthesis and energy metabolism in the muscle. Figure 20.3 displays the chemical structure of HMB. Table 20.2 displays some physical properties of β-hydroxy-β-methylbutyrate.

EXPOSURE

β-Hydroxy-β-methylbutyrate is a popular "anticatabolic," ergogenic agent that is usually part of a training supplementation program designed to improve strength and increase lean muscle mass.[73] Products containing HMB include fat burners, muscle builders, and recovery enhancers. This compound is a natural constituent of citrus, catfish, and breast milk. Both nonprimate animals and humans produce HMB endogenously. The FDA lists this compound as a nutritional supplement rather than a drug. HMB is not listed on WADA's list of banned substances or any other sporting organizations. HMB is an investigative supplement for the improvement of nitrogen balance in both hospitalized and nonhospitalized elderly patients. In a double-blind controlled study of 77 elderly participants receiving a supplement containing HMB, L-arginine, and L-lysine for 1 year, the lean mass in the treated group increased 1.2% ($P = .05$) compared with controls receiving an iso-nitrogenous supplement.[74] However, there was no decrease in the reduction of handgrip and leg strength between the 2 groups over the 1-year study.

DOSE EFFECT

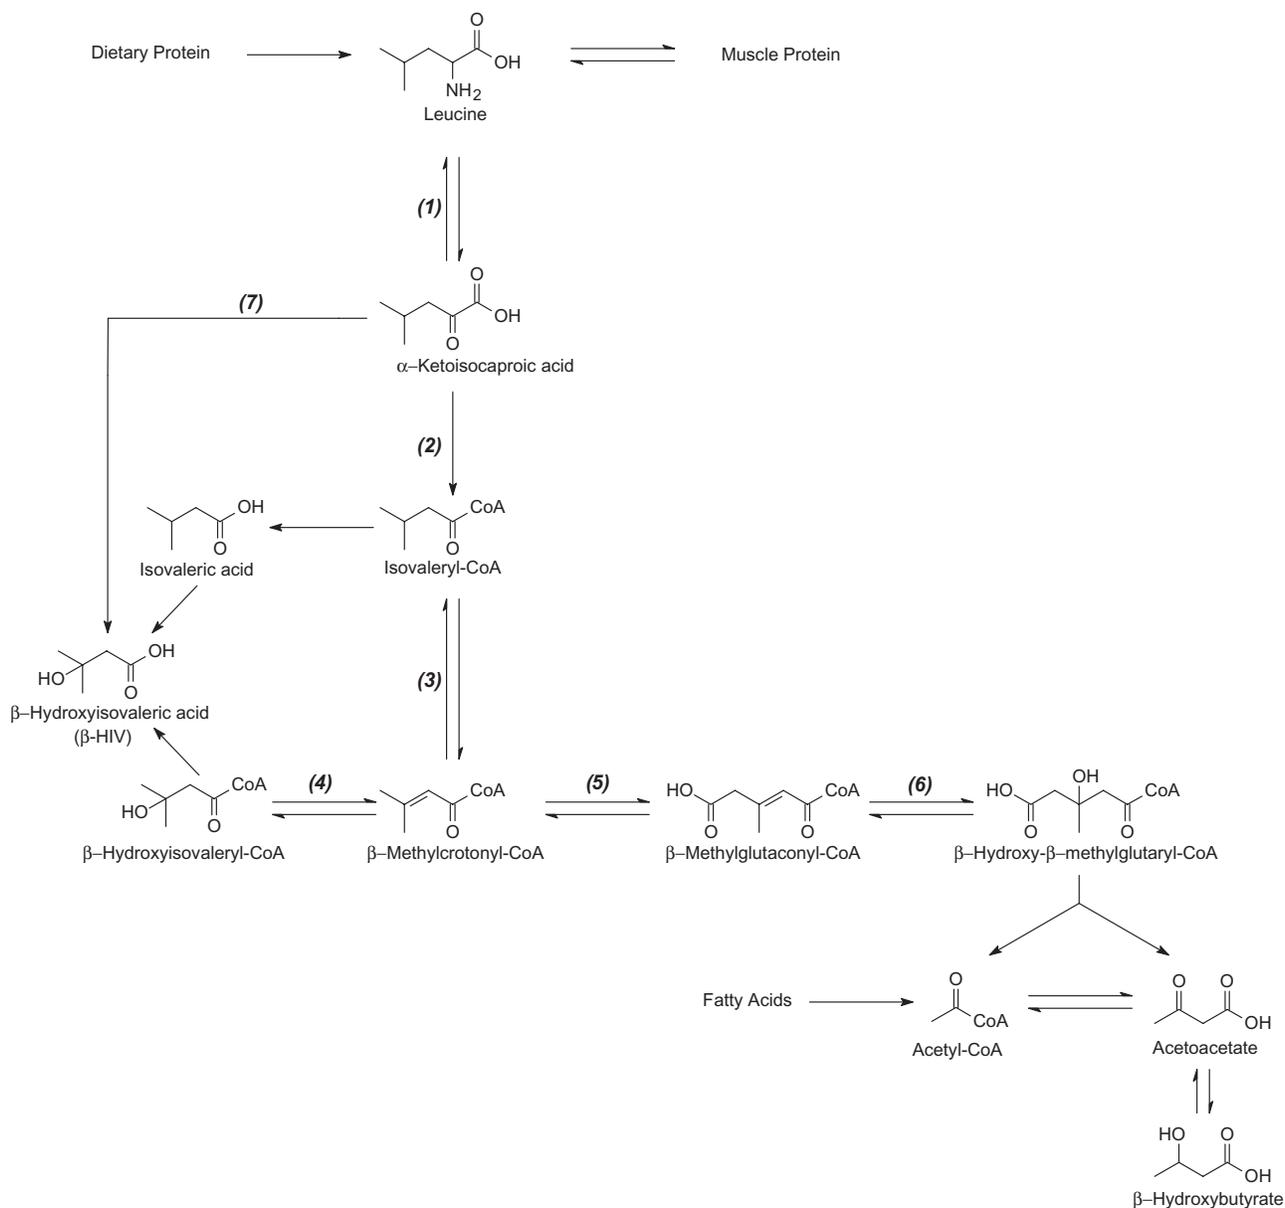
The typical dose of HMB is 3–5 g daily alone or as part of a regimen of other supplements and/or exercise program at bedtime or before training. In a rodent study, the no-observed-adverse-effect level (NOAEL) was 5% calcium HMB (3.49 g/kg body weight males, 4.16 g/kg body weight females) in the diet.[75] There was


FIGURE 20.4. Formation of β-hydroxy β-methylbutyrate (β-hydroxyisovaleric acid). 1 = Branched chain amino acid transaminase; 2 = branched chain ketoacid dehydrogenase; 3 = isovaleryl-CoA dehydrogenase; 4 = enoyl-CoA hydratase; 5 = β-methylcrotonyl-CoA carboxylase; 6 = β-methylglutaconyl-CoA hydratase; 7 = cytosolic α-ketoisocaproate oxygenase.[95]

a statistically significant increase in inorganic phosphate in male animals in the 5% feeding group, but the effect was not considered adverse.

TOXICOKINETICS

Transamination of leucine produces α-ketoisocaproate. The action of the cytosolic enzyme, α-ketoisocaproate dioxygenase, on this latter compound forms β-hydroxy-β-methylbutyrate (HMB). This reaction accounts for about 5% of the oxidation of leucine in animal studies.[76]

Most α-ketoisocaproate undergoes metabolism in the mitochondria by α-ketoisocaproate dehydrogenase. Additionally, production of HMB results from the hydration of methylcrotonyl-CoA by crotonase, particularly in patients with 3-methylcrotonyl-CoA carboxylase or biotin deficiencies. Figure 20.4 displays the formation of HMB from leucine and from methylcrotonyl-CoA. The major metabolic pathway of HMB is probably conversion to β-hydroxy-β-methylglutaryl-CoA and then to mevalonate or acetoacetyl-CoA.[77] There are no data on the maternal-fetal kinetics of HMB.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

The mechanism of action of HMB is not well defined. Clinical studies suggest that this mechanism is different from creatine as a result of the additive effect of HMB when added to regimens including creatine and resistance training.[78] Potential mechanisms of action include the following: 1) promoting muscle growth and cell integrity by enhanced production of membrane precursors (i.e., cholesterol) and 2) improving recovery time by decreasing muscle catabolism and excretion of 3-methylhistidine. Cholesterol enhances membrane fluidity and reduces stretch rupture in the muscle fibers. In the cytosol, β-hydroxy-β-methylglutaryl-coenzyme A forms from HMB, and subsequently cholesterol is produced from fatty acid β-oxidation and/or glycolysis via β-hydroxy-β-methylglutaryl-coenzyme A.

Most clinical studies on HMB supplementation are limited by small sample size, specific populations (e.g., auto immunodeficiency syndrome [AIDS] patients), and unique settings. The existing studies suggest the *potential* for modest enhancement of strength in resistance trained athletes, primarily in lower extremities.[79] The increase in strength measures is variable with some studies demonstrating no clear improvement in strength following HMB supplementation. A meta-analysis of 9 studies of HMB supplementation during resistance training estimated the average net weekly increase in strength gain over about 5 weeks was 1.4% (95% CI: 0.41–2.39%).[5] In a study of 34 resistance-trained men receiving 3 g HMB daily for 9 weeks, 1-repetition maximum leg extension strength increased 9.1% (90% CI: ± 7.5%) between baseline and the end of the study.[80] The effect of HMB supplementation on upper body strength (bench press, biceps preacher curl) was insignificant. Another meta-analysis of 9 studies of both trained and untrained participants demonstrated little benefit of daily HMB supplementation over an average of 5 ± 2 weeks for trained athletes.[81] For untrained participants, there were small benefits for average lower body strength (mean ± 90% CI = 9.9 ± 5.9%) with negligible changes in upper body strength (2.1 ± 5.5%).

Improvements in lean body mass occur following the use of HMB in certain participants including the elderly[82] and patients with muscle wasting diseases (i.e., in combination with L-glutamine and L-arginine).[83] However, the benefits of HMB supplementation in athletes is less clear. In the above meta-analysis of 9 studies, HMB supplementation during resistance training increased the average net weekly gain in lean mass over about 5 weeks ~0.28% (95% CI: 0.13–0.42%).[5] Benefits of HMB supplementation depends on the fitness level of the athlete with untrained athletes probably benefiting more than conditioned athletes.[73] In a 4-week study of athletes training 3 times weekly, the upper body strength increased more ($P = .008$) in the HMB supplementation group (7.5 ± 0.6 kg) compared with the placebo group (5.2 ± 0.6 kg).[84] However, in a double-blind, placebo-controlled study of 35 college football players, there were no statistically significant differences in muscle strength (power cleans, squats, bench press) or lean body mass between the HMB supplementation group (3 g daily for 4 weeks) and the placebo group.[85] Most studies do not demonstrate significant difference in lean body mass before and after HMB supplementation.[81,86]

Intense exercise often causes delayed-onset muscle membrane damage. Short-term supplementation with HMB probably does not reduce the symptoms associated with strenuous exercise. Although some clinical studies suggest that HMB supplementation for 6 weeks decreases muscle damage associated with prolonged exercise as assessed by serum biomarkers (creatine kinase, lactate dehydrogenase), other studies do not demonstrate improvement in measures of exercise-induced muscle damage including delayed-onset muscle soreness, knee extensor range of motion, serum creatine kinase activity, and isometric muscle function.[87] A study of nonresistance-trained individuals demonstrated no benefit from short-term HMB supplementation (40 mg/kg daily for 6 days prior to exercise) on symptoms associated with eccentric muscle damage secondary to a bout of 24 maximal isokinetic eccentric contractions of the elbow flexors, when compared with placebo.[88] Assessment measures included muscle soreness, upper arm girth, and torque measures. Similar negative results occurred in a study of college football players receiving 10 days of HMB supplementation (3 g daily) during preseason training.[89]

CLINICAL RESPONSE

To date, limited data from short-term studies (i.e., up to 8 weeks) have not demonstrated serious adverse effects following the use of HMB. The incidence of side effects associated with HMB supplementation in clinical studies is low. In short-term studies, the administration of 3 g HMB daily for up to 8 weeks does not adversely affect surrogate markers of tissue health and function.[90] The long-term effects of HMB supplementation are unknown.

DIAGNOSTIC TESTING

Analytic Methods

Techniques to detect HMB include high performance liquid chromatography,[91] gas chromatography/mass

spectrometry,[92] and gas chromatography/ammonia chemical ionization/mass spectrometry of the trimethylsilyl derivatives of HMB.[93]

Biomarkers

Normal plasma concentrations of HMB range from about 1–4 μmol/L, but the HMB concentration increases up to 10-fold following leucine supplementation. The kidneys normally excrete small amounts of HMB. Increased urinary concentrations of HMB occur in rare inborn errors of leucine metabolism and in patients with ketoacidosis (e.g., diabetic ketoacidosis).[94,95]

Abnormalities

A study of elite rugby players did not demonstrate any clinical significant abnormalities of health indices in these well-trained athletes when comparing 6 weeks of HMB supplementation and 6 weeks of HMB plus creatine to baseline values.[96] Assessment methods included full blood count, plasma testosterone and cortisol, serum electrolytes, lipids, urea and glucose, sperm count and motility, and evaluation of psychological state. Analysis of clinical studies of HMB supplementation suggests a modest decrease in total cholesterol (about 5%) and LDL cholesterol (about 7%) during use.[90] Short-term supplementation with HMB does not alter the urinary testosterone/epitestosterone ratio. In a study of 6 healthy men, supplementation with 3 g HMB daily for 3 weeks did not cause significant changes in the testosterone/epitestosterone ratio.[97] The baseline ratio was 1.02 ± 0.68 compared with 0.92 ± 0.62 after 2 weeks of daily supplementation with HMB.

TREATMENT

There are few data on the treatment of toxicity associated with HMB use. Adverse effects associated with the use of HMB typically resolve with cessation of use and respond to supportive care.

OTHER SUPPLEMENTS

There are few medical data on the effect of dietary supplements on athletic performance. In a meta-analysis of dietary supplements, only 6 supplements had more than 2 studies that met the criteria for inclusion in the meta-analysis.[5] Most of these supplements (protein, chromium, dehydroepiandrosterone or DHEA, androstenedione) did not significantly increase lean mass or

improve strength. Although chromium has an essential role in maintaining carbohydrate and lipid metabolism (e.g., insulin signalling),[98] most studies on chromium do not demonstrate that chromium picolinate is an effective ergogenic aid including a lack of improvement in body composition,[99,100] lean muscle mass,[101] muscle strength,[102] and exercise capacity.[103] There are few adverse effects associated with the administration of chromium picolinate doses up to 1 mg daily in randomized clinical trials; the use of chromium picolinate at these doses does not alter glucose metabolism in healthy participants.[104,105] However, case reports associate excessive use of chromium picolinate with systemic contact dermatitis (several weeks of diet supplements containing chromium picolinate),[106] rhabdomyolysis (1.2 mg over 2 days for bodybuilding),[107] and hepatorenal dysfunction (1.2–2.4 mg daily for 4–5 months to enhance weight loss).[108] Other trace minerals (e.g., vanadyl sulfate) lack efficacy as ergogenic aids for improving body composition or athletic performance.[109]

The addition of sodium bicarbonate to the body buffers the acidosis associated with anaerobic glycolysis. Theoretically, sodium bicarbonate enhances performance when the exercise is sufficient to cause significant acidosis in the muscles along with adenine nucleotide loss. Although some studies suggest that the ingestion of sodium bicarbonate or citrate (300 mg/kg) up to 1–3 hours before short-term, high-intensity exercise improves performance (e.g., power output),[110,111] there is no clear or consistent pattern of improvement between studies.[112] Adverse GI effects (vomiting, diarrhea) and the need for large volumes to buffer the lactic acidosis limit the usefulness of this supplement for improving athletic performance.[113]

V Ethanol

Chapter 21

ETHANOL

HISTORY

Wine has been part of the human diet and culture for over 6,000 years. According to the Bible (Genesis Chapter IX, Verse 20), Noah established the first vineyard soon after the Ark rested safely on dry land. The oldest chemical evidence for the use of wine is the presence of the calcium salt of tartaric acid on a pottery jar recovered from a mud-brick building in Iran that dates back to 5,400–5,000 BC.[1] Large quantities of this chemical were present only in grapes and in terebinth tree resin used as a bacteriostatic agent for ancient wines. The domestication of the wine grape (*Vitis vinifera* L.) probably occurred in southern Caucasus, and winemaking spread southward to Palestine, Syria, Egypt, and Mesopotamia.[2] By the third millennium BC, wine was used for sacramental purposes in Egypt, but the consumption of wine by the Egyptian population did not occur for about 2,000 more years. The Old Testament contains many references to the physical, psychological, and social consequences of alcohol abuse including descriptions of Noah becoming intoxicated.[3]

IDENTIFYING CHARACTERISTSICS

Ethanol or ethyl alcohol is a relatively simple aliphatic alcohol (i.e., saturated hydroxylated carbon) with the structure of CH_3-CH_2-OH. Ethyl alcohol (C_2H_5OH, CAS RN 64-17-5) is a clear, colorless liquid with a sweet odor having a molecular weight of 46 g/mol and a boiling point of 78.5°C (173.3°F) at atmospheric pressure. The density of ethanol at room temperature (15°C/59°F) is 0.789;

therefore, a 10% v/v solution is equivalent to a 7.89% w/v solution. Ethanol is slightly less polar than water; consequently, ethanol easily crosses cell membranes and diffuses into tissues. The odor threshold of pure ethanol is about 80 ppm in air with the minimum identifiable odor threshold of about 350 ppm.[4]

EXPOSURE

Epidemiology

The medical consequences of acute and chronic ethanol consumption are a ubiquitous part of modern culture as a result of the relationship between ethanol intoxication and a variety of adverse health effects.[5] A study of European mortality rates suggests a positive association between the blood alcohol concentration (BAC) in drivers and fatal traffic accidents in central and southern Europe as well as between ethanol consumption, work-related accidents, and other nontraffic-related accidents in northern Europe.[6] Every year about 40,000 persons in the United States die as a result of motor vehicle collisions. Approximately 17% of the drivers involved in fatal crashes had a BAC exceeding 100 mg/dL, whereas about 6% of these drivers had a BAC between 10–99 mg/dL.[7] The relative risk of involvement in a car crash by a driver under the age of 21 with a positive BAC is greater than predicted from the additive risk of the BAC and age.[8] Overall, the percentage of alcohol-related fatal traffic accidents decreased from 57% in 1982 to 42% in 2000 as defined by anyone involved in the accident having a BAC exceeding 10 mg/dL. Hence,

an alcohol-related accident does not necessarily indicate a causal relationship between ethanol use and the accident. The French population has the highest per capita ethanol consumption in the world. The relative risk of total mortality adjusted for age, smoking habits, and body mass index for men consuming >5 alcohol drinks/day was 1.9 (95% CI: 1.1–3.5) compared with the control group (i.e., men consuming <2 alcohol drinks/day).[9] There was no significant increased risk of premature death in Frenchmen consuming <5 alcohol drinks/day when compared with the control group.

Alcohol dependence is one of the most common psychologic disorders in the United States, affecting about 20% of men and about 8% of women during some part of their lives.[10] In the United States, an estimated 620,000 emergency department visits occur yearly as a result alcohol abuse or dependence.[11] Overall, the mortality rate of chronic alcohol-dependent patients is at least several times higher than the general population.[12] The use of ethanol increases the risk of suicide both in alcohol-dependent and nondependent individuals, particularly with alcohol dependence and completed suicide.[13] The overall lifetime risk of suicide in alcohol-dependent patients is about 2–3%, and the likelihood of suicide is approximately 60–120 times higher in an alcohol-dependent patient than in a patient without psychiatrically definable illness.[14] Thus, alcohol abuse and dependence are contributing factors in about 25% of suicides. Furthermore, acute ethanol use is more common in emergency department patients attempting suicide than in control groups of emergency department patients presenting for illness or injuries (e.g., workplace accidents, domestic animal bites, recreational accidents) traditionally not associated with ethanol use.[15]

Sources

Commercial products containing ethyl alcohol include after-shaves lotions, beverages, colognes, medicinal liquids (antitussives, liniments, rubbing alcohol), mouthwashes, perfumes, and solvents.[16] The production of ethanol beverages involves fermentation when certain yeasts convert carbohydrates and water into ethanol and carbon dioxide. Different types of alcoholic beverages result from different types of fermenting ingredients. Fruits with high sugar contents (e.g., grapes, berries, apricots) are the fermenting ingredients for wine. The production of beer uses starch from cereal grains, whereas winemakers use sugar from grapes. When the ethanol concentration reaches 15% (v/v), most yeast die; therefore, the production of hard liquor (bourbon, gin, vodka, whiskey) requires a distillation process after the fermentation is completed.[17]

PRODUCTS

Ethylene from the cracking of petroleum hydrocarbons is the major source of ethanol for use in commercial products other than alcoholic beverages. The alcoholic beverage industry does not usually use synthetic ethanol for the production of alcoholic beverages as a result of the impurities present in the production of ethanol from ethylene. Commercial uses of ethanol include solvents for resins, fats and oils, synthesis of denatured alcohol, constituent of pharmaceuticals and cosmetics, chemical intermediate, and fuel additives. Ethanol is a constituent of many over-the-counter (OTC) medications and household products including hand sanitizers.[18]

BEVERAGES

Drinking patterns vary between countries as defined by a single beverage type accounting for >50% of the per capita alcohol consumption. Beer-drinking countries include New Zealand, Ireland, Australia, Scotland, England, Canada, Belgium, Denmark, and Czechoslovakia. Prominent wine-drinking countries are Bulgaria, Switzerland, Italy, Spain, France, Portugal, and Greece. Distilled spirits traditionally have been the major source of ethanol consumption in Norway, Sweden, Finland, Poland, Romania, Yugoslavia, and the United States.[19] Overall, the per capita (>15 years of age) alcohol consumption decreased in the United States from 2.76 gallons in 1981 to 2.21 gallons in 1994.[20] However, the decline did not affect ethnic groups equally with the decline being greater in the white population than in African Americans or Hispanics.[21] The natural fermentation of carbohydrates with yeast produces the ethanol present in alcoholic beverages with maximum concentrations of about 14–15%, whereas the production of ethanol concentrations exceeding 14–15% by volume requires distillation. This process involves the evaporation of ethanol from the solution by heating and then collecting the ethanol contained in the distillate by cooling the steam produced.

Alcoholic beverages contain volatile and nonvolatile flavor compounds. Volatile compounds include aliphatic carbonyl compounds, alcohols, monocarboxylic acids and related esters, heterocyclic and aromatic compounds, hydrocarbons, terpenic compounds, and nitrogen- and sulfur-based compounds.[22] The nonvolatile component of alcoholic beverages contains tannic and polyphenolic substances, inorganic salts, dibasic and tribasic carboxylic acids, and unfermented sugars. Most alcoholic beverages contain byproducts of the fermentation or distillation process called congeners (e.g., n-propyl, n-butyl, isoamyl alcohols). Collectively, these

congeners are called fusel oils. Additives and contaminants of alcoholic beverages that are present in minor amounts include sulfur dioxide, cadmium, nitrosamines, urethane, and mycotoxins (e.g., aflatoxins, ochratoxin A, zearalenone).[22] The concentration of ethanol in beverages is usually defined by ethanol volume in volume of solution (i.e., % v/v). Aqueous ethanol is approximately 21% lighter than water (i.e., specific gravity = 0.79) as defined in Equation 21.1. Therefore, an ethanol concentration defined by % v/v must be multiplied by 0.79 (i.e., reduced 21%) to determine an equivalent weight per volume (% w/v). Alternately, the proof of an ethanol concentration is divided by 2 and then multiplied by 0.79 to determine the % w/v.

$$\begin{aligned} \text{Ethanol (w/v)} &= \text{Ethanol (v/v)} \times (0.79) \\ &= \text{Ethanol (Proof/2)} \times (0.79) \end{aligned}$$

(Equation 21.1)

Although the amount of ethanol in a drink varies with glass size and configuration as well as ethanol content, standard US drink equivalents typically are defined as follows: 1) 12-oz beer, 5% v/v; 2) 5-oz glass of wine, 12% v/v; and 3) mixed or straight drink containing 1.5 oz, 40% ethanol (80 proof).[23] Consequently, the standard (US) drink contains about 14 g ethanol.

Beer.   Types of beers include lagers (European pilsner, Oktoberfest, bocks, Australian lagers, American lagers) and ales (amber ale, bitter, mild, pale ale, brown ale, hefeweizen, stout, porter, barley wine). The production of ales involves the action of top fermenting yeast on malted barley, hops, water and yeast at temperatures between 16–21°C (60.8–69.8°F). During the production of lagers, the bottom fermenting yeast produce beer by initial fermentation at 4–16°C (39.2–60.8°F) and then a secondary fermentation at temperatures <4°C (<39.2°F). The exception is steam beer, which is brewed at higher temperatures. Ice beers use the same fermentation process, but the chilling of the beer to near freezing temperatures and the removal of ice crystals produces higher ethanol content. American lagers are typically highly carbonated and are brewed with barley malt and rice, corn, or wheat. Light beers contain fewer calories and slightly lower (i.e., about 15% lower) ethanol content than standard lager beers. The production processes for regular and nonalcoholic beers are similar with the exception that vacuum evaporation at the end of the brewing process removes most of the ethanol in nonalcoholic beer. By legislation, nonalcoholic beers contain <0.5% v/v ethanol; therefore, consumption of unrealistically large quantities of light beer are neces-sary to produce intoxication from the ingestion of nonalcoholic beers. The major flavoring compounds in beer typically include carbonyl compounds (i.e., primarily acetaldehyde), aliphatic ketones (e.g., acetone), alcohols (e.g., glycerol), volatile acids (e.g., acetic acid), lactic acid, esters (e.g., ethyl acetate), amines, phenols (e.g., cresol, 4-vinylphenol), and aromatic acids (e.g., benzoic acid). Formaldehyde, methanol, and oxalic acid are minor constituents of beer.

The ethanol content of beer varies both by type and by brand with the average beer containing about 4–5% ethanol by volume. Analysis of about 50 North American and European beers demonstrate the following median ethanol content for specific types of beer: 1) low-alcohol, 2.3% v/v, 2) light beers, 4.2% v/v, 3) regular beers, 4.7% v/v, and 4) malt liquors/ales, 6.15% v/v.[24] In a study of 113 lagers, the median ethanol concentration was 5.00 % v/v (range, 4.02–15.66% v/v).[25] The median ethanol concentration of 256 ales was 5.25% v/v (range, 2.29–12.69% v/v). Table 21.1 lists the measured ethanol content of samples from American and other beers.[26]

Wine.   Wine contains over 500 compounds in addition to ethanol and water with about one-third of the compounds being esters.[2] The primary ingredients responsible for the taste of wine are aromatic compounds including fusel alcohols, volatile acids, and fatty acid esters. Acetal (1,1-diethoxyethane) is a major constituent of the volatile compounds in wine, whereas beer contains small amounts of this volatile acid.[22] Glycerol and 2,3-butanediol are the principal alcohols in wine. Acetic acid and acetaldehyde are the primary acidic and aldehyde components of the volatile portion of wine, respectively. The principal ester of aliphatic monocarboxylic acids is ethyl acetate with concentrations higher in red wine than in white wine. Phenolic compounds (flavonoids) including phenol and m-cresol are minor constituents of white wine, but these compounds contribute to the taste and quality of red wines. The ethanol content of wines varies from about 8–14% with an average ranging from approximately 10–13%, whereas the ethanol content of fortified wines is somewhat higher (about 15–25%). Japanese sake (rice wine) contains about 10–20% ethanol content with an average of approximately 15% depending on the variety.

Distilled Spirits.   The distillation process alters the concentration of volatile compounds by reducing the concentration of low-boiling and high-boiling compounds. Like wine, acetaldehyde is the major carbonyl compound in distilled spirits. Acrolein is the only unsaturated aldehyde found in unaged whisky distillates. Some spirits (e.g., vodka) contain few flavoring agents

*Approximate ethanol concentration. Actual ethanol concentration may change over time.

and these spirits consist principally of ethanol and water. In contrast, whisky, cognac, brandy, and rum usually contain many volatile flavoring compounds. Methanol is a minor constituent of commercial alcoholic beverages with the exception of some brandies produced from stone fruits (e.g., cherries, plums, apricot) that contain methanol concentrations ranging up to 10 g/L.[22] Small quantities of volatile compounds including acetone, isopropanol, acetaldehyde, *n*-propanol, ethanol, and methanol appear in the blood.[27] Acetic acid, and to a lesser extent decanoic acid, are the major constituents of the acid component in distilled beverages. Distilled spirits typically contain ethanol volumes of 40–50% (80–100 proof).

DOSE EFFECT

Acute

Although the reported lethal ethanol dose is 5–8 g/kg for adults and 3 g/kg for children, acute toxicity varies because of the occurrence of hypoglycemia, drug interactions, and tolerance. The American Academy of Pediatrics arbitrarily established a serum ethanol con-

centration of 25 mg/dL as the maximum safe concentration for a single dose of alcohol-containing medication,[16] but most central nervous system (CNS) effects (e.g., muscular incoordination, behavioral changes, reaction times) occur at serum ethanol concentrations above 100 mg/dL. For example, the ingestion of 40 mL of a 10% ethanol solution produces a serum ethanol concentration of approximately 25 mg/dL in an average-sized 6-year-old child. Chronic alcohol abusers develop a marked tolerance to ethanol, even at blood ethanol concentrations considered potentially fatal to nontolerant individuals (i.e., 500 mg/dL).[28] Ambient ethanol concentrations in air exceeding 20 mg/L are highly irritating with easily recognizable odors that limit exposure to ambient air concentrations of ethanol capable of producing CNS effects.[29]

Chronic

The Royal College of Physicians (UK) recommends a weekly limit of 21 units (168 g) of ethanol for men and 14 units (112 g) for women.[30] One unit equals 8 g ethanol according to the British system. A 360 mL-bottle of beer contains about 1.25 units (10 g), a 750 mL-bottle of wine contains about 7–10 units (55–80 g), and a bottle of hard liquor contains about 30 units (240 g). Consumption of >21 units ethanol weekly does not necessarily produce medical effects, but the ingestion >50 units weekly in men and >35 units in women significantly increases the risk of harm. Social drinkers typically drink <2–3 units of ethanol daily, and these individuals do not become intoxicated. Heavy drinkers regularly drink >6 units ethanol daily without obvious harm. Problem drinkers develop physical, social, family, financial, and occupational problems as a result of their drinking behavior, but evidence of ethanol dependence may be absent. Ethanol dependence occurs in individuals who compulsively drink daily, develop tolerance, and exhibit signs of withdrawal following the cessation of drinking. These individuals continue to drink despite clear evidence of harm.

TOXICOKINETICS

There is substantial variation in the absorption, distribution, and metabolism of ethanol as a result of genetic and environmental factors.[31] Absorption of ethanol following oral ethanol doses occurs primarily in the small intestine, where the rate of absorption depends on a variety of factors including stomach contents, rate of ingestion, composition of the food, rate of gastric emptying, and the timing of food consumption in relation to ethanol ingestion. Ethanol is a small, polar molecule that distributes evenly throughout the body depending on the water content of individual tissues; the volume of distribution is equivalent to total body water. Factors that affect total body water also affect the distribution of ethanol. Elimination of ethanol occurs almost exclusively by metabolism with only about 2–10% of the ethanol dose excreted in the breath, sweat, and urine. Because elimination depends on the hepatic oxidation of ethanol by enzymes (alcohol dehydrogenase, aldehyde dehydrogenase), elimination rates vary considerably depending on the allelic variants of the genes encoding these enzymes.

Absorption

The gastrointestinal (GI) tract is the major route of absorption with about 20% of the absorbed ethanol dose entering the systemic circulation by passive diffusion through the stomach and the remainder through the duodenum and other parts of the small intestine. The potential for ethanol toxicity via the pulmonary and dermal routes is limited by the high water solubility and low lipid solubility of ethanol. Experimental studies indicate that the estimated fraction of ethanol removed from ambient air containing 10–15 mg ethanol/L via inhalation is approximately 55–65%.[29,32] Because of the rapid rate of ethanol metabolism (~7–8 g/h) and the sensory irritation caused by high ambient air concentrations of ethanol, the pulmonary route of ethanol exposure usually produces very low blood ethanol concentrations.[29,33] The low oil-water partition coefficient of ethanol significantly limits the diffusion of ethanol through the keratin layer of intact skin; therefore, dermal absorption is not a significant route of exposure to ethanol.[34]

Physiology of Gastrointestinal Absorption

There is no active transport system for ethanol; consequently, the GI tract absorbs ethanol by passive diffusion along a concentration gradient according to Fick's law. A variety of physiologic factors affect the rate of ethanol absorption from the GI tract including the following: 1) the concentration of ethanol in contact with mucosal surfaces, 2) the time the ethanol remains in contact with the mucous membranes, 3) the amount of blood flow to the area of contact, and 4) the surface area available for ethanol absorption. The absorption of ethanol is slow from the stomach compared with the duodenum. During normal conditions, the stomach absorbs <10–20% of an ethanol dose with a majority of the ethanol passing into the intestines.[29] The small intestine extracts about 80% of an oral ethanol dose because of its large surface area and efficient exchange mechanisms provided by the microvilli. Although the colon is

capable of absorbing ethanol, little absorption occurs in the colon because of the small amount of ethanol remaining in the intestinal tract during transit through the colon.

First-Pass Metabolism

The ingestion of ethanol produces lower blood ethanol concentrations and smaller areas under the concentration-time curves compared with the intravenous (IV) infusion of an equivalent dose of ethanol. The difference between these 2 routes of exposure is the result of first-pass metabolism. Depending on hepatic blood flow, the blood ethanol concentration, and the absorption rate of ethanol, the average amount of ethanol removed during first-pass metabolism is approximately 20%.[35] At low doses (0.15 g/kg) of ethanol, first-pass metabolism occurs primarily in the liver with metabolism in the gastric mucosa accounting for about 2% of the ethanol dose.[36] Delayed gastric emptying increases the first-pass metabolism of ethanol in the stomach, whereas the slower absorption of ethanol into the small intestine enhances hepatic first-pass metabolism.[37] First-pass metabolism is greater in fed individuals with low ethanol doses, intact gastric mucosa, and after chronic ethanol consumption.[38] Fasting and gastrectomy significantly decrease the first-pass metabolism of ethanol. Furthermore, the extent of first-pass metabolism in women is variable and concentration-dependent. In a small study of 6 men and 6 women given a 60-minute IV infusion of 0.3 g ethanol/kg *and* an equimolar dose of deuterium-labeled ethanol/kg orally or intraduodenally, there was limited (i.e., <10%) first-pass metabolism and minor gender-related differences for dilute solutions of ethanol (i.e., 5%).[39] The ethanol content of this solution and beer is similar. However, the ingestion of drinks containing higher ethanol concentrations reduced first-pass metabolism more in women than in men. Baraona et al also demonstrated that first-pass metabolism of oral ethanol was significantly lower in women than in men (35.6±7.4 mg/kg and 72.9±8.9 mg/kg, respectively), when administered as a concentrated ethanol solution (i.e., 40%) similar to whisky.[40] There were no statistically significant gender differences in first-pass metabolism when ethanol was administered as a dilute ethanol solution (i.e., 5%). The smaller amount of first-pass metabolism in the stomach (i.e., reduced gastric alcohol dehydrogenase activity) increases the bioavailability of ethanol in women compared with men.[41]

Determinants of Absorption

Studies of ethanol kinetics in twins indicate that short-term environmental factors account for a large portion of the variance in ethanol kinetics, particularly during the absorptive phase.[42] The rate of increase in the blood ethanol concentration during the absorptive phase depends on the drinking pattern, the type of beverage (beer, wine, hard liquor), gastric contents (fasting vs. fed), type (liquid, solid) and composition (fat, carbohydrate, protein) of food, and changes in GI motility. Factors that delay and reduce peak ethanol concentrations relative to the fasting state include high volumes, high protein diet, trauma, gastric surgery, and reduced bowel motility. Such factors may delay absorption to such an extent that peak blood ethanol concentrations occur several hours after consumption. Additionally, there is substantial variation in peak BAC and the time to reach peak BAC between individuals and in the same individual at different times. In a study of healthy volunteers given low doses (0.3 g/kg) of ethanol, the coefficient of variation (i.e., standard deviation as a percentage of the mean) for intravolunteer and intervolunteer peak BAC during the fed state was 38% and 34%, respectively.[43] The corresponding values of the coefficient of variation for the time to peak BAC were 70% and 52%, respectively. Laboratory studies suggest that heavy smoking may reduce peak ethanol concentrations by delaying gastric emptying. In a study of 8 current cigarette smokers ingesting a 400 mL-radiolabeled nutrient test meal containing 0.5 g ethanol/kg, the mean peak ethanol concentration decreased approximately 20% when comparing smoking (4 cigarettes for first hour) with baseline (no smoking for 1 week).[44] The smoking cessation was associated with an average 50% decrease in gastric emptying.

Food. The presence of food in the stomach before or shortly after ethanol ingestion is the single most important determinate of ethanol absorption.[45] The ingestion of food with ethanol reduces and delays the peak ethanol concentration by prolonging the retention of ethanol in the stomach, where ethanol absorption is much slower than in the duodenum.[46] The consumption of ethanol with a meal reduced the mean blood ethanol concentration about 25–35% compared with the fasting state as well as delaying the mean time to reach the peak BAC by approximately 1.5–2 hours after drinking ceased.[47,48] In 1 study, the peak BAC was approximately 50% higher following a high fat diet than after a high protein diet.[48] High carbohydrate and high sucrose diets produced intermediate BAC. Consumption of food prolongs ethanol absorption past the peak BAC, which defines the time at which the rate of absorption equals the rate of distribution/elimination.[49] Eating during drinking may delay complete absorption for 4–6 hours.

BEVERAGE. Both the dose of ethanol and the type of beverage (e.g., ethanol concentration) impact the shape of the blood ethanol curve. There is substantial variation in blood ethanol concentrations between individuals drinking the same beverage as well as among individuals drinking the same amount of ethanol from different alcoholic beverages. In a study of 6 volunteers fasted at least 2 hours, the consumption of equivalent doses of ethanol as beer and wine produced mean peak blood ethanol concentrations about 20% below peak blood ethanol concentration from an equivalent amount of ethanol as hard liquor.[50] Alcoholic beverages are hyperosmolar; therefore, these beverages delay gastric emptying until the osmolarity of the gastric content approaches isotonicity. Consequently, the time to peak ethanol concentration for the same concentration of ethanol is longer for larger volumes compared with smaller volumes of ethanol. In a study of fasting, healthy adult men, the mean time to peak ethanol concentrations following the ingestion of 0.5 g/kg and 1.0 g/kg was 29.3 minutes (range, 9–114 minutes) and 52.0 minutes (range, 12–166 minutes).[51] In a study of 83 healthy, fasted volunteers given 0.68 g ethanol/kg as neat whiskey, 77% and 97% of the volunteers had peak blood ethanol concentration about 45 minutes and 75 minutes, respectively, after the end of a 30-minute drinking episode.[52] The peak ethanol concentrations ranged from 52–136 mg/dL. Maximum rates of ethanol absorption occurred following the ingestion of beverages containing 10–30% ethanol (v/v). The large volume associated with dilute ethanol solutions limits the contact of ethanol with the intestinal mucosa, and higher concentrations of ethanol probably delay gastric emptying by irritating the gastric mucosa.[53] The consumption of dilute beer (i.e., <1%) does not usually produce blood ethanol concentrations that cause impairment as a result of first-pass metabolism of dilute ethanol solutions and the very large volumes needed to reach high blood ethanol concentrations.[54]

In the fasted state, the ingestion of low doses of concentrated beverages (e.g., whiskey) produces equal or higher blood ethanol concentrations than more diluted ethanol beverages (e.g., beer), whereas the reverse occurs following the consumption of these beverages within 1 hour of a standard meal. In a study of 10 men given 0.3 g ethanol/kg as whiskey or beer 1 hour after a standard meal, the mean peak BAC was approximately 36% higher for the beer-drinking group compared with the whiskey-drinking group (i.e., approximately 31 mg/dL and 23 mg/dL, respectively).[55] The consumption of wine and sherry during the postprandial period yielded intermediate results between beer and whiskey when consumed 1 hour after a standard meal.[56] In a study of 11 fasted Mexican Americans and 11 fasted, non-Hispanic Caucasians, the ingestions of 450 mL of beer delayed gastric emptying more in the Mexican American group than in non-Hispanic Caucasians.[57] However, there was no statistically significant difference in the blood ethanol concentrations. Because of the wide variation of BAC between participants, the use of nomograms based on *mean* kinetic data, gender, and body weight may seriously underestimate or overestimate the BAC.[58]

RATE OF ABSORPTION

The rate of ethanol absorption in the GI tract is a first-order process that depends on the speed of gastric emptying.[59] Factors that delay gastric emptying decrease the rate of ethanol absorption. In healthy, fasting adults receiving single ethanol doses in pharmaceutic studies, about 80–90% of ethanol absorption occurs within 30–60 minutes. However, there is substantial variation between individual participants even when comparing fasting participants.[60] Consequently, accurately estimating the exact time of reaching the peak blood ethanol concentrations at the end of the absorptive phase is difficult because of wide interindividual and intraindividual variation in gastric emptying, portal blood flow, and intestinal transit time. In a study of 24 healthy volunteers administered ethanol in the fed and fasting state, the interindividual variability as measured by the coefficient of variation for the area under the concentration-time curve (AUC) of ethanol was 44% and 21%, respectively.[43] Intraindividual variability for the fed and fasted state as measured by the coefficient of variation for AUC of ethanol was 35% and 22%, respectively.

Ethanol consumption in social settings typically involves divided-dose drinking, and the blood ethanol concentrations during this type of drinking produces slower and stepwise increases in blood ethanol concentrations compared with the ingestion of a single bolus dose in experimental settings. In most social situations without substantial food consumption, the peak blood ethanol concentrations occur within approximately 1 hour after the cessation of drinking,[61] and volunteer studies suggest that the time to peak effect of ethanol occurs earlier than peak BAC. In a study of 40 fasted volunteers, the mean time to peak BAC was 24 minutes earlier than the self-reported peak ethanol effect as measured by a psychological scale on ethanol effects.[62] The menstrual cycle has a minor effect on ethanol pharmacokinetics, including variations in body composition and gastric emptying.[63]

Distribution

Because ethanol is highly water soluble, ethanol distributes into tissues based on the water content. The

ingestion of equivalent doses of ethanol produces higher ethanol concentrations in obese than in lean individuals of the same weight because adipose tissue contains only 10–30% water.[64] The administration of ethanol according to the total body water rather than body weight limits the effect of age and sex on peak blood ethanol concentrations. The highest initial concentrations of ethanol occur in tissues with a large ratio of blood flow to tissue mass (e.g., brain, lungs, kidney, liver). During the absorption and distribution phase, substantial differences (up to 50–100%) occur in ethanol concentrations between the arterial and venous blood.[65] During the absorption phase, the ethanol concentration typically is slightly higher (i.e., about 10–20 mg/dL) in the arterial blood than in venous blood, and the magnitude of the arteriovenous difference depends partly on the rate of ethanol absorption and muscular activity. Rapid absorption exaggerates the difference, whereas slow absorption minimizes the arteriovenous difference. During the postabsorptive phase, the venous BAC slightly exceeds (i.e., 2–10 mg/dL) arterial and capillary BAC, particularly following the ingestion of moderate doses of ethanol.[66] The ethanol concentration in capillary blood more closely resembles the ethanol concentration in arterial blood rather than venous blood.[67]

In a study of fasted volunteers ingesting 0.8 g ethanol/kg, the mean capillary BAC exceeds the venous BAC during the absorptive phase, but the capillary-venous difference decreased when ethanol absorption slowed during the later part of the absorptive phase.[68] The capillary-venous difference 30 minutes and 60 minutes after the start of drinking was 13.6 ± 7.8 mg/dL and 3.3 ± 6.9 mg/dL, respectively. Between 90–360 minutes after drinking started (i.e., postabsorptive phase), the venous BAC exceeded the capillary BAC by a mean of 5.8 ± 3.4 mg/dL. During the IV infusion of 0.4 g ethanol/kg to 13 healthy men over 30 minutes, arterial ethanol concentrations exceeded the venous ethanol concentration by about 10 mg/dL with mean values of 94.8 ± 2.06 mg/dL and 84.7 ± 1.54 mg/dL, respectively.[69] The blood ethanol concentrations decreased rapidly after the infusion ceased with a mean apparent distribution half-life of 7–8 minutes. The arteriovenous ethanol difference was small (1–2 mg/dL) by 5–10 minutes after the infusion stopped.

Volume of Distribution

Ethanol distributes into tissue in direct proportion to the water content, and thus the V_D of ethanol reflects total body water. The V_D of ethanol varies between individuals based on obesity, sex, and age.[70] Adipose tissue contains less water than lean body tissue, and therefore individuals with higher fat content contain relatively less total body water than lean individuals. For example, women have a slightly smaller V_D because they have less water and more fat than men with of an equivalent body weight. The consumption of 45 g of ethanol daily for 3 weeks increased the V_D in men from 0.73 to 0.88 L/kg, but this pattern of ethanol consumption did not affect the mean V_D (0.7 L/kg) in women.[71] In a study of 6 men and 4 women, the average V_D for the women and men was 0.63 (range, 0.54–0.71) and 0.69 (range, 0.63–0.76), respectively.[72] Consequently, women usually attain higher BAC compared with men given the same dose of ethanol and the same body weight, although the time to peak BAC is similar for both sexes.[73] Experimental studies indicate that the anthropometric equation for calculating total body water and the body mass index are more reliable methods for calculating peak BAC than body weight alone.[74,75] In a study of ethanol kinetics in men and women, the mean body water as a percentage of body weight was $65 \pm 2\%$ and $51 \pm 2\%$, respectively.[76] Higher peak BAC concentrations occur in the elderly compared with younger individuals given the same dose of ethanol because of the lower lean body mass and the decreased volume of distribution that accompanies the aging process.[77] The volume of distribution for ethanol is smaller if the concentration-time profile is based on the plasma or serum ethanol concentration rather than whole blood.[78]

Protein Binding

Ethanol does not bind to plasma proteins or tissue, and as a result, the volume of distribution correlates closely to the total amount of water in the body.[78] Ethanol also does not interfere with the binding of other compounds to plasma proteins.

Biotransformation

The main metabolic pathways for ethanol in humans involve alcohol dehydrogenase and the microsomal-ethanol oxidizing system. Although early studies suggested that ethanol oxidation occurs with catalase, the lack of hydrogen peroxide necessary for this reaction limits the use of this pathway for ethanol oxidation *in vivo*. The most important pathway in the biotransformation of ethanol is catalyzed by alcohol dehydrogenase. The end products of ethanol oxidation by this pathway are water and carbon dioxide. In the human brain and other tissues, fatty acid ethyl esters are nonoxidative metabolites of ethanol.[79]

ALCOHOL DEHYDROGENASE (ADH)

The main route of ethanol elimination is hepatic oxidation by alcohol dehydrogenase (ADH) with the cofactor nicotinamide adenine dinucleotide (NAD^+) acting as a hydrogen acceptor during the oxidation of ethanol to acetaldehyde. ADH resides in the cytosol (soluble cell fraction) of hepatocytes, and this pathway becomes saturated at relatively low concentrations of ethanol. There is significant polymorphism of ethanol-metabolizing enzymes including ADH, aldehyde dehydrogenase (ALDH), and CYP2E1. ADH is a dimeric molecule controlled by at least 7 human ADH genes and subunits as defined in Table 21.2. This variability produces gene products with different K_m values. For example, the K_m of ADH1 and ADH2 are 30 µM and 3 µM, respectively.[80] The Michaelis constant (K_m) is the concentration at which the rate of the enzyme reaction is half the enzyme's maximum rate (V_{max}); K_m is an approximation of the affinity of the enzyme for the substrate. Pyrazole, 4-methylpyrazole, other pyrazole derivatives, and monosubstituted formamide compounds inhibit ADH1 and ADH2 isoenzymes.[81,82] The latter selective inhibitors include N-benzylformamide (ADH1B*1), N-1-methylheptylformamide (ADH1C*2), and N-heptylformamide (ADH1B*1, ADH4). There are also several molecular forms of aldehyde dehydrogenase (ALDH) involved with the oxidation of acetaldehyde. ALDH1 is the cytosolic enzyme with limited catalytic efficiency that is distributed throughout the body including the brain. ALDH2 is the mitochondrial enzyme present in the liver and stomach. This enzyme possesses high catalytic efficiency (low K_m) for acetaldehyde oxidation, and ALDH2 is the primary enzyme responsible for the *in vivo* oxidation of acetaldehyde. Asian populations with a deficient ALDH2 phenotype demonstrate characteristic ethanol sensitivity reactions (elevated heart rate, intense facial flushing, erythema, diaphoresis) as a result of acetaldehyde accumulation.[83]

Conversion of ethanol to acetaldehyde by alcohol dehydrogenase involves the re-oxidation of NADH to NAD^+; this reaction is the rate-limiting step of ethanol metabolism. Both alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH) require NAD^+, which reduces the hepatic NAD/NADH ratio during ethanol oxidation. The shift in this redox state of the liver to a more reduced potential causes profound metabolic abnormalities in heavy drinkers and alcohol abusers. The final step of this pathway is conversion of acetate to acetyl CoA and then to CO_2 and H_2O via the Krebs cycle. Inhibitors of ALDH include prunetin (5,4′-dihydroxy-7-methoxyisoflavone, CAS RN: 552-59-0) and daidzin (CAS RN: 552-66-9). The latter compound is the major active principle in extracts of *radix puerariae*, a traditional Chinese medication that suppresses the ethanol intake of Syrian golden hamsters and selectively inhibits ALDH2.[84]

MICROSOMAL ETHANOL-OXIDIZING SYSTEM (MEOS)

The microsomal ethanol-oxidizing system (MEOS) is located in the smooth endoplasmic reticulum, and this pathway requires oxygen and reduced nicotinamide adenine dinucleotide phosphate (NADPH). The major cytochrome P450 enzyme involved in this reaction is CYP2E1, which has a K_m of 12–16 mM (55–75 mg/dL).[80] This microsomal enzyme is an important part of the metabolism of ethanol when large doses (>100 g daily) are ingested over long periods.[85] During the oxidation of ethanol via this inducible pathway, a significant loss of energy occurs along with an increased formation of acetaldehyde. Chronic ethanol consumption induces the

TABLE 21.2. Nomenclature for Alcohol Dehydrogenase Genes and Subunits.[31]

ADH Class	Nomenclature	Former Name	Subunit Name	Efficiency[†]
I	ADH1A	ADH1	α	Low
	ADH1B*1	ADH2*1	β_1	High
	ADH1B*2	ADH2*2	β_2	High
	ADH1B*3	ADH2*3	β_3	Low
	ADH1C*1	ADH3*1	γ_1	High
	ADH1C*2	ADH3*2	γ_2	High
II	ADH2	ADH4	π	Low
III	ADH3	ADH5	χ	Very Low
IV	ADH4	ADH7	σ	High
V	ADH5	ADH6	NA	NA

Abbreviation: NA = not applicable.
†Ethanol catalytic efficiency.

hepatic cytochrome CYP2E1 up to 4–10 times depending on the ethanol dose and duration of drinking.[86] Immunoblot analysis of human liver microsomes indicate that the CYP2E1 content is approximately 4-fold higher in currently-drinking alcohol abusers than in nondrinkers.[87] The induction of CYP2E1 occurs relatively quickly in moderate drinkers. In a volunteer study using the chlorzoxazone test to measure CYP2E1 induction during the daily ingestion of 40 g ethanol (i.e., about 3 standard drinks), CYP2E1 activity increased within 1 week and continued to increase over the 4-week study.[88] After cessation of drinking, CYP2E activity decreased within 3 days and returned to baseline value within approximately 1 week. MEOS includes other cytochrome P450 enzymes, primarily CYP1A2 ($K_m = 24$ mM) and CYP3A4.[89] The MEOS pathway becomes more important as the blood ethanol concentration rises[90] because the velocity constant (K_m) is 4–5 times higher for the MEOS than for alcohol dehydrogenase. Inhibitors of CYP2E1 include pyrazole compounds, diallyl sulfide, and chlormethiazole.

CATALASE

In the peroxisomes, catalase oxidizes ethanol in the presence of a hydrogen peroxide-generating system.[91] However, the peroxidase-catalase system is a minor pathway under physiologic conditions *in vivo* because of the lack of availability of hydrogen peroxide.[92]

Elimination

Metabolic pathways located primarily in the liver account for about 90–95% of the overall elimination of ethanol. Most of the remainder of an ethanol dose is excreted unchanged into the urine, breath, saliva, and sweat. The urinary excretion of unchanged ethanol is relatively small compared with biotransformation, and the portion of unchanged ethanol in the urine accounts for about 0.5–2.5% of the absorbed ethanol dose.[93] The kidney excretes a small fraction (i.e., 0.02%) of the ethanol dose as ethyl β-glucuronide as a result of the conjugation of ethanol with uridine 5′-diphospho-glucuronic acid in the presence of uridine 5′-diphospho-glucuronosyltransferase.[94] Formation of minor amounts of ethyl sulfate also occurs after ingestion of ethanol as a result of the activity of sulfotransferases. Substantial interindividual variations in the formation of these 2 compounds result from considerable polymorphisms in the genes coding uridine 5′-diphospho-glucuronosyl-transferases (UGT1A1, UGT2B7) and sulfotransfer-ases.[95] In a study of 13 healthy volunteers receiving moderate doses of ethanol (mean, 0.51 ± 0.17 g/kg), the mean times from ingestion to peak ethyl glucuronide

and ethyl sulfate concentrations in urine samples were 2.3 ± 0.9 hours and 1.2 ± 0.5 hours, respectively.[96] Eleven hours after the start of drinking, 11 of 13 volunteers still had detectable quantities of ethyl glucuronide (lower limit of quantitation [LLOQ], 0.45 µmol/L) in their urine compared with 2 of 13 volunteers for ethyl sulfate (LLOQ, 0.79 µmol/L).

WIDMARK EQUATION

In 1932, Widmark developed a mathematical equation for the elimination of ethanol from the bloodstream based on Lord Mellanby's observation that the rate of ethanol oxidation was constant during ethanol metabolism.[97] Figure 21.1 displays the graphical representation of the Widmark curve as defined by the Widmark equation. The basis of this equation is a 1-compartment model with zero-order kinetics characterized by a constant rate of ethanol elimination per unit time. Equation 21.2 describes the Widmark equation

$$A = pr(C_t + \beta_t) \qquad \text{(Equation 21.2)}$$

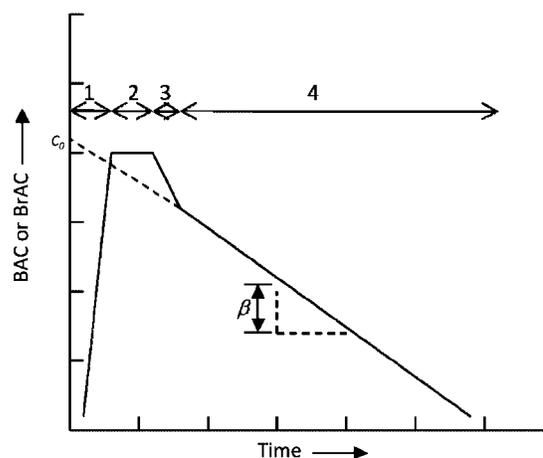
where A = absorbed dose of ethanol (g); p = body weight (kg); r = Widmark factor that represents the apparent volume of distribution as a fraction of body weight (kg/kg); C_t = concentration of ethanol in blood at time t (mg/g blood); β = slope of apparent linear decline of the concentration-time profile of ethanol [mg ethanol/(g blood × minutes)]; and t = time after oral dosing (minutes).


FIGURE 21.1. Theoretical blood ethanol curve based on Widmark equation. BAC = blood ethanol concentrations; BrAC = breath ethanol concentration; 1 = absorption phase; 2 = plateau; 3 = diffusion-equilibration; 4 = elimination (post-absorptive) phase with slope of β.

Widmark calculated the β value from the relatively linear slope of the blood ethanol decay curve between the end of the absorption/distribution phase and the curvilinear portion near the end of the blood ethanol curve. The factor β is the rate of decline of blood ethanol concentration during the postabsorptive phase of the blood ethanol curve that occurs about 1–3 hours after ingestion. The average value for β was 16 mg/dL/h with considerable variation between individuals and a slightly increased slope for women.[98] Widmark defined the *r* value as the ratio of total body ethanol and the blood ethanol concentration. Because of the close relationship between ethanol concentration and the water content in tissues throughout the body, the Widmark factor *r* corresponds to the ratio of total body water and the water content of blood. To calculate the extrapolated, theoretical maximum concentration of alcohol in blood C_0. Equation 21.3 is rearranged as follows:

$$C_0 = \text{Absorbed dose of ethanol (g)}/$$
$$\text{reduced body mass (kg)}$$
$$= A/(p \times r)$$

$$\text{(Equation 21.3)}$$

This equation assumes instantaneous and complete absorption (e.g., during rapid infusion) and distribution without elimination.[99] The use of this equation often overestimates the maximum blood ethanol concentration because of the reduction in bioavailability of ethanol after ingestion by several factors (e.g., ingestion of food, low ethanol-containing beverages). In addition, the use of the traditional average *r* values of 0.7 for men and 0.6 for women tends to overestimate C_0 if calculated according to Equation 21.3. In German-speaking countries, a 10–30% minimum resorption deficit is used to adjust C_0 for this apparent loss of ethanol.[100] The use of total body water calculations improves the accuracy of the Widmark equation when applied to a specific individual because the blood water content is relatively constant except in certain conditions (e.g., anemia, polycythemia, pregnancy).

To calculate the *r* value, Widmark estimated the blood ethanol concentration at time zero (C_0) by using the β slope to draw a straight line through C_t to give C_0, the intercept on the y-axis at time zero. Equation 21.4 defines the calculation of the distribution volume of ethanol corresponding to the Widmark *r* factor.

$$r = A/pC_0 \qquad \text{(Equation 21.4)}$$

The Widmark (distribution) factor was a dimensionless ratio used to correct the body weight for total body water based on drinking experiments with 20 fasting male and 10 fasting female volunteers, who ingested cognac brady over a short drinking time.[97] There was considerable variation in the *r* factor between individuals with a mean value of 0.68 (range, 0.51–0.85) and 0.55 (range, 0.47–0.64) for men and women, respectively. In an experimental study using direct measurements of total body water, the mean distribution factor *r* was 0.75 ± 0.05 (range, 0.60–0.82) for men and 0.66 ± 0.05 (range, 0.52–0.72) for women.[101] These fasting participants did not consume food for at least 2 hours prior to the consumption of beer or wine over a 2.5-hour drinking period. The uncertainty in the calculation of total body water is about ±10–20%, when using a V_D of 0.7 and 0.6 for men and women, respectively. Equation 21.5 estimates the blood ethanol concentration at time *t* during the postabsorptive phase, assuming complete absorption and distribution of the ethanol dose,

$$C_t = C_0 - \beta_t \qquad \text{(Equation 21.5)}$$

where C_0 = extrapolated, theoretical maximum blood ethanol concentration at the start of drinking, Ct = blood ethanol concentration at time *t* during the postabsorptive phase, β = elimination rate, and *t* = time during postabsorptive phase.

POSTABSORPTIVE ELIMINATION

MODEL. The hepatic elimination of ethanol from the body occurs primarily by capacity-limited (i.e., concentration independent) metabolic processes except at very low or very high concentrations in blood where the elimination rate is more concentration-dependent.[102] A zero-order elimination operates during a large portion of the blood-concentration time profile as a result of the saturation of ADH after the absorption of a few drinks. Overall, elimination of ethanol resembles a 1-compartment; the Michaelis-Menten kinetic model describes the concentration-dependent kinetics at very high and very low ethanol concentrations in blood, whereas concentration-independent (zero-order) kinetics best describe the BAC over the middle of the blood ethanol curve. Suggested values for the Michaelis-Menten parameters include an average K_m (Michaelis constant) of 9–11 mg/dL and a V_m (maximal ethanol rate velocity) of 22 mg/dL serum water/hour at ethanol levels <300 mg/dL.[103] Equation 21.6 defines Michaelis-Menten kinetics where C equals the concentration of blood ethanol.

$$-dC/dt = V_m C/(K_m + C) \qquad \text{(Equation 21.6)}$$

Consequently, when the blood ethanol concentration is large compared with K_m (11 mg/dL), the rate of ethanol

elimination is equal to V_m. During the postabsorptive phase of the BAC curve, ethanol elimination resembles zero-order kinetics; however, the elimination rate is not entirely linear, particularly during the immediate postabsorptive phase.[104] Assuming K_m = 9.5 mg/dL and V_m = 22.8 mg/kL/h, the estimated ethanol elimination rate at BAC of 50 mg/dL and 300 mg/dL is about 19.1 mg/dL/h and 22.1 mg/dL/h, respectively. The estimated ethanol elimination rate is substantially less at lower BAC (e.g., 11.7 mg/dL/h at BAC = 10 mg/dL). Alternate routes of elimination of ethanol (e.g., breath, urine) contribute relatively more to overall ethanol elimination when the BAC is very high (>300 mg/dL).

RATE.   Ethanol elimination occurs almost exclusively by hepatic metabolism with unchanged parent drug excreted in the urine, breath, and sweat accounting for about 1–10% of the ethanol dose.[35,77,105] The rate-limiting step during ethanol oxidation is the conversion of ethanol to acetaldehyde by alcohol dehydrogenase in the cytosol. There is substantial polymorphism of this enzyme, leading to racial and ethnic variations in ethanol pharmacokinetics. Although individual variation has the greatest impact on ethanol elimination rate, other factors (chronic ethanol consumption,[106] initial ethanol concentration and point on blood-alcohol curve,[107] gender, day-to-day variation[108]) also alter the rate of ethanol disappearance from the blood.[17,69] The ingestion of ethanol immediately after a meal increases the mean ethanol elimination rate slightly, but the rate of increase is somewhat variable. Volunteer studies using oral doses of ethanol suggest that the effect of food on the ethanol elimination rate is small (1–3 mg/dL/h), but these oral studies do not separate the effect of food on absorption and elimination.[80] The increase in the ethanol elimination rate following food consumption is slightly greater (i.e., up to about 1–4 mg/dL/h) in breath alcohol clamping studies than in oral studies.[109] Age alone does not alter the elimination rate of ethanol significantly.[77] Neither does the administration of IV fluids increase the rate of ethanol elimination. A study of 10 volunteers administered 0.81 g ethanol/kg did not detect a statistically significant difference in elimination rates with and without the rapid infusion of 1 L normal saline (0.9% NaCL).[110] During experimental studies producing peak BAC of 120 mg/dL in blood, the rate of ethanol clearance rate was approximately 10% faster in plasma compared with whole blood.[111] The blood flow to the liver represents about 20–25% of the cardiac output, and factors (e.g., trauma) that reduce hepatic blood flow can theoretically reduce the clearance rate of ethanol from the bloodstream.

Dose Response.   There are limited data on the dose-response curve for ethanol metabolism following large doses of ethanol. However, the ethanol elimination rate usually increases when the blood ethanol concentration exceeds 200–300 mg/dL. In a study of 14 nonrandomly selected alcoholic patients presenting with ethanol intoxication (C_{max} = 336 ± 114 mg/dL), the mean elimination rate was 21.9 ± 7.2 mg/dL/h with a range of 6–36 mg/dL/h.[112] The chronic ethanol use by these patients was not reported; therefore, this elimination rate may not reflect the ethanol elimination rate for nontolerant individuals. Two days later, these 14 patients ingested a test dose of 0.5 g ethanol/kg that produced a C_{max} = 42 ± 11 mg/dL. The mean elimination rate was 33% lower (14.6 ± 4.8 mg/dL/h) than the ethanol elimination rate during the acute intoxication phase. The mean serum elimination rate of 103 patients presenting to the emergency department with acute ethanol intoxication (mean serum ethanol concentration, 299 mg/dL) was 20.43 ± 6.86 mg/dL/h with a range of approximately 10–34 mg/dL/h.[113] Similarly, the chronic ethanol use of these patients was not reported. Case reports document an ethanol half-life of approximately 4 hours at blood ethanol concentrations exceeding 700 mg/dL, which suggest first-order kinetics at such high blood concentrations.[114,115] The BAC declines at a near-constant rate near the lower end of the blood ethanol curve until the BAC reaches about 3 mM (10–15 mg/dL); thereafter, first-order kinetics is a better description of the concentration-time profile.[116]

General Population.   The average rate of ethanol elimination following ingestion of typical doses of ethanol by moderate drinkers is approximately 15–16 mg/dL/h with a range of 8–25 mg/dL/h.[117,118] Blood ethanol concentrations decrease more rapidly (e.g., 23–43 mg/dL/h) at concentrations above 200–300 mg/dL compared with the elimination rate at blood concentrations below this concentration, perhaps because of induction of the microsomal ethanol-oxidizing system.[119,120] Children have higher metabolic rates than adults as a result of larger liver weight/kg body weight and potentially faster rates of ethanol elimination. Although there is a lack of controlled clinical trials in children for ethical reasons, case series document ethanol elimination rates during ethanol intoxication ranging up to 28 mg/dL/h.[121] Several studies suggest that the ethanol elimination rate is slightly faster in women compared with men. In studies involving apprehended drunken drivers and volunteers, the mean ethanol elimination rate in women averaged about 12–18% higher than the elimination rate in men for BAC in the range of 100–200 mg/dL.[122,123] Experimental studies indicate that the time during the

menstrual cycle does not affect the ethanol elimination rate in women.[124]

Chronic Heavy Ethanol Use. Chronic ethanol consumption generally increases the elimination rate of ethanol from blood compared with the general population, primarily as a result of the induction of CYP2E1 from the microsomal ethanol oxidizing system. The change in ethanol elimination rate for alcohol abusers typically involves an increase of <60–100%, but the increase is variable from individual to individual with the ethanol elimination rate exceeding 30–40 mg/dL/h in a few individuals. In a series of 81 chronic alcohol abusers arrested while driving with a BAC >400 mg/dL, the mean clearance rate of ethanol from whole blood was 23 ± 0.01 mg/dL/h with a range of 13–61 mg/dL/h.[125] Three consecutive hourly blood samples were drawn from a convenience sample of 21 drivers arrested with very high blood ethanol concentrations (mean, 405 mg/dL; range, 271–518 mg/dL).[126] The mean blood ethanol elimination rate for this group was 33 mg/dL/h (range, 20–62 mg/dL/h). The mean ethanol elimination rate was about 23 mg/dL/h (range, approximately 20–29 mg/dL/h) in a case series of 8 alcohol abusers with serum ethanol concentrations ranging from 200–400 mg/dL.[85] In the detoxification ward, the ethanol elimination rate was remeasured at serum ethanol concentrations of approximately 50 mg/dL. At this concentration, the mean elimination rate decreased on average by 49% to give a mean of 16 mg/dL/h. Substantial increases in the ethanol elimination rate occur following chronic ethanol use over more than several weeks. After the administration of 45 g ethanol daily for 3 weeks to volunteers without a history of alcohol abuse, the plasma ethanol elimination rate did not change significantly compared with control values before the beginning of the study.[71]

Maternal and Fetal Kinetics

Because ethanol distributes into total body water, ethanol diffuses into the placenta and breast milk.[127] The average water content of breast milk and blood are 87.5% and 85%, respectively. Although ethanol rapidly distributes into breast milk, the concentration in breast milk is close to the mother's BAC; further dilution into the total body water of the neonate results in relative low ethanol concentrations compared with the mother. The concentration of ethanol in a breastfeeding child depends on the mother's BAC, the volume of breast milk consumed, and the drinking time. Only a small fraction of the maternal blood ethanol concentration can be measured in the blood of the neonate; however, the rate of ethanol elimination in the neonate is sub-

stantially less than later in life.[128] Nomograms are available to determine the time between consumption of alcohol and nondetectable ethanol concentrations in breast milk.[129] The risks associated with drinking ethanol while breastfeeding are not well defined. Potential adverse effects include altered sleep patterns, decreased milk intake, hypoglycemia, and slowed motor development. Limited clinical data are conflicting with some studies demonstrating impaired motor development in 1-year-old infants breastfeed by drinking, lactating mothers,[130] while other studies of 18-month infants failed to duplicate these findings.[131]

Tolerance

ACUTE

Acute (within-session) tolerance refers to the greater effect of a specific blood ethanol concentration on the ascending portion of the blood ethanol curve compared with the effect of the same ethanol concentration on the descending portion of the curve. Mellanby first described acute tolerance in 1919,[132] and the Mellanby effect is associated with the phenomena of acute tolerance. Acute tolerance is a complex phenomenon that depends on a variety of factors including the dose of ethanol, speed of drinking, rate of absorption, and prior experience with ethanol as well as the measure of outcome.[133] The presence of chronic tolerance interferes with the expression of acute alcohol tolerance. Generally, the occurrence of acute tolerance is greater in light drinkers than in moderate or heavy drinkers,[134] especially for more complex cognitive tasks (e.g., learning, recall, coding) rather than simpler motor performance (e.g., pursuit rotor).[135] Although the results of human studies on acute tolerance are inconsistent,[136,137,138] impairment of information processing tasks displays less variation between the ascending and descending BAC curve than pure motor skills (e.g., pursuit rotor task), when tested at moderate BAC (≤100 mg/dL).[139] In a study of social drinkers, peak self-reported intoxication levels were significantly lower and occurred earlier for heavy drinkers than for light or moderate social drinkers.[140] Self-reported responses to questions using the alcohol scale of the Addiction Research Centre Inventory were less on the descending limb than on the ascending limb of the blood-alcohol curve for all types of social drinkers.

CHRONIC

Chronic (between-session) tolerance refers to the reduced effect of a specific blood ethanol concentration following repeated use compared with the effect of the

same concentration in alcohol-naive individuals. Chronic tolerance involves both metabolic (pharmacokinetic) and functional (pharmacodynamic) processes. Functional tolerance implies resistance to ethanol effects at the cellular level, whereas metabolic tolerance refers to changes in duration of ethanol effects that result from alterations of absorption, distribution, and elimination.[141] Functional tolerance to the CNS effects of ethanol may occur without proportional increases in the elimination rate of ethanol from the body.[142] The clinical effects of high BAC may not be obvious in patients, who chronically consume large amounts of ethanol. In a study of alcohol abusers presenting voluntarily to a detoxification center, 24% of the patients with serum ethanol concentrations exceeding 200 mg/dL did not demonstrate clinical signs of ethanol intoxication.[28] Although all patients with serum ethanol concentrations exceeding 350 mg/dL demonstrated some signs of ethanol intoxication, some of these individuals also had normal speech, stable gait, or adequate verbal comprehension. The development of chronic tolerance is dose-dependent with high ethanol doses producing more rapid appearance of chronic tolerance.[143] The dose-response curve for the development of functional tolerance to the effects of ethanol is not well defined. Experimental studies suggest that small changes in the performance of psychomotor tasks begin about 1 week after chronic administration of ethanol, depending on the ethanol dose.[144] Following heavy continuous ethanol use, experimental studies of alcohol abusers with a history of withdrawal suggest that impairment of some psychomotor skills in this group begins at higher BAC compared with the general population.[145]

Drug Interactions

The effect of chronic ethanol consumption is difficult to predict because of the multitude of pharmacokinetic and pharmacodynamic effects of ethanol use. Prolonged ethanol intake induces CYP2E1, whereas acute ethanol use inhibits the metabolism of drugs (warfarin, barbiturates, phenytoin, rifampin) that require the CYP2E1 isoenzyme.[146] Although chronic ethanol consumption decreases the metabolism of carbamazepine, fewer side effects occur because of the increased tolerance to the CNS side effects of carbamazepine.[147] There is no clear evidence that OTC medication (e.g., H$_2$-receptor antagonists, acetaminophen, aspirin) alter ethanol metabolism or cause higher ethanol-blood concentrations.[148]

Disulfiram-like Reactions

Disulfiram blocks the metabolism of acetaldehyde to acetate, leading to an accumulation of acetaldehyde in the blood and adverse effects (e.g., nausea, vomiting). Case reports suggest that certain other drugs produce a disulfiram-like reaction, possibly by inhibiting the enzyme aldehyde dehydrogenase. These include metronidazole, sulfonamides, cefamandole, cefoperazone, griseofulvin, hypoglycemic agents, the mushroom *Coprinus atramentarius* (Bull.) Fr., and some industrial chemicals (amides, oximes, carbamates, dithiocarbamate compounds, thiram derivatives).[149,150]

Gastric Motility and ADH Secretion

The daily administration of 1,200 mg cimetidine and 300 mg ranitidine did not alter the ethanol elimination rate in volunteers given 45 g ethanol daily for 3 weeks.[71] Many drugs that decrease hydrochloric acid and pepsin secretion (e.g., cimetidine, cisapride, erythromycin) accentuate the delay in gastric emptying produced by food, but the overall effect of BAC depends on the individual drug.[151] For example, ranitidine affects intrinsic cholinergic mechanisms in addition to H$_2$-blocking effects; therefore, the overall effect of ranitidine on BAC is minor. Consequently, the weight of the evidence suggests that the interaction of H$_2$-blocking agents with ethanol is unlikely to affect BAC at concentrations associated with impairment of psychomotor skills.[152] Proton pump inhibitors (e.g., omeprazole) probably do not have an effect on ethanol pharmacokinetics.[153] In a study of 12 healthy men ingesting 0.80 g ethanol/kg body weight on an empty stomach, pretreatment for 7 days with ranitidine, cimetidine, or omeprazole did not alter the pharmacokinetics of ethanol compared with controls.[154]

Pharmacodynamic Effects

Common direct interactions involve sedation following the concomitant ingestion of CNS depressants and ethanol. The pharmacokinetic interaction between acute ethanol ingestion and single doses of benzodiazepines are complex, depending on the dose, timing of ingestion, and chronic use of ethanol and/or other drugs. Most fatalities resulting from the ingestion of ethanol and benzodiazepines involve triazolam.[155] Impairment of psychomotor performance may occur following the ingestion of ethanol with older, sedating antihistamines, tricyclic antidepressants, and benzodiazepines.[152] The specific interaction varies depending on the pharmacodynamic properties of the particular drug involved.

Caffeine

The interaction of caffeine and ethanol is complex, and this interaction depends on a number of variables

including type of task, BAC, portion of the BAC curve, the dose of caffeine, and the timing of the ingestion of these 2 compounds.[156,157] Although caffeine increases alertness and reduces reaction time when ingested alone, the ingestion of caffeine and ethanol does not completely antagonize impairment of psychomotor skills, even at low BAC.[158] In a study of 15 healthy, young adults, the mean brake latency during testing in a driving simulator for the ethanol limb (75–85 mg/dL) and the caffeine (400 mg) and ethanol limb increased 17% and 11% compared with controls (no drugs).[159] Additionally, caffeine does not reverse the subjective effects of ethanol.[160] Most of these studies do not simulate the situation where an intoxicated individual drinks coffee and then drives shortly thereafter. However, existing data suggest that the ingestion of caffeine will not ameliorate ethanol-induced impairment of driving skills.[161]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

There are no specific ethanol receptors in the CNS. However, ethanol affects endogenous opiates and several CNS receptors including γ-aminobutyric acid (GABA), dopamine, and glutamate.[162] Ethanol alters the function of several ligand-activated ion channels including N-methyl-D-aspartate (NMDA), serotonin (5-HT$_3$), glycine, and γ-aminobutyric acid type A (GABA$_A$) receptors.[163] Ethanol activates the inhibitory chloride influx mediated by the GABA$_A$ receptors; this property contributes to the anxiolytic and sedative properties as well as to the impairment of coordination associated with ethanol use. *In vitro* studies indicate that action of ethanol on GABA$_A$ receptors is more complex than benzodiazepines with individual receptor subtype sensitivity to ethanol varying substantially between different neurons in the brain (e.g., in hippocampus); these studies suggest that modulation of the GABA$_A$ receptors does not account for all of the effect of ethanol on the brain.[164] Furthermore, ethanol increases GABAergic neurotransmission through indirect effects including the presynaptic release of GABA, elevation of endogenous GABAergic neuroactive steroids, and dephosphorylation of GABA$_A$ receptors promoting increases in GABA sensitivity.[165] Ethanol inhibits the function of the excitatory NMDA type of glutamate receptor as well as interacting with serotonin and dopamine receptors to increase dopamine in the reward centers of the brain.

Mechanism of Toxicity

ACUTE

Ethanol is a CNS depressant that selectively depresses the reticular activating system. The mechanism of action probably involves interference with ion transport (i.e., sodium flux) at the cell membrane rather than at synapses, similar to the action of general anesthetic agents. The frontal lobes are sensitive to low ethanol concentrations, resulting in alteration of thought and mood before changes in vision (occipital lobe) and coordination (cerebellum). Preferential suppression of inhibitory (GABA) neurons probably causes the excitation seen at low ethanol concentrations. Ethanol is a vasodilator that produces decreased preload, afterload, and systemic vascular resistance in healthy adults after acute ingestion.[166] Chronic ethanol consumption is associated with dilated cardiomyopathy (alcoholic cardiomyopathy) characterized by cardiomegaly, reduced myocardial contractility, myocardial fibrosis, and disruption in the myofibrillary architecture. Potential toxins (ethanol, acetaldehyde) may directly contribute to this cardiomyopathy by enhancing catecholamine concentrations and reactive oxygen species; however, other potential mechanisms (oxidative stress, protein-acetaldehyde adduct formation, accumulation of fatty acid ethyl esters, modification of lipoprotein and apolipoprotein particles) may also contribute to the development of alcohol cardiomyopathy.[167]

CHRONIC

Chronic alcohol abuse produces profound metabolic changes as a result of alterations in the cellular redox state resulting from a decreased NAD+/NADH ratio. These changes include 1) shift from pyruvate to lactate that results in lactic acidosis, 2) elevation of serum uric acid from reduced clearance, 3) alteration of lipid metabolism with accumulation of hepatic triglycerides, 4) reduced gluconeogenesis, 5) depressed protein synthesis, and 6) reduced active bone resorption and formation resulting from inhibition of bone remodeling by a mechanism independent of calciotropic hormones.[168]

ADDICTION.   Although the specific gene associated with alcohol dependence has not been identified, epidemiologic studies on alcohol dependence (twin, adoption) suggest that genetic factors account for up to about one-half of the risk of alcohol dependence.[169] First-degree relatives of alcohol abusers have an approximate 3- to 4-fold increased risk of alcohol dependence and the risk of alcohol dependence increases another 2-fold for identical twins.[170] Alcohol sensitivity is related to

pharmacogenetic variation in the ability to rapidly remove acetaldehyde during ethanol metabolism through the enzymatic action of aldehyde hydrogenase, primarily ALDH2. Individuals with the biologic inactive form of ALDH2 (ALDH2*2) develop increased heart rate, facial flushing, and nausea after ethanol ingestion as a result of the decreased ability to reduce aldehyde concentrations. Less than 10% of Japanese alcohol abusers are heterozygotes for the inactive form of aldehyde hydrogenase (ALDH2*2), whereas the prevalence of ALDH2*2 heterozygotes in the general Japanese population is approximately 40%.[171]

WITHDRAWAL.   Although the exact mechanism of withdrawal remains poorly defined, tolerant patients develop a compensatory physiologic state that opposes the depressant actions of ethanol. The withdrawal of ethanol leads to unopposed compensatory mechanisms, which are clinically manifested as autonomic hyperexcitability. The chronic ingestion of ethanol inhibits NMDA receptors leading to upregulation, reduces excitatory glutamatergic transmission, and excites GABA$_A$ receptors resulting in downregulation.[172] During abstinence from prolonged ethanol use, enhancement of NMDA receptor function, reduced transmission at GABA receptors, and dysregulation of the dopaminergic system contribute to the clinical features of ethanol withdrawal.[173] Although hypomagnesemia and hypokalemia may also contribute to clinical effects, changes of electrolyte concentrations in plasma or in cerebrospinal fluid do not cause delirium tremens (DTs).[174] Proposed compensatory mechanisms accounting for the hyperadrenergic state include a decreased affinity for the inhibitory transmitter (GABA), false transmitter formation, decreased prostaglandin E synthesis, and increased Na/K-ATPase activity. Ethanol itself does not exhibit proconvulsant properties. Etiologies of seizures during alcohol withdrawal include cerebral trauma (subdural or epidural hematoma), alcohol-related metabolic brain disorder, intracranial hemorrhage or infarct, CNS infection, and precipitation of idiopathic or posttraumatic epilepsy as well as alcoholic withdrawal seizures. Alterations in the number and function of NMDA (e.g., NR1, NR2B subtypes) and GABA$_A$ receptors probably contribute to the occurrence of seizures during ethanol withdrawal.

WERNICKE ENCEPHALOPATHY AND KORSAKOFF PSYCHOSIS.
Wernicke encephalopathy is an acute neuropsychiatric condition that results from biochemical changes secondary to inadequate stores of intracellular thiamine (vitamin B$_1$). The body stores little thiamine; depletion occurs within 2–3 weeks of reduced thiamine intake. These changes involve impairment of carbohydrate metabolism and nerve cell conduction resulting from inadequate amounts of the active form of thiamine (diphosphate ester of thiamine); initially these changes are reversible. However, the continuing lack of adequate thiamine stores produces the chronic form of the disease (Korsakoff psychosis), which is characterized by loss of short-term memory and difficulty processing new information. The Wernicke-Korsakoff syndrome refers to these 2 entities. Thiamine deficiency disrupts several thiamine-dependent enzyme complexes [i.e., pyruvate dehydrogenase complex, transketolase (pentose phosphate pathway), 2-oxoglutarate or α-ketoglutarate dehydrogenase (Krebs cycle)] resulting in damage to the myelin sheaths, inhibition of glucose and lipid metabolism, decreased branched chain amino acid production, and increased lactic acid production (See Figure 21.2).[175] Thiamine deficiency leads to decreased concentrations of the coenzyme thiamine pyrophosphate, causing alterations in the metabolism and the membrane structure of the nervous system. Ethanol interferes with active GI transport of thiamine and chronic liver disease reduces thiamine activation and storage.[176] Symmetrical pathologic changes occur in anterior cerebellum (vermis), periaqueductal region, floor of the fourth ventricle, mammillary bodies, and the paraventricular portions of the anterior medial nuclei, thalamus, and medial dorsal nuclei.[177] Patients with acute Wernicke encephalopathy have edema in these areas on T2-weighted late-echo sequences during magnetic resonance imaging (MRI),[178] whereas MRI studies demonstrate atrophy of the mammillary bodies and thalamus on sagittal cuts in patients with Korsakoff syndrome as a result of the loss of surrounding gray matter nuclei.[179] Modest volume deficits also occur in the medial septum/diagonal band of Broca as well as in the cerebellar hemisphere, anterior superior vermis, and pons. The lack of the Wernicke-Korsakoff syndrome in most thiamine-deficient alcohol abusers suggests genetic susceptibility to the development of this syndrome.

MARCHIAFAVA-BIGNAMI DISEASE.   This rare disease results from the necrosis and demyelination of the corpus callosum, particularly the medial zone.[180] Patients are usually middle-age male alcohol abusers with poor nutrition and heavy consumption of ethanol over 10–20 years.[181] The course of the illness may be acute or chronic with signs of severe global dementia, seizures, alteration of conscious progressing to coma and death. MRI studies demonstrate T1 hypointensities and T2 hyperintensities in the corpus callosum, centrum semiovale, and other periventricular white matter.[179]

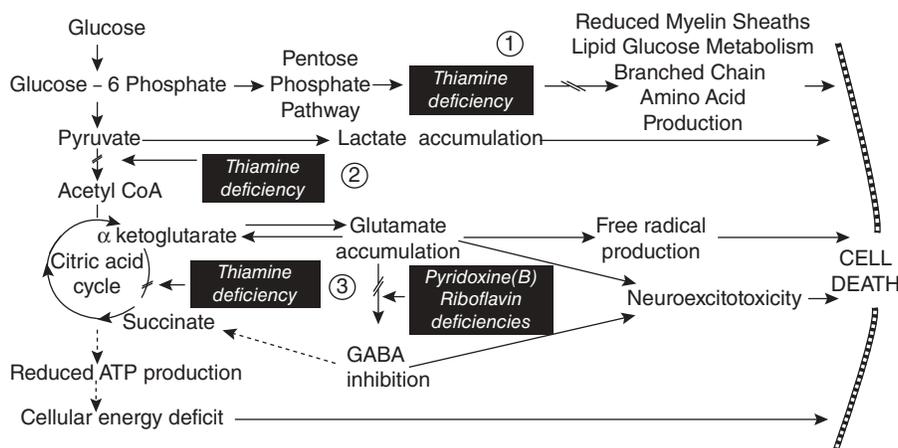
POLYNEUROPATHY.   A polyneuropathy commonly occurs in alcohol abusers, particularly in association with nutritional deficiencies (i.e., thiamine). However, the clinico-


FIGURE 21.2. Pathophysiology of brain damage from Wernicke encephalopathy. (1) Thiamine-dependent enzymes, (2) pyruvate dehydrogenase complex, and (3) α-ketoglutarate dehydrogenase complex. (Reprinted from AD Thomson, CCH Cook, R Touquet, JA Henry, The Royal College of Physicians report on alcohol: guidelines for managing Wernicke's encephalopathy in the accident and emergency department, 2002, Vol. 37 Issue 6, p. 516, by permission of Oxford University Press.)

pathologic features of these 2 neuropathies are distinct.[182] Alcoholic neuropathy is a painful, slowing progressive, sensory-dominant polyneuropathy affecting primarily superficial sensation. Sural nerve biopsies demonstrate predominately small-fiber loss of axons with segmental demyelination and remyelination resulting from widening of consecutive nodes of Ranvier. In contrast, thiamine-associated polyneuropathy (i.e., beriberi neuropathy) manifests an acute, motor-dominant polyneuropathy affecting both superficial and deep sensation. These clinical effects are associated with large-fiber axonal loss and subperineurial edema. The combination of chronic alcohol abuse and thiamine deficiency obscures the clinicopathologic differences between alcoholic neuropathy and thiamine-deficiency neuropathy.

METABOLIC DISTURBANCES. The oxidation of ethanol by the alcohol dehydrogenase pathway causes the loss of hydrogen and the concomitant reduction of NAD^+ to NADH. The formation of large amounts of reducing equivalents disrupts redox homeostasis and produces metabolic alterations including hyperlactacidemia and hypoglycemia, particularly during reduced carbohydrate intake by alcohol abusers. During glycolysis, glucose is converted to pyruvate. Under normal aerobic metabolism, acetyl CoA is formed from pyruvate, and acetyl CoA enters the Krebs cycle where the end products are ATP, water, and carbon dioxide. The accumulation of NADH during ethanol metabolism favors the conversion of pyruvate to lactate by the enzymatic action of lactate dehydrogenase. Elimination of lactate involves the regeneration of glucose in the liver via gluconeogenesis, which involves the cofactors biotin and thiamine. Ethanol increases serum lactate concen-

tration by increasing the formation of NADH and shifting the redox potential to favor lactate formation. Additionally, chronic ethanol consumption and malnutrition impairs the elimination of lactate by limiting the availability of cofactors necessary for gluconeogenesis. The inducible microsomal ethanol-oxidizing system (MEOS) produces acetaldehyde, which can enhance the formation of oxygen radicals and toxic metabolites from other xenobiotics.[183]

Alcohol-induced ketosis reduces the capacity of the kidney to excrete uric acid, producing a secondary hyperuricemia. Increasing amounts of NADH restricts lipid oxidation and promotes fatty acid synthesis and accumulation, resulting in increased formation of keto-acids, β-hydroxybutyrate, and acetoacetate.[184] The hypoglycemia associated with ethanol intoxication in young children appears related primarily to the inhibition of hepatic gluconeogenesis.[185] In the presence of significant depletion of hepatic glycogen stores (i.e., secondary to starvation or fasting), alcohol impairs hepatic gluconeogenesis, probably by reducing the intracellular NAD^+/NADH ratio. Consequently, life-threatening hypoglycemia may occur in alcohol abusers.

Postmortem Examination

ALCOHOL-RELATED LIVER INJURY. The earliest and most common hepatic response to ethanol abuse is the asymptomatic accumulation of fat in the liver cells with minimal elevation of serum hepatic transaminases.[186] Occasionally, the severe form of fatty liver disease mimics extrahepatic obstructive jaundice with dark urine, acholic stools, and mild to moderate elevation of serum hepatic transaminases. Long-term ethanol use

transforms stellate cells into collagen-producing myofibroblast-like cells that cause fibrosis around central veins and venules (i.e., terminal hepatic venules).[187] Even after decades of ethanol abuse, only a fraction of heavy ethanol users develop alcoholic hepatitis characterized as inflammatory necrosis of the liver. Histologic changes of alcoholic hepatitis include ballooning and disarray of the hepatocytes in the perivenular area, lymphocytic and polymorphonuclear infiltration of the parenchyma and portal areas, steatosis, cholestasis, necrosis, and fibrosis.[186] Mallory bodies (i.e., irregular hyaline cytoplasmic inclusions) are diagnostic features of alcoholic hepatitis, but these inclusion bodies are not present in all cases of alcoholic hepatitis. Cirrhosis distorts the normal architecture of the liver by the formation of fibrous bands between the central and portal zones that may develop in the absence of overt alcoholic hepatitis.[188] As cirrhosis advances, irregular nodules and perivenular fibrosis impair blood flow from the sinusoids, producing postsinusoidal portal hypertension. Eventually, portal hypertension causes splenomegaly, increasing hepatomegaly, esophageal and gastric varices, and GI hemorrhage.

ALCOHOL-RELATED SUDDEN DEATH. Sudden death occurs in chronic alcohol abusers, particularly in those alcohol abusers that drink heavily over several days without adequate dietary intake. Although postmortem examination demonstrates diseases (e.g., GI hemorrhage, cardiovascular disease, trauma, hepatorenal failure) that account for death in a majority of these cases, a cause of death is not apparent in some cases.[189] The most common histologic abnormality in these cases is the presence of extensive microvesicular fatty droplets in hepatocytes along with varying amounts of macrovesicular fatty change.[190] Metabolic disturbances (e.g., metabolic acidosis, ketoacidosis, hypoglycemia, hyperammonemia), renal dysfunction, hypothermia, and cardiac arrhythmias probably contribute to the occurrence of alcohol-related sudden death.

CLINICAL RESPONSE

Use

Ethanol is a selective CNS depressant in low doses, whereas high ethanol doses cause global depression of consciousness. The degree of neurologic impairment depends on a number of variables, including genetic factors, absolute amount ingested, tolerance, rate, and direction of blood ethanol elevation, simultaneous ingestion of other drugs and alcohol products, trauma, underlying nutritional status, and complications of chronic alcohol abuse.

INTOXICATION

ACUTE.   The most common symptoms in children and young adolescents under medical supervision for ethanol intoxication were coma and vomiting.[119] The rapid ingestion of ethanol by adolescents increases the risk of the rapid onset of coma and hypothermia in cold environments. Although ethanol intoxication causes vomiting and diuresis by inhibiting antidiuretic hormone, dehydration is uncommon in patients without other causes. Initially, ethanol produces exhilaration that progresses to loss of restraint, behavioral abnormalities, loquaciousness, slurred speech, ataxia, gait disturbances, irritability, drowsiness, stupor, coma, and respiratory depression as the ethanol dose increases. Other clinical features of ethanol intoxication include flushed face, dilated pupils, excessive sweating, nausea, vomiting, and rarely, alcohol-induced urticaria.[191] The ingestion of ethanol can produce dysrhythmias (e.g., atrial fibrillation) in nontolerant binge drinkers as well as in chronic alcohol abusers, but dysrhythmias are not a common complication of ethanol intoxication. Seizures during acute ethanol intoxication are rare without the presence of underlying intracranial pathology.[192] Common complicating factors associated with acute ethanol intoxication include concurrent trauma (e.g., subdural hematoma) and underlying medical diseases (liver, kidney, heart) as well as the use of other drugs and toxic alcohol substitutes (i.e., methanol, ethylene glycol). There is no direct evidence that acute ethanol intoxication predisposes or causes sleepwalking or related disorders.[193]

VISIBLE OR OBVIOUS.   Visible or obvious intoxication refers to a series of observable actions and behaviors that are consistent with gross impairment of cognitive and motor abilities following the ingestion of ethanol or other drugs. This impairment involves 1) diminished inhibitions (inappropriate response to social and/or environmental cues), 2) psychomotor impairment (slurred or slow speech, poor coordination, unsteady gait), and 3) cognitive impairment (poor concentration/memory, forgetfulness, difficulty performing simple tasks, inability to follow directions).[194] Observational instruments are available to assess the presence and level of alcohol intoxication; however, the reliability of observation alone in detecting moderately elevated BAC (100–140 mg/dL, 0.1–0.14 % w/v) is relatively low. Items in these observational instruments include the smell of alcohol, fine motor control (dropping or difficulty handling objects), gross motor control (stumbling, difficulty walking, falling), slurred speech, change in volume or pace of speech, sleepiness or decreased alertness, conjunctival erythema, sweating and change in

respiratory pattern.[195] None of these items is uniquely associated with visible intoxication; therefore, the combination of items must be interpreted together with the circumstances surrounding the actions. Some behaviors associated with visible intoxication also occur in sober individuals; consequently, observational instruments do not usually include behavioral changes (e.g., boisterous, argumentative, confrontational, obnoxious) in the evaluation of individuals for visible intoxication.

The ability of observers to reliably determine visible intoxication in an individual is limited until the BAC is high (>150 mg/dL), regardless of the experience of the evaluator.[196] In a study of videos containing moderate drinkers seated in a chair, experienced police officers were unable to reliably determine if individuals were too intoxicated to be served another drink or to drive until the BAC exceeded 150 mg/dL.[197] This study was an observational study that did not allow the police officers to smell the odor of ethanol or to conduct a field sobriety test. Other studies using college counselors and college students also indicate that the determination of alcohol impairment is difficult without specific testing (e.g., BAC, field sobriety test) unless the BAC is relatively high (>150 mg/dL).

Although the likelihood of visible intoxication increases with the BAC, not all individuals with the same BAC are visibly intoxicated. Factors affecting the clinical appearance of ethanol intoxication at a given BAC include chronic tolerance, the phase on the BAC curve (acute tolerance), fatigue, hangover, drinking habits, the environment, culturable norms on acceptable behavior, personality, age, ingestion of other drugs, underlying disease states, and general health.[198,199,200] A review of experimental data dating back to the 1930s concluded that visible signs of intoxication are present in a majority of individuals with BAC exceeding 150 mg/dL, and almost all individuals with BAC exceeding 200 mg/dL are visibly intoxicated, regardless of tolerance.[194] However, a few exceptional individuals do not display visible signs of intoxication despite a BAC well above 200 mg/dL as a result of chronic ethanol abuse.[201] Therefore, the determination of visible intoxication is not based on the BAC alone, but requires observation of the individual for visible signs of impaired motor and cognitive abilities.

The definition of what specifically (i.e., number and type of observable signs and symptoms) constitutes visible intoxication is not well defined, even for court proceedings. In a study of patients seeking admission for alcohol dependence, the criteria for visible signs of intoxication were gross gait abnormalities (staggering, swaying, reeling) plus 2 of the following signs: speech abnormality, flushed face, dilated pupils, or alcoholic odor on breath.[202] About 50% of the individuals averag-

ing 150 mg/dL (range, 125–175 mg/dL) met this criteria compared with 84% in individuals averaging 200 mg/dL (range, 175–225 mg/dL), as measured by the analysis of oxalated blood samples using the potassium dichromate method. With the same criteria for occasional drinkers and nondrinkers, 4 of 8 (50%) individuals with BAC averaging 100 mg/dL (range, 75–125 mg/dL) were considered intoxicated compared with 4 of 7 (57%) in the range of 125–175 mg/L and all 5 individuals in the 175–225 mg/dL range.[203]

Hangover. Although a hangover shares some of the adverse effects associated with acute alcohol withdrawal, a hangover is probably a separate entity that has a different, albeit poorly understood etiology.[204] Although relatively uncommon in alcohol abusers, an alcoholic hangover occurs frequently in mild to moderate ethanol users as a result of binge drinking. Common symptoms include a variety of affective, biologic, and physiologic effects including general misery, malaise, headache, anorexia, tremulousness, dizziness, dry mouth/thirst, fatigue, nausea, diarrhea, poor concentration, decreased attention, irritability, anxiety, and decreased sleep (rapid-eye-movement [REM] and total sleep time).[205,206] There is substantial interindividual and intraindividual variability in the severity of a hangover. Symptoms develop as the BAC declines substantially, reaching maximum effects when the BAC falls to zero; resolution of symptoms occurs within 12–24 hours after ethanol consumption ends. The consumption of alcoholic beverages (e.g., wine, brandy, whiskey, tequila, dark liquors) that contain relatively high concentrations of congeners (e.g., fusel oil, acetaldehyde, ethyl acetate) increases the severity of a hangover compared with alcoholic beverages with no congeners (e.g., vodka); however, ethanol consumption is a stronger determinant of hangover than congener content.[207,208] Medical and social factors that increase the severity of a hangover include sleep deprivation, poor food consumption, dehydration, increased physical activity during acute ethanol intoxication, and poor physical conditioning.[209] The etiology of a hangover remains unclear;[210] sleep deprivation and dehydration do not account for all the effects of a hangover.[211] The evidence for impairment of psychomotor skills, memory, and attention during an alcohol hangover in nonalcohol abusers is conflicting as a result of methodologic differences between studies (e.g., differences in timing of testing between controls and drinking study participants, documentation of zero blood ethanol concentrations, matching baseline skills, sleep deprivation, and personality differences between study participants and controls).[212,213] For crew members of civilian aircraft, the US Federal Aviation Administration prohibits the use of ethanol within 8

hours of flying or a BAC of ≥0.4% w/v during flight. There is no clear evidence that currently popular interventions for the prevention or treatment of a hangover are efficacious including the use of propranolol, glucose, fructose, ethanol, borage (*Borago officinalis* L.), and prickly pear [*Opuntia ficus-indica* (L.) P. Mill.].[214]

BEHAVIORAL ABNORMALITIES

The existence of alcohol idiosyncratic intoxication (i.e., pathologic intoxication) is highly controversial.[215] The *Diagnostic and Statistical Manual of Mental Disorders, 3rd Edition* (*DSM-III*) listed a syndrome (291.40) involving marked behavioral changes (usually aggressive) following ethanol doses that are usually insufficient to produce intoxication.[216] The behavioral changes frequently involve combative, irrational behavior that results in both property damage and personal injury followed by amnesia. The definition of this syndrome did not include aggressive behavior associated with marked intoxication.[217] Because of lack of medical data to support the existence of this syndrome, pathologic intoxication was no longer included as a separate diagnosis in *DSM-IV*.[218] The *DSM-IV-TR* includes clinically significant maladaptive behavioral and psychologic changes (e.g., inappropriate sexual or aggressive behavior, mood lability, impaired judgment, impaired social or occupational functioning) with other signs of acute alcohol intoxication (e.g., slurred speech, incoordination, unsteady gait, nystagmus, impairment of cognition, memory, and consciousness).[219] There is no category for this type of behavior without the usual signs of acute ethanol intoxication.

MENTAL DISORDERS

ALCOHOL ABUSE AND DEPENDENCE. Alcohol abuse and dependence is a chronic, often progressive and fatal disorder characterized by impaired control over ethanol use and preoccupation with drinking despite serious adverse social and physical consequences.[220] The *DSM-IV-TR* defines alcohol abuse as a maladaptive pattern of ethanol use during the last year that is manifest by clinically significant impairment in at least one of the following areas:[219]

1) Recurrent ethanol use resulting in a failure to fulfill major obligations at work, school, or home (e.g., absenteeism, poor work performance, suspension, neglect of children or household duties).

2) Recurrent ethanol use that causes physically hazardous behavior (e.g., driving while intoxicated, operating machinery while impaired).

3) Recurrent legal problems associated with ethanol use (e.g., disorderly conduct, driving while intoxicated).

4) Continued ethanol abuse despite recurrent legal, social, or medical problems.

The presence of symptoms of tolerance, withdrawal, and compulsive use of ethanol suggests the diagnosis of ethanol dependence rather than ethanol abuse. However, some patients with alcohol dependence do not develop clinically significant signs of alcohol withdrawal, and only about 5% of alcohol-dependent patients develop severe complications (grand mal seizures, DTs). Patients with alcohol dependence devote substantial time to obtaining and consuming alcoholic beverages; this compulsive behavior persists despite serious adverse psychologic and physical effects (e.g., blackouts, liver disease, depressions).[219]

Early detection of alcohol abuse and dependence requires a careful medical and psychosocial evaluation to prevent the serious health effects associated with this disease. To promote early detection, the National Council on Alcoholism assembled data in 1972 that divided criteria for alcohol dependence into the following 2 areas with major and minor categories:[221] Track I: Physiological and Clinical, and Track II: Behavioral, Psychological, and Attitudinal. Each criterion was weighted to grade the degree of implication for the presence of alcohol dependence that the specific sign or symptom suggested. Depending on the overall evaluation, there were 3 diagnostic categories:

1) *Diagnostic Level 1 (Definite).* A person who fits this criterion must be diagnosed as an alcohol dependent (e.g., withdrawal seizures, delirium tremens, alcoholic hepatitis, serious disruption of interpersonal relationships).

2) *Diagnostic Level 2 (Indicative).* In a person who satisfies this criterion, the diagnosis of alcohol dependence should be strongly suspected.

3) *Diagnostic Level 3 (Possible).* These manifestations may arouse the suspicion of alcohol dependence, but other evidence is needed to confirm the diagnosis of alcohol dependence.

The diagnosis of alcohol dependence requires 1 or more major criteria or the presence of several minor criteria in both Tracks I and II. However, the use of this set of criteria and diagnostic levels is relatively complex compared with the *DSM-IV-TR* definitions, and use of the National Council on Alcoholism criteria results in some overlap between various diagnostic levels and major/minor criteria.[220]

WERNICKE ENCEPHALOPATHY AND KORSAKOFF PSYCHOSIS. The Wernicke-Korsakoff syndrome refers to an acute or subacute neurologic disorder (i.e., Wernicke encephalopathy) that progresses to a chronic memory disorder called Korsakoff psychosis (amnestic-confabulatory psychosis with relative preservation of other intellectual function), when the underlying thiamine deficiency is not treated promptly. The classical signs of Wernicke encephalopathy are confusion, ataxia, and ophthalmoplegia, but the classic triad occurs only in a small portion of patients with Wernicke encephalopathy.[222] Typically, Wernicke encephalopathy occurs along with signs of alcohol withdrawal (e.g., tremor, hypotension, hypothermia, obtundation), but some alcohol abusers may develop this illness without obvious withdrawal symptoms.[223] The most reversible signs of the Wernicke encephalopathy are ocular abnormalities, including diplopia, blurred vision, nystagmus (bidirectional), and lateral gaze palsy. The latter sign is the most common; the palsy may be asymmetrical. Gait ataxia results from a polyneuropathy (decreased deep tendon reflexes and sensation) as well as from CNS dysfunction.

The term alcoholic cerebellar degeneration refers to the gait disturbances when these neurologic abnormalities occur with relatively little dysfunction of speech, upper motor movement, or ocular motility. The pathologic gait disturbances of alcoholic cerebellar degeneration and Wernicke encephalopathy are clinically indistinguishable. Other abnormalities associated with thiamine-deficient states include cardiac failure and GI distress (nausea, vomiting, abdominal pain). Thiamine deficiency produces Wernicke encephalopathy, the common underlying neuropathologic cause of most cognitive impairment in chronic alcohol abusers. Wernicke encephalopathy is also associated with other medical conditions causing nutritional deprivation (malignancy, hyperemesis gravidarum, intestinal obstruction). Changes in mental status occur in >90% of patients with Wernicke encephalopathy, and the cognitive abnormalities of Korsakoff syndrome are the least responsive to treatment. Approximately 80% of surviving patients with Wernicke encephalopathy develop Korsakoff syndrome characterized by retrograde (inability to recall information) and anterograde (inability to assimilate new information) amnesia. Memory is usually divided into working memory (information held seconds while allocating resources) and secondary memory (information held on a semipermanent or permanent basis). Episodic memory involves recalling memories from the past; this type of secondary memory is severely affected in these patients, often the amnesia extends 20–30 years.[224] Semantic memory involves the learning and recall of facts, concepts, and language; the effect of Korsakoff syndrome on this type of memory is variable. Implicit memory (i.e., response to priming and perceptuomotor memory) usually remains intact. Confabulation and decreased initiative also occur, but otherwise impairment of sensorium is minimal. Although some improvement in memory and learning occurs over years in 75% of abstinent Korsakoff patients, the remainder does not improve and may require long-term institutional care.[223] The improvement occurs much more slowly than resolution of the acute clinical features of Wernicke encephalopathy.[224]

Alcoholic pellagra encephalopathy is a neurologic condition associated with niacin deficiency and chronic ethanol abuse. Clinical features of this disease include confusion, oppositional hypertonus and myoclonus, hallucinations, insomnia, tremor ataxia, incontinence, peripheral neuropathy, seizures, anxiety, and depression.[225]

MEDICAL COMPLICATIONS

The complications of ethanol abuse are protean as outlined in Table 21.3. Polydrug use and alcohol substitutes (methanol, ethylene glycol) may complicate the diagnosis of ethanol abuse/dependence. Nutritional deficiencies (e.g., B_1, B_6, B_{12}, Zn) produce a variety of diseases including alcoholic beriberi and Wernicke encephalopathy. A substantial portion of abstinent alcohol abusers exhibit cognitive dysfunction after detoxification, particularly in visuospatial abilities, perceptual-motor integration, abstract reasoning, short-term memory, and mental flexibility.[226] Although most of the improvement in cognitive function occurs in the first several months of abstinence, some of these cognitive deficits may improve over a 2-year period.[227]

CARDIOMYOPATHY. An idiopathic (nonischemic), dilated cardiomyopathy occurs in chronic alcohol abusers.[228] The onset of alcoholic cardiomyopathy begins after consuming at least 7–8 standard drinks daily for over 5 years. The average duration of heavy drinking for these patients is approximately 15 years.[229] Clinical features of alcoholic cardiomyopathy include dilated left ventricle, fatty infiltration in the perivascular region, the intraventricular septum and the liver, atrophy of the myocytes, normal or reduced left ventricular wall thickness, and increased left ventricular muscle mass. Symptoms range from none to the typical symptoms associated with severe congestive heart failure (New York Heart Association Class IV).[230] There are no specific criteria or laboratory abnormalities that separate alcoholic cardiomyopathy from other causes of cardiomyopathy. Consequently, the diagnosis of alcoholic cardiomyopathy is a diagnosis of exclusion based on a history of

TABLE 21.3. Diseases Associated with Excessive Ethanol Consumption.

Organ System	Disease/Disorder
Skin/Musculoskeletal	Pellagra, nutritional stomatitis, cheilosis, scabies, alopecia, myopathy
Trauma	Automobile accidents, rib fractures, pneumothorax, chronic subdural hematoma, suicide
Blood	Hemolysis, anemia, Zieve syndrome (jaundice, hyperlipidemia, hemolytic anemia)
Neurologic System	Acute intoxication, dementia, seizures, Wernicke encephalopathy, Korsakoff psychosis, stroke, subarachnoid hemorrhage, amblyopia, alcoholic withdrawal/delirium tremens, central pontine myelinolysis, cerebral atrophy, cerebellar degeneration, polyneuropathy, Marchiafava-Bignami disease, peripheral motor/sensory neuropathy
Respiratory	Tuberculosis, pneumonia, atelectasis, chronic obstructive pulmonary disease from heavy long-term smoking
Cardiovascular	Cardiomyopathy, hypertension, congestive heart failure, arrhythmias, beriberi
Reproduction	*Male*: hypogonadism, male impotence, reduced testosterone concentrations, erectile dysfunction, loss of libido, impaired spermatic function, small testes, scant pubic hair
	Females: infertility, sexual dysfunction, loss of secondary sexual characteristics, menstrual irregularities, fetal alcohol syndrome
Metabolic/Endocrine	Malnutrition, vitamin B deficiencies, diabetes mellitus, hypoglycemia, hyperglycemia, excessive lactate, hyperuricemia, alcoholic ketoacidosis, hypophosphatemia, electrolyte disorders, hypomagnesemia, hypercholesterolemia, hypertriglyceridemia
Gastrointestinal	Esophagitis, diffuse esophageal spasm, Mallory-Weiss tear, esophageal perforation with mediastinitis, gastrointestinal cancer, erosive gastritis, peptic ulcer, diarrhea, upper gastrointestinal bleeding, pancreatitis, pancreatic pseudocyst
Liver	Fatty infiltration, alcoholic hepatitis, cirrhosis, liver failure

heavy alcohol abuse. Sudden death may occur in chronic alcohol abusers with cardiomyopathy despite the absence of histologic evidence of coronary artery thrombosis or a recent myocardial infarction.[231,232] Heavy beer drinkers also may develop alcoholic cardiac beriberi.

DYSRHYTHMIAS. Ischemic heart disease is the most common natural cause of out-of-hospital death in alcohol dependent men, and sudden cardiac death contributes significantly to the excess mortality in chronic alcohol abusers even several years after detoxification.[233] Dysrhythmias are particularly common during and immediately after alcohol withdrawal.[234] Heavy drinking of ethanol can induce arrhythmias (e.g., atrial fibrillation, ventricular dysrhythmias) in chronic alcohol abusers without underlying cardiovascular disease or electrolyte imbalance, particular during withdrawal.[235,236] In a prospective study of sudden cardiac death in England, Wales, and Scotland, the unadjusted risk of sudden death was increased several fold in heavy drinking (>6 drinks daily) men without preexisting ischemic heart disease compared with occasional or light drinkers without preexisting ischemic heart disease.[237] Adjustment for age, social class, smoking, and systolic hypertension reduced the mean relative risk of sudden death in heavy drinking men to about 1.7, but the difference between the 2 groups was not statistically sig-

nificant. In chronic alcohol abusers with preexisting heart disease and a history of dysrhythmias, the acute ingestion of moderate ethanol doses (e.g., 90 mL of 80-proof whiskey) may produce atrial or ventricular dysrhythmias including ventricular tachycardia and atrial flutter/fibrillation.[238] Heavy drinking is associated with hypertension, particularly during withdrawal.[239] The elevation of blood pressure is relatively mild following the daily consumption of 2–3 drinks per day.[240]

Abstinence Syndrome

This hyperadrenergic syndrome of physical dependence ranges from mild tremor and anxiety to hallucinations and seizures, particularly in regular heavy drinkers after a 5- to 10-year latency period. These individuals frequently demonstrate high tolerance to the acute effects of ethanol and to other drugs. The severity of the syndrome depends on individual susceptibility (i.e., genetic variability) as well as ethanol dose during the period immediately before the cessation of drinking.[241,242] Consequently, substantial differences in withdrawal symptoms occur in alcohol abusers consuming similar amounts of ethanol. A period of binge drinking for several days to a week by a heavy drinker frequently precedes the onset of withdrawal symptoms. In a study of heroin addicts confined to a closed ward, mild with-

drawal symptoms (tremulousness, nausea, diaphoresis, insomnia) occurred in 4 volunteers after discontinuance of alcohol after about 2–4 weeks of daily intoxication.[243] Of the 6 volunteers who drank heavily for 1½–3 months, withdrawal symptoms were more severe. Two of these inpatients had seizures, 2 had hallucinations, and 3 patients had delirium. One of the latter patients required treatment for DTs. In a study of 10 alcohol abusers with a prior history of withdrawal, the administration of progressive increasing daily doses of 86-proof whiskey (maximum 40 ounces) over 24 days produced withdrawal symptoms in 8 of 10 volunteers following cessation of drinking.[244]

Structured, withdrawal severity assessment scales (Clinical Institute Withdrawal Assessment Scale-Revised, Alcohol Withdrawal Scale)[245,246] are available to objectively quantify the severity of withdrawal. Table 21.4 outlines the scoring used for the Clinical Institute Withdrawal Assessment for Alcohol (CIWA-Ar) Scale. A CIWA-Ar score below 15 indicates mild withdrawal, whereas scores between 16 and 20 indicate moderate withdrawal symptoms.[247] Severe withdrawal is consistent with scores above 20. High total scores on the Alcohol Use Disorders Identification Test (AUDIT) suggest an increased risk of the development of withdrawal symptoms. A total score of ≥27 was sensitive (0.92), but not specific (0.24) for the necessity of medication for the treatment of withdrawal symptoms during the hospitalization of 55 patients at an inpatient addiction treatment unit.[248]

MINOR ABSTINENCE SYNDROME

The earliest and most common manifestations of alcohol withdrawal are generalized tremulousness, irritability, and GI distress (nausea, vomiting, anorexia) that develop within about 6–8 hours after the cessation of drinking. Other clinical features of the abstinence syndrome include diaphoresis, tachycardia, agitation, hyperexcitability, preoccupation with personal misery, muscular weakness, headache, insomnia, flushed facies, and conjunctival injection. Although most patients are asymptomatic within 72 hours, some symptoms persist for a week.

ALCOHOL DEPENDENT HALLUCINOSIS

Disordered perception occurs in about one fourth of tremulous alcohol abusers typically within 24–36 hours after cessation of drinking. This disorder of perception ranges from disturbing dreams to illusions and hallucinations (visual, auditory). The patient usually remains fully oriented.

SEIZURES (RUM FITS)

Seizures associated with ethanol usually occur during periods of abstinence preceded by binge drinking; the etiology of these seizures is multifaceted and complex.[249] Less than 10% of alcohol abusers develop seizures during withdrawal. The occurrence of seizures during the withdrawal phase is an indication of serious alcohol addiction with the potential for the development of DTs. Although seizures rarely develop after hallucinations, about one third of alcohol abusers with withdrawal seizures develop DTs. Most of these seizures are single, generalized, tonic-clonic seizures that occur with a peak incidence of 24 hours after the cessation of drinking and a range of about 6–48 hours.[250] The occurrence of focal seizures suggests the presence of concurrent lesions (e.g., hemorrhage, infection, metabolic abnormalities, illicit drug use, trauma, neoplastic lesions, cerebrovascular diseases). Multiple seizures may occur within several hours, but only about 3% of hospitalized alcohol abusers develop status epilepticus.[177]

DELIRIUM TREMENS

Symptoms of DTs typically develop 3–5 days after cessation of ethanol and rarely symptoms occur during the first 2 weeks of abstinence. Prodromal symptoms include sleep disturbances, restlessness, anxiety, and GI distress. Seizures occur in approximately one third of patients with DTs, and seizures almost always precede the development of DTs.[177] Prominent features of DTs include agitation, confusion, disorientation, delusions, hallucinations (visual, tactile), and autonomic hyperactivity (fever, sweating, tachycardia, dilated pupils, hypertension, and piloerection). The average duration of the acute psychosis is about 3 days.[251] Delirium tremens represents a true medical emergency with a 5–10% mortality rate. Alcohol dependent patients with a previous history of DTs, concomitant medical illness (infection, metabolic disease, trauma), and chronic alcohol-related illness are high-risk candidates for the development of DTs.

Reproductive Abnormalities

Heavy abuse of alcohol during the prenatal period produces a wide range of facial abnormalities, cognitive dysfunction, and neurodevelopmental delay.[252] In 1973, Jones and Smith described the fetal alcohol syndrome as the pattern of anomalies associated with children born to alcohol dependent mothers.[253] The fetal alcohol syndrome is a combination of intrauterine or postnatal growth retardation, CNS dysfunction (reduced head circumference, developmental delay, mental retardation),

TABLE 21.4. Clinical Institute Withdrawal Assessment for Alcohol (CIWA-Ar) Scale.[245,246]

Clinical Effect	Question/ Observation	Scoring	Score
Nausea and Vomiting	Ask "Do you feel sick to your stomach? Have you vomited?"	0 No nausea and no vomiting 1 Mild nausea with no vomiting 4 Intermittent nausea with dry heaves 7 Constant nausea, frequent dry heaves, and vomiting	
Tremor	Arms extended and fingers spread apart.	0 No tremor 1 Not visible, but can be felt fingertip to fingertip 4 Moderate, with patient's arms extended 7 Severe, even with arms not extended	
Paroxysmal Sweats		0 No sweat visible 1 Barely perceptible sweating, palms moist 4 Beads of sweat obvious on forehead 7 Drenching sweats	
Anxiety	"Do you feel nervous?"	0 No anxiety, at ease 1 Mildly anxious 4 Moderately anxious, or guarded, so anxiety is inferred 7 Equivalent to acute panic states as seen in severe delirium or acute schizophrenic reactions	
Agitation		0 Normal activity 1 Somewhat more than normal activity 4 Moderately fidgety and restless 7 Paces back and forth during most of the interview, or constantly thrashes about	
Tactile Disturbances	Have you any itching, pins and needles sensations, burning sensations, numbness or do you feel bugs crawling on or under your skin?"	0 None 1 Very mild itching, pins and needles, burning or numbness 2 Mild itching, pins and needles, burning or numbness 3 Moderate itching, pins and needles, burning or numbness 4 Moderately severe hallucinations 5 Severe hallucinations 6 Extremely severe hallucinations 7 Continuous hallucinations	
Auditory Disturbances	Are you more aware of sounds around you? Are they harsh? Do they frighten you? Are you hearing anything that is disturbing to you? Are you hearing things you know are not there?"	0 Not present 1 Very mild harshness or ability to frighten 2 Mild harshness or ability to frighten 3 Moderate harshness or ability to frighten 4 Moderately severe hallucinations 5 Severe hallucinations 6 Extremely severe hallucinations 7 Continuous hallucinations	
Visual Disturbances	Does the light appear to be too bright? Is its color different? Does it hurt your eyes? Are you seeing anything that is disturbing to you? Are you seeing things you know are not there?"	0 Not present 1 Very mild sensitivity 2 Mild sensitivity 3 Moderate sensitivity 4 Moderately severe hallucinations 5 Severe hallucinations 6 Extremely severe hallucinations 7 Continuous hallucinations	
Headache, Fullness in Head	"Does your head feel different? Does it feel as if there is a band around your head?" Do not rate for dizziness or lightheadedness. Otherwise, rate severity.	0 Not present 1 Very mild 2 Mild 3 Moderate 4 Moderately severe 5 Severe 6 Very severe 7 Extremely severe

TABLE 21.5.   Abnormalities Associated with Fetal Alcohol Syndrome.*

Category	Abnormalities
Facial Anomalies	Short palpebral fissures, small eye opening, premaxillary zone changes (flat, thin upper lip, flat midface, flattened philtrum, low nasal bridge, short nose)
Growth Retardation	Low birth weight, poor weight gain, disproportional height-to-weight ratio
Neurodevelopmental	CNS anomalies (small head size, structural brain abnormalities), performance deficits (fine and gross motor movement, visual-spatial tasks, tandem gait, eye-hand coordination, intelligence)

*The partial fetal alcohol syndrome label applies to children born to alcohol dependent mothers when these children manifest only some components of facial anomalies along with complex cognitive and behavioral abnormalities (learning deficits, behavioral problems, memory and attention difficulties, poor school performance).

and facial dysmorphology (short palpebral fissures, abnormal philtrum, thin upper lip) in children with known exposure *in utero* to alcohol.[254,255] Table 21.5 lists the birth abnormalities associated with the fetal alcohol syndrome. Functional abnormalities associated with facial hypoplasia include dental malocclusions and malalignments as well as eustachian tube dysfunction. The degree of craniofacial abnormalities correlates to the persistence of cognitive dysfunction and growth retardation.[254] The alcohol-related neurodevelopmental disorder is applied to individuals born to mothers using moderate to heavy doses of ethanol who do not have the characteristic facial abnormalities associated with fetal alcohol syndrome. These individuals have more subtle neurobehavioral deficits than individuals with the fetal alcohol syndrome, particularly in the sequential manipulation of information linking environmental input with information retrieved from memory (i.e., working memory).[256] Sustained attention, focusing of attention in the presence of distractions and execution of appropriate responses are less affected.

There is no single mechanism responsible for the wide array of fetal abnormalities associated with maternal alcohol abuse. Risk factors include maternal age, socioeconomic status, ethnicity, genetic/metabolic factors, smoking, diet, and multiple-drug dependence.[257] The risk of the recurrence of the fetal alcohol syndrome in alcohol dependent mothers is high when the mother continues to drink, but not all children born to these mothers develop fetal alcohol syndrome. The incidence of fetal alcohol syndrome is about 4% among heavy drinkers.[258] The safe level of ethanol use during pregnancy is not clearly established, in part because of the variable definition of heavy drinking and the averaging of drinking behavior among groups in most epidemiologic studies on fetal alcohol syndrome. However, most of the serious teratologic effects of ethanol result from alcohol abuse rather than casual ethanol consumption. There is no conclusive evidence that the ingestion of ≤83 g ethanol/weekly (low-moderate ethanol consumption) during pregnancy causes adverse fetal effects (e.g., miscarriage, stillbirth, intrauterine growth restriction, prematurity, reduced birth weight, birth defects).[259]

Fetal alcohol syndrome is a diagnosis of exclusion. There are 2 sets of diagnostic criteria for the evaluation of children with suspected fetal alcohol syndrome including the 1996 Institute of Medicine (IOM) criteria and the highly-detailed Washington criteria[260] as well as a combination of the IOM criteria and the 4-Digit Diagnostic Code.[261] The IOM criteria developed the following 5 categories: fetal alcohol syndrome with confirmed maternal alcohol exposure, fetal alcohol syndrome without confirmed maternal alcohol exposure, partial fetal alcohol syndrome with confirmed maternal alcohol exposure, alcohol-related birth defects, and alcohol-related neurodevelopmental disorder. Although no specific parameters were originally established for each diagnostic category, recommended revi-

399

sions provide more specific details.[262] The presence of short palpebral fissures (≤3%), smooth or flattened groove between lip and nose called the philtrum (4 or 5 on the 5-point Likert scale of the lip-philtrum guide) and thin vermillion border of the upper lip (4 or 5 on the 5-point Likert scale) is highly suggestive of fetal alcohol syndrome.[261]

Carcinogenesis

The International Agency for Research on Cancer lists ethanol as a known human carcinogen (Group 1) as a result of epidemiologic studies causally relating alcohol drinking to increased incidences of cancers of the oral cavity and pharynx (2- to 5-fold), larynx (2- to 5-fold), esophagus (2- to 4-fold), and liver (2- to 3-fold).[263] Both chronic alcohol consumption and heavy cigarette smoking are strong risk factors for the development of upper aerodigestive tract cancers including the oropharynx, hypopharynx, larynx, and esophagus.[264] The epidemiologic data for a causal relationship between alcohol consumption and breast, colon, or stomach cancer is inconclusive. There is no direct relationship between lung cancer and ethanol consumption. Most of the statistically significant associations between ethanol and cancer involve patients with high alcohol consumption (>35 drinks/week).[265] These associations persist following adjustment for smoking, and there is no indication that the causal effect is dependent on type of beverage. Although there are insufficient data on the carcinogenicity of ethanol in animals, a metabolite (acetaldehyde) of ethanol is a known animal carcinogen.

DIAGNOSTIC TESTING

Conversion Factors

SI Units

$$1 \, mg/dL = 0.217 \, mmol/L$$

$$100 \, mg/dL = 21.7 \, mmol/L$$

$$1 \, mmol/L = 4.606 \, mg/dL$$

Mass/Volume

$$0.1\% \, w/v = 100 \, mg/dL$$

[100 mg/dL (whole blood) = 94.8 mg/100 g = 0.948 g/kg, assuming the relative density of 1 mL whole blood = 1.055 g. Typically, the relative whole blood density of 1.055 g/L is based on a blood water fraction of 80% (w/w), and the plasma density of 1.027 g/L is based on a plasma water content of 92% (w/w).]

$$1 \, ‰ = 1 \, mg/mL = 100 \, mg/dL$$

[Promile (‰) means part per thousand; this measure is commonly used in Germany, Poland, Netherlands, Lithuania, and Latvia.]

Volume/Volume

$$80 \, proof = 40\% \, v/v$$

Mass/Mass

1 mg ethanol/g whole blood =
   1 mg ethanol/g whole blood×1.055 g whole blood/mL
   = 1.055 mg/mL

$$1 \, ppm = 1.88 \, mg/m^3$$

$$1 \, mg/L = 531 \, ppm$$

Analytic Methods

Techniques

Currently, gas chromatography (GC) with a flame ionization detector using either a direct injection technique or headspace sampling is the reference method of choice for ethanol determinations, particularly for legal purposes.[266] Headspace analysis measures the blood ethanol concentration in the equilibrated vapor phase above the liquid sample within a closed container maintained at constant temperature (50°C/122°F or 60°C/140°F). This procedure has relatively good specificity for ethanol; the presence of other alcohols (e.g., methanol, isopropanol) or acetone does not usually interfere with the quantitative determination of ethanol using this method.[267] The precision of this method is high with interlaboratory coefficients of variation ranging from about 3–5% and within laboratory <1%.[268] Total uncertainty (random plus systemic errors) using this method of alcohol determination ranges from ~4–6%.[269] Typically, BAC below 10 mg/dL is reported as negative because ethanol concentrations below this value are near the limit of quantitation for head space GC.[270]

Although GC is the reference method of choice for ethanol analysis, enzymatic ethanol assays are less costly and useful as more rapid screening methods. These enzymatic assays use the oxidation of ethanol to acetaldehyde by alcohol dehydrogenase with the concurrent

reduction of nicotinamide adenine dinucleotide (NAD^+) to NADH. The generation of NADH increases the absorbance at 340 nm that correlates to the ethanol concentration in the sample, whereas oxidized NAD^+ does not absorb UV light at 340 nm. Other substances (e.g., methanol, isopropanol, formaldehyde) that use NAD as a coenzyme to generate NADH potentially interfere with the enzymatic assays for ethanol. However, the ADH enzyme from yeast is more specific; additionally, the very slow oxidation of methanol at room temperature limits the interference of methanol in forensic and clinical practice. Elevated serum lactate and lactate dehydrogenase (LDH) also produce falsely elevated serum ethanol concentrations when analyzed by enzymatic methods. Although standard blood collection techniques use nonalcohol containing skin antiseptics, experimental studies indicate that the type of antiseptic does not significantly alter the results from blood ethanol determinations when using current enzymatic methods. In a study of 50 emergency department patients presenting with suspected ethanol intoxication, there was no statistically significant difference in the serum ethanol concentration between paired samples using 70% isopropanol or povidone-iodine impregnated cotton swabs as measured with the DuPont automatic clinical analyzer (ACA).[271] An experimental study using 100% ethanol as a skin preparation and the same clinical analyzer did not demonstrate an increased serum ethanol concentration unless the ethanol-containing sponge directly contaminated the needle during withdrawal.[272] The cross-reactivity of isopropanol with ethanol using the ACA was 3.9%. Consequently, the type of skin-cleansing agent used during collection of blood specimens should not affect the results of ethanol measurements determined with the ACA, when the correct phlebotomy technique is used.

Techniques for the qualitative determination of ethanol in urine specimens include adding volumes 10% potassium dichromate in 50% sulfuric acid to an equal volume of urine.[266] In a strongly acidic potassium dichromate solution, reduction of the yellow-orange chromic ion to the chromous ion changes the solution to blue-green; a green color indicates a positive test for alcohol. The Widmark method and modified Widmark methods (Cavett, Southgate and Carter) are based on the colorimetric changes associated with acidifying potassium dichromate solutions.[273] Older methods for the determination of ethanol concentrations include the use of the Conway cell where ethanol diffuses from the biologic fluid in the outer chamber to an acid dichromate solution in the inner compartment.[274] The change in the color of the reduced solution is analyzed spectrophotometrically. The presence of methanol, formaldehyde, and paraldehyde, but not acetone, interfere with this reaction leading to false high ethanol results. The dichromate solution remains bright orange in the absence of ethanol and these other compounds.

Enzyme immunoassays (DRI® EtG immunoassay, Thermo Fisher Scientific, Waltham, MA) are available for the detection of ethyl glucuronide in urine samples with lower limits of quantitation <0.1 mg/L.[275] Cutoffs typically are set at 0.5 mg/L to increase specificity. Case reports suggest that cross-reaction of this assay with chloral hydrate or metabolites (trichloroethyl glucuronide) may occur.[276] Detection of ethyl glucuronide in hair requires high sensitivity (pg/mg range), such as achieved by liquid chromatography/tandem mass spectrometry or gas chromatography/mass spectrometry (GC/MS). The limit of detection (LOD) for ethyl glucuronide in a 100-mg hair sample using liquid chromatography/tandem mass spectrometry after solid-phase extraction was 51 pg/mg.[277] Analysis of the same sample size by gas chromatography/electron impact/mass spectrometry after derivatization with pentafluoropropionic anhydride produces a LOD of 25 pg/mg with interassay precision <7%.[278] Using gas chromatography/negative chemical ionization/tandem mass spectrometry following solid-phase extraction and derivatization with perfluoropentanoic anhydride, the LOD and lower limit of quantitation (LLOQ) for ethyl glucuronide in a 30-mg hair sample are 3 pg/mg and 8.4 pg/mg, respectively. The bias (trueness) is <15% and <20% at the LLOQ.

SERUM/WHOLE BLOOD RATIO

ETHANOL.   Plasma and serum ethanol concentrations are essentially identical; therefore, these values are interchangeable.[279] However, the ethanol concentrations in serum and plasma averages at least 11–14% higher than the corresponding concentrations in whole blood samples from healthy individuals.[280] In a study of 235 healthy volunteers administered ethanol orally, the mean ratio of serum ethanol/whole blood ethanol was 1.14 ± 0.04 with a range of 1.04–1.26 as measured by head-space GC.[281] Consequently, blood samples from healthy individuals with a plasma or serum ethanol concentration >100 mg/dL reliably predicts a whole blood ethanol concentration exceeding 80 mg/dL.

The ethanol content of whole blood is a weighted average of the ethanol concentrations in plasma as well as various blood elements including erythrocytes, leukocytes, and platelets. Medical conditions (e.g., hypovolemic shock, dialysis, anemia, pregnancy, hyperlipidemia, dehydration) alter intracellular fluid balance and these conditions lower the ratio of plasma or serum ethanol to whole blood ethanol.[280] In a study of duplicate blood samples from 211 emergency department patients containing serum ethanol concentrations up to 622 mg/dL,

the mean serum/whole blood ethanol ratio was 1.16 (95% CI: 1.14–1.17).[282] There were several outliers resulting in a range of serum/whole blood ethanol ratios from 0.88–1.59. In a study of 17 hospitalized patients receiving IV ethanol, the mean plasma/whole blood ratio was 1.10 with a range of 1.03–1.24.[280] Consequently, a single serum ethanol concentration can correspond to a range of whole blood concentrations, and the conversion of a single serum ethanol concentration to a corresponding whole blood ethanol concentration requires the use of a range (e.g., 1.10–1.18) covering individuals with variable distribution of water between blood components.

ETHYL GLUCURONIDE/SULFATE. Analysis of whole blood measures the total amount of a substance in blood, whereas serum excludes the erythrocytes and leukocytes. In contrast to serum, plasma does not contain fibrinogen; however, fibrinogen is not known to bind drugs and therefore plasma and serum concentrations for ethyl glucuronide and ethyl sulfate are almost identical as noted above for ethanol. In a study of 13 serum and whole blood samples from patients admitted for ethanol detoxification, the median serum/whole blood ratio of ethyl glucuronide was 1.69 (range, 1.33–1.90), whereas the median ratio for ethyl sulfate was 1.30 (range, 1.08–1.47).[283]

STORAGE

ETHANOL.   Optimum storage conditions for the determination of postmortem ethanol concentrations include the collection of blood in an air-tight container containing 1–2% w/v sodium or potassium fluoride, particularly if analysis occurs more than a few days after autopsy. Significant variation in BAC from living individuals does not usually develop in blood specimens collected within 14 days of analysis, regardless of the storage conditions.[284] In a study of whole blood, plasma, and serum stored with and without preservatives at room temperature and under refrigeration (4°C/39.2°F), there was no statistically significant difference between type of collection tube or the storage condition during the 10-day study.[285] The blood ethanol concentration ranged from 60–90 mg/dL. The loss of ethanol from preserved, well-sealed samples stored at ambient temperatures is also small during the first month of storage.[286] However, loss of ethanol may occur during long-term storage of blood samples, particularly when multiple aliquots are removed from the container. Mechanisms of ethanol loss from stored samples include diffusion from the air (headspace) inside improperly sealed containers, ethanol metabolism by microorganisms, and temperature-dependent ethanol oxidation reactions.[287] Specimen

containers should contain small air-space to minimize evaporation of the ethanol. Temperature, fluoride concentration, tightness of the seal, and length of storage are the most important variables in loss of ethanol during storage.[288,289] The loss of ethanol from whole blood samples is minimal when stored at 4°C (39.2°F) in sealed containers with 1% sodium fluoride. The average monthly loss of ethanol from unopened whole blood samples stored at 4°C (39.2°F) with 1% sodium fluoride averaged about 0.2–0.3% per month over 1 year.[290] The ethanol loss was independent of initial BAC in the samples. Even at ambient temperature, the loss of ethanol from preserved samples over the course of 1 year at ambient temperatures is usually small (<10%).[291] In unopened blood specimens containing 0.36% w/v sodium fluoride and stored at room temperature, the mean loss of ethanol over 3.0 and 6.75 years was 19 mg/dL and 33 mg/dL, respectively.[292]

One study compared the change in ethanol concentrations of 32 paired, refrigerated samples of postmortem whole blood and vitreous humor.[293] The former was stored in 50-mL polypropylene tubes containing sodium fluoride as a preservative and potassium oxalate as an anticoagulant, whereas the vitreous humor was stored in 10-mL gray-top Vacutainer tubes containing 20 mg potassium oxalate and 25 mg sodium fluoride. Over 5–6 years the average reduction in ethanol concentration in the postmortem blood samples was 48% (absolute range, 10–290 mg/dL) compared with an average decline in ethanol concentration in vitreous humor samples of 9% (absolute range 0–40 mg/dL).

Frequent opening of the container increases the loss of ethanol. Following the inoculation of whole blood samples with 150 mg/dL ethanol, the loss of ethanol averaged about 10–20% during the month of storage at ambient temperatures despite the presence of 1% sodium fluoride.[294] The containers were opened 16 times during the 35 days of the study. The serum concentrations of ethanol were not significantly different over the course of the study. Microbial action in a blood specimen usually reduces the ethanol concentration in the sample. Strains of *Serratia marcescens* and *Pseudomonas* species are capable of metabolizing ethanol in blood samples containing 1% sodium fluoride stored at room temperature.

The production of ethanol in well-preserved blood samples is unlikely. In a study of BAC in blood samples preserved with sodium fluoride/potassium oxalate and stored at 4°C (39.2°F) for 1 year, significant increases in BAC did not occur in any of the samples.[295] Production of ethanol in nonpreserved, antemortem blood specimens may occur as a result of the fermentation by microbes, particularly in diabetic individuals with high blood glucose concentrations. Fermentation (i.e., the

metabolic conversion of glucose to ethanol) by most microbes is inhibited by 1% sodium fluoride with the exception of *Candida albicans*.[296] Experimental studies suggest that fermentation processes following direct inoculation or contamination with *C. albicans* depend on ambient storage temperatures. Under refrigerated conditions, no ethanol was formed from fermentation during 6 months of storage in blood samples preserved with 1% sodium fluoride and inoculated with *C. albicans*.[297] Experimental studies indicate that the storage of urine in 1% sodium fluoride at 0°C (32°F) prevents the formation and loss of ethanol from the urine sample.[298,299]

ETHYL GLUCURONIDE. Ethyl glucuronide remains fairly stable in urine samples in air-tight containers, when stored at 4°C (39.2°F) for 5 weeks; however, storage at room temperature in ventilated vials during this period resulted in some loss (mean, 37.5%; range, 30–80%) of ethyl glucuronide from the samples.[300] At the end of the study period, ethanol was no longer detectable in samples stored at room temperature in ventilated vials. There was no ethyl glucuronide formation in postmortem samples of blood or liver spiked with 100 mg/dL ethanol. False-negative results may occur in the analysis of ethyl glucuronide in heavily putrefied samples, particularly when stored at room temperature without preservatives.[301] The use of preservatives (chlorhexidine, potassium fluoride) improves the stability of ethyl glucuronide in samples stored at room temperature for 1 week.[302] Although ethyl sulfate is relatively stable in storage, experimental studies suggest that extreme conditions (e.g., putrefaction) for 1 week may cause some bacterial degradation of ethyl sulfate.[303]

Biomarkers

Ethanol diffuses into a variety of body fluids including the aqueous portion of the blood, bile, urine, saliva, cerebrospinal fluid, vitreous humor, and bone marrow.[304] Saliva is an alternative sample for the determination of ethanol, but studies on the correlation of saliva to blood are conflicting. In a study of volunteers ingesting 0.72 g ethanol/kg body weight, the mean saliva/blood ethanol ratio *during* the postabsorptive phase was 1.077 (95% CI: 1.065–1.088).[305] Experimental studies suggest that the salivary ethanol concentration correlates better to capillary blood than to venous blood.[306] Analysis of vitreous humor samples helps confirm the validity of blood ethanol samples because postmortem vitreous humor is relatively resistant to putrefaction processes.[307] Analyses of these specimens also provide information about the status of ethanol absorption (i.e., absorptive vs. elimina-

tion phase). Variation in the ratio of liver to blood ethanol concentrations is relatively large. Postmortem analysis of 71 cases with a blood ethanol concentration ≥40 mg/dL demonstrated a mean liver/heart blood ratio (± SD) of 0.56 ± 0.30 (range, 0–1.40).[308]

BREATH

The ethanol in expired air occurs almost exclusively as a result of the diffusion of ethanol from the bronchial circulation to conducting airways rather than from the alveoli.[309] Portable methods of breath ethanol detection provide rapid, simple, and noninvasive ways of estimating the arterial ethanol concentrations based on the ethanol concentration in expired air and a blood/breath ratio ranging from 2,000–2,300. The standard conversion value in the United States for forensic purposes is 2,100:1. The estimation of the blood/breath ethanol ratio depends on the extrapolation of Henry's law, which determines partition of a chemical between the liquid and gas phases at equilibrium based on constant pressure and temperature in a closed system. However, Henry's law provides only an estimation of the concentration of ethanol in blood from the vapor phase because the lungs are not a closed system. Consequently, the actual ratio varies substantially between individuals and within individuals as a result of a variety of physiologic factors (e.g., temperature, humidity, breathing pattern, etc.) that affect the equilibrium of ethanol between end-tidal gas and the blood in the bronchial circulation.[310] Additionally, the blood/breath ratio is lower during the absorption phase compared with the postabsorption phase. In the absorptive phase, the breath/blood ethanol concentration is a better measure of arterial ethanol concentrations and exposure of the brain to ethanol than venous ethanol concentrations. To minimize the effects of physiologic variables, sampling techniques require the use of breath samples obtained from deep expiration after at least 15 minutes of breathing ambient air of normal temperature.

PHYSIOLOGIC VARIABLES. In volunteer studies, hyperventilation decreases the BrAC, whereas breath holding increases the BrAC.[311] Increasing body temperature distorts the BrAC curve upward compared with the BAC. During an experimental study, the core body temperature of 9 male volunteers increased a mean of about 2.5°C.[312] The average increase of the BrAC above the BAC was approximately 8.6%/°C increase in core body temperature. Similar volunteer experiments on reducing the core body temperature indicated that the BrAC curve was displaced downward an average of 6.8%/°C.[313] Thus, alterations of core temperature change the likelihood of detecting ethanol concentrations, which exceed

legal limits. At these core temperatures (i.e., ± 2.5°C), the ethanol clearance did not change significantly.

Variables impacting on the accuracy of a BrAC measurement include tests performed with 15 min of the use of alcohol or alcohol-containing medications or products.[314,315,316] Other factors include arteriovenous differences in ethanol concentrations during the absorption phase, recent belching or vomiting, inadequate end expiratory specimen (i.e., poor cooperation), presence of obstructive pulmonary disease (FEV$_1$< 2L, FVC <2.6 L),[317] and poor technique or maintenance.[318] Experimental studies suggest that the presence of gastrointestinal reflux disease (GERD) does not significantly alter the BrAC curve during the postabsorptive phase.[319] Swallowing ethanol-containing products including beverages is unlikely to produce falsely high BrAC values when >15 minutes elapses between the ingestion and the testing. In a study of volunteers swallowing 10 mL of diluted gin (20% v/v ethanol), about 7% of the breath samples were positive as measured by the Intoxilyzer 5000™ (CMI, Inc., Owensboro, KY) in tests performed 10 minutes after ingestion.[320] The range of positive samples was 0.007–0.024 g% (7–24 mg ethanol/dL). Potential interfering substances include volatile compounds with enough vapor pressure to diffuse across the alveolar membrane and absorb infrared light at the same wavelength regions as ethanol; these substances include acetone, ether, isopropanol, methyl ethyl ketones, toluene, and methanol. Newer machines in the Intoxilyzer™ series (e.g., 5000EN) display an "interferent" message that appears with aborting of the test when the interferent concentration exceeds 0.01 g/210 L. However, case reports indicate that some interference may occur without detection. A 47-year-old intoxicated, suicidal man was found in a public park with a breath ethanol concentration of 0.288 g/210 L breath as analyzed by an Intoxilyzer 5000™ EN.[321] Analysis of his blood in the emergency department demonstrated a methanol concentration of 589 mg/dL and no detectable ethanol. The presence of ether in expired air may interfere with the analysis of BrAC, when analyzed by machines using a single wavelength of 9.5 μm to determine the presence of ethanol.[322]

Blood/Breath Ratio.   The mean blood/breath ratio of ethanol is approximately 2,400–2,450. In a study of 799 drivers apprehended for driving under the influence, the mean of the time-adjusted blood/breath ratio was 2,407 ± 213 (95% CI: 1,981–2,833) as measured by the Intoxilyzer 5000S™.[323] In a similar study using the Intoxilyzer 5000S™ in 18 healthy volunteers administered 0.4–0.65 g ethanol/kg over 20–30 minutes, the mean blood/breath ratio was 2,448 ± 540 (95% CI: 1,836–4,082).[324] Although the mean elimination rates in venous blood and breath samples were statistically different, the absolute differences were small (i.e., 0.157 ± 0.021 mg/g/h and 0.161 ± 0.021 mg/g/h, respectively). There was no statistical difference in the blood/breath ethanol ratio between men and women. The dynamics of ethanol exchange in the conducting airways produce a positively sloped plateau in the breath ethanol concentration that contributes to the dependence of breath ethanol concentrations on breathing pattern. At a constant flow rate, the breath ethanol concentration increases as an individual exhales into the breath analyzer. Consequently, ethanol breath measurements are approximations of the actual BAC.

The coefficient of variation for the blood/breath ratio ranges from approximately 9–19% as a result of both analytic and biologic factors.[325] The variability of the blood/breath ratio is substantially greater during the absorptive phase compared with the postabsorptive phase,[326] and the interindividual variation in BrAC is too large to accurately determine ethanol elimination rates between successive samples.[327] The breath ethanol measurement depends on instrumental, biologic, and procedural factors, and the variability increases as the blood ethanol concentration increases.[328] Interfering substances identified in the breath of drinking drivers with Intoxilyzer 5000S™ and Intoxilyzer 4011AS-A™ usually involve high concentrations of toluene, acetone, isopropanol, or methyl ethyl ketone.[329,330] Typically, the Intoxilyzer 5000S™ aborts the evidential breath test when these substances appear in the breath samples above a certain threshold value. Modern infrared instruments can distinguish ethanol from acetone and if necessary correct the result or abort the test.[331] Variability in the blood/breath ratio indicates that breath ethanol concentrations should be reported as such, and not as blood ethanol concentrations. Studies of populations of drivers suspected of driving under the influence suggest that the Intoxilyzer 5000S™ tends to underestimate the actual venous BAC. In a study of drivers arrested for operating a motor vehicle while intoxicated (mean BAC, 180 mg/dL, range, 0–338 mg/dL), the breath ethanol concentration was higher by >0.01 g/210 L than the corresponding BAC (<1 hour sampling difference) in approximately 67% of the samples.[332] Only 2% of the samples contained a breath ethanol concentration >0.01 g/210 L lower than the corresponding BAC. There are few data on the correlation of breath ethanol concentrations to BAC in populations with BAC <80–100 mg/dL. In many social situations, peak BrAC occurs within 0.45–1 hour of the cessation of drinking.[333]

ANTEMORTEM BLOOD

Although yeasts (e.g., *Candida albicans*) readily produce ethanol *in vitro*, the endogenous production of clinically significant quantities of ethanol in healthy adults is unlikely. In healthy adults and adults with diabetes, hepatitis, and cirrhosis, the typical range of ethanol in venous blood from endogenous ethanol production is about 0–0.08 mg/dL.[334] Consequently, the endogenous ethanol concentration in these conditions does not cause impairment. Rare case reports document the presence of BAC >80 mg/dL in Japanese individuals with serious yeast infections.[335] These individuals probably have genetic defects (e.g., aldehyde dehydrogenase-2) that cause the formation of higher concentrations of ethanol and acetaldehyde in the gut. Significant concentrations of endogenous ethanol can occur in children with short bowel syndrome. The formation of clinically significant concentrations of ethanol during rectal or vaginal candidiasis in healthy adults is highly unlikely.

ACUTE CLINICAL EFFECTS.   Ethanol consumption produces a dose-related depression of consciousness, and the BAC correlates generally to clinical signs, depending on several factors including the presence of tolerance, trauma, hypoglycemia, drug interactions, and preexisting diseases.[336,337] Table 21.6 correlates clinical symptoms with the BAC (whole blood) in a population without a history of substantial ethanol use. Signs of ethanol intoxication are less prominent in chronic drinkers compared with nondrinkers or occasional drinkers.[203] The clinical presentation of a tolerant patient at a given BAC is less predictable, and serum ethanol concentra-

tions of 400–500 mg/dL in these patients may not cause serious CNS depression or vital sign abnormalities.[338] In a series of 204 consecutive patients presenting to an emergency department with serum ethanol concentrations >400 mg/dL (mean, 467 mg/dL, range, 400–719 mg/dL), 88% of the patients were oriented to person, place, and time.[339] Although none of the 4 patients with serum ethanol concentration >600 mg/dL were alert and oriented, neither did any of these patients require measures of advanced cardiac life support (intubation, vasopressors).

Gross intoxication involves obvious impairment of perception, psychomotor tasks, motor coordination, reaction time, cognition, and judgment. These impairments usually produce easily observable signs of intoxication including stumbling, falls, breaking of objects, poor execution of motor tasks, increased laughter, agitation, and quarreling.[340] Typically, individuals displaying these signs have serum ethanol concentrations >150–200 mg/dL. However, many chronic drinkers with a serum ethanol concentration within this range can adequately perform simple and even moderately complex tasks, particularly if the tasks are not prolonged. Estimation of the serum ethanol concentration is difficult both for the drinking individual and the observer. In a study of 161 volunteers with BAC ranging from 0–295 mg/dL as measured by gas chromatography with flame ionization detector, only 31% of the participants estimated their actual BAC within 20 mg/dL.[341] There was a tendency for individuals with low BAC to overestimate their actual BAC and for individuals with a high BAC to underestimate their BAC. Experimental studies suggest that observers tend to underestimate the

TABLE 21.6. Correlation of Blood Ethanol Concentration with Acute Clinical Effects in Individuals without History of Heavy Ethanol Use.[266]

BAC*	Clinical Stage	Signs and Symptoms
10–50	Sobriety	Behavior normal with observable effects. Minimal changes potentially present by special testing.
30–120	Euphoria	Mild euphoria with increased sociability, loquaciousness, self-confidence. Some decreased inhibitions and diminution of attention and judgment. Reduced performance on complex psychomotor tests.
90–250	Excitement	Emotional instability with decreased inhibitions, loss of critical judgment, impairment of memory and comprehension. Some loss of muscular coordination, increased reaction time, and decreased sensory response.
150–300	Confusion	Disorientation, mental confusion, dizziness, exaggerated emotional states (fear, anger, grief), disturbance of vision (diplopia, distortion of forms and motion), reduced pain sensation, impaired balance and coordination, slurred and/or incoherent speech.
270–400	Stupor	Apathy, marked decreased responsiveness, marked lack of muscular coordination with inability to stand, incontinence, impaired consciousness (lethargy, stupor).
350–500	Coma	Unconsciousness, depressed reflexes, respiratory depression, aspiration.
>450–500	Death	Respiratory insufficiency.

*Whole blood ethanol concentration in mg/dL.

BAC, and that there is substantial variation between observers.[342]

Chronic ethanol users often do not demonstrate signs of gross ethanol intoxication even when the serum ethanol concentration is 200–400 mg/dL. In particular, recognizing chronic alcohol abusers with a serum ethanol concentrations >150–200 mg/dL is frequently difficult for trained health professionals (physicians, alcohol counselors) despite the use of observation instruments (e.g., alcohol symptoms checklist).[343] In a study of 110 consecutive admissions to a detoxification unit, patients were evaluated for intoxication based on measures of vision, pupil size, speech, verbal comprehension, coordination, and the ability to dress.[28] There was no clinical evidence of intoxication in 24% of 54 patients with a serum ethanol concentration >200 mg/dL. Although none of the 26 patients with serum ethanol concentrations >300 mg/dL exhibited normal responses to all field sobriety tests, 11 patients had normal speech and 6 patients had normal gait. In a study of 76 emergency department patients that admitted to recent ethanol ingestion and were released after minor trauma, the mean blood ethanol concentration was 268 mg/dL with a range of 120–540 mg/dL as measured by gas chromatography.[344] The criteria for release was whether the patient was ambulatory, oriented, able to calculate change for money, had no obvious neurologic abnormalities, and was capable of assuming his or her own care.

A serum ethanol concentration exceeding 450–500 mg/dL is usually considered a potentially fatal concentration in individuals without a history of chronic ethanol use, depending on the presence of supportive care. A 30-month-old child with an initial blood ethanol concentration of 455 mg/dL after ingestion up to 16 oz of wine was comatose when admitted to the emergency department and evaluated by the clinical laboratory (method not reported).[345] The victim survived without intubation and recovered without sequelae. Two case reports document the presence of high serum ethanol concentrations (1,121 mg/dL, 1,510 mg/dL) in patients with slight confusion.[346] Both these patients were alert and able to respond to questions. Several patients were deeply comatose with serum ethanol concentrations ranging from 700–1,500 mg/dL; these patients survived without sequelae.[114,115,347] These chronic ethanol abusers survived without sequelae.

Death occurs from respiratory depression at ethanol concentrations in blood samples exceeding 500 mg/dL. Alcohol dependence is common in fatalities associated with BAC exceeding 300 mg/dL.[348] Chronic alcohol abusers may exhibit few clinical signs of intoxication at ethanol concentrations in blood from 300–450 mg/dL, and these patients may survive ethanol concentrations exceeding 500 mg/dL if they do not aspirate.[338]

ESTIMATING BLOOD ETHANOL CONCENTRATION. Calculation of the serum ethanol concentration based on the serum osmolality or the presence of an osmolal gap *approximates* the blood ethanol concentration.[349] However, the presence of other, potentially unmeasured solutes limits the accuracy of these determinations, particularly in trauma patients.[350] Accurate estimation of blood ethanol concentrations based on antegrade or retrograde extrapolation requires the acceptance of several assumptions about elimination rates, status of absorption/distribution, and an accurate measurement of the blood ethanol concentration.

Antegrade (Forward Estimation). The accuracy of forward estimations of BAC depends on the presence of the following factors: 1) the forward estimate of the BAC at time "t" occurs during the postabsorptive phase, 2) known clearance rate or range of clearance rates that probably includes the true clearance rate, 3) there is 100% availability of the dose of ethanol, 4) the metabolic rate is constant from the beginning of drinking, and 5) the true volume of distribution is known. Under these conditions Equation 21.7 defines the BAC at time t,

$$BAC_t = BAC_0 - (\beta_{60} \times t) \qquad \text{(Equation 21.7)}$$

where BAC_t = blood alcohol concentration (mg/dL) at time t since drinking started; BAC_0 = theoretical BAC (mg/dL) at time 0 if total dose of ethanol is distributed instantaneously throughout total body water; β_{60} = blood alcohol clearance rate (mg/dL/h); t = time between start of drinking and time in question (h).

The theoretical BAC_0 is equivalent to the C_0 defined by Widmark and illustrated in Figure 21.1. This value represents the theoretical BAC if the entire dose was absorbed and distribution in total body water, which is the volume of distribution (V_D) into which the dose of ethanol diffuses. Consequently, the value of BAC_0 depends on the ethanol dose, the amount of first-pass metabolism, age, gender, total body water, and the fraction of water in the blood as defined by Equation 21.8,

$$BAC_0 = D/TBW \times F_w \times 100 \qquad \text{(Equation 21.8)}$$

where D = dose of ethanol (g); TBW = total body water volume (L), F_w = fraction of water in the blood (v/v).

The ethanol elimination rate in whole blood samples from healthy, nontolerant adults typically ranges from about 8–25 mg/dL/h with a mean of approximately 15–16 mg/dL. The actual rate may vary during the descending portion of the blood alcohol curve as a result of environmental factors and prevailing ethanol concentration. Sources of error in the forward and backward

estimation of the BAC involve inaccurate elimination rates, variability in the onset of the postabsorptive phase, and inappropriate values of V_D. Determination of the onset of the postabsorption phase depends on a number of variables including the type of beverage, the drinking history, and the consumption of food. When the drinking pattern involves the ingestion of a few drinks at the end of a drinking binge over a period of hours, the delayed absorption of the last few drinks probably does not alter the estimation of the already high BAC.[351] The V_D depends on total body water, which varies with body habitus, sex, and age.[352] Compared with other tissues, ethanol is relatively excluded from fat with a fat-water partition coefficient of 0.018. The volume of distribution (i.e., total body water) decreases with age and obesity, resulting in relatively higher blood ethanol concentrations for the same dose at a given body weight compared with younger individuals with ideal body weights.

In general, 1 ounce of 80-proof liquor (e.g., 1 glass of wine, 1 shot of whiskey, 1 can of beer) raises the blood ethanol concentration about 20–25 mg/dL for 100% bioavailability of the ethanol dose. Factors affecting the extrapolation of the blood ethanol concentration after a specific amount of ethanol include an accurate time of consumption, time for complete absorption, variability of test method (i.e., typically ± 5%), time between incident and withdrawal of the blood sample, storage and collection methods, variability in volume of distribution, and position on the blood alcohol curve (i.e., greater on ascending than descending portion).[353] There are few clinical data on the effect of trauma and blood loss on the blood alcohol curve. The rapid alteration of fluids in the intravascular space during hemorrhagic shock theoretically increases the whole blood ethanol concentration as the intravascular water content increases relative to the erythrocyte content.[354] However, serum ethanol concentrations do not vary substantially. Although trauma potentially can reduce ethanol metabolism by reducing hepatic blood flow, studies so far have not detected major changes in the blood alcohol curve as a result of infusion of fluids during the resuscitation of multiple trauma victims except during periods of severe hypotension or poor hepatic perfusion.[355] In a volunteer study of 10 individuals ingesting ethanol to produce BAC of 105–210 mg/dL, the removal of 200–500 mL blood (4.5–8.7% total blood volume) did not alter the blood alcohol curve when compared with the same individuals under control conditions.[356]

Retrograde Extrapolation (Back Estimation). Estimating blood ethanol concentrations at a time prior to analysis requires careful evaluation of a number of factors that affect the blood ethanol curve. These factors include the phase of the blood alcohol curve during the time in question, the elimination rate during the time in question, the time of the last drink, the type of sample (serum, whole blood, breath), interindividual variation in the elimination rate, the time of reaching the peak BAC, and any short-term fluctuations in the elimination rate.[65] The accurate estimation of the BAC at a time prior to the collection of a blood sample requires the presence of several of the following conditions: 1) the time of the estimated BAC and the blood sample must occur during the postabsorptive phase of the blood alcohol curve, 2) the ethanol elimination rate must be known or estimated as a range of probable values, and 3) the time of the sample and the estimated BAC must occur during the linear declining phase of the elimination curve (i.e., BAC = 20–200 mg/dL). In general, studies of healthy, fasted volunteers indicated that the blood alcohol curve is linear over the period 2–7 hours after rapid consumption of ethanol.[357] However, the onset of the postabsorptive phase varies with a variety of factors including food, medications, drinking pattern, and physiologic abnormalities (see Toxicokinetics-Absorption). Attempted back extrapolation of the BAC during a period of continuing ethanol absorption (i.e., the absorption and distribution phases) causes serious errors in the estimation of the BAC.[358]

Timing of Postabsorptive Phase. Most absorption of ethanol in *fasted* individuals occurs within 60 minutes of starting to drink; therefore, the mean peak ethanol usually occurs within 1 hour after the cessation of drinking, particularly after a period of heavy drinking. However, some absorption may occur after reaching the peak ethanol concentrations. Drinking scenarios during experimental settings frequently differ from those encountered during real-world social situations. Factors that affect the timing of the postabsorptive phase include the dose and concentration of ethanol, the rate of consumption, the timing and type of food consumed near the time of drinking, age, weight, sex, and race. In an experimental study of 54 beer-drinking participants, who drank variable amounts of beer as fast as possible (range, 20–103 minutes) beginning about 3 hours after a light meal, the mean peak BAC was about 132 mg/dL (range, 52–254 mg/dL), and the mean time between the cessation of drinking and the peak BAC was approximately 1 hour with a range of about 0.3–2 hours.[359,360] Consequently, the postabsorptive phase usually begins about 1–2 hours after drinking ceases in individuals, who have not consumed a meal within several hours before drinking starts. The peak blood ethanol concentration may also occur within approximately 1 hour of cessation of drinking of relatively small quantities of beer. The ingestion of 660 mL of light beer (about 3%

w/v ethanol) by 9 volunteers produced a mean time to peak capillary ethanol concentration of approximately 32 minutes (range 30–50 minutes).[361] Because ethanol absorption continues after peak BAC, retrograde extrapolation of the BAC to the period within 2 hours after drinking stops produces considerable variation with the true BAC, even in fasted individuals.[104] Therefore, retrograde extrapolation should be limited to the portion of the blood alcohol curve 2 hours after the cessation of drinking. Cross-sectional studies suggest that a majority of drivers with BAC exceeding 100 mg/dL are in the postabsorptive phase at the time of the accident. In a study of 129 fatalities, about 67% of the drivers were in the postabsorptive phase at the time of the accident based on a urine/blood ethanol ratio exceeding 1.2.[362]

Elimination Rate.   The accuracy and precision of retrograde and antegrade extrapolations depend on the assumed rate of ethanol elimination from blood. In a study of healthy fasted volunteers, the use of the actual mean plasma elimination rate (18.6 mg/dL/h) to extrapolate plasma ethanol concentrations during the postabsorptive phase produced small mean errors, but there was substantial interindividual variation in the difference between estimated and actual plasma ethanol concentrations (-28 mg/dL to +21 mg/dL).[357] The use of bracketing plasma elimination rates (15 mg/dL/h, 23.8 mg/dL/h) produced large mean errors between estimated and actual plasma ethanol concentrations as well as large interindividual variations in the retrograde extrapolations. Consequently, calculations involving retrograde extrapolation should include a sufficiently broad range of elimination rates (e.g., 10–25 mg/dL) that likely includes the individual's elimination rate as well as a mean rate of elimination (13–17 mg/dL/h). Although there are theoretical reasons for assuming that the ethanol elimination rate decreases during trauma and shock, there are limited clinical data to support this notion. A German study did not detect substantial changes in the ethanol elimination rate between patients with traumatic intracranial lesions and patients with torso injuries.[363] However, this study did not separate patients by the severity of shock.

Ethanol elimination rates of selected populations (e.g., suspected drunk drivers) and the general population may differ because of the relative overrepresentation of alcohol abuse in the former group. In a study of drivers apprehended in the Netherlands for driving under the influence, the mean elimination rate (whole blood) for drivers with BAC <250 mg/dL was approximately 21 mg/dL/h with a range of 11–57 mg/dL/h.[364] For the subset of 197 drivers with an initial BAC ranging from 50–99 mg/dL, the mean elimination rate was

20 mg/dL (range, 10–36 mg/dL). At least 2% of the drivers were not in the postabsorptive phase of the blood alcohol curve based on rising BAC between the 2 blood samples. Compared with this study, the mean ethanol elimination rates in whole blood from healthy, fasted volunteers during experimental studies using BAC near 100 mg/dL are lower (11–17 mg/dL/h) with substantially lower upper ranges (i.e., <30 mg/dL/h).[111,117,365] Low elimination rates calculated from 2 blood samples suggests that the sampling occurred near the peak of the blood-alcohol curve, which may be on a plateau as a result of delayed gastric emptying (e.g., after food). The elimination rate of ethanol is nonlinear at very low BAC (i.e., <10–20 mg/dL).[116]

ALCOHOL DEPENDENCE

Recall bias produces substantial underreporting of ethanol consumption. Despite careful sampling and assessment of ethanol intake, surveys based on self-reported history account for only about 40–60% of the known ethanol consumption of a country or region.[366] No laboratory test is reliable enough to support the diagnosis of alcohol dependence without confirmation from other sources.[367] Questionnaires depend on the awareness and willingness of the patient to acknowledge the negative effects of drinking, and the questionnaire and serum biomarkers of excessive ethanol consumption probably detect ethanol abuse in overlapping populations.[368] Consequently, questionnaires used in combination with biomarkers (MCV/GGT, CDT/GGT) may be the most sensitive tests for the detection of excessive drinking.

Serum ethanol concentrations are not sensitive tests for the detection of alcohol abuse.[369] Popular questionnaires on the detection of alcohol dependence include CAGE, MAST (Michigan Alcoholism Screening Test), and AUDIT (Alcohol Use Disorders Identification Test—World Health Organization). Common biochemical markers of ethanol abuse include gamma glutamyl-transferase (GGT), aspartate aminotransferase (AST), and erythrocyte mean cell volume (MCV). Newer biomarkers of excessive ethanol use include serum mitochondrial AST, carbohydrate-deficient transferrin (CDT), serum 5-hydroxytryptophol, acetaldehyde adducts, and β-hexosaminidase. Of these newer markers, only the serum CDT offers some limited advantages over older biomarkers because of much higher specificity.

QUESTIONNAIRES. Both the CAGE questionnaire (Table 21.7) and the Brief Michigan Alcoholism Screening Test (Table 21.8) are useful screening tests for covert alcohol abusers, particularly in young, male

patients in a general hospital psychiatric ward. However, these questionnaires are less-sensitive tests for the detection of alcohol dependence in the general community or in populations containing large numbers of female or elderly patients.[370] Both the CAGE and MAST questionnaires involve abnormal past drinking behavior (morning drinking, alcohol-related problems), but these 2 questionnaires probably cover different aspects of unsafe drinking as reflected in the fact that persons testing positive on one questionnaire frequently do not test positive on the other.[371] In addition to abnormal drinking behavior, the AUDIT questionnaire (Table 21.9) includes the level and frequency of recent (i.e., past year) ethanol consumption as well as adverse consequences of drinking. The AUDIT questionnaire was designed to identify heavy drinkers, and this questionnaire specifically seeks information about alcohol consumption, alcohol-related problems, adverse psychologic reactions, and symptoms of dependence over the past year.[372] Any positive response to the 4 questions on the CAGE questionnaire indicates the need for a more detailed clinical assessment for alcohol dependence. The major criticism of the CAGE questionnaire is lack of

specificity for individuals highly concerned about the health and religious implications of ethanol use as well as the failure to detect recent heavy drinking, particularly in women and in the elderly.[373,374] The sensitivity and specificity of the CAGE questionnaire for the detection of excessive ethanol consumption ranges from

TABLE 21.7. CAGE Questionnaire.*

1. Have you ever felt you should <u>C</u>ut down on your drinking?
2. Have people <u>A</u>nnoyed you by criticizing your drinking?
3. Have you ever felt bad or <u>G</u>uilty about your drinking?
4. Have you ever had a drink first thing in the morning to steady your nerves or to get rid of a hangover (<u>E</u>ye-opener)?

*One positive answer indicates the need for follow-up, whereas 2 or more affirmatives indicates alcohol dependence.

TABLE 21.9. Alcohol Use Disorders Identification Test (AUDIT) Questionnaire.*

1. How often did you have a drink containing alcohol in the past year?
2. How many drinks containing alcohol did you have on a typical day when you were drinking in the past year?
3. How often did you have 6 or more drinks on one occasion in the past year?
4. How often during the last year have you found that you were not able to stop drinking once you had started?
5. How often during the last year have you failed to do what was normally expected from you because of drinking?
6. How often during the last year have you needed a first drink in the morning to get yourself going after a heavy drinking session?
7. How often during the last year have you had a feeling of guilt or remorse after drinking?
8. How often during the last year have you been unable to remember what happened the night before because you had been drinking?
9. Have you or someone else been injured as a result of your drinking?
10. Has a relative or friend or doctor or other health care worker been concerned about your drinking or suggested you cut down?

*Responses are rated 0 to 4: 0 = never, 1 = less than monthly, 2 = monthly, 3 = weekly, and 4 = daily or almost daily. Almost all alcohol abusers score 10 or above. The maximum score is 40.

TABLE 21.8. Brief Michigan Alcoholism Screening Test (MAST) Questionnaire.*

Question	Yes -Points	No -Points
Do you feel you are a normal drinker?	0	2
Do friends or relatives think you are a normal drinker?	0	2
Have you ever attended a meeting of Alcoholics Anonymous?	5	0
Have you ever lost friends or girlfriends/boyfriends because of drinking?	2	0
Have you ever gotten into trouble at work because of drinking?	2	0
Have you ever neglected your obligations, your family, or your work for 2 or more days in a row because you were drinking?	2	0
Have you ever had delirium tremens (DTs) or severe shaking, or heard voices or seen things that weren't there after heavy drinking?	2	0
Have you ever gone to anyone for help about your drinking?	5	0
Have you ever been in a hospital because of drinking?	5	0
Have you ever been arrested for drunk driving or driving after drinking?	2	0

*Score ≥6 suggests the diagnosis of alcohol-use disorder.

about 60–95% and 40–95%, respectively, depending on the particular population assessed.[367,375,376] For example, the CAGE questionnaire is relatively insensitive in primary care populations containing large numbers of Caucasian women.[377] The original MAST questionnaire contained 25 questions, and there are several modifications including the Brief MAST (Table 21.8). The sensitivity of the original MAST questionnaire for the detection of alcohol dependence ranges up to 85%,[378] but the length of the questionnaire limits the clinical usefulness of this test for the general practitioner. The sensitivity and specificity of the AUDIT questionnaire ranges from about 80–95%.[379]

BLOOD TESTS.   Laboratory markers of excessive ethanol consumption potentially help identify alcohol dependent patients. However, no laboratory marker is reliable enough alone to diagnosis alcohol dependence, and the diagnosis of alcohol dependence requires the combination of physician interview, questionnaire, and biomarkers.[380] Typically, these biomarkers indicate prolonged heavy ethanol consumption (≥5 standard drinks/day for 5 days or more/week); these markers usually return to normal values within several weeks of abstinence. The usefulness of biomarkers (GGT, CDT, MCV) remains controversial because of the low correlation of biomarkers to alcohol consumption and the wide range of normal values in the nondrinking population.[381] Both the CDT and GGT are sensitive markers for the excessive use of alcohol, although GGT is less specific than CDT.[382] The BAC alone is not a sensitive screening test for alcohol dependence or problem drinking. In a cross-sectional study of 86 drinking drivers, a BAC >150 mg/dL identified only approximately one-third of problem drinkers in the sample.[383]

Gamma-Glutamyl Transferase (GGT). Gamma-glutamyl transferase is a membrane-bound enzyme that catalyzes the transfer of the γ-glutamyl moiety of glutathione to peptide acceptors. GGT is a sensitive marker of ethanol-induced liver damage in the absence of biliary stasis, but specificity of this biomarker is limited by elevation of GGT in some patients with pancreatitis, prostate disease, diabetes mellitus, obesity, other liver disease, or use of some drugs (anticoagulants, antiepileptics).[384] Although the serum GGT does discriminate between alcohol-induced liver disease and other hepatic disease, about 75% of established alcohol abusers have elevated serum GGT concentrations with a range of 60–90% depending on the comparison population.[385] The initial elevation of serum GGT in chronic ethanol abusers results from enzyme induction rather than hepatic damage; therefore, the serum GGT may be the only hepatic enzyme elevated during the early stages of

alcohol dependence.[386] The sensitivity of the serum GGT as a marker for alcohol dependence drops substantially (<25–50%) when screening patients in the primary care setting where the population contains large numbers of women and healthy young (<30 years of age) male, episodic drinkers.[387,388] The serum GGT rarely increases in persons under the age of 30 years despite their heavy consumption of ethanol. The presence of drug interactions, obesity, medications (barbiturates, anticonvulsants, anticoagulants), and hepatobiliary disease limits the specificity of the serum GGT.[389] The serum half-life of the GGT is about 2–4 weeks, and the serum GGT returns to normal in alcohol abusers during the first 2 months of abstinence.[387] Potential confounders of detecting alcohol dependence by elevated concentrations of GGT include obesity and smoking.[390]

Serum Carbohydrate-deficient Transferrin (CDT). Carbohydrate-deficient transferrin (CDT) is a component of serum transferrin with an abnormally high isoelectric point that results from changes in the carbohydrate composition of these chains in the presence of chronic ethanol consumption. In general, this biomarker has similar sensitivities as other serum biomarkers of chronic ethanol consumption, but CDT is somewhat more specific than GGT.[391] The serum CDT has a high sensitivity (80%) and specificity (80–95%) for detecting alcohol dependence in men, but the sensitivity of this test for detecting heavy drinking (>60 g/day) in the general population and in women is relatively low (12–45%).[392] The specificity of serum CDT for alcohol abuse is relatively high with some rare hepatic diseases (hepatocellular carcinoma, chronic hepatitis C, chronic active hepatitis, primary biliary cirrhosis) and the genetic D-variant of transferrin-limiting specificity.[393] In general, the use of CDT for the detection of alcohol dependence in the general population does not offer an advantage over the use of GGT, particularly in women. The main advantage of using the serum CDT over serum GGT is the monitoring of patients for increased ethanol consumption during abstinence or in the detection of alcohol dependence in patients with liver disease, particularly changes of the baseline GGT in men.[367] Elevation of the CDT requires at least the average daily intake of >4–6 drinks over the preceding 1–2 weeks.[394] In large, multicenter, community-based populations, the CDT is probably not significantly better than the GGT in detecting high- or intermediate-risk alcohol consumption, particularly in women.[395]

Serum Aminotransferases (AST, ALT).   Although elevation of the serum aspartate aminotransferase (AST) and alanine aminotransferase (ALT) often occurs in alcohol abusers, the sensitivity of these tests for the

detection of heavy ethanol consumption is relatively low (25–60% and 15–40%, respectively).[367,396] The amount of AST and ALT elevation depends on the extent of hepatic damage and the timing of ethanol intake. Acute ethanol consumption (3–4 g/kg body weight) may increase the concentration of these 2 markers within 1–2 days after ingestion by healthy individuals. The AST/ALT ratio >1.5–2.0 is highly suggestive of alcoholic hepatitis, particularly if these enzymes do not exceed 400 IU/L.[397]

Mean Corpuscular Volume (MCV). The increases in the MCV correlates to the amount and frequency of ethanol consumption, but generally the ingestion of >60 g ethanol daily for >1 month is necessary to increase the MCV above the reference range.[398] The MCV is less sensitive (i.e., 40–50%) than GGT in alcohol abusers, particularly in the primary care setting.[399] However, a variety of diseases increase the MCV including hemolysis, vitamin deficiencies (B_{12}, folic acid), hypothyroidism, nonalcoholic liver disease, smoking, and medications (anticonvulsants, azathioprine, zidovudine). The presence of both elevated concentrations of GGT and MCV increases the likelihood of alcohol dependence. Some individuals may ingest large doses of ethanol (>60 g/day) for a prolonged period without developing alteration of the MCV or hepatic aminotransferases.[400]

HAIR. Fatty acid ethyl esters (FAEE) are minor, non-oxidative metabolites of ethanol biotransformation. These compounds are formed by the etherification of fatty acids or fatty acyl-CoA by fatty acid ethyl ester synthase or acyl CoA/ethanol *O*-acyltransferase, respectively; almost all tissue contains FAEE synthase activity. The dominant fatty acid ethyl ester is ethyl oleate followed by ethyl palmitate with substantially lower concentrations of ethyl myristate and ethyl stearate. These compounds are eliminated from blood within 24 hours.[401] Several studies suggest that the concentration of fatty acid ethyl esters in scalp hair is a biomarker of chronic ethanol consumption. In studies of chronic alcohol abusers and teetotalers, the total concentrations of these 4 FAEE in scalp hair above 1 ng/mg indicated chronic excessive ethanol consumption, whereas ≤0.4 ng/mg indicates abstinence.[402,403] However, there is large inter-individual variation in the deposition of FAEE in hair, and drinking histories do not correlate well to the concentrations of these compounds in hair samples. Furthermore, the use of cosmetic products (deodorants, hair spray, hair lotion) with very high concentrations of ethanol may produce false-positive tests (i.e., FAEE > 1 ng/mg hair).[404]

Ethyl glucuronide is detectable by high performance liquid chromatography/tandem mass spectrometry with LLOQ in the range of 0.05 ng/mg (LOD, 0.025 ng/mg).[405] In general, studies of alcohol abusers and teetotalers suggest that the mean ethyl glucuronide concentration in hair correlates to the daily intake of ethanol; however, the range of ethyl glucuronide concentrations is relatively large.[406,407] Although external contamination and differences in melanin content are unlikely to affect ethyl glucuronide concentrations in hair, some differences occur in the deposition of ethyl glucuronide in hair at different sites on the body. Analysis of paired hair samples suggest that higher ethyl glucuronide concentrations may occur in pubic hair and sites other than scalp hair when compared with scalp hair samples.[408,409]

POSTMORTEM SAMPLES

Ethanol distributes into tissues antemortem based on water content. Therefore, postmortem changes in ethanol concentrations may result from changes in blood water content. Under certain conditions during decomposition, postmortem production of ethanol may also occur. A number of factors affect the postmortem redistribution of ethanol including the postmortem interval between death and sampling (>10 hours), ambient temperature, the presence of microorganisms in the body, chest and abdominal trauma, location and quality of the sample collection, diffusion of ethanol from the stomach to pericardial fluid, and diffusion of aspirated ethanol into cardiac blood.[410] Several of these factors increase the concentration of ethanol in chest fluid; therefore, the ethanol concentration in fluid drawn from the chest cavity does not reliably reflect the BAC at the time of death.[411]

BLOOD. Case series of postmortem examination of fatalities in alcohol abusers indicate that alcohol and drugs are common causes of death in addition to natural causes (coronary artery disease, pneumonia, intracranial lesions, trauma).[412] Based on postmortem examination and toxicologic analysis of 73 alcohol abusers, death was attributed to the following causes: nonethanol-related drugs, 19%; alcohol/drug combination, 15%; acute ethanol intoxication, 8%; and alcoholic ketoacidosis, 7%.[413] The causes of death for the other alcohol abusers in these data were not attributed to drugs or ethanol. The presence of postmortem ethanol does not necessarily imply the chronic use or abuse of ethanol.[414] Postmortem ethanol concentrations potentially result from several sources including ethanol administration during the period immediately before death, diffusion from the stomach or aspirated vomitus after death, or from the postmortem formation of ethanol. The concentration of ethanol necessary to cause death depends on several factors including

tolerance, genetic susceptibility, and the presence of other CNS depressants. In postmortem blood samples from patients dying of acute ethanol intoxication in the absence of the detection of other drugs or causes of death, the majority of the blood ethanol concentrations range from approximately 300–450 mg/dL.[415,416] The determination of acute ethanol intoxication as the cause of death requires careful evaluation of the events surrounding death including evidence of asphyxiation, aspiration, and hypothermia. Average postmortem blood ethanol concentrations of alcohol abusers dying of chronic ethanol abuse are substantially lower (i.e., median, ~150 mg/dL) than the blood ethanol concentration from fatal, acute ethanol intoxication (360 mg/dL). Deaths in chronic alcohol abusers are usually the result of the presence of serious underlying medical diseases (e.g., cardiomyopathy, hepatitis, cirrhosis, liver failure, pancreatitis).[417]

Factors to consider when evaluating postmortem ethanol concentrations include the site and method of sample collection, time after death and condition of body during sample collection, storage conditions and preservatives (e.g., sodium fluoride), condition of the sample (desiccation, evidence of putrefaction including smell, color, fluidity, and consistency), and analytic procedures (method, time interval between collection and analysis).[418] Both water content and ethanol concentrations in blood samples tend to decrease after death, particularly with long postmortem intervals.[419] In living humans, the average water content of fresh whole blood is about 80% w/w (84% w/v assuming a density of 1.05 g/mL for whole blood) with the average for men being slightly less than women because of the lower female hematocrit.[270] Ethanol is hydrophilic; therefore, this substance distributes easily into total body water with relatively small differences between sampling sites after distribution is complete. However, some differences in postmortem ethanol concentrations between different sampling sites will occur as a result of differences in water distribution from postmortem redistribution (clotting, collapsed vessels). Because ethanol distributes to a greater extent into serum than into red blood cells, the ethanol concentration in blood samples will vary depending on the hematocrit. Hemorrhagic shock increases the blood water content and therefore the blood ethanol concentration as a result of the influx of extracellular fluid and rapid equilibrium of alcohol between liquid and solid parts.[410] However, the correction factor is relatively small (i.e., 80% × normal body water/existing water content). Trauma also potentially complicates the interpretation of intrathoracic ethanol specimens, particularly extensive GI trauma (e.g., aviation accidents). The ethanol concentrations in a majority of transthoracic samples *approximate* the ethanol

concentration in heart blood.[420] However, postmortem diffusion of gastric ethanol during decomposition or direct contamination from a ruptured stomach can falsely elevate the ethanol concentration in transthoracic fluid and heart blood, particular in deaths occurring shortly after a period of heavy ethanol consumption.[421] In a retrospective study of 6,000 postmortem cases, 8 of the 19 cases with BAC >500 mg/dL in heart blood resulted from truncal trauma, aspiration, or postmortem contamination.[422]

Ethanol Production. Fermentation of glucose by certain fungi as well as decomposition of protein by specific bacteria leads to production of ethanol, particularly in anatomic sites with high glucose content (e.g., liver, blood, muscle). Many postmortem blood samples contain large amounts of bacteria or yeast as contaminants, whereas microbial contamination is less common in the intact vitreous humor.[423] Many yeast (*Candida albicans, Saccharomyces cerevisiae*), gram-positive bacteria (*Bacillus* spp., *Staphylococcus aureus*, *Streptococcus faecalis*, α- and β-hemolytic *Streptococcus*, *Clostridium perfringens*) and gram-negative bacteria (*Escherichia coli*, *Proteus vulgaris, Pseudomonas* spp., *Enterobacter* spp., *Klebsiella pneumoniae*) are capable of fermenting carbohydrates (primarily glucose), lactate, glycerol, and amino acids in human blood to form ethanol.[424] Other carbohydrate substrates for postmortem ethanol formation include galactose, maltose, sucrose, and lactose. The combination of abundant bacteria, high glucose concentrations, insufficient preservatives, and prolonged postmortem interval are a factor that favors postmortem formation of ethanol. In postmortem blood samples from a 40-year-old diabetic (vitreous glucose, 996 mg/dL) stored at 4°C (39.2°F) in 0.21% potassium fluoride, the blood ethanol concentration increased from 40 mg/dL on storage day 2 to 350 mg/dL on day 10.[425]

Little ethanol production occurs in corpses stored at low temperature, but the rise in ethanol concentration of putrefying blood reaches a peak within 5–15 days of storage without preservatives at room temperature in association with a rapid decrease in blood glucose concentration.[426] Blood ethanol produced by postmortem decomposition does not usually exceed 50–70 mg/dL unless the body is in advanced stages of putrefaction and/or high glucose concentrations are present along with ethanol-producing microorganisms.[427,428] Analysis of samples from 130 bodies in various stages of putrefaction demonstrated endogenous production of ethanol in 23 bodies.[429] The blood ethanol concentration ranged up to 220 mg/dL with 83% of the samples containing ≤70 mg/dL. In another study of 286 bodies in various stages of putrefaction, the highest ethanol concentra-

tion attributable only to putrefactive production of ethanol was 70 mg/dL, but the ethanol concentration from the combination of endogenous production and exogenous ethanol ranged up to 160 mg/dL.[430] A study of 27 decomposed bodies (9 slight, 9 moderate, 9 severe), the endogenous ethanol concentration in postmortem samples from the chest cavity averaged 31 mg/dL with a range of 8–76 mg/dL.[431]

Abnormal distribution of ethanol between blood sampling sites suggests the possibility of postmortem ethanol formation, whereas relative similarity of ethanol concentrations between various postmortem sampling sites supports the absence of significant amounts of postmortem ethanol formation. The presence or absence of volatiles (e.g., *n*-propanol, isopropanol, *n*-butanol, isobutanol, acetone, acetaldehyde) alone does not provide sufficient information to determine the origin of ethanol in postmortem samples or to exclude endogenous formation of ethanol.[432] In a study of 62 human bodies with water content ranging from 62–86% (mean, 72%), the postmortem blood ethanol concentration increased 0.01 g/kg for each 1 mg/kg increase in the postmortem concentration of *n*-propanol.[410] Most embalming fluids contain methanol rather than ethanol, but the use of ethanol by the embalmer can contaminate postmortem fluids (e.g., vitreous humor).[433] Methanol is not usually formed postmortem by microbial synthesis.[270] Postmortem blood samples from individuals with poorly controlled diabetes should be interpreted cautiously (i.e., with vitreous humor samples) because of the potential of microorganisms to transform high concentrations of blood glucose into ethanol. Postmortem fermentation of glucose to ethanol is highly variable, in part because many microorganisms also consume ethanol. The presence of ethyl glucuronide in the liver helps confirm the antemortem consumption of ethanol.

Fluoride ion, mercuric ion, and cold storage inhibit the formation of ethanol in tissue by microorganisms. The addition of 1% sodium fluoride to tissues from fatal airplane accidents prevented the formation of ethanol in tissue stored at 4°C (39.2°F) and 25°C (77°F) for 96 hours.[434] Within 24 hours of death, little ethanol is formed even at room temperature. No blood specimen from bodies refrigerated within 4 hours of death and stored up to 28 hours contained ethanol concentrations exceeding 10 mg/dL.[435] Criteria suggestive for endogenous ethanol production include the following: 1) presence of ethanol only in blood or chest fluid samples, 2) atypical distribution of ethanol among several body fluids, 3) reliable historical information, and 4) the presence of high concentrations of other low-molecular-weight alcohols (*n*-butanol, *n*-propanol).[430] Fatty acid ethyl esters are esterification products of ethanol and

fatty acids, and these compounds are present in the blood for up to approximately 24 hours after the ingestion of ethanol. The presence of >10,000 pmol fatty acid ethyl esters/g liver helps confirm the antemortem ingestion of ethanol.[436]

Ethanol Diffusion. In general, case series of postmortem ethanol specimens indicate that the mean ethanol concentration is similar between different sites in the body (e.g., femoral, heart blood, central veins, aorta).[437,438] However, on an individual basis there can be substantial variation between different sampling sites, particularly if ethanol is present in the stomach at the time of death.[439] Large variations (>50%) between postmortem ethanol concentrations in femoral and central (e.g., heart, aorta, chest) samples develop most often when the stomach contains an ethanol concentration >500–800 mg/dL or aspiration of stomach contents has occurred.[440] These conditions usually result from the ingestion of ethanol within 1 hour of death. Potential contamination of heart blood with ethanol results from inadvertent puncture of the stomach depending on the presence of high concentrations of ethanol in the stomach and diffusion of decomposing chest fluid from sources near the stomach. In a study of multiple sampling sites in 61 cadavers, there was >25% variation in the blood ethanol concentration between different sampling sites in 33% of the cadavers, particularly when the ethanol concentration in the stomach exceeded 500 mg/dL.[441] Pleural or pericardial samples may contain ethanol concentrations up to 190 mg/dL higher than those of the corresponding femoral blood samples because ethanol can diffuse from the stomach into the pericardium.[442] The presence of ethanol concentrations in blood below 50 mg/dL suggests that the gastric diffusion of ethanol is relatively small, particularly in peripheral samples.[443] Postmortem blood circulation patterns may alter the ethanol concentration both in peripheral and central sampling sites as a result of changes in water content.[441] Additionally, collection techniques may account for some of the differences between collection sites. The collection of low volume-blood samples in fluoride-containing containers usually produces lower blood ethanol concentrations when compared with companion specimens of larger volume specimens unless special techniques are employed (e.g., saturation of the blood sample with excess sodium chloride) when measured by headspace gas chromatography.[438] Fatalities from drowning in sea water can exacerbate differences in postmortem ethanol concentrations between right heart or femoral blood and left heart blood as a result of changes in tonicity of blood in the lungs and GI tract, particularly after antemortem and postmortem aspiration.[444]

VITREOUS HUMOR.   The use of vitreous humor for post-mortem ethanol analysis helps distinguish endogenous from exogenous ethanol sources because microbial infiltration of the vitreous humor occurs late in the time course of the putrefaction process, provided that the globe remains intact.[429] Anatomically, the vitreous humor is relatively protected from trauma. This clear, serous fluid demonstrates good chemical stability because of the protected position of the vitreous humor and the relative resistance to postmortem ethanol formation.

Ethanol.   Typically, the BAC is less than the concentration of ethanol in vitreous humor unless death occurred before steady-state equilibrium of ethanol, postmortem ethanol formation developed in blood, or the sample was contaminated internally by trauma or externally by ethanol.[445] The absence of ethanol in vitreous humor specimens and the presence of ethanol in postmortem blood samples suggest the postmortem formation of ethanol. In a retrospective review of nonpreserved specimens from 347 cases, almost all (99%) of blood samples with BAC >50 mg/dL had detectable quantities of ethanol in vitreous humor samples.[446] The highest BAC with a nondetectable concentration of ethanol in vitreous humor was 120 mg/dL. The presence of other putrefactive products (e.g., *n*-propanol, *n*-butanol) in the vitreous helps confirm the endogenous postmortem production of ethanol.[447] Factors other than endogenous ethanol formation that account for substantial differences (postmortem blood > vitreous ethanol concentrations) include contamination of the blood sample prior to collection, diffusion of ethanol from the stomach into surrounding tissue, and the ingestion of large doses of ethanol immediately prior to death.[448]

Blood/Vitreous Ethanol Ratio.   Based on the ratio of water content between blood and vitreous, the theoretical ethanol blood/vitreous ratio is approximately 0.79, assuming full distribution of ethanol at the time of death and the absence of postmortem ethanol formation or diffusion.[419] Early forensic literature suggested a conversion factor for the blood/vitreous humor ethanol ratio (± SD) ranging from 0.72 ± 0.09[449] to 1.01 ± 0.04.[450] Correlation of the blood ethanol concentration to the vitreous humor ethanol concentration decreases as the blood ethanol concentration exceeds 200 mg/dL even during the postabsorptive phase.[451] Although analysis of vitreous humor samples helps confirm the presence of exogenous sources of ethanol in the blood, the variation of the vitreous/blood ratio is too large to accurately predict blood ethanol concentrations from vitreous humor samples alone.[452] In a study of 349 cases involving the collection of postmortem vitreous humor and blood samples, regression analysis suggested that a vitreous humor ethanol concentration >150 mg/dL was necessary to predict a blood ethanol concentration of 80 mg/dL with 95% certainty.[453] In a study of 706 forensic necropsies, the median femoral blood/vitreous humor ratio was 0.847 (95% CI: 0.52–1.63).[452]

The blood/vitreous humor ratio depends on the phase of the blood ethanol curve at the time of death. During the early absorption phase (urine/blood ethanol ratio <1.20), the blood/vitreous ratios demonstrate large variation as the ethanol content of vitreous fluid lags behind the ethanol concentration in blood. A urine/blood ethanol ratio of <1.2 suggests that death occurred during the early absorption phase, whereas a urine/blood ethanol ratio >1.33 indicates that death occurred during the elimination phase.[454] Using the urine/blood ethanol ratio of <1.2 as indicating the early absorptive phase, the blood/vitreous humor ethanol ratio during this period in 200 postmortem specimens averaged 1.21 ± 0.45 (range, 0.84–3.07).[455] During the late absorption and elimination phase (urine/blood ethanol ratio >1.20), the mean blood/vitreous ethanol ratio was 0.84 ± 0.15 (range, 0.43–1.21). A blood/vitreous ethanol ratio exceeding unity suggests that death occurred during the absorptive phase.[454] However, both the standard deviation (0.57) and the range (0.71–3.7) were large for the blood/vitreous humor ethanol ratio, and this range overlapped the range (0.32–1.28) for the late absorptive and elimination phases. Consequently, the blood/vitreous humor ethanol ratio helps confirm the phase of ethanol distribution, but this ratio alone does not prove when death occurred in relation to the blood alcohol curve.

Ethyl Glucuronide.   In general, the concentration of ethyl glucuronide in vitreous is lower than urine and blood.[456] Because vitreous is relatively protected from bacterial contamination, the presence of ethyl glucuronide in vitreous is an aid to determine the occurrence of antemortem drinking, depending on the time and amount of drinking prior to death. However, both false-positive and false-negatives may occur,[301,457] and the vitreous ethyl glucuronide concentration must be interpreted along with the BAC, ethyl sulfate, the medical history, and the circumstances surrounding the death.

URINE.
Urine/Blood Ethanol Ratio.   Compared with ethanol biotransformation, the urinary excretion of unchanged ethanol is relatively small with renal excretion of unchanged ethanol accounting for about 0.5–10% of the ethanol dose. The ingestion of ethanol produces a temporary increase in urine flow, and volunteer studies indi-

cate the maximum diuresis in healthy adults occurs during the absorptive phase (i.e., <1–2 hours after drinking ceases).[93] Based on comparative water content, the urine/blood ethanol ratio is about 1.23–1.33.[458,459] The actual ratio depends on the average BAC during the time of the collection of the urine in the bladder.

Fresh–Voided Specimens. The accuracy of estimating the BAC from the UAC in antemortem samples is controversial. For the estimation of BAC, the first voided specimen is discarded and a second urine sample obtained 30–60 minutes after emptying the bladder. The ethanol concentration in this second void is used to estimate the BAC using a UAC/BAC ratio of 1.3.[460] Generally, during the postabsorptive phase, the urine ethanol concentration exceeds the BAC. Therefore, a urine/blood ethanol ratio ≥1.3 in a fresh-voided specimen indicates that drinking occurred at least 1–2 hours prior to the collection of the fresh-voided sample.[461]

The validity of this estimate depends, in part, on the phase of ethanol absorption. Although wide variation exists between individuals, volunteer studies in healthy adults suggest, but do not prove, that a UAC/BAC ratio <1.0–1.2 indicates continuing ethanol absorption.[462] A UAC/BAC >1.3 suggests the sample was obtained during the postabsorptive phase. The combination of UAC/BAC >1.3 and decreasing UAC in 2 successive urine samples indicates that the ingestion of ethanol within 1–2 hours of the sample is unlikely. The postsampling formation of ethanol in urine complicates the interpretation of the UAC/BAC ratio in diabetics and in patients with urinary tract infections.[463,464] Incomplete emptying of the bladder also complicates the interpretation of the UAC/BAC ratio, depending on the amount of urinary retention. Correction of the urine sample for dilution using the urine creatinine or specific gravity is not necessary because experimental studies indicate that the urine creatinine does not correlate to the UAC or to the UAC/BAC ratio.[458]

Postmortem Specimens. Postmortem urine samples represent pooled bladder specimens; therefore, the postmortem urine ethanol concentrations (UAC) do not necessarily correlate to the BAC at the time of death. Although the average urine/blood ratio of ethanol in autopsy cases frequently average about 1.3:1, the range is usually large; therefore, correlations between postmortem BAC and urine ethanol concentrations is usually low.[465] Analysis of UAC and BAC obtained simultaneously from postmortem specimens demonstrated a mean UAC/BAC ratio of 1.28 (95 % CI: 0.36–2.20).[466] Using a urine/heart blood conversion factor of 1.28, only 44 % of the 148 autopsy cases had <20 mg/dL

difference between the calculated and actual BAC. Consequently, the main value of postmortem UAC is the determination of the likelihood of postmortem ethanol changes in blood. Postmortem fermentation occurs much later in the bladder than in the blood as long as the urine does not contain high concentrations of glucose (i.e., as in diabetes). A large discrepancy between the BAC and UAC suggests postmortem ethanol formation, particularly if death occurred during the postabsorptive phase (i.e., low ethanol concentrations in gastric contents).[467]

Ethyl Glucuronide. The rapid elimination of ethanol results in the disappearance of ethanol within 12 hours in the plasma and slightly longer in the urine. Ethyl glucuronide is a potential biomarker of recent ethanol ingestion that remains measurable in urine samples longer than ethanol.[468,469] However, back-extrapolation of urine ethyl glucuronide concentrations to blood ethanol concentrations or levels of impairment is inaccurate. Hence, urine ethyl glucuronide concentrations indicate prior ethanol exposure rather than the ethanol dose or impairment. This minor, nonoxidative metabolite of ethanol is a nonvolatile, acidic, water-soluble substance that forms during phase II reactions by uridine diphosphate-glucuronosyltransferase (UGT). *In vitro* studies indicate that multiple UGT isoforms catalyze the addition of glucuronic acid to ethanol with UGT1A1 and UGT2B7 being the 2 most prevalent isoforms;[470] however, the involvement of multiple UGT isoforms limits the forensic consequence of polymorphism with UGT1A1.[471] In a study of 10 male volunteers receiving 0.5 g ethanol/kg, the median excretion of ethyl glucuronide over about 2 days was 0.017% of the administered dose.[472] Pharmacokinetic studies indicate that ethyl glucuronide does not accumulate in urine following repeated dermal or oral exposures. In a study of 9 female volunteers receiving 0.4 g ethanol/kg twice daily for 8 days, no significant accumulation of ethyl glucuronide occurred in urine samples.[473]

Detection Times. Urinary ethyl glucuronide concentrations are detectable within 1 hour after ethanol ingestion and for at least 6–10 hours and longer after blood ethanol concentrations are undetectable depending on the ethanol dose, urine specific gravity, individual variation, timing of previous drinking, and the sensitivity of the test (i.e., cutoff concentrations).[474] Volunteer studies indicate that detection of ethyl glucuronide in oral fluid is only a few hours longer than ethanol; therefore, analysis of ethyl glucuronide in urine is superior to oral fluid for detection of ethanol use.[475] In a volunteer study, the peak urine concentration of ethyl glucuronide occurred about 2–3.5 hours after the peak ethanol

concentration.[476] The presence of ≥100 ng ethyl glucuronide/mL indicates ethanol exposure within the previous 3–4 days.

Nineteen volunteers were divided into low dose (1.4 standard drinks), medium dose (2.9 standard drinks), and high dose (4.3 standard drinks) groups.[477] At 24-hours postingestion, all urine samples were positive for ethyl glucuronide in the high-dose group, whereas ethyl glucuronide was not detectable in the urine samples from the low-dose group as measured by liquid chromatography/tandem mass spectrometry (cutoff, 100 ng/mL). All urine samples obtained 48 hours after ethanol ingestion contained no detectable amounts of ethyl glucuronide. In a study of volunteer students ingesting an average of about 9 standard drinks based on questionnaire data, 100% were positive for ethyl glucuronide in urine samples 40 hours after the last drink, 77% of the urine samples were positive for ethyl glucuronide at 54 hours, and 18% at 78 hours after the last drink as measured by liquid chromatography/tandem mass spectrometry (cutoff, 100 ng/mL).[478] The students ingested ethanol in various drinks (wine, beer, spirits) over a 6-hour meeting; ethanol was nondetectable in all blood samples 15 hours after the last reported drink. Ethyl glucuronide was not detectable in all urine samples at 103.5 hours postingestion. In general, the elimination half-lives of ethyl glucuronide in social and heavy drinkers are similar, depending on renal function. In a study of 16 alcohol abusers admitted to an alcohol withdrawal clinic, the median elimination half-life of ethyl glucuronide in their blood samples was 3.3 hours (range, 2.6–4.3 hours).[479] In a study of 32 alcohol dependent patients undergoing detoxification with initial breath ethanol concentrations from 100–340 mg/dL, the median time for urinary ethyl glucuronide concentrations to drop below the cutoff (<0.5 mg/L) was 78 hours (range, ~40–130 hours).[480] The median urinary detection time for ethyl glucuronide after the estimated zero ethanol concentration was 66 hours (range, ~30–110 hours) compared with 56 hours (range, ~30–70 hours) for the urine concentration adjusting for relative dilution. The cutoffs were 0.5 mg/L and 0.5 mg/g creatinine, respectively.

Sensitivity/Specificity.   The presence of ethyl glucuronide in the urine is not a unique biomarker of recent ethanol ingestion as a result of the high sensitivity of this biomarker to trivial quantities of ethanol. Small quantities of ethyl glucuronide (i.e., <120 ng/mL) may appear in the urine as a result of unrecognized ethanol exposure (e.g., mouthwash, nonalcoholic wine, cough medication, cosmetics, etc.) or endogenous ethanol metabolism. The presence of ethyl glucuronide must be interpreted cautiously because of the occurrence of false-positive as well as false-negative reactions.[481,482] The former occurs following exposure to ethanol-containing products or after bacterial or yeast contamination that produces ethyl glucuronide, particular when the sample contains *E. coli* and glucose.[483] Case reports indicate that false-positive results may result from the absorption of ethanol from mouthwash or ethanol-containing hand sanitizer.[484] In a study of 9 volunteers, gargling 4 ounces of 12% ethanol-containing mouthwash over 15 minutes, 39 urine samples were collected during the first 24 hours after gargling.[485] Twenty of these urine samples had ethyl glucuronide concentrations over 50 ng/mL and 12 samples contained ethyl glucuronide concentrations exceeding 100 ng/mL. In a drinking study of 12 volunteers ingesting 1 g or 3 g ethanol, the maximum ethyl glucuronide concentration in urine normalized to creatine was 320 ng/mL and 1,530 ng/mL, respectively.[486] The estimated ingestion of ethanol in food and nonalcoholic beverages is <1 g compared with 1–2 g for ingesting 10–20 mL of mouthwash containing 12% ethanol. There was substantial interindividual variation in the urinary excretion of ethyl glucuronide during this study. Following repetitive daily dermal exposure to hand sanitizer (60% ethanol) by 9 adults, the ethyl glucuronide concentrations in 88 first-morning void urine samples ranged from <10–114 ng/mL.[487] False-negative results may occur as a result of the hydrolysis of ethyl glucuronide by strains of β-glucuronidase-containing *E. coli* that contaminate urine samples. Additionally, the sensitivity of this biomarker decreases significantly in dilute urine when substantial amounts of water are ingested within 1 hour of sampling.[488] False-negative results may occur during analysis of dilute urine samples (e.g., urine creatinine <25 mg/dL); normalization of the urine ethyl glucuronide to urine creatinine (e.g., 100 mg/dL) eliminates the effect of urine dilution on the sensitivity of the urine ethyl glucuronide analysis.[489]

Postmortem.   The presence of ethyl glucuronide in postmortem urine suggests recent ethanol consumption, but does not necessarily prove that a person died with a high blood ethanol concentration. Ethyl glucuronide is stable in urine samples stored at room temperature at least 4 days. Although *in vitro* formation of ethanol occurs as result of the fermentation of glucose, particularly in those with diabetes, formation of ethyl glucuronide does not result from glucose fermentation.[490] This biomarker along with increased ratio of 5-hydroxytryptophol/5-hydroxyindole-3-acetic acid can help to distinguish recent ethanol ingestion from postmortem ethanol artifacts.[491,492] Case reports suggest that ethyl glucuronide (and ethyl sulfate) does not form during the putrefaction process; these compounds may

persist for years in mummified corpses (i.e., without preservation) despite some postmortem hydrolysis during the putrefaction process.[493]

Serum Ethanol/ Ethyl Glucuronide Ratio.   In a study of 10 male volunteers consuming 0.5 g ethanol/kg body weight in a fasted state, the median peak serum ethanol ethyl glucuronide concentrations occurred about 4 hours (range, 3.5–5.0 hours) after ingestion, whereas the median peak ethanol in blood was 1 hour (range, 0.5–2.0 hours).[472] The blood ethanol/ethyl glucuronide ratio as measured in g/L and mg/L, respectively, was >1 for the first 3.5 hours after drinking (range 2.5–3.5). Thus, a ratio above 1 suggests drinking < 3.5 hours before sampling, whereas a ratio less than 1 suggests drinking > 2.5 hours before sampling. The ingestion of multiple doses of ethanol complicates the interpretation of this ratio.

Ethyl Sulfate.   Ethyl sulfate is another minor, water-soluble metabolite of ethanol that is a potential biomarker of ethanol ingestion; this metabolite is formed during phase II reactions by sulfotransferase (SULT). The median times of occurrence and ranges for ethyl sulfate and ethyl glucuronide concentrations in urine following ethanol consumption are similar.[480] Ethyl sulfate is less susceptible to postsampling formation than ethyl glucuronide but there is less kinetic data for ethyl sulfate compared with ethyl glucuronide.[494]

Serotonin Metabolites.   Ethanol alters serotonin metabolism by 1) decreasing the reduction of the intermediate serotonin metabolite, 5-hydroxyindole-3-acetaldehyde (5-HIAL) to 5-hydroxyindole-3-acetic acid (5-HTOL) and 2) increasing the oxidation of 5-HIAL to 5-hydroxytryptophol (5-HIAA).[495] The ratio, 5-HTOL/5-HIAA, remains elevated 5–15 hours after the elimination of ethanol from the body depending on the ethanol dose.[496] Consequently, a 5-HTOL/5-HIAA ratio exceeding 15 pmol/nmol is not definitive proof of the presence of ethanol at the time of death. A 5-HTOL/5-HIAA ratio below 15 pmol/nmol indicates that the consumption of ethanol is unlikely within about 24 hours prior to the collection of the urine sample.[497] This change in the 5-HTOL/5-HIAA ratio is probably not affected by the use of selective serotonin reuptake inhibitors or the consumption of serotonin rich foods.[498]

LIVER.   At equilibrium, the ethanol concentration is lower in liver tissue than in blood as a result of the relatively lower water content of the liver. In a case series of 10 deaths attributed to acute ethanol intoxication, the liver/blood ratio was 0.60 ± 0.056 (range, 0.54–0.72).[502] The average liver/heart blood ratio in 71 postmortem samples that contained heart blood concentrations exceeding

40 mg/dL was 0.56 ± 0.30 (range, 0–1.40).[308] The presence of ethanol in the liver in the absence of detectable concentrations of ethanol in the vitreous humor and the urine suggests postmortem ethanol formation.

BILE.   The gallbladder in relatively well protected from trauma and this organ usually remains free of contamination, even in violent deaths. In general, the postmortem blood and bile concentrations are similar.[499] Typically, mean postmortem blood/bile ratio is about 0.92–1.10. In a study of autopsied cases without thoracic or GI trauma, 19 paired heart blood and bile samples yielded a mean blood/bile ratio of 1.09 (range, 0.56–1.54).[422] A study of ethanol concentrations in 33 cadavers demonstrated a mean heart or aorta blood/bile ratio of 1.01 ± 0.19 (range, 0.44–1.40).[304] In a study of specimens from 189 cadavers, the mean heart or aorta blood/bile ratio was 1.03 (range, 0.32–2.91).[500] The wide variation in the blood/bile ratio for ethanol concentration limits the reliability of the extrapolation of bile ethanol concentrations to blood ethanol concentrations. The correlation of ethanol concentrations in simultaneous blood and bile samples improves when the blood ethanol concentration exceeds 100 mg/dL.[501] Bile ethanol concentrations exceeding 175 mg/dL suggest that blood ethanol concentrations exceed 150 mg/dL, whereas bile ethanol concentrations below 50 mg/dL usually correlate to blood ethanol concentration below 100 mg/dL. Extrapolation of blood/bile ratios for determining blood ethanol concentrations improves substantially when death occurs immediately (i.e., 30 minutes) after an incident and no drinking occurred shortly (i.e., 30 minutes) before the incident. The presence of high ethanol concentrations in bile compared with other sampling sites (e.g., blood) suggests that death occurred rapidly after ethanol ingestion.[502,503] The presence of a substantially lower postmortem ethanol concentration in blood than in bile also suggests the possibility of metabolism of blood ethanol shortly before death. However, there are inadequate data to determine the ethanol time-concentration curve for bile after ethanol ingestion.

Abnormalities

ACUTE INGESTION

The acute ingestion of large doses of ethanol produces an increase in serum osmolality along with a fall in the concentration of plasma vasopressin and an increase in free water clearance. In a volunteer study of 6 men ingesting 3.3 L of beer over 3 hours, the changes in water balance included a small decrease in the plasma concentrations of urea and creatinine as well as a mild rise in plasma potassium.[504] Under these experimental

conditions, there was no hypoglycemia or significant increase in serum transaminase, creatine kinase, or γ-glutamyl transferase. Acute ethanol ingestion by itself does not usually produce dehydration or electrolyte imbalance, and the presence of laboratory abnormalities consistent with dehydration indicates the presence of a condition (e.g., reduced fluid intake, vomiting, pancreatitis) other than acute ethanol intoxication.[505]

Serum Osmolality.   Osmolality (osmoles per kilogram solvent) and osmolarity (osmoles per liter of solution) are the number of particles dissolved in solution, and the osmolal gap is a rapid approximation of the unmeasured, osmotically active constituents.[506] Equation 21.9 approximates the serum osmolarity (O_C) based on the concentrations of sodium, glucose, and blood urea nitrogen (BUN) in traditional units including correction of the serum water fraction (i.e., assumed to be 93% in healthy individuals). The correction factor for traditional units is the BUN concentration in mg/dL divided by 2.8 and the glucose concentration in mg/dL divided by 18,

$$O_C = 2[\text{Na}^+ \text{ in meq/L}] + 0.39[\text{BUN in mg/dL}] + 0.059 \text{ [glucose in mg/dL]}$$

(Equation 21.9)

where O_C = Calculated osmolarity.

The measured osmolality (O_M) is normally about 270–290 mOsm/kg H_2O, and the difference between the measured osmolality and the calculated osmolality is the osmolal gap. Freezing point depression is the method of choice for the determination of osmolality because the vapor pressure method underestimates the contribution of volatile alcohols.[507,508] Equation 21.10 calculates the osmolal gap (O_G), which usually ranges from 10–15 mOsm/kg H_2O depending on the variability of the reference ranges and coefficients of variation for the specific laboratory instruments.[509]

$$O_G = O_M - O_C$$ (Equation 21.10)

The presence of an elevated osmolal gap suggests the presence of significant concentrations of osmotically active compounds (ethylene glycol, propylene glycol, methanol, ethanol, isopropanol, acetone). The ingestion of ethanol causes an increase in the osmolal gap. For each milligram of ethanol per deciliter, the osmolal gap rises by about 0.22 mOsm. An ethanol concentration of 100 mg/dL raises the osmolal gap approximately 22 mOsm/kg H_2O, whereas serum ethanol concentrations of 300 mg/dL result in an osmolal gap of about 66 mOsm/kg H_2O. Serum osmolal gaps are screening measures for the presence of selected osmotically active constituents rather than estimates of serum ethanol concentrations. A discrepancy between serum osmolality and serum ethanol concentration suggests, but does not confirm, the presence of other osmotically active solvents. In the absence of an increased osmolal gap, ethanol is an unlikely cause of coma and other causes of coma should be considered (e.g., subdural hematoma, stroke, another CNS depressant drug). Nonethanol-related causes for elevated osmolal gaps include the presence of fructose, glycerin, IVP dye (diatrizoate), mannitol, propylene glycol, sorbitol, and alcoholic ketoacidosis.[510] Occasionally, alcoholic ketoacidosis may cause a high anion gap metabolic acidosis and markedly increased serum osmolal gap in the absence of detectable concentrations of ethanol.[511] This metabolic pattern may be misdiagnosed as ethylene glycol or methanol poisoning in chronic alcohol abusers as a result of the formation of high concentrations of acetone and other ketone bodies (acetoacetate, β-hydroxybutyrate) during alcoholic ketoacidosis.

Hypoglycemia.   Ethanol-induced hypoglycemia occurs during ethanol intoxication, particularly in children under the age of 5 years,[512] but this laboratory abnormality is a relatively uncommon occurrence.[513,514] In a study of 143 children under the age of 14 years admitted for acute alcohol intoxication, 12% of the children developed hypoglycemia.[515] The vast majority of these children were under 5 years of age. The severity of the hypoglycemia is not necessarily related to the quantity of alcohol ingested. Clinically significant hypoglycemia is rare during ethanol intoxication in older children, and the biochemical disturbances associated with ethanol intoxication in children aged 11–16 years old and adults are similar. In a series of 268 children (8–16 years) hospitalized for ethanol intoxication, there were no cases of severe hypoglycemia.[516] Other laboratory abnormalities associated with ethanol intoxication in adolescents include mild hypokalemia and mild respiratory acidosis.[517]

Chronic Ethanol Abuse

Alcohol dependence and alcohol dependent liver disease produce a variety of laboratory abnormalities including hypoalbuminemia, mild to moderate serum hepatic aminotransferase elevation, hyperbilirubinemia (primarily unconjugated), low BUN, and a prolonged prothrombin time depending on the severity of hepatic impairment.[186] Hypoalbuminemia results from protein malnutrition, malabsorption, albuminuria, loss into the peritoneal space, and impaired hepatic production. Typically, serum electrophoresis demonstrates a decrease in the albumin and prealbumin along with a

broad elevation of the β- and γ-globulins and occasionally elevation of IgA, IgG, and IgM. Failure of the prothrombin time to respond to vitamin K indicates serious hepatic damage.[518] Even during alcoholic hepatitis, the elevation of hepatic aminotransferase concentrations is usually mild to moderate (<10 times normal), and a >10-fold increase in these enzymes suggests another cause (viral, drug, toxin).[519] The serum AST is typically elevated to a greater degree than the ALT with a ratio of approximately 1.5–2.0 in alcoholic liver disease. The presence of an AST/ALT ratio <1 suggests, but does not necessarily indicate another cause of hepatocellular disease.[520] Common electrolyte disorders, particularly in alcoholic cirrhosis, include hyponatremia, hypokalemia, hypophosphatemia, and hypomagnesemia. Hyperuricemia occurs following acute ethanol intoxication as well as long-term ethanol abuse.[521]

Metabolic acidosis in an alcohol abuser may also be associated with uremia, diabetic ketoacidosis, lactic acidosis, alcoholic ketoacidosis, or fructose therapy. Alcoholic ketosis (acetoacetate, β-hydroxybutyrate) typically occurs in a alcohol dependent patients, who stops drinking after a heavy binge. β-Hydroxybutyrate is usually elevated disproportionally to acetoacetate, and the nitroprusside reaction may not be strongly positive despite large amounts of ketones because this reaction is relatively insensitive to β-hydroxybutyrate. The ketosis is not usually severe, and a metabolic acidosis may not be present. Patients with alcoholic ketoacidosis usually have low or nondetectable concentrations of ethanol, normal or low blood glucose, urinary ketones, and normal or moderately elevated urea and creatinine, whereas alcohol dependent patients with lactic acidosis typically have elevated serum ethanol concentrations along with an increased risk of sepsis, seizures, thiamine deficiency, or severe impaired liver function.[522] The metabolic acidosis with ethylene glycol, methanol, or paraldehyde occurs after the elimination of ethanol from the blood and the restoration of alcohol dehydrogenase function. A hypochloremic metabolic alkalosis may result from volume depletion and loss of hydrochloric acid from vomiting. Anemia occurs commonly in alcohol dependent patients, and mild macrocytosis (mean corpuscular volume 100–110) develops in about one-half of alcohol dependent patients after several months of heavy drinking.[523] Causes of anemia in alcohol abusers include anemia of chronic disease, folate deficiency, sideroblastic anemia, and GI bleeding.

WITHDRAWAL

Risk factors for alcohol-related seizures include hypoglycemia, electrolyte disturbances, intracranial hemorrhage, CNS infection, illicit drug use, isoniazid toxicity, prior withdrawal seizures, multiple previous detoxifications, and high total ethanol consumption. The electroencephalogram helps separate alcohol withdrawal seizures from epilepsy. The typical pattern in the former is a normal low-amplitude recording, whereas generalized spike and wave points occur with epilepsy.[524] However, the predictive value of a normal electroencephalogram in this setting is limited.

Driving

Driving involves a variety of behavioral and psychomotor tasks including perception (visual acuity, depth perception, glare recovery), divided attention, information processing, sensory and motor skills (coordination, reaction time, steering, tracking, maintenance of speed, and braking), and judgment. Driving is a monotonous task interrupted by unpredictable demands on decision-making and reactions. The threshold of impairment, as defined by changes from baseline measurements of psychomotor testing, depends on the type of testing and the specific body function tested as well as the BAC. Because driving is a complex task, no single psychomotor test provides valid information to determine the causal role of ethanol in driving accidents. All behavioral skills are not equally impaired by the same dose of ethanol, and there are gender differences in some psychomotor skills (choice reaction time, tracking).[525] In general, tests of simple sensory and motor tasks (e.g., visual acuity, brightness thresholds, tracking, braking) demonstrate little impairment at BAC <80–100 mg/dL, particularly in experienced drinkers with good psychomotor skills.[58,526] Psychomotor testing indicates impairment at BAC <100 mg/dL on complex tasks (e.g., processing and acquisition of information, performance on divided-attention tasks, judgment). However, biologic differences between individuals cause some overlap in performance measures at different ethanol concentrations.[527] The magnitude of the decrements in performance on psychomotor tests depends on a variety of factors, including the type of test, the specific BAC, and the phase of the BAC curve. In general, impairment is greater on the ascending than the descending BAC curve (i.e., Mellanby effect), but the differences are usually relatively small (<20%) and not all cognitive tasks are similarly affected.[528,529] Above a BAC of 100 mg/dL impairment of almost all driving skills occurs, and the relative risk of an accident increases dramatically when the BAC reaches or exceeds this concentration.[530]

SENSORY, MOTOR, AND COGNITIVE TASKS

Driving involves a variety of behavioral and psychomotor skills that are sensitive to the effects of ethanol, but

there are limited data on which impairments (e.g., reaction times, tracking errors, psychomotor skills, vigilance, perceptual speed) cause an increase in the risk of vehicular accidents. Typically, the ethanol-related accidents involve a single vehicle leaving the road. Intoxicated drivers are also frequently involved in rear-end and head-on crashes. These types of crashes suggest the presence of reduced alertness, decreased attentiveness, and impaired tracking abilities. Driving is primarily a monotonous visuomotor task with visual input accounting for about 90% of information received by the driver.[531] Correlating a BAC to a specific level of impairment is complicated by the wide range of BAC and individual variation in most studies; however, there is a progressive impairment with increasing BAC. Modest impairment in some psychomotor tasks does correlate selectively to BAC <100 mg/dL; above this range, the number of tasks and degree of impairment progressively increases.

VISION.   Ethanol intoxication has negative effects on visual perception and eye movements at BAC concentrations up to 100 mg/dL, primarily involving central information processing rather than sensory receptors.[532] Not all visual functions are equally sensitive to the effects of ethanol in the range of 80–100 mg/dL. In general, ethanol concentrations near this range decrease contrast sensitivity modestly (10–20%), but visual acuity, color vision, accommodation (near vision), and perception of motion are relatively unaffected.[533] Studies on the effect of ethanol in this range on stereoacuity (i.e., smallest detectable difference in images presented to both eyes) and binocular vision (i.e., ability to use both eyes to fuse slightly dissimilar objects) is inconsistent. A variety of environmental factors add to the visual impairment caused by ethanol including weather (fog, rain, snow, dust, fog), illumination during twilight or night, local obstructions (foliage, buildings, cars, curves in the road), objects in the car (dirty windshield), and speed. The latter effects result from the reduction of peripheral visual input as the driver looks progressively ahead as the speed of the car increases.[534] As the BAC increases above 100 mg/dL, the number of impaired visual functions and the degree of impairment increases. There are limited data on the effect of BAC in the range of 125 mg/dL and above because of ethical constraints. Existing data indicates that most visual functions are impaired significantly in this range including visual acuity, eye movements, depth perception and distance judgment, glare recovery, and peripheral vision; however, there is some interindividual variation.[535] The baseline visual acuity also affects the visual field and the individual's ability to detect objects ahead of the vehicle. An individual with 20/20 vision driving at 60 mph requires

3.9 seconds to read a highway sign with 6-inch letters; whereas the time to read the sign decreases to 1.95 seconds and 0.78 seconds when the baseline visual acuity is 20/40 and 20/100, respectively.[536] Substantially more illumination is necessary at night to read these signs as 20/40 vision during the day is equivalent to 20/100 at night; the effect of ethanol on visual acuity is relatively greater under twilight conditions compared with daytime lighting conditions.[537]

Visual Acuity.   Visual acuity is the ability to resolve fine detail. Although visual acuity depends on a variety of variables (e.g., luminance, pupil size, eye movements, accommodation, chromatic aberrations, contrast, motivation/attention), experimental studies typically measure visual acuity in high-contrast environments. Dynamic visual acuity task determines the number of correct responses to the detection of the direction of a broken circle on a moving screen. Within 1 second of the target sweep, the participant must indicate the orientation of the missing arch from the circle. The visual near point is the distance at which an individual begins to lose focus on a visual cue (e.g., card). In general, low to moderate doses of ethanol (BAC <100 mg/dL) do not substantially impair optometric visual function (e.g., visual acuity, color vision, dark adaption, perception of motion, accommodation, peripheral vision).[538] In experimental studies, minor decrements in visual acuity occurred in individuals with BAC 100–125 mg/dL.[539] Some loss of near vision (accommodation, convergence) occurs as the BAC increases above 100–125 mg/dL.[532] Experimental studies suggest that low doses of ethanol (<70 mg/dL) do not significantly alter the perception of velocity.[540] At BAC concentrations in the range of 80–100 mg/dL, lighting conditions do not affect driving skills associated with simulated driving tests.[541] Motion parallax is the ability to recover depth from retinal motion generated by observer translation. The visual perception of depth depends on motion parallax to determine the relative positions and direction of obstacles in the visual field. In a repeat measures within-participants study of 15 paid volunteers, the average observer threshold for motion parallax was significantly higher ($P = .004$) in the intoxicated state compared with the sober state.[542] The mean BrAC at the beginning of testing was 0.085% (range, 0.07–0.14%). However, there was wide interparticipant variability with no difference in the threshold for motion parallax for the intoxicated and sober states in 5 participants. Depth perception as measured by thresholds for binocular stereopsis was unaffected in this study, whereas perception of depth from motion parallax that relies on slow eye movements was affected.

The critical fusion frequency (CFF) test determines the threshold (i.e., highest frequency) at which an individual ceases to perceive the flickering of a flashing light and sees the flashing light as a continuous source; the critical flicker frequency test requires judgment about whether the frequency of a flickering light is increasing or steady. Reduction in critical fusion frequency (CFF) suggests impairment of visual temporal processing. CFF is the temporal analogue of spacial resolution acuity. Visual acuity and CFF provide information about the detection of fine detail and rapidly changing targets. The critical flicker fusion test is relatively insensitive to BAC <100 mg/dL.

Contrast/Glare Recovery.   Contrast sensitivity involves distinguishing spatially distinct differences in luminance over a range of different spatial frequencies; in contrast to visual acuity, contrast sensitivity measures visual process in low-contrast situations. The testing of contrast sensitivity involves the use of a series of light and dark bars (i.e., grating pattern) with modulating luminance profiles. Contrast sensitivity is the reciprocal of the lowest detectable level of contrast; higher values mean greater contrast sensitivity. Experimental studies suggest that the consumption of ethanol delays light adaptation and reduces contrast sensitivity after intense light exposure,[543,544] but the dose response of this effect is not well defined.[545] In general, changes in contrast sensitivity are relatively small to nondetectable at BAC below 80–100 mg/dL, depending on testing of static or dynamic conditions.[546] In a crossover, controlled study of 20 individuals studied with and without ethanol, the mean contrast sensitivity for stationary sine wave grating decreased about 8% under white light conditions.[547] The projected ethanol concentration during testing was 80 mg/dL, but no confirmation of ethanol concentrations was reported.

In a crossover study of 12 healthy volunteers, the reduction in contrast sensitivity in the intoxicated state was about 2½ times greater during the testing of moving gratings of high spatial frequency (-0.29 log-unit) than for stationary gratings (-0.11 log-unit); for the moving gratings, the reduction was <10–15% of baseline.[548] The estimated BAC was 100 mg/dL based on the ingestion of 1.4 mL 95% grain ethanol/kg body weight, but the actual BAC was not measured. The estimated mean BAC was 88 mg/dL; the estimated BAC correlated to the dynamic contrast sensitivity, but not the static contrast sensitivity. Pearson and Timney reported larger decrements in stationary contrast sensitivity.[549] In their crossover study of 6 paid graduate students, the mean reduction in stationary contrast sensitivity over all spatial frequencies was 43% . The measured BrAC for this group was 60 mg/dL. There was substantial interin-

dividual variation (e.g., 215% change in 1 participant) with the reduction generally higher at higher spatial frequencies. The effect of ethanol on glare recovery is variable with some studies demonstrating decrements while other studies indicated some enhancement of glare recovery scores.

Depth Perception/Binocular Vision.   Gain is the ratio of eye velocity to target velocity; maintaining fixation on a moving target requires a gain near 1. Inhibition of slow eye movements results in the necessity of recruiting fast eye movements to maintain fixation. Ethanol reduces the gain of slow eye movements as well as the slowing of the initiation and the velocity of saccadic eye movements.[550] By requiring the visual system to recruit fast eye movements to generate a "catch-up saccade," jerky eye movements develop during ethanol intoxication, as exhibited by horizontal gaze nystagmus. Saccadic eye movements are quick jumps of the eye (20–700°/sec) in response to a visual target stimulus jumping 3–25°. Measured variables include saccade latency, maximum saccade velocity, saccade amplitude, and saccade overshoot. Smooth pursuit eye movements measure the ability of an individual to match velocity of the eye with the velocity of a visual target stimulus that moves at a rate of 1–30°/s as measured by the ratio of eye velocity to target velocity. BAC near 100 mg/dL decreases smooth-pursuit eye movement and increases the number of catch-up saccades.[551] Individuals still recognize exciting and relevant areas of visual scenes, but there is a reduction of visual exploration. Distance judgment and depth perception depends on sensory feedback from ocular muscles that control binocular convergence. In general, moderate ethanol doses (80–100 mg/dL) cause some esophoria (i.e., tendency for inward deviation of eyes) for far viewing and somewhat less exophoria (i.e., tendency for outward deviation of the eyes) for near viewing.[552,553] The effect of these changes on driving skills has not been established.

Fusion/Diplopia/Accommodation.   Under normal circumstances, adjustment (i.e., vergence) of ocular muscles focuses the sensory input from both eyes on the respective retinas in a similar pattern that allows fusion of the 2 images. Failure of this fusion causes diplopia. The near point and far point of fusion are the minimum and maximum viewing distances, respectively, at which fusion occurs. Fusion latency is the time required to attain fusion. Laboratory studies of healthy volunteers suggest that moderate doses of alcohol that produce BAC in the range of 80–100 mg/dL reduce the near and far point of fusion as well as increase the fusion latency, particularly at maximum viewing distances.[554]

421

Accommodation typically is not affected by BAC <100 mg/dL.

HEARING.   There are limited data on the effects of ethanol consumption on hearing. Existing data are conflicting, probably as a result of differences in ethanol dose, experimental design, and/or duration of ethanol exposure. One volunteer study indicated that ethanol reduces the auditory threshold at all frequencies tested (250–8,000 Hz) beginning 30 minutes after the ingestion of 250 mL beer (estimated peak BAC 25 mg/dL).[555] However, the effect of ethanol at higher frequencies was smaller and the duration shorter than lower frequencies. All effects of ethanol on auditory threshold resolved within 480 minutes. Another volunteer study demonstrated increased auditory threshold for low frequencies (monaural and binaural 200 Hz, monaural only 400 Hz) following the ingestion of ethanol (estimated peak BAC approximately 60–80 mg/dL).[556] In this study, the effects of ethanol on detection thresholds were greater on lower frequencies (200 Hz, 400 Hz) than higher frequencies (800 Hz, 1,600 Hz, 3,200 Hz). Additionally, monaural stimuli were more affected by ethanol than binaural stimuli. A study of 8 healthy volunteers receiving moderate doses of ethanol sufficient to cause mild clinical intoxication (BAC not reported) did not detect any effect of ethanol consumption on pure-tone auditory thresholds.[557] There was a temporary reduction in distortion product otoacoustic emissions (i.e., sounds emitted in response to 2 simultaneous tones of different frequencies) at high frequencies, but not at low frequencies. These studies suggest that the effect of ethanol on hearing is a central effect rather than a peripheral one.

VIGILANCE AND ATTENTION.   Vigilance is a state of readiness to detect and respond to unpredictable and rare events. Vigilance tasks (e.g., continuous reaction times) require the ability to concentrate attention on a task for a prolonged period. Vigilance is relatively resistant to the effects of ethanol.[558] Volunteer studies indicate that ethanol intoxication impairs cognitive control of attention by limiting the ability to voluntarily allocate and use attention in a variety of tasks.[559] The spatial distribution of visual tasks is probably affected by ethanol consumption as well as the difficulty of the task. In a volunteer study using mean BrAC concentrations equal to 80 ± 10 mg/dL, participants in the alcohol group had difficulty disengaging attention from the center of their visual field; they fixed their attention more diffusely in the center when compared with the control group.[560] This experiment suggests that ethanol concentrations in the range of 80 mg/dL impair the ability to dissociate attention from gaze.

Driving is a divided attention task involving 1) a tracking task that maintains the vehicle in the proper lane and direction, and 2) a search and recognition task that monitors the driving environment for vital information on vehicles, pedestrians, traffic signals, and hazardous events. Negotiating a turn is a classic divided attention task requiring an accurate estimation of the degree of curvature and precise tracking of the curved portion of the road. Because maintaining the vehicle in the correct position is a continuous task, ethanol-impaired drivers tend to focus on steering and miss important cues in the periphery of the driving environment.[561] Divided attention tasks require individuals to perform 2 tasks simultaneously (e.g., central tracking and peripheral visual search). Sustained attention tasks require maintaining attention to a single source of information for an unbroken period. Sustained attention tasks are less sensitive to ethanol than selective attention tasks that involve attention to 1 source of information and the exclusion of another.[562]

SIMPLE MOTOR TASKS.
Reaction Times.   Reaction times vary from individual to individual as well as with the type of task and the level of attention (fatigue) over different sensory areas.[563] For example, alcohol increases reaction time for foot responses (e.g., braking) relatively more than for hand responses (e.g., steering).[564] Theoretically, reaction times are divided into perception time (i.e., time from the presentation of the stimulus until movement) and movement time (i.e., time from start of movement until a defined motor end point). Reaction times slow as the BAC increases above 80–100 mg/dL. In general, increased reactions times in this range are <10%, whereas large increases (>40–50%) occur at BAC above 150 mg/dL.[565] Choice reaction times typically are slower than simple reaction times, depending on the complexity of the task; ethanol diminishes the difference between these 2 tests as the BAC increases above 125–150 mg/dL.

Simple.   Reaction times measure the speed of a response to an auditory or visual stimulus, and these tests involve components of attention and motor coordination. Tests of simple reaction time measure mostly perception because the length of time required for the motor component is minimal compared with the time required for sensory input. To simulate real driving situations, brake time represents the time from the presentation of a stimulus (e.g., auditory, visual) to the time the foot touches the brake pedal. Simple reaction times are an important component of braking; the braking

reaction to an unexpected obstacle in the driving path is an example of simple reaction time.[530] In general, the motor response is more rapid to an auditory stimulus than to a visual stimulus.[566] The average braking time (i.e., time between presentation of visual stimulus and movement of foot to the brake pedal) in simulated driving situation is about 0.6–0.8 seconds with substantial interindividual variation.[567,568] Experimental studies of simple reaction times indicate that decrements in response times are small (<10–15%) in individuals with BAC of 80–100 mg/dL,[539,569,570,571] whereas large decrements occur when the BAC exceeds 150 mg/dL.[530] The consumption of ethanol increases both simple reaction times and perceptual speed.[572] Under laboratory conditions with a fairly high degree of expectancy, the mean brake reaction time ranges from approximately 0.45–0.60 seconds with perception time accounting for most of the total brake reaction time.[573] In a Swedish study of 321 drivers using their own cars, the median brake reaction time to an *anticipated* auditory stimulus on a road was 0.66 seconds with a wide range (i.e., 0.3–2.0 seconds).[573] A road block was established by police on a local road, and police requested that the driver participate in a braking study. The test group represented all 321 drivers stopped by police. There were no measurements of ethanol concentrations.

A randomized, placebo-controlled study of 18 healthy adults using a driving simulator set to approximately 84 ft/s (i.e., 55–60 mph) measured the mean brake latency as represented by the time between the appearance of a road hazard and the time the participant touched the brake pedal.[574] The mean brake latency increased from about 0.6 seconds under placebo conditions to approximately 0.7 seconds with a BrAC of 90 mg/dL. At a speed of 60 mph, this difference in the reaction time means that the car traveled about 10 feet further under the latter condition. The average brake latency commonly cited by the US National Highway Traffic and Safety Administration (NHTSA) is 0.75 seconds.[575]

Choice.   Simple reaction time measures 1 behavioral response to a stimulus, whereas choice reaction time tasks use multiple stimuli and response possibilities. Therefore, performance on choice reaction tasks places a greater information processing load on individuals than simple reaction tasks, depending on the difficulty and the familiarity of the individual with the tasks. Complicated choice reaction tests measure information retrieval time from short-term memory, and choice reaction tests are more sensitive to ethanol than simple reaction tasks.[564] There are minor differences (<10–12%) in choice reaction times between sexes (i.e., men are faster than women) and age categories (i.e., young adults faster than adults near retirement).[568] The interaction between speed and accuracy in these tests reflects rates of information processing. Significant decrements (i.e., >10–15%) in choice reaction times does not usually occur below BAC 80–100 mg/dL unless the task is very difficult.[530] In a study requiring the selection of the appropriate key after a visual display of 5 choices, the IV infusion of ethanol sufficient to produce a BAC of 80 mg/dL caused a statistically significant ($P < .01$) increase in reaction time compared with placebo (no ethanol).[576] The mean choice reaction time increased 0.12 seconds, which corresponds to traveling an additional 13 feet at a speed of 70 mph.

Tracking.   Steering is classically a skill requiring sensorimotor coordination to keep an object on a path, and a tracking task that uses hand–eye–limb coordination necessary to steer. The effect of ethanol on tracking tasks depends on the type of tracking test. Adaptive tracking requires individuals to match the movement of a stimulus with an index. The difficulty level is adjusted to the ability of the individual. Pursuit tracking requires individuals to maintain a control index in a constant position relative to a moving index. Compensatory tracking entails the maintenance of an index on a predetermined position while a forcing function continuously moves the index off target. This test is analogous to driving on a racetrack with a lateral incline. Critical tracking is an unstable compensatory tracking task that becomes increasingly difficult as the forcing function gradually increases in magnitude. Pursuit tracking tasks are more sensitive to the effects of ethanol compared with compensatory tracking. Simple tasks of tracking are relatively resistant to the effects of ethanol <100 mg/dL,[577] whereas tests simulating evasive maneuvers required for emergency situations are much more sensitive to the effects of ethanol.[578]

DRIVING COURSES AND SIMULATORS

Driving simulators rely on sensorimotor skills (e.g., tracking) along with some judgment. The effects of ethanol on performance in driving simulators are variable depending on the task as well as age, health, and baseline psychomotor abilities. Ageing is associated with some loss of visual acuity, reduced peripheral vision, response slowing, increased reaction time, decline in ability to divide attention, and difficulty with problem-solving and perceptual speed.[579] In a study comparing the driving skills of older (mean age 69 ± 5.2 years) and middle-aged (36 ± 5.8 years) individuals on a driving simulator, the older drivers demonstrated greater driving impairments in speed control and braking.[580]

The older drivers drove slower, spent more time nego- tiating left turns, had more inappropriate braking, made fewer appropriate full stops, had more speed variability, and had more crashes. However, the older men were no more sensitive to ethanol intoxication (BAC >80 mg/ dL) than middle-age drivers in regards to driving per- formance, awareness of intoxication, and judgment.

Drivers with BAC in the range of 70–100 mg/dL demonstrate some increase in braking time and steering errors in response to changes in angulation of the simu- lated roadway.[530] Generally, the most consistent changes in drivers using driving simulators with BAC of 70– 100 mg/dL involve information processing, decision- making, and judgment as manifest in speed and braking parameters. Limitation of closed-course driving involves the use of low speeds and the lack of unpredictable road hazards. Tests of driving in closed course conditions usually measure braking time, steering errors, and other control maneuvers, as well as subjective changes in driving behavior. Some adaption to the effects of ethanol on driving skills under closed-course conditions may occur following the chronic use of ethanol. In a study of light, intermediate, and heavy drinkers, the percentage of participants in each group with evidence of impair- ment at a mean BAC of 79 mg/dL was 68%, 47%, and 40%, respectively.[623]

Culpability Studies

Although the consumption of ethanol is a major risk factor for collisions, the consumption of ethanol per se is not a necessary or sufficient cause of automobile acci- dents. Many fatal accidents and most nonfatal accidents are not associated with the use of ethanol by the driver. However, the risk of involvement increases dramatically as the BAC exceeds 80–100 mg/dL, and the relative risk of involvement in a crash exceeds 20 when the BAC increases above 150–200 mg/dL.[58] Sharp increases in the risk of a fatal accident for more experienced drinkers do not occur until the BAC increases above 100 mg/ dL.[581] Although the relative risk of a fatal accident increases substantially in the range of 80–100 mg/dL, many drivers with a BAC >80 mg/dL do not crash.[582] In general, the use of alcohol is relatively more common in single-vehicle accidents.[583]

Human Factors.   Factors that affect the relative risk of driving accidents include personality, mood, stress, fatigue, and marital status. Personality traits that predis- pose an individual to an increased risk of auto accidents include impulsiveness, overt hostility or aggression, low frustration tolerance, feelings of discontent, depression, irritability, emotional instability, and thrill-seeking

motives.[584] The effect of ethanol on these traits and the increased risk of driving accidents are not well defined. In a study of 20 female volunteers administered a risk- taking paradigm as part of a randomized, double-blind, 2-period laboratory study, testing 45 minutes after the ingestion of 0.7 g ethanol/kg did not increase risk taking.[585] The mean blood ethanol concentration was 65 ± 10.5 mg/dL; therefore, almost all of these volun- teers had a BAC below 80 mg/dL. The effect of acute ethanol intoxication on executive function and decision making is not well defined. Experimental studies suggest that doses of ethanol producing mean blood ethanol concentrations near 70 mg/dL (i.e., as estimated by breath analysis) affect executive function by subtly impairing the ability to use emotional signals (gains, losses, probabilities) while making risky decisions.[586] Measuring the effect of acute ethanol intoxication on impulsivity is complicated by disagreement on the defi- nition of impulsivity (e.g., outcome of the decision, the load placed on working memory, other measures).

Motor Vehicle Accidents. The consumption of alcohol is a major factor in both fatal and nonfatal inju- ries from motor vehicle accidents. Studies of alcohol use in patients requiring hospital care after nonfatal acci- dents indicate that the incidence of alcohol use is high in this population, ranging from ~23–66%.[587] Alcohol involvement is also relatively greater in single-vehicle accidents and those crashes occurring on weekends.[588] Frequently, alcohol-related, single-vehicle accidents occur during the negotiation of a curve, which demands attention divided between estimation of the degree of curvature and precise tracking of the curved path.[589] The major difference between alcohol-related and nonalcohol-related single-vehicle crashes on rural Australian roads was road alignment. The percentages of alcohol-related and nonalcohol-related, single-vehicle accidents occurring on a curve were 50% and 36%, respectively.

The Fatal Accident Reporting System (FARS) of the US National Highway Traffic Safety Administration (NHTSA) collects yearly data on all fatal crashes (i.e., death within 30 days) that occur on public roadways and involve a motor vehicle in transport. A fatal crash is considered alcohol-related if *any* of the following 3 con- ditions occur: 1) the investigating officer determines that at least 1 driver was drinking, 2) the BAC is >10 mg/ dL, or 3) the police officer cites an involved driver for driving while intoxicated. When any of these 3 condi- tions occur, the accident is presumed to be alcohol- related without determining actual fault based on accident analysis. The term drinking refers to any sign of alcohol consumption by a driver, including BAC below the legal limit of intoxication for driving. Because

a BAC is not available for many drivers involved in fatal crashes, the NHTSA uses a statistical method to estimate missing BACs.[590]

In 1999, approximately 36,000 vehicle occupants and about 6,000 nonmotorists (pedestrians/pedal cyclists) died within 30 days of a motor vehicle accident.[591] Since 1982, there has been a steady decline in the number of fatal accidents associated with ethanol.[592] Between 1981 and 1999, the percentage of all fatal accidents involving at least 1 drinking driver (i.e., BAC >10 mg/dL) declined from 57% to 38%. During this period, the percentage of fatally injured motor vehicle occupants with no detectable alcohol increased from 43% to 62%, whereas the percentage of dead occupants with BAC 10–99 mg/dL and ≥100 mg/dL decreased from 11% to 8% and 46% to 30%, respectively. According to 1999 FARS data, the percentage of all drivers in fatal accidents with BAC 10–99 mg/dL and ≥100 mg/dL was 23% and 17%, respectively. Drinking drivers were overrepresented during the evening and night hours (6:00 PM–5:59 AM). During the evening hours, the percentage of drivers with BAC 10–99 mg/dL and ≥100 mg/dL was 40% and 31%, respectively, compared with 10% and 6%, respectively, during the daytime. The percentage of drinking drivers (BAC ≥10 mg/dL) involved in fatal accidents peaks from midnight to 3 AM. During this period, the percentage of drinking drivers in single-vehicle and multiple-vehicle accidents was 77% and 70%, respectively, compared with 14% and 8%, respectively, for the period between 9 AM and noon. Analysis of FARS data and the 1996 National Roadside Survey of Drivers indicates that the relative risk of involvement in a fatal, single-vehicle accident decreases with age and female gender.[593] At a BAC of 90 mg/dL, the relative risk of a fatal single-vehicle crash varied between 11.4 (≥35 years old) to 51.9 (male driver, age 16–20 years). With few exceptions, women and older drivers had lower relative risk of involvement in fatal, single-vehicle crashes compared with men and younger drivers. However, the use of alcohol among young female drivers is increasing compared with earlier data.[594] Among fatally injured drivers, heavy drinkers are overrepresented compared with social drinkers. In a study of fatal traffic accidents in Texas, the mean BAC values for drivers judged to be responsible or not responsible for the accident were 190 mg/dL and 150 mg/dL, respectively.[595]

PEDAL CYCLES. The etiology of serious bicycle crashes is multifactorial. Potential factors include environmental causes (night-time riding, rain, time during the day), adverse road conditions (pot holes, traffic congestion, poor visibility, areas of construction), bicycle-related factors (speed, use of helmets, poor decisions regarding traffic), and the sharing of transportation routes with motorists. Severe head injury is the most common cause of death, and falls from bicycles cause more head injuries than limb or spinal trauma.[596] Age is also a variable for fatal bicycle accidents. In a retrospective study, bicyclist error accounted for 79% and 55% of the fatal bicycle accidents in the age groups <10-years-old and 10–19-years-old, respectively, whereas motorist error accounted for 63% of the fatal bicycle accidents among bicyclists 20–44-years-old.[597] In general, the relative risk of a fatal bicycle accident increases with age >44, night-time bicycle riding, and male gender.[598] Night-time fatality rates are approximately triple the day-time fatality rates after adjustment for mileage.[599] Exclusive of alcohol-related accidents, reduced visibility during dark hours contributes to the relative increase in fatalities for pedestrians and pedal cyclists. Analysis of FARS data from 1980–1990 demonstrated that about 12% of the fatal pedestrian/pedal cycle collisions involved a drinking driver, whereas approximately 44% of all other fatal accidents involved a drinking driver.[600]

The FARS reporting system includes only bicyclists who die on a public road after a collision with a motor vehicle. This data system does not include fatal bicycle accidents when the accident occurs on private property or when a motor vehicle is not involved. A review of the FARS data between 1987–1991 demonstrated that of the 1,711 fatal bicycle accidents reported in the 15 and over age group, an estimated 32% of the bicyclists had been drinking and 23% were legally intoxicated.[601] There are few data on the BAC of motor vehicle drivers involved in fatal bicycle accidents. In an unmatched case-control study of injured bicyclists who arrived at a hospital within 6 hours of injury, the risk of injury was approximately 10 times higher for bicyclists with BAC >100 mg/dL when compared with sober controls.[602]

PEDESTRIANS. Pedestrians provide lower contrast and smaller obstacles compared with vehicles. During 1999, approximately 4,400 pedestrians died within 30 days of an accident involving a motor vehicle based on FARS data.[591] Of these fatalities, the percentage with BAC 10–99 mg/dL and ≥100 mg/dL was 7% and 34%, respectively. In a study of injured pedestrians presenting to a trauma center, 30% had detectable BAC and about 22% had a BAC >100 mg/dL.[603]

Standardized Field Sobriety Tests (SFSTs)

Police officers use field sobriety tests to help assess whether or not a driver is impaired and to give probable cause for an arrest. In 1977, Burns and Moskovitz conducted laboratory tests to determine which field sobriety tests were the most sensitive indicators of impairment (i.e., BAC >100 mg/dL).[604] The horizontal gaze nystag-

mus, the walk-and-turn, and the one-leg stand test were the 3 most sensitive tests for the assessment of impairment based on BAC >100 mg/dL. A follow-up of the original work of Burns and Moskovitz by Stuster and Burns concluded that the field sobriety tests were 91–94% accurate in estimating BAC < 80 mg/dL or >80 mg/dL in drivers arrested for suspected driving under the influence.[605] The preferred method of analyzing the BAC during this study was breath testing (i.e., BRAC), but the participants had the choice of testing their ethanol concentration by analysis of their blood or urine samples. The report did not contain a distribution of these 3 methods of testing the BAC during the study. The data from these studies are heavily weighted to very high measured blood alcohol concentrations (MBAC), and reanalysis of the data indicate that the accuracy of the field sobriety tests depend on the MBAC, particularly in the MBAC range of 0.04–0.12%.[606] Table 21.10 demonstrates the traditional statistics of test performance for symmetrical ranges around the MBAC of 0.08% (80 mg/dL). Although the accuracy of determining whether the MBAC is above or below 0.08% is 91% for the whole range of MBAC from 0–0.33%, the accuracy is much less when the sample contains only MBAC below 0.12%.

Although these field sobriety tests are sensitive for determining if the MBAC is ≥80 mg/dL, the results of this and other studies[607,608] indicated that these tests lack specificity below MBAC <100–120 mg/dL.[609] In these 2 studies, about 32–47% of the participants judged impaired by the field sobriety tests had MBAC <100 mg/dL. In addition, there is substantial variation in test-retest and interrater reliability, depending on the scoring criteria and the training of the officers. Scoring systems are available to increase reliability based on a standardized scoring system involving a maximum of 6 points for the horizontal gaze nystagmus (HGN), 5 points for the one-leg stand, and 9 points for the walk-and-turn.[610] The HGN test accounted for most of the sensitivity of the standardized field sobriety test; similar results occurred following the use of HGN test along with A to Z alphabet recital and rapid, alternate hand clapping for detection of elevated BAC during boating.[611]

HORIZONTAL GAZE NYSTAGMUS (HGN).   Of the ocular signs (conjunctival erythema, eyelid lag, slow pupillary light reflex, convergent pupils) associated with ethanol intoxication, HGN correlates best to BAC. The HGN measures the angle of gaze from the sagittal plane to the onset of rapid jerking movements (saccades) of the eye while visually tracking an object horizontally. As the BAC increases, the movement of the eyes becomes jerky as a succession of irregular saccades replaces smooth pursuit movements.[612] The amplitude of the rapid, jerking movements in the direction of gaze increases with increased deviation from the midline. Although HGN correlates roughly to BAC, HGN is *not* a direct measure of impairment because the presence of saccadic eye movements does not impair vision. The main value of the HGN is a screening test to detect high BAC rather than an indicator of impairment. Consequently, the HGN test does not eliminate the necessity of determining the BAC by standard laboratory methods.

At a BAC of 100 mg/dL, the onset of nystagmus usually begins at approximately 40° laterally from the midline.[608] The angle of onset of nystagmus decreases as the BAC increases,[613] and the onset of nystagmus at 45° may occur at BAC <80 mg/dL.[614] Consequently, the presence of a positive HGN test by itself does not necessarily imply a BAC >80 mg/dL. In an experimental setting involving 20 healthy volunteers, BAC in the ranges of 40–60 mg/dL and 80–100 mg/dL were associated with the onset of nystagmus at 45–50°, whereas BAC in the range of 100–120 mg/dL was associated with the onset of nystagmus at 35–40°.[615] The coadministration of the equivalent of 2–4 cups of coffee (i.e., up to 500 mg caffeine) did not alter the angle of onset of nystagmus.

TABLE 21.10. Reanalysis of National Highway Traffic Safety Administration 1998 Report on the Standardized Field Sobriety Test Battery at Various Breath Ethanol Ranges.[606]

MBAC*	Number	Accuracy (%)	Sensitivity (%)	Specificity (%)	PPV (%)	NPV (%)
0.07%-0.09%	36	72	96	36	70	83
0.06%-0.10%	65	75	95	44	73	85
0.05%-0.11%	97	79	97	55	75	92
0.04%-0.12%	135	82	95	63	79	90

Abbreviations: MBAC = measured blood alcohol concentration in g%, where 0.1 g% = 100 mg/dL; Accuracy = percentage of cases correctly classified as above or below MBAC 0.08%; PPV = positive predictive value; NPV= negative predictive value.

*The follow-up study (Reference 605) used breath alcohol concentrations preferentially, but measurements of blood and urine also were accepted. The study did not report the distribution of these 3 types of ethanol measurements.

The 6-point scoring system of HGN includes a point for the following signs in each eye: 1) onset of nystagmus before 45° (40° between 12 PM and 5 AM), 2) moderate, rapid, and distinct nystagmus in the direction of gaze when eye moves as far as possible laterally (end-position nystagmus), and 3) eye cannot follow a moving object smoothly.[610] End-position nystagmus occurs in the normal nondrinking population, particularly in a fatigued individual.[616] Nonpeer-reviewed, pilot studies indicated that about 80% of individuals with scores >4 have a BAC exceeding 100 mg/dL,[608] but there are few peer-reviewed data on the predictive value of total test scores from the general population. During ethanol intoxication, the ocular findings are usually similar in both eyes. Visual acuity does not affect HGN; therefore, glasses are usually removed prior to testing.[617] Hard contacts may limit lateral movement of the eye and other field sobriety tests are used for individuals wearing hard contacts. Other conditions associated with nystagmus include high refractive errors, myasthenia gravis, multiple sclerosis, cerebellar atrophy, congenital nystagmus, Ménière disease, cataracts, corneal lesions, encephalitis, poliomyelitis, stroke, sedative-hypnotic medications, and other drugs of abuse (e.g., phencyclidine, opiates, marijuana).[618] There are few data on the effect of various medications (e.g., sedatives, anticonvulsants, analgesics) on the presence of HGN. Under normal conditions, nystagmus occurs at extreme lateral gaze, and the presence of mild, endpoint nystagmus does not indicate ethanol intoxication.[609] Chronic alcohol abusers may not demonstrate HGN at BAC >100 mg/dL.[619] The accuracy of the HGN test is unaltered by the position (i.e., standing, sitting, supine) of the individual during testing.[620]

DIVIDED ATTENTION TASKS.   Other sobriety tests require divided attention during mental and physical tasks. The walk-and-turn test requires the individual to stand on a line in a heel-to-toe position while listening to instructions. The individual then takes 9 steps in a heel-to-toe fashion, pivots, and returns along the same straight line also in a heel-to-toe fashion. The one-leg stand is a balance task that requires individuals to stand with arms at their side while extending 1 foot 6 inches off the ground. The individual must maintain that position while counting for 30 seconds without extending the arms or losing balance.

BODY SWAY.   Along with the finger-to-nose test, body sway is a simple test (Romberg test) of sensorimotor coordination. These tests classically are part of the field sobriety tests administered by police personnel. The Romberg test is relatively sensitive to BAC exceeding 100 mg/dL[621] Compared with other psychomotor tests, tasks involving sensorimotor coordination (e.g., finger-to-nose, Romberg test) demonstrate the greatest degree of resistance to the effects of ethanol consumption by chronic ethanol consumption.[622,623]

ODOR.   Although pure ethanol is relatively odorless, alcoholic beverages (i.e., beer, wine, spirits) contain a variety of high aroma compounds at concentrations as low as 1–10 ng/L; fractionation of aroma extracts of Spanish wine with high pressure liquid chromatography identified over 70 aroma compounds.[624] Detection of the odor of alcohol is highly subjective, depending on a variety of factors in addition to the BAC including the sensitivity of the evaluator's odor perception, the type of beverage, recent ingestion of a meal, and the presence of aromatic compounds in the beverage. Experimental data suggests that the odor threshold of alcoholic beverages is in the range of 60–80 mg/dL; however, the odor of ethanol is not necessarily present in individuals with blood ethanol concentrations exceeding older or newer levels of legal intoxication. In a study of 562 drinking adults evaluated by physicians trained to detect ethanol intoxication, the odor of ethanol was detected in 33% of participants with blood ethanol between 61–80 mg/dL compared with slightly less than 50% of participants with blood ethanol in the range of 140 mg/dL.[625]

The presence of an odor of alcohol is an indication of recent alcohol consumption, but the strength of the odor is not an accurate measure of the BAC or impairment. Although breath odor is frequently cited by police officers in alcohol-related traffic cases, there is little scientific data to support the use of odor as a means of estimating blood alcohol concentration or impairment. In a pilot study of the cues used by officers to detect drivers under the influence of alcohol, 75 volunteers were either controls (no alcohol) or they drank sufficient alcohol over 1.5–2 hours to produce a BAC ranging from 50–150 mg/dL.[626] After a 30-minute waiting period, the participants drove a car over a closed course to a check-point where officers examined the participants for various cues including the odor of alcohol on their breath. For controls, the false-positive rate was 7%; for participants with a BAC 50–100 mg/dL and BAC 100–150 mg/dL, the false-negative rates were 61% and 39%, respectively. Moskowitz et al studied the ability of 20 experienced police officers to detect an alcohol odor on the breath of 14 individuals with blood alcohol concentrations ranging from 0–0.13% (0–130 mg/dL).[627] After a 30-minute waiting period, the individuals were placed behind a screen and asked to blow into a tube next to the officer. For controls, the false-positive rate was 17–23%. When asked to categorize a detected odor into 1 of 3 concentrations (<40 mg/

dL, 40–80 mg/dL, >80 mg/dL), the correct responses ranged from 19–35%. Consequently, the odor strength estimates were poorly correlated to BAC.

HEALTH SURVEILLANCE

Exposure of workers to ambient air concentrations of ethanol does not usually produce blood ethanol concentrations high enough to cause impairment. Exposure of a healthy volunteer to 1,900 mg/m^3 (UK occupational exposure limit) for 3 hours produced a blood ethanol concentration below the LOD (<0.2 mg/dL).[33]

TREATMENT

Stabilization

Acute ethanol intoxication usually responds to supportive care with special attention to prevention of aspiration, monitoring of respirations, and replacement of fluid and electrolytes as necessary. All obtunded patients should be rapidly evaluated for the adequacy of oxygenation (pulse oximetry, arterial blood gases [ABGs]), circulation, and serum glucose (e.g., Accu-Chek®, Roche Diagnostics, Indianapolis, IN). If rapid measures of blood glucose are not available, 50 mL 50% dextrose in water (D$_{50}$W) should be administered intravenously after blood samples are drawn. Other drugs of immediate importance in obtunded, alcohol dependent patients include naloxone (0.4–0.8 mg IV titrated up to 2 mg IV, if no effect) for suspected opioid use and thiamine (100 mg IV). Hypothermia may complicate the course of acute ethanol intoxication; depending on severity, warming measures should include passive rewarming (blanket) and active rewarming (warm humidified oxygen, warmed IV fluids, heating blanket). A severe metabolic acidosis may occur in alcohol dependent patients as a result of alcoholic ketoacidosis and primary lactic acidosis (hypoxia, hypoperfusion).[628] Management includes IV fluid therapy, sodium bicarbonate for pH <7.1, correction of underlying abnormalities, and treatment of associated conditions (trauma, GI bleeding, hepatorenal failure, encephalopathy). Evidence of trauma in the alcohol dependent patient indicates the need for cervical immobilization, cervical x-rays, and a careful search for cervical and cerebral trauma. A computed tomography (CT) scan of the head is usually necessary in alcohol dependent patients with altered consciousness and evidence of head trauma.

Gut Decontamination

The rapid absorption of alcohol limits the effectiveness of decontamination measures, and there are few clinical data to support the use of activated charcoal in cases of ethanol poisoning. In general, decontamination measures do not alter the clinical course of drug ingestions, when initiated >1–2 hours after ingestion. A study of volunteers administered ethanol did not detect a statistically significant difference (P = .08) in peak concentrations or time-to-peak concentrations when comparing volunteers receiving superactivated charcoal prior to ethanol with the same volunteers ingesting only ethanol.[629] However, animal studies indicated that the concomitant administration of charcoal with 95% ethanol reduces ethanol concentrations at 1, 2, and 3 hours to 62%, 73%, and 82% of control values, respectively.[630] There are no data on the efficacy of cathartics following ethanol ingestions. Asymptomatic children who ingest an ethanol-containing product and remain symptom free for 1–2 hours do not require decontamination.

Elimination Enhancement

Although hemodialysis increases ethanol clearance by 3- to 4-fold, supportive care is usually sufficient to prevent serious complications. Potential indications for hemodialysis include blood ethanol concentrations >500 mg/dL with deteriorating vital signs or poor hepatic function with the failure of supportive care. The IV administration of fructose or saline are not clinically effective methods for increasing the elimination of ethanol from the blood.[631]

Antidotes

There are inadequate clinical data to support the use of naloxone during ethanol intoxication, and the efficacy of naloxone for the reversal of an ethanol-induced coma is equivocal. Although rare case reports associate the reversal of ethanol-induced coma by naloxone, there are no well-controlled studies that confirm the usefulness of naloxone in ethanol-induced coma. A volunteer study composed mostly of alcohol abusers did not detect a significant reversal of the clinical features of ethanol intoxication following the administration of naloxone.[632]

Supplemental Care

Supportive care includes close observation of ventilation, replacement of nutritional deficiencies (magnesium, thiamine [vitamin B$_1$], riboflavin [vitamine B$_2$], pyridoxine [vitamin B$_6$], nicotinamide, vitamins K and C), correction of dehydration, electrolyte and acid-base imbalance, and evaluation for underlying illness and withdrawal symptoms. Poorly nourished alcohol abusers

require high, initial doses (i.e., at least 200 mg) of par-enteral thiamine diluted in 100 mL of saline over 30–60 minutes, particularly when these patients receive IV glucose.[633] Oral thiamine does not adequately replace depleted stores of thiamine.[223] Laboratory evaluation of the seriously ill alcohol dependent patients includes the following tests: electrolyte depletion abnormalities (potassium, magnesium, phosphorus, calcium), ECG abnormalities (dysrhythmias, cardiomyopathy, hypertension), arterial blood gases (metabolic acidosis, hypoxemia secondary to aspiration pneumonia), urinalysis (myoglobin, unusual crystals such as calcium oxalate), serum amylase or lipase (pancreatitis), chest x-ray (aspiration pneumonia, pulmonary tuberculosis, congestive heart failure), blood glucose (hypoglycemia/hyperglycemia), complete blood count with red cell indices for anemia, coagulopathies (prothrombin time and platelet count for hepatic dysfunction), and serum creatinine (renal function). Patients with alcoholic keto-acidosis should be hydrated with 5% dextrose (IV saline may paradoxically worsen acidosis) as well as potassium, magnesium, and phosphate supplementation as needed.[522]

Withdrawal Syndromes

Standard supportive care for alcohol withdrawal includes general nursing care in a quiet environment, monitoring of vital signs, reassurance, reality orientation, hydration, and the administration of thiamine. The usual initial dose of thiamine to prevent Wernicke encephalopathy is at least 50–100 mg intravenously. Nutritionally deficient alcohol dependent patients receiving glucose should also receive thiamine, but the urgent administration of glucose for hypoglycemia should not be withheld pending thiamine administration.[634] In otherwise healthy alcohol-dependent patients undergoing withdrawal, the minimum oral dose of thiamine during detoxification is 300 mg/day.[635] For patients with a high risk of developing Wernicke encephalopathy, larger doses of thiamine (i.e., 250 mg thiamine intramuscularly or intravenously daily for 3–5 days) are recommended. The value of the prophylactic use of multivitamins and other B vitamins remains unproven. Patients with CIWA-Ar scores ≤10 and normal mentation (i.e., no hallucination or disorientation) usually require only supportive care unless comorbid illness is present. Treatment for alcohol dependence after acute withdrawal and detoxification involves maintaining the patient in remission and developing a lifestyle compatible with long-term abstinence. Traditional approaches include psychosocial intervention (Alcoholics Anonymous, counseling) and pharmaceutic adjuncts (naltrexone, acamprosate, disulfiram) to reduce

the risk of relapse to drinking. Clinical trials indicate that naltrexone and acamprosate are more effective than placebo in reducing the risk of relapse to heavy drinking,[636] but there are inadequate data to conclude that these drugs substantially enhance complete abstinence even when administered with cognitive–behavioral therapy.[637,638] The efficacy of disulfiram, lithium, and serotonergic agents to maintain abstinence in alcohol abusers is unproved.

COMMON ABSTINENCE SYNDROME

Symptoms of alcohol withdrawal typically begin about 8 hours after substantial reduction in drinking, peak on day 2, and decrease significantly by day 4–5.[639] Although clonidine, carbamazepine, beta blockers, and neuroleptics all reduce the symptoms associated with alcohol withdrawal, benzodiazepines are the drugs of choice for alcohol withdrawal, particular for the treatment of DTs and seizures.[640] All benzodiazepines appear equally efficacious in the amelioration of withdrawal symptoms. Longer-acting benzodiazepines (e.g., diazepam) produce a smoother withdrawal from alcohol and reduce the incidence of seizures, but these agents may cause oversedation. The dosage of benzodiazepines should be individualized depending on the severity of withdrawal symptoms, previous history of serious complications during withdrawal, comorbid illness, and the specific benzodiazepine selected. Mild withdrawal (CIWA-Ar scores <8–10) may be managed with supportive care without pharmacologic intervention, whereas patients with higher scores benefit from benzodiazepine administration.[640]

Therapeutic regimens for alcohol withdrawal include fixed-schedule, front-loading, and symptom-based schedules. Candidates for fixed-schedule therapy include patients who require treatment because of the potential for serious withdrawal symptoms (seizures, DTs) as well as patients with concurrent illness, particularly if the patient is pregnant (see Table 21.11). The front-loading regimen is an alternative to the fixed-schedule regimen that delivers high doses of mediation early in the course of withdrawal rather than over 3 days. A symptom-based regimen is appropriate for symptomatic patients (AIWA-Ar ≥8–10), and this regimen usually delivers less medication over a shorter period compared with the fixed regimens.[641] Short-acting oxazepam (i.e., half-life, ~ 8 h) may be safer than diazepam in patients with severe liver or lung disease (15–60 mg every 6–8 h). Carbamazepine (600–800 mg in divided doses on day 1 tapered over 7 days to 200 mg) is an alternative to lorazepam, particularly for patients with severe underlying liver disease.[642] Gabapentin is also an alternative to lorazepam. In a study of 100 individuals seeking

TABLE 21.11. Benzodiazepine Therapy for Alcohol Withdrawal.

Regimen	Drug	Dose
Fixed-Schedule	Chlordiazepoxide	Day 1: 50–100 mg orally every 6 hours*
		Day 2–3: 25–50 mg orally every 6 hours
Front-Loading	Diazepam	20 mg orally every 2 hours until symptoms resolve[†]
Symptom-Based	Chlordiazepoxide	25–100 mg orally every hour while symptomatic[†]
Delirium Tremens	Diazepam	10 mg intravenously, then 5 mg every 5 minutes until awake and calm

*Additional 25–100 mg every 1–2 hours as needed for severe tremor or autonomic dysfunction. A dose may deleted if the patient is sleeping or resting comfortably.
†CIWA-Ar ≤8.

outpatient treatment of alcohol withdrawal, gabapentin (400 mg 3 times a day [tid] × 3 days, then 400 mg twice daily [bid]) was at least as effective as lorazepam (2 mg tid × 3 days,then 2 mg bid) as measured by the Clinical Institute Withdrawal Assessment for Alcohol—Revised (CIWA-Ar) scale.[643] There was no statistically significance difference between these 2 groups in self-reported side effects. Clonidine and beta-blockers are adjunctive agent for the treatment of mild to moderate withdrawal symptoms (e.g., tachycardia, hypertension, tremor), whereas preliminary data suggests that the glutamate release inhibitor, lamotrigine, and the AMPA/kainate receptor inhibitor, topiramate may improve the dysphoric mood and reduce the severity of withdrawal in combination with benzodiazepines.[644]

ALCOHOL DEPENDENT HALLUCINOSIS

Treatment involves primarily protection from harm and maintenance of a supportive environment. If behavior disturbances threaten the patient, physical restraint combined with benzodiazepines and the possible addition of haloperidol (2–5 mg intramuscularly or 5–10 mg orally) may be necessary.

ALCOHOL DEPENDENT SEIZURES

Most seizures are brief and self-limited, and therapy primarily involves protection from harm and support of the airway. Intravenous diazepam or lorazepam are the anticonvulsants of choice, and prophylactic or long-term phenytoin therapy is not usually indicated.[645] Although hypomagnesemia often occurs in alcohol abusers undergoing withdrawal, routine supplementation of benzodiazepines with magnesium does not reduce the severity or frequency of seizures or delirium.[646] The administration of phenytoin does not prevent the recurrence of seizures during alcohol withdrawal.[647] Recurrent seizures require evaluation for concurrent illness (e.g., intracranial hemorrhage, infection) and electrolyte imbalances (e.g., hypoglycemia, hypokalemia, hypo-

magnesemia). Disposition options for patients with a single withdrawal seizure vary from discharge from the emergency department observation unit after 6–12 hours to hospital admission for at least 24 hours depending on the severity of the withdrawal symptoms and the presence of concurrent illness. The consensus recommendations from a European panel on alcohol-related seizures included hospital admission of all of these patients for at least 24 hours.[648]

DELIRIUM TREMENS

Although initially overhydration may occur during alcoholic withdrawal as a result of the relative increase in the secretion of antidiuretic hormone, serious dehydration may result from the presence of diaphoresis, hyperthermia, tachypnea, and vomiting. Fluid requirements may approach 5 L within 24 hours.[649] Supportive care includes the correction of magnesium and phosphorus deficiencies as required by serum analysis, administration of IV thiamine before the administration of IV glucose (unless hypoglycemic), and a quiet well-lit room with reassurance and reorientation. Parenteral magnesium is not required unless indicated by low serum magnesium concentrations. Patients with impending DTs should be observed in an intensive care setting with frequent monitoring of vital signs and physical restraints as needed. Risk factors for the development of DTs should be evaluated including hypothermia, hypoglycemia, electrolyte imbalance, pancreatitis, thiamine deficiency, alcoholic ketoacidosis, GI bleeding, cerebral trauma, and chronic liver disease. High doses of benzodiazepines are necessary to ameliorate the symptoms associated with DTs. The use of benzodiazepines should be started early to limit the progression of withdrawal. Intravenous diazepam is effective in 5- to 10-mg loading dose followed by 5 mg every 5–10 minutes until the patient is calm and lightly sedated.[650] Large doses of benzodiazepines may be necessary to calm the patient. The administration of large benzodiazepine doses based

on withdrawal symptoms should be used with caution when comorbid illness is present because the symptoms of alcohol withdrawal are nonspecific. Large doses of diazepam can be safely administered in this setting as long as the patient is observed closely for excessive sedation and the development of hepatic encephalopathy. Lorazepam has a relatively short half-life (~5–10 hours) compared with diazepam, and this property limits oversedation in the elderly and patients with severe liver or lung disease. The use of lorazepam 1–4 mg intravenously every 10–15 minutes is an alternative to diazepam. Diazepam 20 mg is equivalent to lorazepam 4 mg. However, there are no clear clinical data to indicate the superiority of any specific benzodiazepine during the treatment of DTs.[651] Although neuroleptics are not routinely recommended for DTs because of the potential to lower seizure threshold, the use of haloperidol (0.5–5 mg IM or IV) in addition to benzodiazepines may be necessary every 1–4 hours to control severe agitation or hallucinations. Intravenous infusion of propofol (10–100 µg/kg/min) with intubation is an option for severe refractory DTs.[652,653]

Wernicke Encephalopathy

The presence of Wernicke encephalopathy requires high parenteral doses of thiamine (e.g., 500 mg tid for 3 days, then 250 mg daily for 3–5 days) as a result of the poor oral absorption of thiamine during this illness.[633] Parenteral solutions of thiamine may contain benzyl alcohol, and the dilution of the thiamine in 100 mL saline followed by infusion over 30 minutes reduces adverse reactions. Resolution of the ophthalmoplegia is the first response to thiamine administration for Wernicke encephalopathy, usually within hours of thiamine administration. Improvement in cognitive impairment requires much longer, and the cognitive abilities of the patient may not return to baseline levels despite adequate treatment. Korsakoff syndrome is the chronic form of Wernicke encephalopathy, characterized by short-term memory loss and confabulation. The relative preservation of other intellectual functions separates Korsakoff syndrome from the global reduction in intellectual function associated with alcohol dependent dementia.

Disulfiram Reaction

Disulfiram (Antabuse®, Teva Pharmaceuticals, Petach Tivka, Israel) is one of several aldehyde dehydrogenase inhibitors that raise plasma acetaldehyde concentrations following the consumption of ethanol. Elevated plasma acetaldehyde concentrations are associated with histamine release that produces cutaneous and systemic vasodilation, facial flushing, hypotension, tachycardia, tachypnea, palpitations, anxiety, headache, nausea, and vomiting.[654,655] Management of the ethanol-disulfiram reaction involves monitoring of blood pressure and cardiac rhythm, support of blood pressure [IV infusion of saline with pressor support (e.g., dopamine) as needed], and antihistamines.[656] 4-Methylpyrazole (Antizol®, Paladin Labs, Dover, DE) is a potentially useful antidote for the ethanol-disulfiram reaction because of the blockade of ethanol metabolism into acetaldehyde.[657] However, there are few clinical data on the efficacy of 4-methylpyrazole during the ethanol-disulfiram reaction.
